Ultrastructural studies have shown abnormal mitochondrial morphology in muscle, intramuscular nerves and

liver as well as within spinal cord motor neurons (Nakano et al., 1987; Okamoto et al., 1990; Sasaki & Iwata, 1996).

Alteration in the activity of mitochondrial respiratory chain enzymes

Increases in the activities of complex I and/or complex II/III, suggested to represent a compensatory mechanism for oxidative damage, have been reported in the frontal cortex of patients with SOD1 related familial ALS (Browne et al., 1998). Fujita and coworkers reported a decrease in complex IV activity in the spinal cord ventral horn in MND cases (Fujita et al., 1996). Borthwick and colleagues, using a histochemical technique, reported reduced complex IV activity in individual spinal motor neurons from MND cases (Borthwick et al., 1999). Complex IV deficiency has also been reported in muscle from sporadic MND cases (Vielhaber et al., 2000). One patient has been described with an MND phenotype and severe deficiency of muscle complex IV, which was due to a microdeletion in subunit 1 of cytochrome c oxidase (complex IV) (Comi et al., 1998).

Alterations in the mitochondrial genome

Veilhaber and colleagues (2000) screened the mtDNA in skeletal muscle from 17 MND patients and found one patient with multiple mtDNA deletions and a further 13 patients showed total mtDNA levels below those of control cases. Dhaliwal and Grewal (2000) measured levels of the so-called common deletion, a 4977 base pair deletion of mtDNA previously shown to be increased in the brain of aged individuals. The levels of the common deletion were higher in the motor compared to temporal cortex and an average of 11-fold higher in MND cases compared to controls.

Evidence from cellular and animal experimental models

A neuronal cell line transfected to express mutant SOD1 has been reported to show loss of mitochondrial membrane potential, together with an increase in cytosolic calcium concentration, suggesting a reduction in the ability of the mitochondria in these cells to sequester calcium (Carri et al., 1997). Studies in transgenic mouse models of SOD1-related ALS have shown that one of the very early features of motor neuron injury, occurring before the animals develop clinical evidence of motor neuron dysfunction, is the appearance of abnormal mitochondria (Wong et al., 1995). The mitochondria are initially noted to be dilated, with disorganized cristae and fractured outer membranes, with the eventual formation of vacuolar structures. Therapeutic effects of compounds which have an effect on mitochondrial function have also begun to be investigated in the SOD1 transgenic mouse models. Creatine buffers energy levels within the cell, maintains ATP levels and stabilizes mitochondrial creatine kinase which inhibits opening of the mitochondrial permeability transition pore. Administration of creatine to G93A transgenic mice improved motor function and extended survival in a dose-dependent manner, as well as causing a reduction in biochemical indices of oxidative damage in the spinal cord (Klivenyi et al., 1999).

Other pathogenetic hypotheses in ALS

These include the potential contributions of viral infection, exogenous toxins and immune-mediated mechanisms which have been reviewed elsewhere (Strong, 2000; Appel et al., 2000). There is emerging evidence that, following initiation of cellular injury in MND, the motor neurons may eventually die by a programmed cell death pathway or apoptosis (for review see Sathasivam et al., 2000).

Management of MND

General aspects of management

The main roles of the neurologist in the care of patients with MND are to: (i) establish the diagnosis; (ii) manage symptomatic therapy; (iii) coordinate paramedical services and the provision of aids and appliances quickly once the patient has need of them. The timing of discussion and the provision of these measures is very important: too early can be as bad for the morale of the patient as too late; (iv) educate and counsel patients and their families as appropriate for the stage of the disease. This is particularly important in MND where the patient may not have time to adapt to one level of disability before new problems have to be faced; (v) offer patients the opportunity to participate in therapeutic trials or clinical research projects where possible.

There is a growing tendency in the United Kingdom and other countries for patients with MND to be managed in specialist clinics, with input from nursing staff with specialist training. Other paramedical staff whose expertise may be of great value in the care of MND patients include the physiotherapist, the occupational therapist, the speech therapist, the dietician, the social worker and the orthotist. The coordinated action of multiple health care professionals within a multidisciplinary team can lessen the difficulties experienced by patients with MND and by their carers and families.

Table 116.4. Symptom control in amyotrophic lateral sclerosis

Symptom	Therapies
1 Cramp	Quinine sulphate (baclofen, diazepam, phenytoin)
2 Fatigue	Occasionally pyridostigmine
3 Spasticity	Baclofen, diazepam, tizanidine
4 Dysphagia	Nutritional supplements, liquid thickeners, PEG
5 Drooling	Hyoscine patches, atropine, amitriptyline, suction machine, parotid gland irradiation
6 Constipation	Ispaghula, methyl cellulose, lactulose, glycerol suppositories
7 Emotional lability	Amitriptyline, imipramine (L-dopa preparations)
8 Depression	Tricyclic agents or serotonin reuptake inhibitors
9 Insomnia	Address underlying cause, fluorazepam, diphenhydramine
10 Pain	Address underlying cause + analgesia
11 Dyspnea	Antibiotics for aspiration pneumonia, chest physiotherapy, sublingual lorazepam for acute attacks of dyspnea. Consider NIPPV in selected patients. Morphine for end-stage respiratory distress

Medical aspects of symptom control in MND (Table 116.4)

Symptomatic therapy aimed at alleviating the distressing symptoms, which often arise during the course of MND, can do much to improve the quality of life for the patient. Many of the symptomatic therapies currently recommended by clinicians have not been assessed in rigorous controlled trials. The evidence base for many of these therapies has recently been reviewed by an American Academy of Neurology task force (Miller et al., 1999).

Cramps

Painful muscle cramps are common in MND, particularly in the early stages of the disease. This symptom often responds to quinine sulfate in a dose of 200–400 mg per day. Other therapies which can be useful in alleviating cramp include phenytoin, baclofen and diazepam.

Weakness and fatigue

There is little that can be done pharmacologically to alleviate weakness in MND. A variety of aids and appliances may help to maximize mobility and function including foot-drop splints, walking frames, wheelchairs, mobile arm supports, supporting collars. Fatigue is a common symptom and patients may obtain temporary benefit from anticholinesterase medication such as pyridostigmine, although the beneficial effect is likely to recede within a few months.

Spasticity

The use of muscle relaxants to treat spasticity may be helpful in some patients. However, many patients are intolerant of such therapy, because reduction of tone in the limbs may increase the sensation of weakness and reduce mobility. If spasmolytic therapy is required, baclofen, tizanidine or a benzodiazepine such as diazepam may be used.

Dysarthria

Decreasing the speed of speech and the use of key words and short phrases may improve intelligibility. When speech becomes unintelligible, communication aids of varying sophistication may be required.

Dysphagia

In early dysphagia, alteration in food consistency may suffice to maintain adequate nutrition. If the patient is continuing to lose weight, then nutritional supplements of liquid or semisolid consistency may be helpful. The insertion of a PEG (percutaneous endoscopic gastrostomy) tube should be considered when the following problems are apparent: (i) continuing weight loss (more than 20% of the normal body weight); (ii) dehydration; (iii) aspiration with resultant respiratory infections; (iv) meal times have become intolerable due to frequent choking spells. PEG feeding represents one of the major advances in symptomatic care for patients with MND. After PEG placement many patients report great relief and increased well-being, though as yet no large-scale quality of life studies have been conducted. Whether early PEG placement results in increased duration of survival has not yet been convincingly demonstrated (Mazzini et al., 1995). The PEG procedure should not be postponed until the patient has severely compromised respiratory function. At this stage in the disease the patient may develop respiratory failure following the procedure.

Drooling of saliva

The mainstay of therapy is the use of anticholinergic medication. The most commonly used medications are amitriptyline, atropine and hyoscine skin patches. A portable suction device which can be used to remove pools of saliva may be useful. Carbocysteine or propranolol are sometimes recommended to reduce the viscosity of secretions (Borascio & Volz, 1997). If pharmacological agents do not successfully control salivation problems, then staged, low-dose parotid irradiation may be considered.

Constipation

Constipation may be a major and distressing problem in MND. Contributory factors include inability to adequately perform a Valsalva manoeuvre due to weakness of the abdominal muscles, spasticity of the pelvic floor muscles, immobility, dehydration, dietary alterations with reduced fibre intake and medication including anticholinergics and opiates. Severe constipation and abdominal distension may exacerbate respiratory dysfunction. Potential remedies include increasing dietary fluid and fibre intake, adjustment of constipating medication and administration of laxative preparations.

Emotional and psychological problems

Emotional lability often reponds to amitriptyline or imipramine therapy. L-dopa preparations and serotonin reuptake inhibitors may also be of benefit (Borascio & Volz, 1997). Antidepressant or anxiolytic therapy may be required for some patients. The psychological state of patients with MND has been shown to correlate with survival (McDonald et al., 1994) and it is therefore important that clinically significant mood changes should be looked for and treated.

Sleep disturbance

The management of sleep disturbance in patients with MND depends on assessment of the underlying cause. Attention to sleeping position, a pressure relieving mattress or an electrically powered bed may be helpful. Pain management may be required. A night time prescription of amitriptyline may be helpful, both for its sedative and antidepressant actions. Care should be taken in prescribing sedative medication to patients with MND as respiratory depression may occur. Diphenhydramine is a sedative preparation well tolerated by older individuals, which has the added benefit of reducing muscle cramps.

Pain

Effort should be made to establish the site and reason for the patient's pain. This may prove a challenge in the late stages of the disease with its attendant communication difficulties. Non-steroidal anti-inflammatory agents and physiotherapy will help to control pain arising from joint stiffness. Pharmacological agents may be employed to alleviate cramps, spasticity and constipation, as described above. Analgesic agents of increasing potency may be required in the later stages of the disease.

Respiratory failure

The management of the respiratory complications of MND include the following general measures. Attention should be given to the detection and prevention of aspiration pneumonia. Antiobiotic therapy should be used at the first indication of a chest infection. Chest physiotherapy and postural drainage should be used when the patient has difficulty in clearing secretions from the chest. Patients will breathe more comfortably during sleep if placed in an upright position. When patients experience bouts of severe dyspnea, accompanied by extreme anxiety or panic, a small dose of lorazepam (0.5–1 mg) sublingually may be helpful (Borascio & Volz, 1997). If breathlessness causes distress during the later stages of the disease, the use of small amounts of morphine will be useful. Depression of respiration can usually be avoided if the initial dose is small and increments are gradual (Saunders et al., 1981).

Assisted ventilation, coupled with appropriate nutritional support, could theoretically extend the patient's life indefinitely, and the implications of initiating such respiratory support must be clearly thought through and discussed for each patient. Full 24-hour intermittent positive pressure ventilation via a tracheostomy, is an option that is only rarely chosen by fully informed patients. The costs, in terms both of financial resources and the caregiver support required, are substantial. Non-invasive intermittent positive pressure ventilation (NIPPV) via a mask is the most practical form of assisted ventilation which may be considered (Fig. 116.6). Use of ventilatory support during sleep may lead to subjective improvement in sleep, resolution of morning headache and improvement in exercise tolerance, mobility, respiratory function and fatigue during the day (Howard et al., 1989). Controlled trials of this form of therapy with attention to quality of life parameters are warranted.

Terminal care

The aim of medical intervention in the terminal phase of the disease is to ensure that the patient is comfortable. Morphine therapy should be administered as required to alleviate discomfort or distress. This can be given via the PEG, by subcutaneous or intravenous injection or via a

Table 116.5. Recent clinical trials of potential neuroprotective therapies in motor neuron disease

Antiglutamate agents	Neurotrophic factors
Riluzole	Ciliary neurotrophic factor (CNTF)
Gabapentin	Insulin-like growth factor 1 (IGF-1)
Lamotrigine	Brain derived neurotrophic factor (BDNF)
	Glial-derived neurotrophic factor (GDNF)

nebuliser. Diazepam or chlorpromazine may be given to alleviate anxiety.

Neuroprotective therapy aimed at slowing clinical and pathological progression in MND

There is no therapy currently available, which has a dramatic effect in slowing disease progression in MND. However, some small steps have been made towards this ultimate goal in the last few years. A detailed critique of all the recent therapeutic trials (Meininger & Salachas, 2000) is beyond the scope of this chapter, and only the key results will be highlighted (Table 116.5).

Antiglutamate therapy

Several trials of antiglutamate therapy have taken place. Riluzole is a sodium channel blocker which inhibits glutamate release, and has several other potentially neuroprotective effects. Two double-blind, placebo-controlled clinical trials of riluzole have been carried out in more than 1100 patients with MND (Bensimon et al., 1994; Lacomblez et al., 1996). The results of both studies showed a statistically significant, though modest, benefit in prolonging survival and the drug has been licensed for use in MND. Riluzole therapy is relatively expensive (approximately £3700 per patient per year) and the average survival benefit to be expected is modest, but against this must be weighed the arguments that the patient population requiring the drug is relatively small, and that these patients are facing a lethal disease, for which no other therapy is available. At present it is unknown whether the modest overall therapeutic effect of riluzole conceals responders and non-responders.

Gabapentin, an anticonvulsant drug with antiglutamate activity, was evaluated in MND in a pilot therapeutic trial (Miller et al., 1996a,b) which showed a trend indicating potential slowing in the rate of decline of limb strength. Unfortunately, this positive trend was not replicated in a further trial, using higher doses of gabapentin.

Antioxidant therapy

No large-scale trials of antioxidant therapy have yet been conducted in MND. An under-powered trial of *N*-acetylcysteine therapy in 110 patients showed a trend towards improved survival in patients with limb-onset disease, which just failed to reach statistical significance ($P = 0.06$) (Louwerse et al., 1995). In the G93A SOD1 transgenic mouse model of MND, the anti-oxidant vitamin E, delays the onset of the disease, though does not influence disease duration (Gurney et al., 1996). The effect in human patients is unproven, though many patients are empirically prescribed vitamin E, because of the emerging evidence that free radicals may contribute to motor neuron injury.

Neurotrophic factors

Multiple neurotrophic factors contribute to the health and survival of motor neurons and exert neuroprotective effects in experimental paradigms and animal models of motor neuron injury. Several neurotrophic factors, administered by subcutaneous injection, have been assessed in recent trials, so far with rather disappointing results. Ciliary neurotrophic factor (CNTF) showed no therapeutic benefit, when administered by this route in MND, and actually appeared to have a detrimental effect in the high dose group (Miller et al., 1996a,b). In the USA recombinant human insulin-like growth factor 1 (IGF-1), in a trial

involving 266 patients, slowed progression of functional impairment and the decline in health-related quality of life (Lai et al., 1997). A similar trial conducted in Europe failed, however, to replicate this result and IGF-1 has not been licensed for use in MND. A trial of subcutaneously administered brain-derived neurotrophic factor (BDNF) showed no significant benefit and a further trial of glial-derived neurotrophic factor (GDNF) administered by the intraventricular route has been aborted. Concern has been expressed about the half-life and access to motor neurons of neurotrophic factors administered by the subcutaneous route and BDNF is currently being evaluated administered by continuous intrathecal delivery.

In conclusion, in several ways MND is a disease which is uniquely challenging to medical and health care professionals. Rapidly progressive disability, without periods of remission, and usually in the presence of preserved intellectual function, make MND a particularly difficult disease for patients and their families to face. A nihilistic approach from medical attendants can add to the distress and suffering of these families. There is much that can be done during the course of the disease to alleviate symptoms, maximise functional independence and to provide counselling and support. A coordinated, multidisciplinary approach is the best way of managing the disease, with the development of links between hospital-based, community and palliative-care personnel. At the present time drug therapies are becoming available which may have a modest effect in slowing the progression of MND and prolonging survival. Quality of life issues will be important in the evaluation of the place in management of these new neuroprotective therapies.

The hereditary ataxias

Puneet Opal[1] and Huda Y. Zoghbi[2]

[1] Department of Pediatrics and Institute for Molecular Genetics, Baylor College of Medicine, Houston, TX, USA
[2] Howard Hughes Medical Institute, Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX, USA

The hereditary ataxias are a group of disorders characterized by motor incoordination resulting from dysfunction of the cerebellum and its connections. Although these diseases are easily recognizable due to the obvious cerebellar dysfunction, distinguishing among them is no easy matter. On the one hand, there is a great deal of clinical overlap between genetically heterogeneous diseases; on the other, the manifestations of any given genetic ataxia are protean. Today, although we as clinicians might wish to believe otherwise, we feel forced to conclude that in most instances, once a general diagnosis of hereditary ataxia has been made, determining the specific type relies more on genetic testing than on clinical criteria. Genetic testing, because of its specificity, is a powerful tool; if positive, the diagnosis is irrefutable. This might suggest that the role of the neurologist has been circumscribed, but this is really not the case. Rather, we must take on new responsibilities. Not only must we become familiar with the scientific, ethical, and statistical implications of genetic testing, but we must also learn how best to counsel our patients, an activity previously limited to geneticists in tertiary health-care centres.

The hereditary ataxias fall into two main classes. The first group of ataxias result from enzyme defects and can be either intermittent (e.g. when caused by defects in intermediary metabolism) or chronic (e.g. ataxia telangiectasia, caused by deficiency in DNA repair). These ataxias are inherited in an autosomal recessive or X-linked manner and are typically present in childhood. The second group, consisting of the progressive degenerative ataxias, do not appear to be caused by catalytic abnormalities. They can be further divided based on the mode of inheritance: the autosomal recessive ataxias, of which Friedreich's ataxia is by far the most common; the relatively large group of autosomal dominant inherited ataxias; the rare X-linked ataxias; and, finally, those resulting from defects in mitochondrial function. In this chapter we discuss the genetics of hereditary ataxias within this broad framework, focusing on the chronic degenerative ataxias and their differential diagnosis.

Ataxias resulting from specific enzyme defects: the metabolic ataxias

This heterogenous group of ataxias are best viewed as a subset of inborn errors of metabolism. The cerebellar dysfunction stems from specific enzyme defects that result in either toxic by-products or a deficiency in metabolites that affect neuronal function. The dissection of metabolic pathways in the early half of the twentieth century has played an important role in suggesting candidate enzymes in cloning strategies. This is in contrast to the degenerative ataxias, for which positional cloning, a more time-consuming process, was needed to identify genes encoding novel proteins whose functions are still to be unveiled.

Like most disorders resulting from catalytic deficiencies, the metabolic ataxias tend to be recessive, since the presence of half the complement of enzymatic activity in heterozygotes is sufficient for most metabolic activities to proceed. Because metabolic pathways lie at the root of several housekeeping functions, the resulting ataxia is just one component of a complex clinical phenotype. It is this clinical picture, taken as whole, that usually betrays the underlying metabolic defect. These ataxias are best managed by pediatricians familiar with metabolic derangements and their ramifications. For the clinical neurologist we present only a brief outline. These ataxias can be divided into one of two groups (see Table 117.1). The first group comprises those ataxias that present intermittently when the biochemical abnormalities are at their worst; the second category is characterized by a more chronic and progressive ataxia induced by specific enzyme deficiencies.

Table 117.1. Genetics of inherited ataxias with known enzyme defects

Disease	Chromosomal localization	Enzyme/protein deficiency
I Intermittent ataxias		
Hyperammonemias and aminoacidurias		
OTC deficiency	Xp21.1	Ornithine transcarbamylase
Citrullinemia	9q34	Arginosuccinate synthetase
Arginase deficiency	6q23	Arginase
Arginosuccinaciduria	7cen-q11.2	Arginosuccinate lyase
Hyperornithemia–hyperammonemia–homocitrullinuria syndrome	13q14	Mitochondrial ornithine transporter
Hartnup disease	11q13	–
Isovaleric acidemia	15q14–q15	Isovaleric Acid CoA dehydrogenase
Disorders of pyruvate and lactate metabolism		
Pyruvate dehydrogenase complex	Xp22.2–p22.1	E1-alpha subunit of PDH complex (most common)
Pyruvate carboxylase deficiency	11q13.4–q13.5	Holocarboxylase synthetase
II Progressive ataxias from metabolic insufficiency		
Hexosaminidase deficiency – GM2 gangliosidosis (Tay Sachs disease)	Genetically heterogenous	Hexosaminidase A, B or S isozymes
Niemann Pick	11p15.4–15.1	Acid sphingomyelinase
Niemann Pick type C	18q11–q12	NPC1
Cerebrotendinous xanthomatosis	2q33–qter	Mitochondrial sterol 27 hydroxylase
Metachromatic leukodystrophy	22q13.31–qter	Arylsulfatase A
Adrenoleukodystrophy	Xq28	Adrenoleukodystrophy protein
Abetalipoproteinemia	4q22–q24	Microsomal triglyceride transfer protein
Hypobetalipoproteinemia	2p24	ApoB
Ataxia with Vitamin E deficiency	8q13.1–q13.3	Alpha-tocopherol transfer protein
Lesch–Nyhan syndrome	Xq26–q27.2	Hypoxanthine–guanine phosphoribosyltransferase
Wilson disease	13q14.3–q21.1	ATP7B protein
Ceroid lipofuscinosis	Several variants	Multiple gene products
X-linked ataxia, ichthyosis and tapetoretinal dystrophy	Xpter-p22.32	Arylsulfatase C
III Progressive ataxia associated with defective DNA repair mechanisms		
Ataxia telangiectasia	11q2.3	ATM kinase
Xeroderma pigmentosa	Several variants	Multiple
Cockayne syndrome	Several variants	Multiple

The intermittent ataxias result chiefly from deficits of urea cycle enzymes or disorders of pyruvate and lactate metabolism. In all of these conditions, affected infants usually display mental retardation and developmental delay. It is, however, important to distinguish between these subtypes, since some of the supportive measures aimed at preserving biochemical homeostasis differ. Inheritance of urea cycle deficits is autosomal recessive, with the notable exception of the X-linked and relatively common ornithine transcarbamylase deficiency (OTC) (Xp21.1). Ataxias seen in the aminoacidurias, such as intermittent branched-chain ketoaciduria and isovaleric acidemia, are usually diagnosed by the characteristic odour of the urine of these infants. Hartnup disease, another aminoaciduria that results in ataxia, is caused by a defect in renal and intestinal transport of amino acids. Because of the associated niacin deficiency, other features of pellagra such as dermatitis and mental confusion are often seen. Treatment of the aminoacidurias consists of a dietary protein modification so as to counter the protein loss, along with nicotinamide supplementation.

Pyruvate dehydrogenase deficiency, a less common form of metabolic intermittent ataxia, is most often caused by a mutation in the E1 alpha subunit of the pyruvate dehydrogenase enzyme (Xp22.2–p22.1) (Dahl et al., 1992). This condition is characterized by lactic acidosis, seizures, mental retardation and spasticity. Biotin responsive multiple carboxylase deficiency, another autosomal recessive ataxia, is caused by a variety of mutations in the holocarboxylase synthetase (*HLCS*) gene at locus 21q22 and characterized by seizures, myoclonus and nystagmus (Aoki et al., 1999; Dupuis et al., 1996).

Metabolic ataxias are usually diagnosed by screening biochemical tests when the neurological abnormalities are first noticed. If the family history is positive, it is even possible to diagnose OTC deficiency and several of the hyperammonemias from blood samples taken in utero. Pyruvate dehydrogenase deficiency can, in addition, be corroborated by a relatively simple biochemical assay on cultured fibroblasts. Despite the identification of individual gene defects, genetic testing is impractical at present because of the large number of mutations in the relevant genes. This scenario is certain to change with the development of low-cost and high-throughput DNA sequencing of genes, especially since diagnosis determines key management decisions.

Progressive metabolic ataxias, much like the intermittent ataxias, can also be caused by a variety of gene defects. Unlike the intermittent ataxias, however, these diseases usually present in later childhood or adolescence and the persistence of the biochemical abnormalities explains the progressive nature of the symptoms. These diseases can mimic the degenerative hereditary ataxias, although most of these diseases have characteristic clinical pictures and hallmark diagnostic tests. For instance, Niemann–Pick is characterized by foamy storage cells in bone marrow. When accompanied by the typical supranuclear gaze palsy, the diagnosis is virtually certain. Adrenoleukodystrophy is often suspected when X-linked inheritance is confirmed, and there are elevated levels of very long chain fatty acids in the blood. Although there is no cure for a number of these ataxic syndromes, there is a growing list of ataxias for which specific measures can be taken to at least halt progression (Table 117.2). As a consequence, efforts to develop cheap genetic tests are gaining centre-stage. Wilson's disease or hepatolenticular degeneration, characterized by copper overload, is probably the best known. Although the disease was described by Kinnier Wilson in 1911, the relevant gene, *ATP7B*, encoding a copper transporting ATPase, was discovered only in the last decade (Tanzi et al., 1993). This gene maps to13q14.3–q21.1. Because there are at least 25 different disease-causing mutations in a gene that occupies 80kb of genomic DNA, genetic testing is currently not possible and diagnosis rests on clinical tests, including the demonstration of Kayser–Fleischer rings and characteristic liver biopsy findings (Thomas et al., 1995). Medical management consists of instituting a diet low in copper, along with zinc that reduces copper absorption from the gut and the chelating agent, D-penicillamine. Other pharmacological agents include triethylenetetramine dihydrochloride (Trientine) and ammonium tetrathiomolybdate, both of value when penicillamine is not tolerated because of occasional toxicity.

Vitamin E deficiency induced by mutations in the alpha tocopherol transfer protein (8q13.1–q13.3) can present as a slowly progressive ataxia syndrome with neuropathy (Gotoda et al., 1995; Ouachchi et al., 1995). Hypovitaminosis E can also occur as part of abetalipoproteinemia, also known as Bassen–Kornzweig disease or acanthocytosis because of the presence of acanthocytes in peripheral blood smear evaluations. Characterized by hypocholesterolemia, hypolipidemia and reduction of fat soluble vitamins A, D, E and K, this ataxia is inherited in an autosomal recessive fashion. Patients often suffer from pigmentary retinopathy from the coexisting deficiency of vitamin A. Mutations in the microsomal triglyceride transfer protein (MTP) that result in an inability to form the apoB peptide of LDL and VLDL cause this syndrome (Sharp et al., 1993). Recently, genetic defects in the apoB gene itself have been identified to cause a virtually indistinguishable ataxic syndrome. Oral supplementation with vitamin E in high doses is effective in slowing down the progression in all these vitamin E deficient states (Martinello et al., 1998).

Cholestenolosis or cerebrotendinous xanthomatosis (CTX) is a relatively rare cause of progressive ataxia. Caused by any one of a variety of defects (missense, nonsense and frameshift) in the mitochondrial 27 hydroxylase gene (locus 2q33–qter), CTX is characterized by autosomal recessive ataxia, neuropathy, cataracts, and achilles tendon xanthomas (Leitersdorf et al., 1993). Magnetic resonance imaging reveals cerebral atrophy and evidence of demyelination. The diagnosis is confirmed by elevated serum cholestanol in the face of normal cholesterol. There is some evidence to suggest that treatment with chenodeoxycholic acid slows progression of the disease (van Heijst et al., 1998).

Refsum disease is yet another treatable ataxia caused by an enzyme deficiency, in this case a deficiency of phytanoyl-CoA hydroxylase that maps to locus 10pter–p11.2. Refsum should be suspected in any autosomal recessive ataxia presenting with the triad of ichthyosis, retinitis pigmentosa and neuropathy (Jansen et al., 1997; Mihalik et al., 1997). Toxicity as a result of the elevation of phytanic acid

Table 117.2. Treatable hereditary ataxias

Disorder	Metabolic abnormality	Clinical features	Treatment
Bassen Kornzweig syndrome	Abetalipoproteinemia	Acanthocytosis, retinitis pigmentosa, fat malabsorption	Vitamin E
Ataxia with isolated vitamin E deficiency (AVED)	Deficiency of alpha-tocopherol transfer protein	Progressive ataxic syndrome	Vitamin E
Hartnup disease	Tryptophan malabsorption	Pellagra rash, intermittent ataxia	Niacin
Mitochondrial complex defects	Complexes I, III, IV	Encephalomyelopathy	Riboflavin, CoQ10, dichloroacetate
Multiple carboxylase deficiency	Biotinidase deficiency	Alopecia, recurrent infections, variable organic aciduria	Biotin
Pyruvate dehydrogenase deficiency	Block in pyruvate metabolism	Lactic acidosis, ataxia	Ketogenic diet, chloroacetate
Refsum disease	Phytanic acid, alpha hydroxylase	Retinitis pigmentosa, cardiomyopathy, hypertrophic neuropathy, ichthyosis	Dietary restriction of phytanic acid
Urea cycle defects	Urea cycle enzymes	Hyperammonemia	Protein restriction, arginine, benzoate, alpha ketoacids

can be minimized by avoiding food containing this substance or its precursors.

Progressive ataxias associated with defective DNA repair

Although caused by known enzymatic defects, these autosomal recessive disorders are usually separated from the metabolic ataxias because they result from a specific inability to repair DNA damage. As might be expected, all of these closely related conditions, ataxia telangiectasia, xeroderma pigmentosum and Cockayne syndrome, are characterized by wide-ranging deficits in organ systems most vulnerable to the fell effects of genome instability.

Ataxia telangiectasia (AT)

AT is the most common of the three, appears in early childhood as growth retardation, hypotonia and diminished reflexes. As the disease progresses, children develop ataxia along with oculomotor apraxia, nystagmus and peripheral neuropathy (Stell et al., 1989). The hallmark telangiectases usually develop by the age of 7 and are most often seen in the conjunctiva of the eyes and in exposed areas of the skin. In the absence of telangiectases, either early in the course of the disease or in atypical cases, AT can be difficult to distinguish clinically from other chronic ataxic syndromes (Maserati et al., 1988). If ataxia develops early, it may be misdiagnosed as an ataxic variety of cerebral palsy; when the onset is delayed, it is most often mistaken for Friedreich's ataxia.

Apart from neurodegeneration, growth retardation and gonadal dysfunction, this disease is also characterized by a tendency to develop cancer and immune function defects. The malignancies typically affect the lymphoreticular system, but there is also a predisposition to cancers of the breast, skin and stomach. Infections resulting from deficiency in both cellular and humoral immunity typically affect the airway and are often life threatening. Other features of AT contributing to morbidity include glucose intolerance because of peripheral insulin resistance and the associated complications of diabetes. Since cloning the *AT* gene, it has been realized that abnormalities in even one copy of the gene might predispose heterozygotes to an increased incidence of cancer, particularly of the breast although this is a matter of still some dispute (Angele & Hall, 2000).

Of diagnostic importance are the low levels of IgA and IgE, a testimony to the defects in humoral immunity. In addition, deficient cellular immunity is reflected in anergy to intradermal injections of a battery of test antigens, which has been of some diagnostic value in the past. Another suggestive feature seen in more than 90% of patients is the elevation of serum alpha-fetoprotein levels (Waldmann & McIntire, 1972).

Both the central and peripheral nervous systems are involved in AT. The central nervous system pathology is

more severe, with cerebellar atrophy and loss of Purkinje cells, whereas the peripheral nervous system involvement is characterized by Schwann cell abnormalities. In line with deficits in the immune system, the thymus is characteristically hypoplastic, with fewer lymphocytes and absent Hassall's corpuscles (Peterson et al., 1964).

AT is difficult to treat and has an especially poor prognosis because of its multisystem involvement. There is no specific treatment for the ataxic syndrome. Most therapies are directed at treatment of infections and malignancies. Diagnostic tests involving X-rays and ionizing radiation should be kept to a minimum, to avoid causing iatrogenic somatic mutations and malignancies. Treatment of malignancies is complicated by the fact that these patients cannot tolerate conventional doses of radiation therapy. Despite the best supportive measures, most patients die in their third decade.

The *AT* gene was mapped to chromosome 11q22.3 in 1988 and the gene was finally cloned in 1995 (Gatti et al., 1988; Savitsky et al., 1995). The gene product, ATM or ataxia telangiectasis mutant, is a protein ubiquitously expressed in all tissues of the body and belongs to a family of important protein kinases called inositol-3 kinases (Brown et al., 1997). The ATM kinase, in particular, appears to play a key role in cell cycle progression. Overwhelming evidence suggests that ATM is involved in a surveillance mechanism designed to stall progression of the cell cycle if and when there is detectable DNA damage. This supervisory function of ATM offers the cell an opportunity to repair the damage rather than bequeath inappropriate genetic information to daughter cells. In the absence of this checkpoint, cells build up somatic mutations and increase their risk of becoming cancerous (Dasika et al., 1999).

The major mechanistic steps in ATM pathogenesis are only now coming to light. It appears that in response to double-stranded DNA damage, the ATM kinase interacts directly with, and phosphorylates, the tumour suppressor protein p53 (Khanna et al., 1998), a transcriptional activator of genes that cause cell cycle arrest or apoptosis. More recently, ATM has been shown to phosphorylate another tumour suppressor, Brca1, one of the genes implicated in breast cancer (Cortez et al., 1999). This interaction may explain how ATM predisposes patients and heterozygotes to breast cancer. Mouse models of the disease promise to increase our understanding of the molecular mechanisms of pathogenesis (Barlow et al., 1996). This is an exciting area of scientific research at the crossroads of tumour biology, cell cycle research and neurodegeneration (Canman & Lim, 1998; Rotman & Shiloh, 1998).

A disease very similar to AT, known as the Aicardi variant, was in the past separated from AT by the lack of telangiectasia and severe limitation in vertical eye movements. This disease is now known to share the same genetics as AT. There is, however, at least one disorder that closely mirrors AT but results from a defect in a gene other than ATM. Called ataxia–telangiectasia-like-disorder (ATLD), this disorder is caused by a mutation in the gene hMRE11 encoding a protein involved in the DNA repair complex of which AT is another component (Stewart et al., 1999).

Xeroderma pigmentosum (XP) has an incidence of approximately 1 in a million. This disease is characterized by a range of cutaneous lesions varying from mild freckling to xerosis, erythema, bullae, telangiectasia, actinic keratosis and skin malignancies. Most of these lesions occur around the eyes and eyelids. The eyes are also threatened by an increased incidence of keratitis, opacification of the cornea, iritis with synechia formation, and malignant melanoma of the choroid. The neurological features of xeroderma pigmentosa consist of progressive cognitive decline, sensorineural deafness, peripheral neuropathy and choreoathetosis. As with AT, XP is characterized by an increased risk of neoplasms (Kraemer et al., 1984). Oral administration of retinoic acid has been shown to be helpful in preventing skin cancer (Kraemer et al., 1988).

At a molecular level, XP constitutes a genetically heterogenous group of disorders characterized by defects in genes encoding proteins involved in excision repair (Lehmann et al., 1994). There are several complementation groups based on functional studies using fibroblasts derived from human patients. Patients in the same complementation group have a similar constellation of symptoms with variable neurological involvement that can range from severe to none at all. Ultraviolet-sensitive chinese hamster cells have also been successfully used to identify genes involved in excision repair. Because some of these genes were named by both of these methods, there is an unfortunate redundancy in the nomenclature.

Cockayne syndrome (CS) is a rare disorder (Nance & Berry, 1992). Although the clinical phenotype shows some overlap with XP in deafness and ataxia, patients with CS also show characteristic retinal degeneration and early aging without displaying a tendency to develop cancer. Pathologically, there is evidence for demyelination in the central nervous system and basal ganglia calcification, both of which are detected in imaging studies. Like XP, CS is genetically heterogenous, with several complementation groups. In fact, there are a few patients with a mixed XP–CS phenotype. The key defect in most cases appears to be insufficiency of transcription or transcription-translation coupled repair, a phenomenon that pertains to excision repair of DNA that must precede the transcription of active genes (van Gool et al., 1997).

Table 117.3. Genetics of chronic progressive hereditary ataxias

					Repeat lengths	
Disease	Gene	Chromosome	Protein	Mutation	Normal	Disease
Friedreich's ataxia	X 25	9q13.1–21.1	Frataxin	GAA repeat expansion in intron 1 of the gene	7–34	>100
SCA1	SCA1	6p23	Ataxin-1	CAG repeat in coding region of gene	6–44[a]	36–121
SCA2	SCA2	12q24.1	Ataxin-2	CAG repeat in coding region of gene	15–31	36–82
SCA3 (Machado Joseph disease)	SCA3, MJD1	14q32.1	Ataxin-3	CAG repeats in coding region of gene	12–40	55–84
SCA4	SCA4	16q22.1				
SCA5	SCA5	11p11–11q11				
SCA6	SCA6	19p13	Alpha-1A voltage-dependent calcium channel subunit	CAG repeat in coding region of gene	4–18	21–33
SCA7	SCA7	3p12–13	Ataxin-7	CAG repeat in coding region of gene	4–35	37–306
SCA8	SCA8	13q21	None	CTG repeat in the 3′ terminal exon (antisense)	16–37	110–<250?
SCA10	SCA10	22q13ter	–	Pentanucleotide repeat in intron	extremely large ATTCT expansions in disease	
SCA11	SCA11	15q14–q21	–	–	–	
SCA12	SCA12	5q31–33	Protein phosphatase 2A	CAG repeat in 5′ UTR	7–28	66–78
SCA13	SCA13	19q13.3–q13.4	–	–		
SCA14	SCA14	19qter–q13.4	–	–		
DRPLA	DRPLA	12q	Atrophin-1	CAG repeat in coding region of gene	6–35	49–88

Notes:
34–100 can be premutations (see text).
[a] Alleles with 21 or more repeats are interrupted by 1–3 (CAT) units; disease alleles contain pure CAG tracts.

Degenerative ataxias not caused by specific enzyme deficiencies

In the past, the degenerative ataxias were distinguished from the previous group by the paucity of knowledge regarding the causative mechanisms and the lack of correspondence to clear-cut enzyme deficiencies. Nonetheless, major strides have been made in the last decade in understanding their molecular basis (Table 117.3). Surprisingly, several of these ataxias appear to result from a common mutational mechanism: a repeat expansion within the disease-causing gene (Zoghbi & Orr, 2000). When the repeat expansion occurs in the coding region of the gene, it causes an expanded polyglutamine repeat in the resulting protein. This family comprises dentatorubropallidoluysian atrophy (DRPLA), spinocerebellar ataxias (SCAs) 1, 2, 3, 6 and 7. The family of ataxic disorders characterized by a repeat expansion in the noncoding region of the gene consists of the trinucleotide disorders Friedreich's ataxia and the spinocerebellar ataxias 8 and 12, a pentanucleotide repeat disorder (SCA10), and a dodecamer repeat disorder (Baltic myoclonus).

The expanded repeats, whether in the coding or noncoding region, show repeat instability, with a tendency to expand in germline transmission. For the afflicted family, this unfortunately results in the phenomenon of 'anticipation', an earlier disease onset and a progressively worse phenotype with each subsequent generation. All trinucleotide repeat disorders that cause ataxia are autosomal dominant with the exception of Friedreich's ataxia, which is inherited in an autosomal recessive manner. Besides the triplet repeat diseases, there are a few other genetic conditions that present with similar ataxic syndromes; although

most are quite rare, they are discussed in the differential diagnosis to make the list comprehensive.

The autosomal recessive cerebellar ataxias

Friedreich's ataxia

Friedreich's ataxia (FRDA) is the most common autosomal recessive spinocerebellar ataxia, with a prevalence rate of 1 to 2 per 100 000. In the typical case, symptoms begin in late childhood or adolescence. The neurological phenotype is characterized by the cerebellar features of ataxia, scanning speech and nystagmus. In addition, eye movements tend to be sluggish, the gait is disorganized and lurching, and patients demonstrate signs of motor and sensory neuropathy. Because of the motor neuropathy, especially in the later stages of the illness, the distal extremities become weak and wasted while sensory neuropathy causes loss of vibration sense and proprioception. Early evidence for sensorimotor neuropathy can be elicited clinically by absent ankle reflexes and impairments on electrophysiological tests. These constitute the core features of the diagnosis (Harding, 1984).

Other noteworthy neurological features include incontinence, visual disturbance because of optic atrophy and, rarely, deafness from degeneration of cochlear neurons. Occasionally extrapyramidal involvement in the form of choreiform movements may be seen. Besides involvement of the nervous system, patients with FRDA often have musculoskeletal abnormalities such as scoliosis, kyphoscoliosis and pes cavus. Often this requires orthopedic intervention. Cardiac pathology is another hallmark of the disease and usually results from muscular subaortic stenosis and hypertrophic cardiomyopathy. In the later stages, a dilated form of cardiomyopathy with wall motion abnormalities replaces the earlier hypertrophic picture. In the early stages of the disease, however, a wide range of abnormal ECG findings have been observed: T wave abnormalities, deep Q waves, low QRS complexes, and the more obvious heart block. Thus all patients should be closely followed by yearly ECGs and chest X-rays. Although there is variability in the progression of the disease, the mean age of death is in the fourth decade (Hewer, 1968). Death occurs because of cardiac complications or bulbar dysfunction. As in AT, approximately one-fourth of the patients with Friedreich's ataxia develop glucose intolerance and diabetes that increases morbidity.

Since discovery of the gene and the availability of genetic testing, we are beginning to appreciate atypical presentations of FRDA, which can present as early as infancy and should be suspected when delay in achieving motor milestones is associated with skeletal abnormalities. This early onset phenotype tends to be associated with a worse prognosis than typical Friedreich's. Surprisingly, FRDA can also present much later in life, even beyond the age of 40, in a so-called 'very late onset FRDA' (Bidichandani et al., 2000; Palau et al., 1995). Since several of the cardinal features of FRDA are milder in this instance, with a preservation of reflexes, this variant was bracketed into a separate category in the pregenetic era: 'autosomal recessive ataxia with preserved reflexes'.

In the past, the diagnosis of FRDA was primarily a clinical one, resting on the aforementioned signs and symptoms and supported by only a few ancillary tests. Electrophysiologic testing provides additional evidence for motor and sensory axonal neuropathy, whereas ECG findings present supportive evidence relating to the cardiac manifestations of the disease. MRI scans in FRDA often show evidence of spinal cord and cerebellar atrophy. Today, the only necessary diagnostic test is genetic, and it should be performed in all recessive, chronic ataxic syndromes.

FRDA is caused by a GAA repeat expansion in the first intron of the gene called *frataxin* or *X25*. This gene is located on chromosome 9q13 (Campuzano et al., 1996). Most normal individuals carry alleles ranging from 7 to 34 GAA repeats, while patients with the disease have alleles with a tract of over 100 repeats. Tract sizes that vary between 34 and 100 do not result in disease, but are further divided based on whether or not they are interrupted by non-GAA repeats. If interrupted, they are considered non-pathological, because the interruption stabilizes the repeat against expansions in subsequent generations. On the other hand, uninterrupted repeat tracts with 34 to100 GAAs are considered to be pre-mutations, since without the stabilizing influence of the interruption they can expand to over 300 repeats in just a single generation (Cossee et al., 1997). The unstable repeats tend to expand in paternal transmission, and can expand or contract in maternal transmission. Because of the recessive nature of the disease, with a requirement for two expanded alleles, there is no anticipation. Nonetheless, disease severity and onset of disease correlate with repeat length. This is not just confined to the neurological phenotype, but also holds true for the glucose intolerance and the skeletal and cardiac abnormalities as well (Filla et al., 1996; Monros et al., 1997).

As might be expected from its recessive genetics, Friedreich's ataxia is caused by a loss of function of the gene product, frataxin. The intronic repeat expansion results in a reduced expression of the messenger RNA encoding this

210 amino acid protein. That Friedreich's is caused by a loss of function mechanism is supported by the observation that a Friedreich's phenotype can also be seen in patients carrying only one expanded allele of frataxin, provided their second allele is inactive due to a point mutation (Bartolo et al., 1998). This situation might be more common than currently recognized, since most genetic tests search for expansions and not for other types of mutations.

Recent research has aimed to delineate the function of frataxin and explain why its loss should result in such widespread and profound pathology. It appears that frataxin is a mitochondrial protein, expressed at particularly high levels in tissues undergoing degeneration such as the brain, heart and pancreas (Campuzano et al., 1996; Koutnikova et al., 1997; Puccio & Koenig, 2000). Studies of the yeast frataxin homologue suggest that this protein is involved in the normal efflux of iron from mitochondria (Babcock et al., 1997). Inactivation of the protein causes iron to accumulate in the mitochondria, which in turn might disrupt mitochondrial respiratory chain function, resulting in oxidative stress (Radisky et al., 1999). In humans, iron deposits have been found in the myocardium of FA patients (Rotig et al., 1997). This raises the intriguing possibility that chelating agents and antioxidants might reverse pathology (Rustin et al., 1999).

Differential diagnosis of recessive progressive hereditary ataxias

As mentioned earlier, atypical cases of AT can be misdiagnosed as FRDA until the disease progression tilts the spectrum of symptoms towards the one or the other. Another autosomal dominant condition with a better prognosis, hereditary motor and sensory neuropathy type I (HMSN I), can also mimic FRDA because of areflexia and a sensory ataxia. Nerve conduction tests in HMSN I, however, usually reflect an underlying dysmyelination as opposed to the axonal pathology of FRDA.

Harding separated 'hereditary ataxia with retained tendon reflexes' from Friedreich's ataxia as a distinct clinical entity (Harding, 1981). Recent genotype–phenotype correlations, however, indicate that this disorder actually represents a milder variant of Friedreich's in which the repeat size is relatively small. There are autosomal recessive cerebellar ataxias that can mimic FRDA but have a distinct genetic basis. Most are rare, but they can occur at higher rates in isolated pockets of the world because of consanguinous marriages. One such disorder is autosomal recessive spastic ataxia of Charlevoix–Saguenay, named after the region in Quebec where it was first described. The recently cloned gene, mapping to chromosome 13q11 (Engert et al., 2000), encodes a large protein with a predicted molecular weight of 437 kDa that shares some homology to molecular chaperones, proteins that play a role in protein misfolding. This is intriguing, since protein misfolding appears to play a central role in the polyglutamine-induced autosomal dominant ataxias, as will be discussed later in this chapter.

Infantile onset spinocerebellar ataxia is another geographically isolated condition (Koskinen et al., 1994). Recently identified as an autosomal recessive ataxia in the North Carelia province of Finland, this ataxia maps to 10q24 (Nikali et al., 1997). It is characterized by early-onset ataxia with ophthalmoplegia and hearing loss. In addition, affected infants have EEG abnormalities and seizures.

Wolfram syndrome, characterized by diabetes insipidus, diabetes mellitus, optic atrophy and deafness (DIDMOAD) (4p16), can also present with ataxia. It is now known to be caused by a mutation in a transmembrane protein expressed predominantly in the pancreas and the brain (Strom et al., 1998). Among the cerebellar ataxias yet to be genetically characterized are Marinesco–Sjögren's syndrome, characterized by cerebellar ataxia, congenital cataracts, impaired physical growth, mental deficiency, myopathy and skeletal abnormalities, and Matthews Rundle syndrome with ataxia and hypogonadism. In passing it should be mentioned that the term Ramsay Hunt syndrome was used in the past to describe ataxia combined with myoclonus. This syndrome is actually not a distinct disease entity; its combination of symptoms can be seen in some of the storage disorders described above, particularly sialidosis, and in some of the ataxias due to defects in mitochondrial function (described below). Myoclonus is also a hallmark of the autosomal recessive Baltic myoclonus of Unverricht–Lundberg, in which the underlying defect is in the gene encoding the protease inhibitor cystatin B (Pennacchio et al., 1996). Surprisingly, in most instances this is also a repeat disorder, but it is a dodecamer repeat in the gene's promoter (Lalioti et al., 1997).

The autosomal dominant hereditary ataxias

The autosomal dominant cerebellar ataxias have an interesting history. They were first recognized by Marie in 1893 as a syndrome distinct from FRDA because of their autosomal dominant pattern of inheritance (Marie, 1893). Gordon Holmes rightly recognized Marie's ataxia or the 'hereditary olivo-pontocerebellar atrophies' as a clinically

Table 117.4. Correlation between Harding's clinical classification and genetic classification

Harding's classification	Genetic typing
ADCAI: Ataxia with ophthalmoplegia, optic atrophy, dementia or extrapyramidal features	SCA1, SCA2, SCA3, SCA4, SCA12, possibly DRPLA
ADCAII: Ataxia with pigmentary maculopathy with or without ophthalmoplegia or extrapyramidal features	SCA7
ADCAIII: Relatively pure ataxia	SCA5, SCA6, SCA8, SCA10, SCA11, SCA13, SCA14

Table 117.5. A few differentiating features of the autosomal dominant spinocerebellar ataxias

AD spinocerebellar ataxia	Distinguishing features
SCA1	Relatively nondescript spinocerebellar ataxia with neuropathy and pyramidal signs
SCA2	Slow saccades, myoclonus, areflexia
SCA3	Bulging eyes, fasciolingual fasciculations, extrapyramidal signs
SCA4	Sensory neuropathy
SCA5	Slow course despite early onset
SCA6	Very late onset, mild, apparently sporadic onset
SCA7	Macular degeneration
SCA8	Mild
SCA9	Unassigned
SCA10	Generalized or complex partial seizures
SCA11	Mild
SCA12	Tremor, dementia
SCA13	Mental retardation
SCA14	Sometimes myoclonus
DRPLA	Chorea, seizures, myoclonus

and pathologically heterogenous group (Holmes, 1907). Since this observation, numerous classifications have been proposed to sort individual members of the group by clinical presentation, the most recent being proposed by Anita Harding in 1984 (Harding, 1984). She divided these ataxias into three distinct groups called autosomal dominant cerebellar ataxia types I, II and III.

Over the last several years, however, a new classification based on the genetic loci of the spinocerebellar ataxias (SCA) has gained wide acceptance. These disorders have been numbered based on their order of identification: SCA1 through 14, with a locus for SCA9 yet to be assigned. We have tried to correlate the older Harding classification with this genetic nomenclature for the sake of smoothing the transition between systems, but because of the broad overlap of clinical features and phenotypic variations within each disorder, such a correspondence is difficult to achieve in clinical practice (Tables 117.4 and 117.5). As mentioned earlier, several of the SCAs are nucleotide repeat disorders and therefore present with the common findings of anticipation and increased severity correlating to the size of the nucleotide expansions within the relevant gene.

SCA1 was the first dominantly inherited ataxia gene to be linked to a locus (6p22–23) (Zoghbi et al., 1989). It is characterized by progressive cerebellar ataxia, dysarthria, and bulbar dysfunction that results in death. Other accompaniments include hyperreflexia, increased tone and extensor plantar responses. Occasionally, the peripheral nervous system involvement can obscure these upper motor neuron findings and lead to wasting of the extremities and generalized fasciculations. Oculomotor signs include nystagmus, lid retraction and slowing of saccades. Atypical features include chorea, dystonia and bladder incontinence. The disease most often presents in the third decade of life, but can appear as early as age 6 or as late as the 70s. It was this clinical feature that led to a targeted search for trinucleotide repeat expansions, known to be the defect in causing anticipation in other neurological conditions. The natural history of this disease is also variable, with an earlier onset forecasting an accelerated progression. The mean duration of the illness ranges from nine to sixteen years.

SCA1 is caused by a CAG repeat expansion in the coding region of the gene *SCA1* encoding the protein ataxin-1 (Orr et al., 1993). At the time of this writing, the normal function of ataxin-1 remains unknown. Immunolocalization studies show that mutant ataxin-1 aggregates into single ubiquitin-positive nuclear inclusions (NI) that are approximately 2 microns in size (Skinner et al., 1997). NIs have been noted in other glutamine repeat diseases as well. These inclusions often contain not only the relevant disease-causing protein, but they also stain positive for chaperones and components of the ubiquitin–proteasomal pathway, which

are both instrumental in protein clearance. Recent work suggests that ataxin-1 tends to accumulate in SCA1, probably because of an altered conformation induced by the polyglutamine tract. Ubiquitination and proteosomal degradation probably represent a cellular protective response: interventions to prevent these processes in SCA1 and other polyglutamine diseases only increase neuronal toxicity (Chai et al., 1999; Cummings et al., 1999; Saudou et al., 1998). Based on these findings, strategies aimed at improving protein folding or clearance are gaining centre stage.

SCA2 distinguishes itself from SCA1 by the clinical feature of slow saccadic eye movements in afflicted patients. Genetically, however, it was set apart from SCA1 when its locus (12q23–24) was identified (Auburger et al., 1990; Orozco et al., 1990). The *SCA2* gene encodes a protein called ataxin-2 that contains structural elements that appear to be important in RNA splicing. Disease-causing alleles contain 36–63 repeats, whereas healthy people harbour 15–31 repeats. Like SCA1, SCA2 is also characterized by variable features. Some patients display tremors, some complain of severe muscle cramps, some occasionally suffer incontinence. When *SCA2* alleles contain more than 200 repeats, the disease can present as early as infancy with hypotonia, developmental delay, dysphagia and retinitis pigmentosa (Babovic-Vuksanovic et al., 1998). The genetic background may be relevant, since atypical features are seen in geographically distinct families: mental deterioration in an Italian family (Babovic-Vuksanovic et al., 1998; Malandrini et al., 1998), chorea and dystonia in families from Tunis and Martinique (Belal et al., 1994; Dürr et al., 1995).

SCA3 or Machado–Joseph disease (MJD) is probably the most common of the autosomal dominant spinocerebellar ataxias and also has a broad clinical spectrum. The disease initially linked to the spinocerebellar ataxia 3 locus was not recognized as an MJD variant, since the initial SCA3 patients did not exhibit the extrapyramidal syndrome which was then thought to be characteristic of the MJD syndrome. Only when linkage analysis assigned both of these ataxic syndromes to the same genetic locus on the long arm of chromosome 14 (14q24.3–q32) did it become clear that they were one and the same disease (Kawaguchi et al., 1994). *SCA3* encodes the 42 kDa ataxin-3, a predominantly cytoplasmic protein, which is the smallest polyglutamine disease protein. The glutamine tract is close to the C terminal of the molecule.

Besides ataxia, clinical features in SCA3 include slow saccades and saccadic pursuit. Other features include lid retraction that gives the impression of a persistent stare, and signs of brainstem dysfunction including dysarthria, difficulty in swallowing, poor cough and tongue fasciculations. Because of peripheral nervous system involvement, the neurological examination usually shows a mix of upper and lower motor neuron findings. Thus tone can range from hypotonia to significant rigidity and reflexes can be exaggerated or absent. The plantar response tends to be extensor. The common extrapyramidal features include rigidity and dystonia. In the past MJD had been classified into three subtypes: type I, when spasticity was the major sign without significant ataxia; type II when ataxia occurred on its own; and type III when ataxia was accompanied by peripheral neuropathy. This classification formalizes the phenotypic variability that we now know is most likely contributed by genetic background and polyglutamine length.

SCA4 has no features that distinguish it from the other ataxias, except perhaps for an exaggerated sensory axonal neuropathy that results in absent reflexes. Otherwise, it is almost a purely cerebellar syndrome with little in the way of brainstem dysfunction. The gene, which maps to 16q22.1, has yet to be identified.

SCA5 and 6 are both characterized by an almost pure cerebellar syndrome. SCA5, in particular, is a relatively mild syndrome with a slow progression. In SCA6, there is occasional horizontal and vertical nystagmus and abnormal vestibulo-ocular reflex (Gomez et al., 1997). Both diseases begin in the third decade, and MRI examinations on affected patients show cerebellar atrophy. The CAG tract in SCA6 is the shortest polyglutamine repeat length of all the SCAs: 21–33 repeats in the disease state, with normal alleles less than 18 (Zhuchenko et al., 1997). Moreover, SCA6 is unique among the dominant ataxias in that its gene encodes a protein with a known function: the P/Q type calcium channel alpha-1a subunit. Intriguingly, this gene has been implicated in episodic ataxia type 2 and familial hemiplegic migraine, although the mutational mechanisms are distinct (Ophoff et al., 1996). Nonetheless, compromise of the function of the calcium channel might be central to all three, since there is some overlap of symptoms. Like episodic ataxia, SCA6 can present with intermittent ataxia in the early stages, and all three conditions (SCA6, EA2 and familial hemiplegic migraine) often involve cerebellar atrophy.

Among the spinocerebellar ataxias, SCA7 has perhaps the most variable expression. With childhood onset, the usual features of ataxia are accompanied by seizures, myoclonus, and cardiac involvement. In adults, ataxia develops along with oculomotor abnormalities. In both childhood and adult cases, visual loss from pigmentary macular degeneration is almost invariable, and can precede the ataxic syndrome. Since this sets it apart from the other autosomal dominant ataxias, defects in colour vision and

electroretinogram abnormalities might suggest the diagnosis in early cases (Gouw et al., 1995). SCA7 is a glutamine repeat disorder mapping to chromosome 3p12–p21.1. Expanded alleles have repeats between 38 and 306; normal alleles range from 7 to 17. Another notable feature of SCA7 is the remarkable intergenerational instability, with expansion particularly likely upon paternal transmission (David et al., 1997; Stevanin et al., 1998). As in SCA2, it is the expanded allele that contributes to the severe infantile phenotype (Benton et al., 1998).

SCA8 is difficult to distinguish clinically from the other SCAs, yet it is the only SCA with a possibly novel mechanism of pathogenesis for triplet repeat disorders. The repeat expansion in this case occurs in a CTG tract in the non-coding region of the relevant gene. Data suggest that the *SCA8* gene might encode an antisense RNA that regulates the levels of a neighboring messenger RNA (Koob et al., 1999). This hypothesis has recently become a point of dispute, since the expansion has been seen in normal individuals as well and might simply represent a polymorphism in linkage disequilibrium with the disease-causing mutation.

In SCA10, seizures coexist with spinocerebellar ataxia, and this ataxia appears to be more common among Mexicans. This spinocerebellar ataxia at locus 22q13–qter, is a repeat disorder with anticipation, although in this case the repeat is an intronic expansion of a pentanucleotide ATTCT (Matsuura et al., 1999, 2000; Zu et al., 1999).

SCA11 is a relatively mild ataxia assigned to locus 15q14–q21, but little is known about disease pathogenesis (Worth et al., 1999). SCA12 is a trinucleotide repeat disorder caused by a CAG trinucleotide expansion in the 5′ UTR of a gene encoding a brain-specific regulatory subunit of protein-phosphatase 2A (Holmes et al., 1999). This ataxia is often complicated by tremors and dementia in the later stages of disease progression. SCA13 is a childhood-onset ataxia with associated features of mental retardation and developmental delay (Herman-Bert et al., 2000). SCA14, a novel ataxia identified in Japan, causes older patients to display ataxia whereas those with a younger age at onset frequently display myoclonus (Yamashita et al., 2000). The genes responsible for SCA 13 and 14 are unknown, but both diseases appear to map to distinct loci on the long arm of chromosome 19.

Based on this brief summary of the known autosomal dominant spinocerebellar diseases and their phenotypes, it should not be misconstrued that all genes contributing to dominant spinocerebellar ataxia have been identified. Only 60–70% of patients have mutations in the known loci. This situation is likely to change and on-line resources such as the Online Mendelian Inheritance in Man (www.OMIM.org) provide an excellent means for keeping track of advances in this area.

Besides the numbered spinocerebellar ataxias, there are other autosomal dominant conditions that result in ataxias. Dentatorubropallidoluysian atrophy (DRPLA) is relatively common in Japan, and should be suspected when ataxia and rigidity are accompanied by choreoathetosis, myoclonic epilepsy and dementia. Other features include hyper-reflexia and slowing of saccades. Caused by an expanded CAG repeat, anticipation is more common with paternal transmission. The relevant protein encoded by the *DRPLA* gene (locus 12p) is called atrophin-1. This is a cytoplasmic protein with a molecular weight of 125 kDa (Nagafuchi et al., 1994; Onodera et al., 1995). Calcification of the basal ganglia and leukodystrophic changes are often seen on imaging studies. Haw–River syndrome is a variant of DRPLA, without the characteristic myoclonic epilepsy, and is seen in a few families of African–American descent in North Carolina (Burke et al., 1994).

Another class of diseases that may resemble the spinocerebellar ataxias are the prion disorders with mutations in the prion or *PRNP* gene. Of these, Gerstmann–Straussler–Scheinker disease (GSS), particularly the ataxic variant, is the most likely to mimic a spinocerebellar syndrome. GSS is diagnosed when autosomal dominant ataxia coexists with cognitive and motor decline alongside pathological findings of prion protein-containing amyloid plaques. Unlike those afflicted with the other SCAs, GSS patients often complain of altered sensation or even pain in their legs; moreover, they rather rapidly develop cognitive decline and EEG changes, similar to the more common variants of prion diseases such as Creutzfeldt–Jakob Disease (CJD). GSS represents a group of at least six mutations in the *PRNP* gene, with the ataxic variant caused by a proline to leucine missense mutation at codon 102 (Dohura et al., 1989; Hsiao et al., 1989; Prusiner & Hsiao, 1994).

Diagnostic studies in the autosomal dominant spinocerebellar ataxias

In all autosomal dominant ataxias, neuroimaging studies by MRI and computerized axial tomography (CAT) mirror the clinical and pathological phenotypes of each of the spinocerebellar ataxias. Cerebellar atrophy is the most commonly reported finding, along with enlargement of the fourth ventricle. The relative degrees of degeneration vary, with SCA2 patients showing the most atrophy and those with SCA5 and 6 the least. Brainstem atrophy, which one would expect to be almost universal, can be minimal in SCA3 and DRPLA, and is rare in SCA6. On the other hand,

it is quite characteristic of SCA1, 2 and 7. Cerebral atrophy and compensatory enlargement of the lateral ventricles can be seen in DRPLA, SCA2 and the infantile variant of SCA7. But one of the chief advantages of imaging is to help exclude other causes of ataxia such as posterior fossa lesions, tumours, or demyelinating conditions such as multiple sclerosis.

More expensive imaging studies such as magnetic resonance spectroscopy and positron emission tomography (PET) scanning are sensitive markers for deterioration and show abnormalities beyond the structural changes revealed by MRI scans. Their utility in diagnosing these diseases, however, is controversial and at the moment these modalities should be reserved for research rather than diagnosis.

Most spinocerebellar ataxias cause defects in nerve conduction, especially SCA4. The predominant axonal neuropathy affects mainly sensory neurons, and sural nerve action potentials are commonly absent. Nerve conduction abnormalities, however, are rarely helpful in determining the genetic subclass of the ataxia. On the other hand, visual-evoked potentials can be helpful to suggest SCA7, while interictal electroencephalograph (EEG) abnormalities might suggest DRPLA. Although seizures are common in SCA10, interictal EEGs are typically normal.

Genetic testing is the only definitive diagnostic test. The Harding clinical classification and the few differentiating features (Tables 117.4 and 117.5) may help in suggesting likely candidates for a step-wise screen. More often, blood is sent out to test for mutations in a battery of genes. So far, this list includes SCA1, 2, 3, 6, 7, 8 and DRPLA, but it is likely to increase. Once again, on-line resources, e.g. www.geneclinics.org, are extremely informative.

Episodic ataxias

There are two varieties of dominantly inherited episodic ataxias called episodic ataxia type 1 (EA1) and 2 (EA2). Both of these diseases begin in late childhood or adolescence and respond to treatment with acetazolamide.

Patients with EA1 show short episodes of ataxia rarely lasting beyond a few minutes. Ataxic spells sometimes are induced by exercise and may be accompanied by myokymia in the hands and face. Pathology is minimal, with mild atrophy of anterior cerebellar vermis. The genetic basis for EA1 is the presence of point mutations in a voltage-gated potassium channel gene, *KCNA1*, located on chromosome 12p13 (Browne et al., 1994; Scheffer et al., 1998).

In EA2 the attacks are longer, lasting usually for a few hours or even days. Moreover, these episodes appear to result in cumulative damage, as patients often go on to develop cerebellar symptoms and atrophy. Subtle cerebellar signs such as nystagmus and mild clumsiness should therefore tilt the diagnosis towards EA2 rather than EA1. As mentioned in the context of SCA6, EA2 is caused by mutations in the α-$_{1A}$ subunit of the calcium channel gene, the gene involved in SCA6 and also familial hemiplegic migraine. Known mutations in EA2 include a frameshift mutation in the coding region of the channel itself and a substitution in a conserved region of an intron that may affect splicing of the gene (Ophoff et al., 1996).

The episodic ataxias are difficult to diagnose in children, from whom a history can be difficult to elicit. Diseases that can mimic this syndrome (apart from the metabolic ataxias mentioned earlier) include the non-hereditary causes of ataxia such as posterior fossa masses, basilar migraine, seizures, benign paroxysmal vertigo and the accidental ingestion of toxins.

X-linked ataxias

Besides adrenomyeloneuropathy, which can present as an ataxic syndrome, there are a few X-linked progressive ataxias. These can be almost purely cerebellar syndromes (Lutz et al., 1989; Spira et al., 1979) or associated with a wider spectrum of signs such as anemia, deafness, spasticity or dementia (Apak et al., 1989; Arts et al., 1993; Farlow et al., 1987; Raskind et al., 1991). In most instances the genetic loci are still unknown, with the exception of an early onset X-linked ataxia that is characterized by deafness and loss of vision and links to locus Xq21.2–q24 (Kremer et al., 1996).

Mitochondrial ataxias

Mitochondrial deficits can present with a progressive or intermittent ataxia. For instance, Leigh's syndrome, a genetically heterogeneous syndrome caused by mutations in several genes affecting mitochondrial function, often presents with an intermittent ataxia and a necrotizing encephalitis not unlike that seen in thiamine deficiency. An MRI scan is informative in revealing characteristic subcortical necrotic lesions.

Leigh's syndrome is also often accompanied by cardiomyopathy, presumably because of mitochondrial energy failure in cardiac muscle. Ataxia and myoclonus can also be seen in other defects of the mitochondrial genome. Both larger deletions and duplications characteristic of Kearns–Sayre syndrome and maternally inherited point mutations in mitochondrial genes encoding tRNA, the

MELAS (mitochondrial encephalopathy, lactic acidosis and stroke-like episodes) and MERRF (myoclonic epilepsy with ragged red fibres) have been associated with the ataxic phenotype.

Genetic testing in the hereditary ataxias

Genetic testing is the only definitive way to pinpoint the nature of a hereditary ataxia. Because of the expense of such testing, a detailed history of the patient and his or her family, in addition to a thorough clinical examination, should be used to guide the selection of molecular tests. In the case of ataxias resulting from catalytic insufficiency, it is still relatively difficult to test for genetic mutations in large genes, where a variety of mutations can produce a similar picture. In these instances the biochemical sequelae of the disease form the basis for most diagnostic tests. Automated and high throughput screening should make genetic testing more feasible in the future. This would be an especially fortunate situation, since so many of these diseases are amenable to therapeutic intervention.

In the case of the progressive degenerative ataxias caused by nucleotide repeat expansions, the situation is diametrically opposite. It is already possible to provide genetic tests of high specificity and sensitivity, but there is little in the way of therapeutic intervention. For patients presenting with symptoms, these tests are diagnostic and exclude further search for other causes of ataxia. If the test result is positive, patients should be counselled not just with regard to their own prognosis but also about the implications for family members (present and future) and their risk for the disease. Several neurology departments and physicians have created helpful web page links to support groups such as the National Ataxia Foundation (www.ataxia.org) and non-profit organizations such as www.wemove.org, that help patients and families to understand and cope with their disease.

Genetic testing of asymptomatic family members for diseases for which there is no therapeutic intervention is debatable. Such testing should be performed only after the implications are explained. For instance, if the grandchild of a patient with autosomal ataxia tests positive, the intermediate generation must be a carrier, even if this person did not submit to testing. Ethical norms should be scrupulously followed, especially with regard to respecting the right of the individual to make the decision for themselves about whether to know or keep their status in the dark. Confidentiality is an extremely important issue in the present climate of managed care, when insurance companies might discriminate based on this information. Genetic testing of asymptomatic children should be avoided.

In conclusion, a decade ago, it would have been difficult to predict the rapid advances that have taken place in our understanding of the genetics of hereditary ataxias. This progress has not been confined to the identification of the genetic basis of individual diseases; we have begun to sort out candidate pathways in pathogenesis using tools from the growing armamentarium offered by present day molecular biology and genomics. The development of animal models, in particular, is now recognized as a notable first step in hypothesis testing. The various species, mice, *Drosophila*, *C. elegans* and yeast, offer powerful, complementary tools for elucidating complex pathways at the level of the whole organism. In the prevailing climate of combinatorial chemistry and rational drug design, we anticipate high-throughput screens for chemical modifiers using simple animal models. Using such techniques pharmaceutical companies could identify candidate agents that could then be tested as therapeutic agents first in animal models and then in the human patient.

For the patient, there is reason for hope, even though the desired outcome of actual therapies remains years in the future. Genomics and web-based dissemination of information have already wrought changes in the way patients view their illnesses. They are better informed about the genetics of transmission and disease prognosis and are therefore in a better position to plan their lives. In return, they are often more willing to provide blood samples for DNA analyses and enrol in the clinical trials that are crucial for our collective progress.

Huntington's disease

Christopher A. Ross[1] and Russell L. Margolis[2]

[1] Department of Psychiatry and Neuroscience, Johns Hopkins University School of Medicine, Baltimore, MD, USA
[2] Department of Psychiatry, Johns Hopkins University School of Medicine, Baltimore, MD, USA

History

George Huntington saw his first cases of HD when he was about 8 years old, while accompanying his father and grandfather on their medical rounds in East Hampton, Long Island. His longitudinal experience with several families of patients, as part of a three-generation family of physicians, was crucial to his famously concise and accurate account of the disease that now bears his name (Huntington, 1872). As William Osler commented in his paper reporting two additional families with HD (Osler, 1893), 'In the whole range of descriptive nosology there is not, to my knowledge, an instance in which a disease has been so accurately and fully delineated in so few words.' George Huntington's description over a century ago identified the key aspects of the disease, an adult onset hereditary disorder progressing inexorably to death, and characterized by abnormal movements, as well as cognitive and emotional changes. The pathologic changes in the corpus striatum and cerebral cortex were later described by Meynert, Alzheimer and Hunt in the early part of the twentieth century.

The discovery of the CAG repeat expansion mutation in the gene *huntingtin* in 1993 greatly facilitated the application of modern molecular and cellular techniques to the study of HD. The consequent development of biochemical, cellular and animal models of the disorder has led to new insights into its pathogenesis. The hope is that these approaches will foster the development of rational therapeutics in the near future.

Clinical course

HD can be described as a triad of motor, cognitive, and emotional disturbances (Folstein, 1989; Harper, 1996; Penney et al., 1990; Ross et al., 1997). Onset is usually insidious, and may occur at any time from childhood to old age, though mid-life onset is most common. Early complaints include clumsiness, difficulty with balance, and jerky movements or tremor. Death occurs an average of 15 to 20 years after the appearance of symptoms, with some patients dying earlier from falls or suicide and others surviving for 30 to 40 years (Fig. 118.1).

The most striking movement disorder of HD consists of abnormal involuntary movements. Chorea or choreoathetosis, continuous and irregular jerky or writhing motions, are the clinical manifestation most frequently associated with Huntington disease. While most commonly present in the limb and trunk, movements may also include motor tics or chorea involving respiratory, laryngeal, pharyngeal, oral or nasal musculature.

Though chorea is often the most obvious feature of HD on superficial examination of typical patients, incoordination and other disturbances of voluntary movement are in fact more highly correlated with functional disability and the extent of brain pathology. These disturbances include abnormal eye movements, such as slow, hypometric saccades and catchy smooth pursuit movements; uncoordinated, arrhythmic, and slow fine motor movements; dysphasia and dysarthria; dysdiadochokinesis; and a characteristic gait disturbance, consisting of a writhing, dancing walk.

The nature of motor impairment in HD has recently been evaluated with the assistance of sophisticated robotic methods to quantify movement irregularities (Smith et al., 2000). Patients with HD displayed impaired error correction, especially toward the ends of movements, and increased movement jerkiness. The impaired error correction was seen both in response to internally generated errors and externally imposed errors. Most striking, an impairment in error correction could be observed seven to

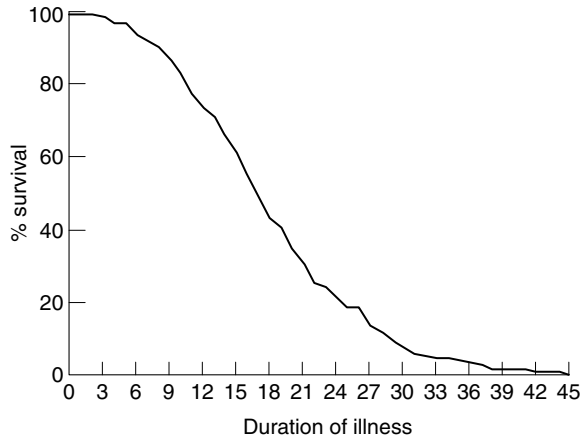

Fig. 118.1. HD survival curve. Percentage of patients surviving as a function of years since disease onset. The curve is derived from 163 patients enrolled in the Baltimore Huntington's Disease Center with a record of both age at disease onset and age at death. (Reprinted with permission from Lippincott, Williams and Wilkins; Ross et al., 1997).

ten years prior to expected onset in presymptomatic gene-positive individuals. These methods promise to improve our understanding of motor control abnormalities in HD, and may provide sensitive measures of movement abnormalities useful long before the onset of clinically diagnosable disease. In addition, it is possible that some of the cognitive deficits of HD can be conceived of as a kind of cognitive error correction abnormality, perhaps leading to improved understanding of cognitive dysfunction as well.

Chorea may plateau, and even decrease, in the later stages of the disease, but disturbances in voluntary movement continue to progress. In late stage HD, patients are often akinetic and largely non-verbal, and may have severe rigidity and joint contractures. At this point, they may have few involuntary movements except for occasional movements of the entire body, resembling myoclonic jerks, when disturbed. Difficulties with swallowing commonly lead to death, either directly from suffocation or aspiration or indirectly from starvation.

When HD begins in childhood or adolescence (juvenile onset HD), the presentation is often somewhat different, with bradykinesia, rigidity and dystonia but minimal chorea. Involuntary movements may take the form of tremors, and patients may develop seizures and myoclonus.

The cognitive disorder of HD is distinctive. In contrast to patients with Alzheimer's disease (AD), patients with HD seem to have more trouble with retrieval than storage of memories. They are more apt than AD patients to recognize words from a previously memorized list or to respond to other cues to help them recall information. This distinction has led to the classification of HD as a 'subcortical dementia' (Brandt et al., 1988). Early in the course of HD, aphasia and agnosia are usually much less obvious than in the cortical dementias such as Alzheimer's disease, while deficits in cognitive speed and flexibility are more common. Cognitive losses accumulate progressively. Deficits in memory, visuospatial abilities, and judgement develop, and late-stage HD patients demonstrate profound global impairment similar to patients with late-stage AD, though their paucity of speech can make assessment difficult.

The emotional disorders of HD can be very disruptive to patients and families, and may be the first signs of the disorder. The behavioural expression of these symptoms may include aggressive outbursts, impulsiveness, social withdrawal, and suicide (which was recognized by George Huntington as an important feature of the disorder). Yet the psychiatric manifestations of HD are the most amenable to treatment (Rosenblatt et al., 1999).

Affective (mood) disorder is extremely common. Epidemiological and phenomenological evidence indicates that affective disorder in HD is a function of the brain disease itself, rather than a reaction to changes in life circumstance (Penney et al., 1990; Folstein, 1989). HD-related major depression resembles the idiopathic form of major depression. Prominent symptoms include feelings of worthlessness or guilt, self-blame, changes in sleep and appetite, anxiety, anhedonia, loss of energy, hopelessness, and diurnal variation of mood with more severe symptoms in the morning. Delusions and hallucinations, when present, tend to be mood congruent: delusions of poverty, illness, or guilt; auditory hallucinations of derogatory or threatening voices. The diagnosis of major depression may be more difficult in patients with advanced disease, but is often signalled by a departure from baseline levels of activity or functional capacity.

Apathy and irritability are other common symptoms. Irritability and aggression may occur in patients without a prior history of a short temper, but are more common in patients who have had these traits lifelong. Apathy may become evident at any time in the course of the disease. Once present, it tends to persist or worsen. Irritability can coexist with apathy. Either apathy or irritability may exist independently or as part of an affective syndrome.

HD patients occasionally develop classic obsessive–compulsive disorder (OCD), with typical symptoms such as fear of contamination or excessive hand-washing. More commonly, however, patients may display perseverative preoccupation with particular ideas or plans, obtaining

cigarettes, getting a refill of coffee, etc., and become irritable when these requests are not honoured. Rarely, patients develop a schizophrenia-like syndrome, with prominent delusions, hallucinations, and/or thought disorder in the absence of an abnormal mood.

In summary, adult-onset HD falls roughly into three stages. Early in the disease, manifestations include subtle changes in coordination, minor involuntary movements, difficulty thinking through problems, and, often, a depressed or irritable mood. In the middle stage chorea usually becomes prominent, and difficulty with voluntary motor activities becomes more evident with worsening dysarthria and dysphagia. As cognitive deficits increase, the patient becomes unable to hold a job or carry out most household responsibilities. Patients with late-stage disease may have severe chorea, but are often rigid and bradykinetic. They are largely non-verbal and bedridden with a more global dementia, although retaining a significant degree of comprehension.

Differential diagnosis of HD

While the clinical diagnosis of HD is straightforward in a patient with a known family history, typical choreiform movements, and cognitive dysfunction, diagnosis may be more difficult in patients with uncharacteristic presentations or a lack of family history (Harper, 1996). For instance, patients may present with very little chorea or with movements that are predominantly athetoid, dystonic or even tic-like. Occasional patients (particularly with late onset) may have only subtle movement abnormality and relatively little cognitive disorder (Harper, 1996). Recent genetic modelling studies have suggested the possibility that late onset HD may be underdiagnosed (Falush et al., 2000). Fortunately, with the availability of the HD gene test, it is now possible to definitively establish the diagnosis of HD, even in patients with no family history or an atypical presentation. Most patients thought to have HD on clinical examination, but who do not have the HD mutation have atypical features, more characteristic of spinocerebellar ataxias or other multisystem atrophies.

HD is now recognized as one of a family of related neurodegenerative disorders caused by expansions of triplet repeats, in many cases CAG encoding glutamine (Zoghbi & Orr, 2000; Margolis et al., 1999). The diseases share a number of clinical features, especially ataxia and dementia, and can be confused with each other. Many of them affect an overlapping set of brain regions, including cerebral cortex, basal ganglia, certain brainstem nuclei, and cerebellar Purkinje cells or deep cerebellar output nuclei.

Dentato-rubral and pallido-luysian atrophy (DRPLA), MIM 125370 involves degeneration in the dentate nucleus of the cerebellum, red nucleus, globus pallidus and subthalamic nucleus, and cerebral cortex and other brainstem nuclei. Cases with adult onset can be phenotypically very similar to HD, despite the different pattern of pathology. Cases with juvenile onset, rather than having the rigid bradykinetic presentation often seen with HD, tend to be mobile, but ataxic and incoordinated, and prone to seizures which can be difficult to control. While extremely rare in the US and Europe, it is more common in Japan.

Other disorders that can be mistaken for HD include SCA3 or Machado-Joseph disease (MIM 109150) and SCA2. Like HD and DRPLA, these are both polyglutamine expansion diseases. They are characterized by degeneration in the cerebellum as well as brainstem regions and less degeneration in the basal ganglia.

Some families have an HD-like disorder but do not have any of the known triplet repeat expansions. We have followed one such family in our clinic for a number of years (Rosenblatt et al., 1998). Affected individuals from this pedigree have chorea or dystonia, rigidity, hyperreflexia, incoordination, ataxia, dementia, psychiatric syndromes, and weight loss (Margolis et al., 2001). All affected individuals and none of the unaffected individuals have a novel CTG expansion in a variably spliced exon of junctophilin 3 (Holmes et al., 2001). At least six other unrelated pedigrees, all with HD-like phenotype, have the same mutation. Thus, this appears to be a rare HD-like disorder, tentatively named HD-like 2.

A variety of other diseases may also present with HD-like symptoms (see Table 118.1), including Wilson's disease, Creutzfeldt–Jakob disease, forms of ceroid neuronal lipofuscinoses, chorea with red blood cell acanthocytosis, hereditary non-progressive chorea, paroxysmal choreoathetosis, mitochondrial disorders, corticobasal degeneration, basal ganglia calcification, forms of hereditary dystonia, Sydenham's chorea, vitamin E deficiency, and cerebral vascular disease (Harper, 1996, Ross et al., 1997).

Genetics

The mutation that causes HD was identified in 1993 (Group HDCR, 1993). The mutation proved to be an expansion of a CAG repeat in a gene termed *IT15* or *huntingtin*, the third CAG expansion mutation discovered (Zoghbi & Orr, 2000; Ross, 1995). The human and mouse gene both

Table 118.1. Selected Mendelian disorders in the differential diagnosis of HD

Disease	Inheritance	Distinctive features	Gene	Mutation
DRPLA	AD	Very HD-like	Atrophin-1	CAG expansion
SCA2	AD	Cerebellar signs	Ataxin-2	CAG expansion
SCA3	AD	Cerebellar signs	Ataxin-3	CAG expansion
Familial CJD	AD	Seizures common	Prion	Multiple
HD-like 2	AD	Very HD-like	Junctophilin-3	CTG expansion
Benign hereditary chorea	AD (AR form?)	Non-progressive	Linkage to 14q	Unknown
Choreoacanthocytosis	AR	Hemotologic findings	Chorein	Multiple
Wilson's disease	AR	Liver disease, low ceruloplasmin	ATP7B	Multiple
Neuronal ceroid lipofuscinosis (multiple forms)	AR, some AD	Lipoprotein deposits	Multiple	Multiple
Paroxysmal choreoathetosis (multiple forms)	AD	Episodic	Linkage to 2q, 1p, 16	Unknown
Familial basal ganglia calcification	AD, AR	Imaging findings	Unknown	Unknown

contain 67 exons. The human gene is located on chromosome 4p16.3, spans a genomic region of over 200 kb and is transcribed into two versions of mRNA, varying only in the length of the 3' untranslated regions. The open reading frame encodes a protein of about 350 kDa with no strong homology to known proteins (HDCR Group, 1993).

CAG repeats with fewer than 27 triplets in the HD gene are within the normal range. The rare repeats with 27 to 35 triplets are considered of intermediate length, prone to expansion but not in themselves of sufficient length to produce the disease phenotype. Repeats with 36 or more triplets are considered expansions. Within the expanded range, there is a striking correlation between the length of the triplet repeat expansion and the age of onset with longer repeats yielding earlier age of onset (Duyao et al., 1993). Most patients with adult onset have repeat lengths between 40 and 50 triplets, while most patients with juvenile onset have 60 or more CAG units. Overall, the length of the CAG repeat explains approximately 50–60% of the variance of the age of onset. However, especially for the adult onset cases, there is a wide range of variability in the age of onset, and thus triplet repeat length is not very useful for predicting age of onset for individual patients.

HD was previously considered to be 100% penetrant. However, with the discovery of the triplet repeat expansion mutation, it is now clear that penetrance (currently defined as the presence of signs or symptoms of HD by the age of 65) is less than 100% in individuals carrying an allele with 36 to 39 triplets (Rubinsztein et al., 1996). Since alleles with 36–39 triplets are uncommon, the frequency of non-penetrance is difficult to estimate reliably, but may be close to 50% for repeats with 36 or 37 triplets.

Anticipation, the phenomenon of decreasing age of onset and increasing disease severity in successive generations, has long been recognized in HD, and known to be selective for paternal transmission (Duyao et al., 1993, Ranen et al., 1995). There is no significant change from parent to child in the age of onset in maternal transmission, but a mean advance of eight years in paternal transmission. In addition, a great majority of cases with juvenile onset, arguably a more severe form of HD, arise from paternal transmission. Two features of the molecular genetics of HD explain the phenomenon of anticipation. First, age of HD onset is inversely correlated with repeat length. Second, the length of the expanded triplet repeat is unstable in vertical transmission. Paternal alleles more frequently expand then contract during transmission, while maternal alleles have an equal probability of expanding and contracting. Instability increases as repeat length increases. The net result, driven by paternal transmissions, is a skew toward earlier ages of onset in successive generations of a family.

While the length of the CAG repeat has a striking influence on age of onset, it appears to have much less influence on the rate of clinical progression. The rate of progression may be more rapid in cases with longer repeats (Aylward et al., 1997), but this is not a universal finding (Kieburtz et al., 1994). On postmortem examination, pathological changes in cases with longer triplet repeats were more advanced than in cases with the same

duration of illness but shorter repeats, providing support for a correlation between repeat length and rate of progression (Furtado et al., 1996). However, longitudinal studies of large numbers of patients are likely to be necessary to demonstrate the effect conclusively, and it appears to be relatively small. This raises the possibility that factors affecting age of onset and rate of progression may be different; thus different treatments may be required to delay onset in presymptomatic mutation positive individuals and slow progression in patients with the disease.

Furthermore, the rate of progression of HD is itself probably not constant. In a large study of patients from the multicentre Huntington Study Group database (Marder et al., 2000), the rate of change of functional capacity was relatively rapid early in the course, but slower later in the course. While this finding may reflect floor effects of the measurement instrument, an actual change in the rate of disease progression may be present, since the rate of change stabilized or even slightly increased very late in the illness. This change in the rate of decline of functional capacity can be contrasted with apparent relatively steady decline in the volume of the striatum as assessed by structural MRI studies (Aylward et al., 2000).

The genetics of HD provides some important clues about disease pathogenesis. Most prominently, there is strong evidence supporting a toxic gain-of-function of the mutated gene product. First, HD, like all the other polyglutamine repeat disorders, has a dominant mode of inheritance, which is typically the result of gain-of-function mechanisms rather than loss-of-function mechanisms. Secondly, the age of onset for homozygotes for the HD mutation generally is not markedly less than the age of onset for cases with only one copy of comparable repeat length (Wexler et al., 1987) (though this is not necessarily the case in the other glutamine repeat diseases). Thirdly, no cases of HD or related polyglutamine disorders have been identified with deletions or point mutations in any of the causative genes. In contrast, the fragile X phenotype can be caused by a triplet repeat expansion leading to impaired transcription, a deletion, or a point mutation; all three types of mutations result in loss of normal protein function. Consistent with this gain-of-function model, mice with targeted deletions of the HD gene, resulting in very low levels of HD gene expression, have developmental abnormalities rather than a progressive neurological disorder. As discussed below, however, other mouse models indicate that loss-of-function could play some role in HD pathogenesis.

The genetics of HD also suggests that toxicity increases as a function of the length of the glutamine repeat, with a threshold effect at 35–40 glutamines, strikingly similar to the other glutamine expansion diseases. In addition, genetic evidence demonstrates that factors other than repeat length must also influence the age of disease onset; the quantitative nature of these relationships should facilitate efforts to find these factors. Statistical genetic analyses have already suggested two genes (GluR6 and CA150) that may play a small role in modifying HD age of onset (MacDonald et al., 1999; Rubinsztein et al., 1997; Holbert et al., 2001).

Neuropathology

The neuropathology of HD (Figs. 118.2 and 118.3, see colour plate section) is notable for selective atrophy and neuronal loss (Vonsattel et al., 1985; Ross, 1995). The most prominent atrophy is found in the caudate nucleus and putamen (which together comprise the corpus striatum within the basal ganglia). Striatal atrophy leads to marked dilatation of the lateral ventricles. In addition, there is overall atrophy of the brain. Total brain weight is reduced by 25 to 30% in advanced cases, reflecting atrophy of the cerebral cortex and underlying white matter, the basal ganglia, and other brain regions.

Within the striatum, atrophy begins in dorsal and medial regions, and progressive loss of neurons occurs in ventral and lateral regions as the disease progresses. There is severe loss of medium spiny projection neurons, especially those synthesizing enkephalin and GABA (Richfield et al., 1995) but relative preservation of large and medium aspiny interneurons (Kowall et al., 1987). Neuronal loss is accompanied by reactive astrocytosis (gliosis). Other areas of the basal ganglia, especially the globus pallidus and subthalamic nucleus, also become atrophic, though less than the striatum. A 0–4 rating scale of gross and microscopic neurodegeneration, based primarily on changes in the caudate and putamen, has been used to semiquantitatively grade the severity of HD (Vonsattel et al., 1985). Cases with more severe neurodegeneration have greater clinical impairment prior to death, and tend to have longer expanded repeats (Furtado et al., 1996; Myers et al., 1988).

Later in the course of the disease, the cerebral cortex also undergoes atrophy. Large cortical neurons appear to be most severely affected, and there is laminar specificity, with greatest loss in layer VI and significant loss in layers III and V. The neurons lost in the greatest numbers appear to project to the thalamus, rather than to the striatum. In addition, the extent of cortical degeneration does not closely correlate with the severity of striatal degeneration.

Thus the loss of neurons in the cortex does not appear to arise simply from retrograde changes beginning in the striatum.

Within the striatum, the surviving neurons often appear to be undergoing regenerative or plastic changes (Graveland et al., 1993). These neurons in HD cases have more dendrites, more long recurved dendrites, greater density and larger size of dendritic spines, and greater somatic area compared to neurons from control brains. A complete understanding of the pathogenesis of HD will need to encompass an explanation for these regenerative changes as well as neuronal death and brain atrophy.

The severity of many of the clinical symptoms of HD is correlated with pathology in the basal ganglia and cerebral cortex. The motor changes are believed to stem from interruption of a set of neuronal circuits interconnecting the cerebral cortex, the basal ganglia, and the thalamus. The involuntary and voluntary movement abnormalities in HD may arise from early degeneration of specific populations of medium spiny neurons. Changes in the basal ganglia also likely underlie the early and relatively mild 'subcortical' cognitive changes seen in HD. The more severe global dementia seen late in the illness may relate to the later widespread loss of neurons in the cerebral cortex.

Occasional cases arise of individuals with clinically diagnosed HD but no discernible cell loss at autopsy. These have been termed 'grade zero' in the Vonsattel severity scale (Vonsattel et al., 1985), since there is little or no appreciable gliosis or neuronal loss. Therefore, it is possible that symptoms in these patients arise more from functional changes than actual neuronal loss. In fact, it may be the case that many of the early signs and symptoms of HD relate more to neuronal dysfunction than neuronal loss.

In severe cases, degeneration is also observed in other regions of the brain, including the brain stem, the cerebellum, and hypothalamic regions, including the lateral tuberal nucleus, the amygdala and portions of the thalamus. The relationship between these changes and clinical features is not clear.

The characteristic pathology of HD consists of intranuclear neuronal inclusion bodies (Fig. 118.3). Studies of human postmortem HD brain tissue using antibodies directed at the N-terminus of huntingtin have revealed small intranuclear inclusions present in neurons but not in glia (DiFiglia et al., 1997; Becher et al., 1998). While present in other brain regions, inclusions are most abundant in the cortex and the caudate. The density of inclusions is significantly correlated with the length of the CAG repeat. However, the neurons containing the inclusions are not necessarily the ones which suffer the most severe degeneration (Gutekunst el al., 1999).

The inclusions cannot be detected by antibodies directed at internal epitopes of huntingtin, suggesting that huntingtin within the inclusions is truncated. However, it is also possible that it is misfolded in a way such that internal epitopes are hidden. The inclusions can be detected with antibodies to ubiquitin, a tag for proteins undergoing proteolytic degradation. This could mean that huntingtin within inclusions has been targeted for degradation but cannot be removed by proteolysis. Ultrastructural analyses of the inclusions indicate that they are composed of a mixture of granules, straight and tortuous filaments, and masses of parallel and randomly oriented fibrils, not enclosed by an intracellular membrane. Similar inclusions were originally detected in transgenic mouse models of HD (Davies et al., 1997).

In addition, huntingtin has been found in aggregates in dystrophic neurites in HD brains (DiFiglia et al., 1997). These were present predominantly in cortical layers V and VI and appeared to be contained within neurofilament-labelled axonal processes. Such dystrophic neurites may reflect dysfunction of retrograde axonal transport. In adult-onset cases the intranuclear inclusions are less prominent than in juvenile-onset cases, but the neuritic aggregates are more prominent.

Neurotoxic models of HD

Before the discovery of the genetic etiology of HD, animal models of HD had been generated using neurotoxins. Injections of NMDA receptor agonists, such as quinolinic acid, into the striatum induce HD-like pathology, with loss of medium spiny projection neurons and sparing of cholinergic and NADPH diaphorase neurons (Beal et al., 1986). Peripheral injections into rodents or primates of several mitochondrial toxins, including 3-nitroproprionic acid (3–NPA), also reproduce aspects of striatal pathology found in HD (Beal et al., 1993). Other metabolic poisons cause preferential toxicity in different regions of the brain, often those regions affected in other glutamine repeat diseases.

These neurotoxin experiments suggest several pathways that could be involved in HD cell death. For instance, both excitotoxicity and metabolic poisoning may be mediated, in part, by damage from free radicals. Also, neurotoxic stimuli can give rise to apoptosis, a form of cell death under control of cellular machinery that plays an essential role in normal development. The process is triggered by a group of aspartate proteases termed caspases, and GAPDH and

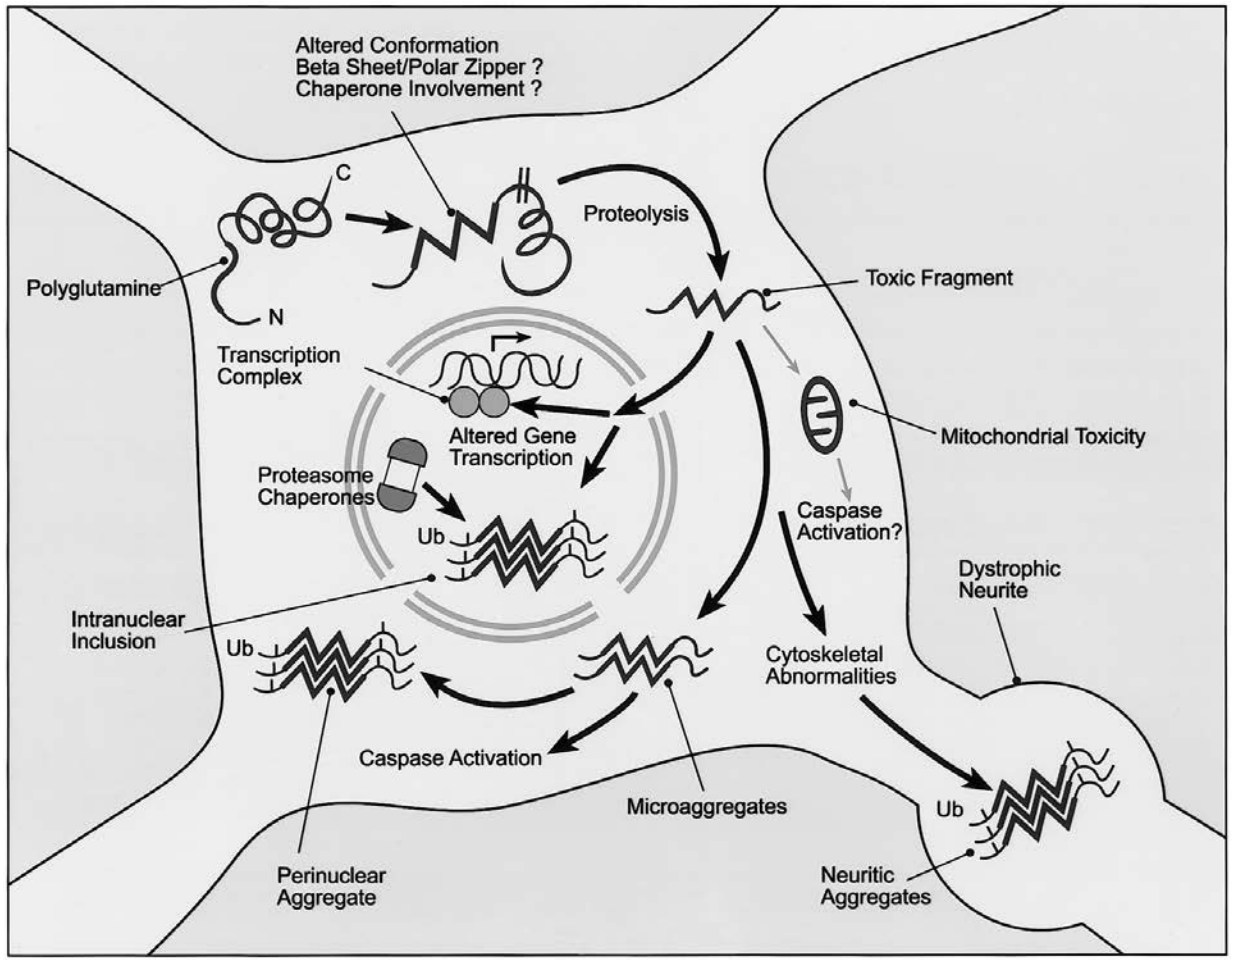

Fig. 118.4. A model of HD pathogenesis. We propose that HD pathogenesis begins with altered conformation of the protein containing the expanded polyglutamine repeat. Proteolysis generates a fragment that leads to toxicity through several pathways. Nuclear importation may lead to altered gene transcription with a detrimental effect on cell survival. Inclusions also form in the nucleus but may not be a major cause of cell death. Huntingtin fragments may interfere with mitochondrial energy metabolism, either directly, or more likely indirectly, perhaps via altered gene transcription. Microaggregation of the fragment may lead to caspase activation and the consequent initiation of cell death pathways. Fragments may be transported into neurites, interfering with cytoskeletal function. Toxicity may also be mediated by the full-length huntingtin protein with the expanded repeat. As discussed in the text, many of the steps remain speculative.

other metabolic enzymes may also serve as initiating factors.

Studies of subjects with HD have yielded results consistent with some of these neurotoxicologic mechanisms. For instance, NMR spectroscopy suggests the presence of metabolic compromise within neurons (Koroshetz et al., 1997). Marked biochemical defects of mitochondrial complex II and complex III activity, and moderate defects of complex IV activity, have been detected in mitochondria isolated from the brain tissue of individuals with HD. Evidence of free radical activation is also present in HD postmortem tissue (Gu et al., 1996).

The huntingtin protein and aggregation

The protein product of the *HD* gene, or huntingtin, is widely expressed in both the brain and peripheral tissues (Sharp et al., 1995; Di Figlia et al., 1995). The CAG repeat, even when expanded, is translated into polyglutamine (Trottier et al., 1995). Immunocytochemical and subcellular fractionation studies indicate that huntingtin is present in neuronal perikarya, dendrites and terminals, with a generally cytoplasmic localization. Huntingtin has not been consistently detected in the nucleus, though it is possible that it cycles through the nucleus without normally accu-

mulating there. The protein appears to associate with cytoskeletal elements and intracellular vesicles, with enrichment in endosomal compartments and Golgi complex membranes, and it is detected at all stages of embryonic and postnatal brain development.

The presence of the glutamine repeat with huntingtin provides some hints about its normal function. Many proteins contain stretches of polyglutamine, and such tracts are more common than repeats of other amino acids. Proteins containing glutamine repeats often appear to have a role in the regulation of development and neurogenesis, and a number of proteins with glutamine repeats are transcription factors. Glutamine-rich regions may function as factor interaction domains in transcription factors, but it is unclear if glutamine repeats serve this or more specialized functions. The lengths of glutamine repeats tend to vary considerably in homologous genes from different species; mouse huntingtin has only seven consecutive glutamines and the puffer fish homologue has only four. This may reflect a tolerance for repeat length variation in the normal function of huntingtin or species specific variations in huntingtin function modulated by repeat length.

One hypothesis for the role of glutamine repeats in human disease is based on the 'polar zipper' model proposed by Perutz (1999). He suggested that two antiparallel beta strands of polyglutamine can be linked together by hydrogen bonds between their main chain and side chain amides, forming beta sheets and potentially leading to protein aggregation and precipitation. Circular dichroism, electron microscopic and X-ray diffraction studies of synthetic peptides provide in vitro evidence supporting the formation of beta strands and possibly beta sheets by glutamine repeats. Alternatively, it has been suggested that the covalent modification of glutamines via an isopeptide linkage to lysine by the enzyme transglutaminase could lead to an insoluble precipitate of proteins containing long stretches of glutamine.

In support of the idea that huntingtin by itself can aggregate, an in vitro filter assay has been used to demonstrate that a small portion (exon 1 only) of the huntingtin protein with an expanded glutamine repeat can aggregate to form amyloid-like fibrils (Scherzinger et al., 1999). These fibrils show green birefringence when stained with Congo red and viewed by polarized light microscopy, consistent with the presence of amyloid. Aggregation does not occur if the polyglutamine repeat is of normal length. The kinetics and concentration dependence of huntingtin aggregation show many of the features of seeded polymerization (Lansbury, 1997), a process which has been implicated in the protein aggregation characteristic of several neurodegenerative diseases.

Aggregation in vitro only occurs if a huntingtin fragment with an expansion of typical length is first cleaved from the carrier protein to which it was fused during synthesis for the assay. The implication, consistent with cell and mouse models described below, is that generation of a proteolytic fragment of HD may be an important step in HD pathogenesis. Consensus cleavage sites for caspase-3 exist at approximately position 513 and 530 of huntingtin, and huntingtin can be cleaved by purified caspase-3, caspase-6, caspase-8. However, other cleavage events may also take place.

To obtain additional clues about the normal function of huntingtin and HD pathogenesis, an intensive effort has been devoted to finding proteins that interact with huntingtin. Interactors of particular interest include HIP1, HAP1, GAPDH, and SH3GL3 (Gusella & MacDonald, 1998). Some of these proteins are directly or indirectly associated with microtubule motor proteins and intracellular vesicles, suggesting a role for huntingtin in cytoskeletal function or vesicular transport. The interaction of huntingtin and other proteins containing glutamine repeats with the metabolic enzyme GAPDH is of potential significance given the possible role of GAPDH in apoptosis. Huntingtin also interacts with the nuclear corepressor protein (NCoR), and the strength of the interaction correlates with the length of the huntingtin glutamine repeat (Boutell et al., 1999). This interaction suggests that huntingtin may have some role in transcriptional regulation.

Cell and animal models

The development of cell models has facilitated research into the pathogenesis of HD, and has generally supported the gain of function model. Huntingtin has been introduced into cells through transient transfection, or by engineering cell lines that stably express huntingtin. In general, short truncations of huntingtin containing the expanded polyglutamine appear to be much more toxic than full-length huntingtin, and more liable to aggregate (Hackam et al., 1998; Cooper et al., 1998). However, aggregate formation and cellular toxicity can be disassociated, suggesting that cell toxicity is not related in a simple way to aggregation (Saudou et al., 1998). Elimination of caspase cleavage sites may reduce the toxicity of mutant huntingtin (Zoghbi & Orr, 2000; Wellington & Hayden, 2000; Sanchez et al., 1999). The cell death in these cell models does not correspond to all characteristics of apoptosis, but can be decreased or blocked in several models with caspase inhibitors (Moulder et al., 1999; Saudou et al., 1998).

A role for nuclear localization of the mutant huntingtin protein in huntingtin toxicity has been suggested, but is

still not proven. Transfection of primary neurons with constructs incorporating a nuclear export signal diminished toxicity, while the addition of nuclear localization signals appeared to enhance toxicity (Peters et al., 1999; Saudou et al., 1998). However, other studies have suggested that both the nucleus and cytoplasm can be the site of pathogenesis.

Transgenic mouse models have provided additional evidence for the gain-of-function hypothesis of HD pathogenesis. The first mouse model of HD was constructed using exon 1 of huntingtin with a very long expanded repeat. These animals developed progressive neurological deficits strikingly similar to HD, including incoordination, abnormal involuntary movements, seizures, and weight loss. However, unlike in HD patients, neuronal cell loss was not prominent. These mice also developed intranuclear inclusions containing the truncated huntingtin transgene product, but not the full-length endogenous huntingtin protein (Davies et al., 1997). The intranuclear inclusions are present at the time, and perhaps before, the animals have neurologic signs or brain or body weight loss. As in HD patient postmortem material, the intranuclear inclusions are clearly distinct from the nucleolus, and no membrane separates them from the rest of the nucleus.

Several other transgenic HD mouse models have been constructed, using various forms of the huntingtin protein, each with an expanded repeat. A truncated N-terminal fragment of huntingtin driven by the prion protein promoter resulted in mice with progressive hypoactivity, incoordination, and weight loss. Neuropathologically, the brains have intranuclear inclusions and neuritic aggregates, and moderate neuronal degeneration (Schilling et al., 1999). A transgene consisting of a full-length huntingtin cDNA driven by the CMV promoter resulted in a line of mice with a rather different phenotype, characterized by early weight gain and hyperactivity followed later by hypoactivity. These mice have both intranuclear inclusions and some loss of neurons (Reddy et al., 1998)

A promising mouse model of HD involves the use of YAC constructs, so that the transgene consists of the entire human *HD* gene with an expanded repeat, including the human *HD* promotor and all introns. These mice develop neurological signs and electrophysiologic abnormalities, and have a shortened life-span (Hodgson et al., 1999). Pathological investigation of a single founder with a long repeat revealed striking evidence of selective striatal neurodegeneration and nuclear localization of N-terminal epitopes of huntingtin in striatal neurons. If these initial results are confirmed and extended to mice with longer repeat lengths or higher levels of expression, these mice may prove to be the best model of the human disease yet generated.

A model with conditional inactivation of Huntington has recently provided evidence that loss of function of huntingtin may also yield a neurodegenerative phenotype (Dragatsis et al., 2000). Mice were generated in which huntingtin expression could be deleted using the Cre/loxP system with Cre-recombinase under the control of the CaM Kinase II promotor. With this strategy, mice develop to adulthood with normal levels of huntingtin expression, and then forebrain huntingtin expression can be reduced by 90% or more. These mice have neurological abnormalities, including limb clasping that is somewhat similar to that of some of the transgenic models. They also have neuronal degeneration in both grey matter and white matter. The distribution of degeneration is different from HD, with degeneration in lateral cortical grey and white matter. Another study has indicated that there is a loss of function contribution to cell death in the testis in vivo (Leavitt et al., 2001). These data raise the possibility that loss of function may contribute to the HD phenotype. Presumably a dominant negative effect would be required to explain why only one mutant allele can cause the HD phenotype, since heterozygous knockout animals are essentially normal. In light of this data, it is puzzling why the homozygous mutant patients described in Venezuela (Wexler et al., 1987) have a phenotype so similar to that of the heterozygous mutant patients. Overall, the role of loss-of-function in HD pathogenesis remains an open question.

Another approach to model HD is to insert the CAG expansion into the endogenous mouse *huntingtin* gene, as a so-called 'knockin', thus avoiding the confounding factor of the presence of the human transgene. So far, mice generated using this strategy may need to have a very long repeat to develop a robust behavioural and pathological phenotype (Wheeler et al., 2000; Lin et al., 2001). There is evidence of translocation of huntingtin into the nucleus, selectively in striatal neurons. Thus, these mice may provide a model for studying early stages of HD pathogenesis. Study of another similar knockin model has revealed N-terminal fragments of huntingtin, enriched in cell nuclei and migrating at 40 kDa on Western blots, consistent with a role for proteolytic processing and nuclear transport of mutant huntingtin.

The difficulties in generating a mouse knockin model with a phenotype may be overcome by making a very long polyglutamine insert. Mice with a 150 triplet CAG repeat exhibit late onset neurological and neuroanatomical abnormalities consistent with HD, including gait and other motor abnormalities as well as intranuclear inclusions and gliosis (Lin et al., 2001). They do not appear to have substantial loss of neurons. However, the gliosis appears to be selective to the striatum, suggesting that this model may

also address early pathogenic events in striatal neurons.

The construction of an inducible mouse model of HD has yielded additional insight into HD pathogenesis (Yamamoto et al., 2000). A transgene containing exon 1 of *huntingtin* with an expanded glutamine repeat was inserted using the tet-off system, such that the timing of transgene expression could be controlled by the presence or absence of an antibiotic in the animals' food. With the transgene on, mice developed neurological signs and neuropathologic changes including nuclear inclusions. Remarkably, when the expression of *huntingtin* was turned off, these abnormalities partially reversed. This suggests that the brain may have more restorative and plastic ability than previously appreciated. Thus, if the pathological changes of HD could be halted, substantial repair may be possible.

Invertebrate models offer the potential of using powerful genetic techniques to search for genetic factors that enhance or suppress an experimentally induced phenotype. Several drosophila models of polyglutamine-induced neurodegeneration have been generated (Warrick et al., 1999; Kazemi-Esfarjani & Benser, 2000), with many of the same features of neuronal degeneration observed in mammalian cell models and mouse models. Genetic screens have been used to demonstrate that molecular chaperones such as HDJ1 and HSP70 can suppress the phenotype (Kazemi-Esfarjani & Benser, 2000). *C. elegans* models may prove to be of similar value.

Current models of polyglutamine pathogenesis

A model for HD pathogenesis is depicted in Fig. 118.4. Several of the steps are speculative and the data supporting the model are at times conflicting. Here, we highlight areas of uncertainty and recent hypotheses.

Many lines of evidence indicate that the initial step in pathogenesis is a conformational change in the region of the protein with the expanded polyglutamine repeat. Proteolytic cleavage of huntingtin may be the next step; however, evidence for proteolytic cleavage of huntingtin remains indirect. The fact that nuclear inclusions can be labelled by antibodies against N-terminal epitopes of huntingtin, but not antibodies against internal or C-terminal epitopes, is consistent with proteolytic cleavage, but could also result from masking of epitopes. In addition, details of the cleavage, including whether it is processive or endoproteolytic and where in the cell it may occur, are uncertain. The figure shows the cleavage event in the cytoplasm, but this is speculative. It is equally possible that the full-length protein may be transported into the nucleus.

Another uncertainty is the role of aggregation. Abnormal

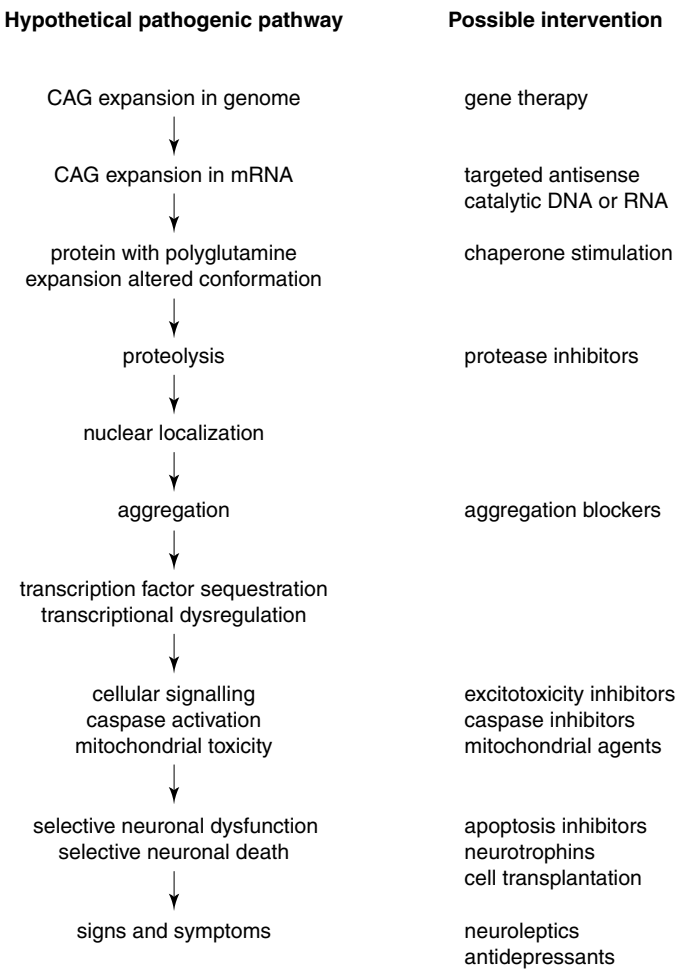

Fig. 118.5. Approaches to HD therapy. Possible interventions at different stages of a model of HD pathogenesis. While the figure depicts a linear process, it is likely that some steps are actually parallel rather than in series, and that each step may not be equally important in leading to the disease phenotype. The role of aggregation, in particular, remains uncertain. The therapeutic approaches include accepted treatments (e.g. neuroleptics, antidepressants), agents in clinical trials (e.g. excitotoxic inhibitors), agents under active preclinical investigation (e.g. aggregation blockers, caspase inhibitors, cell transplantation), and agents that are presently speculative (e.g. gene therapy).

conformation appears to be a necessary step in pathogenesis. However, the large inclusion bodies visible by light microscopy appear to represent a downstream event, an epiphenomenon, or even a protective reaction, and therefore may not be directly tied to pathogenesis. An earlier step is likely to involve abnormal interactions between mutant huntingtin and other cellular proteins, including other proteins with short polyglutamine repeats. The result

may be the sequestration of proteins that normally contain short polyglutamine repeats. An example of such protein is CREB binding protein (CBP); an important transcriptional regulator; sequestration of this and similar proteins could have marked effects on neuronal function and survival (Nucifora et al., 2001, in press).

Recent evidence has pointed toward a role for abnormalities of gene transcription in huntingtin pathogenesis (Cha et al., 2000). In the exon-1 mouse model, decreases in transcription of a number of neurotransmitter receptors is an early event (Cha et al., 1998). A gene expression screen using gene chip technology revealed that while the expression of most genes is unchanged, a subset show significant changes. Most of these are decreases (Luthi-Carter et al., 2000). Many of the gene products with decreased expression are involved in neuronal signalling pathways or intracellular calcium regulation, suggesting that these pathways may be involved in pathogenesis. However, it is also possible that they represent compensatory responses.

The mechanism of such changes in gene transcription is still uncertain. Interference with co-activator function mediated by CBP is one possibility (Nucifora et al., 2001). Another possibility is alteration of p53 mediated transcription (Steffan et al., 2000; Sawa, 2001), which could also explain mitochondria dysfunction, since a number of p53-regulated gene products have mitochondria functions. A common downstream mechanism could be abnormal histone acetylation (Nucifora et al., 2001; McCampbell et al., 2000, 2001; Steffan et al., 2001).

The relative importance of nuclear and cytoplasmic events also remains unclear. In our model, the location of mutant huntingtin in the nucleus leads to altered gene transcription. However, mutant huntingtin could act also within the cytoplasm to interfere with proteins that might otherwise be imported into the nucleus (Nucifora et al., 2001). Furthermore, toxicity might also arise from the interaction of mutant huntingtin with cytoplasmic molecules, including microtubules or microtubule motors, caspase adaptors, and other proteins.

Symptomatic treatments

There are no currently accepted specific treatments to slow the rate of clinical progression of HD (Penney et al., 1990; Rosenblatt et al., 1999). However, symptomatic management of both movement and emotional disturbance is currently possible. A detailed handbook of HD treatment options has been prepared by Rosenblatt and colleagues (Rosenblatt et al., 1999).

Dopamine receptor blocking agents such as haloperidol can be quite effective inhibitors of chorea, especially early in the illness. Dosage should be kept as low as possible. The starting dose of 1–2 mg a day of haloperidol may prove sufficient for some patients. If not, the dose can be increased slowly. Most patients will get benefits at doses of about 2–5 mg a day, though occasional patients have some beneficial effect up to 10 mg a day or more. Side effects of stiffness, rigidity, bradykinesia and sedation may severely limit effectiveness of this class of medicines. In addition, these agents are of no benefit for incoordination and ataxia (unless caused by chorea), which are more disabling than chorea for most patients.

Occasionally patients, especially those with juvenile onset, may have focal dystonia that may improve with botulinum toxin injections. In addition, for some juvenile onset patients, the rigidity and bradykinesia is so prominent that dopamine agonists such as L-DOPA may be tried, though they are rarely of any marked benefit.

Depression in HD can be treated much as idiopathic major depression, and should be sought out actively. It should not be assumed that patients who are discouraged or demoralized have an understandable reaction to their illness. Most patients with HD are able to carry on in remarkably good spirits even in the face of a disabling progressive illness. Bipolar disorder is less common than unipolar depression, but does occur in HD, and can be treated successfully with lithium or anti-convulsant mood stabilizing agents. A bipolar type 2 phenotype, with periods of depression and brief periods of hypomania, appears to be more common than classic bipolar 1 disorder. This may or may not require mood stabilizers, depending on the extent of the hypomania. Bipolar type 2 may respond better to anti-convulsant mood stabilizers than to lithium.

Other emotional features may also be prominent in HD. Whenever possible, non-pharmacologic intervention should be tried for behavioral manifestations of HD. Patients may have so-called catastrophic reactions, brief periods of emotional upset when confronted by unexpected events or unpredictable changes in their environment. Family and caretakers should be counselled to give patients advance warning of changes in plan or schedule. They should also be counselled that patients may forget, and may need frequent reminders.

Some patients have obsessive–compulsive features and these may be treated with serotonin-selective reuptake blockers. Occasional patients have delusions in the absence of mood changes, and these can be treated with neuroleptics, especially the newer ‘atypical’ agents. A common problem is irritability in the absence of mood

changes. This may respond to serotonin selective reuptake inhibitors, anticonvulsant mood stabilizers, or neuroleptics. Apathy and loss of interest in the patient's surroundings can be a difficult problem. However, one should search carefully for an affective disorder before concluding that pure apathy is the problem.

Towards rational therapeutics

Recent biochemical, cell and animal studies are beginning to suggest approaches for development of rational therapy for the progress of the disease itself (Fig. 118.5). The first generation of agents designed to slow the progression, or delay the onset, of HD have emerged from neurotoxicologic models of HD. A major multicentred trial has evaluated the CARE-HD Study (Coenzyme Q and Remacemide Evaluation in Huntington's Disease) Coenzyme Q (a mitochondrial cofactor) and remacemide (a glutamate receptor antagonist), both of which have efficacy in neurotoxicological mouse models. The CARE-HD Study was the first major multicentre HD drug trial, and involves 340 patients treated for 30 months under the sponsorship of the Huntington Study Group (Huntington Study Group, 2001). Neither drug has a significant effect on the primary outcome measure, though post hoc analysis suggested the possibility that Co-EnzymeQ might have had a modest effect. Neurotoxicologic models have also led to smaller trials of other agents, including vitamin E, idebenone, and lamotrigine. No clear efficacy has been demonstrated for any of these drugs (Shoulson et al., 1989; Kieburtz et al., 1996; Feigin et al., 1996; Ranen et al., 1996; Peyser et al., 1995).

Another approach to HD therapeutics involves transplantation, either of fetal striatal cells or of cells secreting growth factors (Boucoud-Levi et al., 2000; Freeman et al., 2000). These methods have met with, at best, limited success so far, but may have promise for the future. Stem cells, if they can be differentiated into striatal neurons in a controlled fashion, might have great potential as therapeutic agents. Gene therapy is likely to be very difficult, given that HD appears to have predominantly a gain-of-function genetic mechanism. Catalytic DNA or RNA may conceivably be used to decrease huntingtin levels (Yen et al., 1999); however, it may be dangerous to decrease levels too much.

A screen for therapeutic agents that may alter polyglutamine aggregation is currently in progress using the filter aggregation assay developed by Wanker and colleagues. Early results indicate that congo red and related dyes that intercalate into beta sheets (Heiser et al., 2000) and members of the heat shock protein/chaperone family can reduce aggregation. The effect of these agents in animal or cell models of HD is unknown, and even if effective, it is unclear if these agents would themselves be suitable therapeutic compounds. Based on these results with histone acetylation, histone de-acetylation inhibitors may appear to be good candidates (McCampbell et al., 2001; Steffan et al., 2001). New compounds may emerge based on those already shown to be effective in vitro, or entirely new classes of useful agents may be discovered with further screening.

Mouse models are now in active use to test therapeutic compounds. Based on work in cells, the role of caspase inhibitors on disease progression has been investigated. Caspase inhibition led to a modest but significant beneficial effect in the exon-1 HD transgenic mouse model (Ona et al., 1999). A genetic cross of these transgenic mice with a line of mice over-expressing a caspase-1 dominant negative construct (and hence deficient in caspase-1 activity) also suggested that caspase inhibition can slow disease progress. Creatine, chosen based on its effect in neurotoxicologic models of neuronal cell death, also has a significant effect on disease progression in the exon-1 HD transgenic mouse (Ferrante et al., 2000). Minocycline, which has shown some efficacy in ischemic models, also has a beneficial effect on this mouse line (Chen et al., 2000). Cystamine has also been reported to be of benefit (Karpuj et al., 2002). The magnitude of the effect on disease progression observed in these studies is significant but modest. A similar effect can be induced by altering the environment in which the mice are raised (van Dellen et al., 2000). It is possible that a combination of several of these agents may have enhanced effectiveness. Also, most of the agents tested so far have been targeted at relatively downstream points in the presumed pathogenetic pathway. Agents targeted at earlier steps in the pathogenetic pathway may be more effective. As the pathogenesis of HD is unravelled, development of rational and effective therapeutics should become possible.

Acknowledgments

Supported by NIH NS 16375, 34172, 38144 and 38054, and grants from the HDSA and HDF. We thank the staff of the Baltimore HD Center, founded by Drs Paul McHugh, Susan Folstein, and Marshal Folstein. We thank Ms Debbie Pollard and Ms Marie Sonderman for expert assistance in manuscript preparation, and Dr Adam Rosenblatt for assistance with data analysis and figure construction. Finally, we thank our patients with HD and their families for their inspiration, patience and cooperation. Parts of

this review were adapted from previously published material (Margolis & Ross, 2001) with permission from the publishers.

Progressive cerebral degeneration of childhood

Gerald V. Raymond

Department of Neurology, Johns Hopkins University School of Medicine, Kennedy Krieger Institute, Baltimore, MD, USA

The progressive cerebral degenerations of childhood are a heterogeneous group of disorders characterized by the loss of previously acquired skills during development. They stand in contrast to the static encephalopathies, mental retardation, cerebral palsy, and autism. The causes of both progressive and static disorders are varied and include infectious, inflammatory, neoplastic, and vascular etiologies, this chapter will, however, deal only with those that result from genetic mechanisms. The importance of these disorders even with this restriction is emphasized by the series of Dyken and Krawiecki which found that genetic neurodegenerative conditions made up approximately 15% of admissions to pediatric neurology services in two institutions over a 10-year period (Dyken & Krawiecki, 1983).

General comments on evaluation

The evaluation of degeneration results in special difficulties when presenting in childhood. For the young child, the early findings may be subtle and may be mistaken for normal variation or static difficulties such as mental retardation or cerebral palsy. It is only when evaluated over time, or with a clear presentation, will the diagnosis be uncovered. It is not difficult to suspect a particular disorder when all the characteristic symptoms and signs are present – the challenge comes in doing this early in the course (Clarke, 1997).

Once the suspicion has arisen that one is dealing with a progressive condition, the evaluator must cope with a seemingly endless list of disorders (Dyken & Krawiecki, 1983). Compounding this difficulty, disease classification by biochemical abnormality, typical for these disorders, usually does not serve the purpose of clinicians. This type of designation allows one to determine the appropriate biochemical test, but does not easily direct the clinical diagnosis. Algorithms and computerized database programs have been developed to assist the clinician. When appropriately used they may be of significant benefit, however, one must recognize that the symptom complex does not appear all at once, but evolves. A knowledge of the course of disease and timing of the evolution of signs is therefore useful (Clarke, 1997).

These challenges aside, it is to be emphasized that presently there is the ability to make a diagnosis in many of the conditions which previously either were simply clinical descriptions or required invasive pathologic investigation. There are now morphological, biochemical, and genetic tools available that allow diagnosis to be made. Neuroimaging can demonstrate important alterations in the brain. This is particularly important in the evaluation of leukodystrophies, destructive disorders of myelin, but will also show abnormalities of the cerebral cortex, basal ganglia, or cerebellum. The addition of magnetic resonance spectroscopy can demonstrate changes in the concentration of certain molecules. Biochemically, by sampling with spectroscopy or directly by examining tissues, one can confirm the presence and composition of stored material or document the absence of specific enzyme activity. Diagnosis by genetic means has been the latest in the diagnostic methods and is extremely important in those disorders that do not have an easily measured biochemical assay. Examples of the latter include myotonic dystrophy and Huntington disease, which lack the classic storage material.

The purpose of the diagnosis should be clear. While therapy is ultimately hoped for, as will be seen, this is a rarity in these conditions. Instead, one of the main reasons must be to give clear genetic information and some guidance of the course of the illness. Once a diagnosis is obtained, the clinician must be certain that the family is

informed of the availability of carrier testing, recurrence risk, and the availability of prenatal testing when available.

Neonatal encephalopathies

Disorders that present in the newborn period are not typically seen as disorders of degeneration, but there are an important group of disorders that have their onset in this period and have progressive cerebral effects (Table 119.1). Deterioration in the level of alertness, irritability, seizures, liver dysfunction, and feeding intolerance may be initial clues, but also share features with other conditions such as intracerebral hemorrhage or infections. A level of vigilance is essential whenever evaluating newborns because institution of appropriate therapy may not only be life saving but result in a normal outcome. The institution of newborn screening with therapy has been one of the triumphs of genetic medicine.

The evaluation of the newborn infant with encephalopathy is one instance where rapid, inclusive testing is indicated. While the details of the acute illness may be non-specific, the events of the pregnancy, delivery, and the interval before onset of illness should be determined. The family medical history should always be reviewed and may be informative. The emphasis is on neonatal deaths and other children with either mental retardation or other perceived static difficulties. Laboratory evaluation of the acid–base balance including bicarbonate, lactate and pyruvate; ammonia; glucose; hepatic function; calcium; phosphorous; magnesium; amino and organic acid; carnitine; and urine for reducing substances should be performed in all infants presenting with acute encephalopathy. In addition, the infant with altered consciousness requires evaluation of cerebrospinal fluid, neuroimaging and EEG.

As can be seen, there are many disorders that can present in this age group. Three categorical examples will be presented: disorders of amino and organic acids, peroxisomal disorders, and disorders of glucose transporters.

Table 119.1. Neonatal metabolic disorders

Urea cycle disorders
N-acetylglutamate synthetase (NAGS)
carbamylphosphate synthetase (CPS)
ornithine transcarbamylase (OTC)
argininosuccinate synthetase
argininosuccinate lyase
arginase
Hyperornithemia–hyperammonemia–homocitrullinuria (HHH)
Non-ketotic hyperglycinemia
Maple syrup urine disease: branched chain alpha keto acid dehydrogenase
Isovaleric acidemia: isovaleryl-CoA dehydrogenase
Proprionic acidemia
Methylmalonic acidemia
Sulfite oxidase deficiency and molybdenum cofactor deficiency
Neonatal mitochondrial encephalopathies
Disorders of pyruvate metabolism
Pyruvate dehydrogenase complex deficiency
Pyruvate carboxylase deficiency
Respiratory chain disorders
Defects in mitochondrial fatty acid oxidation
Holocarboxylase synthetase deficiency
Peroxisomal disorders
Zellweger syndrome
Rhizomelic chondrodysplasia punctata
Multifunctional enzyme deficiency (bifunctional enzyme deficiency)

Disorders of amino and organic acid metabolism

Neurological manifestations are especially common in this group of disorders and may present with life-threatening encephalopathy, e.g. urea cycle disorders or more insidiously, e.g. phenylketonuria. Features seen include progressive neurological symptoms of ataxia, myoclonus, extrapyramidal symptoms, metabolic stroke and macrocephaly. Many of these conditions are diagnosed by the examination of plasma amino acids and urine amino and organic acids. It is important to emphasize assessment of the clinical setting and the use of ancillary studies. Disorders that result from the inability to handle certain types of amino acids may not present until the infant has been on full feeds and toxic levels of metabolites have accumulated. Specific measurements such as cerebrospinal fluid amino acid levels in non-ketotic hyperglycinemia may be required and are indicated in the evaluation of neonatal seizures (Lyon et al. 1996).

The final method of diagnosis, availability of prenatal testing in future pregnancies, and treatment will rest on the specific diagnosis. Certain circumstances such as phenylketonuria or maple syrup urine disease (disorder of branched chain amino acid catabolism) are the paradigm for inborn errors of metabolism and respond to a diet restricting specific amino acids which cannot be catabolized. Unfortunately, not all disorders even within this group are amenable to such manipulations.

Disorders of peroxisome

Peroxisomal disorders can be divided into two broad categories, those that involve single enzyme dysfunction and those that affect peroxisome biogenesis. Peroxisomal diseases can present at a variety of ages, but the newborn presentation is particularly common, but still often underdiagnosed.

Zellweger syndrome and the related neonatal adrenoleukodystrophy and infantile Refsum disease are disorders of peroxisome assembly or biogenesis. The affected newborn presents with hypotonia, characteristic craniofacial features, and may develop seizures in the first days of life. Children often have evidence of liver dysfunction, skeletal stippling, renal cysts, and ophthalmologic findings such as cataracts and glaucoma. If not already evident at birth, there is progressive visual and hearing loss. Survival beyond the second year of life is unusual for those with the severest form of the disease. Neonatal adrenoleukodystrophy and infantile Refsum disease are now known to be phenotypic variations of the more severe Zellweger syndrome. They are characterized by somewhat milder clinical features and longer survival. Multiple biochemical abnormalities secondary to the inability to assemble peroxisomes are seen in affected children. These include defects in the beta oxidation of very long chain fatty acids, defects in plasmalogen synthesis, abnormalities in phytanic acid oxidation, and pipecolic acid metabolism. These abnormalities may be seen in a variety of tissues including blood, fibroblasts, and liver as well as amniocytes and chorionic villi cells, which allow prenatal diagnosis.

Peroxisome assembly disorders are caused by genetic defects in PEX genes and the altering of their proteins, peroxins, which are necessary for the importation of targeted proteins into the peroxisomes. It has now been determined that disorders of peroxisomal assembly are genetically heterogeneous and defects in ten PEX genes have been identified. The largest group of abnormalities is in PEX1, a AAA-type ATPase involved in the import of targeted proteins (Raymond, 1999).

While the specific genes are varied, all forms to date are autosomal recessive and prenatal diagnosis is available using biochemical assay for subsequent pregnancies. There is presently no curative therapy, but appropriate symptomatic treatment is indicated.

Single enzyme disorders include the X-linked adrenoleukodystrophy (ALD), acyl-CoA oxidase deficiency and peroxisomal multifunctional enzyme, all defects in very long chain fatty acid beta oxidation. The X-linked form of adrenoleukodystrophy does not present in the newborn and is discussed in the chapter on leukodystrophies (Chapter 100). However, the other two typically present in the neonatal period with hypotonia and seizures and are progressive in their course. The multifunctional enzyme defect results in very profound hypotonia and progressively severe seizures often resistant to therapy. Death occurs typically at 9 months. Acyl CoA oxidase appears initially to be more mild in presentation, and the children may gain some developmental milestones before the onset of regression after the first year or two of life. Initial diagnosis of these disorders is made by the demonstration of abnormalities in very long chain fatty acid levels in plasma and subsequently confirmed by the demonstration of a defect in very long chain fatty acid oxidation and confirmation of the specific defect in fibroblasts (Watkins et al., 1995). Prenatal testing is available using the biochemical assay of beta oxidation. There is no curative therapy available for either defect.

Disorders of glucose transporters

De Vivo and his associates have reported children who presented in infancy with severe seizures, acquired microcephaly, mental retardation and motor delays (De Vivo et al., 1991). Diagnosis rests on low glucose concentrations in the cerebrospinal fluid with normal blood glucose levels. The impaired glucose is due to a defect in the glucose transporter responsible for the facilitative diffusion of glucose across the blood–brain endothelial barrier. The transporter designated GLUT1 belongs to a family of closely related glucose transporters. Wang et al. (2000) described 15 children who presented with typical features of heterozygous mutations in the GLUT1 gene (Wang et al., 2000). The type of mutations varied, but the resultant deficiency in the transporter reduced cerebrospinal fluid glucose concentrations and erythrocyte glucose transporter activities in the patients.

The use of the ketogenic diet as a supply of alternative fuel for the brain has been therapeutic. Ketone bodies, which use a different transport mechanism prevent the neurological damage seen in the untreated condition. Seizures resolve and there is normal brain growth in treated children (De Vivo et al., 1991).

Progressive encephalopathies of childhood

These diagnoses come into consideration when there is neurological regression or arrest of development. There may be additional clues such as familial recurrence, non-neurological abnormalities including retinal and other

ophthalmological abnormalities, and the presence of a particular neurological sign as in the acoustic startle seen in Tay–Sachs disease. It is traditional to distinguish leukodystrophies from polioencephalopathies by the characterization that progressive white matter destruction presents with the early onset of spasticity and that encephalopathies present with seizures. Unfortunately, there are too many exceptions for this to be a useful rule. Many cerebral diseases involve both grey and white matter, and seizures may be the presenting sign of certain white matter disorders. Rather than rely on clinical means for the type of disorder, magnetic resonance imaging is extremely useful for determining the areas of involvement and should be performed in any child with evidence of a progressive condition.

Non-neurological abnormalities are extremely important in the evaluation and therefore warrant a careful search for their presence. Inclusions in certain cell types including leukocytes, histiocytes, and fibroblasts may be noted. The finding of storage material should prompt an appropriate search. Electron microscopy for ultrastructural details may be diagnostic (Ceuterick-de Groote & Martin, 1998; Ceuterick & Martin, 1992). Other features that the child should be examined for include unexplained failure to thrive, skeletal changes, changes of skin and hair, and pulmonary involvement. Specific craniofacial features may be seen in the peroxisomal disorders and progressive coarsening noted in certain mucopolysaccharidoses. The presence of liver and spleen enlargement in certain storage disorders, cardiomegaly in Pompe disease and mitochondrial conditions, and liver or kidney cysts in peroxisomal disorders are other examples.

Lysosomal storage disorders

This group of disorders are characterized by the accumulation of storage material in the autophagocytic vacuoles, the lysosome. Based on the storage material, lysosomal disorders may be separated into sphingolipidoses, mucopolysaccharidoses, glycopeptide, glycogen storage disorders, lipid storage, peptide abnormalities, transport defects, and multiple enzyme disorders (abnormalities of targeting) (Hopwood & Brooks, 1997). Several of these disorders are especially important in the evaluation of the child with cerebral degeneration. A complete discussion of this large group is not possible, but specific examples will be highlighted including Tay–Sachs disease, Niemann–Pick type C, neuronal ceroid lipofuscinosis, and the mucopolysaccharidoses that affect the nervous system directly (Table 119.2).

Sphingolipidoses: Tay–Sachs disease

Tay–Sachs or infantile GM_2 gangliosidosis is an early infantile degeneration with megalencephaly and blindness. It is seen predominantly in Ashkenazi Jewish children and in certain other populations including French Canadians. The incidence is reported to be 1/112 000 of live births in the general population and 1/3900 in the Jewish population.

The infant, normal at birth, develops an exaggerated startle to sounds at 4 months. There is quick extension of the arms and legs followed by few clonic jerks, blinking with a startled look and neck extension. No adaptation occurs. This needs to be distinguished from seizures which occur later in the disease. While this may be seen in other conditions, it is nearly always present in this disorder. Deterioration is usually not seen until 6 months of age. The affected child loses the ability to roll over, is unable to sit, spontaneous vocalization stops, and then loses head control. Axial hypotonia and spasticity develops. With further progression, there is development of seizures, tonic–clonic as well as minor motor, and unusual laughing spells. The EEG changes and hypsarrhythmia may occur. It eventually becomes obvious that the child is blind and pendular nystagmus, evidence of early visual loss, may develop. A bilateral cherry red spot is seen in the majority. This is a large conspicuous grey circular zone of retinal degeneration, in the centre of which is the contrasting red macula (Lyon et al., 1996).

A late feature is an increase in the head circumference. This may not be seen until the second year of life and actual separation of the sutures may occur. This is a true enlargement of the brain secondary to stored neuronal material and is not secondary to hydrocephalus. There is no visceral or skeletal involvement; no peripheral nerve involvement; no abnormalities found in the bone marrow or leukocytes; and no abnormal excretion of oligosaccharides. The disease is relentlessly progressive and usually fatal between 3 and 5 years of age (Lyon et al., 1996).

There is an accumulation of GM_2 gangliosides and related glycolipids in neurons and other organs. Normally the hydrolysis of gangliosides is accomplished by the action of two structurally related lysosomal enzymes hexosaminidase A and hexosaminidase B with the involvement of GM_2 activator protein. Hexosaminidase A is composed of two subunits, α and β, encoded on chromosome 15 and chromosome 5, respectively. Hexosaminidase B contains only beta subunits ($\beta\beta$). The activator protein is also encoded on chromosome 5 and is necessary for the degradation of GM_2 ganglioside by hexosaminidase A. Mutations at any one of the gene loci can result in the accu-

Table 119.2. Selected lysosomal storage disorders

Clinical syndrome	Enzyme abnormality	Accumulated material
GM1 gangliosidoses	β-galactosidase	GM1 gangliosides, galactosyl oligosaccharides, keratan sulfate
Tay-Sachs (Variant B)	Hexosaminidase A (α-subunit)	GM2 gangliosides
Sandhoff (Variant O)	Hexosaminidase A and B (β-subunit)	GM2 gangliosides, other sphingoglycolipids and glycoproteins with terminal β-hexosamine residues including globosides and GA2 glycolipids
GM2 gangliosidosis (Variant AB)	GM2 activator protein	GM2 gangliosides
Krabbe	Galactosylceramidase (galactocerebroside beta-galactosidase)	Galactosylceramide, galactosylsphingosine (psychosine)
Gaucher	β-glucosidase (glucocerebrosidase)	Glucoceramide globosides (glucosylceramide)
Metachromatic leukodystrophy	Arylsulfatase A	Sulfatides
Farbers	Acid ceramidase	Ceramide
Niemann–Pick type A and B	Sphingomyelinase	Sphingomyelin
Niemann–Pick type C	Niemann–Pick C1 protein	Unesterified cholesterol
MPS I (Hurler Disease)	α-L-iduronidase	Dermatan sulfate Heparan sulfate
MPS II (Hunter Disease)	Iduronate 2-sulfatase	Dermatan sulfate Heparan sulfate
MPS III (Sanfilippo Disease)		
Type A	Heparan *N*-sulphatase	Heparan sulfate
Type B	α-*N*-acetylglucosaminidase (NAGLU)	Heparan sulfate
Type C	Acetyl CoA: α-glucosamine *N*-acetyl transferase	Heparan sulfate
Type D	*N*-acetylgalactosamine-6-sulfatase	Heparan sulfate
Infantile NCL (Santavuori–Haltia Disease)	Palmitoyl-protein thioesterase (PPT1)	Palmitoylated proteins
Late infantile NCL (Jansky–Bielschowsky Disease)	Tripeptidyl-peptidase I precursor (TPP-I) (Pepstatin-insensitive carboxypeptidase)	Subunit c of mitochondrial ATP synthase
Juvenile NCL	CLN3 protein (Battenin)	Unknown

mulation of GM_2. Three varieties have been reported. Defects in the α subunit give rise to defective hexosaminidase A and Tay–Sachs and other later onset variants. Defects in the β subunit result in a defect in both hexosaminidase A and B and gives rise to the Sandhoff disease. Activator protein deficiency or the AB variant, because there are normal levels of hexosaminidase A and B, also can result in a similar accumulation (Lyon et al., 1996).

Diagnosis requires the demonstration of a deficiency of hexosaminidase A with normal or elevated levels of hexosaminidase B. Enzymatic studies can be performed on leukocytes using artificial compounds or the natural GM_2 gangliosides as substrates. Heterozygotes can be detected by assays of hexosaminidase A in serum, leukocytes, or cultured fibroblasts. The carrier frequency is 1/31 in the Jewish population compared to 1/167 in the general population (Petersen et al., 1983). This has led to widespread screening programmes in this population, which in conjunction with available prenatal testing has resulted in a decreased incidence of disease.

There presently is no known treatment, but recent studies of the compound *N*-butyldeoxynojirimycin in the Tay–Sachs mouse has raised the potential for therapy. The treatment of Tay–Sachs mice with *N*-butyldeoxynojirimycin prevented the accumulation of GM_2 in the brain. This agent appears to act by interfering in the synthesis of GM_2 and other glycosphingolipids (Platt et al., 1997).

Defects in lysosomal lipid metabolism

Niemann–Pick Type C

The Niemann–Pick disorders are characterized by the accumulation of sphingomyelin in reticuloendothelial cells and other cell types throughout the body. Features of the condition are progressive neurologic deterioration, hepatosplenomegaly and retarded growth. Early on in the description of the disorder, it appeared that there were different presentations and four varieties were labelled A, B, C and D. Group A and B patients clearly had a defect in sphingomyelinase leading to accumulation of sphingomyelin. The enigma was that while sphingomyelinase levels were low in type C, they were not absent. It has subsequently been determined that type A and B are allelic and are a separate disorder from type C. Niemann–Pick type C is not a primary defect in sphingomyelinase (Vanier & Suzuki, 1996). While type A is more common than the others, the recent understanding of the biochemical mechanism of type C has given new insights into lysosomal lipid metabolism and it will be discussed.

To state that Niemann–Pick type C is variable in presentation is an understatement. The disease may present from the perinatal period through adulthood. Neurological and visceral manifestations are important but appear to be indefinite in severity and timing. Liver involvement may be present prenatally or in the neonatal period. Cholestatic jaundice is present in about half of the cases. This typically spontaneously resolves, but has been reported to result in liver failure. Neurological findings consist of ataxia, dysarthria, progressive dementia, cataplexy, seizures, dystonia, and a supranuclear vertical gaze palsy. When presenting early on, there is delayed motor development and hypotonia followed by pyramidal signs (Vanier & Suzuki, 1996).

The presentations that have been described are based on the age of onset and presenting signs. There is a late infantile/juvenile form, severe infantile form, adult presentation, and finally a rapidly fatal neonatal form characterized by cholestatic liver failure (Fink et al., 1989; Vanier & Suzuki, 1996). The late infantile and juvenile forms are the most common presentation and are characterized as a slowly progressive disease. Children are initially normal, then develop neurological abnormalities with loss of previously acquired speech, the appearance of mild intellectual impairment, supranuclear vertical gaze palsy, ataxia and later associated with dementia and variably seizures and extrapyramidal deficits.

Biochemically, there are elevated levels of sphingomyelin in the liver and spleen with normal total sphingomyelinase activity. However, by isoelectric focusing sphingomyelinase activity in the acidic range was markedly reduced. These findings led to the confusion concerning the classification of this disorder. Pentchev et al. (1985) subsequently demonstrated that there was a major block in cholesterol esterification and an accumulation of unesterified cholesterol in cells (Pentchev et al., 1985). The gene subsequently labelled NPC located on 18q11–q12 was identified. The translated protein has similarity to the putative sterol-sensing regions of SREBP cleavage activating protein and 3-hydroxy-3-methylglutaryl coenzyme A reductase (Carstea et al., 1997).

Nerve cells demonstrate not only storage of cholesterol but also neurofibrillary tangles containing paired helical filaments similar to the tangles present in Alzheimer's disease and other disorders, but this does distinguish it from other forms of Niemann–Pick. Auer et al. (1995) demonstrated tau protein in Western blots from brain tissue in five cases of Niemann–Pick type C (Auer et al., 1995). The NPC mouse showed that the terminal fields of axons and dendrites are the earliest sites of degeneration and occur well before the appearance of a neurological phenotype.

The clinical diagnosis is not difficult when faced with typical findings, but atypical presentations are not rare and will present problems. It is estimated that 10% of cases will not have overt organomegaly. Foam cells and sea-blue histiocytes, which may be present in bone marrow, are nonspecific and may be lacking. Ultrastructural analysis of biopsies may demonstrate storage in a variety of tissues, but false-negatives are reported (Vanier & Suzuki, 1996).

Diagnosis depends on the demonstration of lysosomal accumulation of unesterified cholesterol in cultured fibroblasts as shown by a characteristic pattern of intense perinuclear fluorescence after staining with filipin, a probe that forms complexes with unesterified cholesterol, and abnormal intracellular cholesterol homeostasis as defined by impaired LDL-induced cholesterol homeostasis (Vanier & Suzuki, 1996).

No strict correlation has been noted between the severity of alteration in intracellular cholesterol homeostasis and the clinical phenotype. Provided marked abnormalities have been demonstrated in the first affected individual, similar tests for prenatal detection of affected fetuses using cultured chorionic villi cells or amniocytes can be performed. Since some heterozygotes may show significant alterations, prior studies of parents are advised (Vanier & Suzuki, 1996).

No specific treatment is available. Bone marrow transplantation has not, to date, been evaluated and liver transplantation did not influence the course of the neurological deterioration (Gartner et al., 1986). Combined transplantation did not have a beneficial effect on neurological deterioration in animal models (Vanier & Suzuki, 1996).

Neuronal ceroid lipofuscinosis (NCL)

Neuronal ceroid lipofuscinosis encompasses a group of lysosomal diseases with defects in different aspects of lysosomal protein catabolism. All are inherited in an autosomal recessive fashion with an overall frequency of 1 in 12 500 births. The terms neuronal ceroid lipofuscinosis and Batten disease are now used interchangeably. They are delineated by seizures, retinal disease, visual loss, cognitive impairment and motor decline. There are presently defined an infantile form, late infantile, juvenile, and adult. There are also variants recognized that have ultrastructural features of one form, but an atypical clinical presentation (Boustany, 1996).

Infantile NCL (Haltia–Santavouri disease)

Primarily a Finnish disease, infantile NCL is characterized by normal initial development and then psychomotor retardation with onset between 8 and 18 months, hypotonia, myoclonus, progressive microcephaly and blindness. Vision begins to deteriorate at 12 months and there are obvious retinal changes by 2 years. Infants become microcephalic by 2 years of age. By age 3, they are bedridden, blind, spastic with frequent myoclonic jerks. On ultrastructural analysis, lysosomes contain granular, osmiophilic deposits referred to as GROD (Boustany, 1996).

Late infantile NCL

Early development proceeds in a normal fashion with attainment of walking, talking, and other motor skills at the appropriate age (Boustany et al., 1988). Children then develop ataxia, hypotonia, drop attacks, and tonic–clonic seizures around three years of age (Boustany, 1992). Visual deterioration secondary to tapetoretinal degeneration follows at age 4 and the child then enters a period of rapid deterioration. By age 5, the child is mute, bedridden with frequent seizures. An enlarged amplitude is seen on visual-evoked potentials. The typical ultrastructural abnormalities on skin biopsy are curvilinear or C-shaped structures enclosed within lysosomal membranes (Carpenter et al., 1977). The typical profile is also seen in a variety of tissues including smooth muscle, macrophages, endothelial cells, Schwann cells, mast cells, pericytes and eccrine duct cells. Pathologically, the brain is extremely atrophic with extensive narrowing of the cortical layers and cerebellar atrophy. Microscopically, there is nearly complete depletion of the neuronal elements with gliosis and total loss of Purkinje and granular cells in the cerebellum. The remaining cells are distended with granular autofluorescent lipopigment.

Juvenile NCL

The first symptom to appear is deteriorating vision secondary to retinitis pigmentosa at the ages of 4–6 years. Macular degeneration evolves with time, and the electroretinogram and visual-evoked potentials become flat. Around age 10, there is cognitive decline, poor school performance, decreased attention span and deteriorating speech. Children then develop seizures although the EEG is usually abnormal prior to this showing runs of spike-wave. Speech develops a monotonous cadence with perseveration and echolalia. In their teenage years, patients develop rigidity and tremor (Boustany, 1996).

Vacuolated peripheral lymphocytes help distinguish this type from others (Schwendemann, 1976). The other distinctive feature is the lesser amount of storage material with a higher incidence of fingerprint profiles. Vacuoles in cells appear enclosed by a limiting membrane. Osmiophilic inclusions resembling smudged fingerprint impressions associated with lipid-like droplets are considered a hallmark. Curvilinear profiles are seen as well. Various tissues may be examined including suction rectal biopsies (Rapola et al., 1984).

All discerned forms of NCL are autosomal recessive. The elucidation of the molecular biology has assisted the understanding of NCL categories. The gene for INCL was assigned to chromosome 1p32 and then determined to code for palmitoyl-protein thioesterase (PPT1), an enzyme that modifies proteins by removing fatty acid groups from S-acetylated proteins (Vesa et al., 1995). The accumulation of undigested substrates leads to the formation of neuronal storage bodies that are associated with the clinical symptoms. There have been variant phenotypes associated with PPT1 mutations. The gene responsible for late infantile NCL is *CLN2*, which encodes for a tripeptidylpeptidase (Ezaki et al., 1999; Liu et al., 1998; Rawlings & Barrett, 1999; Sleat et al., 1997; Sohar et al., 1999). The juvenile form is secondary to mutations in CLN3 which appears to be involved in the maintenance of the appropriate pH in the intracellular vacuolar compartments essential for normal cell function (Golabek et al., 2000). The predominant mutation is a 1.02 kb genomic deletion that accounts for nearly 85% of the disease alleles (Munroe et al., 1997). This deleted portion causes a frameshift and subsequent premature stop codon resulting in a truncated protein, which cannot move out of the endoplasmic reticulum (Haskell et al., 2000; Jarvela et al., 1999).

Mucopolysaccharidoses (MPS)

MPS are a clinically, biochemically and genetically heterogeneous group of disorders of lysosomal glycosaminoglycan metabolism. Abnormal systemic accumulation of partially degraded glycosaminoglycan fragments is present in nearly all tissues (Lyon et al., 1996; Whitley,

1996). Each disorder results from deficiency of an enzyme required in the sequential process of catabolism. These compounds are large complex heteropolysaccharide molecules derived from extracellular components chiefly connective tissue proteoglycans. After endocytosis into the lysosome, the series of enzymes removes monosaccharide and sulfate groups from the non-reducing end of the molecule (Whitley, 1996).

Deficiency of any of the ten enzymes results in a disorder in this group with accumulation of their substrates. The compounds that accumulate include heparan sulfate, dermatan sulfate, keratan sulfate and the chondroitin sulfates. In affected patients they are synthesized in the normal fashion and become integral components of connective tissue. The accumulation of heparan sulfate is associated with the nervous system involvement which is seen in Hurler, Hunter, Sanfilippo, and Sly disease. Injury, however, may be secondary to an associated accumulation of gangliosides. Diagnosis of the mucopolysaccharidoses rests on the demonstration of specific enzymatic abnormalities. Screening for this group of disorders may be performed by examining the urine for mucopolysaccharides (Lyon et al., 1996).

Hurler syndrome is an autosomal recessive disorder caused by a deficiency of alpha-L-iduronidase. There is coarsening of facial features, hepatosplenomegaly, skeletal manifestations, and progressive neurologic deterioration. Severe disease presents around the first 12 months of life. Lumbar kyphosis and recurrent upper respiratory infections are the most common presenting findings (Cleary & Wraith, 1995). The course is characterized by early, progressive airway issues including obstructive sleep apnea and eventually neurological deterioration with loss of motor and language skills. The progressive dementia is sometimes associated with frank hydrocephalus, which may benefit from shunting. Combined hearing loss is common. There are also ophthalmological abnormalities including photophobia, progressive corneal clouding, a retinal pigmentary dystrophy, optic nerve swelling and glaucoma. Other organ systems are also involved and there is pulmonary and cardiovascular disease, skeletal changes with dysostosis multiplex, hepatosplenomegaly, skin thickening and hirsutism. Progressive respiratory and cardiac failure are the underlying cause of death.

The only X-linked recessive disorder among the MPS, Hunter syndrome is secondary to a deficiency of the lysosomal enzyme iduronate-2-sulfatase. It shares several features in common with the more common Hurler syndrome and, in boys, the early differentiation between the two often relies solely on enzyme determination. There are stiff joints, short stature, hepatosplenomegaly, and coarse facial features (Young & Harper, 1983). There is the insidious onset of dementia between 4 and 8 years of age, then mental age levels off and behavioural problems become manifest. Unlike Hurler syndrome, there is no corneal clouding. Cervical cord compression may occur secondary to pachymeningitis or a stenotic cervical canal. Conductive and sensorineural hearing loss occur. Bone marrow therapy has been attempted, but has not been curative.

Sanfilippo syndrome is secondary to the accumulation of heparan sulfate and there is marked urinary excretion of heparan sulfate. There are four types identified depending on the enzyme abnormality: type A: heparan *N*-sulfatase; type B: alpha-*N*-acetylglucosaminidase (NAGLU); type C: acetyl-CoA: alpha glucosaminide *N*-acetyltransferase; type D: *N*-acetylglucosamine 6-sulfatase (Lyon et al., 1996). Neurological deterioration which is the primary manifestation of this disorder is first noted between 4 and 6 years. Behavioural problems are often the initial feature and sleep disturbances, aggression, hyperactivity and difficulties with attention are particularly common (Cleary & Wraith, 1993). Motor activities remain intact until late in the course of the disease. Speech may, or may not, be acquired, but if so it is eventually lost. Seizures occur in approximately 40% of individuals (van de Kamp et al., 1981).

Sly syndrome is a rare condition secondary to β-glucuronidase deficiency with accumulation of the β-linked glucuronic acid residues: dermatan sulfate, heparan sulfate and chondroitin sulfate. It is characterized by short stature, hepatosplenomegaly, progressive dysostosis multiplex, intellectual impairment; and mental retardation marked by speech delay. It is variable in presentation and course (Lyon et al., 1996).

Therapy for the MPS has been limited. Bone marrow transplantation has been used as therapy in Hurler disease in early affected individuals (Whitley, 1996). It has not been effective in Hunter or Sanfilippo disease. There are presently ongoing investigations of lysosomal enzyme infusions and gene therapy in appropriate animal models for most of the lysosomal storage diseases.

Other categories of neurodegenerative disease

As noted, not all the degenerative conditions presenting in childhood are lysosomal storage diseases. In addition to the lysosomal diseases, there are mitochondrial, peroxisomal, abnormalities of copper metabolism, disorders of amino and organic acid, as well as other single gene disorders for which the molecular defect may or may not be

known. In addition, while the majority of the chapter has focused on disorders affecting cortical neuronal function, it is obvious that there are other presentations for degenerative disorders presenting in childhood and these will be briefly touched upon.

Progressive myoclonic epilepsies

While it is recognized that many of the disorders discussed in this chapter may make their initial presentation through seizures, the progressive myoclonic epilepsies are sufficiently distinct to warrant some additional comments. This group is characterized by the combination of seizures with myoclonus or polymyoclonus (Lyon et al., 1996). The list of progressive myoclonus epilepsy include Unverricht–Lundborg or Baltic myoclonus, Lafora disease, Alpers disease, Sialidosis type 1 (cherry red spot-myoclonus), NCL, MERRF, and dentatorubro-pallidoluysian atrophy (DRPLA). There are also other disorders which may have this as a feature, these include Gaucher disease, Krabbe and certain other diseases both genetic as well as infectious. The pattern of inheritance when clear may provide useful information. While the majority are recessive, the importance of recognizing the dominantly inherited DRPLA or maternal inheritance seen in the mitochondrial disorder, MERRF, should be readily apparent.

Disorders affecting the basal ganglia

The extrapyramidal signs of athetosis, chorea, dystonia, and rigidity characterize this group. Dementia and seizures may accompany the other findings. Included are juvenile Huntington disease, which often presents with rigidity and seizures. When presenting in childhood, it is usually secondary to paternal inheritance and anticipation, the earlier, more severe presentation of disease secondary to expansion of the triplet repeats causing disease. The other disorder which should be considered with this presentation is Wilson disease. This is particularly important because both liver and brain symptoms may be treated or more accurately prevented if recognized early and treatment instituted. Other disorders are the familial dystonias including Dopa-responsive dystonia, Hallevorden–Spatz and the choreas including chorea–acanthocytosis.

Disorders associated with strokes

While it is traditional to think of cellular degeneration as the archetype of progressive disorders, it must be recognized that as in the adult multiple infarctions can result in progressive neurologic disease. Homocystinuria, Fabry disease, sickle cell disease, hereditary coagulopathies, pseudoxanthoma elastica, and others can result in loss of neurological function and should be considered in the child who presents with a vascular event. Appropriate testing of the child with a cerebrovascular event will depend on the nature of the event, distribution, and associated findings. Evaluation will include hematological and coagulation studies, amino acids, liver function and appropriate imaging of the vasculature.

Disorders that may have regressive component

There are disorders which appear to combine a regressive period as well as a static phase. Certain previously acquired skills are lost and there is no further progress made, but the relentlessly progressive degeneration seen, for instance, in the lysosomal disorders does not occur. Specific examples of this include Rett syndrome, which is due to a defect in MECP2 gene and the expanding congenital disorders of glycosylation (CDG) previously labelled carbohydrate deficient glycoprotein disorders. The latter are diagnosed by examination of the electrophoretic pattern of transferrins (Aebi et al., 1999; Matthijs, 2000).

In conclusion, tremendous progress has been made in the diagnosis and understanding of the pathogenesis of many of the disorders that result in cerebral degeneration in childhood. It is also apparent that therapies are presently markedly inadequate for many of these disorders. The promise of gene therapy has yet to be fulfilled, but complete pessimism is also inappropriate when dealing with affected individuals and their families. As previously stated, these children deserve an appropriate evaluation and continued therapy to maintain function and comfort.

For most of the disorders covered in this chapter, there are family support organizations with most maintaining webpages. With this access to information, families are often surprised and sometimes resentful that a busy physician does not have complete information on new developments. Caretakers should be aware of these resources and must certainly maintain some familiarity with new developments when dealing with a particular disorder. However, it is also important to maintain balance and explain the difference between research and practical clinical therapies.

Mitochondrial encephalomyopathies

Salvatore DiMauro[1] and Anthony H.V. Schapira[2, 3]

[1]Department of Neurology, Columbia University College of Physicians and Surgeons, New York, NY, USA
[2]University Department of Clinical Neurosciences, Royal Free and University College Medical School
[3]Institute of Neurology, University College London, London, UK

This chapter deals with those mitochondrial disorders due to defects of the mitochondrial respiratory chain and oxidative phosphorylation (MITOX) system. Although usually referred to as mitochondrial encephalomyopathies, they often involve multiple systems and their mode of manifestation is protean. Thus, the MITOX diseases are a diverse group and this is also reflected at the molecular genetic level, because the respiratory chain is under dual genetic control, with thirteen proteins encoded by mitochondrial DNA (mtDNA) and all others encoded by nuclear DNA (nDNA). A variety of causative mutations have been identified in both the mitochondrial and nuclear genomes (Table 120.1). The spectrum of the primary mitochondrial disorders has complicated an estimation of their frequency in the general population. However, studies from three Northern European regions with homogeneous health systems and limited migration have come up with similar estimates. A study from western Sweden suggested that mitochondrial diseases (defined by clinical, morphological, biochemical, and molecular criteria) affect 1 in 11 000 preschool children (Darin et al., 2001), whereas a study from northeastern England found that mtDNA mutations cause disease in 6.57/100 000 adults (Chinnery et al., 2000). The third study focused on a specific mtDNA mutation (the A3243G MELAS mutation) and estimated that it has a frequency of at least 16.3/100 000 in the population of Northern Ostrobothnia, a region of northern Finland (Majamaa et al., 1998). Thus, defects of the respiratory chain may be amongst the commoner of the genetic causes of neurological disease.

Table 120.1. Genetic classification of respiratory chain defects

Defects of mtDNA
Mutations in genes affecting mitochondrial protein synthesis
(tRNA, rRNA, rearrangements)
Mutations in protein-coding genes
Multisystemic (LHON; NARP/MILS)
Tissue-specific (exercise intolerance/myoglobinuria)
Defects of nDNA
Mutations in genes encoding respiratory chain subunits
Complex I; Complex II
Mutations in genes encoding ancillary proteins
Complex IV (SURF1; SCO2; COX10; SCO1)
Defects of intergenomic signalling
mtDNA depletion
AR-PEO with multiple mtDNA deletions
(ARCO; MNGIE)
AD-PEO with multiple mtDNA deletions

Notes:
Abbreviations: LHON, Leber's hereditary optic neuropathy; NARP, neuropathy, ataxia, retinitis pigmentosa; MILS, maternally inherited Leigh syndrome; AR, autosomal recessive; AD, autosomal dominant; PEO, progressive external ophthalmoplegia; ARCO, autosomal recessive cardiomyopathy and ophthalmoplegia; MNGIE, mitochondrial neurogastrointestinal encephalomyopathy.

Mitochondrial biogenesis and biochemistry

Mitochondria are ubiquitous in mammalian cells, their number varying from one cell type to another in accordance with the aerobic metabolic demands of the host tissue. Thus brain, skeletal muscle, and cardiac muscle have particularly high concentrations of mitochondria. Each mitochondrion contains 2–10 molecules of mtDNA. MtDNA is a circular, double-stranded molecule 16.6 kilobases in length (Fig. 120.1). It encodes two ribosomal RNAs (rRNA), 22 transfer RNAs (tRNA) and 13 proteins, all of

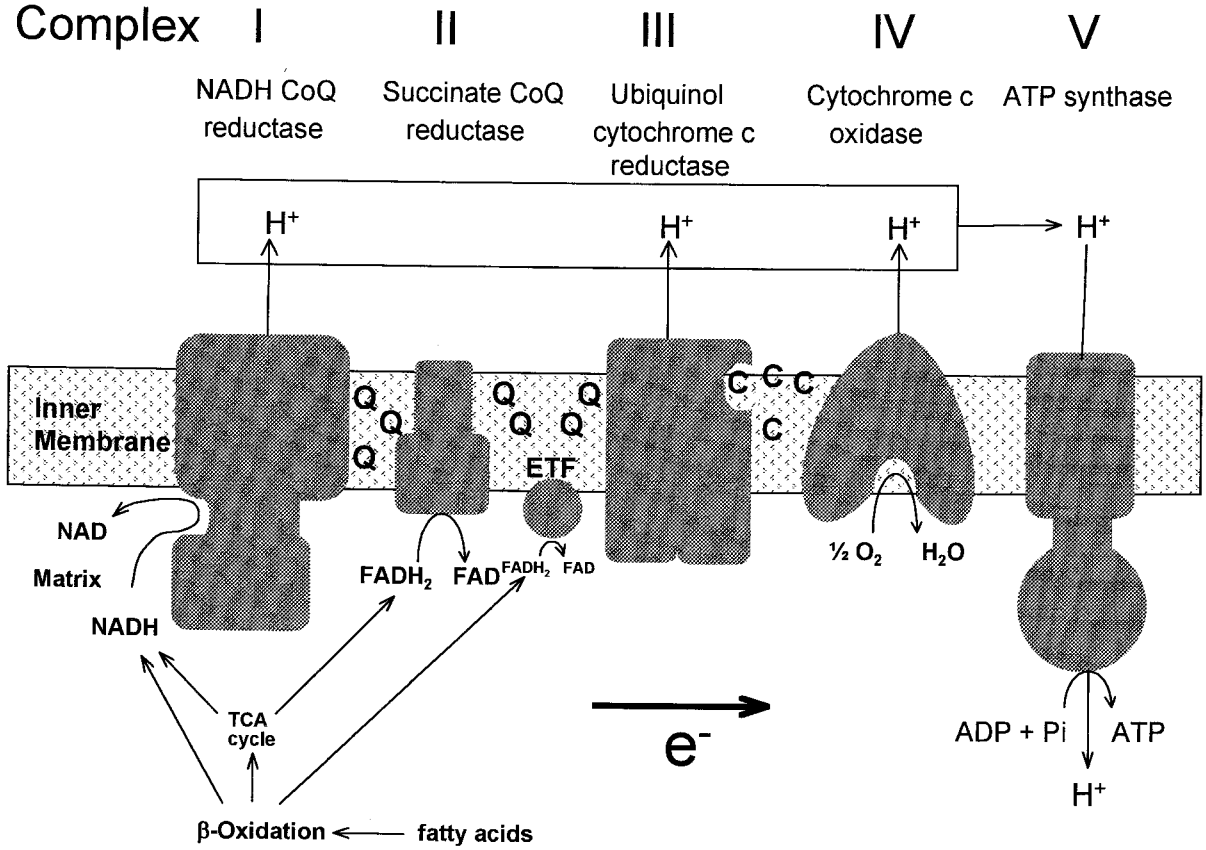

Fig. 120.1. The mitochondrial respiratory chain and oxidative phosphorylation system (NADH = the reduced form of nicotinamide–adenine dinucleotide; CoQ = ubiquinone; ATP = adenosine triphosphate; NAD = nicotinamide-adenine dinucleotide; TCA = tricarboxylic acid cycle; $FADH_2$ = the reduced form of flavin adenine dinucleotide; FAD = flavin adenine dinucleotide; ETF = electron transfer flavoprotein; e = electron; ADP = adenosine diphosphate; Pi = inorganic phosphate). (Reprinted with permission from Cooper & Clark, 1994).

them subunits of various complexes in the respiratory chain (Fig. 120.2). Mitochondria are slaves of the nucleus, and MtDNA is dependent upon nuclear encoded factors for its transcription, translation, replication and repair. The MITOX system comprises five multi-subunit complexes located in the inner mitochondrial membrane. Complex I is the largest of these and has seven subunits encoded by mtDNA. It is responsible for the reduction of NAD-linked substrates such as pyruvate, malate, glutamate and β-hydroxybutyrate and the passage of electrons to ubiquinone (coenzyme $Q_{10,}$ CoQ_{10}). Complex II, otherwise known as succinate dehydrogenase (SDH), is the only component of the MITOX system that is entirely encoded by nuclear genes and is not only part of the respiratory chain but also of the Krebs citric acid cycle. It is responsible for the reduction of FAD-linked substrates such as succinate and feeds reducing equivalents to ubiquinone. Cytochrome *b* is the only mtDNA-encoded subunit of complex III. This complex receives electrons from ubiquinone and shuttles these to complex IV (cytochrome oxidase) via cytochrome *c*. Cytochrome oxidase (COX) has three components encoded by mtDNA (COI, COII, COIII) and is responsible for the reduction of oxygen. Complexes I, III, and IV pump protons out across the inner mitochondrial membrane thereby creating an electrochemical gradient, which is used by complex V (ATPase) to generate ATP from ADP. The MITOX system therefore constitutes the most important component of oxidative phosphorylation, and mtDNA, in turn, devotes all its protein-coding genes to the production of subunits of this system. It is not surprising, therefore, that mutations in the mitochondrial genome result in deficits of oxidative phosphorylation and ATP production.

MtDNA is exclusively inherited through the maternal line. Thus, mtDNA is passed from the mother to all offspring and

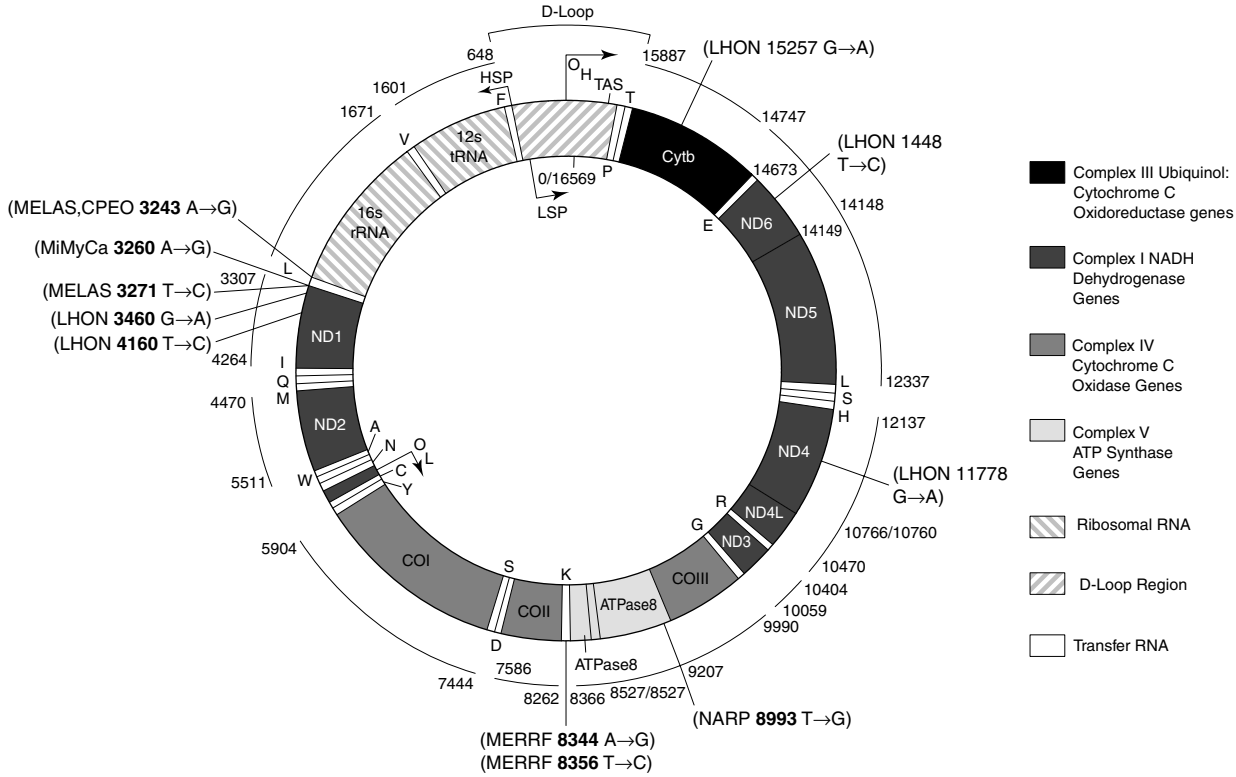

Fig. 120.2. Human mtDNA. O_H and O_L are the origins of heavy and light strand replication respectively. The more common mtDNA mutations associated with mitochrondrial encephalomyopathies are shown. (NADH = the reduced form of nicotinamide-adenine dinucleotide; ATP = adenosine triphosphate) (Reprinted with permission from Rahman & Schapira, 1999).

subsequently through the female line. Primary mtDNA mutations therefore exhibit maternal inheritance, although it is important to note that a maternal history is available in less than half of patients who are subsequently identified as having a mtDNA mutation. For instance, the vast majority of patients with single deletions in mtDNA manifest as sporadic cases, and only about 40% of patients with the G11778A mutation of mtDNA associated with Leber's hereditary optic neuropathy have a maternal history. The absence of such a history, particularly in patients with mtDNA point mutations, is usually either due to the development of a spontaneous mutation, or to the presence of oligosymptomatic family members. Secondary mutations of mtDNA can result from a primary nuclear mutation: these are multiple mtDNA deletions or mtDNA depletion. Multiple mtDNA deletions have been associated with autosomal recessively inherited myoneurogastrointestinal encephalopathy (MNGIE) and with autosomal dominant chronic progressive external ophthalmoplegia (CPEO) (see below).

Despite the wide variation of clinical manifestations of the mitochondrial disorders, the majority of patients can be grouped into one of a number of phenotypes according to their predominant features. Such grouping remains useful at both the clinical and, to some extent, the molecular genetic levels as there are broad generalizations that can be applied to such groups. Whilst such simplification is pragmatic, it must be recognized that a significant number of patients occupy 'overlap' syndromes. In addition, a given phenotype may be caused by a variety of molecular genetic mutations and a single mutation may give rise to a number of different phenotypes. In describing the main phenotypes of MITOX disorders, we will follow the genetic classification in Table 120.1.

Defects of mtDNA

Mutations in genes affecting mitochondrial protein synthesis

These include single mtDNA deletions (which always encompass one or more tRNA genes), and point mutations in rRNA or tRNA genes. These mutations are usually associated with multisystem disorders, lactic acidosis, and

massive mitochondrial proliferation resulting in the 'ragged-red' appearance of fibres in the muscle biopsy (Engel and Cunnigham, 1963). Histochemical studies have shown that RRFs react intensely with the succinate dehydrogenase (SDH) stain, but weakly or not at all with the cytochrome c oxidase (COX) stain. This is in agreement with the fact that SDH is entirely encoded by nDNA (and is therefore unaffected by mtDNA mutations), whereas 3 of the 13 subunits of COX are encoded by mtDNA.

Chronic progressive external ophthalmoplegia

Chronic progressive external ophthalmoplegia (CPEO) is probably the commonest manifestation of the mitochondrial myopathies. Patients may develop features from early to late adulthood and symptoms usually include slowly progressive bilateral, usually symmetrical ptosis and ophthalmoplegia involving all directions of gaze. Diplopia is relatively uncommon. Approximately 5–10% of patients may present with unilateral ptosis, around 66% have a salt and pepper retinopathy and 50% have an associated proximal limb myopathy characterized by muscle weakness and fatigue.

Kearns–Sayre syndrome (KSS) is a subset of CPEO, which involves the development of ptosis and ophthalmoplegia before the age of 20, together with the presence of a salt and pepper retinopathy and one of the following: cardiac conduction defect (heart block), elevated CSF protein or ataxia (Rowland, 1992). Additional encephalopathic features may most commonly develop in the KSS subgroup and include deafness and dementia. Seizures are distinctly uncommon and usually related to electrolyte disturbances, as may occur in hypoparathyroidism, one of several endocrine disorders often associated with KSS.

The prognosis for patients with CPEO and purely myopathic features is good. Life span is usually normal and clinical features translate to only mild or moderate functional disability. Such patients rarely become dependent on a wheelchair. The prognosis for patients with KSS is less good. Cardiac conduction defects are an important cause of death in these patients. Thus, regular cardiac evaluation may allow identification of patients in need of a pacemaker. Progression with the development of severe ataxia, diabetes mellitus, cognitive impairment and metabolic acidosis results in a shortened life-span with most patients not surviving beyond age 30.

Diagnosis is based upon the characteristic morphological features and the identification of mtDNA deletions in skeletal muscle. The great majority of patients with CPEO or KSS are sporadic. Males with a mtDNA deletion will not pass on the disorder. Mothers have a relatively low risk of passage to offspring, which is estimated at around 5%.

Accurate family history is important in the differential diagnosis of CPEO. Whereas sporadic cases are most likely due to single large-scale deletions of mtDNA, maternally inherited cases are usually attributable to the A3243G MELAS mutation in one of its several phenotypic variations (Moraes et al., 1993b), and, more rarely, to the A8344G MERRF mutation. About a dozen other point mutations in tRNA genes have been associated with CPEO, although many of these patients were sporadic and the mutations were identified only after Southern blot analysis excluded the presence of mtDNA rearrangements. The autosomal dominant and recessive forms of CPEO are described below.

Mitochondrial encephalomyopathy, lactic acidosis and stroke-like episodes (MELAS)

The clinical features of MELAS may manifest at any age from early adolescence to late adulthood, although the great majority of patients present before age 40. The initial clinical presentation may involve myopathy or encephalopathy, an endocrine disturbance such as non-insulin dependent diabetes mellitus, or an oligosymptomatic feature such as sensorineural deafness. Acute presentations may involve seizures or stroke-like episodes causing hemianopia, hemianesthesia or hemiplegia. On examination, patients are frequently of short stature with generalized muscle thinning but no focal wasting. As mentioned above, ophthalmoplegia may be a presenting sign. The myopathy usually comprises a proximal muscle weakness with premature fatigue. There may be ataxia, cognitive impairment, and sensorineural deafness. Additional neurological deficits may relate to stroke-like episodes: in this setting, movement disorders, particularly dystonia, may occur.

In many patients, initial manifestation may be oligosymptomatic but they invariably progress to additional features typical of the full syndrome. Neurological problems may accrue as a consequence of stroke-like episodes. These appear particularly to involve the parieto-occipital region. MELAS is an important differential diagnosis in young-onset stroke. The progressive course of MELAS is punctuated by episodes often involving headache, nausea, vomiting, seizures and/or strokes, usually in association with lactic acidosis. Acute deterioration may occur in the context of intercurrent illnesses such as infection. Treatment is supportive, with appropriate and gradual correction of the acidosis (bicarbonate is commonly used but a double-blind trial of dichloroacetate is currently under way), and treatment of seizures with anticonvulsants, avoiding sodium valproate, if possible, due to its interaction with mitochondrial metabolism (Silva et al., 1997; Tein

et al., 1993). There have been anecdotal reports of patients with intractable seizures responding to steroids although the pathophysiological basis of this is unclear. Steroids, however, are not recommended in the long-term management of these patients.

The etiology of the stroke-like episodes remains unclear. They do not characteristically follow specific vascular territories. Abnormal mitochondria staining strongly positive for SDH have been observed in the endothelial cells of intracerebral small blood vessels. It is likely that the pathogenesis of these episodes involves abnormal vascular tone, decreased blood flow and abnormal oxidative metabolism resulting in an area of cerebral damage consequent upon both vascular and metabolic deficits.

The diagnosis of MELAS rests upon the clinical manifestations, supported by abnormal muscle morphology (characteristically, RRFs in patients with typical MELAS are COX-positive) and/or the identification of the relevant mitochondrial DNA mutation in blood or other accessible tissues (hair follicles, urinary sediment, cultured skin fibroblasts).

The prognosis for patients with MELAS depends upon the extent and severity of their tissue dysfunction. Life span is invariably shortened. The development of seizures and recurrent stroke-like episodes are poor prognostic indicators. Common causes of death include cardiopulmonary failure, status epilepticus, aspiration pneumonia or intestinal obstruction.

MELAS is usually due to a mtDNA point mutation, most frequently an A-to-G substitution at nt-3243 in the $tRNA^{Leu(UUR)}$ gene (Goto et al., 1990). However, a total of 11 point mutations (plus one microdeletion) have been associated with the MELAS phenotype: five of these are in the $tRNA^{Leu(UUR)}$ gene (Goto et al., 1991, 1994; Morten et al., 1993; Nishino et al., 1996), four in other tRNA genes (Hanna et al., 1998a; Manfredi et al., 1996; Nakamura et al., 1995; Taylor et al., 1996), and, rather surprisingly, two are in protein-coding genes (De Coo et al., 1999; Manfredi et al., 1995; Santorelli et al., 1995). Point mutations are invariably systemically distributed and the transmission rate of the most common mutation (A3243G) is relatively high, particularly when a woman has a high mutation load in blood (>40%).

Myoclonic epilepsy with ragged red fibres (MERRF)

The predominant clinical features of MERRF are myoclonus, ataxia and seizures. Myoclonus is often the presenting symptom and may be precipitated by action, noise or photic stimulation. However, these patients may also experience drop attacks, focal seizures and generalized tonic–clonic epilepsy. Skeletal muscle involvement is usually relatively mild. Some patients may have ophthalmoplegia and ptosis, deafness, sensorimotor axonal peripheral neuropathy and lipomas. Patients may manifest from early childhood to late adulthood.

The diagnosis of MERRF rests upon identification of the characteristic morphological changes in skeletal muscle biopsy and/or identification of a specific mtDNA mutation in blood or muscle.

Prognosis is intermediate between CPEO and MELAS. Seizures are controlled with standard anticonvulsant therapy, avoiding sodium valproate. As a generalization, there is a closer correlation between the level of mutation in muscle and clinical outcome in MERRF. The most frequent mutation identified is the A8344G in the $tRNA^{Lys}$ gene (Shoffner et al., 1990), but two other mutations in the same gene have been associated with MERRF (Ozawa et al., 1997; Shtilbahns et al., 2000; Silvestri et al., 1992). The proportion of mutation in the blood also gives some guide as to risk of transmission. Those mothers with <30% mutation have a <5% chance of transmission.

Leigh syndrome

Leigh syndrome (LS) most frequently presents in infancy or early childhood with generalized spasticity, somnolence, blindness and deafness. Progression is usually rapid and prognosis poor, particularly in the early-onset cases. Less severe forms of LS can involve hypotonia, failure to thrive, respiratory abnormalities, ophthalmoplegia, seizures and lactic acidosis.

Diagnosis is often suggested by neuroimaging, which demonstrates bilateral symmetrical abnormalities in the brainstem, including low T1, high T2 signal changes on magnetic resonance imaging.

Lactic acidosis is frequent. Changes on muscle biopsy are rarely typical of mitochondrial myopathy (there are no RRF, SDH-hyperintense, or isolated COX-negative fibres), but diffuse COX deficiency can be seen histochemically in patients with nuclear defects of complex IV. Mutations affecting both nuclear and mitochondrial genomes have been identified in LS. As mentioned above, the T8893G mutation, when present in high mutation load, may cause this disorder. Other mtDNA mutations in transfer RNAs have also been identified, including the common A8344G MERRF mutation (Howell et al., 1996; Santorelli et al., 1998), the rarer G8363A MERRF mutation (Shtilbahns et al., 2000), and the common A3243G MELAS mutation (Koga et al., 2000; Vilarinho et al., 1999). Nuclear gene mutations affecting subunits of complex I and complex IV are discussed below. The prognosis for LS is poor, with most infantile-onset cases dying in early childhood, and rare patients surviving beyond adolescence.

Table 120.2. Patients with pure myopathy (without ophthalmoplegia) and point mutations in tRNA genes of mtDNA

Gene	Base change	Clinical features	Family history	References
$tRNA^{Leu(UUR)}$	T3250C	Respiratory/SIDS	+	Goto et al. (1992); Ogle et al. (1997)
	A3302G	Respiratory	+	Bindoff et al. (1993)
	A3288G	Respiratory	+	Hadjigeorgiou et al. (1999)
$tRNA^{Pro}$	G15990A	Myopathy	−	Moraes et al. (1993a)
$tRNA^{Phe}$	T618C	Respiratory	+	Kleinle et al. (1998)
$tRNA^{Trp}$	G5521A	Ptosis	+	Silvestri et al. (1998)
$tRNA^{Met}$	U4409C	'Dystrophy'	−	Vissing et al. (1998)
$tRNA^{Leu(CUN)}$	A12320G	Ptosis	−	Weber et al. (1997)

Note:
SIDS = sudden infant death syndrome.

Cardiomyopathy

Cardiomyopathy may develop in many of the mitochondrial myopathies. Cardiac disease usually presents as conduction defects and is seen most frequently in KSS. However, isolated, usually hypertrophic cardiomyopathy has also been observed in patients with the A3243G MELAS mutation (Silvestri et al., 1998; Vilarinho et al., 1997), in patients with a variety of other tRNA mutations, especially involving $tRNA^{Ile}$ (DiMauro & Hirano, 1998), as well in patients with multiple mtDNA deletions (see below). A mutation in the 12S rRNA of mtDNA has also been identified in a family with maternally inherited cardiomyopathy (Santorelli et al., 1999). This mutation, A1555G, is also associated with aminoglycoside-induced deafness (Prezant et al., 1993).

Diabetes

Diabetes mellitus is a relatively frequent finding in patients with mitochondrial myopathy. Indeed, it is estimated that up to 1% of patients with non-insulin dependent diabetes mellitus are positive for the A3243G mutation (Kadowaki et al., 1994). As mentioned above, diabetes mellitus may be part of a multisystem involvement in mitochondrial disorders, for instance in MELAS and KSS. In addition, diabetes mellitus may occur in association with diabetes insipidus, optic atrophy and deafness (Wolfram's syndrome) and multiple mtDNA deletions (Barrientos et al., 1996). Diabetes mellitus may also occur in association with deafness alone (Remes et al., 1993; van den Ouweland et al., 1992).

Hematological disturbances

Besides CPEO and KSS, single mtDNA deletions can cause Pearson syndrome (PS), which is characterized by sideroblastic anemia and pancreatic failure (Rotig et al., 1990). This may be associated with diabetes mellitus, hepatic disease, de Toni Fanconi syndrome and lactic acidosis. Onset is usually in infancy and patients have single mtDNA deletions or duplications. These mutations are predominantly present in blood, but they are also systemically distributed throughout tissues. The great majority of cases are sporadic and most die in infancy or early childhood. Occasional survivors have been reported and interestingly these appear to develop features of KSS in later life (Larsson et al., 1990; McShane et al., 1991).

Myopathy

While mutations in tRNA genes are usually associated with multisystem disorders, in rare cases there is involvement of a single tissue, most commonly skeletal muscle. In Table 120.2, we have listed eight patients with pure myopathy, excluding progressive external ophthalmoplegia. It is noteworthy, and a useful diagnostic clue, that all three mutations in the $tRNA^{Leu(UUR)}$ affected preferentially respiratory muscles (Goto et al., 1992; Hadjigeorgiou et al., 1999; Ogle et al., 1997). It is also interesting that one such mutation was associated with dystrophic features in the muscle biopsy, although serum CK levels were normal (Vissing et al., 1998). Family history was negative in three of the eight patients with pure myopathy (Moraes et al., 1993a; Vissing et al., 1998; Weber et al., 1997), suggesting that the mutations in these patients occurred *de novo*. In most of the patients, the mutation was also present in blood or cultured skin fibroblasts, implying that the selective muscle involvement was due to 'skewed heteroplasmy', with preferential accumulation of the pathogenic mutation in skeletal muscle. In one patient, however, there was no evidence of the mutation in blood cells, cultured fibroblasts or cultured muscle, suggesting that this was a 'somatic mutation', which arose during embryogenesis in myogenic stem cells after germ-layer differentiation (Weber et al., 1997).

Exercise intolerance is a common complaint in patients with mitochondrial encephalomyopathies, but it is often overshadowed by other symptoms and signs. Only recently have we come to appreciate that exercise intolerance, myalgia, and myoglobinuria can be the sole presentation of respiratory chain defects. These are most commonly caused by mutations in protein-coding genes and are discussed below.

Mutations in protein-coding genes

Leber's hereditary optic neuropathy (LHON)

LHON is characterized by acute or subacute loss of vision with onset usually between 18 and 30 years and marked predominance in men. Typical ophthalmoscopic features are circumpapillary telangiectatic microangiopathy and pseudoedema of the optic disk. Associated features may include hyperreflexia, cerebellar ataxia, peripheral neuropathy, or cardiac conduction anomalies (pre-excitation syndrome).

Laboratory tests may show mild lactic acidosis and muscle biopsy is usually normal.

LHON is associated with three main mutations in complex I (NADH dehydrogenase, or ND) genes: G11778A in ND4 (Wallace et al., 1988), G3460A in ND1 (Huoponen et al., 1991), and T14484C in ND6 (Johns et al., 1992).

Neurogenic weakness, ataxia and retinitis pigmentosa (NARP)

The key features of NARP are peripheral neuropathy, ataxia and retinitis pigmentosa, often accompanied by seizures and dementia. Maternal inheritance is usually ascertainable.

Muscle biopsy may reveal neurogenic features but RRF and the other classic morphological changes of mitochondrial myopathy are not present. Diagnosis rests upon recognition of the clinical syndrome and lactic acidosis, when present. The most frequent mtDNA mutation causing NARP is the T8893G mutation in the ATPase 6 gene of complex V (Holt et al., 1990). The mutation is present in blood and the mutation load is usually >70%. When >90%, this mutation is most frequently associated with Leigh syndrome (Tatuch et al., 1992).

Prognosis is variable and there is perhaps a closer correlation with mutation load in the blood than in other mitochondrial disorders (White et al., 1999b). This also relates to the risk of transmission where rates are high with high mutation loads in the blood. Prenatal diagnosis has been performed in mothers with NARP, and fetuses aborted when a high mutation load has been identified in chorionic tissue (Harding et al., 1992; White et al., 1999a).

A milder phenotype often associated with the neuroradiological features of bilateral striatal necrosis (BSN) is associated with a T-to-C instead of a T-to-G mutation at the same nucleotide, 8993, of the ATPase 6 gene (De Meirleir et al., 1995; Santorelli et al., 1992).

Other encephalomyopathies

As mentioned above, three mutations in protein-coding genes were associated with the MELAS phenotype, one in the COX III gene (Manfredi et al., 1995), another in the ND5 gene (Pulkes et al., 1999; Santorelli et al., 1997), and the third in the cyt *b* gene (De Coo et al., 1999).

Besides the COX III gene mutation in the patient with MELAS, other mutations in COX genes have been associated with encephalomyopathies. A 5-bp microdeletion in the COX I gene was found in a 32-year-old man with early-onset motor neuron disease and a negative family history (Comi et al., 1998). A 36-year-old woman with exercise intolerance, proximal myopathy, lactic acidosis, and episodes of confusion after exercise had a stop-codon mutation in the COX III gene (Hanna et al., 1998b). A mother and son suffered from a multisystem disorder dominated by ataxia, dementia, optic atrophy, and pigmentary retinal degeneration: they harboured a heteroplasmic missense mutation in the COX II gene (Clark et al., 1999). A 22-year-old woman had a stormy lifelong clinical course characterized by sensorineural hearing loss, cataracts, myoclonic epilepsy, weakness, ataxia, and visual loss. Alone in her family, she harboured a heteroplasmic nonsense mutation in the COX I gene (Bruno et al., 1999).

Symmetrical lesions in the putamina, reminiscent of Leigh syndrome, were seen in an 11-year-old girl with spastic paraparesis, ophthalmoparesis, and mental retardation. She had a frame-shift mutation in the COX III gene and a negative family history (Tiranti et al., 2000).

Myopathy

Exercise intolerance (without myoglobinuria) was the predominant clinical feature in two sporadic patients with *complex I deficiency* and COX-positive RRF in their muscle biopsies. One had a nonsense mutation (G11832A) in the ND4 gene (Andreu et al., 1999b), the other (Bet et al., 1990) had an intragenic inversion of seven nucleotides within the ND1 gene, resulting in the alteration of three amino acids (Musumeci et al., 2000).

Nine patients with isolated *complex III deficiency* in muscle complained of exercise intolerance, but only two had myoglobinuria (Andreu et al., 1999a; DiMauro, 1999). All patients in whom muscle histochemistry was performed showed COX-positive RRF. The nine mutations in

the cytochrome *b* gene were different from one another although, except for a single deletion, they were all G-to-A transitions. Most patients had no detectable mutant mtDNA in blood or fibroblasts, but one patient had low levels (0.7%) mutation in non-muscle tissues, suggesting skewed heteroplasmy (Keightley et al., 2000). Two other patients had pathogenic mutations in the cytochrome *b* gene. One was a 20-year-old man with signs of Parkinsonism and MELAS and an apparently *de novo* microdeletion (De Coo et al., 1999). The other was an infant girl who died of histiocytoid cardiomyopathy and in whose muscle complex III deficiency and decreased concentration of reducible cytochrome *b* had been documented (Papadimitriou et al., 1984). Molecular analysis has now revealed a missense mutation (G15498A) in the cytochrome *b* gene (Andreu et al., 2000).

The first mtDNA molecular defect identified in a patient with *complex IV (cytochrome c oxidase, COX) deficiency* was a 15-bp microdeletion in the COX III gene. The patient was a 16-year-old woman with recurrent myoglobinuria triggered by prolonged exercise or viral illness (Keightley et al., 1996). Between attacks, both physical and neurological exams were normal, as were routine laboratory tests, including serum creatine kinase (CK) and lactate. No tissue other than muscle was affected, and family history was entirely negative. Muscle biopsy showed many SDH-positive, COX-negative RRF and marked isolated COX deficiency. A nonsense mutation (G5920A) in the COX I gene of muscle mtDNA was identified in a 34-year-old man with lifelong exercise intolerance and recurrent myoglobinuria induced by intense or repetitive exercise (Karadimas et al., 2000). His muscle biopsy showed scattered COX-negative RRF and numerous COX-negative non-RRF, and isolated COX deficiency. The mutation was not present in blood or fibroblasts from the patient nor in blood from his asymptomatic mother and sister. Proximal weakness without myoglobinuria characterized the clinical picture of a 14-year-old boy with a missense mutation in the COX II gene: no one else in his family was similarly affected (Rahman et al., 1999).

Defects of nDNA

Leigh and Leigh-like syndromes

Considering that most proteins of the respiratory chain are encoded by nDNA and that proper assembly and functioning of respiratory chain complexes requires multiple ancillary nDNA-encoded factors, this relatively new area of investigation promises to yield exciting results. This prediction is borne out by the number of recent papers on the subject (Table 120.3). Most of the patients described thus far have had early-onset, multisystemic disorders that almost invariably involved the brain and often had the neuroradiological and neuropathological stigmata of LS (see above). This is not too surprising when we consider that two of the commonest causes of LS are complex I deficiency and complex IV (COX) deficiency, both inherited as autosomal recessive traits (DiMauro & De Vivo, 1996). The early onset of these disorders also comes as no surprise, as nuclear defects tend to be 'all-or-none', with very little residual activities of affected enzymes but sufficiently high residual activities in heterozygotes as to prevent disease expression in carrier patients or siblings. This contrasts with the 'rheostat effect' of heteroplasmy in mitochondrial genetics. For example, in NARP/MILS, almost homoplasmic levels of the T8993G mutation in the ATPase 6 gene of mtDNA cause LS, whereas slightly lower mutation loads (around 70%) cause the later-onset and milder NARP syndrome (see above).

Mutations in genes encoding respiratory chain subunits

Mutations have been identified in genes encoding subunits of complex I and complex II, but not (at least, not yet) in genes encoding subunits of complex III or complex IV.

The strategy used by the University of Nijmegen group to facilitate the identification of pathogenic mutations in the 'mare magnum' of the 34 nDNA-encoded subunits of complex I was to focus on those that have homologues in the much simpler complex I of yeast. In short order, they identified seven different mutations. Three of these affected NDUFV subunits in children with leukodystrophy and myoclonic epilepsy (Schuelke et al., 1999). The other four were found in families with autosomal recessive LS and involved NDUFS subunits (Loeffen et al., 1998; Triepels et al., 1999; van den Heuvel et al., 1998). A fifth mutation in the NUDFS4 gene was reported in a child with Leigh-like syndrome and cardiomyopathy (Petruzzella et al., 2001).

Complex II is composed of two subunits, both encoded by the nuclear genome. The first mutation in a nDNA-encoded respiratory chain protein was reported in 1995 in two sisters with LS: it affected the flavoprotein subunit of complex II (Bourgeron et al., 1995). Two more mutations, also affecting the flavoprotein subunit, were identified in a compound heterozygous patient with LS (Parfait et al., 2000).

Mutations in genes encoding ancillary proteins

Thorough searches for mutations in nuclear genes encoding COX subunits were fruitless (Adams et al., 1997; DiMauro et al., 1994). However, defects of COX have been associated with mutations in COX-assembly genes, in a sort of 'murder-by-proxy' mechanism. In yeast, there are at least 30 different complementation groups for COX assembly (Tzagoloff et al., 1975). Several of these genes have mammalian homologues (Petruzzella et al., 1998), and mutations in four of them have been identified in patients with COX deficiencies.

Numerous mutations were initially found in the *SURF1* gene (Tiranti et al., 1998; Zhu et al., 1998), which encodes a protein apparently involved in the early stages of COX assembly (Zeviani et al., 2000). Mutations in *SURF1* appear to be the most common cause of COX-deficient LS, although the frequency varies widely in different series (Sue et al., 2000) and remains to be established.

The second COX-assembly gene associated with COX deficiency and encephalomyopathy was *SCO2* (Papadopoulou et al., 1999). The SCO2 protein is required for the insertion of copper into the mtDNA-encoded subunits COX I and COX II, and mutations in *SCO2* are associated not with typical LS, but, rather, with hypertrophic cardiomyopathy and encephalopathy manifesting soon after birth (Jaksch et al., 2000; Papadopoulou et al., 1999; Sue et al., 2000). Comparative biochemical and histochemical studies showed that COX deficiency in muscle is more severe with *SCO2* than with *SURF1* mutations, whereas the opposite is true for COX deficiency in fibroblasts (Sue et al., 2000).

Mutations in the *COX10* gene have been associated with neurological features (hypotonia, myopathy, ataxia, seizures) and renal proximal tubulopathy (Valnot et al., 2000b). *COX10* encodes a heme A: farnesyltransferase that catalyses the conversion of protoheme to heme O. Heme O, in turn, is the precursor of heme A, which is the prosthetic group of the COX I subunit.

The latest COX-assembly culprit gene is *SCO1*: two mutations have been identified in a large family with fatal infantile hepatic failure and encephalopathy (Valnot et al., 2000a). This is an interesting counterpart to the clinical picture associated with *SCO2* mutations, where brain was also involved, but heart rather than liver was the 'target' organ. Both *SCO1* and *SCO2* genes are involved in copper insertion into the holoenzyme: the apparent 'tissue specificity' of mutations in each gene remains to be confirmed in more patients but raises interesting questions about differential tissue expression of distinct COX-assembly genes.

Although mutations have already been discovered in four COX-assembly genes, many patients with COX deficiency, manifesting as LS or as other multisystemic syndromes remain unexplained at the molecular level (Horvath et al., 2000; Sue et al., 2000). Based on recent developments, it seems safe to predict that many more mutations will be identified in the near future both in already known and in as yet unrecognized COX-assembly genes.

As mentioned above, no mutations have yet been described in nuclear genes encoding subunits of complex III, complex IV, or complex V. It has been suggested that mendelian, 'all-or-none', mutations might not be compatible with life because these complexes are arranged 'in series', with no alternative pathway. In contrast, mutations in subunits of complex I or complex II may be better tolerated because these complexes are arranged 'in parallel', both feeding electrons to CoQ10 (Sue & Schon, 2000).

Defects of intergenomic signalling

The dependence of the mitochondrial genome renders it vulnerable to defects in nuclear encoded proteins responsible for its replication and maintenance. Both autosomal dominant and autosomal recessive disorders associated with multiple mtDNA deletions have been described. In

addition, a quantitative defect of mtDNA (mtDNA depletion) has also been reported.

Mitochondrial DNA depletion: myopathy, hepatopathy and multisystem disorders

Onset of myopathy can be at or soon after birth, sometimes associated with renal dysfunction ('congenital myopathy'), or develop at about one year of age ('infantile myopathy') (Hirano & Vu, 2000; Moraes et al., 1991). There is lactic acidosis and serum creatine kinase is often elevated, an unusual feature of most other mitochondrial myopathies. Muscle biopsy may show RRF but most frequently is characterized by COX-negative fibres. It is important to remember that initial biopsies in children with infantile myopathy may show non-specific changes and mitochondrial abnormalities may become apparent only in later biopsies. Immunohistochemistry using anti-DNA antibodies has demonstrated reduced levels of mtDNA. Biochemical analysis usually demonstrates multiple respiratory chain defects. Cultured myoblasts from patients with mtDNA depletion may demonstrate this defect and this is most readily documented by immmunocytochemistry. Decreased mtDNA levels are identified by Southern blotting and comparison with an age-matched control tissue. Prognosis is poor, although patients with only moderate mtDNA depletion (>30% residual mtDNA) may survive and develop normally with resolution of the mtDNA depletion.

Hepatopathy can coexist with myopathy in the same family (Boustany et al., 1983; Moraes et al., 1991). It usually presents during the first year of life and progresses rapidly to intractable liver failure. Liver biopsies show mitochondrial proliferation and multiple respiratory chain defects.

The nuclear origin of mtDNA depletion has been documented in one patient whose enucleated fibroblasts were fused with a human cell line lacking mtDNA (rho^0). The resulting cybrids regained normal mtDNA concentration and respiratory chain function, showing that the nucleus of the rho^0 cell line had replaced the defective factor (or factors) in the mtDNA depleted cells (Bodnar et al., 1993). The molecular genetic defect in mtDNA depletion syndrome has not as yet been identified. It is likely however that, similar to Leigh's syndrome, the etiology of mtDNA depletion syndrome will prove to be heterogeneous at the molecular level.

Autosomal dominant CPEO syndrome

This was first described in an Italian pedigree which exhibited early adult onset of CPEO, ptosis, facial and limb weakness, bulbar symptoms, cataracts and early death (Zeviani et al., 1989). Additional families were described with features that included cardiomyopathy, neuropathy and ataxia. Lactic acidosis was common. Muscle biopsy demonstrated ragged-red and COX-negative fibres (Servidei et al., 1991). Three separate loci were identified on chromosomes 3, 4 and 10 (Kaukonen et al., 1996, 1999; Li et al., 1999; Suomalainen et al., 1995). However, the locus on chromosome 3 was recently excluded upon re-examination of the one small family on which it was based (Kaukonen et al., 2000). The chromosome 10-linked disease is due to a mutation in the adenine nucleotide translocator 1, which exchanges ADP and ATP across the inner mitochondrial membrane (Kaukonen et al., 2000). ANT-1 knockout mice developed a severe cardiac and skeletal myopathy (Graham et al., 1997). All gene loci have been associated with multiple mtDNA deletions.

Autosomal recessive cardiomyopathy/ophthalmoplegia (ARCO)

The association of CPEO and severe cardiomyopathy (requiring cardiac transplantation) has been reported in two families from the eastern area of the Arabian peninsula (Bohlega et al., 1996). One family was consanguineous. Muscle biopsies showed ragged-red COX-negative fibres, multiple respiratory chain enzyme defects, and multiple mtDNA deletions by Southern blot. The molecular etiology of ARCO remains unknown.

Mitochondrial neurogastrointestinal encephalomyopathy (MNGIE)

This is an autosomal recessive disorder characterized by peripheral neuropathy, CPEO and gastrointestinal dysmotility (Bardosi et al., 1987; Hirano et al., 1994). Gastrointestinal symptoms may include recurrent nausea, vomiting and diarrhea and may result in cachexia. Onset is usually in late adolescence or early adulthood. Patients may have lactic acidosis. Muscle biopsy demonstrates ragged-red, COX-negative fibres against a background of neurogenic changes. Biochemical analysis demonstrates multiple respiratory chain defects, and mtDNA analysis demonstrates both multiple deletions and depletion. MNGIE is due to mutations in the thymidine phosphorylase gene and is associated with a severe reduction in the activity of this enzyme (Nishino et al., 1999, 2000). Consequently plasma thymidine levels are high. It has been suggested that an imbalance in the mitochondrial deoxynucleotide pools may result in impaired replication of mtDNA.

Investigations

As gleaned from the description of individual disorders, the laboratory investigation of patients suspected of

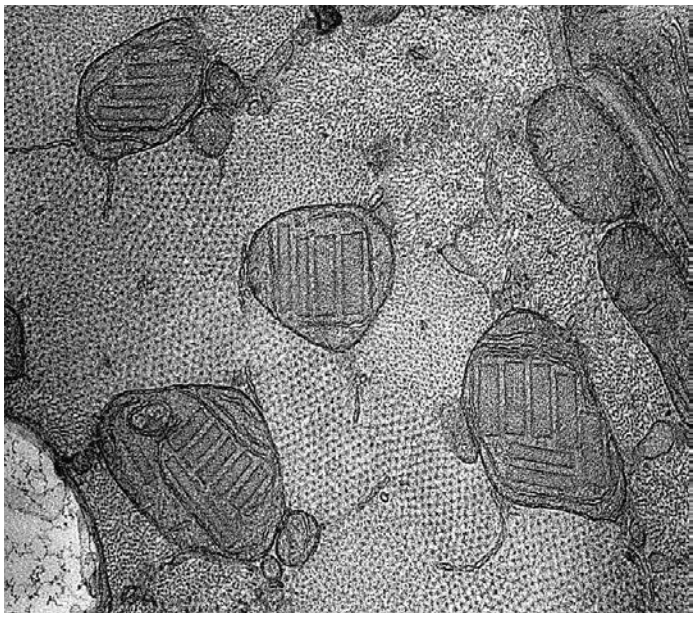

Fig. 120.4. Electron microscopy of a muscle biopsy from a patient with mitochondrial myopathy showing intramitochondrial paracrystalline inclusions.

having mitochondrial disorders includes hematological, biochemical, neurophysiological, radiological, morphological and molecular genetic analysis.

Hematological abnormalities are usually confined to the presence of sideroblastic anemia in Pearson syndrome. Routine biochemical investigations may demonstrate an elevated glucose in patients with diabetes mellitus. Appropriate endocrinological investigations are indicated in these cases and when thyroid or parathyroid abnormalities are suspected. Serum creatine kinase may be normal or modestly elevated, except in children with mtDNA depletion myopathy.

A resting lactic acidosis should raise suspicions of an underlying mitochondrial defect. If a patient is suspected of having a mitochondrial disorder but has a normal resting lactic acid level, he/she should undergo exercise testing, which may elevate the lactate level and also increase the lactate/pyruvate ratio. Increased lactate (and lactate/pyruvate ratios) in the CSF may be present in patients with CNS involvement, even when blood lactate is normal.

Nerve conduction studies may demonstrate a sensorimotor axonal peripheral neuropathy. Electromyography may be normal or show myopathic changes. Visual-evoked potentials may be abnormal in patients with optic atrophy and electroretinograms are abnormal in the majority of patients with pigmentary retinopathy. Electroencephalography may show a variety of abnormalities including epileptiform discharges and generalized slow waves indicative of an underlying encephalopathy.

Muscle biopsy is probably the most sensitive guide to the diagnosis of mitochondrial myopathy. The morphological hallmark of these disorders is the RRF. This is observed with the modified Gomori trichrome stain in which abnormal fibres exhibit central and peripheral accumulation of red staining material denoting increased aggregation of mitochondria. These same fibres stain strongly positive for SDH. This histochemical stain is more sensitive in detecting RRFs (Fig. 120.3(*a*), (*b*), see colour plate section). The SDH-positive fibres are often negative for COX staining in patients with mitochondrial DNA mutations affecting protein synthesis (Fig. 120.3(*c*), see colour plate section), except for the MELAS mutation (see above). Strongly SDH-positive fibres are also COX-positive in patients with protein-coding mtDNA mutations, except, of course, for mutations in COX genes. There may be a coexisting lipid storage myopathy due to carnitine deficiency, which may be secondary to the MITOX abnormality. Neurogenic changes may be seen in patients with a motor neuropathy. Electron microscopy may demonstrate intramitochondrial inclusions (Fig. 120.4).

The morphological changes, although sensitive in the diagnosis of mitochondrial myopathy, are not specific. Some patients may have a normal muscle biopsy but subsequently be shown to have abnormal biochemistry and mutations in mtDNA or nDNA. In particular, most patients with LS have normal muscle biopsies, including those with pyruvate dehydrogenase (PDH) deficiency, complex I deficiency, complex IV deficiency (except by COX histochemistry), and those with maternally inherited LS (MILS). On the other hand, scattered SDH-positive COX-negative fibres may be seen in patients over the age of 40 and can represent up to 5% of fibres in old age (Johnston et al., 1995). These mitochondrial changes are also observed in polymyositis and inclusion body myositis (IBM) (Santorelli et al., 1996).

The function of the mitochondrial respiratory chain and oxidative phosphorylation system may be analysed either in mitochondria freshly isolated from skeletal muscle or alternatively on muscle homogenates. The use of isolated mitochondria allows the application of polarography to assess oxygen consumption in response to specific substrates. This may allow a respiratory chain defect to be defined down to the individual complex. Individual respiratory chain enzyme assays on mitochondria or muscle homogenates may likewise enable individual respiratory chain complex deficiencies to be identified. More frequently, however, combined respiratory chain defects are

seen, particularly involving complexes I and IV. These combined deficiencies are often seen in mutations affecting mitochondrial protein synthesis as a whole, i.e. single or multiple deletions of mtDNA, mutations in tRNA or rRNA mtDNA genes and mtDNA depletion.

Part XVII

Neurological manifestations of systemic conditions

121

Neurological aspects of pregnancy

Peter W. Kaplan

Department of Neurology, Johns Hopkins Bayview Medical Center, Baltimore, MD, USA

Introduction

Pregnancy often modifies the clinical expression of neurological disease. It also introduces concerns regarding the safety of treatment of the mother on the developing fetus. Management of problems of the central and peripheral nervous system (whether major or minor), therefore present the treating clinician with particular challenges.

This chapter will review some of the more important neurological diseases modified by, or affecting, pregnancy and some entities exclusively seen in pregnancy. A comprehensive review is beyond the scope of this chapter. The interested reader can consult a text on this subject (see references).

Sex differences in regional brain structure and function

Several mammalian and avian species have significant gender differences in brain morphology and connectivity, although the study of humans shows more subtle gender differences. Principal among them, are the findings on neuroimaging of the relatively larger callosal isthmus in females, and the decreased lateralization of brain activation in females measured by fMRI during phonological processing of particular tasks (Shaywitz et al., 1995; Witelson, 1991). Studies have only begun to appreciate the effects of sex and age on the differences of brain structure, and future studies with functional imaging may reveal other differences.

The effect of ovarian hormones on the nervous system

During menstruation and pregnancy, the nervous system is exposed to different absolute and relative levels of estrogen and progesterone. In the brain, estrogen may have both trophic and transmitter roles with receptors being present in the CA 1 and CA 3 regions of the hippocampus, locus ceruleus, raphe nuclei, central grey matter and cingulate gyrus, but even more so in the preoptic region. Estrogen can induce new NMDA-mediated synapse formation and dendritic spine formation particularly in the limbic system, magnified by the presence of progesterone (McEwen et al., 1997). Estrogen also induces choline acetyl transferase in the basal forebrain cholinergic regions and their secondary projections (Luine, 1985). Progesterone often appears to have an opposite effect on neuronal systems.

These hormones may influence the clinical expression of neurological problems such as migraine, epilepsy, brain tumours, autoimmune diseases and neuromuscular diseases. Accurately predicting how a particular disease will be clinically modified by hormones, or basing therapy on these presumed changes, remains in its infancy.

Migraine

Women have migraine more frequently than men by a factor of up to 3: 1 (Stewart et. al., 1992) with a peak incidence in those of childbearing age. Curiously, a high proportion of women become migraine-free during pregnancy, beginning in the third to fourth month of pregnancy (Vinken & Bruyn, 1968). Patients with catamenial migraine exacerbations are most likely to improve (Ratinahirana et al., 1990), particularly during the third and fourth trimester of pregnancy. About 50% show significant improvement (Maggioni et al., 1995), and about a sixth may report complete remission (Granella et al., 1993), possibly associated with the elevation of estrogen levels. Conversely, in some series, about a quarter of women fail to improve,

and several per cent may worsen (Somerville, 1972). There is no increased risk of complications from migraine during pregnancy, such as eclampsia, miscarriage or abortion, and children have no increased incidence of birth defects.

After birth, headaches may return within the first week, possibly due to withdrawal of estrogen and progesterone (Stein, 1981). Breast-feeding occasionally alleviates migraine. This is thought to be due to an effect of oxytocin on cerebral vasculature (Dooling & Sweeney, 1974).

Differential diagnosis

Since migraine typically improves after the first trimester, worsening, or severe headache persisting into the third trimester may signal a less benign process. Other causes of headache include tumours, intracranial hemorrhage, cerebral venous occlusion, and eclampsia. Pituitary tumours, meningiomas, choriocarcinoma tend to grow rapidly during pregnancy. Occlusive arterial disease peaks in the puerperium, presenting with migraine-like vision changes and worsening headache.

Investigation

With a history of typical migraine, laboratory and radiological investigation are rarely needed during pregnancy. Only with new onset, severe headache, particularly with neurological findings on clinical examination, or a sudden change in the chararacter of headache, should radiological testing be considered. Danger to fetal development is less after the first two trimesters of pregnancy. With head CT scanning, radiation exposure to the fetus is about 2 mrad. Scanning can be used to look for mass lesions or intracranial blood in the appropriate clinical context. Although the safety of head MRI during pregnancy has not been established, there are few data to suggest that it poses a significant fetal risk. With open MRI, previous restrictions on body size have been minimized.

Treatment

Identifying and removing trigger factors, psychophysiological techniques, and relaxation provide an alternative to pharmacotherapy. Drugs should be used when only absolutely necessary as many medications have teratogenic risk. Drugs should be particularly avoided in the first trimester and used only when absolutely necessary at their minimal effective doses. In the acute attack, acetaminophen, meperidine, dimenhydrinate and prednisone are regarded as safe, as may possibly be codeine and prochlorperazine (Koren et al., 1998). For prophylaxis, some regard propranolol as relatively safe, but the safety of amitriptyline and fluoxetine are less established. Most prophylaxis agents are in category 'C'. Low doses of beta-adrenergic blockers, valproic acid (Depakote®), serotonin reuptake inhibitors, tricyclic antidepressants, calcium channel blockers and gabapentin (Neurontin®) have been used safely particularly in late months of pregnancy, but there are reports of fetal and neonatal toxicity. Some beta-adrenergic blockers such as nadolol (Corgard®) and atenolol (Tenoretic®) have been reported to retard growth. With regard to tricyclic antidepressants, amitriptyline (Elavil®), nortriptyline (Aventyl®) and imipramine (Tofranil®) are in category 'D', because of reports of fetal malformations. Valproic acid (Depakote®; Depakene®) poses a risk for neural tube defects of 1% to 2%. The teratogenic risk for gabapentin (Neurontin®) is not known. Calcium channel blockers such as verapamil have not been reported to be teratogenic in animals; nonetheless most are in category 'B' and 'C'. The SSRI fluoxetine (Prozac®) poses a minor risk for anomalies and premature labour. However, five studies involving more than 450 pregnancies have shown no risk for birth defects (Robert, 1996). Nonsteroidal anti-inflammatory drugs (NSAIDs) are believed to be safe during the first two trimesters of pregnancy, but concerns that they may decrease the volume of amniotic fluid, or increase bleeding, limits their use during the third trimester. There are concerns about the use of indomethacin: after 32 weeks gestation, indomethacin may increase closure of the ductus arteriosus in the developing fetus, as well as reducing urine production. Although Fiorinal® which contains butalbital has an FDA safety category 'C' for pregnancy, the barbiturate butalbital may lead to neonatal barbiturate withdrawal problems, usually if the medication has been used for an extended period of time. For more severe headaches, narcotics are safe if used for brief periods. Codeine taking during the first two trimesters has been associated with hip dislocation, cleft palate, cardiopulmonary defects and inguinal hernias (Briggs et al., 1994) and is also FDA category 'C'. Propoxyphene may also be teratogenic. Most other narcotics are FDA category 'B'. Ergot alkaloids are contraindicated in pregnancy because of their effect on vasculature and consequent risk for abortion. To help abort migraine, antiemetic drugs have also been given in combination with NSAIDs. Medications in category C such as prochlorperazine (Compazine®), metoclopramide (Reglan®), or chlorpromazine (Thorazine®), are generally regarded as being safe if used occasionally and in low doses. Table 121.1 shows the FDA and TERIS risk categories for drugs taken during pregnancy. Table 121.2 shows medications for headache used in pregnancy.

Table 121.1. FDA and TERIS risk categories

FDA risk categories	TERIS risk rating	
Category A Controlled human studies show no risk	N	None
Category B No evidence of risk in humans, no controlled human studies	N-Min	None–minimal
Category C Risk to humans has not been ruled out	Min-S	Minimal–small
Category D Positive evidence of risks to humans from human and/or animal studies	S	Small
	S-Mod	Small–moderate
Category X Contraindicated in pregnancy	Mod	Moderate
	H	High
	U	Undetermined

FDA, Food and Drug administration, USA; TERIS, a consensus assessment of known or suspected teratogens. (See Friedman & Polifka, 1994.)

Cerebrovascular diseases

The largest recent study of stroke during pregnancy is the Baltimore–Washington Cooperative Stroke Study, examining all strokes in women of child-bearing age in the region (Kittner et al., 1996). Comparing stroke and pregnancy with the first 6 weeks postpartum, the authors found a 2.5-fold increase in stroke during pregnancy and the postpartum period. Although ischemic stroke did not increase during pregnancy, it was nine times as likely in the first 6 weeks postpartum. This contrasts with a 2.5-fold increase in intracerebral hemorrhage (ICH) during pregnancy, but a 28-fold increase in the first 6 weeks postpartum. Thus, the overall stroke risk during this period is 8.1 per 100 000 pregnancies. These data are similar to those from the French study (Sharshar et al., 1995) which contained a greater number of women with eclampsia, and inclusion of African–Americans in the US study vs. predominantly Caucasians in the French study.

Looked at another way, a third of all strokes in women of child-bearing age are related to pregnancy, and 25% occur in the first week postpartum (Bickerstaff, 1975). Some studies show an incidence of one ischemic stroke per 3000 pregnancies (ten times the risk of young non-pregnant women) (Wiebers & Whisnant, 1985), but most occur in women younger than 30 years. The oral contraceptive pill increases the chance of ischemic stroke (Vessey & Doll, 1968). Patients, however, are mostly over 30 years of age, usually smoke cigarettes, and may have hypertension, diabetes and lipid abnormalities.

Most strokes involve the carotid artery but only three-quarters of angiograms show arterial occlusion. In pregnancy, there is a predilection for the middle cerebral artery territory (Cross et al., 1968). Conversely, the oral contraceptive pill is associated with occlusions of the vertebrobasilar artery in up to 40% of strokes (Bickerstaff, 1975).

Although a quarter of women with strokes have the clearly identifiable usual risk factors such as diabetes, hypertension or hyperlipidemia, half may have rare underlying conditions, and in 25%, no cause can be found. Causes of ischemic stroke in pregnancy are given in Table 121.3.

Investigation

Investigation may be done with head CT and head MRI, supplemented by cerebral angiography with abdominal shielding limiting the fetal exposure. The American College of Obstetricians and Gynecologists (ACOG) warns that women should be informed that fetal exposure to less than 5 rads of ionizing radiation has not been demonstrated to increase fetal abnormality (1995). Other tests such as transesophageal echocardiography can be safely performed during pregnancy, and may reveal valvular abnormalities, intramural clots and or patent foramen ovale. Magnetic resonance angiography now approaches the sensitivity and specificity of the more invasive standard angiography, and for some vascular problems, should be considered.

Hematological studies should include prothrombin and activated partial thromboplastin time (PT/INR; PTT); complete blood count with platelet count; fibrinogen, protein C and S, activated antithrombin III, factor V Leiden, prothrombin-gene mutation, and antiphospholipid antibody profile.

Table 121.3. Causes of stroke in pregnancy

Pre-eclampsia and eclampsia
Coagulopathies
Atherosclerosis
Antiphospholipid antibody
Hemocystinuria
Antithrombin III deficiency
Sickle cell anemia
Protein C and S deficiencies
Factor V Leiden deficiency
Thrombotic thrombocytopenic purpura (TTP)
Cardio-embolic disease
Rheumatic heart disease
Endocarditis
Paradoxical embolism via ASD or PFO
Postpartum cardiomyopathy
Carotid artery dissection

Treatment

When anticoagulation is indicated, heparin can be given as it does not cross the placenta, however it does have teratogenic properties if given in the first trimester. Coumadin is problematic as it does cross the placenta.

Indications for anticoagulation include deep vein thromboses, atrial fibrillation, peripartum cardiomegaly and hypercoagulable states.

Subarachnoid hemorrhage (SAH)

Subarachnoid hemorrhage may arise from arteriovenous malformations (AVMs), or aneurysms, and may account for 30% to 80% of maternal deaths from cerebral hemorrhage, the third most common cause of non-obstetric maternal death (Dias & Sekhar, 1990; Miller & Hinckley, 1970). Ruptures may occur at any time during pregnancy, but favour the last trimester and the first six weeks postpartum. The severe sudden-onset headache with meningismus and focal neurologic signs (such as intrinsic and extrinsic ocular palsies) suggest the diagnosis. Up to 50% of patients may have a sentinel bleed 7 to 10 days before the more catastrophic hemorrhage (Verweij et al., 1988). Predisposing causes for SAH include AVMs, aneurysms, moya-moya disease, Marfan syndrome, polycystic kidneys and fibromuscular dysplasia.

Diagnosis

Diagnosis is made with an unenhanced head CT scan, and IV contrast can outline an aneurysmal or vascular malformation source, but head MRI/MRA provides better resolution. If both imaging modalities fail to reveal evidence of blood, a spinal tap can be diagnostic.

Treatment

Current treatment favours early operation and ligation of the aneurysm, but treatment must be individualized and obstetric issues must be balanced against neurologic needs. Neurosurgical treatment can be combined with cesarian section if the fetus is viable. The optimal mode of delivery of the infant is still under contention, but vaginal delivery and cesarian section have been successfully performed.

Other causes of, or associations with, stroke

These include alcohol intoxication, intravenous and oral substance abuse (particularly with central stimulants such as amphetamine and cocaine), or following a vasculitic reaction or infection from intravenous drug use. Intracerebral and subarachnoid hemorrhage may result from the sudden hypertension after crack cocaine or following emboli from bacterial endocarditis.

Migraine only occasionally causes cerebral infarction and during pregnancy. Patients should be evaluated for antiphospholipid antibody syndrome.

Cardioembolic causes of stroke

Patent foramen ovale

Patent foramen ovale is associated with an increase in strokes in young women. When the right atrial pressure exceeds that in the left atrium, a right-to-left shunt allows an embolus to enter the cerebral circulation. Such reversals of pressure gradients occur with Valsalva manoeuvres. Forceps rotation and cesarian section favour thrombosis in the pelvic and leg veins during pregnancy and the puerperium, which may then paradoxically embolize to the brain. Diagnosis is made with transesophageal echocardiography and the microbubble test.

Atrial septal defects

Atrial septal defects (ASDs) are usually asymptomatic. Strokes may occur with right-to-left shunting via the defect or with cardiac dysrhythmias.

Atrial fibrillation

Atrial fibrillation and heart failure may occur after rheumatic heart disease with significant mortalities for the mother and fetus. Emboli occur in 10% to 23% of pregnant women with atrial fibrillation, and up to a 10% risk of cerebral embolus (Mendelson, 1956; Szekely & Snaith, 1961). When atrial fibrillation occurs during pregnancy, cardiac failure is frequent. Because of the embolic risk with atrial fibrillation, patients should be anticoagulated.

Mitral valve prolapse

Mitral valve prolapse affects 6% of women, but with a low risk for stroke. In patients with strokes or transient ischemic attacks, there is a three times increased risk of having mitral valve prolapse.

Arterial dissection

Vertebral and carotid artery dissections are rare, possibly triggered by vigorous neck movements during labour and delivery. Fibromuscular dysplasia is a rare underlying cause. Diagnosis is made by angiography, and anticoagulation is indicated.

Cerebral venous thrombosis (CVT)

CVT occurs in 1–2 per 10 000 childbirths, mostly in the puerperal period. Eighty percent occur in the second to

third weeks postpartum (Lanska & Kryscio, 1998). Dehydration would appear to be an important risk factor, but other causes are estrogen, vitamin K and coagulopathies. Frequently, primary thrombosis occurs in the superior sagittal sinus and lateral sinuses with secondary extension to the cortical veins.

CVT may be accompanied by seizures, focal weakness and lateralizing neurological signs (Ameri & Bousser, 1992). A persistent and often increasing headache lasting more than several days to a week engenders suspicion for this non-benign cause of headache. Common clinical features of CVT are focal weakness, seizures, decreased consciousness and papilledema. The differential diagnosis includes migraine, pseudotumour cerebri, arterial venous malformations, intracerebral hemorrhages, meningitis and late postpartum eclampsia.

Investigation

Unenhanced head CT may show single or multiple hemorrhages, and intravenous contrast may reveal the lack of enhancement of the blood within the cerebral sinuses: 'The empty delta sign'. Magnetic resonance imaging may show hyperdensities on T_1-weighted images, and older lesions on T_2-weighted images. Hematological studies indicated include those listed under investigation of stroke.

Treatment

Treatment remains controversial and balances the benefits of anticoagulation of a potentially extending thrombus, against the risk of bleeding from hemorrhagic infarction. The absence of hemorrhagic changes on unhanced head CT may favour the use of heparin, partially in the presence of other concurrent thrombotic diatheses, such as intercurrent pelvic or leg thrombophlebitis. Anticoagulation is usually given for up to 3 months using heparin (Einhaüpl et al., 1991) or low-molecular weight heparinoids. Intraclot thrombolysis with rtPA or prourokinase, or therapy combined with anticoagulation, have been tried (Frey et al., 1999). Treatment of blood pressure, hydration, raised intracranial pressure, and antiseizure drugs may be needed.

Outcome

Outcome after CVT has improved. Mortality can be as low as 5% to 10% with outcomes being better in the obstetric population (Cantù & Barinagarrementaria, 1993). Follow-up for periods of up to 63 months has revealed the absence of permanent sequelae in most patients (86% of 77 patients) (Preter et al., 1996). Seizures were recurrent in only 14% and no patient had recurrent CVTs.

Hemoglobinopathies

Twenty per cent of women with sickle cell disease may have a first trimester miscarriage and one-half will have a sickle cell crisis during pregnancy (Adams, 1957). Sickle cell trait does not significantly increase maternal morbidity. Stroke is thought to be produced by the sludging of the sickle cells in the small vessels resulting in thrombosis, or by affecting vessels supplying the brainstem. This process may also result in encephalopathy and seizures. If hemoglobin S constitutes less than 20% of the hemoglobin, cerebral angiography is generally safe (Keeling et al., 1980; Powars et al., 1986). Red cell exchange and exchange transfusions may be helpful although reactions may occur (Perry, 1990).

Thrombotic thrombocytopic purpura (TTP)

This multisystem disorder frequently presents with transient ischemic attacks and strokes (Wiebers, 1985; Upshaw et al., 1985). It mimics pre-eclampsia, but in contrast, there is a normal level of antithrombin III. Stroke risk increases with the duration of pregnancy and in the puerperium. If anticoagulation is not possible, low-dose aspirin may be used in the third trimester.

Amniotic fluid emboli

Amniotic fluid emboli usually occur after childbirth or abortions, and result in sudden shortness of breath, cyanosis or shock (Chatelain & Quirk, 1985). In women over age 30 years, a prolonged and traumatic labour is a predisposing factor with amniotic fluid entering via tears in the cervix, vagina or uterus. Seizures occur in 10% of patients and mortality is over 80% (Chatelain & Quirk, 1990; Mulder, 1985).

Fat emboli

Fractures of the long bones can result in embolization of fat, causing shortness of breath, encephalopathy and petechial eruptions. A fat embolism in itself is usually a self-limited disorder.

Air emboli

These may occur with the rupture of the membranes during labour, allowing air to enter the circulation, and resulting in shortness of breath, cyanosis, tachycardia, anxiety, and shock (Nelson, 1960). Hypoxia, convulsions, and death are frequent. Treatment relies on the rapid diagnosis and turning the patient on the left side to trap air in the right chambers of the heart, from where it can be aspirated (Muth & Shank, 2000). Up to 1% of maternal deaths can arise from venous air emboli (OSMACMH, 1972),

often introduced by poorly performed abortions (Nelson, 1960).

Epilepsy

Epilepsy is one of the more common neurologic diseases that can affect women of child-bearing years, and there is, therefore, a significant number of births involving women with epilepsy (0.3% to 0.5% of births). Women with epilepsy who become pregnant face several diagnostic and management problems. There are even challenges to becoming pregnant: fertility in women (and possibly men) is decreased. Furthermore, there are several interactions that can occur including the effect of seizures on the fetus, the effect of seizures on the course of pregnancy, the effect of pregnancy in altering seizure threshold and seizure control, and the influence of pregnancy on the pharmacokinetics and pharmaco-dynamics of antiepileptic drugs (AEDs). Antiepileptic drugs themselves have known teratogenic effects in the developing fetus and may enter breast milk in the postpartum period.

Pregnancy in patients with epilepsy is usually uneventful. However, about 25–30% of women will have a worsening frequency or severity of seizures during pregnancy (Morrell, 1997), particularly during the sixth and seventh months; most women have no significant change in frequency, and a few improve. In recent years, closer monitoring of epilepsy during pregnancy has improved seizure control. About 10% of pregnant women will have a complication during pregnancy. Up to 20% of babies will have a congenital anomaly, and 4% to 8% will have malformations, most frequently cardiac (2%); orofacial clefts (1.8%); skeletal anomalies (0.9%), and severe CNS malformations (0.7%) (Morrell, 1997). A maternal history of epilepsy confers twice the risk for epilepsy in the child than if the father has epilepsy. Epilepsy susceptibility may be transmitted by a mitochondrial gene or by imprinting of a nuclear gene from the mother. The most common genetic epilepsies are the idiopathic generalized epilepsies, and localization-related epilepsies such as benign rolandic epilepsy.

Women with epilepsy are more prone to miscarriage, spontaneous abortion, or preterm delivery, possibly related to the consequence of hypoxia and acidosis with tonic–clonic seizures, and the pulsatile release of luteinizing hormone (LH) that compromises implantation (Morrell, 1997). There is also a higher incidence of low birth-weight infants and fetal head growth retardation.

Causes of increased seizures during pregnancy include an increased volume of AED distribution and clearance, resulting in decreases in AED levels. Conversely, the fall in serum albumin, and competition for binding sites by sex steroids may increase the unbound (active) AED fraction. Poor adherence to taking AEDs may be caused by maternal fears that AEDs may damage the developing fetus, and it is therefore of great importance that women of childbearing age and pregnant women be counselled regarding these interactions, and the consequent deleterious effect of convulsions on the fetus.

Counselling should also include the teratogenic risks of AEDs such as congenital heart defects (atrial septal defects, tetralogy of Fallot, ventricular septal defects, pulmonary stenosis, patent ductus arteriosus, and coarctation of the aorta). There is a three- to four-fold increase in the incidence of these defects over the background rate. Neural tube defects may appear in 0.5% to 1% of children whose mothers take carbamazepine, and 1% to 2% of those on valproate (Omtzigt et al., 1992; Rosa 1991). Minor abnormalities such as epicanthal folds, nasal growth deficiency, abnormal ears, distal digital hypoplasia, and nail hypoplasia, low hairline and hypertelorism occur with phenobarbital, primidone, carbamazepine, phenytoin, and probably valproate, but many of these dysmorphic features may be outgrown after several years of life (Koch et al., 1992). The effects of the newer AEDs: felbamate, neurontin, lamotrigine, topiramate, oxcarbazepine, tiagabine, zonisamide and levetiracetam, are not known, but all have gained a category 'C' FDA classification.

AED polypharmacy significantly increases the risks for major and minor birth defects, reaching 20% in women on four or more AEDs (Oguni et al., 1992). Since neural tube defects rarely occur on valproate when taken in doses below 1 gram per day, more frequent dosing intervals and minimizing dosage may help. Neural tube defects may be detected by the 16th week of gestation with more than 95% sensitivity using maternal serum alpha fetoprotein and a level II ultrasound that can detect cardiac and neural tube malformations (ACOGPEB, 1996).

Folic acid deficiency contributes to neural tube defects, and folate supplementation is strongly advocated (400 μg to 4 mg/day). The optimal daily folate dose is not known, but folate should optimally be taken prior to pregnancy and particularly during the first 28 days of gestation.

During pregnancy, mothers should be seen monthly, at which time AED levels can be measured, particularly if convulsions increase. Oral or intramuscular vitamin K should be given in the last months of pregnancy to forestall the bleeding tendency in newborns produced by phenytoin and barbiturate exposure in utero. Infants should receive 1 mg of phytonadione after birth.

Although AEDs enter breast milk, most experts endorse breast-feeding.

Chorea gravidarum (Dike, 1998; Petri, 1998)

Chorea gravidarum by definition is peculiar to pregnancy. This rare condition represents the sudden appearance of chorea during pregnancy, often preceded by cognitive changes or emotional lability. Choreiform movements may be unilateral or involve the four limbs, and be severe enough to impair routine activities of daily living. Although previously a highly morbid condition leading to maternal death in 13% and fetal death in 50%, morbidity and mortality has markedly decreased to a few per cent. Up to a quarter of women, however, will relapse during subsequent pregnancies.

The most frequent causes are rheumatic fever and autoimmune disorders, with the chorea appearing in the first trimester and decreasing during the second and third trimesters. It is believed that many women have had Sydenham's chorea in childhood with consequent basal ganglia injury, which is reactivated during pregnancy in association with the hormonal changes. Increased striatal metabolism has been demonstrated using PET-fluorodeoxy-glucose imaging.

Symptomatic treatment with chlorpromazine (Thorazine®) can be used in the first trimester, but may cause sedation and orthostatic hypotension. Haloperidol (Haldol®) can be used after the first trimester (because of concerns of teratogenic limb deformity), because it is less sedating than chlorpromazine. Because of the frequent association of rheumatic heart disease, prophylactic antibiotics are advised during instrumentation and delivery to prevent endocarditis. Curiously, chorea resolves within hours of delivery.

A rarer cause of chorea gravidarum is seen in association with the antiphospholipid antibody syndrome (APS) or with systemic lupus erythematosus (SLE). Chorea gravidarum in this setting is usually a more morbid condition and treatment is directed at the underlying condition: steroid immunosuppression with SLE, and symptomatic treatment as outlined above. Treatment of antiphospholipid antibody syndrome during pregnancy involves low molecular weight or subcutaneous heparin, often in combination with steroids and antiplatelet agents. Some improvement has been obtained with corticosteroids. With SLE and APS, there is a greater probability of structural brain injury and chorea may persist after delivery.

Even rarer causes of chorea initially appearing during pregnancy are Wilson's disease and Huntington's chorea.

Eclampsia

Pre-eclampsia/eclampsia is a syndrome characterized by pregnancy-induced hypertension, proteinuria, and edema after the 20th week of pregnancy. This multisystem disorder may affect clotting, kidney and liver function, and the lungs. Neurological features include headache, visual hallucinations, blindness, confusion, seizures, and coma. The appearance of seizures signals the evolution of pre-eclampsia to eclampsia, but seizures may appear with few if any signs of pre-eclampsia. Many eclamptic seizures appear postpartum, and only at that time, may hypertension be noted. Pre-eclampsia affects 6% to 8% of pregnancies (Chesley, 1978) and is more frequent in black primigravidas and twin pregnancies, the poorly nourished, nulliparous women, and women over the age of 35, as well as in women who have had pre-eclampsia in previous pregnancies (Sibai, 1989, 1990).

The hypertension of pre-eclampsia/eclampsia may be mild, representing a rise of 30 millimetres Hg in systolic pressure, or 15 millimetres Hg in diastolic blood pressure above first trimester blood pressure readings (Committee ACOG, 1986). Antenatal history may be lacking, and an absolute blood pressure of 140/90 has been used to diagnose hypertension.

Unlike the frequently seen ankle edema in normal pregnancy, preeclamptic edema is more marked, and affects the face and hands. Proteinuria is determined by the repeated finding of 1+ proteinuria on two occasions six hours apart, or the presence of 300 mg of protein in a 24-hour urine collection (Committee ACOG, 1986).

Seizures may start focally but are usually noted once a generalized convulsion occurs. Most women will not have repeated seizures once the baby is delivered, but even on magnesium sulfate therapy, up to 10% may have two or more seizures (Pritchard et al., 1984).

There are a number of pathophysiological mechanisms invoked in the eclamptic process including immunological dysfunction, coagulation abnormalities, endothelial damage, endocrine, dietary, genetic and vasospastic factors (Friedman et al., 1991). The hypertension is believed to stem, in part, from the incomplete deactivation of autonomic innervation of uterine spiral arteries in the inner myometrial layer preventing their maturation into utero placental arteries, which release nitric oxide (Furchgott, 1996). A failure in nitric oxide production favours vasoconstriction and the increase in circulating serotonin and affecting the renin–angiotensin–aldosterone systems (Khong et al., 1986; Talledo et al., 1968).

Many aspects of cerebral pathology are attributable to the loss of cerebral autoregulation with increased cerebral

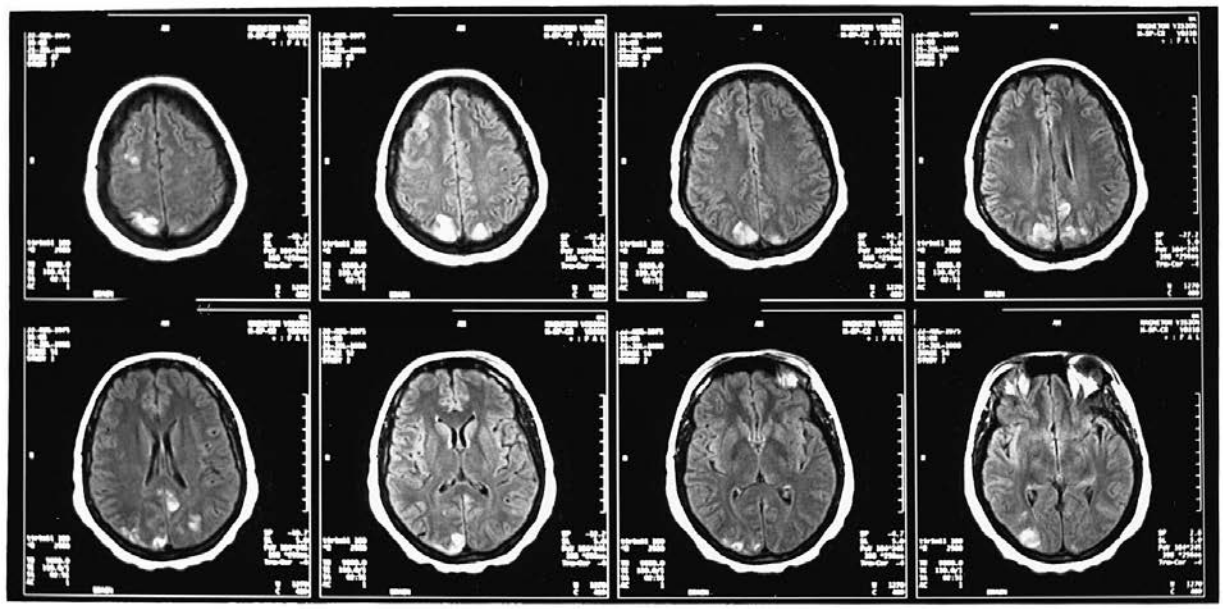

Fig. 121.1. Axial T_2-weighted MRI study shows peripheral edema in the frontal and parieto-occipital watershed zones. (From Kaplan, 1999, reproduced with permission from Masson Editeur.)

perfusion pressures. As hypertensive encephalopathy appears, there is associated vasospasm and areas of ischemia, as well as petechial and larger hemorrhages that can occur in most brain regions. The watershed zones, particularly posteriorly, are those most affected by ischemic changes (Fig. 121.1). The brain may be further adversely affected by platelet consumption and an active coagulopathy superimposed on a hypertensive and multifocally hemorrhagic brain (Anderson & Sibai, 1986; Gant et al., 1973).

Pre-eclampsia/eclampsia largely remains a clinical diagnosis, and where focal signs are seen, imaging for associated pathological problems such as cerebral venous thrombosis and intracranial hemorrhage should be performed. Recent MRI studies have shown a typical serpiginous or curvilinear, grey–white junction T_2-weighted signal increase, particularly in watershed zones (Digre et al., 1993).

Neurologists are usually consulted in the management of atypical cases of eclampsia, often complicated by intracranial hemorrhage, or coma. In addition to efforts aimed at rapid delivery of a viable baby, and decreasing maternal blood pressure to within the autoregulatory range, magnesium sulfate is widely advocated (Pritchard et al., 1984; Eclampsia Trial Collaborative Group, 1995). Although not an anticonvulsant, there is increasing evidence that it may have an effect on the vasospastic component of eclampsia which, in itself, may forestall further seizures and brain damage (Kaplan et al., 1988). Should seizures persist, intravenous phenytoin (Repke et al., 1992) or fosphenytoin are useful.

Multiple sclerosis (MS)

MS has no significant effect on conception, fertility, fetal viability or delivery, and some believe that pregnancy improves long-term prognosis. There is a very small increased risk for MS in the child.

Although previously pregnancy was considered to be contraindicated in MS patients, more recent studies fail to confirm a negative effect on MS. A recent study found that MS risk was higher in nulliparous women, with pregnancy appearing to confer a protective effect (Runmarker & Andersen, 1995). MS relapses decrease during gestation, particularly in the latter half, possibly via immune suppression with the changes in cytokines, prostaglandins, cell-mediated immunity, and enhancement of immunoglobulin responses (Abramsky, 1994; Gilmore et al., 1997).

Diagnosis and investigation

Most patients who are pregnant with MS will have had the diagnosis made before becoming pregnant. As noted, few

initially develop MS during pregnancy. Consequently, investigation with MRI, LP and evoked potentials are rarely warranted during pregnancy. Gadolinium contrast crosses the placenta but has no known teratogenic effects; nonetheless, it is not recommended in pregnancy. The slight concerns regarding unenhanced CT or MRI imaging during pregnancy are noted in the section on strokes, but regarding evoked potentials or lumbar puncture, there is no evidence that they pose a problem for mother or fetus.

Treatment

The newer maintenance immunotherapies used to prevent future demyelination such as glatiramer acetate (Copaxone®) and the interferon-betas, are contraindicated in pregnancy. Most studies indicate a postpartum rebound in relapses with a threefold increase, occurring 3 to 6 months postpartum (Coyle, 1998). Twenty to 40% of postpartum women with MS may have a clinical attack. A recent study suggests that postpartum immunotherapy may prevent such relapses (Achiron et al., 1996). Many medications used in the symptomatic treatment of MS enter breast milk, as do interferon-betas and glatiramer acetate, and cannot safely be used during breast feeding. There is no contraindication to vaginal delivery (nor to breast feeding), but spinal anesthesia is not recommended. Conversely, epidural anesthesia does not carry a particular risk for MS relapse and can be used for delivery. Steroid cover for the stress of delivery should be considered in women who have received 2 or 3 weeks of corticosteroid therapy in the prior year.

Peripheral nerve disease and muscle disease

Bell's palsy

Bell's palsy is 3.3 times higher in pregnancy, with 85% of cases occurring in the third trimester or first two weeks postpartum (Hilsinger et al., 1975; Mair Iain et al., 1973). Successful treatment has been obtained with steroids, or with symptomatic treatment only.

Carpal Tunnel Syndrome

By questionnaire, up to a quarter of women have had symptoms of carpal tunnel syndrome, particularly in the third trimester (Conwit & Good, 1998). It has been attributed to the increase in relaxin, a hormone that peaks in the third trimester, and that may cause relaxation of the transverse carpal ligament (Nicholas et al., 1971). Fluid retention and edema may cause local nerve compression. Surgery is rarely needed during pregnancy.

Neuralgia paresthetica

Neuralgia paresthetica (produced by compression of the lateral femoral cutaneous nerve of thigh as it goes under the lateral third of the inguinal ligament) increases with weight gain and abdominal girth, particularly after the 30th week of gestation. Most patients remit by 3 months.

Other neuropathies

Nutritional deficiency neuropathy is seen in developing countries, and the rare porphyric neuropathy may flare up in pregnant women with acute intermittent porphyria.

Compression neuropathies (Conwit & Good, 1998)

Compression neuropathies include sciatic nerve compression within the pelvis and lumbosacral plexopathies from compression by the descending fetal head, which most often affect the peroneal nerve, causing pain and foot drop. Femoral mononeuropathies may be produced by the lithotomy position used during vaginal deliveries, and mostly resolve within a few months. The iliohypogastric nerve may be stretched during pregnancy, presenting with pain in the pubic or periumbilical region, abdominal flank or back, but without weakness. The obturator nerve can be compressed by the fetal head against the lateral pelvic wall, producing pain in the groin and upper thigh with adductor weakness.

Myotonic dystrophy (Gilchrist, 1998)

Pregnancy rarely affects myotonic dystrophy, although the condition may first become symptomatic during pregnancy, particularly in the third trimester. Conversely, myotonic dystrophy may affect pregnancy, causing prolongation of the first and second stages of labor (because of poor uterine contractions), and increased postpartum hemorrhage from the failure of uterine contraction. There are risks with anesthesia and surgery because of the 'sensitivity' to depolarizing neuromuscular blockade with succinyl-choline. Non-depolarizing agents may be safely used. Thiopental may cause respiratory depression and local anesthesia is preferred.

Myasthenia gravis

In myasthenia gravis, studies have shown that 40% of pregnant women may worsen, 28% may improve, and the remainder remain unchanged (Plauche, 1991); however, long-term outcome is not changed (Batocchi et al., 1999). Exacerbations may be sudden, often with respiratory failure, and may change with subsequent pregnancies (Batocchi et al., 1999). Maternal mortality may reach 10% from cholinergic crisis, myasthenic crisis, or postpartum hemorrhage (Plauche, 1991).

The treatment of myasthenia is little affected by pregnancy, and anticholinergic agents, corticosteroids, and even plasmapheresis can be used. Pyridostigmine is not excreted in breast milk and does not cross the placenta.

One in eight babies of women with myasthenia have transient neonatal myasthenia with spontaneous remission in two to four weeks as the level of antiacetylcholine receptor antibody declines (Namba et al., 1970). There is increased perinatal infant death with neonatal myasthenia (Frenkel & Ehrlich, 1964).

The brain and the cardiovascular system

James L. Januzzi, Jr[1] and Guy M. McKhann[2]

[1] Cardiology Division and Department of Medicine, Massachusetts General Hospital, Harvard Medical School, Boston, MA, USA
[2] Department of Neurology, Johns Hopkins University Medical Center, Baltimore, MD, USA

Normally, the brain and heart function in seamless harmony. The heart supplies the brain with nutrients and oxygen, while the brain regulates cardiac function. It is a long-standing fact that cardiovascular disease is a major source of neurological dysfunction. In addition, however, it has become recently apparent that besides playing a major role in basic cardiac homeostatis, the brain directly influences certain cardiovascular disease states. Among these influences are profound effects on the incidence of, and outcome from, coronary artery disease, congestive heart failure, and cardiac arrhythmias.

The influences of the heart on the brain

There is a strong association between heart disease and subsequent neurological dysfunction. Focal neurological syndromes due to cardiac diseases most often arise from emboli, typically associated with arrhythmias, valvular heart disease, myocardial infarction, as well as rarer situations, such as intracardiac tumours. Cardiac surgery, particularly coronary artery bypass grafting and valve replacements, may be associated with showers of athero-, air, and thromboemboli at the times of aortic manipulation.

In addition to embolic injury, other cardiac causes of neurological dysfunction include cardiac arrhythmias or cardiac arrest, which may result in anoxic injury to the brain. Finally, congestive heart failure may lead to a number of subtle neurological findings.

Cerebral embolic strokes of cardiac origin

The percentage of strokes that are cardioembolic is at least 20%, and may be as high as 50%. The major underlying cardiac conditions leading to cardioembolic strokes include atrial fibrillation, myocardial infarction, valvular heart disease, infectious endocarditis, and non-bacterial thrombotic endocarditis. Less common conditions which may be associated with cardioembolic strokes include patent foramen ovale, intracardiac tumours, and calcifications of the mitral or aortic valves/annulus.

Cardiac arrhythmias

Atrial fibrillation is a major risk factor for stroke, with a stroke rate of approximately 5%/year (Nademanee & Kosar, 1998). However, the risk varies greatly. For those under 65, without risk factors, the risk is about 1%/year. For others with increasing age, systemic arterial hypertension, diabetes, valvular heart disease, a dilated left atrium, thyrotoxic atrial fibrillation, mitral annular calcification, previous TIA/stroke, or poor ventricular function the risk can be as high as 10–12%/year (Nademanee & Kosar, 1998). The actual incidence of embolic infarction is undoubtedly higher than these percentages, as evidenced by the increased numbers of 'silent' brain infarctions on brain imaging studies in patients with arrhythmias (Ezekowitz et al., 1995).

There appear to be particular times in the evolution of atrial fibrillation that embolic complications are likely to occur: the onset of paroxysmal atrial fibrillation, and the first year after the transition from paroxsymal atrial fibrillation to chronic atrial fibrillation. In addition, as noted above, there exist certain high-risk clinical factors, which may identify those patients at risk for a cardiocerebral embolism. This emphasizes the need for attempts at maintenance of normal sinus rhythm, either by removing the 'fibrillogenic' stimulus (i.e. thyrotoxicosis), or by using antiarrhythmic agents to suppress the arrhythmia, or to prevent transition to chronic atrial fibrillation. Additionally, the role of anticoagulents for stroke prevention in atrial fibrillation of recent onset is crucially established (Petersen et al., 1989), as up to 7% of patients undergoing conversion of atrial fibrillation without therapeutic anticoagulation experience a significant cardiocerebral event (Munshauer et al.,

1997). This risk may be lowered to less than 1% with adequate anticoagulation therapy with oral warfarin sodium (Petersen et al., 1989; Koefoed & Petersen, 1999). In those at low risk there is less substantiated therapeutic benefit of aspirin, however data does exist to suggest that those patients with a structurally normal heart, with left atrial dimensions less than 45 mm (so-called 'lone' atrial fibrillation), may be safely managed with daily antiplatelet therapy (the SPA III Writing Committee, 1998; Hart et al., 1999). Finally, the stroke risk engendered by atrial fibrillation may persist for up to a month following restoration of electrical sinus rhythm, as mechanical atrial systole may not return for several weeks (Grimm et al., 1997). Anticoagulation is therefore mandatory during this period.

Electrical or pharmacological conversion of atrial fibrillation is a commonly used therapy for the acute conversion of this arrhythmia, typically with simultaneous oral anticoagulation. The use of transesophageal echocardiography (TEE) to evaluate for the presence of left atrial appendage thrombosis has been suggested to reduce the risk of stroke significantly, even in the absence of therapeutic anticoagulation, however the risk of stroke in contemporary TEE series is still measurable (Roijer et al., 2000).

The role of other atrial arrhythmias (especially atrial flutter) in the genesis of cardioembolic stroke remains hotly debated (Irani et al., 1997). As a small amount of atrial function persists during atrial flutter, it has been argued that the stroke risk is much lower than that of atrial fibrillation. Numerous studies do, in fact, support this contention, however the incidence of cardioembolic strokes due to atrial flutter still remains measurable (Grimm et al., 1997; Irani et al., 1997; Roijer et al., 2000), thus similar anticoagulation guidelines should be followed. Since a large percentage of patients with atrial flutter have concomitant atrial fibrillation, the true stroke risk of atrial flutter remains undefined.

Myocardial infarction

Most often, concomitant myocardial and cerebral infarction raises the possibility of a ventricular thrombus (usually in the setting of anterior/apical wall infarction), but less commonly one may see a similar picture from coronary/cerebral embolism from endocarditis. The multifocal nature of certain other causes of concomitant MI and cerebrovascular injury may mimic embolic events. Notable among these syndromes are coronary/cerebral arterial spasm in the setting of subarachnoid hemorrhage or migraine headaches. These are discussed later.

In the absence of appropriate anticoagulation therapy, embolism to the central nervous system following an acute myocardial infarction is not an infrequent event. The most common source of emboli is generally believed to be mural thrombi, which typically form at the site of infarcted, akinetic ventricular myocardium. In the setting of an anterior myocardial infarction, the risk of a cardiocerebral embolism may be as high as 40% among non-anticoagulated patients (Keren et al., 1990). This risk may be dramatically reduced with an appropriate anticoagulation regimen, including intravenous or subcutaneous heparins acutely, followed by chronic oral anticoagulation with warfarin sodium.

Although uncommon, concomitant coronary and cerebral events may be due to emboli arising from valvular lesions of endocarditis (see below). This should be suspected in any patient with a fever accompanying their event.

Valvular heart disease

Mitral stenosis is associated with embolic disease, particularly, as mentioned above, if there is coexisting atrial fibrillation (Munschauer et al., 1997). The annual incidence of embolic events in untreated patients is about 4%/year. For those with previous embolic events it is twice that. This emphasizes the fact that recurrent embolism is common, occurring in the majority of untreated patients. These reoccurrences occur in the first month in 40% and in the first year in 67% of patients (Munschauer et al., 1997). Fortunately, the long-term use of anticoagulents markedly reduces this risk of recurrent embolization, as much as 90% (Munschauer et al., 1997).

Mitral valve prolapse is a common disorder of the mitral valve, occurring in 1–3% (Freed et al., 1999) and defined by strict echocardiographic criteria (Levine et al., 1988, 1989). Clinically, mitral valve prolapse is most often due to myxomatous degeneration of the valve leaflets, resulting in redundancy, loss of competence, and consequent mitral regurgitation. Due to stress/strain effects on the mitral chordal apparatus, the chordae tendineae become elongated, and may ultimately snap, leading to chest pain, as well as worsening mitral incompetence. Mitral valve prolapse is a common source of either atrial or ventricular arrhythmias.

There is controversy regarding mitral valve prolapse as a source of emboli. Earlier studies suggested that in those under 45 years of age with transient ischemic attacks or strokes, mitral valve prolapse was found in 40% as compared to 7% in controls. However, in more recent studies (Marks et al., 1989; Freed et al., 1999; Gilon et al., 1999) mitral valve prolapse detected by either auscultation or transthoracic echocardiology was not associated with an increased number of strokes.

Infective endocarditis is commonly affected by neurological complications, including as a presenting sign of the disorder. Infective endocarditis should be actively sought in any patient presenting with concomitant neurological

symptoms and fever. Among these complications of endocarditis are focal neurological deficits (simulating a stroke), intracerebral or epidural abscess formation, mycotic aneurysms, seizures, as well as a diffuse meningoencephalitis (Tunkel & Kaye 1993; Roder et al., 1997; Heiro et al., 2000). Certain clinical factors predispose a patient with endocarditis to CNS complications. These include antecedent embolic events, large or bulky vegetations, those caused by *Staphylococcus* or *Streptococcus*, as well as fungal endocarditis (Sanfilippo et al., 1991). Although antibiotic therapy reduces the risk of CNS embolism in the setting of infective endocarditis, it does not eliminate the risk entirely, and some authors advocate valve replacement therapy if high-risk lesions are identified, or if a previous cardiocerebral embolism has occurred. This is because the risk of mortality is significantly increased in the setting of a neurological complication of endocarditis (Moon et al., 1997).

Non-bacterial thrombotic endocarditis (NBTE) is a lesser-recognized cause of cardiocerebral stroke. It is most often due to the development of sterile, thrombotic vegetations, which may be attached to one or more heart valves (Lopez et al., 1987). It may occur in association with advanced terminal illnesses, especially those resulting from neoplasia or acquired immunodeficiency syndrome (Johnson & Roodman, 1989; Kaul et al., 1991; Pinto, 1996). Furthermore, NBTE has been associated with certain acquired states of hypercoagulability, notably the anticardiolipin/lupus anticoagulent syndrome. Irrespective of the underlying cause NBTE is managed with anticoagulation therapy, reserving valve surgery for large/bulky vegetations, or recurrent embolic events.

Following valve replacement

Both mechanical and biologic prostheses are used for both mitral and aortic valve replacement and in addition to the risk of embolic events at the time of their implantation (see below), may be subsequently implicated in cardiocerebral embolism.

Given their synthetic nature, valve prostheses are a potential nidus for the development of thrombi and/or endocarditis. The risk of embolic disease varies with the type of valve used. Mechanical prosthetic valves require the use of long-term anticoagulation while biologic valves, those obtained from bovine, porcine or human sources, may not (Al-Ahmad et al., 2000; Braunwald, 2000). With the use of more modern 'low profile' mechanical prostheses and more aggressive anticoagulation protocols, the risk of thromboembolic events has been reduced substantially (Al-Ahmad et al., 2000).

Due to lower flow (as well as a higher incidence of concomitant/preoperative atrial arrhythmia), the risk is higher with mitral valve replacement, with the risk of thromboembolism with mechanical valves being about 3%/year even with anticoagulation, and about one-half that with porcine/bovine valves. Whether the growing use of human sources for aortic valve replacement (either pulmonary–aortic autografting or cadaveric homografting) will further lower this risk remains unclear (Kassai et al., 2000; Stahle, 2000).

The development of infective endocarditis on a prosthetic valve is a medical emergency, frequently accompanied by embolic events, and which almost always requires surgical intervention.

A recently recognized cause of embolic stroke following valve replacement or repair is thromboembolism originating from an incompletely ligated left atrial appendage (Katz et al., 2000). Katz and colleagues suggest that the small residual amount of flow entering the atrial appendage might allow for the formation of a thrombus, which could then potentially exit to the systemic circulation, and lead to cerebrovascular events.

Patent foramen ovale

Patent foramen ovale (PFO) is a common condition (up to 40% of the population), and may be associated with a higher than expected incidence of cerebral embolism (De Castro et al., 2000; Chant & McCollum, 2001; Sastry & McCollum, 2001). It consists of incomplete fusion of the septum primum and septum secundum, resulting in an interatrial connection, which is either continuously present or at least provokable with manoeuvres that raise the right atrial pressure (e.g. following Valsalva release), the so-called probe-patent PFO. In addition, patients with PFO not infrequently have abnormalities of the interatrial septum (e.g. hypermobility or redundancy), which are thought to further promote 'opening' of the foramen, with transient increases in shunt flow. It has been suggested that concomitant hypermobility with PFO of the interatrial septum increases the risk for cerebral embolism (Zhao et al., 1999; Marshall & Lock, 2000; Mattioli et al., 2001).

Like mitral valve prolapse, the association of PFO with embolic events is not clear. Several studies (Devuyst & Bogousslavsky, 1997; d'audiffret et al., 1999; De Castro et al., 2000; Chant & McCollum, 2001) suggest that the patent foramen ovale is a risk factor for recurrent embolism in young as patients, particularly those with right-to-left shunting as detected by transesophageal echocardiography (TEE). Whether long-term anticoagulation or prophylactic closure of the defect with either surgical or percutaneous techniques offers long-term protection against recurrent events is currently under investigation (Hung et al., 2000; Windecker et al., 2000; Hijazi et al., 2001).

Intracardiac tumours

The most common cardiac tumour implicated in cerebral embolism is a left atrial myxoma (Larsson et al., 1989; Majano-Lainez, 1997). These tumours may give rise to tumour emboli large enough to occlude cerebral arteries, which might be expected to lead to symptomatic neurological events (Reichmann et al., 1992; Vahedi & Amarenco, 2000). The cardiac symptoms of myxomas depend on numerous factors, especially how obstructive the mass is to the mitral orifice. Patients with atrial myxomata may present with a neurological event as their first sign of the syndrome (Bayir et al., 1999; Yuan et al., 1999), or may develop systemic symptoms, with an elevated erythrocyte sedimentation rate, arthralgias, fever of unknown origin (Andrews & Pollock, 1996; Boullanger et al., 1996), and changes in mental status (Saravay & Gupta 1998; Nhiwatiwa, 2000). It is believed that these unusual manifestations are due to production by the tumour of large amounts of inflammatory cytokines, such as interleukin-6 (Wiedermann et al, 1992). Furthermore, although rare, myxoma emboli may exhibit malignant potential, growing as cerebral tumours following embolism (Wada et al, 1993; Kanda et al., 1994). Embolism is particularly likely if the myxoma is of the villous variety (Shimono et al., 1995; Ha et al., 1999). Infective endocarditis of atrial myxoma ('myxocarditis') may be accompanied by an extremely high rate of embolism (Marshall & McDonald 1998; Revankar & Clark 1998). Urgent surgical extirpation is indicated whenever such a tumour is diagnosed.

Another cardiac tumour notably associated with a risk of cerebral embolism is the valvular papillary fibroelastoma (Brown et al, 1995; Yee et al., 1997). These uncommon tumours have a characteristic frond-like appearance, may be up to 3–4 mm in size, are occasionally multiple, and may occur on any valve structure, but in adults are most often found on the mitral or aortic valves (Giannesini et al., 1999; Golbasi et al., 2000; Grandmougin et al., 2000; Sastre-Garriga et al., 2000). Papillary fibroelastomas are thought to arise from focal injury to the valve structures, and thus may share a common pathogenesis with Lambl's excrescences, common irregularities found on heart valves, most often at the site of antecedent damage (Loire et al., 1998; Speights et al., 1998; Watchell et al., 2000). Both fibroelastomas and Lambl's excrescences may be diagnosed with cardiac ultrasound (Hicks et al., 1996; Yee et al., 1997). The treatment for symptomatic embolism in the setting of a papillary fibroelastoma is generally agreed to be valve replacement. The role of valve replacement for embolism in association with Lambl's excrescences is totally undefined.

Miscellaneous causes of cardioembolism

Calcification of the mitral annulus is diagnosed in a high percentage of patients with cryptogenic embolic strokes (Benjamin et al., 1992; Madias, 1992; Roijer et al., 1996; Vahedi & Amarenco, 2000). It is not entirely clear whether mitral annular calcification is the source of these emboli, however, on gross inspection, annular calcification may demonstrate fresh overlying thrombus, possibly explaining the higher risk of stroke noted among these patients. The risk of embolism has been clearly demonstrated in patients with mitral annular calcification and atrial fibrillation. Calcification of either the aortic or mitral valve leaflets themselves is occasionally implicated as a source of emboli, and may be the first sign of valve pathology in some patients (Oliveira-Filho et al., 2000).

A poorly defined entity known as 'valve stranding' has been documented among patients with cryptogenic embolic strokes (Tice et al., 1996; Nighoghossian et al., 1998; Palazzuoli et al., 2000; Vahedi & Amarenco, 2000). Most commonly noted on the mitral valve, it is thought that these strands represent fibrin, which coalesced under low flow conditions. The true stroke risk associated with fibrin valve stranding has not been defined.

Cardiac surgery and the brain

Coronary artery bypass surgery

Over 500 000 persons in the United States and 800 000 worldwide undergo coronary bypass grafting (CABG) each year for the treatment of coronary artery disease. There is little question that the surgery is very effective in reducing angina, and in stabilizing ventricular function in the majority of patients. For example, 5 years after CABG for severe, unstable angina, 86% of patients were free of angina, and of those with angina, only 3% had the severe, unstable form; 94% of patients remained free of angina without additional surgery (Bypass Angioplasty Revascularization Investigation, 1997). Those at higher risk have improved survival with CABG than with medical therapy (Solomon & Gersh, 1998; Yusuf et al., 1994).

With advances in anesthetic and surgical techniques, the population eligible for this coronary artery bypass grafting (CABG) is not only older, but also more likely to have associated health problems such as hypertension or diabetes. In addition, an increasing number of patients have had a previous angioplasty procedure, delaying the age of initial CABG. There is increasing recognition, however, that although CABG may be successful for the heart, it may have an adverse effect on the brain. Four neurological and

cognitive complications have been observed after CABG: stroke, postoperative delirium, short-term cognitive change and possible long-term cognitive change (Selnes, 1999a).

Stroke

Stroke is a well-recognized complication of CABG. The reported incidence ranges from 0.8% to 3.2% in retrospective series (Martin & Hashimoto, 1982; Coffey et al., 1983) and from 1.5% to 5.2% in prospective studies (Breuer et al., 1983; Roach et al., 1996). Stroke after CABG is reported to be more common than is stroke after other surgical procedures (Limburg et al., 1998). Moreover, the mortality among patients with strokes is 20%, whereas overall mortality for CABG patients is reported as 2 to 4% (McKhann et al., 1997). In addition to patient suffering, the economic impact of stroke is considerable: length of stay both in the intensive care unit and in the hospital are significantly prolonged, and hospital costs are doubled (Roach et al., 1996) (Table 122.1).

Table 122.1. Clinical evidence of stroke after cardiac surgery procedures

Procedure	Total cases	Stroke incidence
CABG	3974	3.2%
Valve	828	2.8%
CABG/Valve	463	6.7%
CABG/CEA	52	17.3%
CABG/Other	76	9.2%
Aortic procedures	310	4.2%
Heart transplant	94	1.1%
Other	174	1.1%
Total	5971	3.6%

Notes:
CABG = coronary artery bypass grafting; CEA = carotid endarterectomy; Other = other cardiac procedures requiring cardiopulmonary bypass (e.g. repair of atrial septal defect or left ventricular aneurysm)
Source: Adapted from McKhann et al. (1997).

A number of studies have developed models to identify patients at higher risk for stroke (McKhann et al., 1997; Newman et al., 1996; Herlitz et al., 1998) (Fig. 122.1, see colour plate section). In general, these predictive models are dominated by factors associated with cardiovascular disease such as hypertension, diabetes, peripheral vascular disease, evidence of cerebrovascular disease, and age. It is the combination of these factors that more strongly predicts outcome. Single factors alone, even age or diabetes, are less predictive. Thus, a 75-year-old man without a history of hypertension, diabetes, or a previous stroke, is at low risk for a stroke after CABG. In contrast, a 65-year-old man with a history of hypertension, a previous stroke, and diabetes is at high risk for stroke. The ability to identify patients at high risk for stroke has important implications. All of these risk factors can be assessed by a general physician in his/her office, before surgery. Thus, this information can assist informed decision making by patients and their families and physicians. For example, some patients may be better candidates for continued medical management or percutaneous transluminal coronary angioplasty (PTCA). For others, modification of the surgical procedure can be considered, such as changes in the placement of the aortic cannula from the cardiopulmonary pump, and different methods of clamping the aorta. Decisions at the time of surgery can be aided by evaluating the degree of arteriosclerosis of the ascending aorta. Recent studies have indicated that epiaortic ultrasound or transesophageal echocardiography are effective methods for detecting both the presence and severity of aortic arteriosclerosis (Davila-Roman et al., 1996). Identification of the location of arteriosclerotic plaques and subsequent modification of the surgical procedure can decrease the rate of stroke (Wareing et al., 1993).

Finally, although not proven, it would be expected that the increasing use of 'off pump' surgery (which minimizes the need to manipulate the aorta) would be accompanied by a lower incidence of embolic stroke.

Postoperative delirium

The symptoms of postoperative delirium are well known to the medical personnel involved with the care of elderly patients after major surgery. In one of the few prospective studies of this problem, Marcantonio and colleagues found that postoperative delerium occurred in 9% (117 of 1341) patients undergoing non-cardiac surgery (Marcantonio et al., 1994). The reported incidence after CABG has varied. In older studies it was as high as 10% to 28% (Breuer et al., 1983; Kornfeld et al., 1978), but recent experience suggests that the incidence may be decreasing (Van Der Mast & Roest, 1996). The mechanism of the encephalopathy postoperatively is not clear. However, the use of DWI imaging suggests that many of these patients have multiple small embolic infarctions (Wityk, 2000).

These patients are similar to stroke patients in length of hospital stay and consequent hospital costs (McKhann et al., 1997). The cognitive outcome in patients with postoperative delirium has not been systematically investigated. It is not known whether these are the patients who have subsequent cognitive deficits, particularly in the long term.

Cognitive changes

As a result of significant advances in anesthesiological and surgical techniques over the past several years, it is widely assumed that the incidence of postsurgical cognitive decline has been reduced. The benefits of such technological advances, however, may have been offset by inclusion of older patients with more comorbid disease. The extent to which postoperative cognitive dysfunction is detected will depend on measurement techniques, timing of the assessment, and statistical methods. Some of these methodological issues have been addressed by international consensus conferences in 1994 and 1997 (Murkin et al., 1995, 1997). One concerns the selection of neuropsychological tests. Because the cognitive changes may arise from more than one etiological mechanism, a test procedure that assesses all major cognitive domains is preferable. This is particularly relevant when interpreting studies with 'null' findings. If the test battery did not include assessment of, for example, frontal lobe functions such as planning and abstraction, or parietal lobe functions such as spatial and constructional abilities, abnormalities in these areas are missed. Because of limited time available for neurobehavioural testing preoperatively, few studies have included tests covering all major cognitive domains.

A second, but until now, relatively unexplored issue concerns presurgical baseline performance. There is considerable variability in neuropsychological performance at baseline, with some patients performing at expected age- and education-adjusted levels and others performing significantly below expected levels. It has been assumed that this variability might arise from high levels of presurgical emotional distress in some patients. More recent studies, however, have suggested that a subset of candidates for CABG may actually be cognitively impaired prior to surgery (Vingerhoets et al., 1977). These findings have several implications for interpretation of cognitive outcome studies. First, decline secondary to CABG in patients who are already impaired at baseline might be underestimated. A second, and more unexpected implication is the possibility that chronic cardiovascular disease may be associated with mild neurobehavioural impairment, which may actually improve as a result of CABG.

Several methods have been used to measure post-CABG cognitive change. The first, and most common strategy has been to assess the frequency of any cognitive change. The outcome measure is typically defined as decline in performance by, for example, 1 standard deviation on two or more tests. This approach is useful for estimating the incidence of cognitive change, particularly in intervention studies, such as reducing the number of microemboli (Stump et al., 1996). The second approach is to evaluate the frequency of change by specific cognitive domains, thus addressing the question of what proportion of patients show change in memory, language, and other areas. This approach is useful when addressing questions of pathophysiology of the cognitive changes after CABG. For example if, as has been suggested, some regions of the brain are more susceptible to the effects of emboli, changes might occur in certain cognitive domains but not in others. This domain-specific approach also has the advantage that the pattern of cognitive changes may be differentiated from expected changes with normal aging, Alzheimer's disease, or other causes of cognitive decline in the elderly.

Short-term changes

In the first few weeks after surgery the most common complaints relate to memory functions. The recognition of such cognitive changes by patients, their families and their physicians, led to series of studies in which different areas of cognitive performance were tested before, and at varying intervals after CABG. Many of these tests were administered at short times after surgery: while patients were still in hospital, or days and weeks after surgery. Estimating the relevance of short-term outcomes is complicated by the wide range of reported incidence of cognitive decline (from 33 to 83%) (Savageau et al., 1982; Shaw et al., 1987). Some of the discrepancies can be attributed to use of different tests and to evaluating diverse populations (for example, in general, European studies involved younger patients (Newman et al., 1987) and some studies excluded patients with comorbid disorders (O'Brien et al., 1992). More importantly, the majority of studies of outcomes after CABG reported in the literature are limited by lack of appropriate control groups. Thus although cognitive changes are well documented, it has been difficult to determine whether they are specifically related to the procedure itself or whether other surgical procedures would produce similar postoperative cognitive changes.

In a study comparing 1218 postoperative (non-cardiac) patients with non-operated controls, cognitive dysfunction was reported in about 26% of patients 1 week after surgery and about 10% of patients 3 months after surgery, compared with 3.4 and 2.8% of non-operated controls after 1 week and 3 months, respectively (Moller et al., 1998). Williams-Russo et al. (1995) compared outcomes in patients after CABG with outcomes in patients after total knee or hip replacements, and found a similar incidence of cognitive decline in both groups 1 week and 6 months after surgery. The cognitive domain with the highest frequency of decline was memory, with nearly 30% of patients showing clinically significant decline at 6 months. Vingerhoets and colleagues (Vingerhoets et al., 1997) and

Murkin et al. (1995) also found similar frequencies of cognitive decline after surgery for patients undergoing major vascular or thoracic surgery and those undergoing CABG. These findings suggest that some of the short-term cognitive changes after CABG may not be specific to this procedure, but may also accompany other surgical procedures.

Long-term changes

The longer-term cognitive complaints of patients are more difficult to characterize. They involve more subtle deficits, such as problems in following directions, especially in new locations, in planning complex acts, such as playing chess, and in performing calculations. Such changes are sometimes described by the non-specific complaint 'I'm just not quite right.' Although only a few studies have followed patients beyond 6 months, there have been reports of persisting cognitive symptoms, and in some cases, delayed cognitive decline (Aberg et al., 1983; Sotaniemi et al., 1986; Klonoff et al., 1989).

By extending the follow-up period to 1 year and beyond, we have found that some cognitive deficits persist and some, such as constructional praxis (the ability to copy a complex figure) may even progress from 1 month to 1 year. In the analysis at 5 years, the performance on cognitive testing had a two-stage course. From baseline to 5 years patients did well in most domains, actually improving in some. However between 1 year and 5 years after surgery, there was decline in almost all domains. Newman et al. (2001) have found a similar 'late decline' 5 years after surgery, but in a much higher proportion of patients. Interpretation of both of these studies is hampered by the lack of comparison with a non-operated group with similar risk factors for cardiovascular and cerebrovascular disease. This comparison is important because both hypertension and diabetes are association with cognitive decline, even in a middle-aged population (Knopman, 2001). Thus it is not clear that this late decline is specific to the surgery or would occur in a similar 'at risk' population over time.

A possible delayed effect of CABG may reflect damage, and possible continuing damage to an area of the posterior parietal cortex where the three vascular territories come together. This area, designated a so-called 'watershed area', is particularly vulnerable to effects of hypoperfusion (Howard et al., 1987). Although some of these changes may be subclinical in nature, they may nonetheless be markers of underlying brain changes.

One of the few studies that have compared cognitive outcomes after CABG and angioplasty at later time intervals such as 5 years concluded that long-term cognitive function did not differ between the two groups (Hlatky et al., 1997). However, this study did not include any measures to assess visuoconstruction or visual memory, domains that others have found to be particularly susceptible to longer-term change (Aberg et al., 1983; Sotaniemi et al., 1986; Klonoff et al., 1989).

Predictive factors for cognitive outcome

Several studies have attempted to identify pre- or intraoperative predictors of cognitive change after CABG. It appears that short-term studies have consistently identified a set of predictors different from those in long-term studies. For example, in shorter-term evaluations (1 week to 1 month), increasing age, low education and increased numbers of emboli as determined by carotid ultrasound, are all associated with a higher incidence of cognitive change (Pugsley et al., 1994). In longer-term assessment, age and education were not associated with worse outcomes, but diabetes and severity of arteriosclerotic disease of the aorta were associated with declines in specific cognitive domains (Newman et al., 1995). This provides additional support to the interpretation that some of the immediate postoperative changes may be due to non-specific effects of surgery or anaesthesia, whereas the persistent or late cognitive changes may be more directly attributable to the effects of CABG (Selnes, 1999). It is not clear at present whether short-term decline predicts late decline. However, the studies of Newman (Newman, 2000) suggest this may be the case.

Depression and cardiac surgery

Depression is commonly reported after most cardiac surgery procedures, with a frequency of up to 25% (Langeluddecke et al., 1989). Most of the reports, however, do not take into account the preoperative mood of the patient in relation to the incidence of postoperative depression. Recent studies indicate that newly acquired depression after CABG is relatively uncommon and that preoperative depression is the best predictor of postoperative depression (McKhann et al., 1997; Timberlake et al., 1997). A common perception among physicians is that depression accounts for the cognitive changes, particularly deficits in memory, that occur after CABG. However, these same studies found no association between depressed mood and change in cognitive performance. As with outcome after myocardial infarction, discussed below, depression either before or in the postoperative period influences the response to CABG. Those with depression at these time points are significantly more likely to have the return of angina at 1 year or 5 years after surgery, as compared to those without depression.

Mechanisms of neurological injury following cardiac surgery

There has been considerable interest in the possible mechanisms of brain injury. Two major mechanisms have been proposed: intraoperative hypotension and multiple emboli. A degree of genetic susceptibility may also play a role.

Intraoperative hypotension

Many patients (60%) who undergo CABG have a history of hypertension. Since the mean arterial pressure during cardiopulmonary bypass is often quite low, less than 50 mm Hg, these previously hypertensive patients are subjected to temporary or fluctuating hypotension. Nevertheless, on the basis of an automated anesthesia record, Newman and colleagues (Newman et al., 1995) did not find a correlation between mean arterial pressure and cognitive outcome, except in the visual memory in older patients, suggesting that hypotension and hypoperfusion may be more important in older patients, but in younger patients a different mechanism may be involved. Another possibility is that longer-term follow-up is required to detect the neurobehavioural effects of hypoperfusion.

The role of emboli

Pathological examination of the brain after CABG by Moody and colleagues (Moody et al., 1990) revealed the presence of thousands of emboli lodged in brain microvessels. Small capillary/arteriolar dilatations (SCADS), as they were named by these authors, were first thought to be the response to air emboli. It is now thought that SCADS are lipid-containing emboli and that they also contain silicon and aluminium, which may be derived from the cardiopulmonary circuit and its tubing. Other studies indicate that the degree of arteriosclerotic disease of the aorta and the number of emboli detected by transcranial Doppler ultrasound are correlated with changes in cognitive function, adding support to the hypothesis that the cognitive changes are related to multiple cerebral emboli (Stump et al., 1996). The distribution of these emboli in the brain might account for the selective changes in specific cognitive domains that we and others have observed. Showers of these small emboli most likely scatter to distant branches of vessels.

It is possible that both hypoperfusion and embolic factors, as well as the effects of anesthesia, are involved in neurobehavioural changes: short-term abnormalities might be related to the combined, and perhaps additive effects of embolic damage and anesthesia. In contrast, longer-term changes may be more specifically associated with the CABG procedure with the concurrent use of cardiopulmonary bypass, hypothermia, and the manipulation of a diseased aorta (Brown et al., 1997).

The role of genetic factors

Tardiff and colleagues (Tardiff et al., 1997) examined the role of apolipoprotein E-e4 (APO E-4), a known genetic marker for late onset Alzheimer's disease. APO E-4 was associated with a decline in cognitive function at hospital discharge and 6 weeks postoperatively in four out of nine cognitive measures. The authors suggest that some individuals have decline in cognitive function because of genetically determined deficits in maintenance and repair of neuronal functions, but further study is required to confirm this possibility.

Cardiac arrest

The term 'cardiac arrest' refers to people who have the sudden onset of ineffective cardiac function. About half of these people have ventricular fibrillation or tachycardia with the remainder having asystole or pulseless electrical activity. Most cardiac arrests occur outside hospitals, and overall survival of this group is poor, despite prompt response of emergency personnel. For example, in New York City, the overall survival varied from 2% to 12% depending on the presence of emergency medical services (Westfal, 1996). In smaller cities, perhaps with better-organized emergency services, survivals are better: 14% are discharged from the hospital alive and 12% are alive 1 year later (Bottiger, 1999). The best survivals are in those with ventricular fibrillation/tachycardia, the worst in those in asystole or pulseless electrical activity. Favourable circumstances are younger persons with ventricular fibrillation, a witnessed cardiac arrest, early CPR by bystanders, and arrival of trained medical personnel within a very short time (four or less minutes) (Grubb, 2001).

Not surprisingly, the outcome after an in-hospital cardiac arrest is significantly better than when the event occurs outside the hospital. In addition, the increasing use of more novel antiarrhythmic agents (such as intravenous Amiodarone) to suppress further arrhythmia, together with higher-dose epinephrine or vasopressin (to promote a 'head-heart' circulation) may improve the initial procedural success.

Following successful resuscitation, the immediate survival in those with restored circulation is more dependent on cardiac than neurological factors, involving the prevention of further arrhythmias, maintenance of blood pressure, management of cardiac ischemia. Given the generally poor neurological outcome of cardiopulmonary arrest,

long-term improvements in cardiac outcome do not often translate to sustained benefits, however the combination of intravenous antiarrhythmic agents together with aggressive efforts towards revascularization may reduce the long-term mortality of such patients. Whether this translates to lower morbidity rates remains unproven.

Neurological outcomes after cardiac arrest

The increasing availability of emergency medical services and a more general use of CPR by the public has resulted in more people with cardiac arrest having restored circulation but with severe brain damage that is either irreversible or incapacitating. Thus it becomes increasing important to be able to make predictions about possible outcomes. If a person has a very low probability of surviving to discharge from the hospital then persistent acute management, such as continuing CPR, use of antibiotics and life saving interventions may be not be indicated. Further, if the long-range prognosis for functional brain recovery is slight, the family should be informed and discussion of approaches to therapy initiated (Grubb, 2001).

Outcomes predictions have been based primarily on clinical criteria, but have been augmented by neurophysiologic, laboratory and neuroimaging evidence. It is important to be clear about what time points after the arrest are being used in making predictions. In addition, the outcomes being judged should be defined, and may include: survival, motor function and/or cognitive ability.

Clinical criteria for outcomes after cardiac arrest

Immediately, and during the first few days after a cardiac arrest, the focus has been on the persistence and depth of coma and the lack of brainstem reflexes. Lack of pupillary light responses, corneal responses to touch and eye movements in response to head movements or cold caloric stimulation all indicate severe brainstem damage, with the possible exception of those exposed to suppressive medications. The use of the responses to predict outcome has been exemplified by the work of Levy, Caronna and coworkers who evaluated over 200 comatose patients, 150 of whom had had cardiac arrest. Patients were examined at 1, 3, 7 and 14 days after arrest and functional state was then categorized at 1, 3, 6 and 12 months into five grades: (i) no recovery (i.e. coma until death), (ii) persistent vegetative state (i.e. wakefulness awareness), (iii) severe disability (i.e. conscious but dependent on others for aspects of daily living), (iv) moderate disability (i.e. independent but with residual neurological deficits), (v) good recovery (i.e. able to resume prior level of function) (Levy, 1985).

Certain early signs were associated with relatively good chances of recovery. At the initial examination, the most favourable sign was incomprehensive speech (moaning), but this was rare. At 1 day, the following signs were each associated with at least a 50% chance of regaining independent function: confused or inappropriate speech, orientation of spontaneous eye movements, normal oculocephalic or oculovestibular responses, obedience to commands, and normal skeleton muscle tone. Although the pattern of motor responses eventually correlated with recovery, neither the initial absence of motor responses nor the presence of extensor of flexor posturing ruled out recovery. After 3 days, however, absent or posturing motor responses were incompatible with future independent living.

The absence of certain brain stem reflexes at the initial examination identified patients with little or no likelihood of meaningful recovery. Most patients destined to recovery wakened within a short time. By 3 days, 25 patients had regained consciousness; 19 of them went on to regain independent function. By 2 weeks, the number of conscious patients had risen to only 28, with 21 of them recovering independence. The vegetative state also developed rapidly in many patients; 47 patients appeared vegetative within the first day, but only 11 subsequently became independent. Of the surviving 33 vegetative patients at 1 week, only 3 patients ever improved to an independent state. The number of comatose patients dropped rapidly after the insult, with 106 still comatose after 1 day but only 57 at 3 days and 17 at 1 week. Only one of the 17 comatose patients at 1 week subsequently regained consciousness. Improvement after 1 month was rare. None of the 15 patients who were vegetative at 1 month ever regained independent function, and only 3 of 16 patients who were severely disabled at 1 month did so.

The death rate associated with anoxic coma of 6 hours or more was extremely high: 4 patients (20%) died within the first 24 hours, 86 patients (41%) by the end of 3 days, and 134 patients (64%) by the end of the first week. Only 19 patients (10%) survived 1 year after cardiac arrest, the majority of whom succumbed to non-neurologic causes.

This study showed that mortality and morbidity are high among patients in coma after anoxia, but some patients still have the neurologic capacity to do well. The study also found that careful analysis of early clinical information distinguished between good-prognosis and poor-prognosis patients. Patients with the best chance of recovery had intact brain stem function at the time of the initial examination after the cardiac arrest (reactive pupils and motor responses), as well as spontaneous roving eye movements. At 1 day and beyond, evidence of intact cortical function (motor response withdrawal or better and orienting eye movement) indicated the patients who would recover.

Neurophysiological testing and cardiac arrest

The techniques of EEG and cerebral evoked potentials have been used as possible predictive measures. EEG patterns of alpha coma, burst suppression or isoelectric activity have all been associated with poor prognosis, but are not absolutely specific. To be sure, an isoelectric, flat EEG is incompatible with life. At the other extreme, an EEG with normal alpha rhythms suggests a good prognosis. The grades in between indicate severe brain abnormality at the time of recording, but may not accurately predict prognosis. The absence of central responses to somatosensory stimulation, usually elicited by repetitive stimulation to the median nerve, indicates a poor prognosis. Conversely, those with normal central responses may have good recoveries. These neurophysiological tests are used as adjuncts to the clinical examination. They may prove useful as outcome measures for pharmacological interventions that might promote recovery.

Laboratory tests and cardiac arrest

There has also been interest in laboratory tests that reflect structural damage to the brain such as protein S.100 and neuron-specific enolase (NSE) (Martens et al., 1998). Most studies of these compounds have been made in small numbers of comatose patients. In general they do correlate with severe brain damage and poor outcomes, but it is not clear that they have prognostic value for those destined to survive, but with significant brain damage.

Brain imaging and cardiac arrest

The sequence of responses of the brain, particularly the cerebral cortex, can be followed by diffusion-weighted magnetic resonance imaging (DWI). Normally in the brain, water molecules move in random fashion (Brownian motion), resulting in low signal intensity on high-strength DWI images. With global anoxia, cytytoxic edema occurs, which leads to restriction of Brownian motion and an enhanced signal intensity. Whereas more conventional imaging techniques, such as CT scanning and MRI may be normal or equivocal, particularly in the first few hours after a cardiac arrest, DWI can reveal specific changes (Arbelaez et al., 1999). Within 24 hours, a bright signal may be present in basal ganglia, cerebellum, and cerebral cortex. Between 1 and 13 days, bright signals are seen cortex and may also be in deeper structures like the basal ganglia or thalamus. Some of these changes are also seen on conventional MRI, but are better demonstrated by DWI. These changes on DWI imaging reflect the selective vulnerability of specific neuronal populations to anoxic damage. The reasons for this vulnerability are not known but a higher metabolic rate by neurons, abnormal blood flow, particularly in the border zones between the distribution of vascular territories, and the presence of receptors for excitatory amino acids, such as glutamate may all play a role. In later periods (21 days or more) following the insult, the changes in cortex may disappear, but new changes appear in the white matter. Some investigators have detected these white matter changes even earlier, suggesting a myelinotoxic effect of anoxic/ischemic insult (Chalela et al., 2001).

Imaging techniques that indicate the degree of brain perfusion, such as positron emission tomography (PET) or single photon emission computed tomography (SPECT) indicate hypoperfusion of frontal areas as well as areas of hypoperfusion in the border areas between vascular distributions (so-called 'watershed' areas), but the logistics of these techniques are difficult to accomplish with these severely ill patients.

At present, no prospective study of outcome after cardiac arrest, combining the clinical observations with promising imaging (DWI) and neurophysiological (evoked potentials) techniques has been performed. Such a study is badly needed, not only for the desirability of making more accurate predictions in clinical situations but also to determine outcomes for therapeutic attempts.

Treatments following cardiac arrest

A number of treatment measures have been tried, either singly or in combination. These include attempts to decrease brain metabolism (hypothermia, barbituates, or administration of glucose), to decrease brain edema (dexamethasone) or block movement of calcium into cells (Nimodipine). Few of these measures have been consistently shown to improve outcomes or have been evaluated in clinical trials. However, for most persons undergoing cardiac arrest the damage has already been done by the time medical intervention is possible. Thus, the focus is on preventing further damage to nerve cells. There are a number of agents that are being evaluated in experimental animals as neuroprotective agents such as antioxidants, NMDA receptor antagonists, calcium channel blockers or statins. Some of these agents will undoubtedly be tried in attempts to improve outcome after cardiac arrest.

Congestive heart failure

Patients with congestive heart failure may have encephalopathic symptoms, with varying levels of confusion, variability in neurological findings, and global decrease in intellectual functions (Caplan et al., 1999). Sometimes this

encephalopathy is secondary to poor perfusion or embolic damage to other organs such as the liver, kidneys or lungs. At other times the condition is related to the use of medications such as those to treat pain, anxiety or the congestive failure. Others may have an underlying disorder of blood volume or electrolyte balance. When these underlying conditions are ruled out or corrected, there remains a group of patients for whom the cause of the encephalopathy is not known. Caplan et al. have described two clinical syndromes: the first resembles the encephalopathy of other causes. The second they refer to as 'abulia', a condition characterized by a marked reduction in spontaneous behaviour. Such people are listless, may be non-responsive, or very slow in responding. The mechanism is not clear, but these authors suggest there is retention of CSF within the cranial cavity. Such patients may improve after removal of fluid by lumbar puncture.

The influence of the brain on the heart

Although suspected to be the case for many years, the influence of the central nervous system on several cardiovascular disease states is now undeniable (Januzzi et al., 2000). Several diseases have well-established associations with both acute and chronic heart disease. Among these are migraine headache, subarachnoid hemorrhage, cerebral infarction, head trauma, and seizure disorder. Each of these may result in marked electrocardiographic abnormalities, occasionally associated with arrhythmias, or even myocardial necrosis.

In the case of migraine headache, a clear association with coronary vasospasm has been established, which may explain the link to myocardial injury states that have been occasionally reported in migraneurs without CAD (Wayne, 1986; Lafitte et al., 1996). Typically, the patient with concomitant migraine and myocardial infarction, is female, and has a history of diffuse vasospastic tendency, including Raynaud's phenomenon. The role of agents used for the treatment of migraine (such as the ergot alkaloids) in coronary spasm has also been established (Koh et al., 1994; Dahlof & Mathew, 1998). In addition, even in the absence of clear signs of coronary spasm, these agents frequently lead to chest pain of an ischemic nature (Koh et al., 1994; Dahlof & Mathew, 1998), and may lead to elevations in markers of myocardial injury in the absence of clear electrocardiographic abnormalities (J.L. Januzzi: personal observation).

The association between blood in the subarachnoid space and myocardial necrosis has been recently clarified (Zaroff et al., 1999; Zaroff et al., 2000a,b). The myocardial injury associated with subarachnoid hemorrhage may be diffuse; however, an unusual predilection for both 'apex-sparing' and 'apex-only' left ventricular dysfunction has been described (Zaroff et al., 2000a,b). Similar to the phenomenon of combined cerebral/coronary spasm seen in migraine headache, coronary spasm might be operative in the setting of subarachnoid hemorrhage as well. In many cases, however, a single epicardial vascular occlusion cannot adequately explain the wall motion abnormalities produced. In an experimental model, the possible involvement of direct neurological-mediated injury to the myocardium in the setting of subarachnoid hemorrhage was proposed, as the wall motion abnormalities closely approximated the distribution of the sympathetic nerve terminals in the myocardium (Zaroff et al., 2000a,b).

The most common cardiac manifestation of cerebral hemorrhage, large cerebral infarctions, seizures or head trauma are the so-called 'cerebral' changes on the electrocardiogram (Salvati et al., 1992; Lindgren et al., 1994; Strauss & Samuels 1994). These changes typically consist of giant precordial T-wave inversions. In addition, marked QT interval prolongation has been described. Rarely, patients with this 'cerebral' QT interval prolongation may develop polymorphic ventricular arrhythmia (Torsades de Pointes). It is theorized that the cerebral ECG changes are due to an exaggerated imbalance in the balance between sympathetic and parasympathetic cardiac tone.

Among the most studied (but perhaps least well-known) paradigm for the association between the brain and heart is the role of acute and chronic disorders of mood and affect (including stress, anxiety, and depression) on cardiac illness. Similar to other brain–heart syndromes such as those seen with cerebral infarction, these 'psychosocial risk factors' are thought to exert their deleterious effects on the heart via abnormalities in autonomic nervous system balance, with direct effects on the heart. In contrast to the aforementioned syndromes, however, are the rather profound peripheral effects on platelet function and vascular tone as well as due to psychosocial risk factors. Taken together, these effects would be expected to result in an impressive impact on the development and the complications of coronary artery disease, cardiac arrhythmias, and sudden cardiac death. Recent work has confirmed this fact (Januzzi et al., 2000).

The brain and development of cardiac disease

The relationship between the brain and the development of cardiac disease (including arrhythmia and coronary disease) had previously been suggested by numerous studies documenting an elevated risk from stress, anxiety, or depression. In each study, these disorders were associated with significant increases in sudden death or myocardial infarction (Table 122.2).

Table 122.2. Selected modern studies of anxiety (and related syndromes), depression, and the development of heart disease

Authors	Risk factor	End-point(s)	RR (95% CI)
Corywell et al. (1986)	Panic disorder	Death	2.0 (NR)
Haines et al. (1987)	Phobic anxiety	Death	(1.6–8.6)
		MI	1.3 (0.6–2.5)
Kawachi et al. (1994a)	Phobic anxiety	Sudden death	4.5 (2.4–15.7)
		MI	0.9 (0.5–1.8)
Kawachi et al. (1994b)	Anxiety	Sudden death	4.5 (0.9–21.6)
		Fatal CHD	1.9 (0.7–5.4)
Kubzansky et al. (1997)	Worry	MI	2.4 (1.4–4.1)
Anda et al. (1993)	Depressive symptoms	MI	1.5 (1.0–2.3)
Aromaa et al. (1994)	Depressive symptoms	MI	3.5 (1.8–6.8)
Pratt et al. (1996)	Major depression	MI	4.6 (1.7–12.4)[a]
Barefoot & Schroll (1996)	Depressive symptoms	MI	1.7 (1.2–2.3)
Ford et al. (1998)	Depressive symptoms	MI	2.1 (1.2–4.1)

Notes:

[a] RR of 2.1 (95% CI = 1.2–3.7) for symptoms of dysphoria.

NR, not reported; MI, myocardial infarction; CHD, coronary heart disease.

The role of neurological factors in the development of CAD was initially suspected following the recognition that anxious or depressed patients had a higher incidence of angiographically proven CAD (Zyzanski et al., 1976), as well as a fourfold increase in the incidence of myocardial infarction (Pratt et al., 1996). This link has been well supported by the Johns Hopkins Precursor Study, which recently reported that depressed patients had a highly significant doubling in CAD risk over a 40-year follow-up period (Ford et al., 1998).

The association between extreme emotional states and a rather significant increase in sudden cardiac death (as high as sixfold in one study) raised the possibility that these deaths could be related to cardiac arrhythmia (Kawachi et al., 1994a,b). Patients with depression have been demonstrated to have a higher incidence of ventricular tachycardia on non-invasive monitoring (Carney et al., 1993). Furthermore, in studies of patients with extreme mental stress, impressive episodes of malignant ventricular arrhythmias have been demonstrated, even among patients with structurally normal hearts. In addition, an increased incidence of sudden deaths (presumably due to cardiac arrhythmia) has been demonstrated in the setting of major natural catastrophes, such as earthquakes (Rosenman, 1996; Kario & Ohashi 1997) as well as following missile strikes during the Gulf War (Kark et al., 1995).

The mechanism of this increased predisposition to cardiac arrhythmogenesis is probably related to abnormalities in autonomic nervous system (ANS) tone, with increased resting levels of catecholamines (Yehuda et al., 1998; Carney et al., 1999; Grossman & Potter, 1999). In addition, among patients with anxiety and/or depression, derangements in baroreflex sensitivity as well as heart rate variability have been noted. Both of these findings are related to abnormalities in ANS tone (possibly regulated by somatosensory thalamocortical neurons), and are each independently associated with an increased risk for sudden cardiac death. This combination of factors, including elevated levels of catecholamines, would be expected to lead to a propensity to ventricular arrhythmia. Imaging studies would suggest that interactions between these risk factors and the dominant insular cortex may play a role in the genesis of arrhythmias (Svigelj et al., 1994; Eckhardt et al., 1999; Tokgozoglu et al., 1999), but this association has not been confirmed.

In most studies examining the relationship of psychosocial risk factors and CAD, the risk appears to be independent of conventional cardiac risk factors such as tobacco use, and compliance to medical therapies. The biological link to premature or accelerated CAD may be perturbations in blood lipid levels and endothelial function, increased platelet aggregability as well as abnormalities in vascular tone, which have been noted among these patients.

Table 122.3. Selected studies regarding anxiety, depression, and established ischemic heart disease

Authors	Risk factor	End-point(s)	RR (95% CI)
Frasure-Smith (1995a,b)	Anxiety	Fatal/non-fatal MI, UAP	2.5 (1.6–5.6)
Moser & Dracup (1996)	Anxiety	Death, MI, VT/VF, UAP	4.9 (2.1–12.2)
Thomas et al. (1997)	Anxiety	Death	1.06 (NR)[a]

[d] Male patients.

The brain and established heart disease

The link between the nervous system and established heart disease is widely accepted for several syndromes, including the long QT syndrome or those predisposed to neurocardiogenic (vasovagal) syncope. In both of these syndromes, extreme stress may provoke arrhythmic manifestations (ventricular tachycardia and severe bradycardia, respectively), which may be fatal. Until recently, however, the pervasively deleterious effects of the CNS on cardiac outcomes (especially among patients with CAD) were not recognized.

The effects of stress, anxiety, and depression on the outcomes of patients with established CAD is dramatic (Table 122.3). It has been repeatedly demonstrated that following an acute myocardial infarction (MI), the presence of any of these psychosocial risk factors may lead to as high as a fourfold increased risk of death (Frasure-Smith et al., 1995a), which may be due to either an increased incidence of recurrent MI, or malignant ventricular arrhythmias (Carney et al., 1988, 1993).

As among patients without known structural heart disease, the increased risk for CAD patients with stress, anxiety, or depression is probably mediated by the ANS, manifested as imbalances in sympathetic/vagal tone, increased levels of catecholamines, platelet hyperaggregability, high vascular tone, and abnormalities in hemostasis (Manuck et al., 1995; Markovitz et al., 1996, 2000; Markovitz, 1998).

Intense investigation into therapeutic intervention in this area is ongoing. At present, it is unclear whether management for psychosocial risk factors will rectify the increased risk for coronary events among these patients, however treatment with conventional serotonin reuptake inhibitor antidepressants has been shown to be safe in the coronary artery population (Roose et al., 1998; Shapiro et al., 1999). These drugs have been interestingly shown to possess effects on blood platelets, including an antiaggregatory effect (Markovitz et al., 2000). It is unclear whether this would be expected to result in a therapeutic benefit.

Neurological complications of hepatic and gastrointestinal disease

Benjamin H. Eidelman

Department of Neurology, Mayo Clinic, Jacksonville, Florida; Professor of Neurology, Mayo Medical School, Rochester, MN, USA

The liver plays a key role in the regulation of body metabolism, and its functions include the synthesis of essential substances and the degradation of toxins. Liver failure may be accompanied by system-wide disturbances. These are no better exemplified than by the striking cerebral syndromes that occur with hepatic dysfunction.

The brain depends on the gastrointestinal system as a source of nutrition. The neurological disturbances that occur as complications of gastrointestinal disease arise from a wide range of pathological processes and may be quite diverse in presentation.

This chapter focuses on the neurological syndromes that result from various types of liver failure. In addition, it describes the neurological complications of selected gastrointestinal disease.

Neurological complications due to liver disease

The relationship between the liver and the brain has been recognized since the time of Hippocrates. Since then, there have been many accounts of dramatic behavioural disturbances that may occur with liver dysfunction. These have been eloquently reported by Plum and Hindfelt (1976).

The spectrum of nervous system disturbances occurring with liver disease encompasses a wide range of neurological and behavioural disorders. The term 'hepatic encephalopathy' is commonly defined as a neuropsychiatric syndrome arising as a complication of liver dysfunction. Although the term 'encephalopathy' implies a disturbance of consciousness and behaviour only, the neurological syndromes occurring with liver disease encompass a much broader spectrum of neurological disorders. These diverse manifestations do not lend themselves easily to a single definition. Thus, hepatic encephalopathy cannot be regarded as a single clinical entity.

Furthermore, although hepatic encephalopathy has been defined as a reversible metabolic encephalopathy, and although this may often be true, chronic liver failure does sometimes result in progressive, irreversible neurologic dysfunction. The terminology is additionally confusing in that it is not uncommon to use the term 'portal systemic encephalopathy' interchangeably with 'hepatic encephalopathy' (Jones & Weissenborn, 1997) because pathological shunting of blood between the portal and systemic circulation frequently develops.

Liver failure may take several forms. Sometimes it develops rapidly, in a most dramatic fashion, but usually the onset is insidious and the evolution is slow, with permanent disturbances in liver system function occurring over time. Often, the course of chronic liver disease is punctuated by episodes of acute neurological deterioration. These episodes are usually reversible and are frequently related to a well-defined cause.

Syndromes

Thus, although the term 'hepatic encephalopathy' is frequently used to describe the neurological component of liver failure, the diverse neurological manifestations of liver disease do not lend themselves easily to a single definition. The neurological complications of liver disease may be considered as follows.

(i) Fulminant hepatic coma refers to neurological disorders developing as a consequence of acute hepatic failure (Bernstein & Tripodi, 1998).

(ii) Chronic hepatic encephalopathy (Jones & Weissenborn, 1997) has two subtypes: a slowly evolving syndrome and an intermittent disorder. The chronic subtype is gradual in onset, develops in the absence of a definable precipitating event, and becomes more severe over time. The intermittent subtype is character-

ized by sudden episodes of deterioration in neurological function, often precipitated by clearly definable causes such as protein overload or gastrointestinal hemorrhage. Both the chronic and the acute exacerbating syndromes are considered to be reversible.

(iii) Subclinical hepatic encephalopathy (Gitlin et al., 1986) refers to subtle disturbances in cognitive function that occur in association with chronic liver disease. The abnormalities are not clinically evident and are detected only by neuropsychometric testing.

(iv) Acquired hepatocerebral degeneration is a less common neurological complication of chronic liver disease characterized by progressive, non-reversible neurologic disturbances (Victor et al., 1965).

Fulminant hepatic coma

Fulminant hepatic coma occurs in the presence of acute, often fatal, liver dysfunction (Bernstein & Tripodi, 1998). The hepatic failure occurs without pre-existing liver disease, and the encephalopathy usually develops within several weeks of onset of the liver disease. Three subgroups of fulminant hepatic failure have been proposed (O'Grady et al., 1993): hyperacute, acute, and subacute. Causes of fulminant hepatic failure include viral disease, idiosyncratic drug reactions, toxins, metabolic disorders and cardiovascular disease (Shakil et al., 1999). The onset of the encephalopathy is usually abrupt and in some instances may precede the constitutional symptoms (Zacharski et al., 1970). Agitation, delusional behaviour and restlessness may dominate the clinical picture in the early phases, only to be followed by the rapid onset of coma. Restlessness may be an early feature; this often is accompanied by marked facial grimacing. Later, as the patient becomes lethargic and motor activities are reduced, tremors of the limbs may develop, but asterixis is uncommon. Myoclonus may be noted during this phase. Seizure has also been reported (Bernstein & Tripodi, 1998; Saunders et al., 1972). Hypoglycemia is a common complication of a fulminant hepatic failure, and this may be a factor in the causation of seizures (Samson et al., 1967).

The prognosis in fulminant hepatic failure was extremely poor before the introduction of liver transplantation (O'Grady et al., 1988). Now, survival ranges from 50% to 70% (Bismuth et al., 1987; Vickers et al., 1988). The principal reason for high mortality is the development of cerebral edema and resultant raised intracranial pressure (Ede & Williams, 1986).

The management of fulminant hepatic encephalopathy hinges on recognition and treatment of raised intracranial pressure (Ede & Williams, 1986). Intracranial pressure monitoring is required, and measures such as hyperventilation (Ede et al., 1986) or infusion of mannitol (Canalese et al., 1982) have been used to decrease intracranial pressure. Intravenous phenobarbital has a place in the treatment of this disorder (Forbes et al., 1989). Propofol, which is easy to titrate, is also coming into use in the management of fulminant hepatic encephalopathy.

Chronic hepatic encephalopathy

The clinical features of chronic hepatic encephalopathy vary considerably (Adams & Foley, 1953; Sherlock et al., 1954). Slow evolution is the rule. This is a complex syndrome and includes several components, namely neurobehavioural disorders, motor disturbances, and impaired consciousness (Adams & Foley, 1949; Sherlock et al., 1954).

Neurobehavioural disorders

Cognitive decline Cognitive decline may be an early manifestation of liver disease (Read et al., 1967), and the initial features may be subtle and evident only to friends and family members. Individuals become withdrawn and apathetic, lack interest and appear slow in response times. At this stage, bedside testing of cognitive function may reveal abnormalities such as an inability to reproduce simple geometric patterns, and handwriting may be altered. In some instances, verbal skills may be spared; patients are thus able to compensate and mask the true nature of the disturbance. Minor changes in intellectual function over time may give way to severe cognitive impairment, and eventually, severe confusion becomes apparent.

Personality changes Personality changes may become apparent early in the course of the development of this syndrome (Sherlock et al., 1954). The patients' behaviour may become inappropriate and somewhat childlike. These traits, however, are often quite subtle and are also apparent only to family and close friends. Patients also tend to be restless, wandering around aimlessly, often exhibiting irrational behaviour, but sometimes preoccupied by repetitive, seemingly aimless tasks. Inappropriate behaviour may become quite obvious. Patients fail to observe basic social graces and often appear dishevelled and pay little attention to their surroundings.

Disturbances of sleep Other early signs of chronic hepatic encephalopathy include hypersomnia and inverted sleep rhythm (Summerskill et al., 1956).

Motor disorders

Asterixis Asterixis, also known as flapping tremor, is a common feature in chronic liver failure (Adams & Foley, 1953; Read et al., 1967). The features of asterixis have been characterized by Leavitt and Tyler (1964). These authors describe a complex of movement disorders in which tremor is combined with typical asterixis, and the two conditions appear to be inter-related. Asterixis is best demonstrated by maintaining the arm in a static posture, outstretched and with the hand held in a position of fixed dorsiflexion. The involuntary movements develop after a latent period lasting from 2 to 30 seconds. Tremulousness develops first. There tends to be an initial involuntary movement of the fingers taking the form of flexion and extension excursions, with some rotation at the wrist. Fine, random motions of the fingers may also occur. As posture is maintained, tremulousness increases, and the random movements may become more rapid. Then follows the development of the asterixis, which takes the form of a sudden flexion movement of the fingers and hand. This downward movement varies in excursion. This 'flexion lapse' is followed by a rather rapid, sometimes violent, backward movement restoring the extremity to its former posture. Both upper limbs tend to be involved, although the asterixis may occur asynchronously. Often, the movements may occur in 'clusters' of two or three, followed by a quiet phase. The patient is unable to influence the movement. Whereas asterixis is commonly seen in liver disease, it may occur with other types of metabolic dysfunctions (Leavitt & Tyler, 1964; Tyler, 1968) and toxic states (Kobayashi et al., 1985). Electromyographic studies (Adams & Foley, 1953) reveal electrical silence at the moment of the onset of the postural lapse, suggesting inhibition of the anterior horn cell, perhaps secondary to a disturbance of supraspinal motor control.

Myoclonus Multifocal myoclonus may become apparent (Read et al., 1967). This complication is most often seen at times of waning consciousness.

Alterations in tone Liver disease may produce marked changes in muscle tone (Adams & Foley, 1953). This may be of pyramidal or extrapyramidal type. The latter is similar to the rigidity observed in Parkinson's disease.

Extrapyramidal disturbances Extrapyramidal disturbances may be a prominent component and include rigidity, bradykinesia, facial masking, speech disturbances, and tremor (Adams & Foley, 1953; Read et al., 1967; Victor et al., 1965).

Table 123.1. Grading of hepatic encephalopathy

Grade	Mental state
0	Normal function
1	Mild personality and cognitive disturbances
2	Lethargy, disorientation, inappropriate behaviour
3	Somnolence, arousable gross behavioural disturbances
4	Coma or unarousable

Pyramidal system abnormalities Signs of pyramidal tract dysfunction may emerge as hepatic failure progresses. Increased tone with hyperreflexia and clonus may be found (Adams & Foley, 1953; Read et al., 1967; Victor et al., 1965). Plantar responses may be initially flexor but later become extensor in nature. As coma supervenes, tendon responses diminish.

Impaired consciousness and coma

Coma may occur terminally but may also emerge as a component of an intermittent event (see below). Patients become lethargic over time, consciousness gradually dwindles, and patients may slip into profound coma. In some cases, however, the onset of coma may be abrupt (Adams & Foley, 1953). Motor reactions to painful stimuli persist until the late phase of coma. Decerebrate and decorticate posturing may be evident (Conomy & Swash, 1968; Juneja & Yovic, 1972). The pupillary light response and ocular motor reactions are often retained almost to the last (Plum & Hindfelt, 1976). Coma unrelated to a treatable precipitating cause has a poor prognosis (Bustamante et al., 1999), unless liver transplantation is performed.

Whereas disturbed awareness is perhaps the central feature of various forms of hepatic encephalopathy, the state of consciousness may vary considerably during any episode of hepatic dysfunction. Thus, it has become customary to grade hepatic encephalopathy into four stages, based on the level of consciousness. A commonly used scale is outlined in Table 123.1.

Seizures

Seizures may complicate the clinical picture. These may be of the partial or generalized type (Adams & Foley, 1953).

Disturbance of speech

Speech may become deliberate and slow; later dysarthria may become prominent (Adams & Foley, 1953). Paratonic rigidity and grasping and sucking reflexes may occur as coma develops (Adams & Foley, 1953; Sherlock et al., 1954).

Table 123.2. Conditions that may precipitate hepatic encephalopathy

Excessive protein intake
Diuresis
Gastrointestinal tract hemorrhage
Diarrhea and vomiting
Surgical procedures
Infection
Pharmacological agents
Constipation
Alcohol consumption

These signs may be seen in end-stage coma as well as in the episodic syndromes that complicate chronic hepatic disease.

Disorders of ocular motility

Disturbances in eye movements may become apparent as coma evolves: skew deviation and internuclear ophthalmoplegia have been described (Plum & Hindfelt, 1976). These abnormalities may be transient and resolve as metabolic function improves. Divergence of the eyes in the primary position and disturbed oculocephalic responses to caloric testing may also occur (Caplan & Scheiner, 1980; Cartlidge & Bates, 1978). Transient ocular bobbing has also been reported (Rai et al., 1976), as has reversible periodic alternating gaze (Averbuch-Heller & Meiner, 1995). Ocular motility disorders occurring with hepatic coma are reversible but closely resemble the ocular findings in structural brainstem disorders. Awareness of the similarities between eye movement disorders due to liver failure and those due to a structural brainstem process is important because the finding may divert attention from the true nature of the diagnosis (Caplan & Scheiner, 1980).

Intermittent hepatic encephalopathy

Intermittent hepatic encephalopathy is characteristic of chronic liver failure (Jones & Weissenborn, 1997; Plum & Hindfelt, 1976; Sherlock et al., 1954; Victor et al., 1965). The episodes are most often precipitated by well-defined events (Table 123.2) and may come abruptly. Alteration in consciousness occurs and motor disturbances may be prominent. The individuals become increasingly somnolent, and a state of deep coma may supervene. In some instances, however, restless behaviour and agitation may be the dominant manifestation. The patients may become disoriented, and signs of overt delirium emerge. Motor accompaniments include asterixis, involuntary facial movements, and tremulousness. These motor disturbances may abate as coma deepens.

Dramatic as the presentation may be, treatment of the precipitating factor will usually result in remission of the signs and symptoms.

Subclinical hepatic encephalopathy

The term 'subclinical hepatic encephalopathy' was introduced to describe a disorder in patients with chronic liver disease who have no overt signs of nervous system dysfunction, yet cognitive disturbances are evident on formal psychometric testing. This condition was first described by Zeegen et al. in 1970. Other studies have confirmed the presence of abnormality on psychometric testing in patients with chronic liver disease (Conn, 1994; Gitlin et al., 1986; Sarin & Nundy, 1985). Although the reported prevalence of subclinical hepatic encephalopathy varies widely (Groeneweg et al., 2000), there is a strong body of evidence to indicate that this entity does exist (Hartmann et al., 2000; Schomerus & Hamster, 1998; Tarter et al., 1989).

Acquired hepatocerebral degeneration

Acquired hepatocerebral degeneration, a chronic form of hepatic encephalopathy, was described in detail by Victor and colleagues (1965). This disorder usually occurs in patients with chronic liver disease complicated by extensive portal–systemic shunting (Victor et al., 1965). As with other neurological complications of liver disease, the clinical manifestations are diverse. The course is characterized by a steady decline in neurologic function. An episodic deterioration in neurologic status may be superimposed; these exacerbations are often related to defined precipitating factors. The condition progresses over time, and patients become increasingly disabled. There are two major components to this form of hepatic encephalopathy, namely cognitive dysfunction and motor disturbances (Jog & Lang, 1995).

Cognitive dysfunction

Acquired hepatocerebral degeneration evolves out of the more common reversible neurologic disturbances that complicate chronic liver disease. Thus, personality and intellectual changes are often apparent in the early course of the process. In time, cognitive disturbances become severe and persistent. Apathy and slowness in response times become apparent. There is a general lack of interest in the environment. As in other types of dementia, lack of attention to personal appearance and poor hygiene become apparent. However, signs suggestive of focal cortical dysfunction such as language disturbances and apraxia are rarely seen.

Motor disorders
Motor disorders may dominate the clinical picture, and various abnormalities are found.

Tremor Both resting and action tremors have been described. Resting tremor is common. This may resemble Parkinson disease, but a coarser, grosser type of tremor may also occur. The tremor may interfere with skilled tasks and at times may become severe enough to affect ability to perform simple daily tasks. Postural tremor is also common. This is most obvious when the limbs are held with the arms outstretched. The tremor is usually distal and has a large amplitude, with a frequency of 4 to 7 Hz (Jog & Lang, 1995). The upper limbs are more affected than the lower limbs, but such movements may also be seen in the head and trunk. In some instances, the tremors migrate from a distal to a proximal distribution and sometimes may be asymmetrical, involving one side of the body more than the other. The tremor can be disabling, making it impossible for the patient to write or lift a cup without spilling its contents (Read et al., 1967).

Chorea Choreiform movements may be generalized but in some instances may be most prominent in the tongue and face. These have been likened to the abnormal movements seen in Huntington chorea (Victor et al., 1965), but protrusion–retraction movements of the tongue with accompanying grimacing of the face suggest a similarity to tardive dyskinesia (Jog & Lang, 1995). The resulting distortion of facial expression can be quite marked. Repetitive lower limb movements, akathisia-like in nature, may also be present.

Parkinson-like syndrome A fine tremor of the fingers and hands, seen at rest and closely resembling that of Parkinson disease, has been described (Read et al., 1967). Other features suggesting Parkinson disease may also be seen, including mask-like facies, cogwheel rigidity, and severe bradykinesia. The last may involve all extremities. Extrapyramidal dysfunction may contribute to disturbances of speech and balance.

Asterixis Asterixis may be evident during the course of the disease. The clinical features are similar to those found in the reversible form of chronic hepatic encephalopathy as described above.

Disturbances of gait Gait disturbances may take the form of slowness of ambulation, poor postural control with a tendency to fall on turning, and a staggering gait (Victor et al., 1965). The abnormalities of gait may reflect involvement of numerous structures, and in addition to cerebellar disturbances, extrapyramidal and pyramidal impairment may contribute to the overall disruption of gait.

Cerebellar disturbances Cerebellar ataxia is a common feature of chronic hepatic dysfunction and has been described by many authors (Bernstein & Tripodi, 1998; Jog & Lang, 1995; Victor et al., 1965). Both truncal and limb ataxia may be prominent. Intention tremor may be evident in upper and lower limbs. Gait may be wide based and unsteady, with a tendency to lurch from side to side. The disturbance in ambulation may be prominent. Speech may be affected, and in some cases the dysarthria may be extremely prominent.

Myelopathy Myelopathy, although relatively uncommon, is a well-described complication of chronic hepatic failure. Myelopathy in association with chronic liver disease was first reported by Leigh and Card (1949). They described a largely motor syndrome characterized by ambulation difficulties and bladder dysfunction with sparing of sensation. This patient did indeed have features suggestive of hepatocerebral dysfunction, but he later developed Hodgkin disease and spinal cord compression requiring radiation therapy. However, there have since been several reports of hepatic myelopathy (Campellone et al., 1996; Liversedge & Rawson, 1966; Pant et al., 1968; Zieve et al., 1960a,b). The clinical picture is usually of an insidious progression of a spastic paraparesis. Bouts of hepatic encephalopathy may worsen the myelopathic features and the dysfunction appears to accumulate with each episode. Involvement is predominantly of the lower limbs, although some motor dysfunction may also occur in the arms. Sensation is largely spared but disturbance in bladder function does develop.

Pathogenesis of hepatic encephalopathy

Pathology

Histologically, chronic forms of hepatic encephalopathy are characterized by changes in the protoplasmic astrocytes (Bernstein & Tripodi, 1998; Finlayson & Superville, 1981; Victor et al., 1965). These cells proliferate and become hypertrophied, which results in morphological abnormalities termed 'Alzheimer type II astrocytosis'. The astrocytes appear swollen; the nucleus becomes pale. Other changes include prominent nucleolus and margination of the chromatin pattern (Butterworth et al., 1987; Norenberg, 1987). These morphological changes appear to be mirrored by disturbances in cell function, which include altered expression of the enzymes glutamine syn-

thetase (Lavoie et al., 1987) and monoamine oxidase (Rao et al., 1993). Alteration in peripheral-type benzodiazepine receptor density has also been described (Lavoie et al., 1990). These findings may have some implications for the pathogenesis of hepatic encephalopathy (Butterworth, 1998; Hazell & Butterworth, 1999).

Potential gut-derived toxins

The clinical features of hepatic encephalopathy appear to be best explained on the basis of altered brain chemistry induced by gut-derived toxins (Jones & Weissenborn, 1997). Distortion of hepatic cytoarchitecture is a characteristic of cirrhosis of the liver. This promotes the development of collateral venous channels (Gerber & Schomerus, 2000). These channels, which may be internal, namely within the liver itself, or external, result in shunting of blood from the portal to the systemic circulation, allowing blood to bypass the liver. Thus, substances derived from the gut may readily enter the systemic circulation without passing through the liver. As liver disease progresses, the metabolic capacity of the liver declines. This may compromise the ability of the liver to detoxify substances delivered by the portal vein, thus further increasing the systemic load of unaltered, gut-derived factors.

Ammonia

There are many potential toxins that may arise by way of the gastrointestinal tract (Jones & Weissenborn, 1997). Ammonia has received the most attention, and there is a strong body of evidence to indicate that this substance plays a major role in the genesis of hepatic encephalopathy. Ammonia is derived from several sources: intestinal tract, skeletal muscles, kidneys, and catabolism of proteins (Gerber & Schomerus, 2000). Ammonia originating in the gut is produced by the action of the intestinal flora on urea and food-derived protein substances as well as from the intestinal wall catabolism of glutamine. Ammonia is detoxified by two major pathways: (i) the Krebs–Henseleit cycle, resulting in the production of urea, and (ii) the synthesis of glutamine from glutamate by the action of glutamine synthetase.

Ammonia was one of the first toxins to be implicated in the genesis of hepatic encephalopathy, and this view still prevails (Gerber & Schomerus, 2000). Increased ammonia concentrations are often present in the blood of patients in hepatic coma (Gerber & Schomerus, 2000). Also, it has been shown that ammonia readily crosses the blood–brain barrier, and the cerebral metabolic rate for ammonia is increased in hepatic encephalopathy (Lockwood et al., 1991). Furthermore, there appears to be increased brain sensitivity to the adverse effects of ammonia in the presence of hepatic encephalopathy (Hazell & Butterworth, 1999).

Although it is clear that ammonia is toxic to the brain, the chemical basis for this action is complex and appears to involve a number of different processes. These may include alterations in neurotransmission, impairment of brain energy metabolism, increased expression of peripheral-type benzodiazepine receptors, excessive production of nitric oxide, and the inhibition of the ability of astrocytes to accumulate glutamate (Gerber & Schomerus, 2000; Hazell & Butterworth, 1999).

Ammonia appears to play a major role in the genesis of hepatic encephalopathy, but other mechanisms also appear to be involved.

Manganese

Manganese is neurotoxic and is excreted by the hepatobiliary system (Hazell & Butterworth, 1999). Blood manganese concentrations are increased in the presence of hepatocellular failure. Magnetic resonance imaging studies have revealed abnormal signals in the pallidum attributed to manganese deposition (Kulisevsky et al., 1992; Spahr et al., 1996). Histopathological studies have revealed Alzheimer type II astrocytosis in the pallidum of patients where magnetic resonance imaging studies had previously revealed abnormal signal indicative of manganese accumulation (Kulisevsky et al., 1992). Moreover, autopsy studies have confirmed the presence of high pallidal manganese concentrations in chronic liver disease (Krieger et al., 1995; Pomier-Layrargues et al., 1995). These findings suggest a role for manganese in the pathogenesis of certain components of hepatic encephalopathy.

Methionine derivatives

Increased levels of methionine derivatives, mainly mercaptans, have been described in hepatic encephalopathy, and earlier literature suggested they have a role in inducing hepatic encephalopathy (Chen et al., 1970; Phear et al., 1956). However, there are no indications that methionine derivatives increase ammonia concentrations, and they probably have no direct effect in inducing hepatic encephalopathy.

Synergism

Thus, many factors appear to contribute to the development of hepatic encephalopathy. Ammonia appears to play a central role in the genesis of the syndrome, but its actions are complex, affecting many aspects of cell function. Other substances, manganese in particular, appear to contribute to the pathologic disturbances in the central

nervous system, and may synergize with ammonia. Other processes may also be involved.

Neurological disorders after liver transplantation

Various neurological disturbances have been reported to occur after liver transplantation (see Chapter 129). The clinical features of some post-transplantation syndromes bear resemblance to the neurologic disturbances that occur with hepatic encephalopathy. These post-transplantation syndromes thus deserve further review.

Syndromes

Two clinical entities, in particular, are observed after liver transplantation, namely (i) impairment of consciousness and (ii) movement disorders.

Impairment of consciousness

Impairment of consciousness may be encountered in postliver transplantation patients. Well-defined conditions such as anoxic encephalopathy, central pontine myelinolysis, cerebrovascular events, and immunosuppressive agent-induced toxicity may account for the majority of such cases. In some, however, there is no immediate explanation for the patient's state of unresponsiveness.

Many features of such complications resemble the components of hepatic encephalopathy. Patients who fail to regain consciousness after liver transplantation may show decerebrate rigidity and abnormal movements, particularly in the form of facial grimacing, and the reflexes of release may be prominent accompanying features (Eidelman et al., 1991).

Akinetic states occurring after liver transplantation have been attributed to the toxic effect of immunosuppressive agents (Bird et al., 1990; Wijdicks et al., 1994, 1995), but a similar clinical picture may also be apparent in the coma associated with chronic liver disease.

Movement disorders

Severe movement disorders have been described in liver transplant recipients (Bird et al., 1990; de Groen et al., 1989; Eidelman et al., 1991). These have usually been attributed to the immunosuppressant agents tacrolimus and cyclosporine A. Such disturbances include severe postural tremor, myoclonus, bucco-facial-lingual dyskinesia, and Parkinson-like states as well as cerebellar tremor. These clinical disturbances in many instances bear striking resemblance to the movement disorders that may occur in the various forms of hepatic encephalopathy.

Causes of neurological disorders after liver transplantation

Immunosuppressive agents are neurotoxic, and immunosuppressive therapy has been implicated as a cause of postliver transplantation coma and neurologic complications, but this view has been challenged (Burkhalter et al., 1994). Not all postliver transplantation neurologic complications may be new, and the lingering effects of preexisting hepatic coma may contribute to neurological dysfunction after transplantation. Whereas postliver transplantation neurologic complications are likely to develop in patients who have severe, chronic, portal-systemic encephalopathy before transplantation (de Groen et al., 1989; Eidelman et al., 1991), severe neurological complications are less common in kidney and heart transplant recipients who receive similar immunosuppressant medication (Starzl et al., 1990). These findings lend credence to the hypothesis that pre-existing, severe hepatic encephalopathy may predispose to the development of post-transplantation neurological syndromes.

That the clinical syndromes seen after transplantation are extensions of pre-existing hepatic encephalopathy is not entirely unexpected. Even when the transplantation procedure results in the replacement of a functioning liver, the restoration of astrocyte function and reversal of other chemical changes due to the previous liver failure are not likely to occur immediately.

Furthermore, liver transplantation is an extremely complicated and often lengthy procedure and in itself is extremely stressful. Surgical procedures and exogenous factors are known to precipitate hepatic coma. The operation involves three stages: (i) the recipient hepatectomy, (ii) the hepatic phase, and (iii) the period of reperfusion (Carton et al., 1994). Marked hemodynamic fluctuations may occur during the course of the operation. Blood loss may be profound, often necessitating transfusion of large volumes of blood products. Blood pressure will often fluctuate, and profound hypotension may occur. Alterations in electrolyte concentrations may also occur, and at times there may be major fluxes in sodium and potassium concentration. Stress of this nature would be expected to have a negative effect. Thus, the transplantation procedure could itself result in acute neurological deterioration or exacerbate pre-existing hepatic encephalopathy.

Despite these negative effects, the advent of liver transplantation has improved survival of patients with fulminant hepatic encephalopathy (Bismuth et al., 1987) and of

those with more chronic forms of hepatic encephalopathy (Gordon et al., 1991; Jamieson et al., 1991). Post-transplantation improvement in neurological disturbances related to pre-existing hepatic encephalopathy has also been observed (Hockerstedt et al., 1992), demonstrating that recovery of neurological function does occur after transplantation. However, the process is likely to be slow. In one patient with advanced signs of chronic hepatocerebral degeneration, marked improvement in neurological status followed liver transplantation, but this process took 6 months or more (Powell et al., 1990).

Thus, although neurological disturbances occurring after liver transplantation may be due to the stress of the surgical procedures or to negative effects of immunosuppressive therapy, some may be due to previously existing hepatic encephalopathy. It appears possible for hepatic encephalopathy to resolve in the long term after liver transplantation.

Hepatic encephalopathy in the absence of cirrhosis

Portal–systemic encephalopathy

Excessive shunting of blood from the portal to the systemic circulation plays a critical role in the genesis of the neurologic complications observed in chronic liver disease. Abnormal portal–systemic shunting may also occur in the absence of liver dysfunction, resulting in similar neurological disturbances (Watanabe, 2000). The clinical entity of hepatic encephalopathy occurring in the absence of liver disease and associated with congenital intrahepatic shunting was first described by Raskin et al. in 1964. Portal–systemic shunts of various types have since been reported in patients without cirrhosis, and the subject has been extensively reviewed by Watanabe (2000).

The etiology of abnormal vascular channels is varied. Such channels may be of congenital origin and may be either intrinsic or extrinsic in nature. All allow large amounts of blood derived from the gut to bypass the liver, making it possible for gut-derived toxins to reach the brain and promoting the development of hepatic encephalopathy and its many neurological manifestations.

As in the cirrhotic form of hepatic encephalopathy, ammonia appears to play a key role in the development of the neurologic complications associated with this type of encephalopathy. In this entity, however, the clinical and biochemical features of liver disease are absent. Symptoms may be precipitated by protein loading as well as by exogenous factors in common with hepatic encephalopathy. Abnormal portal–systemic shunting, although rare, may be a cause of such neurological presentations as unexplained coma or episodic confusional states.

Increased ammonia concentrations in the absence of other chemical abnormalities indicative of liver disease suggest the diagnosis and should prompt further testing directed at detection of abnormal portal–systemic vascular channels. The diagnosis depends on elevated ammonia levels, absence of clinical and biochemical evidence of hepatic dysfunction, and the demonstration of abnormal vascular channels between the portal and systemic circulation.

Surgical occlusion of the portal–systemic channels may in some cases provide effective treatment. However, liver transplantation may be required if the vascular malformations are diffuse and not amenable to occlusion by surgical or other techniques.

Hyperammonemia

In most cases, increased ammonia concentrations occur as a result of liver-related disorders. Hyperammonemia, however, may occur in other circumstances, including certain bacterial infections, hemodialysis, drug-induced hyperammonemia, and inherited hyperammonemia.

Bacterial infections

Hyperammonemia with accompanying hepatic encephalopathy has been described in association with *Helicobacter pylori* infections (Ito et al., 1995) as well as with high urease-producing bacteria of the proteus type (Kuntze et al., 1985).

Hemodialysis

Ammonia concentrations may increase during the course of hemodialysis with the circle absorptions method together with a dialysis regenerating system (Canzanello et al., 1983).

Medication-induced hyperammonemia

Sodium valproate may induce hyperammonemia by impairing the urea cycle enzymes (Batshaw, 1984).

Inherited hyperammonemic syndromes

Hyperammonemic disorders unrelated to liver disease occur largely as a result of hereditary disorders of metabolism arising out of enzyme deficiencies of the urea cycle (Breningstall, 1986). These conditions are largely autosomal recessive and manifest primarily in the neonatal period or in childhood.

However, two of these disorders present in adulthood, namely ornithine transcarbamylase deficiency (Rowe et al., 1986) and argininosuccinic urea (Walser, 1983). Ornithine transcarbamylase deficiency may be characterized by episodic ataxia, periodic confusion, alterations in tone, bizarre behaviour, seizures, and coma. The episodes may be of short duration, sometimes lasting for only a few hours. They are often precipitated by protein ingestion, although they may occur after anesthesia and surgery. Ammonia and bilirubin concentrations may be increased during attacks. Seizures and intermittent cerebellar ataxia may occur with argininosuccinic acid urea. Excessive dryness and brittleness of the hair may complicate this condition.

An increased ammonia concentration in the absence of other features suggestive of liver disease signals the possibility of an inherited hyperammonemia. The diagnosis, however, rests on specific enzyme assays. Liver tissue is required for this and is usually obtained by biopsy.

Wilson disease

Wilson disease is an inherited disorder of copper metabolism and is transmitted in an autosomal recessive manner (Frydman, 1990). The disease is characterized by impaired hepatic excretion of copper, which accumulates to excess in tissues such as the brain, cornea and liver. Accumulation of copper in the liver eventually results in hepatocellular necrosis with the development of liver failure. Deposition of copper within the cornea produces the development of Kayser–Fleischer rings. Excessive copper within the brain results in degeneration of the basal ganglia and other structures, ultimately leading to nervous system failure (Pfeil & Lynn, 1999).

Pathophysiology

Copper is derived from the diet and is an essential component of some enzymes, including superoxide dismutase as well as dopamine beta-hydroxylase. Copper is normally transported to the liver, where it undergoes metabolic transformation. In one pathway it is incorporated with apoceruloplasmin to form ceruloplasmin. It is also excreted into the bile by an adenosine triphosphate-dependent carrier protein. In Wilson disease, both defective incorporation into ceruloplasmin and impaired biliary excretion occur.

Serum concentrations of ceruloplasmin are usually decreased in Wilson disease, but ceruloplasmin deficiency probably does not play a causative role in the manifestation of the disease, and the low concentrations may be an epiphenomenon (Pfeil & Lynn, 1999).

As copper accumulates, the hepatocytes are damaged. Copper is released into the circulation and deposited in other organs, including the brain and kidneys. Excess copper is toxic, acting as a pro-oxidant to promote the formation of free radicals and resulting in the harmful oxidation of lipids and proteins.

Genetics

The gene for Wilson disease was localized to chromosome 13 by Frydman et al. (1985). The gene has since been cloned (Bull et al., 1993; Tanzi et al., 1993). It codes for a P-type adenosine triphosphatase that functions as a copper transporter. The gene defects include small deletions, insertions, or missense mutations. If the gene defect is present, copper transportation is impaired, with a resultant decrease in biliary copper excretion and accumulation of hepatic copper.

Hepatic dysfunction

Hepatic dysfunction is the initial manifestation in more than 50% of patients with Wilson disease. This may take the form of chronic active hepatitis, cirrhosis, and fulminant hepatic failure.

Neurological manifestations

Nervous system manifestations of Wilson disease usually develop in the second or third decade of life (Strickland & Leu, 1975). Presentation before adolescence or after the age of 40 is unusual. Tremor is the most common initial symptom. This is quite variable, and it may be largely of the resting variety, although a strong postural or kinetic component may also be present. The tremor is often asymmetrical and may vary in amplitude. The head may be involved, and in some instances there may be a marked tremor of the 'wing beating-type' in the proximal upper extremity (Walshe, 1986). Drooling is a frequent early symptom, and this may be accompanied by dysarthria. Dystonia of the bulbar musculature may supervene, impairing movement of the lips, tongue, pharynx and jaw. The resulting speech disturbance may be severe enough to cause a state of mutism. The jaw may hang open and lip retraction may be prominent, resulting in a characteristic facial appearance. Impairment of gait may develop, and patients may eventually become bedridden as a result. Psychiatric features include emotional lability, impulsiveness, disinhibition, and affective symptoms.

Ocular findings

The Kayser–Fleischer ring is a characteristic ocular abnormality in Wilson disease. This is a brownish–green discolouration of the Descemet membrane in the limbic area of the cornea. It may be detected by the naked eye, but a slit lamp is often required to facilitate identification. Sunflower cataracts, night blindness, xerophthalmia and strabismus have also been reported. Kayser–Fleischer rings are present in nearly all patients with Wilson disease complicated by nervous system involvement, but may be evident in only 55% to 70% of patients with isolated hepatic disease (Ferenci, 1999).

Diagnosis

The diagnosis of Wilson disease rests on clinical findings and biochemical tests. There is no single laboratory test that is sensitive enough to specifically detect Wilson disease, but diagnosis rests on the measurements of serum ceruloplasmin, urinary copper excretion, the detection of Kayser–Fleischer rings, and slit-lamp examination. Wilson disease is suggested by the presence of at least two of the following conditions: (i) typical neuropsychiatric abnormalities, (ii) serum ceruloplasmin concentration $<$20 mg/dl; and (iii) demonstration of Kayser–Fleischer ring.

Low serum concentrations of ceruloplasmin are found in most patients with Wilson disease, but 15% of patients have values within the normal range (Steindl et al., 1997; Stremmel et al., 1991). Other conditions such as protein deficiency states may also result in low concentrations of ceruloplasmin. Twenty-four-hour monitoring of urine copper excretion has also been used to diagnose Wilson disease, although in some patients who are not yet symptomatic, copper excretion may not be excessive. High urinary copper concentrations may also occur in cholestatic liver disease, in which copper may be released from hepatocytes. Determination of total serum copper concentration is of little diagnostic value because the low serum ceruloplasmin fraction often contributes to a low total serum copper concentration.

The concentration of free serum copper is usually elevated in Wilson disease, and this may be potentially more useful as a diagnostic test. Although it has been stated that Kayser–Fleischer rings are invariably present once neuropsychiatric signs of Wilson disease have emerged, there are reports indicating that a small percentage of patients with this form of Wilson disease have no detectable Kayser–Fleischer rings (Ross et al., 1985; Willeit & Kiechl, 1991). Thus, if Kayser–Fleischer rings are absent and there is a strong suspicion of Wilson disease, further testing, including liver biopsy, may be required to determine hepatic copper content. This is regarded as a reliable diagnostic test.

Magnetic resonance imaging has increasingly been used to diagnose Wilson disease. A variety of abnormal findings have been detected (Hitoshi et al., 1991; Mochizuki et al., 1997).

Treatment

Treatment of Wilson disease consists of exclusion of copper-containing foods from the diet and use of chelating agents such as penicillamine and trientine. These may be combined with zinc acetate, which binds dietary zinc and copper. Ammonium tetrathiomolybdate, an experimental agent that forms complexes with albumin and copper in the bloodstream and decreases copper availability for cellular uptake, gives promise of being an effective treatment.

Liver transplantation has largely been reserved for treatment of patients with fulminant or end-stage liver disease. However, this mode of therapy has also been used with promising results, primarily for the treatment of neurologic manifestations. Neurological status improved in most patients (Chen et al., 1997; Schumacher et al., 1997).

Selected gastrointestinal disorders

Inflammatory bowel disease

The inflammatory bowel diseases include Crohn disease (regional enteritis) and ulcerative colitis. These conditions differ from each other in many aspects (Pfeiffer, 1996). Ulcerative colitis appears to be an autoimmune disorder, whereas the etiology of Crohn disease is less clear. Ulcerative colitis is largely confined to the colon and rectum. Crohn disease can involve all segments of the gastrointestinal tract. The pathology and clinical features also differ (Pfeiffer, 1996). However, extraintestinal manifestations occur with both conditions, and the neurological complications are similar. Thus, these diseases can be considered together.

General considerations

Nervous system manifestations of gastrointestinal tract disease may take several forms. Complications may arise from nutritional deficiency and from the side effects of the various medications used for treatment of the inflammatory bowel disorder. The majority of neurological complications,

however, appear to be mediated by the same pathophysiological mechanism responsible for the development of the primary intestinal disorder.

The development of the nervous system manifestations may precede the clinical onset of the gastrointestinal tract disease and does not always parallel the severity of the primary organ involvement. Intestinal manifestations may appear to be mild, but the accompanying neurological developments may be extremely severe and disabling. Neurological disturbances may be apparent during exacerbations of gastrointestinal tract disease, and they also occur during phases of remission. The nervous system manifestations of inflammatory bowel disease can be classified as follows.

1 Peripheral nervous system complications
   (a) Peripheral neuropathy
   (b) Myopathy
2 Central nervous system manifestations
3 Complications arising from vascular pathology
   (a) Arterial occlusions
   (b) Venous occlusions
   (c) Vasculitis
4 Complications arising from therapeutic measures
5 Complications of direct spread of infection

Peripheral nervous system

The peripheral nervous system is most commonly affected. Various types of neuropathy may occur, including acute inflammatory demyelinating polyneuropathy, mononeuritis multiplex, and brachial plexopathy. More chronic axonal or demyelinating peripheral neuropathy may also occur (Lossos et al., 1995). Abnormalities of the autonomic nervous system have also been reported (Straub et al., 1997).

Cranial nerves may also be involved, and there are reports of disturbances of the eighth nerve (Hollanders, 1986) and peripheral facial disturbances. The peripheral facial disturbances are a complication of an orofacial, granulomatous process, described as a complication of Crohn disease (Cleary & Batsakis, 1996). The features of the eighth nerve disturbance bear a strong resemblance to the Melkersson–Rosenthal syndrome, which is characterized by facial swelling, peripheral facial nerve palsy, and plication of the tongue. The facial nerve palsy may be recurrent in nature. There is indeed literature to support the contention that the Melkersson–Rosenthal syndrome is a component of Crohn disease (Ilnyckyj et al., 1999).

Inflammatory myopathy as well as dermatomyositis may occur as a complication of both ulcerative colitis and Crohn disease (Kulkarni et al., 1997; Lossos et al., 1995). Orbital myositis manifesting with orbital pain, swelling, and proptosis has also been reported (Durno et al., 1997).

Central nervous system involvement

Brain magnetic resonance imaging studies have demonstrated an increased incidence of focal white matter lesions in inflammatory bowel disease (Geissler et al., 1995). Such lesions are usually asymptomatic and may be of ischemic origin. Multiple sclerosis has also been described in association with ulcerative colitis. The concurrence of these diseases appears to be greater than expected, raising the possibility of similar pathogenesis (Kimura et al., 2000).

Myelopathy may also occur, usually of the chronic, progressive type. A rapidly evolving form of myelopathy occurring as a component of encephalomyeloneuritis has also been described (Kraus et al., 1996).

Neurological complications relating to vascular pathology

Inflammatory bowel disease appears to be associated with an increased risk of thrombosis, although the mechanisms have not been fully elucidated. Cerebrovascular complications have been reported, and these may arise from either arterial or venous thrombosis (Lossos et al., 1995). Venous thrombosis, including both venous sinus and cortical vein occlusion, appears to be more common (Das et al., 1996; Derdeyn & Powers, 1998).

The lupus anticoagulant has been implicated as a risk factor for the development of venous thrombosis in inflammatory bowel disease (Papi et al., 1995).

Central nervous system vasculitis, a complication of inflammatory bowel disease, has been implicated in the genesis of the central nervous system white matter lesions reported in ulcerative colitis (Dejaco et al., 1996).

Complications arising from therapeutic measures

Corticosteroids are used frequently in the treatment of inflammatory bowel disease. Benign intracranial hypertension (pseudotumour cerebri) has been described as a complication of corticosteroid use, both during maintenance therapy (Newton & Cooper, 1994) and during tapering of corticosteroid treatment (Liu et al., 1994).

Acute encephalopathy has been described as a component of sulfasalazine-induced hypersensitivity vasculitis (Schoonjans et al., 1993).

Complications of direct extension of disease

Meningitis and spinal epidural abscess may arise as a result of contiguous spread of infection from the bowel

into adjacent vertebral structures (Wallace & Luchi, 1995). The lumbosacral plexus may be involved in a similar manner (Demarquay et al., 1998).

Whipple disease

Whipple disease was first reported in 1907 (Whipple, 1907) and was then described as a primary gastrointestinal tract disorder. Whipple also identified rod-shaped bacteria, implicating an infectious etiology. It has since become apparent that this disease has wider ramifications and should be regarded as a multisystem disturbance. The diagnosis has traditionally relied on duodenal biopsy and the demonstration of macrophages that stain prominently with periodic acid-Schiff (PAS) (Pfeiffer, 1996). The organism can now be identified by polymerase chain reaction (PCR)-based assay (Relman et al., 1992). There is also evidence to suggest that the organism can under some circumstances be propagated in cell culture (Schoeden et al., 1997). The gastrointestinal manifestations include fever, weight loss, abdominal pain, and chronic diarrhea (Fleming et al., 1988). Extraintestinal features may be prominent, with involvement of the skin, joints, and lymph nodes. In some instances, this involvement may precede the onset of the intestinal symptoms. Neurological involvement, although rare, may result in profound disability. The central and peripheral nervous systems may be affected, and the presentation is quite varied.

Central nervous system manifestations

The neurological features of Whipple disease may include behavioral disturbances, progressive dementia, ataxia, hypothalamic dysfunction, seizures, myoclonus, and meningitis (Adams et al., 1987; Comer et al., 1983; Fleming et al., 1988; Pallis & Lewis, 1980; Pollock et al., 1981). Disturbances of eye movement may be prominent. Nystagmus and disturbances of conjugate gaze may occur (Finelli et al., 1977). An unusual combination of pendular ocular movements and associated syndromes with contraction of facial, masticatory, and limb muscles, termed 'oculomasticatory myorhythmia', is regarded as pathognomonic for cerebral Whipple disease (Adler & Galetta, 1990; Schwartz et al., 1985). The ocular component takes the form of convergent–divergent pendular nystagmus, although rhythmic vertical eye movements have also been described (Knox et al., 1976). The accompanying extraocular movements may include syndromes with contraction of the facial–masticating muscles as well as the limb muscles (Rajput & McHattie, 1997). Both the spinal cord (Clarke et al., 1998) and the peripheral nervous system may be involved.

Diagnosis

The diagnosis of Whipple disease depends on the detection of PAS-positive macrophages and the identification of rod-shaped bacilli within these cells on electron microscopy.

Traditionally, such studies have been carried out on duodenal biopsy specimens, but similar findings have also been reported in brain biopsy specimens (Mendel et al., 1999). PCR as described earlier in this section may be of value in detecting the organism.

Treatment

Treatment of Whipple disease requires the use of antibiotics that cross the blood-brain barrier. Response to antibiotic treatment is variable, but the neurologic manifestations may not remit and may recur after treatment is discontinued (Schnider et al., 1996).

Neurological complications of total parenteral nutrition

The small intestine is the primary site for absorption of food and other substances necessary to maintain adequate nutritional status. The mucosal surface of the small intestine may be compromised by disease processes that affect the absorption capacity of this organ. Trauma, bowel ischemia, and conditions (such as volvulus) that compromise circulation may result in gangrene with loss of a considerable portion of the small bowel, resulting in decreased capacity to absorb nutrition. Adaptive mechanisms may come into play. Depending on the length of surviving bowel, these may be adequate to maintain enteral nutrition. In some instances, however, a state of chronic malabsorption ensues, necessitating parenteral nutrition. This is termed 'short-bowel syndrome'. Permanent total parenteral nutrition (TPN) may be required to sustain life. Small bowel transplantation is a treatment option and may eliminate the need for TPN. However, this procedure is only offered in a few centres, and TPN is the most widely used method for maintaining nutrition in the presence of short-bowel syndrome.

TPN may be complicated by the development of several neurologic disorders. These may arise directly from disturbances occurring at the site of catheter placement but may also be more generalized, often developing as a result of metabolic disturbances (Wolfe et al., 1986).

Local vascular complications

TPN requires the placement of a large catheter in a proximal vein. The presence of such catheters, particularly in the long term, promotes the development of venous thrombosis. This may involve the internal jugular vein, with the secondary development of pseudotumour cerebri (Saxena et al., 1976).

Metabolic complications

Various metabolic disturbances have been described in TPN-supported patients (Wolfe et al., 1986). Hypophosphatemia is one of the more frequently reported occurrences, and this may be complicated by peripheral neuropathy with prominent sensory and motor features (Furlan et al., 1975; Siddiqui & Bertorini, 1998; Silvis et al., 1980). In some instances, hypophosphatemia may evolve rapidly, in a manner suggesting Guillain-Barré syndrome (Furlan et al., 1975; Siddiqui & Bertorini, 1998).

Wernicke encephalopathy has also been reported as a complication of TPN (Vortmeyer et al., 1992). This condition is promoted by inadequate (or lack of) thiamine supplementation. The clinical course has been shown to evolve at a rapid rate. Pathological abnormalities are extensive, and the findings are atypical, both in distribution of pathology and in the histologic abnormalities. This is possibly because of the rapid development of the deficiency state.

Renal disease and electrolyte disturbances

G. Bryan Young and Charles F. Bolton

Department of Neurology, London Health Sciences Centre, University of Western Ontario, Canada

Renal disease can affect neurological function either directly, through the effects of retained uremic toxins, or indirectly through complications of renal failure or its treatment (Fraser & Arieff, 1994). With the exception of urological and ultimately nephrological complications of spinal disease or autonomic neuropathy, nervous system disorders rarely affect the kidney. Some systemic disorders may affect both the kidneys and the brain. These are discussed under the headings uremic encephalopathy (acute and chronic), uremic neuropathies and myopathy, complications of therapy for uremia and systemic disorders.

Uremic encephalopathy

Uremia is a clinical syndrome related to profound loss of renal function. Uremic encephalopathy is divided into acute (ARF) or chronic (CRF) varieties. These differ more than in acuity, as a number of metabolic and endocrine disturbances and compensatory adjustments take time to fully evolve in CRF. Some may ameliorate and others contribute to adverse effects of kidney failure on the CNS.

Acute uremic encephalopathy

Acute renal failure (ARF) can be divided into prerenal (circulatory failure), post renal (obstructions to outflow) and specific renal causes (Conger & Schrier, 1975). At least 40% of ARF cases occur in an acute medical setting (Hou, 1983).

Clinical features

There are few specific features that differentiate uremic encephalopathy from other metabolic encephalopathies. However, the following combination suggests uremia, after the exclusion of exogenous agents: (i) an encephalopathy with hyperventilation from a metabolic acidosis; (ii) excitability, including prominent myoclonus or seizures.

As with other metabolic encephalopathies, early changes include lethargy, irritability, problems with concentration and attention, disorientation, omissions in speech and sleep disturbances (Locke et al., 1961). Patients are usually subdued, but delirium, or an agitated confusional state, may be found. There may be periods of profanity, euphoria, depression or catatonic stupor (Wilson, 1940). Coma from acute uremia is found when the patient is *in extremis* (Gowers, 1888).

Cranial nerves are usually intact, although fundi may reflect arterial hypertension. Seizures, usually in the form of generalized convulsions and often multiple, occur in the oliguric phase (Locke et al., 1961). Focal seizures are not usually consistently from the same site, unless they relate to an associated structural lesion. Patients may feel weak and demonstrate multifocal myoclonus that is so prominent that the muscles appear to be fasiculating (Plum & Posner, 1980). Action myoclonus has been described (Chadwick & French, 1979). Tetany may also be found. Focal signs such as hemiparesis are not rare, but subside with dialysis and may switch sides with recurrent episodes.

Investigations

Blood tests confirm renal impairment and may show the alterations in electrolyte balance, acid–base balance and anemia that commonly accompany uremia. The electroencephalogram (EEG) reflects the level of consciousness: slowing of frequencies occurs in parallel with the severity of the encephalopathy (Cadilhac & Ribstein, 1961). Triphasic waves are commonly encountered in the obtunded patient (Fig. 124.1). Generalized epileptiform discharges occur in about 25% of children with acute uremia, but these are rare in adults (Chaptal et al., 1954).

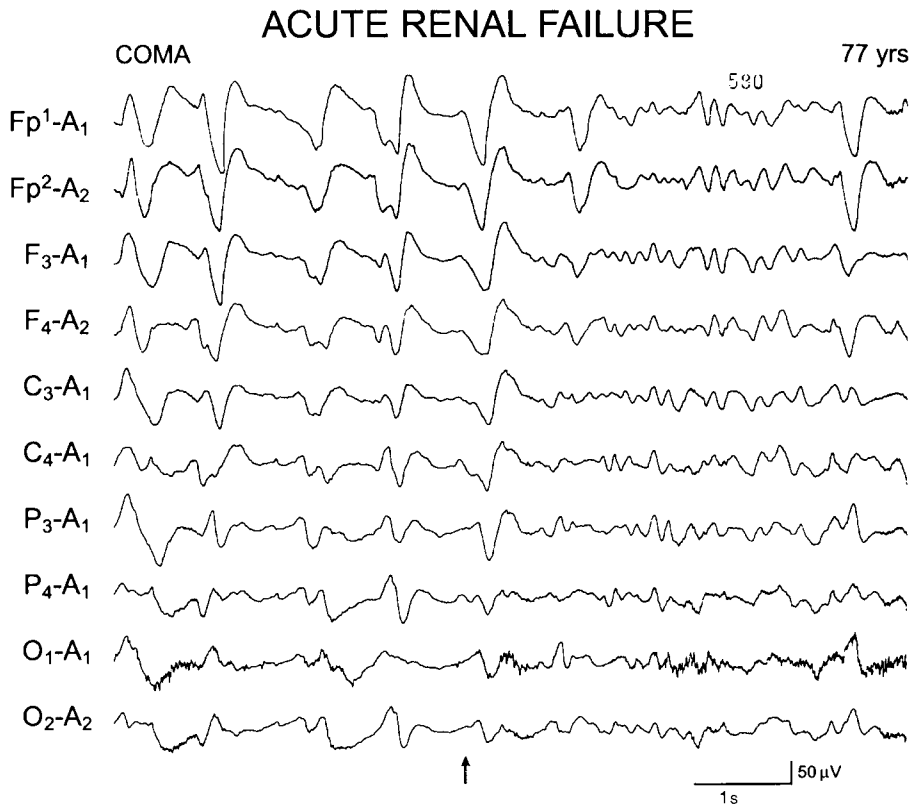

Fig. 124.1. Triphasic waves are seen in this EEG recording in a 77-year-old woman with acute renal failure that occurred with septic shock. The triphasic waves are attenuated and faster frequencies appear after the nail bed was squeezed (at arrow). There is a small amount of muscle artefact (very short duration, high frequency potentials) appearing intermittently in the second last channel.

Differential diagnosis

The main differential diagnosis is accelerated hypertension with hypertensive encephalopathy. The latter is usually associated with papilledema, which is rare and unexpected in uremic encephalopathy. Elevated CSF protein is more characteristic of hypertensive than uremic encephalopathy.

Other conditions that may cause both encephalopathy and systemic acidosis include exogenous toxins such as methanol, ethylene glycol, salicylates and paraldehyde. Diabetic ketoacidosis, anoxia, sepsis with circulatory failure and lactic acidosis should not pose diagnostic difficulty. Penicillin intoxication (with huge doses) may cause an encephalopathy with seizures as well as acute renal failure. In children, lead intoxication enters the differential diagnosis (Needleman, 1994). Papilledema and other evidence of raised intracranial pressure are commonly present in childhood lead intoxication with impaired consciousness. There may be a 'lead line' in the gingivae and radiological bony abnormalities (Needleman, 1994).

Management

The first step is to determine the category and specific cause of ARF, especially reversible causes. Pre- and post-renal causes, precipitants (myoglobin, hemoglobin, urate crystals) and nephrotoxic drugs should be sought first. These require specific management steps contained in general medical texts.

Fluid intake needs to be adjusted with respect to the cause of ARF, but usually needs to be restricted depending on urinary output. Steps should be taken to reduce catabolism by increasing carbohydrate intake. Serum potassium needs to be closely monitored, as life-threatening hyperkalemia is a constant risk. Congestive heart failure, acute hypertension, fluid and electrolyte imbalance and infections need to be looked for, prevented and managed promptly when they occur.

Not all patients require dialysis, but can be managed conservatively with correction of the underlying cause and expectant observation. Absolute indications for dialysis include: development of CNS complications, resistant

hypertension, fluid overload, severe acidosis and uremic pericarditis.

Other management, including antiepileptic drug therapy, is discussed under CRF.

Chronic renal failure

The specific neurotoxin of uremia has not been identified, but it is unlikely that a single retained chemical species will account for uremic encephalopathy for all patients (Massry, 1985; Bolton & Young, 1990; Moe & Sprague, 1994). Uremic neurotoxins could alter: neurotransmitter and synaptic function; enzymes; the sodium–potassium pump mechanism; transcription from DNA to messenger RNA, phosphodiesterase and phosphoinositide functions; or phosphate transfer in various enzymes and microtubular function.

Clinical features

In CRF, signs and symptoms are less florid or fulminant than in ARF; they are also considerably ameliorated by treatment, such as dialysis. Lethargy and fatiguability, problems concentrating, slowness in thinking and impaired memory function are common with CRF whether or not patients are on regular dialysis programmes (Tyler, 1970; Heilman et al., 1975). More detailed neuropsychological studies have shown impairment in complex cognitive functions, including spatial synthesis and other visual perceptual tasks, logical–grammatical and mathematical operations (Bosach & Schlebusch, 1991; Brancaccio et al., 1981). Headaches, sleep disturbances, dysarthric speech and abnormal hormonal, including sexual, functions occur *parri passu* with these issues.

The following motor phenomena are common manifestations of uremic encephalopathy: tremor, myoclonus, asterixis, paratonic rigidity, primitive reflexes (rooting, grasp and snout). A coarse, irregular postural action tremor is best seen on supporting the limbs against gravity or on reaching for something. Myoclonus may be multifocal or synchronous in uremia (Stark, 1981). Asterixis represents centrally mediated brief muscular relaxation in a part of the body that is being actively supported against gravity. Paratonic rigidity is the resistance to passive movement of a limb and tends to disappear when the limb is moved slowly. Seizures, usually generalized convulsions, may occur as a near terminal event, preceded by coma, in very advanced, untreated uremia (Glaser, 1974). They are uncommon in hemodialysed patients, unless they occur near the start of therapy (dialysis dysequilibrium) or if a complication arises, e.g. stroke or metabolic upset, such as a sudden change in acid–base or electrolyte composition or hypocalcemia (Tyler, 1968). Focal seizures are not often repeated in a stereotypic fashion unless there is an underlying structural lesion.

Uremic meningitis may complicate chronic uremic encephalopathy. Consciousness is not seriously compromised, but patients exhibit nuchal rigidity and a positive Kernig's sign (Madonick et al., 1950).

Investigations

Routine EEG may be normal with mild encephalopathy, but often shows intermittent bursts of low voltage theta (>4, <8 Hz rhythmic waves). With more severe encephalopathy the EEG shows slowing of frequencies and an increase in amplitude. The occipital rhythm may show progressive slowing in serial EEGs. Bursts of rhythmic delta (<4 Hz waves) are common, especially on arousal from sleep (Jacob et al., 1965). Triphasic waves (Fig. 124.1) may be superimposed on background slowing. A photomyogenic response (muscle twitches of the face coincident with light flashes) or photoparoxysmal (generalized epileptiform discharges in response to photic stimulation) may be found. Bursts of irregular generalized spike and wave may also occur spontaneously during the recording.

Frequency changes can be detected more readily with quantitative methods using the strategies developed by Teschan, Bourne and colleagues (Teschan, 1975; Bourne & Teschan, 1983). This can be a sensitive method for determining the optimal effectiveness of dialysis strategies. Event-related potentials, especially middle latency auditory evoked responses, can be used in a similar fashion to show improvement with dialysis.

Neuroimaging is usually unhelpful. Cerebral atrophy may accompany dehydration; magnetic resonance imaging (MRI) may show reversible changes (low signal intensity T_1-weighted and high signal on T_2-weighted) in the periventricular white matter, basal ganglia and internal capsule. These disappear or vary with dialysis (Okada et al., 1991).

In patients with CRF and meningismus, the cerebrospinal fluid may show up to 250 lymphocytes/mm^3 and up to 1.0 g/l (100 mg/dl) protein concentration.

Management

Every effort should be made to correct reversible causes of renal failure and to maximize the function of the kidneys with conservative means. Dietary restrictions of fluid, potassium, sodium, phosphate and ultimately protein are usually necessary.

When CNS symptoms persist or develop after correction of reversible factors and institution of conservative therapy, dialysis is necessary. Peritoneal dialysis and

hemodialysis reverse many of the neurological and systemic complications of uremia, but many are incompletely corrected. Patients on dialysis often feel chronically ill, with reduced stamina, problems concentrating or maintaining attention and have memory problems and sleep disorders. Some may continue to have seizures. Peripheral neuropathy may persist. In addition, a host of systemic problems including chronic anemia, secondary hyperparathyroidism, osteopenia, malnutrition, hypertension, immunological deficiency, bleeding diatheses and pruritis may persist.

Many of these are completely reversed by successful renal transplantation (Teschan et al., 1977).

Uremic neuropathies

Uremic polyneuropathy

The nature of the polyneuropathy induced by the toxic effects of renal failure is determined largely by the severity of the renal failure and the effects of various forms of treatment. Thus, it is absent or mild during the acute or the early stages of renal failure, although Brismar and Tegnèr (1984) have shown evidence of neuropathy in ARF in an animal model. By the time end-stage renal disease is reached, however, 50% of patients have polyneuropathy. It tends to stabilize during treatment by chronic hemodialysis or peritoneal hemodialysis, and then regularly improves with successful renal transplantation (Bolton & Young, 1990).

Clinical features

The earliest and most prevalent symptoms are restless leg syndrome, muscle cramping, and distal paresthesias, not always resulting from the neuropathy but at times from transient metabolic disturbances. The burning foot syndrome, caused by a deficiency of the water-soluble B vitamins that are washed out during the hemodialysis procedure, is now rarely seen because of proper vitamin supplementation. In more severe neuropathies, distal weakness (most marked in the legs), a stocking–glove loss of sensation to all modalities, and an unsteady gait occur.

The earliest signs of uremic polyneuropathy are loss of vibration sense in toes and reduction of deep tendon reflexes, beginning with ankle jerks (Jennekens et al., 1971). Severe cases of polyneuropathy causing quadriplegia are now rarely seen because of early institution of hemodialysis or peritoneal dialysis. When such cases do occur, one should be suspicious that intercurrent infection may be the important factor; it is now known that sepsis itself can induce a polyneuropathy called critical illness polyneuropathy (Zochodne et al., 1987).

The cerebrospinal fluid protein level in uremia may be normal or elevated, and the degree of elevation bears some relationship to the severity of the polyneuropathy (Jennekens et al., 1971). The cell counts are normal.

Overt clinical signs of autonomic dysfunction are probably uncommon, but more careful testing reveals abnormalities in a high percentage of patients. This appears to affect both the sympathetic and the parasympathetic nervous systems (Solders et al., 1985). The normal variation in the cardiac RR interval tends to decrease (Fig. 124.2); the more severe the renal failure, the more marked is the decrease. Sympathetic system abnormalities may be demonstrated by the Valsalva test, the tilt test, the forced handgrip test, the cold pressor test, the mental stress test, and the sweat test. Autonomic system neuropathy in uremia can be stabilized by chronic hemodialysis, and it regularly improves after successful renal transplantation.

Neurophysiological studies

Standard motor and sensory nerve conduction studies remain the best method of documenting the incidence and severity of polyneuropathy. Conduction velocity decreases in parallel with renal function, as measured by the creatinine clearance test (Nielsen, 1973b) (Fig. 124.3). Compound muscle and sensory nerve action potential amplitudes decrease because of dispersion from secondary demyelination or fallout of larger myelinated axons from a primary axonal degeneration (Bolton, 1976; Nielsen, 1973a). Needle electromyography may be distinctive. Fibrillation potentials and positive sharp waves may be relatively absent in human uremic muscle, possibly due to the inhibition of extrajunctional acetylcholine receptors. This may also explain failure of collateral reinnervation of muscle, which is dependent on the presence of these receptors (Bolton et al., 1997b). Thus, there may be little spontaneous activity, and motor unit potentials may be decreased in number, small in size, but polyphasic, suggesting a myopathy (as noted below).

Computer analysis (Hanson & Ballantyne, 1978) has shown the number of motor unit potentials as reduced to one-third of the normal value. Single-fibre electromyographic studies (Konishi et al., 1982; Thiele & Stålberg, 1975) indicate that the density of muscle fibres within a unit is normal; this suggests a failure of collateral reinnervation. The variation in the interval between the firing of single muscle fibre potentials, so-called jitter, is likely related to peripheral demyelination. Somatosensory evoked potential studies reveal that conduction is slowed along both the peripheral and the central segments of

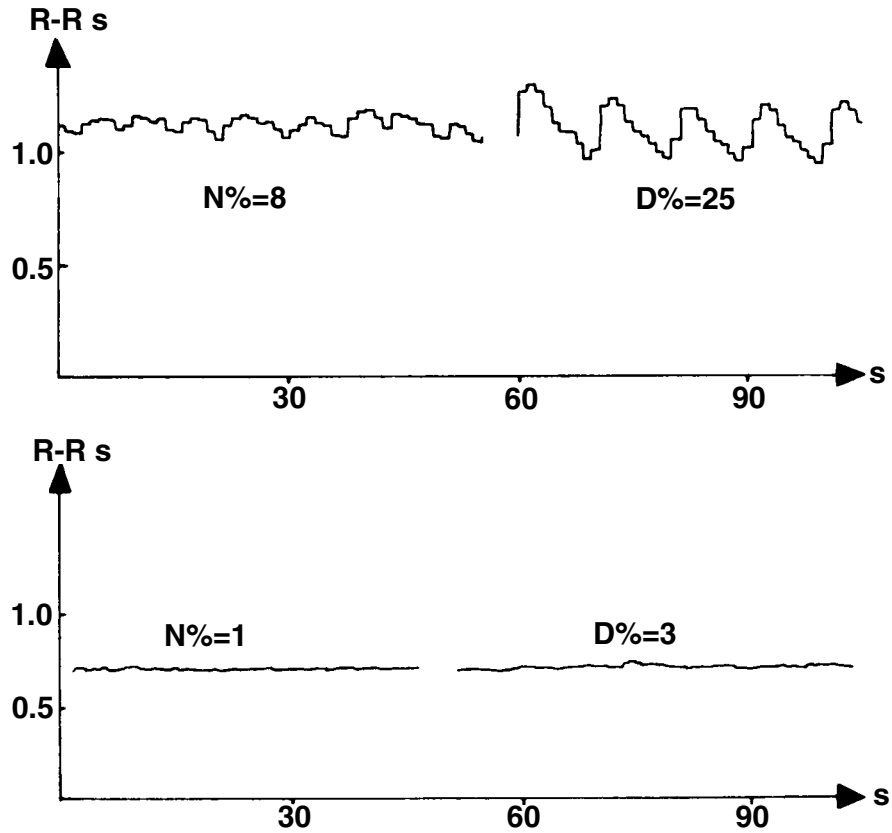

Fig. 124.2. Abnormality in the cholinergic autonomic nervous system in chronic renal failure. (Top) Electrocardiographic RR variation in a patient in advanced renal failure. At this time the RR variation was normal in the resting state and after deep breathing (N% and D% refer to the percentage variation with normal breathing and with deep breathing). (Bottom) The same patient developed more marked renal insufficiency, which required intermittent hemodialysis. The RR interval is now abnormal, with little variation either at rest or with deep breathing, indicating cholinergic autonomic insufficiency. (Reprinted with permission from Solders et al., 1985; Mnksgaard International Publishers Ltc., Copenhagen, Denmark).

primary sensory neurons, including transcallosal conduction (Serra et al., 1979; Vaziri et al., 1981). H reflex and F wave studies, which measure conduction on motor fibres both proximally and distally, have shown some prolongation of latencies in up to 85% of patients in end-stage renal failure, particularly those undergoing chronic hemodialysis (Panayiotopoulous & Laxos, 1980).

Because disordered sensation is the earliest symptom in uremic polyneuropathy, tests to measure it quantitatively would be quite valuable. Studies by Nielsen (1975) and Tegnèr and Lindholm (1985), with the use of hand-held vibrators, have shown elevated thresholds in 83% of patients in end-stage renal failure. Quantitative sensory testing shows abnormalities in 39% of patients with uremic neuropathy, and an unusual perception of heat in response to low temperature stimuli in 42%; it was an early sign of neuropathy (Yosipovitch et al., 1995).

Pathophysiology

The etiology and mechanisms or uremic neuropathy are still not understood (Bolton & Young, 1990). Conduction velocity is slowed in motor and sensory fibres, both large and small, along proximal and distal segments. There is clearly an underlying demyelination because conduction velocity is slowed more than would be expected from pure axonal degeneration. Moreover, there is a relative preservation of compound muscle action potential amplitudes that are often dispersed on more proximal stimulation. However, conduction block has not been seen. There is also elevation of excitation thresholds, a prolonged refractory period, abnormal responses to changes in limb temperature and ischemia, and evidence from voltage-clamp studies that there is a decrease in excitability and in the specific sodium permeability F-nodal membrane. Nielsen (1973a, 1974, 1978) theorized that uremic toxin inhibits the

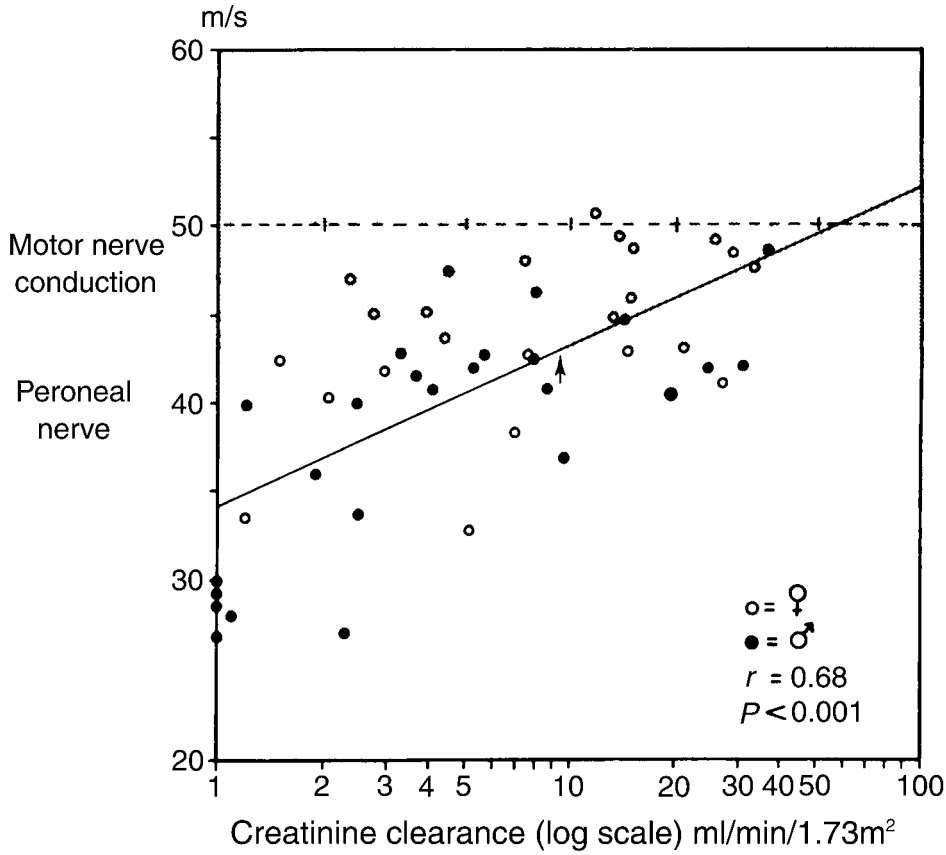

Fig. 124.3. Fall in nerve conduction as kidney function declined in 56 patients before the institution of hemodialysis. The arrow indicates when 50% of patients showed abnormal values. The conduction velocities tended to be lower in males than females ($P<0.01$). (Reprinted, with permission, from Neilsen, V.K., 1973b)

ouabain-sensitive Na^+, K^+-ATPase, resulting in a reduced flux, and increased intracellular sodium concentration, with a resulting decrease in transmembrane potential difference. Several investigations in animals tend to support this theory.

Morphologic studies of peripheral nerve in humans (Asbury et al., 1963; Dyck et al., 1980; Thomas et al., 1971) indicate a primary axonal degeneration of motor and sensory fibres with secondary segmental demyelination. Small and unmyelinated fibres are also involved. However, there is nothing in the pathology that appears to be peculiar to uremic neuropathy.

A wide variety of specific etiological factors have been considered. There appears to be no definite evidence for any of the following: deficiency of B vitamins, deficiency of biotin, accelerated breakdown of muscle protein, or accumulation of certain 'toxins' such as myoinositol, urea and creatinine (see earlier discussion of biochemical pathogenesis). More plausible has been the theory that proteins in the middle molecular mass range (500–500 000 daltons) may accumulate and be toxic to peripheral nerve. The toxicity of the b4–2 or C7 fraction may be even more specific.

Finally, although no vascular changes have been clearly seen in nerve, a microangiopathy has been demonstrated in skin that, in serial studies, did not improve during dialysis but did so after successful renal transplantation (Gilchrest et al., 1980).

Treatment and prevention

During the early stages of renal failure, all methods utilized to treat the underlying cause of the kidney disease and the various systemic effects of renal failure benefit the neuropathy, because it has been shown that conduction velocity falls in parallel with a decrease in renal function, as measured by the creatinine clearance. Such conservative measures include attention to nutrition (Rudman & Williams, 1985).

When end-stage renal disease has been reached, the patient is placed on either chronic hemodialysis or perito-

neal dialysis. It has been shown that both of these methods of treatment halt the progress of uremic polyneuropathy, and a few patients demonstrate either mild improvement or mild deterioration (Bolton & Young, 1990). It is important to start such treatment early enough; if there is some preservation of renal function beforehand, the degree of uremic neuropathy is less. There is no good evidence, however, that specifically manipulating the various hemodialysis schedules necessarily alters the course of uremic polyneuropathy. For example, utilizing hemodialysis techniques that clear middle molecular mass fractions does not necessarily improve uremic polyneuropathy, although it is still an important area of research.

Patients undergoing peritoneal dialysis seem to have the same incidence and severity of uremic polyneuropathy as those receiving hemodialysis (Bolton & Young, 1990). Because diabetic patients achieve better control of blood sugar with peritoneal dialysis than with hemodialysis, the former method is now most frequently used for those patients. The neuropathy, however, does not improve with this treatment, although it does stabilize (Amair et al., 1982).

Kidney transplantation has been shown to produce a much better quality of life than dialysis, and the procedure is much more cost effective (Eggers, 1988). Renal function becomes relatively normal within a month of transplantation, and 1-year survival rate of the transplanted kidney is 68% (Bolton & Young, 1990). The first symptoms of uremic neuropathy improve within a few days or weeks (Nielsen, 1974). The lessening of the distal numbness and tingling coincides with improvement in nerve conduction velocity, as well as in vibratory perception. This improvement is much more protracted when the uremic neuropathy is more severe and residual clinical signs and symptoms may remain (Bolton et al., 1971). Should the transplanted kidney undergo rejection, improved peripheral nerve function can be achieved with a successful second renal transplantation. Mononeuropathies (of a compressive nature) of the ulnar nerve at the elbow or peroneal nerve at the fibular head also improve after successful renal transplantation. Symptoms of autonomic insufficiency, including impotence and infertility, return to normal (Bolton et al., 1971).

The electrophysiological studies improve in parallel with the clinical signs and symptoms. The conduction velocities and distal latencies rise toward normal. The compound muscle (Fig. 124.4) and sensory nerve action potential amplitudes also rise but not to the same extent in more severe neuropathies. Needle electromyographic abnormalities eventually disappear. Autonomic function, as assessed by heart rate variability measurements, also improves (Yildiz et al., 1998).

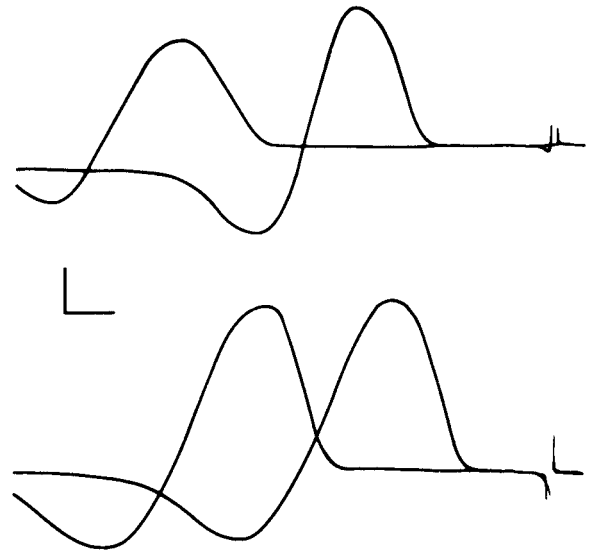

Fig. 124.4. Return of nerve conduction to normal after successful renal transplantation. (Upper trace) Three months before transplantation when the patient had a severe uremic polyneuropathy. (Lower trace) Twenty-seven months after transplanation when almost complete recovery had occurred. The median nerve was stimulated at the wrist, and elbow and the recording was made from the thenar muscle. Conduction velocity rose from 39 to 55 m/s, and the previously dispersed compound action potential became normal, consistent with segmental remyelination. Calibration: vertical, 2 mV; horizontal 2 ms. (Reproduced, with permission, from Bolton & Young, 1990, p. 99.)

The only exception to this improvement in neuropathy occurs in patients who are also diabetic. Here, it has been shown that neuropathy shows only marginal improvement (Kennedy et al., 1990) suggesting that the underlying cause of the neuropathy is mainly diabetes mellitus.

Combined diabetic and uremic polyneuropathy

With the increasing number of diabetic patients receiving chronic dialysis and transplantation, the problem of combined diabetic and uremic polyneuropathy is more prevalent. Both neuropathies manifest a symmetrical motor and sensory polyneuropathy with reduced deep tendon reflexes and varying degrees of ataxia, the distal parts of the limbs being particularly involved. However, diabetic neuropathy is more likely to induce the compressive palsies of ulnar neuropathy at the elbow, carpal tunnel syndrome, and common peroneal nerve palsy; autonomic disturbances and a tendency to multifocal involvement of peripheral nerves are more characteristic. There are also electrophysiological differences: conduction velocities

tend to be lower in chronic renal failure patients who have diabetes mellitus *(*Hansen & Ballentyne, 1978*)*, and in uremia, attempts at reinnervation of muscle (i.e. the re-establishment of nerve supply) are not as successful as they are in diabetic neuropathy (Mitz et al, 1984*)*.

A distinctive variant is subacute uremic and diabetic polyneuropathy (Bolton et al., 1997a). Weakness develops over 2–4 months, and clinical and electrophysiological features suggest a myopathy (with the usual feature of sparse fibrillation potentials and positive sharp waves, as noted previously). Creatine phosphokinase is only mildly elevated and muscle biopsy indicates denervation. Accumulation of advanced glycosylated end products may be a mechanism of this neuropathy, a process reversed by high-flux hemodialysis or renal transplantation, both of which may help these patients. This neuropathy may be similar to the one described by Ropper, except that Ropper's patients had a more acute onset (Ropper, 1993).

Uremic mononeuropathies

The dysfunction of peripheral nerves that occurs in a generalized fashion in chronic renal failure renders these nerves susceptible to local compression (Bolton & Young, 1990). Thus, with the cachexia associated with chronic renal failure, the ulnar nerves at the elbow or the common peroneal nerves at the fibular head are likely to be traumatized. At the time of transplant surgery, compression may occur by operating room equipment. The brachial plexus and radial nerves are particularly susceptible if the arm is kept in an abducted position during anesthesia and surgery. After successful renal transplantation, a patient with simple compressive neuropathies is likely to occur if the treatment of the renal failure is chronic hemodialysis.

Nerves may also be compressed as part of the compartment syndrome; for example, bleeding into the iliopsoas muscle causes acute swelling with compression of the femoral nerves. The process is demonstrated most effectively by computed tomographic (CT) scanning; electrophysiological studies are of little value in the acute stage. This is an emergency situation that requires surgical decompression.

The most common mononeuropathy is carpal tunnel syndrome. As in the non-renal patient, it may be due to narrowing of the carpal tunnel from old age, rheumatism, or other factors. In the renal patient, however, it is particularly likely to occur distal to a Cimino–Brescia forearm arteriovenous shunt used for access during hemodialysis. Here, there is a combination of venous congestion and arterial ischemia.

The signs and symptoms of carpal tunnel syndrome are remarkably similar to those in otherwise healthy persons, except that in uremic patients the symptoms are more pronounced during each hemodialysis procedure. Electrophysiological studies aid greatly in diagnosis by showing prolonged conduction in both motor and sensory fibres through the carpal tunnel region.

Decompressive surgery, with sectioning of the flexor retinaculum, has been found to be an effective method of treatment, particularly if the carpal tunnel syndrome occurs in the arm not containing a Cimino–Brescia forearm fistula. In the case of such a fistula, carpal tunnel surgery, in itself, may not be effective, and consideration may have to be given to either discontinuing or altering the degree of forearm shunting.

It has been previously believed that these were the only mechanisms of carpal tunnel syndrome, but it is known that patients who have received hemodialysis with a Cuprophan membrane for more than 10 years are susceptible to amyloidosis (Gejyo et al., 1986). The amyloid deposit is composed of ß2-microglobulin, which is normally present in small amounts in the serum and other body fluids in healthy persons. It is normally catabolized by the kidneys and, consequently, it rises progressively during renal failure. Such a rise may not occur if dialysis is performed with a newer AN-69-polyacrylonitrile membrane. Levels of α2-microglobulin may be just as high in patients receiving chronic ambulatory peritoneal dialysis; as yet, carpal tunnel syndrome has not yet been reported in this condition, perhaps because the patients have not used this form of dialysis for a sufficient period. Methods of hemodialysis are now being altered to prevent this serious complication, which may cause amyloid deposition not only in the carpal tunnel area but also in the bones and joints, particularly of the upper limbs (Bardin et al., 1986). This more widespread distribution causes a severe arthropathy and intractable pain. Moreover, decompressive carpal tunnel surgery may not relieve the situation; if there is relief, it may be only transient, with a tendency of the syndrome recur later (Fig. 124.5).

Mononeuropathies of a more diffuse nature may occur in the median and ulnar nerves as a result of Cimino–Brescia arteriovenous forearm fistulas. Although they are usually mild and subclinical and are demonstrated only by careful electrophysiological techniques, some dysfunction may occur in up to three-fourths of patients (Knezevic & Mastaglia, 1984). However, shunts located more proximally in the arms, between the brachial artery and antecubital vein, may sometimes produce acute, quite severe, and painful neuropathies involving median, ulnar and radial nerves (Bolton et al., 1979). This is an emergency situation in which electrophysiological studies are not of much value and clinical examination must be relied on. Consideration should be given to taking

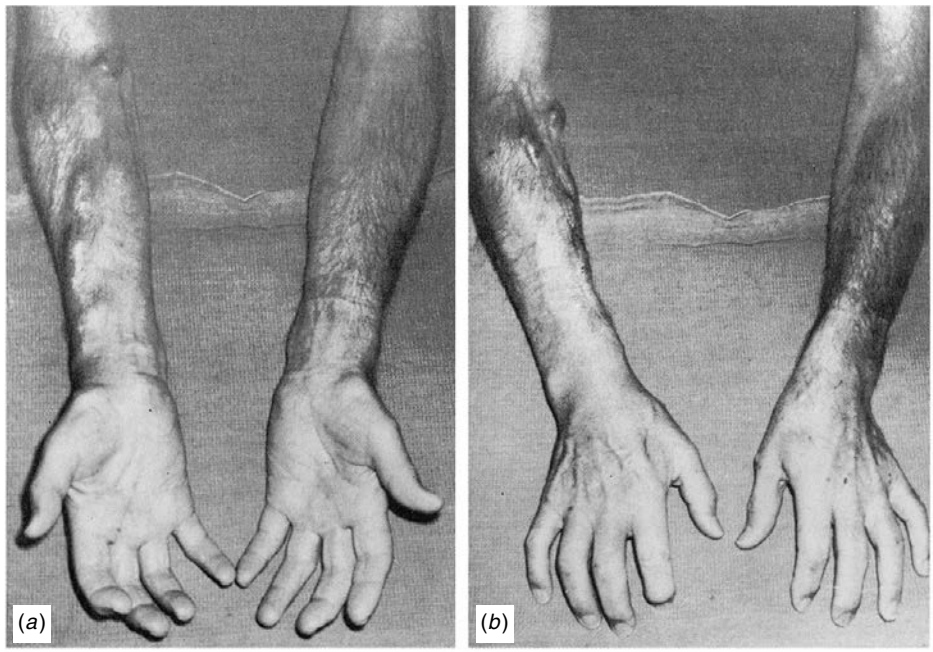

Fig. 124.5. The upper limbs of a patient who had a ß$_2$-microglobulin amyloidosis. It caused (*a*) bilateral carpal tunnel syndrome (note proximal thenar wasting) and (*b*) a right ulnar neuropathy (note the wasting of the interosseous muscles). Tissue biopsied at the time of the carpal tunnel surgery revealed infiltration of blood vessels with amyloid. The pain may have been due to an arthropathy (note thickening and flexion contraction of interphalangeal joints) and periodic nerve ischemia. Repeated surgery for carpal tunnel syndrome provided only transient relief. (The Cimino-Brescia forearm fistula caused the dilated veins in the right forearm.) Reproduced, with permission from Bolton & Young, 1990, p. 110.

down the shunt on an emergency basis, or a severe and possible permanent neuropathy may result. The clinical and electrophysiological studies of these neuropathies are typical of acute nerve ischemia, with a resulting primary axonal degeneration of motor and sensory fibres.

Cochlear and vestibular dysfunction may occur in chronic renal failure as a result of treatment by antibiotics, notably erythromycin and aminoglycosides, and also by diuretic drugs. Uremic toxicity, itself, however, is probably also a factor. Eighth cranial nerve dysfunction may improve during chronic hemodialysis and is most likely to improve after successful renal transplantation.

Myopathy in uremia

A defect in neuromuscular transmission does not occur as a direct manifestation of uremic toxicity, but it may occur as a complication of aminoglycoside antibiotics. Repetitive nerve stimulation studies show an incrementing response typical of the presynaptic defect in this complication. Discontinuance of the drug results in improvement.

Myoglobinuria (Penn, 1986) is an important cause of acute renal failure and may have a variety of etiologies. The clinical picture is mainly determined by the underlying disease. The urine is red, and special tests reveal myoglobin in the urine. The muscles themselves have been traditionally described as weak, swollen and painful, but they may be surprisingly normal on examination. The creatine kinase level is invariably elevated. The muscle disease and the kidney disease are both potentially reversible. Dialysis, or possibly plasmapheresis, may be effective.

Other relatively acute forms of myopathy associated with renal failure are those caused by water and electrolyte disturbances. If muscle weakness occurs in acute attacks, periodic paralysis associated with potassium disturbance should be considered. Hypocalcemia may occur and be manifested as tetany, but this is rare because of the often associated acidosis in renal failure.

A more chronic myopathy may be induced as a complication of steroid therapy.

The chief conditions to be considered in chronic myopathies are, first, the non-specific cachexia associated

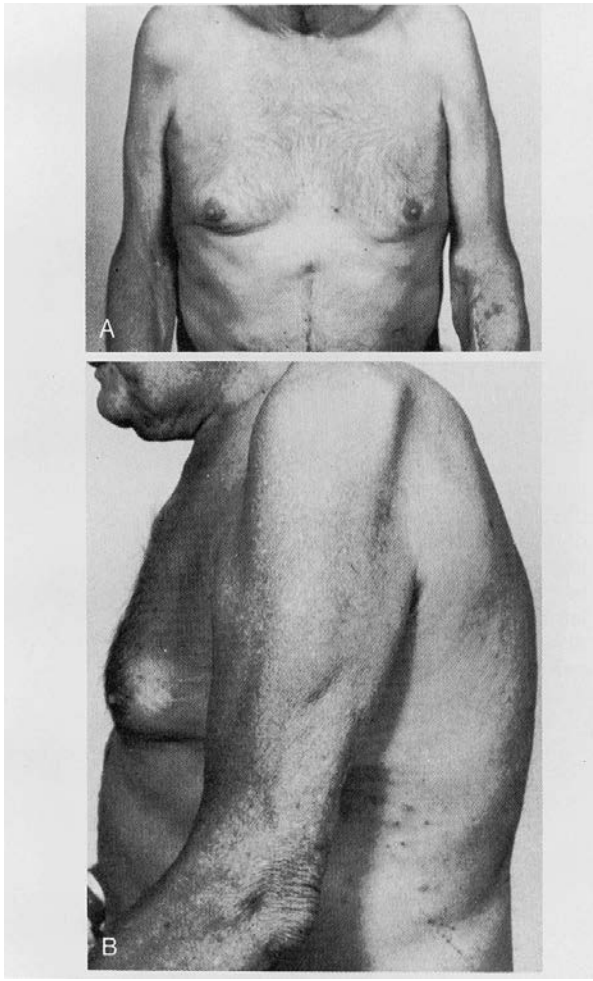

Fig. 124.6. (*a*) and (*b*) Severe muscle wasting in a 67-year-old man who had received chronic hemodialysis for 7 years. It was associated with underlying pain secondary to progressive bone disease. He also had a progressive dementia, but aluminium intoxication was never proved. Although he had a mild uremic polyneuropathy, needle electromyography of shoulder girdle muscles revealed only an increased proportion of polyphasic units, consistent with a primary myopathy. (Reproduced, with permission from Bolton & Young, 1990, p. 158.)

with CRF, and second, perhaps more frequently, the type of myopathy that may be associated with a remarkable proximal wasting of muscle in the limbs (Bolton & Young, 1990) (Fig. 124.6). It is associated with underlying bone disease that is due to either secondary hyperparathyroidism or aluminium accumulation. In both types of cachexia, needle electromyography reveals no clear-cut abnormalities, the creatine kinase levels are usually normal, and biopsy reveals some atrophy of type 2 muscle fibres.

Complications of dialysis therapy

Adverse effects from dialysis, especially hemodialysis, occur in every renal unit. These include: dialysis dementia, dysequilibrium syndrome, subdural hematoma and vitamin deficiencies. These are discussed in turn.

Dialysis dementia

This clinical syndrome was initially described in clusters of patients on chronic hemodialysis, although a similar syndrome may occur in patients on peritoneal dialysis (Alfrey et al., 1972). The condition is related to an accumulation of aluminium in the brain (Wing et al., 1980; Fraser, 1992; Roskams & Connor, 1990). Elimination of aluminium from the dialysate essentially eliminated epidemics of this syndrome; sporadic cases since then relate to the absorption of aluminium from the gastrointestinal tract, usually from the use of aluminium-containing phosphate binders (Sideman & Manor, 1982). Dialysis dementia is progressive and fatal unless recognized early and treated vigorously.

The essential components of the syndrome are an initial non-fluent speech disturbance (aphasia plus dysarthria), involuntary motor phenomena (especially myoclonus and seizures), gait disturbance (apraxia or ataxia) and mental changes (Bolton & Young, 1990). The latter consist initially of apathy and behavioural changes, combined with speech and writing errors. The mental changes can blend with the features described above as part of the uremic syndrome, but a striking behavioural change in a patient with CRF should raise the possibility of dialysis dementia, especially in the face of adequate (e.g. thrice weekly) dialysis. Confusional states appearing transiently shortly after dialysis are a typical early feature. These last longer with further dialysis treatments until they persist. Memory failure, poor attention, disorientation, psychotic behaviour, apraxia and dyscalculia have been described. Eventually the patient becomes bedridden, incontinent and stuporous. The condition is often associated with a fracturing osteodystrophy and a severe, refractory, microcytic anemia.

The EEG can be helpful diagnostically and in following therapy. Typically, patients have frequent 'projected' bursts of rhythmic delta activity, triphasic waves or irregular generalized epileptiform discharges, despite an adequate, e.g. thrice weekly, dialysis programme. (Figs. 124.7 and 124.8). Serum aluminium levels are helpful, but often not definitive. Although serum aluminium levels of <50 ng/l are unlikely to be associated with dialysis dementia, occasional cases may have low levels. Bone aluminium measurements and the desferoxamine infusion test are further refinements (Bolton & Young, 1990).

A high index of suspicion and vigilance for dialysis dementia in the uremic population is vital. With first symp-

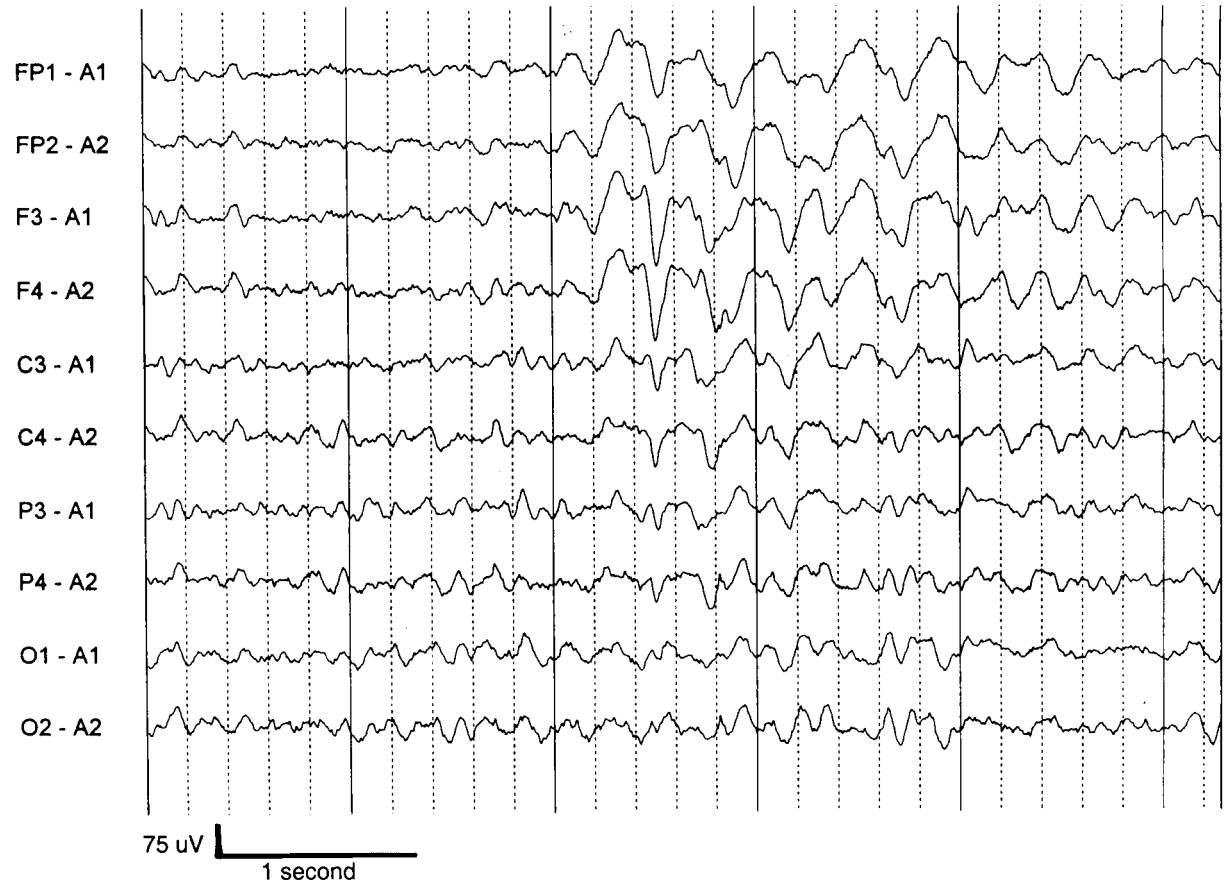

Fig. 124.7. This EEG shows a burst of triphasic waves and rhythmic, frontally predominant delta activity. The patient had secondary hyperparathyroidism and required an aluminium-based, phosphate binder. He had intermittent speech problems and ataxia; serum aluminium was over 800 ng/ml.

toms of the condition, the patient should be withdrawn from all sources of aluminium (especially in dialysate, aluminium-containing antacids). Desferoxamine, a chelating agent for aluminium, can be given safely on an intermittent or long term basis (Bolton & Young, 1990). This can help in arresting progression of the disorder and may reverse many of the features, although sometimes not completely (Bolton & Young, 1990).

Symptomatic therapy with antiepileptic drugs such as phenytoin or valproate may be necessary. Although benzodiazepines may have a transiently beneficial effect on the clinical features, their long-term usefulness has not been demonstrated.

Dialysis dysequilibrium

Dialysis dysequilibrium, a syndrome with close temporal relation to hemodialysis treatment, occurs mainly during, or after, the initial dialysis treatment in patients with CRF. The very young and very old may be more susceptible (Port et al., 1973). Although usually reversible, death or permanent damage from seizures occur in severe cases (Peterson & Swanson, 1964; Wakim, 1969).

Dialysis dysequilibrium syndrome is thought to be related to an osmotic mismatch between the plasma and brain, with relatively lower osmolality in the blood than in the brain during dialysis (Peterson & Swanson, 1964; LaGreca et al., 1982; Pappius et al., 1996). Arieff has shown an intracellular acidosis occurs in the brain, in association with dialysis dysequilibrium (Arieff et al., 1973). The relative roles of osmotic and pH changes are unclear.

Mild cases show headache, nausea, vomiting, restlessness or drowsiness and muscle cramps, variably accompanied by disorientation and tremors. Moderate features include disorientation, somnolence, asterixis and myoclonus. Severely affected patients develop an acute organic psychosis, coma or generalized convulsions. Features begin either during or immediately following the dialysis treatment.

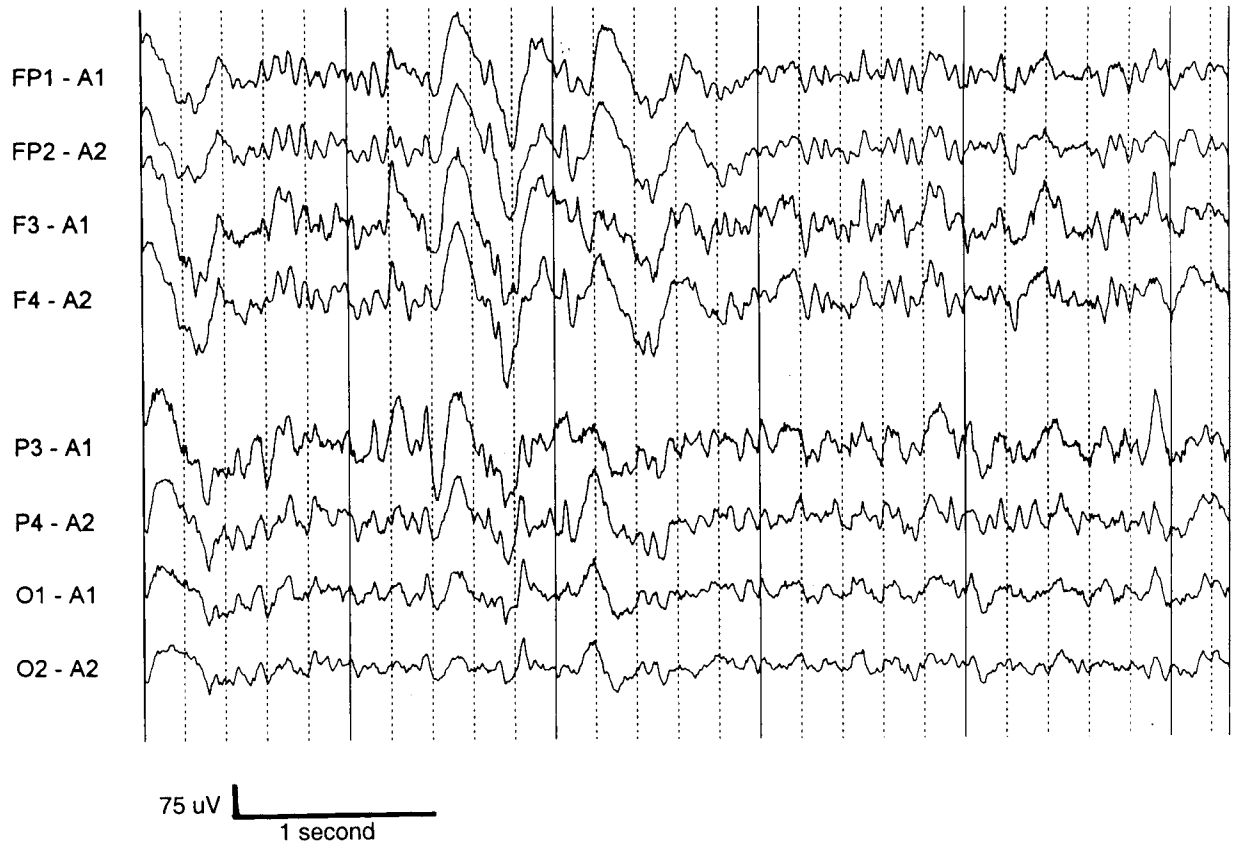

Fig. 124.8. Same patient as in Fig. 124.7; EEG done four months later. The EEG now shows bursts of irregular spike-waves. The occipital rhythm is poorly maintained, while the faster frequencies are from diazepam given for a recent seizure. Despite desferroxamine therapy, the patient worsened clinically and was mute with intermittent myoclonus and seizures at the time of the EEG. The patient subsequently became septic and died. He was thought to have had 'dialysis dementia' from aluminium intoxication.

EEGs show bursts of slow frequency waves, higher voltage and slower with increasing severity of the encephalopathy (Kennedy et al., 1963). These bursts occur against an abnormal, mildly slowed or markedly dysrhythmic background. Generalized epileptiform activity may be found in those with seizures. The EEG returns to normal with resolution of the encephalopathy. Quantitative methods may be more sensitive in detecting early changes during dialysis, but it is difficult to control for normal drowsiness (Arieff et al., 1978). The cerebrospinal fluid becomes acidotic during attacks (Arieff, 1994).

Dialysis dysequilibrium can be prevented by using slower blood flow rates in dialysis, by increasing the osmolality of the dialysate by the addition of urea, sodium, mannitol or glycerol or with the use of hemofiltration followed by dialysis or peritoneal dialysis. (Port et al, 1973; Arieff et al., 1978; Gilliland and Hegstrom, 1963). Glycerol prevents the intracellular acidosis noted by Arieff and colleagues (Arieff et al., 1978). The substitute of bicarbonate for acetate in the dialysate has also been recommended.

Subdural hematoma

Subdural hematomas, found in 1–3% of patients on hemodialysis sometimes associated with anticoagulant therapy, can occur at any age in uremia (Talalla et al., 1970; Leonard & Shapiro, 1975; Rotter & Roettger, 1973). The hematomas are large in about 10% of cases; most show fresh bleeding with evidence of older hemorrhage. Iatrogenic and intrinsic uremic coagulopathies likely both contribute.

Patients usually present with headache and tenderness of the head to percussion. The patient often show decreased alertness and cognition and may seem depressed. These are common features in uremia, so subdurals can easily be overlooked. Focal signs predominate in some patients. Hemiparesis or a language disturbance

may occur, but could be misinterpreted. Gait apraxia in older patients with subdurals is common (McLachlan et al., 1981).

Diagnosis is easily made with CT (beware of the isodense subdural, however) or MRI scans.

Because subdural hematomas are common, life threatening and treatable, they should be considered in any uremic patient who develops a change in CNS function. They can present in a variety of ways and may be insidious; hence a high degree of suspicion and vigilance is necessary.

Treatment is usually surgical drainage. Occasional patients can be managed conservatively, but require close follow-up.

Wernicke's encephalopathy

Wernicke's encephalopathy occurs in those dialysed patients who are too ill to eat or who repeatedly vomit and are placed on intravenous solutions that do not contain thiamine (Lopez & Collins, 1968; Jagadha et al., 1987). Uremics with hyperkalemia may be most at risk, as glucose boluses are often given to reduce the serum potassium concentration. It should be remembered that, in some patients, the classical features of ophthalmoplegia, nystagmus, encephalopathy and ataxia may not all be present. Without the ocular findings, there is great difficulty in differential diagnosis, unless Wernicke's encephalopathy is considered.

Complications of renal transplantation

(Note: Complications of immunosuppressive drugs are discussed in Chapter 129.)

Rejection encephalopathy

Rejection encephalopathy affects mainly patients between 10 and 38 years of age, usually within the first few months of renal transplantation. Symptoms include headache, confusion or convulsions along with systemic features of graft rejection. The release of cytokines may be of pathogenetic importance. The condition is treated symptomatically, mainly with antiepileptic drugs, and increased immunosuppression to combat the graft rejection response. The prognosis is usually favourable.

Infections

Infections of the central nervous system can be divided into viral, fungal and bacterial. Predisposing factors, besides the immunosuppression, include diabetes, intravascular lines, uremia and urinary catheters.

Viral infections peak between 1 and 6 months following transplantation and include cytomegalovirus (can cause retinitis, blindness and an encephalitis) and Epstein–Barr virus. Opportunistic fungi are mainly *Aspergillis fumigatus* and *Nocardia asteroides*. The main bacterial infection is *Listeria monocytogenes*. The same organisms and *Cryptococcus neoformans* may cause infection later, as may the JC virus, causing progressive multifocal leukoencephalopathy, and *Mycobacterium tuberculosis*. Initial symptoms and signs of CNS infection may be dampened by the anti-inflammatory effects of the immunosuppressive therapy, so a high index of suspicion needs to be maintained, with prompt neuroimaging and CSF analysis. Special tests, such as PCR on the CSF, e.g. for the JC virus and *Mycobacterium tuberculosis*, special stains and cultures, are sometimes helpful. Recruitment of expert microbiological expertise is recommended.

Indirectly, the CNS may be affected by hepatic failure in rapidly progressive hepatitis in patients with hepatitis C virus infection. In such patients a decrease or withdrawal of immunosuppressive therapy may improve the early hepatic failure without adverse effects on the graft (Ok et al., 1998).

Post-transplant lymphoproliferative disorder

This includes the proliferation of B-lymphocytes with disorders ranging from monoclonal gammopathy to B-cell lymphomas of the CNS (Patchell, 1994). The latter tend to be periventricular and multiple, with uniform contrast enhancement and indistinct or fuzzy margins. Brain biopsy is usually necessary. The condition may respond initially to radiation and chemotherapy but the overall prognosis is usually poor.

Systemic disorders affecting the nervous system and kidneys

Genetic disorders

Genetic disorders include von Hippel–Lindau disease (VHLD), polycystic kidney disease and Wilson's disease. In VHLD, an autosomal dominant disorder, the CNS is the site of hemangioblastomas, most commonly in the cerebellum (50–70%) and the retina (60%). Renal carcinoma occurs in both Types I and II VHLD. Renal cysts occur in about 85% of cases of VHLD. The VHLD tumour suppressor gene has been located on chromosome 3p25–p26; genetic testing is available (Latif et al., 1993).

Polycystic kidney disease (PKD) exists in both autosomal dominant and recessive forms; the dominant form has

Table 124.1. Systemic disorders affecting the kidney and nervous system

Disease	Renal condition	Neurological complication
Polyarteritis nodosa	renal failure, hypertension, proteinuria, granular casts	peripheral neuropathy, less commonly encephalopathy, strokes, SAH, cranial neuropathies, seizures
Wegener's granulomatosis	proteinuria, hematuria, RBC casts, renal failure	cranial neuropathies, multiple mononeuropathies, polyneuropathies, strokes
Infections: hepatitis B, esp. with polyarteritis nodosa	proteinuria, granular casts, renal failure	encephalopathy, strokes, mononeuropathies
Toxins, esp. with illicit drug use	proteinuria, granular casts, renal failure	encephalopathy, strokes, mononeuropathies
Lymphoid malignancy	proteinuria, granular casts, renal failure	encephalopathy, strokes, mononeuropathies
Systemic lupus erythematosus	hematuria, proteinuria, nephrotic syndrome, renal failure	encephalopathy, seizures, strokes, chorea, cranial and peripheral neuropathies
Rheumatoid arthritis	glomerulonephritis, amyloid kidney disease	polyneuropathies, mononeuropathies, cervical myelopathy (mechanical)
Sjögren's syndrome	tubular dysfunction	neuropathies, ganglionopathy, cranial neuropathies
Plasma cell dyscrasias (POEMS, myeloma, MGUS, Waldenström's, cryoglobulinemia)	proteiuria, nephrotic syndrome, renal failure	root and spinal cord compression/neuropathies, cerebral/cranial n. compression; IIH

Notes:
Legend: IIH = idiopathic intracranial hypertension; MGUS = monoclonal gammopathies of unknown significance; SAH = subarachnoid hemorrhage; POEMS = polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy and skin changes, in association with plasma cell dyscrasia (osteosclerotic myeloma).
Source: Modified from Burn and Bates (1998), Table 3.

been linked to two different genetic loci (still incomplete evidence), the recessive to one locus (Zerres et al., 1994; Ong, 1997; San Millan et al., 1995). Polycystic kidney disease is associated with a risk of intracranial berry (saccular) aneurysms that may rupture and cause subarachnoid or intraparenchymal brain hemorrhage. (It should be noted, however, that there are more cases of hypertensive intracranial hemorrhage than of ruptured berry aneurysm in PKD patients (Ryu, 1990). Other conditions with a less strong association with PKD include arachnoid cysts, eosinophilic granuloma, moyamoya disease, familial amyloidosis, mitral and aortic valve incompetence and mitral valve prolapse (Ruggeri et al., 1994; Pracyk & Massey, 1989; Scelsi et al., 1989).

Wilson's disease is a disorder of copper metabolism and is discussed elsewhere. It should be mentioned that Wilson's disease can sometimes cause renal dysfunction, primarily at the proximal convoluted tubule region. This can result in a Fanconi syndrome, with generalized aminoaciduria, hypophosphatemia (see below) and systemic metabolic acidosis (Hoogrngraad, 1996).

Acquired disorders

Although various systemic disorders and their neurological complications are discussed elsewhere in this book, Table 124.1 summarizes the neurological and nephrological aspects of these disorders. Most of these either cause vascular lesions (either vasculitic or perfusion deficiencies), have a direct immunological effect on nervous tissue, have tissue infiltration by cells or proteins, predispose to chronic infections or a combination of these pathogenetic mechanisms.

Electrolyte disturbances

Hyperosmolality and hypernatremia

Hypernatremia, a rise in serum sodium concentration above 145 mmol/l, relates to a deficit of water relative to sodium and indicates a general hypertonicity of body fluids. Although hypernatremia can be acute or chronic, only the acute variety has established primary effects on the central nervous system. It is difficult to separate

Table 124.2. Causes of hypernatremia

Water loss	Water loss with sodium loss	Water loss with sodium gain
Extrarenal		
Skin: insensible perspiration	Skin: sweat	
Lungs		
Renal	Osmotic diuresis	Excessive sodium administration
Diabetes insipidus (CNS or nephrogenic)		Adrenal hyperfunction (hyperaldosteronism, Cushing's syndrome)
Hypothalamic dysfunction		

Source: Modified from Levinsky, N.G.: Fluids and electrolytes. In Braumwald et al. (1988).

chronic hypernatremia from its associated diseases; the latter are usually more likely than the hypernatremia to affect neurological function.

Pathophysiology of hypernatremia

Hypernatremia can develop with either excessive loss of water, decreased water intake with immobility or impaired consciousness that impair satisfying the strong thirst drive. With an increase in serum osmolality, water shifts from the intracellular to the extracellular compartment. Therefore, net rises in serum sodium or osmolality reflect large losses of body water.

Table 124.2 lists the main causes of hypernatremia. Hypernatremia from antidiuretic hormone (ADH) deficiency or excessive mineralocorticoid activity produces only modest elevation of serum sodium. The former may cause significant hypernatremia only if the patient cannot satisfy thirst needs. Insensible losses of water from skin and lungs may reach several litres per day in cases of extreme heat, fever, burns and hyperventilation. The sudden development of hypernatremia may be an indication of acute pituitary failure, i.e. pituitary apoplexy. Patients who suffer hypothalamic damage and coma are at risk for hypernatremia. Exceptionally, hypernatremia results from excessive sodium administration. This has happened inadvertently in the preparation of infant formulae or hemodialysis solutions, or the excessive administration of hypertonic saline solutions to comatose patients, e.g. correction of metabolic acidosis with the administration of sodium bicarbonate (Snyder & Arieff, 1992).

Central nervous system complications of hypernatremia

Acute/subacute hypernatremia with neurological manifestations occurs predominantly in very young infants and the elderly. It may occur in patients of intermediate ages, especially in the presence of a net loss of water, iatrogenic or self-induced salt loading and obtundation or inability to express needs or to satisfy thirst.

Neurological signs and symptoms relate to loss of volume of cells in the CNS, as brain cell membranes are highly permeable to water, allowing shifts to follow osmotic gradients. To prevent cell shrinkage, there are potent homeostatic mechanisms in the brain that allow neuronal and glial 'regulatory volume increases' in the face of acute hyperosmolality (Pesantes-Morales, 1996). Within minutes, there is an increase in sodium, potassium and chloride ion influx into cells due to activation of a neuronal and glial cotransporter (Pesantes-Morales, 1996). This is followed in about 10 hours by an increase in organic osmolites, especially myoinositol, glutamate, glutamine, and taurine (Pesantes-Morales, 1996). Myoinositol makes up much of the compensatory increase in osmolality; this occurs through increased production of a sodium-dependent cotransporter messenger RNA (Pesantes-Morales, 1996). The increase in organic compounds offsets some of the electrolyte imbalance that can alter neuronal functioning, e.g. seizures (Pesantes-Morales, 1996).

Because the brain adjusts its idiogenic osmoles to maintain cellular volume, only acute hypernatremia causes an acute loss of brain volume. If the rate of water loss outstrips the speed of homeostatic mechanisms, patients may develop lethargy, delirium, stupor or coma (Swanson, 1976). There is typically an increased muscular tone, probably paratonic rigidity. Brain shrinkage may be accompanied by tearing of bridging veins running from the cerebral cortex to the superior sagittal sinus, creating subdural hematomas (Finberg, 1963). Capillary and venous congestion and bleeding with multiple microscopic hemorrhages, macroscopic subcortical intracerebral and subarachnoid

hemorrhages have been described (Luttrell & Finberg, 1959). Furthermore, venous thrombosis, including the superior sagittal sinus, has been described in the context of acute hypernatremia (Luttrell & Finberg, 1959). Seizures can occur related to these vascular complications (Bruck et al., 1968; Finberg, 1963).

Rarely, central pontine myelinolysis can occur with the acute development of hypernatremia, in the context of severe systemic illness (McKee-Winelman et al., 1988).

Seizures mainly occur during the rehydration phase of patients with chronic hyponatremia, presumably due to acute osmotic swelling of cells following the administration of fluids that are lower in osmolality than the patient's sera and brain (Kahn et al., 1979). Patients with elevated serum urea, and acidosis are especially at risk for seizures during rehydration (Khan et al, 1979).

Diagnosis of hypernatremia

Serum electrolyte determination establishes the presence of hypernatremia. The cause should be apparent from the clinical setting.

EEG changes are non-specific, consisting of diffuse slowing that reverses after uncomplicated correction. Epileptiform discharges are not seen in acute or chronic hyponatremia in the absence of vascular complications (Dodge et al., 1962).

Management

Calculations of water deficit should be based on total body water that equals about 60% of body weight in non-obese patients. If there is an associated volume deficit, i.e. combined water and sodium loss, replacement should begin with normal or 0.9% saline solution. Volume deficits must be replaced first (Snyder & Arieff, 1992). Only profound acidosis, with pH less than 7.15, should be treated with sodium bicarbonate (Graf & Arieff, 1986). If the neurological syndrome of acute hypertonicity predominates, replacement should start with half-normal or 0.45% saline. It is best to avoid increases of plasma osmolality of greater than 2 mOsm/l/hour (Snyder & Arieff, 1992). Pure glucose solutions should be avoided, as the brain will not have time to adjust to the resultant shift of water into the intracellular compartment. This will probably result in coma, convulsions and acute brain swelling from cytogenic edema. Such complications are much more likely if the hypernatremia has been established for some time (e.g. days to weeks). Serum electrolytes should be monitored every 2 to 4 hours during acute therapy.

With the above, the underlying disease process should be sought and treated. It is vital to give corticosteroids promptly to patients with pituitary apoplexy. Excessive losses of water should be corrected. This may involve changes of medication and treatment of hyperthermia.

Hyponatremia

Hyponatremia, defined as a serum sodium of less than 135 mmol/l, has an incidence of about 1% and a prevalence of about 3% in inpatients in general hospitals (Anderson et al., 1985). Hyponatremia constitutes the most common electrolyte disturbance and is associated with a number of diseases.

Classification

Hyponatremia reflects water balance, which determines the osmolality of the plasma, and is classified as: isovolemic, hypovolemic, hypervolemic and iso-osmolar. See Table 124.3.

Most cases of hyponatremia are associated with hyposmolality of the blood or a relative excess of solvent to solute. This is associated with the kidney not excreting a dilute urine that can relate to: (i) inappropriate secretion of antidiuretic hormone (ADH) associated with a number of disorders; (ii) increased renal excretion of sodium due to enhanced secretion of naturetic factor or to defective sodium transport in the diluting parts of the nephron; (iii) insufficient glomerular filtrate reaching distal parts of the nephron, either due to decreased glomerular filtration rate or to increased proximal tubular reabsorption of fluid.

Hypo-osmolar hyponatremia can be divided according to volume status. Hypovolemic hyponatremia may be caused by loss of fluid or blood through the gastrointestinal tract, urinary tract (often with secretion of atrial natriuretic factor or loss of aldosterone effect), skin, blood loss from various sites or from third space sequestration (e.g. ascites with hypoproteinemia may be associated with a contraction of the vascular volume). This stimulates the secretion of ADH as volume replacement has precedence over osmolality. Normo- or hypervolemic hyponatremia is usually related to inappropriate secretion of antidiuretic hormone or drugs that cause this effect. As a corollary, the finding of normal volume or central venous pressure helps to separate SIADH from salt wasting and other conditions associated with contraction of blood volume. In some hospitals measurement of ADH (arginine vasopressin) can be performed.

Artifactual hyponatremia is associated with normal osmolality. It may be caused by hyperlipidemia, hyperglycemia or certain intoxications. In hyperlipidemia lipids occupy volume in the plasma as if they formed a compartment. If this compartment is excluded, the osmolality or serum sodium of the remaining component is normal.

Table 124.3. Hypovolemic hyponatremia (combined sodium and water deficiency)

Extrarenal losses: gastrointestinal, skin, third space sequestration (e.g. ascites), skin (sweating, burns)
Renal losses
Renal disease: CRF, salt-wasting tubular disease
Diuretic excess
Osmotic diuresis: diabetes mellitus, iatrogenic (e.g. mannitol)
Mineralocorticoid deficiency: Addison's disease, hypoadrenalism
Isovolemic hyponatremia
(no significant expansion of extracellular compartment)
Nausea, pain, emotion: temporary impairment of water diuresis
Psychogenic polydipsia
Endocrine (glucocorticoid deficiency, hypothyroidism)
SIADH
Drugs
Drugs that potentiate ADH action: clofibrate, NSAIDS, ADH analogues, cyclophosphamide
Drugs that stimulate ADH release: vincristine, Carbamazepine, narcotics, barbiturates
Drugs that potentiate ADH action and stimulate release: Thiazide diuretics, chlorpromazine, ADH analogues
Essential: 'sick cell syndrome'
Hypervolemic hyponatremia
(Expansion of extracellular compartment: edema)
Hepatic failure
Cardiac failure
Nephrotic syndrome
Without plasma hypo-osmolality
Osmotic: hyperglycemia, mannitol
Artifactual: hyperlipidemia, hyperproteinemia

Clinical features

Hyponatremia itself, if symptomatic, causes a metabolic encephalopathy consisting of inappropriate behaviour, confusion, headache, speech problems, lethargy, vomiting, tremor, weakness, malaise and seizures (Price & Mesulam, 1987). The latter are usually generalized convulsions. Muscle twitches and cramps may occur. The patient is much more likely to be symptomatic if the hyponatremia develops acutely or subacutely and if the serum sodium is less than 125 mmol/l. In some chronic cases, the mental changes may be due to the underlying condition, e.g. hypothyroidism, rather than the hyponatremia. Occasionally severe hyponatremia may develop acutely, e.g. in patients who become acutely volume depleted from prolonged outdoor exercise and replace the volume with excessive water. This can lead to life-threatening cerebral edema with coma and signs of herniation (Garigan & Ristedt, 1999).

Risk factors for development of symptomatic hyponatremia include: age over 75 years (and the use of certain drugs, e.g. thiazide diuretics in this age group), female sex, below average body weight, the rate and extent of fall of serum sodium concentration and the presence of underlying serious illnesses (Arieff et al., 1976; Ashraf et al., 1981).

Pathophysiology

A decrease in the osmolality of the plasma creates an osmotic gradient between the blood compartment and the cells of the body, including the brain. Unless the brain decreases its osmolality, there will be a shift of water across the cell membranes, causing the cells to swell. The brain can adjust to hyponatremia, thereby maintaining intracellular volume, by reducing its osmolality (Arieff et al., 1976). If hyponatremia develops quickly, the brain does not have time to adjust by reducing its idiogenic osmoles. With brain swelling, compensation for the increased volume can be accommodated only up to about 50 ml. After this, the swelling causes an increase in intracranial pressure (Ayus et al., 1992).

In addition, the ionic composition of the brain is altered and changes in neurotransmitter function follow. Acute hyponatremia with hypo-osmolality would be expected to cause partial depolarization of nerve cells, related to the extrusion of potassium, which makes them hyper irritable: reduced threshold for firing action potentials and increased tendency for seizures.

Management

The management of hyponatremia depends on the underlying cause and the neurological complications exhibited by the patient. The patient's hyponatremia should be classified into a broad category of hypovolemic, normovolemic, hypervolemic or normo-osmolar. Then the specific underlying disorder determined using clinical and laboratory means described in standard medical texts.

Correction of the underlying disorder usually corrects the hyponatremia. Asymptomatic patients with hypotonic hyponatremia who are hypervolemic or normovolemic are treated with volume restriction to 1.0 l per day and will correct at a maximum rate of 1.5 mmol/l per day (Ayus & Arieff, 1993). This can be supplemented with normal saline at amounts to create a rise in serum sodium of less than 12 mmol/day.

The management of acutely symptomatic patients is controversial. However, those with seizures and cerebral edema require more active treatment than water restriction alone (Ayus et al., 1987; Arieff, 1986). In these extreme and rare circumstances, prompt therapy with mannitol or hypertonic saline with a loop diuretic should be administered

such that the correction is no faster than 0.5–1.0 mmol/l per hour or 20 mmol/l in the first day. Electrolytes need to be checked hourly with prompt reporting facilities.

If possible, it is best not to correct the serum sodium too quickly or to normal values. It is important to give just enough to get the serum sodium concentration in the range of 130 mmol/l and not to strive for prompt normalization of serum electrolytes. This may put the patient at greater risk for CNS demyelination than the rapidity of sodium elevation (Ayus et al., 1987). In both chronically and acutely ill humans rapid correction can result in pontine and extrapontine myelinolysis. There is considerable variation in susceptibility to central myelinolysis, however (Karp & Laureno, 1995). Retrospective studies have led to the recommendation that myelinolysis can be avoided by limiting the rate of rise to less than 12 mmol in the first 24 hours or 25 mmol/l in the first 48 hours (Sterns et al., 1986). However, even with these guidelines, some patients develop CPM (Karp & Laureno, 1995). Karp & Laureno (1995) suggest striving for less than 10 meq/l for the first 24 hours and less than 21 meq/l over the first 48 hours. Studies on acutely hyponatremic animals showed that an increase of more than 12 mmol/l/day may produce CPM if this rate is continued for 2–3 days (Sterns, 1987).

The matter is still shrouded with some controversy. Water restriction, if too vigorous, may be associated with complications. In an experimental study, Ayus and colleagues (1985) found that, if the sodium rose to normonatremic values within 24 hours with water restriction, there were scattered brain lesions, including neuronal necrosis and myelin damage, but not the typical features of CPM. Treatment of hypovolemic shock may be necessary and may force a more rapid rise in osmolality than planned. The use of half normal saline might be considered in this circumstance.

Hypercalcemia

An increase in serum calcium concentration sufficient to cause alteration of central nervous function is not uncommon in certain populations, e.g. 5% of patients with cancer. Hypercalcemia has a prevalence of 0.5% of hospitalized patients (Fisken et al., 1984).

Pathogenesis

Table 124.4 gives a list of causes of hypercalcemia. Severe hypercalcemia is most commonly due to malignancy or hyperparathyroidism, followed by sarcoidosis, milk-alkali syndrome and adrenal insufficiency. In malignancies the main mechanisms are the production of parathyroid related peptide by the tumour and malignant bone destruction itself (Waxman, 1990).

Table 124.4. Causes of hypercalcemia

Disruption of normal bone–extracellular fluid equilibrium
Metastatic tumour
Multiple myeloma
Lymphoma
Hyperthyroidism
Immobilization in a young individual or those with underlying disease, e.g., Paget's disease
Excessive parathyroid hormone
Primary hyperparathyroidism
Non parathyroid-tumour producing parathormone-like substance, e.g. lung, breast, kidney, etc.
Lithium therapy
Familial hypocalciuric hypercalcemia
Excess vitamin D
Hypervitaminosis D
Sarcoidosis (increased formation of 1, 25-dihydrocholecalciferol)
Idiopathic hypercalcemia of childhood.
Other
Adrenal insufficiency
Thiazide administration
Milk-alkali syndrome
Hypervitaminosis A

Calcium plays a vital role in neurotransmitter release and in the activation of intracellular processes that result from neuronal excitation as well as in electrical stabilization of neuronal membranes. A high extracellular concentration of calcium decreases membrane permeability and reduces its excitability.

The early generalized weakness and fatiguability relate to reduced neuromuscular excitability.

Clinical features

The severity of neurological features depends on the serum concentration, the acuity of the hypercalcemia and the associated medical conditions. Mental status abnormalities commonly occur with serum calcium concentrations above 14 mg/dl (3.2 mmol/l) and consist of behavioural changes (ranging from personality changes to severe organic psychosis), confusion, progressing to lethargy, stupor and coma with clinical features of a diffuse or bihemispheric encephalopathy (Wang & Guyton, 1979). Convulsions occasionally occur. Severe hypercalcemia with impaired consciousness is more common with cancer than in hyperparathyroidism.

Ocular palsies, including internuclear ophthalmoplegia, and muscular wasting, weakness and areflexia have been associated with hyperparathyroidism (Patten & Pages, 1984). The association is not necessarily cause and effect, but one patient with this constellation improved with removal of the parathyroid adenoma and the other showed hemorrhagic lesions in the anterior horns of the spinal cord, as has been described with experimental animals with iatrogenic hyperparathyroidism (Patten & Pages, 1984).

Commonly associated problems include marked dehydration, abdominal pains, renal calculi and metabolic bone disease. Renal insufficiency (either prerenal, renal or obstructive uropathy) may add to the acute picture.

Laboratory features

Ionized calcium is the physiologically active component of extravascular calcium. Calcium is largely protein bound, but the ionized unbound portion's concentration is 1.16–1.32 mmol/l. in hypoproteinemia, it is important to correct for serum albumin concentration or to obtain an ionized calcium concentration.

Management

Severe, life-threatening hypercalcemia should be diagnosed from a combination of the clinical and laboratory features. It is important to sort out the underlying cause and to treat it, if possible (Nussbaum, 1993). The decision to treat should be based on the patient's anticipated quality of life and personal preferences, the diagnosis and prognosis of the underlying cause (often cancer). Hypercalcemia secondary to parathyroid adenoma, however, is cured with surgery.

Once a decision to treat has been made, it is usually best not to rapidly correct the hypercalcemia. The first step is to correct dehydration or volume replacement with intravenous saline. Potassium supplements are also usually needed. Subsequent specific treatment involves the correction of hypercalcemia over the next 24–48 hours.

A loop diuretic and further infusion of saline, after intravascular volume is adequate, enhance renal clearance of calcium. An intravenous biphosphonate drug (e.g. pamidronate or clodronate) is currently considered the drug of choice (Heath, 1989). Plicamycin (mithramycin), which inhibits bone resorption, is often effective but has significant dose and dose–duration toxic effects on the liver, bone marrow, coagulation system and kidneys. Gallium nitrate can be used as an alternative to plicamycin. Corticosteroids and calcitonin usually have modest, or transient effect at best, in controlling the hypercalcemia of malignancy (Thalassinos & Joplin, 1970; Hosking & Gilson, 1984). Calcitonin can help acutely while waiting for the effects of the biphosphonate. Corticosteroids may be effective in myeloma, lymphoma, sarcoidosis and vitamin D intoxication. Peritoneal or hemodialysis has been used to treat hypercalcemia from secondary hyperparathyroidism in patients with CRF (Cardella et al., 1979).

To prevent recurrence of the hypercalcemia, the malignant process needs to be controlled. Acute primary hyperparathyroidism requires surgical removal of the offending gland. Oral phosphate is effective in many patients but tolerated by few.

Hypocalcemia

Calcium exists in the plasma in three forms: an ionized or unbound portion (normally 50% of total), a protein-bound fraction (40%) and a chelated component (10%). The ionized portion, normally about 50% of the total, is physiologically active and homeostatically regulated (Zaloga et al., 1985).

Hypocalcemia is defined as a serum calcium of $<$8.15 mg/dl (2.12 mmol/l). About 10% of patients in ICUs have hypocalcemia, after correction for serum albumin levels and ionized calcium concentrations (Zaloga et al., 1985). A considerably smaller proportion is symptomatic.

Pathogenesis

The ionized portion can be altered by a change in pH; for example, with acidosis the protein binding is lessened and the percentage free fraction is increased. Conversely, in respiratory alkalosis the protein binding is increased and the free fraction is less, sometimes producing tetany.

Calcium homeostasis is regulated by secretion of parathyroid hormone (PTH). The parathyroid glands are sensitive to the plasma concentration of ionized calcium; secretion is prompt if the calcium concentration falls. PTH causes increased reabsorption of calcium from the kidney and gastrointestinal tract as well as increased mobilization of calcium from bone. A component of this is the PTH-mediated renal conversion of 25- to 1,25-hydroxyvitamin D. A deficiency of either PTH or Vitamin D can produce hypocalcemia. Parathyroid hormone secretion is inhibited by severe hypo- or hypermagnesemia. Table 124.5 gives a classification of the major causes, with emphasis on patients in the intensive care units.

Extracellular calcium ions have a stabilizing effect on the neuronal membrane. When reduced in concentration, the membrane is hyperexcitable, because of this membrane effect and the decrease in calcium-mediated potassium conductance.

Table 124.5. Causes of hypocalcemia

Category	Specific cause	Mechanism
Hypoparathyroidism	Postsurgical	Reduced PTH secretion
	Autoimmune disease	Reduced PTH secretion
	Infiltrative (e.g., cancer, hemochromatosis, sarcoid	Reduced PTH secretion
	Irradiation	Reduced PTH secretion
	Severe hypomagnesemia	Inhibits PTH secretion
Vitamin D deficiency	Inadequate intake, severe liver or kidney disease	Decreased formation of 25- or 1,25-hydroxyvitamin D
Acute complexing or sequestration of calcium	Acute pancreatitis	Sequestration of ionized calcium in an acute situation
	Rhabdomyolysis	(PTH secretion cannot compensate)
	Massive tumour lysis	
	Phosphate infusion	
	Toxic shock syndrome	
	Acute severe illness	
	Alkalosis	
Increased osteoblastic activity	Hungry bone disease	Postparathyroidectomy
	Osteoblastic metastases	Prostate or breast cancer
Drugs		
Anticalcemic agents	Biphosphonates	
	Plicamycin	
	Calcitonin	
	Gallium nitrate	
	Phosphate	
Antineoplastic agents	Asparaginase	
	Doxorubicin	
	Cytosine arabinoside	
	WR2721	
	Cisplatin	
Others	Ketoconazole	
	Pentamadine	
	Foscarnet	

Intracellularly, calcium is required for the activity of many enzymes and in the maintenance of the integrity of cells (Pappius, 1976). In hypoparathyroidism the concentration of intracellular calcium is reduced by 10% in the cerebral cortex, but by about 35% in the white matter (Pappius, 1976).

Clinical features

Although the threshold for neurological symptoms is not well defined, life-threatening complications frequently develop when the ionized portion falls to less than 2mg/dl (0.5 mmol/l).

Seizures, usually of the generalized convulsive type, are the main complication of acute, severe hypocalcemia (Eastell & Heath, 1992). They are more likely to occur in patients with pre-existing seizure disorders. Mental changes include depression, agitation, hallucinations, psychosis, but these are non-specific. Tetany with carpopedal spasm may occur, along with muscle spasms and cramps, paresthesiae and weakness.

The most important clinical signs are those of neuromuscular irritability: increased deep tendon reflexes and positive Chvostek's and Trousseau's signs. Pseudotumour cerebri with papilledema may complicate hypoparathyroidism.

Many of the classic clinical signs and symptoms of hypocalcemia may be absent or blunted in the ICU because of the use of drugs with paralysing, sedating and antiepileptic properties.

Laboratory features

Most hospital and private laboratories report the total serum calcium concentration; this comprises the protein

bound, free ionized and complexed forms. The normal total serum calcium concentration is 8.5–10.5 mg/dl (2.12–2.62 mmol/l). The concentration of calcium varies with serum albumin; as a rule of thumb, for each 1.0gm/l decrease in albumin, the serum calcium drops by 0.8 mg/dl (0.02 mmol/l). The normal ionized serum calcium is 4.1–5.1 mg/dl (1.02–1.27 mmol/l). One can estimate the ionized calcium under most conditions on regular wards. However, in many ICU situations, especially with rapid chelation by blood transfusions and rhabdomyolysis or pancreatitis, the extent of protein binding varies unpredictably; it is important to measure the ionized serum calcium.

Management

All patients with signs or symptoms of hypocalcemia should be treated. Patients with seizures and impaired consciousness require emergency treatment. Etiology-specific therapy is ideal.

Emergency management of hypocalcemia involves the prompt administration of calcium gluconate. Ten to 20 ml of 10% calcium gluconate, containing 93 mg of elemental calcium, is administered intravenously over 10 minutes. A more rapid infusion may cause cardiac irregularity. A continuous infusion can follow: an infusion of 15mg/kg will raise the serum calcium by 2–3 mg/dl; 11 ampoules are required for a 70 kg man to achieve this (Tohme & Bilezikian, 1993).

Chronic management requires correction of the underlying cause. In the case of hypoparathyroidism, lifetime supplementation is necessary. The mainstay of treatment is vitamin D. Orally administered, elemental calcium supplements, e.g. 1–1.5 g/day of elemental calcium in the form of calcium carbonate, citrate, lactate, gluconate or glubionate, are usually required as well. In malabsorption syndromes there may be malabsorption and deficiency of vitamin D itself. Large doses of vitamin D may be required, leading to a risk of vitamin D intoxication.

Hypocalcemia due to magnesium deficiency does not respond to calcium supplementation alone, but does recover following magnesium replacement. As a corollary, it is generally wise to measure the serum magnesium whenever hypocalcemia is found, and to correct any deficiency.

Hypermagnesemia

Normal serum magnesium ranges from 1.3 to 2.1 meq/l (0.8–1.3 mmol/l; 2–3 mg/dl); values over 2.1meq/l therefore constitute hypermagnesemia, although clinical symptoms begin at 4 meq/l. It is almost certainly under recognized. A survey in an Oklahoma VA hospital revealed elevated serum magnesium in 59 of 1033 samples (5.7%) (Whang & Ryder, 1990). Of these, physicians had requested serum magnesium determination in only 7 (13%).

Pathogenesis

Clinically significant hypermagnesemia mainly occurs in the context of renal failure and magnesium administration. The latter may be administered as a cathartic or as an antihypertensive, e.g. as treatment for pre-eclampsia or eclampsia (Smilkstein et al., 1988). Hypermagnesemia has been reported in cases of abuse of laxatives and/or antacids (Castelebaum et al., 1989).

Magnesium excess reduces the metabolic rate of glucose utilization in both the grey and white matter of the rat spinal cord (Szabo & Crosby, 1988).

Clinical features

Oral ingestion may cause gastrointestinal irritation and diarrhea. Hypotension may occur; this is usually mild, but can be marked if hypovolemia is also present (Zwerling, 1991).

Although hypermagnesemia causes central nervous system (CNS) depression, the loss of deep tendon reflexes usually precedes the mental status changes, and occurs at 5–6 mEq/l. At 8–10 meq/l, CNS depression develops. Neuromuscular paralysis may precede the clinical recognition of encephalopathy. Lethargy and confusion are, however, common early manifestations (Alfrey et al., 1970). High serum levels, e.g. more than 9 meq/l, may also cause parasympathetic paralysis, besides coma, neuromuscular paralysis (including cranial nerve innervated and respiratory muscles) and areflexia (Rizzo et al., 1993). At times, this may mimic a brainstem stroke.

One should be suspicious of hypermagnesemia in any patient with renal failure who develops encephalopathy with weakness and areflexia, with or without palsy of cranial nerve innervated muscles.

Laboratory features

Serum magnesium determination is essential. However, since magnesium is mainly intracellular, it gives only a rough estimate of the total body burden of magnesium.

EEG slowing is found with serum magnesium concentrations above 15 meq/l (Somjen et al., 1966). EMG may show a presynaptic defect in neuromuscular transmission: compound muscle action potential amplitudes are reduced; there is a decremental amplitude of response to muscle nerve stimulation at low rates and marked amplitude

increase following brief exercise or high stimulation rates (Swift, 1979).

Treatment

Since the effects of magnesium on the neuromuscular junction are the most life-threatening and since these are antagonized by calcium, treatment of Mg intoxication includes calcium gluconate administration. This is usually given as 10 ml of a 10% solution and can be repeated as necessary to overcome neuromuscular blockade. Hemodialysis may be necessary to lower the serum magnesium concentration in very symptomatic patients, especially in the presence of renal failure.

Supportive care, especially concerning ventilatory function in the ICU, may be necessary. Blood pressure support, especially with optimization of blood volume, may be necessary if the patient is hypotensive.

Hypomagnesemia

Hypomagnesemia is defined as a serum magnesium of less than 1.7 mg/dl (Al-Ghamdi et al., 1994). Neurological features are usually only present with a serum concentration of less than 0.8 meq/l. Since only 10% of magnesium is extracellular, the estimate of total body magnesium deficiency may be grossly inaccurate. A low serum concentration usually reflects a severe body deficit in magnesium, but the serum magnesium may be normal despite a general body deficiency. Magnesium concentrations are higher in the CSF than in the plasma, due to active secretion by the choroid plexus (Pappius, 1976).

Prevalence and significance

Since magnesium is present in abundance in most foods, its deficiency in normal individuals is rare. In hospitals, however, the estimated percentage of patients with low body amounts of magnesium ranges from 4 to 47% (Croker & Walmsley, 1986; Whang & Ryder, 1990; Rysen et al., 1985). The prevalence is highest in acute care, especially intensive care, settings.

Magnesium is absorbed from the small bowel. Most of the body's magnesium is intracellular and chelated to ATP, ADP, proteins, RNA, DNA and citrate. Only 5–10% of the intracellular magnesium is free or ionized. In the plasma 60% is free or unbound. The kidney is responsible for maintaining the serum concentration of Mg within a narrow range. Phosphate depletion can produce hypomagnesemia through an uncertain renal mechanism. Intracellular Mg is maintained at the expense of extracellular Mg and bone reservoirs (Quamme, 1993).

Etiology and pathogenesis

The most common causes are protein calorie malnutrition, malabsorption, diabetic ketoacidosis, sepsis, diuretic use, alcohol abuse, hyperaldosteronism, hypocalcemia (Olerich & Rude, 1994). In addition, certain drugs such as loop diuretics, aminoglycosides, cisplatin and cyclosporin may lower the body's magnesium stores. There may also be an inborn error of metabolism in some affected infants (Pappius, 1976). Some of these causes may act synergistically to create an acute deficiency syndrome: in alcoholics, pre-existing magnesium depletion, catecholamine-induced Mg redistribution and respiratory alkalosis (causing a shift of Mg intracellularly) may coincide to precipitate seizures and other features of the alcohol withdrawal syndrome (Al-Ghamdi et al., 1994).

The main effects of low magnesium are membrane effects. Low intracellular magnesium can modify current flow through calcium, potassium and chloride channels (Kelepouris et al., 1993). Magnesium ion also reversibly occludes the ion channels governed by the *N*-methyl-*D*-aspartate receptor, one of the main excitatory receptors in the brain. Thus, some ionic currents may be affected. Magnesium, however, probably plays a more important role in relation to receptor sites, because of its association with second messenger systems (Iyengar & Birnbaumer, 1982). Magnesium is involved in many enzyme systems: those for intermediary metabolism, biosynthesis of nucleic acids, proteins and lipids and most enzymes that require adenosine triphosphate (ATP) (Pappius, 1976).

Serum magnesium is maintained in a narrow range by the kidney and small intestine and concentrations in the CSF and brain are well regulated. It requires extremely severe malnutrition to significantly lower brain magnesium concentration to a concentration that would interfere with enzymatic function (Pappius, 1976).

Some of the manifestations of hypomagnesemia may be due to low extracellular concentrations of ionized calcium. This may explain the hyperexcitability found in some patients. In others, the features may be due to the membrane effects of hypomagnesemia itself (Wacker & Parisi, 1968).

Clinical features

Neurological manifestations are similar to those of hypocalcemia, including hyperexcitability, muscle cramps, tetany (with positive Chvostek's and Trousseau's signs), hyperreflexia and seizures. Other clinical features that have been described include vertigo, nystagmus, dysphagia, athetoid movements, focal signs such as hemiparesis and aphasia (Hamed & Linderman, 1978; Leicher et al.,

1991; Hall & Joffe, 1973). An acute organic brain syndrome with psychiatric manifestations may develop.

In children, problems are mainly in the neonate and early infancy: decreased intestinal absorption and impaired renal reabsorption, neonatal hepatitis and maternal conditions (vomiting, diabetes mellitus, diuretics and excessive lactation). Seizures, tetany, hyperirritability and impaired consciousness are the main features.

Serious cardiac complications including arrythmias and congestive heart failure, that are refractory to standard therapy, are due to magnesium deficiency (Whang et al., 1994).

Laboratory investigations

Besides the serum magnesium concentration, there are other methods of estimating the deficiency of magnesium. A simple physiological test is the measurement of magnesium excretion in a 24-hour urine collection (Sutton & Domrongkitchaiborn, 1993). If the value exceeds 24 mg in 24 hours, there is evidence of renal magnesium wasting. If 12 mg or less are excreted, magnesium deficiency is highly likely.

The measurement of magnesium in erythrocytes or leukocytes offers a more accurate assessment of the total body deficit in magnesium (Geven et al., 1993). This is not commonly available, however.

Treatment

Parenteral magnesium is needed when convulsions occur. In such symptomatic magnesium deficiency, the average body deficit is 12–24 mg/kg body weight (Sutton & Dirks, 1991). This should be replaced by magnesium sulfate as a 50% solution, given in divided doses either intravenously or intramuscularly. About 50% will be lost in the urine. It can be given intravenously or intramuscularly for a total dose of 8–12 g of magnesium sulfate or 0.8–1.2 g of elemental magnesium. Caution should be used in the presence of renal failure. In any case, the serum magnesium and deep tendon reflexes should be closely monitored. Calcium should be available as a treatment in the event of hypermagnesemia. Since hypocalcemia often accompanies hypomagnesemia, calcium supplementation is usually needed. Potassium supplements are also often needed in magnesium deficiency (Al-Ghambi et al., 1994).

Caution should be exercised in the presence of renal failure since magnesium toxicity may quickly develop.

Prophylaxis of adding 100–200 mg per day to parenteral nutrition helps to prevent hypomagnesemia in the intensive care setting. A diet rich in magnesium will allow more gradual replacement of magnesium stores. Correction of risk factors (alcoholism, hypophosphatemia, diabetic control) may prevent excessive urinary losses.

Table 124.6. Causes of severe hypophosphatemia

Chronic alcoholism and alcoholic withdrawal
Dietary deficiency and phosphate binding antacids
Severe thermal burns
Recovery from diabetic ketoacidosis
Hyperalimentation
Nutritional recovery syndrome
Marked respiratory alkalosis
Therapeutic hyperthermia
Neuroleptic malignant syndrome
Recovery from exhaustive exercise
Renal transplantation
Acute renal failure
Shock with replacement with high volumes of glucose solutions

Hypophosphatemia

Hypophosphatemia is defined as a serum phosphate of $<$2.5 mg/dl ($<$0.83 mmol/l). 'Severe hypophosphatemia' (Table 124.6), during which symptoms relevant to the serum phosphate concentration appear, is reserved for a serum phosphate of $<$1.5 mg/dl (0.5 mmol/l) (Knochel & Montanari, 1992).

Pathophysiology

Like magnesium and potassium, phosphate is mainly intracellular and a low serum phosphate may or may not reflect a total body deficiency. Most of bound phosphate is attached to calcium in bone. Phosphate is extremely important in cellular energy and enzymatic processes (Pappius, 1976). Intracellular phosphate exists mainly as organic phosphate compounds such as creatine phosphate, adenosine mono-, di- or tri-phosphate. In red blood cells phosphate is involved in 2, 3 diphosphoglycerate (2, 3 DPG) that is involved in the energy metabolism of the erythrocyte. In hypoxia, phosphate stimulates anaerobic metabolism by activating phosphofructokinase, an enzyme that controls the rate of glycolysis (Siesjo et al., 1971).

Hypophosphatemia may arise from loss of total body phosphate, e.g. in the urine in diabetic ketoacidosis, poor absorption or inadequate phosphate in feeds (oral hyperalimentation), shifts from serum into cells (treatment of diabetic ketoacidosis, administration of high volumes of glucose-containing fluids, hyperventilation) and in alcoholism with or without alcohol withdrawal (possibly due to

increased phosphaturia) (Knochel, 1977; Territo & Tanaka, 1973).

The nadir of serum phosphate concentration is within 24 hours in diabetic ketoacidosis, between 2 and 4 days in acutely hospitalized alcoholics and often after 10 days of hyperalimentation (Knochel, 1977).

All levels of the nervous system can be clinically affected in hypophosphatemia. The cause of central nervous system dysfunction in hypophosphatemia is uncertain. This may relate to inadequate oxygenation of tissues due to red blood cell 2, 3-DPG dysfunction. Associated hyperventilation, e.g. in hyperammonemia, hypoxemia, or decreased 2, 3-DPG may cause reduced cerebral blood flow and further compromise cerebral energy metabolism. Altered neurotransmitter function has been found in an animal model, but uncertainty exists as the animal may have been hypotensive (Knochel & Motanari, 1992; Bhaskaran et al., 1987).

In clinical practice, there are often coexisting disorders that may also cause an encephalopathy, e.g. alcoholism with infections, pancreatitis, hypomagnesemia, hepatic failure. It may be difficult to know which are the main factors causing the impaired consciousness. The fact that apparently isolated severe hypophosphatemia, especially if there is cellular depletion of phosphate, can cause encephalopathy is an argument for replacement therapy (Knochel, 1977).

Clinical features

Patients with hypophosphatemia may demonstrate an acute confusional state with irritability and apprehension, variable motor abnormalities including athetosis, ballismus, myoclonus, ataxia, asterixis, weakness or paralysis with areflexia (peripheral) or a Guillain–Barré-like syndrome. Lethargy, distal paresthesiae, dysarthria and abnormal respiratory patterns may be early features (Prins et al., 1973).

A syndrome of impaired eye movements, confusion and ataxia, closely resembling Wernicke's encephalopathy has been noted (Vanneste & Hage, 1986). This can be a diagnostic problem in treating alcoholics or the nutritionally deprived. Hypophosphatemia should be considered in patients with the clinical picture of Wernicke's encephalopathy who fail to respond to thiamine. Leigh's syndrome may also be mimicked in infants. Other cranial nerve palsies may resemble botulism.

Reversible coma can occur, with or without seizures. We have also seen hypophosphatemia mimic brain death in a trauma patient who received large amounts of glucose solutions (Young et al., 1982). The cranial nerve areflexia and paralysis of movements were reversed by phosphate administration.

Management

It is wise to consider hypophosphatemia (as well as hypomagnesemia) when patients at risk (patients with malnutrition who are being fed, patients on hyperalimentation, alcoholics in hospital) show altered consciousness or awareness with or without the other neurological complications mentioned above. Long-term infusions that do not contain phosphate, calcium or glucose may be especially problematic (Prins et al., 1973; Dudrick, 1972).

While replacing phosphate, it is best to temporarily stop the hyperalimentation program, or to reduce calorie supplementation, until the neurological symptoms clear. This is often essential for prompt recovery; phosphate supplementation alone may not affect the clinical condition for some time (Prins et al., 1973).

In most cases it is unclear whether hypophosphatemia reflects a total body deficiency of phosphorus. In previously healthy patients who become acutely ill, it is unlikely that there is a phosphate deficiency. In the nutritionally deprived, however, it is likely that there is such a deficit. In milder cases the need for phosphate supplementation can be determined by history, review of medications, nutrition and therapy, blood gases, urinary phosphorus and creatinine (calculation of fractional excretion of phosphate).

If supplements are needed and the patient is able to take fluids orally, it is safest to give milk, which contains 0.9 mg of phosphorus per ml. Other oral phosphate solutions are available. Parenteral administration of 9mmol of phosphorus in 77 mM NaCl solution over 12 hours to provide 4 mg/kg body weight over this time has been implemented (Vannatta et al., 1981). Magnesium supplementation should also be considered as magnesium deficiency will contribute to further excessive losses of phosphate in the urine (Knochel & Montanari, 1992).

Complications of phosphate administration include hyperphosphatemia, hypocalcemia, hyperkalemia (if potassium salts of phosphate are used), metabolic acidosis, and volume excess with intravenous solutions. Oral treatment may cause diarrhea. It is thus important to monitor the serum phosphate and other electrolytes and calcium during therapy.

Hyperkalemia

Hyperkalemia refers to a serum potassium concentration of over 5.5 meq/l (5.5 mmol/l).

Potassium homeostasis is largely dependent on renal function. Hence, clinically significant hyperkalemia is mainly seen in renal failure. These complications are discussed above. Hyperkalemia may also accompany adrenal

insufficiency, especially with lack of the mineralocorticoid hormone, aldosterone. Acidosis with, or without, insulin deficiency may also be associated with hyperkalemia

Clinical features

Usually cardiac complications of hyperkalemia eclipse any neurological complications. However, hyperkalemia is sometimes associated with diffuse muscle weakness and fatiguability, most strikingly in adrenal insufficiency. Rarely, hyperkalemia can produce a flaccid quadriparesis that mimics an acute motor polyneuropathy.

Hyperkalemia does not appear to have significant central nervous system complications. Patients commonly are lethargic or nervous, but these symptoms may relate to the associated underlying diseases rather than to the potassium concentration.

Hypokalemia

Hypokalemia, defined as a serum potassium concentration of less than 3.5 mEq/L (mmol/L), is the most common electrolyte disturbance. Causes include excessive losses through the gut or kidney (various disorders, some iatrogenic), diminished dietary intake or with shift of potassium into cells (as in hypokalemic periodic paralysis, insulin effect or systemic alkalosis).

Clinical features

The main neurological complication is muscular weakness (Raymond & Kunau, 1987). This begins at about 3.0 meq/l (mmol/l), but concentrations of 2.5 meq (mmol/l) or less are associated with significant proximal weakness. Cranial nerve innervated muscles are typically spared. Rhabdomyolysis may develop with concentrations below 2.0 meq/L (mmol/l). Exceptionally, an encephalopathy may develop; it is rare for this to progress to coma.

Management

The underlying cause should be determined and addressed. When mild, oral supplementation is usually sufficient, but with ongoing losses (e.g. diarrhea), or when hypokalemia is profound, parenteral administration is necessary.

Disorders of intracranial pressure

Romergryko G. Geocadin[1] and Michael A. Williams[2]

[1] Department of Neurology and Anesthesiology-Critical Care Medicine, Johns Hopkins University School of Medicine, Baltimore, USA
[2] Department of Neurology and Neurosurgery, Johns Hopkins University School of Medicine, Baltimore, Maryland

Intracranial pressure (ICP) is the pressure within the cranial vault relative to the atmospheric pressure. Quincke first measured cerebrospinal fluid (CSF) pressure in 1891 via a lumbar puncture (Quincke, 1891). In 1902, Cushing demonstrated hypertension, bradycardia and respiratory changes in an animal model with severe ICP elevation (Cushing, 1902). In 1951, Guillaume and Janny first described the use of continuous ICP monitoring using an intraventricular catheter (Guillaume & Janny, 1951). Nine years later, Lundberg described ICP wave patterns and their response to medical and physiological interventions (Lundberg, 1960).

ICP measurement has been an invaluable tool in research and clinical practice. It has contributed much to the understanding of intracranial pathologies, and assessment of therapeutic interventions. Intracranial hypertension is the elevation of the intracranial pressure to levels that may lead to neurological injury. ICP monitoring is used for patients with neurological disorders that have a high risk of further neurological injury from increased ICP or mass effect. In this chapter, we discuss the physiology related to ICP, the techniques in measuring ICP, interpretation of ICP recordings, common ICP disorders and their management (including intracranial hypotension), and outcome studies of ICP monitoring and management of intracranial hypertension.

Intracranial physiology and intracranial pressure

The pressure wave of the ICP is generated by the transmission of arterial pressure from the major cerebral arteries (Martins et al., 1972) and CSF production by choroid plexus (Cardoso et al., 1983) in the cranial vault. In normal conditions, the transmitted pressure is attenuated by displacement of CSF back and forth through the foramen magnum into the distensible spinal dural sac. This provides a compliance mechanism for the cranial vault (Martins et al., 1972). In adults, the range of normal resting ICP is 0 to 15 mm Hg (0 to 20 cm H_2O). Sustained ICP greater than 15 mm Hg is considered abnormal. The relation of ICP to brain injury depends on the cause, acuity, severity and duration of the ICP. Transient elevations of ICP occur with coughing, sneezing, or Valsalva manoeuvres and do not cause harm in most persons.

Cranial vault mechanics

Monro in 1783, and Kellie in 1823 (Monro, 1783; Kellie, 1824) described cranial vault mechanics in the light that: (i) the skull is a rigid container; (ii) the normal intracranial contents may be considered liquid or viscous gel, and are therefore incompressible; and (iii) any mass added to the cranial vault requires the displacement of one of the normal contents. The intracranial space opens via the foramen magnum to the spinal space. The normal adult intracranial volume is 87% brain, 9% CSF and 4% blood (Rasomoff, 1953). The blood compartment can be further divided into arterial (30%) and capillary/venous (70%) compartments. Intracranial CSF is divided equally between intraventricular and subarachnoid compartments, including the cisterns. Under normal physiological conditions, CSF production is nearly constant at about 20 ml/h or 500 ml per day (Cutler et al., 1968). However, CSF production declines with elevated ICP (Borgesen & Gjerris, 1987) or inadequate cerebral perfusion (CPP) (Weiss & Wertman, 1978).

Intracranial elastance

Elastance is the change in pressure as a function of a change in volume (Miller & Leech 1975). Elastance

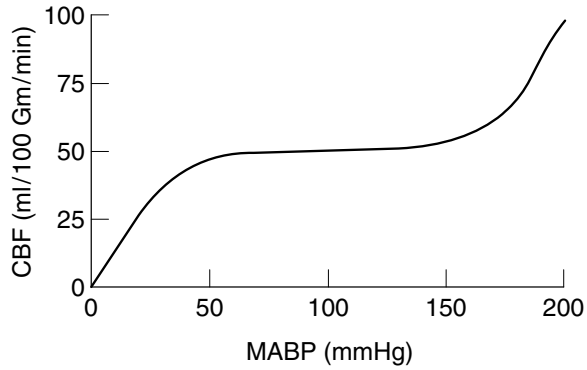

Fig. 125.1. The cerebrovascular autoregulatory curve.

describes the effect of a change in volume on ICP. Given the Monro–Kellie doctrine, displacement of intracranial CSF to the spinal CSF compartment initially accommodates the addition of volume by intracranial masses to the intracranial vault. This compensatory response allows for the maintenance of normal ICP in most cases. Further enlargement of an intracranial mass may not be accommodated, leading to a rise in ICP. After CSF is displaced from the cranial vault, then intravascular blood is displaced, reducing cerebral blood volume, and potentially reducing perfusion. As an intracranial mass further enlarges, brain tissue may be displaced, a process known as cerebral herniation. Depending on the nature of the mass and its rate of expansion, these physiologic and pathophysiologic responses may overlap. While CSF displacement may be asymptomatic, displacement of intravascular blood can lead to ischemia, causing either focal or global deficits. Herniation can cause secondary injury by compression of vascular and neural structures.

Cerebral autoregulation

Cerebral perfusion pressure (CPP) is a critical determinant of cerebral blood flow (CBF). CPP is defined as mean arterial blood pressure (MABP) minus the ICP (or jugular venous pressure (JVP) if it is higher than the ICP). The ability of the brain to maintain a near constant CBF over a wide range of CPP by adjusting cerebrovascular resistance is known as autoregulation. Between CPP of approximately 50 and 150 mm Hg, there is very little rise of CBF (Fig. 125.1). The constancy of CBF over this range is governed by changes in cerebrovascular diameter and resistance. Autoregulation depends on an intact vasculature and blood brain barrier (BBB). Changes in cerebrovascular diameter are associated with corresponding changes in cerebral blood volume, which may affect ICP. When CPP is outside the autoregulatory range, the relationship between CPP and CBF becomes linear. When CPP is too low, as is seen either with severe ICP elevation, or circulatory collapse, the risk of cerebral ischemia is high. When CPP is too high, as in hypertensive encephalopathy, the risk of cerebral microvascular disruption with hyperemia and cerebral edema is high.

Intracranial pressure measurement and monitoring

ICP can be measured continuously via an ICP monitoring system and transiently during lumbar puncture via a manometer attached to the spinal needle. ICP monitoring systems can be categorized by the coupling medium, the interface medium between the patient and the pressure transducer. The 2 types are fluid-coupled and solid-state systems.

Fluid-coupled ICP systems

Fluid-coupled systems with external transducers include intraventricular catheters (IVC), subarachnoid bolts (SA bolt) and lumbar catheters (LC). The IVC is considered the most precise and accurate method of measuring ICP (Anon., 1996b). The catheter is passed through a burr hole into the lateral ventricle for CSF access. The IVC is then coupled to an external transducer via fluid-filled tubing. Injury to brain parenchyma is an important consideration in IVC insertion, although the incidence is low. The most significant risk of IVC usage is infection (Mayhall et al., 1984) and the risk appears to be related to the duration of the IVC (>5 days) (Mayhall et al., 1984). The use of prophylactic antibiotics with IVCs varies among institutions, and its role in preventing infection has not been definitely established.

The subarachnoid (SA) bolt is a hollow, self-tapping bolt that is inserted into the skull via a burr hole, and the dura at the base of the bolt is perforated with a spinal needle to allow subarachnoid CSF to fill the bolt. Fluid-filled tubing establishes the fluid coupling to the transducer. The ICP waveform and pressure reading are reliable, but error may occur if the dural perforations become plugged (Mendelow et al., 1983). The infection risk for SA bolts is low (Winn et al., 1977) and injury to brain parenchyma is rare. The bolt does not require contact with the ventricle, so it can be used in patients with compressed ventricles (Vries et al., 1973).

Lumbar catheters can be used to monitor ICP via the lumbar subarachnoid space. The use of a lumbar catheter

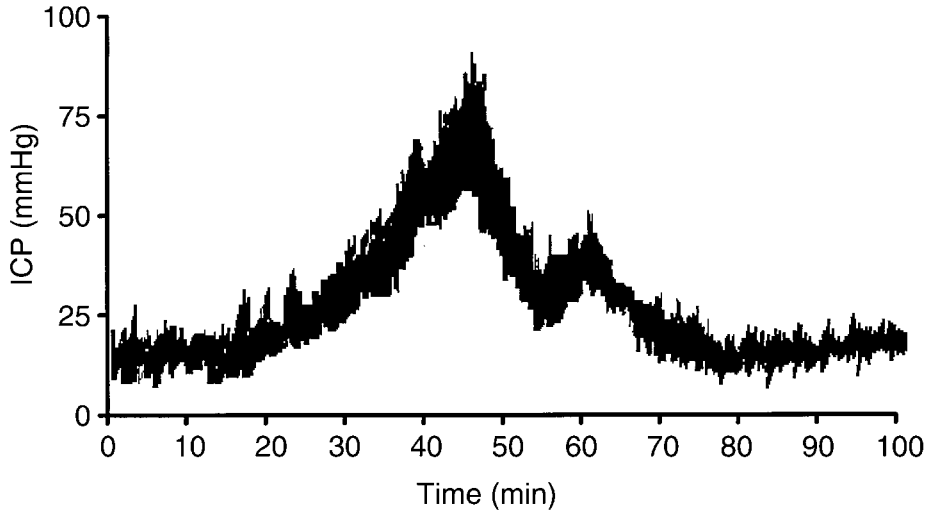

Fig. 125.2. Lundberg A or plateau wave.

is contraindicated with obstructive hydrocephalus or intracranial masses because of the risk of cerebral herniation, and effectively reflects ICP only when the spinal CSF pathways are patent.

Solid-state ICP systems

Solid-state ICP monitors use miniature transducers at the end of a wire, fibre-optic cable, or ventricular catheter that are coupled to an external instrument. These devices can be used for ICP monitoring alone, or incorporated into an IVC for simultaneous ICP monitoring and CSF drainage. Depending on their construction, solid-state devices can be inserted in the ventricles, the brain parenchyma, the subarachnoid space, or the epidural space.

Indications for ICP monitoring

The decision to begin ICP monitoring is often based on individual patients' risk of further neurological injury and deterioration. This is influenced by the primary pathology, coexisting systemic injuries, neuroimaging (head computerized tomography (CT) or magnetic resonance imaging (MRI)), and the availability of skilled physicians to insert the devices, interpret the ICP readings, and undertake therapeutic manoeuvres. The Brain Trauma Foundation (BTF) guidelines for ICP monitoring in severe traumatic head injury (Anonymous, 1996a) recommend ICP monitoring when: (i) GCS is 3–8 after CPR with an abnormal head CT (hematoma, contusion, edema and compressed basal cisterns; or (ii) a normal head CT scan with two or more of the following: age >40 years, unilateral or bilateral posturing, or systolic BP <90 mmHg. Other conditions that can cause secondary cerebral injury by intracranial hypertension may warrant ICP monitoring, including intracranial tumours, massive ischemic strokes, intracranial hemorrhages, cerebral edema, and hydrocephalus. There are no established guidelines for the placement of an ICP monitor in these clinical situations. If a monitor is inserted and the ICP is normal, and the clinical condition suggests no risk of ICP elevation after 24–48 hours of monitoring, the ICP monitor can be removed.

Interpretation of ICP and ICP waveforms

Proper interpretation of ICP requires assessment not only of the mean ICP (the value usually displayed on the ICU monitor), but also the pattern of ICP changes and the response to different stimuli. Lundberg performed systematic observation of ICP and its response to medical and physiological interventions, and described three patterns of pressure fluctuations: A-, B- and C-waves (Lundberg, 1960).

A-waves (plateau waves) are the most extreme form of ICP elevation, consisting of sudden, rapid elevation of ICP from a baseline of 20–30 mm Hg to 70–100 mm Hg and higher (Fig. 125.2). They are sustained for 5 to 20 minutes, and terminated by a rapid decline of ICP to levels at or below the baseline ICP. Plateau waves may represent near exhaustion of intracranial compliance mechanisms (Czosnyka et al., 1999) and often accompany cerebral herniation and cerebral circulatory arrest (Tsementzis et al.,

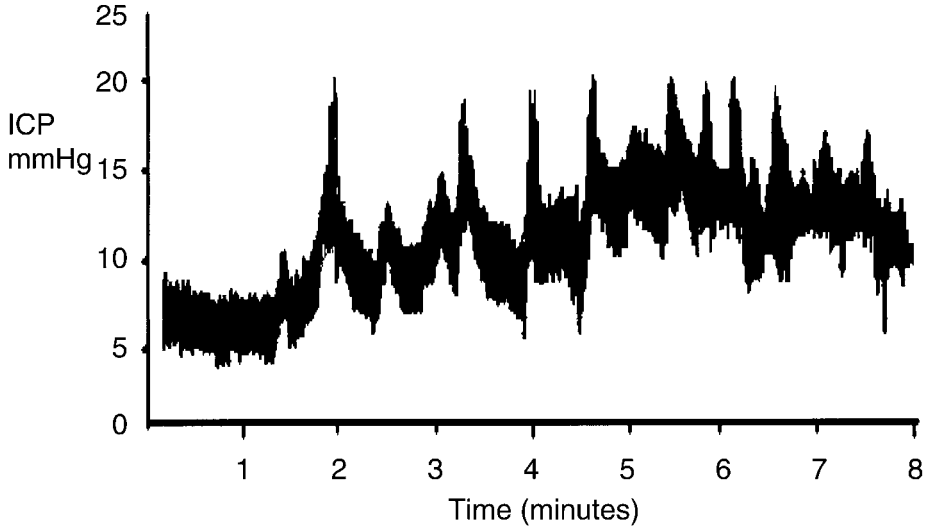

Fig. 125.3. Lundberg B waves.

1979). Emergent intervention with medical and neurosurgical decompression is usually needed.

B-waves are shorter and lesser ICP elevations that occur at a frequency of 0.5 to 2 cycles per minute (Fig. 125.3). B-waves are probably caused by fluctuations of CBV related to hypercapnea or hypoxia-induced cerebral vasodilation, and suggest reduced intracranial compliance, though not to the degree seen with plateau waves. C-waves are low amplitude oscillations with a frequency of 4 to 8 cycles per minute closely related to blood pressure variation (Traube–Hering–Mayer waves) (Kjallquist et al., 1964). The appearance of B-waves is an indication to initiate therapy to reduce ICP; the appearance of C-waves does not require intervention. These waveforms, which last for minutes, are difficult to identify with standard bedside ICU monitors that display only 4–5 seconds of activity.

Disorders of intracranial pressure

Clinical aspects of intracranial hypertension

With mass lesions in the cranial or spinal spaces, pressure gradients may occur. Local, compressive ICP effects are commonly seen with masses, and diffuse ICP effects are seen in hypoxic–ischemic injury, hydrocephalus or pseudotumour cerebri. Causes of disordered ICP include acute obstructive and communicating hydrocephalus; intracranial masses, such as tumour, edema, intracranial hemorrhage (parenchymal, epidural, subdural, subarachnoid and intraventricular); and pneumocephalus. The relation of ICP to secondary neurological injury depends on the etiology, acuity and severity of any ICP change or mass effect.

The signs and symptoms of intracranial hypertension are generally due to pressure effects on critical structures, and can manifest as headache, diplopia, ataxia, nausea, vomiting, drowsiness, stupor, respiratory arrest and coma. Compression of the midbrain is key in central and uncal (transtentorial) herniation syndromes. Central herniation is typically caused by bilateral or centrally placed supratentorial lesions that displace the midbrain caudally below the plane of the tentorial opening (Fig. 125.4). Patients become drowsy and lapse into coma rapidly. Respiration can be impaired, and airway and ventilatory support should be readily available. The pupils can be normal initially, but can rapidly dilate and become unreactive. Loss of extraocular eye movements, and oculovestibular reflexes also occurs. Uncal herniation is typically associated with unilateral lesions in the basal ganglia, thalamus, or the temporal and frontal lobes. The midbrain is generally distorted and compressed, and sometimes is displaced laterally into the tentorial edge, which can incise the cerebral peduncle (Kernohan's notch) (Kernohan & Woltman, 1929). The perimesencephalic cisterns are often effaced, and the posterior cerebral artery or oculomotor nerve can be compressed (Fig. 125.5). The level of consciousness will deteriorate, and a phase of restlessness and irritability is often seen. There can be ipsilateral pupillary change, from round to ovoid, and eventually to an unreactive and dilated pupil. Bilateral pupillary dysfunction may follow, as well as paresis, motor (extensor or flexor) posturing, irregular

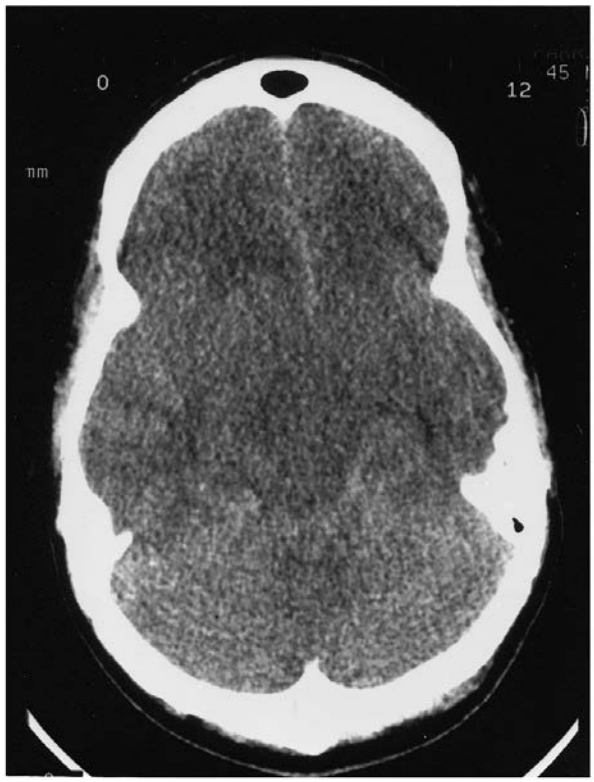

Fig. 125.4. A head CT scan of a comatose 45-year-old man with central herniation syndrome. He had bilateral fixed and dilated pupils, secondary massive cerebral edema and intractable intracranial hypertension. The CSF spaces, especially the perimesencephalic cisterns are effaced.

respiration and hemodynamic instability. The paresis is due to the compression of the cerebral peduncle. Medullary involvement can be manifested as the Cushing reflex: apnea, bradycardia and hypertension.

Management of acute intracranial hypertension

The goals of management are (i) reduction of intracranial pressure, (ii) maintenance of adequate cerebral perfusion pressure, and (iii) prevention of cerebral herniation. The Brain Trauma Foundation guidelines recommend treating ICP above 20–25 mm Hg in severe head injury (Anon., 1996a). ICP at 20 mm Hg or more is a strong predictor of neurological deterioration (Juul et al., 2000), while ICP below 20 mm Hg is associated with improved outcome after head injury (Eisenberg et al., 1988). The interaction of ICP and CPP should not be overlooked, and maintenance of adequate CPP also improves morbidity and mortality outcomes (Rosner et al., 1995).

Therapeutic strategies for ICP reduction can be directed at the different intracranial components: intravascular blood, CSF, brain and the mass lesion. We describe as follows the strategies for rapid ICP reduction, for maintenance or control of ICP, and for surgical intervention.

Medical management

Head positioning

Head elevation to 30 degrees above horizontal may help to optimize cerebral perfusion pressure (Durward et al., 1983; Moraine et al., 2000). The head should be in the midline, rather than turned to the side, in order to preserve jugular venous drainage. Circumferential binding or taping of the neck, as is sometimes done to secure endotracheal tubes, should be avoided.

Endotracheal intubation and hyperventilation

Hyperventilation (HV) is an effective and rapid therapeutic intervention that works by causing hypocapnea, and acute respiratory alkalosis, which leads to vasoconstriction in areas of the cerebrovascular bed that have not been injured. In patients who are not yet intubated, HV can be done manually with a facemask, followed by endotracheal intubation as quickly as is safe and feasible. Endotracheal intubation itself can increase ICP and potentially precipiate cerebral herniation, therefore adequate premedication with drugs such as thiopental, lidocaine or etomidate to blunt this effect is necessary.

The effect of HV is both rapid and short lived (Muizelaar et al., 1991), and excessive HV can potentially cause cerebral ischemia. Moderate hyperventilation (P_aCO_2 to 30 ± 2 mm Hg for 30 minutes) has been shown to be safe after traumatic brain injury with no impairment of global cerebral metabolism (Diringer et al., 2000). Neither prophylactic nor chronic hyperventilation benefits patients and should be avoided (Anon. 1996c). During acute intracranial hypertension, we maintain P_aCO_2 at 30 ± 2 mm Hg for 4 to 6 hours, and initiate other treatments for ICP. Once ICP is controlled, reduction of HV can be attempted gradually.

Treatment of brain edema with corticosteroids

Corticosterids are effective in reducing intracranial pressure associated with tumour-induced cerebral edema (French & Galicich, 1964). Intravenous dexamethasone reduces ICP and improves intracranial compliance leading to fewer and briefer plateau waves in patients with supratentorial tumours (Alberti et al., 1978). Corticosteroids are

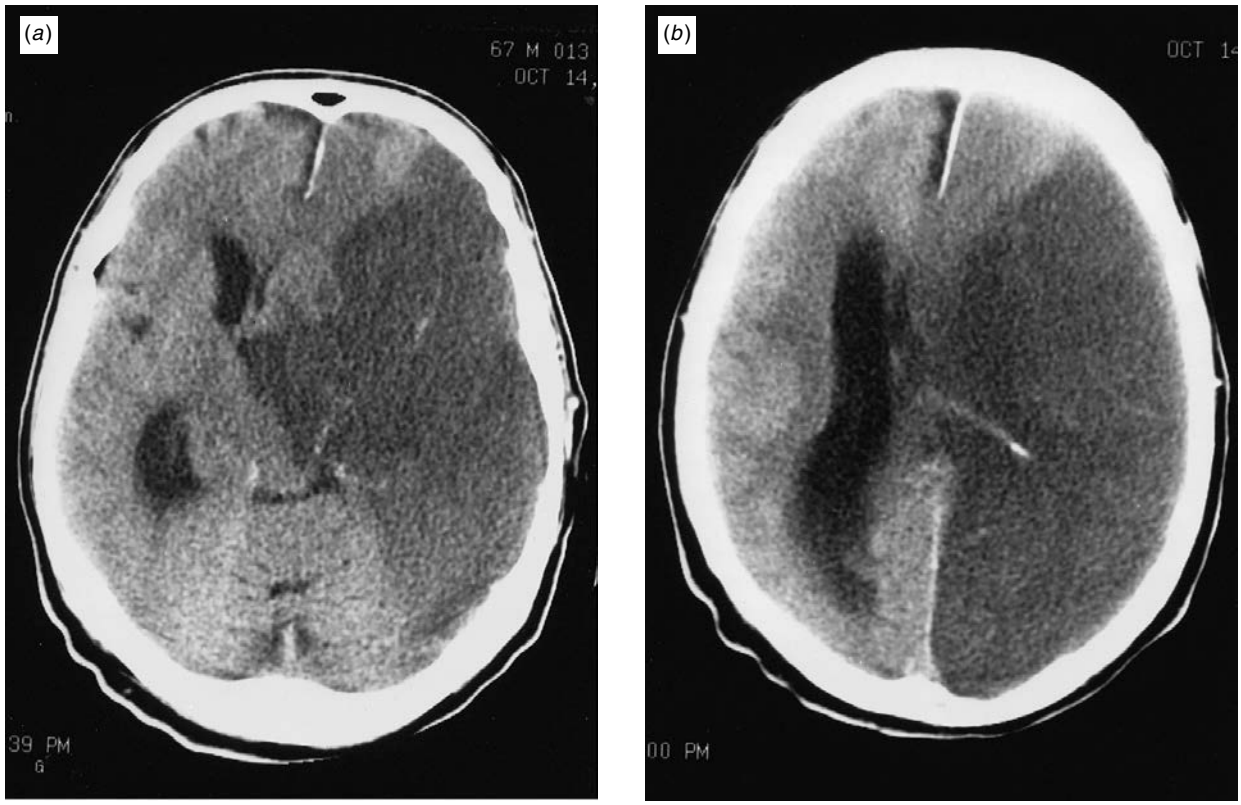

Fig. 125.5(*a*), (*b*). Head CT scan of an 80-year-old man with right MCA infarction and uncal herniation. He had unilateral pupillary dilatation. The herniation caused the infarct of the midbrain region (*a*) and the right occipital lobe. Both areas are perfused by the right PCA. The region supplied by the ACA is spared.

not effective in traumatic brain injury (Anon., 1996f), or in focal (Patten et al., 1972) or global cerebral ischemia (Jastremski et al., 1989). Corticosteroids can cause hyperglycemia, which should be monitored and controlled.

Hyperosmolar therapy: mannitol

Hyperosmolar therapy depends on establishing an osmotic gradient across an intact blood brain barrier that leads to the reduction of cerebral edema volume, leading to ICP reduction. Mannitol is the most commonly used osmotic agent in the United States, and is effective in head injury (Anon., 1996d). Mannitol has immediate and delayed actions in controlling ICP. The immediate action is believed to be caused by rheologic and plasma-expanding effects leading to reduction of hematocrit and blood viscosity. This increases cerebral oxygen delivery to the brain, which results in vasoconstriction believed to cause the ICP reduction (Muizelaar et al., 1983, 1984). The immediate effect occurs within minutes, and is best accomplished with bolus infusion in the range of 0.25–1.0 g/kg. The delayed effect is attributed to establishment of an osmotic gradient across the blood–brain barrier, which can decrease the water content of the brain by as much as 6% (Nath & Galbraith, 1986). ICP control may last for 90 minutes to 6 hours. Because mannitol is an osmotic agent with diuretic effect, it can cause hypovolemia and hypotension, which may cause cerebral ischemia. Attention to intravascular volume status after mannitol administration is important. Intermittent boluses of mannitol may be more effective than continuous infusion (Anon., 1996d).

Hyperosmolar therapy: hypertonic saline

Hypertonic saline solutions are re-emerging as a popular therapy for intracranial hypertension. NaCl is tightly regulated at the blood–brain barrier, and does not pass freely across it. Intravascular hypernatremia (i.e. increased serum Na concentration) reduces intracranial pressure, and avoids hypovolemia. Saline infusion (3% NaCl) to maintain serum Na at 145–155 meq/l reduces ICP. This therapy seems to work better in head trauma and postoperative brain edema, than in non-traumatic intracranial hemorrhage or cerebral ischemia (Qureshi et al., 1998).

Bolus administration of concentrated saline solutions (23.4% NaCl (4 meq/ml)) is effective in treating refractory ICP elevation, and this effect lasts about 6 hours (Suarez et al., 1998). The potential risks of hypertonic saline therapy include renal injury, injury to myelinated tissues (i.e. central pontine myelinolysis), intravascular fluid overload and hyperchloremic acidosis. Controlled studies comparing hypertonic saline to mannitol have not been performed, and hypertonic saline is not yet accepted as a standard therapy.

Metabolic suppression: barbiturate coma

The ultimate purpose of CBF is the delivery of oxygen (DO_2) to the brain. Impaired CPP and CBF cause a mismatch between DO_2 and cerebral metabolic demand ($CMRO_2$) which can cause cerebral ischemia or infarction. Barbiturates reduce $CMRO_2$, which is coupled to DO_2 and CBF in intact brain. CBF reduction is caused by vasoconstriction, which lowers CBV and ICP. Thus, barbiturate therapy can be used to correct this mismatch between DO_2 and $CMRO_2$ by reducing $CMRO_2$. The goal of this therapy is to reduce ICP while maintaining adequate CPP.

Barbiturate therapy entails the induction and maintenance of general anesthesia for a prolonged period of time (days to weeks), and thus carries significant risks along with the potential benefits. First, barbiturates obliterate neurological responsiveness, and much of the clinical examination cannot be used to monitor the patient's response to therapy. The pupillary light reflex is relatively preserved, though attenuated, and pupillary changes such as dilation secondary to herniation may still be observed. It is essential to monitor ICP because the goal of therapy is ICP and CPP control. Very high dose barbiturate administration can produce a clinical examination that mimics brain death, including bilaterally dilated and unreactive pupils. Therefore, screening tests of cerebral circulation (such as transcranial Doppler sonography or assessment of CPP) may be necessary to guide clinical suspicion of brain death, which would then require specific testing of cerebral circulation to confirm.

Barbiturates also suppress autonomic nervous system tone and myocardial contractility, and hypotension is commonly seen. The beneficial effects of barbiturates cannot compensate for hypotension so severe that it compromises CPP, and hemodynamic monitoring with a pulmonary artery catheter and aggressive hemodynamic support with fluids and vasopressors are often needed. Barbiturates cause ileus, and enteral feedings often cannot be continued, so that parenteral nutrition is often needed. Barbiturates also suppress ventilatory drive, as well as mucociliary function in the tracheobronchial tree, putting patients at high risk for atelectasis and pneumonia. Strict attention to pulmonary toilet is required. Fever may not manifest with the use of barbiturates, and infection surveillance should be pursued with a high index of suspicion. The risk for deep venous thrombosis and pulmonary embolism is higher because of immobility, and preventive therapies such as subcutaneous heparin should be used.

The Brain Trauma Foundation guidelines suggest use of high dose barbiturate therapy in hemodynamically stable and salvageable traumatic brain injury patients with medically and surgically refractory intracranial hypertension (Anon., 1996e). Pentobarbital is the most commonly used barbiturate. We use a loading dose of 10 to 40 mg/kg i.v. over approximately 2 hours, followed by a maintenance dose of 1–2 mg/kg/h, with the goals of ICP control, a pentobarbital serum concentration of 20–40 μg/ml, or burst–suppression pattern on EEG. After controlling the ICP for 48 to 72 hours, or if the mass effect is seen to diminish on neuroimaging studies, the pentobarbital infusion rate can be reduced gradually over 24–48 hours. If intracranial hypertension recurs, the pentobarbital can be restarted.

Surgical management

Reduction of cerebrospinal fluid volume

When hydrocephalus is the cause of ICP elevation, CSF should be removed. The method of removal depends on the cause of hydrocephalus and the presence of an intracranial mass, if any. An intraventricular catheter (IVC) is required for obstructive hydrocephalus (Figs. 125.6, 125.7(*a*) and (*b*)). Common concerns with IVC insertion and CSF drainage are worsening shift of intracranial contents when hemispheric lesions are present (Frank, 1995), and the possibility of 'upward herniation' when infratentorial lesions are present (Cuneo et al., 1979). After an IVC has been inserted, CSF is drained externally until adequate spontaneous CSF circulation and resorption is restored. Once this has occurred, the IVC can be safely removed. CSF resorption is roughly gauged by the CSF drainage rate. If resorption is intact, then there will be little external CSF drainage. If it is impaired, the CSF drainage volume will be high. No standards for abnormal CSF drainage volumes exist. In clinical practice, we consider CSF resorption to be adequate if 100 ml CSF or less drains per day with the drip chamber at 20 cm H_2O (15 mm Hg) above the head. CSF drainage is then stopped and ICP is monitored for 24–48 hours. If ICP stays in an acceptable range, the IVC can be

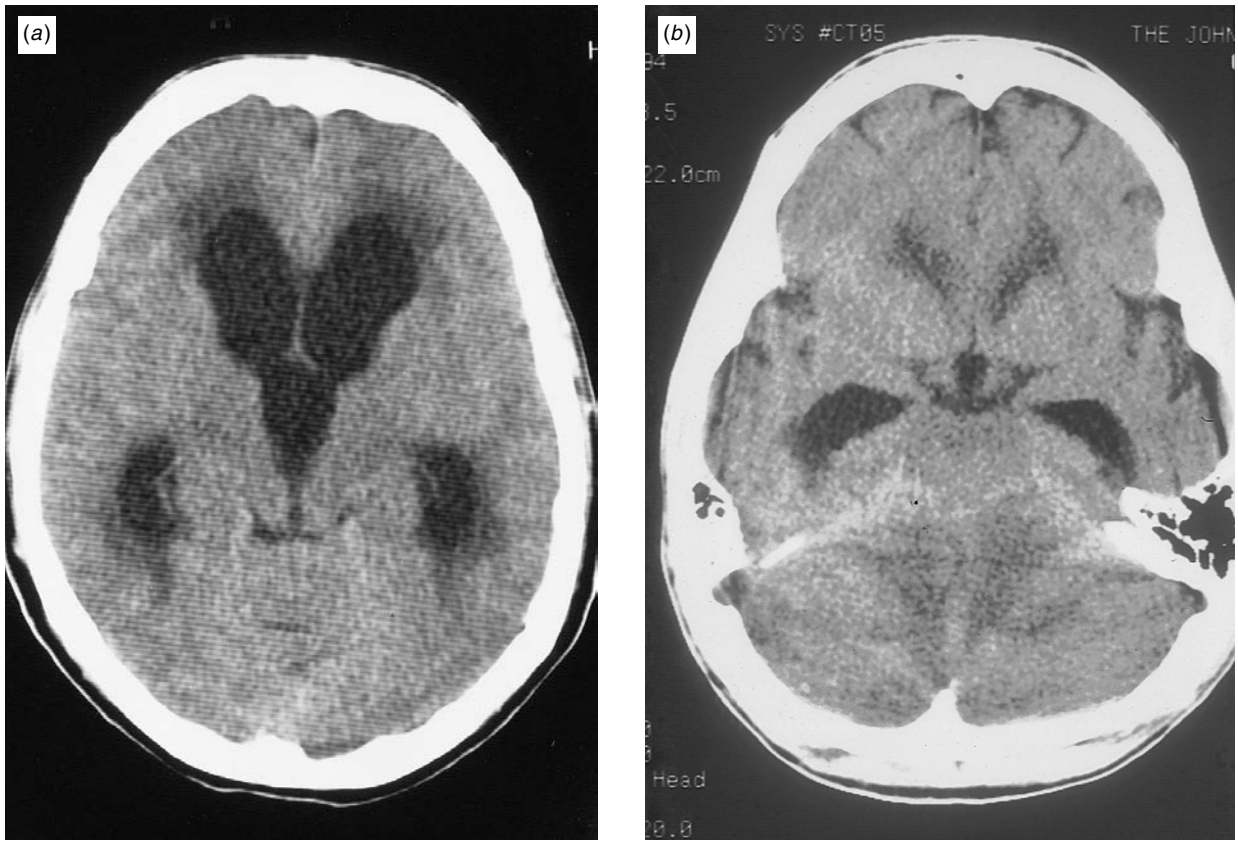

Fig. 125.6(*a*). Head CT scan of a 36-year-old woman with obstructive hydrocephalus. There is dilatation of the bilateral frontal and temporal ventricles. The third ventricle is also oval and dilated. Transependymal edema is noted in the frontal and temporal horns.
Fig. 125.6(*b*). Same patient. Lower cut. The perimesencephalic cisterns are effaced.

removed. If ICP rises, the IVC should be reopened for drainage.

Removal of intracranial masses

Depending on the nature of the lesion, surgical removal of masses causing ICP elevation can be an important ICP management strategy. Surgical removal is indicated for subdural and epidural hematomas, tumours, abscesses, and cerebellar infarction and hemorrhage. Surgical removal of hemisperhic intracerebral hemorrhage can be successful in individual cases, but cohort outcome studies do not show definite benefit (Batjer et al., 1990; Morgenstern et al., 1998).

Decompression of the cranial vault

There is a high incidence of cerebral herniation (Hacke et al., 1996) and death (Schwab et al., 1998) associated with massive cerebral infarctions. Neuronal death is associated with the breakdown of the Na-K ATPase pump leading to cellular swelling, or cytotoxic edema. As yet, there is no effective medical therapy for cytotoxic edema. The only promising therapeutic strategy is hemicraniectomy, which does not treat the edema directly, but rather makes room for the swollen brain by removing a large bone flap, incising the dura, and expanding it with a patch (Schwab et al., 1998). A recent study highlighting the importance of the hemicraniectomy size, reported that complication such as hemicraniectomy-associated bleeding occurred more often with smaller hemicraniectomies (Wagner et al., 2001). Early recognition of neurological deterioration and early surgical decompression (within 24 hours symptom onset) may result in better functional outcome (Schwab et al., 1998) with lower mortality (Rieke et al., 1995). If it is to be done for a large hemispheric infarction, we recommend that hemicraniectomy be performed prior to frank clinical herniation. Controlled clinical trials are still needed to definitely validate this therapy.

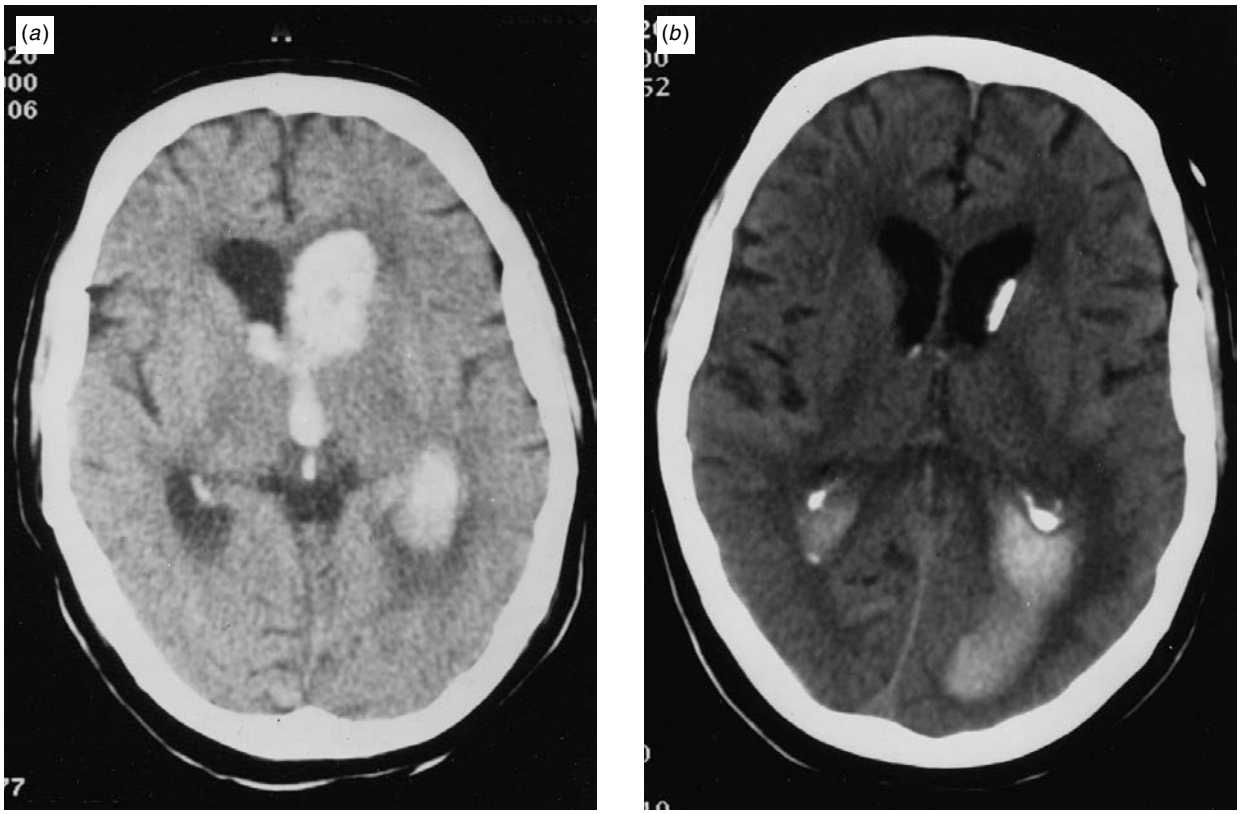

Fig. 125.7(*a*), (*b*). Head CT scan of an 81-year-old man with intraventricular hemorrhage. The blood clot has casted the left frontal, left temporal and third ventricles. Mild spillage of blood is seen in the right frontal horn. Blood in the ventricles led to the formation of an obstructive-type hydrocephalus. The insertion of a left intraventricular catheter (*b*) facilitated drainage of CSF and blood and the relief of the obstructive hydrocephalus.

General factors that may initiate or aggravate intracranial hypertension

Agitation and pain can elevate ICP, and agitation poses the risk of self-injury, including extubation, or removal of vascular catheters or IVCs. Thus, sedation and analgesia are important adjunctive therapies for ICP. The goals of sedation are to prevent ICP elevation and risk of self-injury, while preserving the ability of the ICU team to perform frequent neurological examinations. Short-acting drugs (propofol or midazolam) or drugs that can be readily reversed (i.e. fentanyl) are preferred. Sedation with propofol may control ICP better than morphine (Kelly et al., 1999). We do not routinely use neuromuscular blockade for ICP control because it masks the neurological examination, but in some instances paralysis is necessary. Neuromuscular blockade should not be used without analgesia or sedation.

Prolonged use of neuromuscular blockade in patients with severe head injury does not improve outcome and may lengthen ICU stay (Hsiang et al., 1994). Sedation, analgesia, and neuromuscular blockade pose the significant risk of suppression of airway reflexes, respiratory drive, or both, particularly in patients with coma or diminished level of consciousness, and these therapies are best reserved for patients with protected airways (i.e. intubation).

Brain temperature can mitigate or aggravate neurological injury. Rising brain temperature leads to increased $CMRO_2$ and CBF that can further increase ICP. Fever can be treated or prevented with antipyretics or cooling blankets, but care is necessary to avoid shivering. Seizures occur in as many as 20% of patients with head injury (Vespa et al., 1999). Seizures also can increase $CMRO_2$ and CBF, leading to a rise in ICP. Antiepileptic agents should be used to prevent seizures, especially if cortical injury is present.

Outcome studies and ICP control

The impact of ICP monitoring on patient outcomes is still unclear. The majority of studies show reduced mortality and improved functional outcome when ICP is monitored and treated in head-injured patients (Narayan et al., 1982; Saul & Ducker, 1982), although the Traumatic Coma Data Bank results suggest that ICP has no effect on neurobehavioural outcome one year after injury (Levin et al., 1990).

In subarachnoid hemorrhage (SAH), the presence of B-waves or maximum daily ICP over 30 mm Hg has been associated with poor outcomes (Takeuchi et al., 1989). Early aggressive monitoring of intracranial hypertension and hydrochephalus has been shown to benefit patients with severe SAH (Hunt–Hess Grade IV or V) (Bailes et al., 1990).

A relationship between ICP management and long-term outcome in spontaneous intracerebral hemorrhage has not been demonstrated nor seriously evaluated.

Up to 80% of patients with large hemispheric infarction die from cerebral herniation and brain death (Schwab et al., 1996). Yet, ICP monitoring in stroke has not demonstrated a group benefit (Woodcock et al., 1982) and may not be helpful in guiding long-term treatment of ICP elevation (Schwab et al., 1996). However, in cases of massive hemispheric strokes, we believe that the decision for aggressive management such as hemicraniectomy must be made before the measured ICP is elevated or before frank clinical herniation.

Cerebral venous or dural sinus thrombosis can lead to ICP elevation. ICP monitoring can improve outcome in dural sinus thrombosis when it is used to guide therapies that reduce cerebral blood volume simultaneously with treatments to restore normal venous drainage (Hanley et al., 1988).

Encephalitis is often accompanied by cerebral edema that can lead to cerebral herniation. Monitoring and treatment of ICP leads to better neurological outcomes (Schwab et al., 1997).

Cerebral edema and intracranial hypertension are well-recognized complications of fulminant hepatic failure (FHF) that contribute significantly to its morbidity and mortality. The presence of overt signs of intracranial hypertension at the time of hospitalization in patients with FHF complicating viral hepatitis is associated with poor outcome (Dhiman et al., 1998). The management of ICP in hepatic encephalopathy is complicated by the fact that insertion of ICP monitoring devices has a higher risk of hemorrhagic complication because of coagulation defects.

Drowning can cause global hypoxic/ischemic injury and resulting brain edema and ICP elevation. No clear improvement in outcome has been demonstrated by monitoring ICP in drowning (Bohn et al., 1986; Donovan et al., 1998). ICP elevation in drowning may merely be a marker of severe global hypoxic injury which is not amendable to ICP therapies.

Chronic disorders of intracranial pressure

Normal pressure hydrocephalus (NPH)

Normal pressure hydrocephalus (NPH) is an important, treatable syndrome of dementia, gait apraxia, and urinary incontinence that may be the underlying cause in 5% of demented patients (Vanneste & van Acker, 1990). The importance of making this distinction is the treatable nature of NPH, as opposed to the essentially untreatable nature of most dementias. NPH is treated by surgical cerebrospinal fluid (CSF) shunting, often with significant neurologic recovery, which results in improved functional outcome (Borgesen, 1984; Raftopoulos et al., 1994).

The selection criteria for identifying patients who will actually respond to shunt surgery are poor. The most common tests used to identify NPH have proven to be less accurate than desired; other more accurate tests exist but are in limited use because of their invasive nature. Adding to the diagnostic confusion is that NPH clinically overlaps with many conditions that can coexist in elderly patients, including vascular dementia, Alzheimer disease, vitamin B12 or folate deficiency, and disorders such as cervical spondylitic myelopathy, lumbar stenosis, and peripheral neuropathy. As a result, inaccurate treatment decisions can occur in two ways. First, many patients with the potential to respond to surgery are not identified and thus not shunted, resulting in unnecessary disability. Secondly, patients with no potential to respond to surgery are selected for surgery, resulting in unnecessary risk and potential for long-term complications. On average, only 50% of patients with suspected NPH have a good response to shunt surgery (Thomsen et al., 1986; Vanneste & van Acker, 1990).

Although a syndromic triad characterizes NPH, there are no signs, symptoms or symptom onset order that are specific to NPH (Raftopoulos et al., 1994). The most frequent presentation of gait disturbance in NPH appears to be imbalance (Adams et al., 1965; Hakim & Adams, 1965). Falling is a frequent, serious problem and most patients require the use of an assistive device for ambulation. With progression of the disease, the gait pattern is characterized by shorter, shuffling steps and difficulty with turns. Eventually standing, sitting, and even bed mobility are impaired.

The urinary incontinence of NPH typically presents as urinary urgency and frequency, and appears to be associated with a hyperreflexic bladder (Ahlberg et al., 1988). The reversibility of urinary incontinence in NPH distinguishes it from other cerebral lesions that cause voiding dysfunction (Gerstenberg et al., 1982). The urological symptoms are believed to be distinct from the gait disturbance or dementia components of NPH and have an independent course (Jonas & Brown, 1975). The pathophysiology is postulated to involve a loss of voluntary supraspinal control of micturition, probably from the effects of ventricular enlargement, but there has been virtually no systematic evaluation of the neurourological aspects of NPH.

The dementia syndrome of NPH is characterized by slowing of mental processes, memory impairment, visuoconstructional impairment, inattention and apathy (Benson, 1985). Mental status abnormalities vary according to disease severity, and cognitive testing has suggested a pattern of abnormalities common to the subcortical dementias (Thomsen et al., 1986), but no features of the subcortical dementia in NPH are thought to be specific. Attempts to predict the response to shunting by measuring change in cognitive performance after temporary CSF removal have had meagre results. One study found improvement in a subgroup of patients for some cognitive tests with temporary CSF removal. However there were a number of false negatives compared with the response to surgical shunting (Wikkelso et al., 1986).

Computed tomography (CT) and magnetic resonance imaging (MRI) studies are in widespread clinical use for diagnosing NPH. Common features associated with NPH include rounding of the temporal and frontal horns of the lateral ventricles, rounding of the third ventricle, and enlargement of the lateral and fourth ventricles. Characteristic MRI findings associated with NPH include periventricular white matter hyperintense signal, CSF flow void in the Sylvian aqueduct, and thinning of the corpus callosum (Jack et al., 1987). A common subjective criterion used to distinguish NPH from hydrocephalus *ex vacuo* is 'ventricular enlargement out of proportion to cortical atrophy', that is, widened cortical sulci. However, a direct comparison of ventricular size and sulcal width to CSF outflow resistance (see below) found that these CT criteria do not distinguish NPH from brain atrophy (Kosteljanetz & Ingstrup, 1985).

Radionuclide CSF imaging, or cisternography, has a physiologic basis relevant to NPH. It should demonstrate slowed CSF passage through the ventricles and subarachnoid space caused by the increased resistance to CSF flow. Diagnostic crtieria usually quoted for lumbar radionuclide injection are ventricular entry (i.e. retrograde CSF flow) and prolonged retention in the cranial vault (i.e. delayed conductance or resorption) (McCullough et al., 1970). The clinical experience with cisternography has not matched its physiologic potential (Black, 1980). The best studies of cisternography in NPH have a positive predictive value of 50% or less, and studies that directly compared cisternography to CSF conductance testing further confirm the poor diagnostic power of this test (Borgesen, 1984). Cisternography seems to have little utility in the diagnosis of NPH.

The relationship between disordered CSF circulation and NPH is well established, and tests to evaluate this have a high predictive value for outcome after shunt surgery. There are complex interactions between CSF pressure, resistance to CSF flow and resorption, cerebral venous pressure and the area of the ventricular surface that determines the development and maintenance of NPH. Implicit to the development of ventricular enlargement in hydrocephalus is the development of increased resistance to CSF flow or resorption that is necessary to raise CSF pressure. Whether the site of increased resistance is the subarachnoid space or the arachnoid villi, CSF pressure increases proximal to the site of resistance and the ventricles dilate. Diseases that are known to predispose to NPH (subarachnoid hemorrhage, head injury, tumour, meningitis and encephalitis) commonly cause inflammation and scarring of the arachnoid mater or the arachnoid villi that can increase resistance to CSF flow or resorption (Albeck et al., 1991).

Tests of CSF physiology used to diagnose NPH fall into three categories: (i) tests of CSF conductance, (ii) CSF pressure monitoring, and (iii) tests of response to CSF removal. CSF conductance is a quantitation of the ease with which CSF flows through the subarachnoid space to the arachnoid villi. Mathematically it is the inverse of CSF outflow resistance. CSF conductance determination usually consists of the infusion of artificial CSF into the lumbar subarachnoid space through a spinal needle while recording the CSF pressure response simultaneously at a second site (usually another spinal needle) (Borgesen & Gjerris, 1982). Objective, reproducible measurements of the CSF pressure–flow or pressure–volume relationships are obtained, and can be compared to normal values for CSF conductance, CSF production rate, and pressure–volume relationships (Albeck et al., 1991). There is strong evidence that these tests are highly predictive of shunt responsiveness in NPH, with a high likelihood of improvement seen with CSF conductance above 0.12 ml/min/mmHg (Borgesen & Gjerris, 1982) or CSF outflow resistance above 18 mm Hg/ml/min (Boon et al., 1997), although not all investigators have found such high diagnostic accuracy (Malm et al., 1995).

CSF pressure (Pcsf) monitoring was first advocated as a diagnostic test for NPH about 30 years ago (Nornes et al., 1973). Although it is a chronic disorder, NPH has the same abnormal Pcsf waveforms that were originally described in patients with brain tumour or acute injury (Borgesen & Gjerris, 1982). Some patients have Pcsf that is nearly always over 15 mm Hg (20 cm H_2O), but many others have normal baseline Pcsf that is punctuated by B-waves and A-waves, indicators of impaired intracranial compliance from impaired CSF resorption. The presence of unstable Pcsf wave forms (predominantly B-waves) in NPH is well documented (Borgesen & Gjerris, 1982; Williams et al., 1998) and the correlation of unstable Pcsf with NPH shunt responsiveness varies from 50% to 90% (Pickard et al., 1980; Borgesen & Gjerris, 1982; Williams et al., 1998). Most Pcsf monitoring in NPH has been done with ventricular catheters, subarachnoid bolts or other intracranial devices (Borgesen & Gjerris, 1982; Raftopoulos et al., 1994). As a result, the technique never gained favour as a diagnostic test for NPH because of fear of causing cerebral injury (Borgesen & Gjerris, 1982). Pcsf monitoring can be performed safely via lumbar catheter (Williams et al., 1998). Clinical response to CSF drainage via a lumbar catheter has been reported to correlate with response to shunting in NPH (Haan & Thomeer, 1988; Williams et al., 1998). The advantage over a single LP is that CSF can be drained continuously for several days, providing a more sustained and controllable normalization of ICP and intracranial volume/pressure relationships. Continuous CSF drainage can be considered as a trial of shunt-like conditions without shunt surgery.

Common characteristics to these three categories of CSF physiology tests are invasiveness, labour intensity, and a generally high predictive value for response to shunting. Unfortunately, the invasiveness and labour intensity have made these tests unpopular for the diagnosis of NPH. A revealing survey of neurologists and neurosurgeons from the Netherlands found that few used the more invasive techniques of CSF infusion tests or ICP monitoring despite the higher predictive value (Vanneste & van Acker, 1990).

Idiopathic intracranial hypertension

Idiopathic intracranial hypertension (IIH), also known as pseudotumour cerebri or benign intracranial hypertension, is a syndrome characterized by increased ICP in the absence of intracranial masses or hydrocephalus. Quincke first described the syndrome and its cardinal presentation of bilateral papilledema (Quincke, 1897). The term benign intracranial hypertension has been used, but because serious visual impairment may occur, many prefer the term idiopathic intracranial hypertension.

The incidence of IIH is 0.9 per 100 000 per year in the general population (Durcan et al., 1988; Radhakrishnan et al., 1993) and 3.5 per 100 000 per year in women between the ages of 15 and 44 years (Radhakrishnan et al., 1993). Obesity is a significant risk factor. The incidence is 19 per 100 000 for those 20% or more over ideal weight from age 20 to 44 years (Durcan et al., 1988). Recent weight gain is also associated with the diagnosis with IIH (Ireland et al., 1990).

The most common presenting symptom is headache, which may be associated with diplopia. Pulsatile tinnitus has also been described (Sismanis et al., 1990). The most common clinical finding is papilledema, usually bilateral, but sometimes unilateral (Chari & Rao, 1991). Sixth, and occasionally seventh nerve palsies can be appreciated (Krishna et al., 1998). Visual loss is the most serious complication of IIH (Corbett et al., 1982), and its prevention should be the focus of therapy (Brourman et al., 1988). Detailed ophthalmologic evaluation is critical for the diagnosis and monitoring of disease progress. A variant of IIH without papilledema has been described typically in young obese women with elevated intracranial pressure (Marcelis & Silberstein, 1991).

The diagnosis of IIH should be based on the signs and symptoms of intracranial hypertension, verification of ICP elevation by lumbar puncture, normal CSF composition, and the absence of intracranial masses or hydrocephalus on neuroimaging (Brazis & Lee, 1998). In addition to ruling out intracranial masses, thin-section CT of the orbits can also show enlarged optic nerve sheaths and empty sella (Gibby et al., 1993).

The pathophysiology of IIH is still unclear. Increased cerebral water (Gideon et al., 1995) and increased cerebral blood flow have been described in comparison to controls (Gross et al., 1990). Obesity and increased intra-abdominal pressure are also thought to contribute (Sugerman et al., 1997; Brazis & Lee, 1998). The list of differential diagnosis for IIH is provided in Table 125.1.

The mainstay of medical therapy for IIH is acetazolamide, a carbonic anhydrase inhibitor that reduces CSF production. Furosemide can also be used (Schoeman, 1994). Serum electrolytes should be monitored because of the risk of metabolic acidosis and hypokalemia. In obese patients, weight reduction has been associated with more rapid recovery of papilledema and visual field deficits compared to those who do not lose weight (Kupersmith et al., 1998). One study found that weight loss of about 6% was more effective in reducing papilledema than acetazolamide (Johnson et al., 1998). Surgical-induced weight loss was also effective (Sugerman et al., 1995). The headache is usually relieved once ICP is controlled, but symptomatic treatment with analgesics may be necessary.

Table 125.1. Differential diagnosis for IIH

Disorders of cerebral venous outflow
Cerebral venous sinus thrombosis
Jugular vein thrombosis
Intrathoracic disorders affecting cardiac venous return
Infections and autoimmune disorders
Syphilis
Lyme's disease
Infectious meningitis
CNS lupus
Antiphospholipid antibody syndrome
Sarcoidosis
Drugs associated with IIH
Corticosteroids
Minocycline
Erythromycin
Cyclosporine
Vitamin A intoxication
Growth hormones
Lithium carbonate
Medical or physiological conditions associated with IIH
Pregnancy
Hypothyroidism

The decision to proceed to surgical therapy depends on the response to medical therapy and the progression of visual loss (Corbett & Thompson, 1989). Optic nerve sheath fenestration can stabilize or improve vision in the majority of patients (Sergott et al., 1988; Kelman et al., 1992; Spoor & McHenry, 1993). Visual improvement with optic nerve fenestration may be related to improvement of retrobulbar circulation (Mittra et al., 1993). Shunting of CSF, usually with a lumboperitoneal shunt (LPS) is a satisfactory treatment for the majority of patients with IIH who require surgical therapy (Johnston et al., 1988). The vision of most patients improves or stabilizes (Miller & Leech, 1975), but CSF shunting is associated with high failure rate and side effects (Rosenberg et al., 1993). In a retrospective study of 27 patients treated with at least one LPS and followed for a mean of 77 months, 15 patients (56%) required surgical revision (Eggenberger et al., 1996).

Intracranial hypotension

The syndrome of intracranial hypotension (IH) is characterized by frontal or occipital headaches, worse when erect or straining, and ameliorated by lying down. This is commonly seen after a lumbar puncture and is attributed to reduced CSF pressure and volume likely caused by persistent dural leak. In some cases, there is also nausea, vomiting, photophobia, or tinnitus. Cranial nerve palsies (III and VI) have been also described (Ferrante et al., 1998). IH occurring in the absence of LP, or any procedure, or overt cause of CSF leak is known as spontaneous intracranial hypotension. The symptoms are similar to the post LP cases and may last for weeks. The mechanism is believed to be spontaneous CSF spinal leakage, most commonly occurring in the cervicothoracic or thoracic spine (Schievink et al., 1996). Other sites of CSF leakage are the cribriform plate and spinal dural diverticuli. The clinical presentation is very often suggestive of IH, with orthostatic headaches, but coma and bilateral subdural hematoma have also been reported (Nakajima et al., 1996).

The diagnostic work-up includes head CT scan, which may show subdural CSF collection or hematoma. MRI of the head typically shows diffuse pachymeningeal gadolinium enhancement, often with imaging evidence of sinking of the brain, subdural fluid collections, engorged cerebral venous sinuses, enlarged pituitary gland, or decreased size of the ventricles (Mokri, 2001). The dural venous sinuses may also appear engorged and diffuse venodilation is believed to cause the gadolinium enhancement on MRI (Bakshi et al., 1999). Other diagnostic tests include radionuclide cisternography and contrast myelography to show the site of the leak. The urinary excretion of radioisotope after spinal injection may reflect a dural deficit with the passage of the tracer from the subarachnoid space to the systemic circulation (Benamor et al., 1998). Performance of lumbar puncture in these patients may worsen the problem. The CSF pressure is low, as would be expected, and 'dry' tap may be encountered. High CSF pressure can occur, which may signify subdural CSF collection or hematoma formation.

Symptoms of IH are usually self-limited and supportive care includes hydration and analgesics. With careful anatomic location of the CSF leak, a blood patch (Mokri, 2001) can be used, and surgical repair of dural defect (diverticuli) is sometimes needed (Schievink et al., 1996).

Neurological manifestations of endocrine disease

Gary M. Abrams and Cheryl A. Jay

Department of Neurology, University of California, San Francisco, San Francisco, CA, USA

Neurological signs and symptoms occur in virtually every known endocrine disturbance. This chapter focuses primarily on the neurological manifestations of diseases of the thyroid and the adrenal glands. The neurological complications of parathyroid disease largely reflect disordered calcium metabolism and are discussed in Chapter 124. The numerous neurological complications of diabetes mellitus, hypoglycemia, and pancreatic disorders are also dealt with elsewhere. Neurological manifestations of the hypothalamus and pituitary disease are reviewed in Chapter 57. The endocrine disturbances associated with anorexia nervosa are considered in Chapter 54.

Neurological complications of thyroid disease

Hyperthyroidism

Neuropsychiatric disorders, seizures, and headaches

Neuropsychiatric symptoms are common in hyperthyroidism. Many patients complain of feeling nervous, anxious and restless. They note difficulty in concentration and a shortened attention span. Friends or relatives describe them as irritable or capricious. Frank psychoses are uncommon, but agitated depression has been reported in severe thyrotoxicosis (Logothetis, 1961). In elderly patients, an apathetic state with lethargy, depression (Ettigi & Brown, 1978) or cognitive impairment may occur (Martin & Deam, 1996). Although the mechanism by which thyroid hormone produces these mental changes is unknown, symptoms usually resolve when thyroid function is restored to normal.

In patients with the life-threatening forms of hyperthyroidism known as thyroid storm, agitated delirium progresses to lethargy and coma (Newcomer et al. 1983). Patients may have signs of bulbar palsy (see below) and convulsions can occur. There are serious systemic complications, including hyperpyrexia, tachycardia and other cardiac arrythmias, and a variety of electrolyte abnormalities. Treatment includes hydration, cooling, antithyroid medication, iodine, and corticosteroids (Tiegens & Leinung, 1995). Plasmapheresis may be useful (Newcomer et al., 1983).

Patients with epilepsy may show increased frequency of their seizures with hyperthyroidism. In some cases, hyperthyroidism is associated with a seizure disorder that disappears after the patient becomes euthyroid (Smith & Looney, 1983). In one study, nearly 10% of hyperthyroid patients had convulsions as their initial symptom (Jabbari & Huott, 1980); however, this figure is unusually high. The electroencephalogram in hyperthyroid patients may be moderately abnormal and returns with restoration of the euthyroid state (Leubscher et al., 1988)

Headache is a common symptom with hyperthyroidism. It is usually symmetric, periorbital, and frontal in location. Many patients complain of paroxysms of fullness in the head or episodes of tinnitus. In some cases, headache may be related to vascular mechanisms or coexisting exophthalmos.

Movement disorders

A fine tremor that resembles an exaggerated physiological tremor is common. It appears to be mediated by peripheral ß-adrenergic receptors (Marsden et al., 1970; Young et al., 1975). The movements are most prominent in the small metacarpophalangeal joints of the fingers and in the tongue and eyelids. The tremor is regular, with a rate of 8–10 Hz and is of small amplitude. It is best seen when the patient attempts to maintain a posture against gravity, such as when holding the arms and fingers extended forward. The movements persist during action and are

present at rest. Electromyographic studies show simultaneous activity in agonist and antagonist muscles.

Chorea and athetosis are rare complications of hyperthyroidism (Nagaoka et al., 1998). The disorder has been attributed to enhanced striatal dopaminergic sensitivity (Delong, 1996). Paroxysmal choreoathetosis has also been reported (Fischbeck & Layzer, 1979; Drake, 1987).

Cranial nerve abnormalities

Many of the ophthalmic signs of hyperthyroidism (except for ophthalmoplegia) appear to be caused by increased tissue sensitivity to activity of the sympathetic nervous system. The palpebral fissures appear widened and the lids seem retracted (Dalrymple's sign). The patient seems to be staring and blinks infrequently (Stellwag's sign). When the patient looks down, the upper lids remain elevated, leaving a larger than normal portion of the sclera visible (von Graefe's sign). Patients seem to have convergence insufficiency (Möbius' sign) and often do not contract the frontalis muscle when looking up (Joffroy's sign).

Some cranial nerve abnormalities result from compression by an enlarged thyroid. Compression of the recurrent laryngeal nerve can produce vocal cord paralysis with dysphonia. In severe cases with bilateral laryngeal nerve compression, there may be respiratory stridor. Laryngeal nerve involvement may occur with benign thyroid disease (Fenton et al., 1994), but should always raise the suspicion of malignancy. Compression of the sympathetic chain can produce Horner's syndrome. Dysarthria or dysphagia may be seen with one of the coexisting neuromuscular problems associated with hyperthyroidism such as bulbar paralysis or myasthenia gravis.

Neuromuscular disorders

Spinal and peripheral nerve disorders

Hyperthyroid neuropathy is uncommon, although an association of hyperthyroidism and polyneuropathy with primarily proximal weakness (Basedow's paraplegia) has been recognized for many years. Signs of peripheral neuropathy with hyperthyroidism have been reported to resolve with treatment of the thyroid disease (Fisher et al., 1985). A carefully studied case of acute areflexic quadriparesis in association with thyroid storm revealed evidence of a mixed axonal and demyelinating sensorimotor neuropathy. Ultrastructure of the sural nerve showed abnormalities in mitochondria and cytoskeletal elements. Neuromuscular function improved with treatment of the hyperthyroid state (Pandit et al., 1998). Upper motor signs are rare, but well documented. In a few cases, they are accompanied by muscular wasting and fasciculations, producing a clinical picture resembling amyotrophic lateral sclerosis (Logothetis, 1961).

Subclinical motor axonopathy has been detected by electrodiagnostic studies in about half of patients with hyperthyroidism (McComas et al., 1974). Muscle twitching or fasciculations occur in some patients (Puvanendran et al., 1979) and, in a few cases, takes the form of generalized myokymia involving the face, tongue, limb and trunk. The electromyogram may show continuous, repetitive, grouped discharges, apparently arising from distal portions of the motor nerves (Harman & Richardson, 1954).

Thyroid ophthalmopathy

Thyroid ophthalmopathy is present in about 50% of patients with Graves disease (autoimmune hyperthyroidism). The disorder may also be seen in euthyroid or hypothyroid individuals, presumably due to a shared immunologic abnormality. Orbital tissue, predominantly the extraocular muscles, becomes inflamed and edematous, with infiltration of lymphocytes and histiocytes. The etiology of the syndrome remains uncertain with thyroid postulated to possess an antigen, possibly the TSH receptor, which cross-reacts with orbital tissue. Cellular and humoral immune responses initiate an inflammatory reaction that leads to a proliferation of connective tissue and swelling of orbital contents (Warwar, 1999). Clinically, eyelid retraction (Dalrymple's sign) is seen at presentation in 75% of patients and ocular pain may be the most common symptom (30%) (Bartley et al., 1996). The process is usually bilateral, but asymmetric, with erythema and swelling of the lids and conjunctiva, proptosis and restriction of eye movements. The abnormality in eye movement is mainly mechanical with forced duction tests showing resistance to passive movement. Rarely, in severe cases, compressive-ischemic optic neuropathy, papillitis, and papilledema may develop. Visual-evoked potentials may be useful in identifying those patients at risk for the developing optic nerve damage in thyroid ophthalmopathy (Salvi et al., 1997).

Thyroid ophthalmopathy can usually be distinguished from other causes of orbitopathy by imaging studies. Classic findings demonstrate exophthalmos, herniation of retrobulbar fat through the orbital septum, enlargement of extraocular muscles with normal tendons and enlargement of the lacrimal glands (Perros & Kendall-Taylor, 1992). Treatment may include immune suppression usually with corticosteroids (Wiersinga, 1992), radiotherapy, and surgical decompression of the orbit.

Myasthenia gravis

It has long been recognized that myasthenia gravis can occur in association with hyperthyroidism (Drachman,

1962; Engel, 1961). Myasthenia may accompany, follow, or precede the development of thyrotoxicosis. Treatment of the hyperthyroidism does not have a predictable effect on the myasthenia. In some cases, the myasthenia appears to worsen as the hyperthyroidism is controlled. Differentiation between the ophthalmoplegia associated with myasthenia gravis and thyroid ophthalmopathy should not be difficult. Unlike patients with thyroid eye disease, patients with ocular myasthenia gravis usually have ptosis, do not develop exophthalmos or conjunctival edema, and have no impairment of forced ductions. Antibodies to acetylcholine receptor are usually present in myasthenia and orbital imaging is abnormal in thyroid ophthalmopathy.

Myopathy

Muscle weakness is common in hyperthyroid patients and the majority of patients have clinical signs of myopathy (Ramsay, 1974). Painless weakness is most prominent in the muscles of the shoulder girdles and the upper arms and in the proximal lower limbs. A few patients experience significant respiratory muscle weakness. The deep tendon reflexes are brisk and fasciculations are occasionally noticeable. Serum creatine kinase levels are normal to mildly reduced (Graig & Smith, 1965), although elevated creatine kinase levels have been reported in association with treatment with antithyroid medications (Suzuki et al., 1997). The electromyogram shows myopathic abnormalities without fibrillations; fasciculations and myokymia may also be found. Muscle biopsy usually shows few abnormalities, although there may be scattered, non-selective atrophy of single muscle fibres (Carpenter & Karpati, 1984). Muscle weakness partially improves in thyrotoxic patients when treated with propanolol and improves further with restoration of the euthyroid state. This suggests that thyroid hormone and catecholamine in concert contribute to mediate the muscle dysfunction (Olson et al, 1991).

A few hyperthyroid patients experience bulbar muscle weakness that is not related to coexisting myasthenia gravis. Dysphagia, aspiration or regurgitation of liquids, nasal dysphonia, and hoarseness may occur, sometimes with weakness of the face, jaw, tongue or ocular muscles. Most of these patients have proximal limb weakness. This syndrome tends to have a fulminating course, sometimes associated with thyroid storm. The weakness may improve with beta-blocker therapy (Kammer & Hamilton, 1974; Weinstein et al., 1975) and, similar to other myopathic symptoms, resolves when the patients become euthyroid (Joasoo et al., 1970).

Periodic paralysis

Attacks of hypokalemic periodic paralysis, indistinguishable from the familial variety, may accompany endogenous or exogenous thyrotoxicosis (Layzer & Goldfield, 1974). The disorder is rare in non-Asian populations and in the United States, patients with thyrotoxic periodic paralysis reflect the ethnic make-up of the local population (Ober, 1992). Although thyrotoxicosis is much more common in women, 90% of patients with thyrotoxic periodic paralysis are male. Attacks of periodic paralysis may be the first symptom of thyrotoxicosis, which is the most common cause of non-hereditary periodic paralysis in adults.

As in the familial form, attacks of weakness come on during rest after exercise and especially during sleep. Attacks can be precipitated by insulin or a carbohydrate-rich meal. Weakness starts in the proximal lower extremities and spreads upward, usually sparing the bulbar, cardiac, and respiratory muscles. The serum potassium level is usually reduced during a major attack, because of a shift of extracellular potassium into muscle cells (Shizume et al., 1966). Two varieties of familial hypokalemic periodic paralysis have been identified as 'channelopathies' with genetic defects in calcium channels resulting in defective coupling of excitation-contraction in muscle (Greenberg, 1999). The genetics of thyroid periodic paralysis or the mechanism by which thyroid hormone may influence excitation–contraction in muscle is unknown (Layzer, 1982). Administration of potassium hastens recovery from an attack. Beta-blockers tend to prevent attacks (Conway et al., 1974; Yeung & Tse, 1974) and restoration of normal thyroid function abolishes the disorder.

Hypothyroidism (myxedema)

Cerebral symptoms

Cognitive and psychiatric symptoms are common in hypothyroidism. In their most mild form, these consist of headaches, difficulty in concentrating, poor memory, and generalized dulling of mental processes. The clinical picture may be easily mistaken for depression. Excessive sleepiness is probably a direct cerebral symptom of thyroid deficiency, but there is controversy as to whether hypothyroidism may contribute to the development of obstructive sleep apnea (Skjodt et al., 1999). Alveolar hypoventilation attributable to diaphragmatic weakness may also occur and possibly contribute somnolence (Martinez et al., 1989).

Frank psychiatric disorders or dementia may appear in more profoundly hypothyroid individuals. 'Myxedema madness' refers to a syndrome characterized by irritability, suspiciousness, hallucinations, delirium and psychosis (Asher, 1949; Pitts & Guze, 1961). Dementia is often associated with apathy, sleepiness, and slowing of speech and

thought processes (Jellinek, 1962). These symptoms may be only partially reversible with correction of thyroid deficiency (Dugbartey, 1995).

Untreated patients may develop hypothermia, hypotension, and respiratory failure. Hypoglycemia and hyponatremia occur and seizures or fatal myxedema coma will follow. Although the mortality of myxedema coma is significant, the advent of intensive respiratory care and use of intravenous thyroxine has resulted in improved survival, with mortality dropping from 60–70% to 15–20% (Jordan, 1995). Neuropathological studies of myxedema coma are few. There is generally evidence of cerebral edema and non-specific generalized neuronal damage. ^{31}P magnetic resonance spectroscopy of brain shows that the phosphocreatine/inorganic phosphate ratio increases with L-thyroxine treatment indicating reversible alterations in phosphate metabolism (Smith & Ain, 1995).

Seizures and electroencephalographic changes

There appears to be a higher than expected incidence of seizures among patients with hypothyroidism. Nearly 20% of these patients, in one series, had seizures or syncope (Millichap, 1974). In some patients, return to a euthyroid state facilitates seizure control. The electroencephalogram generally shows slow alpha rhythms and low-voltage activity. In extreme cases, the electroencephalogram may appear virtually flat.

Ataxia of gait

Some hypothyroid patients (5–10%) have a syndrome of cerebellar ataxia (myxedema staggers) (Cremer et al., 1969; Harayama et al., 1983). Many patients seem heavy, slow or stiff. In others, the gait ataxia seems typically cerebellar, but limb ataxia is uncommon. The truncal ataxia is presumed to be of cerebellar origin and cell loss has been detected in the anterior superior vermis (Barnard et al., 1971). The dysarthria of hypothyroidism is usually caused by enlargement of the tongue, rather than cerebellar disease. The gait ataxia usually resolves with thyroid replacement.

Cranial nerve abnormalities

Deafness and tinnitus are common symptoms. In one series, 85% of patients had hearing loss, usually bilateral with improvement noted after treatment (Van't Hoff and Stuart, 1979). However a more recent study of a group of hypothyroid patients showed no difference in hearing with an age- and sex-matched population. Thyroid hormone replacement did not improve hearing thresholds, speech reception thresholds, or speech discrimination (Parving, 1990). Taste disturbances have been reported (McConnell et al., 1975). Disturbed visual acuity with optic atrophy may occur. Visual evoked responses may be abnormal (Ladenson et al., 1984). Other cranial nerve involvement is quite rare and not well documented. The slow, muffled, gravely voice appears to be due to local changes in the tissues of the larynx, rather than neural factors.

Neuromuscular disorders

Myopathy

Neuromuscular disorders are common in hypothyroidism, but severe disturbances of function are unusual. Many patients have pain and stiffness, probably because of slow muscle contraction and relaxation. Muscle stiffness may increase during physical activity. Deep tendon reflexes, particularly the ankle jerks, will show a prolonged relaxation phase. The slow relaxation is probably due to a reduced uptake of calcium by the sarcoplasmic reticulum (Fanburg, 1968). Direct percussion of muscle may elicit a local contracture with transient mounding of muscle (myoedema). This electrically silent contracture is thought to result from mechanically induced local release of calcium from the sarcoplasmic reticulum (Mizusawa et al., 1983). Myoedema is not specific for hypothyroid muscle disease and may not be indicative of a neuromuscular disorder (Hornung & Nix, 1992). True muscle cramps are common in hypothyroidism and are thought to be of neural origin. Subclinical hypothyroidism is also associated with an increase in neuromuscular symptoms such as paresthesiae, cramps, weakness and fatigue. These symptoms correlate directly with TSH levels and inversely with calcium levels, although total calcium and ionized calcium are in the normal range (Monzani et al., 1999).

Muscle enlargement occurs in 20% of hypothyroid children (Najjar, 1974; Tashko et al., 1999) producing an unusual 'infant Hercules' appearance (Kocher–Debré–Semélaigné syndrome). Muscle enlargement with pain and stiffness occurs less commonly in adults with hypothyroidism (Hoffmann's syndrome) (Norris & Panner, 1966). The cause of muscle enlargement is unknown. Overactivity of muscle caused by slow relaxation may contribute to the muscle enlargement, however, histologic studies do not show hypertrophy of muscle fibres (Ono et al., 1987).

Exercise intolerance and fatigue, without overt weakness, are common in hypothyroid patients. In subclinical hypothyroidism, blood lactate is elevated with exercise and correlates with the duration of the disease (Monzani et al., 1997). In general, MR spectroscopy of muscle has shown impaired oxidative metabolism that is reversed by thyroid hormone. This suggests that hypothyroidism may cause secondary mitochondrial dysfunction in muscle (Argov & Arnold, 2000).

Circulating creatine kinase levels are elevated in hypothyroid myopathy (Graig & Smith, 1965). Creatine kinase levels may be increased due to diminished turnover or clearance in myxedema thus may not be indicative of muscle disease. EMG abnormalities consistent with myopathy are common with nearly 50% of patients having evidence of myopathy in one recent series (Cruz et al., 1996). Muscle biopsy is typically non-diagnostic. Type II fibres have been reported to be atrophic and decreased with increased numbers of central nuclei (McKeran et al., 1975), although Type II fibres were found to predominate over Type I fibres in other series (Ono et al., 1987). With thyroid hormone replacement, the myopathy usually resolves in a few months.

Myasthenia

Hypothyroidism occurs in up to 6% of patients with myasthenia gravis and at autopsy, 12–19% of myasthenic patients have Hashimoto's disease (Ramsay, 1974). Thyroid antibodies are also found more often in patients with myasthenia than in control subjects. A few hypothyroid patients have muscle weakness that appears to be caused by a defect of neuromuscular transmission that differs from that in myasthenia gravis.

Peripheral nerve disorders

Minor signs of a distal, mainly sensory polyneuropathy occur in about 10% of hypothyroid patients (Rao et al., 1980). Rarely a severe polyneuropathy occurs with diminished motor nerve conduction velocities and evidence of axonal degeneration on nerve biopsy (Pollard et al., 1982). Carpal tunnel syndrome occurs in 15–29% of hypothyroid patients, whereas hypothyroidism increases the risk of carpal tunnel syndrome by 70% (Solomon et al., 1999). Deposits of mucopolysaccharide in the soft tissue of the carpal tunnel have been suspected to cause the problem, although definitive evidence is lacking. Carpal tunnel caused by hypothyroidism rarely requires surgical intervention. Symptoms usually subside with hormone replacement therapy.

Cerebrospinal fluid and pseudotumour

The cerebrospinal fluid protein is often elevated in patients with myxedema. Levels between 100 and 340 mg/dl were found in 44% of reported cases (Fishman, 1980). The protein elevation reflects an increased permeability of the blood–cerebrospinal fluid barrier, and possibly impaired function of the arachnoid villi, as well (Fishman, 1980). In children, pseudotumour cerebri may occur after initiation of thyroid replacement for hypothyroidism (Van Dop et al., 1983). This may be related to increased cerebral blood flow (Sokoloff et al., 1953), which in turn may lead to increased intracranial pressure.

Cretinism

Cretinism results from thyroid deficiency in the prenatal period or during early postnatal development (LaFranchi, 1999). In the United States, cretinism is rare due to the vast majority of patients with neonatal thyroid deficiency being identified through newborn screening programmes. Sporadic cases of cretinism usually result from dysgenesis of the thyroid with the remainder due to genetic defects in thyroid hormone biosynthesis. Iodine deficiency remains the most important cause of cretinism worldwide, having been essentially eliminated from the United States due to iodine supplementation of food staples such as bread.

The clinical syndrome is one of striking grotesque physical abnormalities and severe mental deficiency. Children are generally dwarfed and have thick necks, short crooked limbs, a protuberant abdomen, thin dry hair, coarse baggy skin, and a virtually pathognomonic facial appearance. The forehead is low; the eyes are puffy; the nose is broad and flat; lips are thick and the tongue is large and protruding. Neurologically, there is mental retardation, with pyramidal and extrapyramidal signs in a proximal and truncal distribution. Squint, deafness and primitive reflexes are common (Halpern et al., 1991). MR imaging abnormalities in cretinism have been noted in the globus pallidus and substantia nigra (Ma et al., 1993). In many patients, thyroid hormone therapy administered within the first two months of life results in nearly complete restoration of normal physical and mental function. Treatment should begin during the first two weeks of life for optimal intellectual development (Bongers-Schokking et al., 2000). Thyroid function tests should be monitored frequently for several years. When therapy is delayed beyond 6 months, significant improvement is rare.

Pathological studies indicate that thyroid deficiency in utero results in diminished size and density of neurons and defective myelination (Rosman, 1976). However, MR studies in newborns with congenital hypothyroidism before treatment have been reported to show no abnormalities in myelination patterns and no morphological abnormalities (Siragusa et al., 1997).

Neurological complications of parathyroid disease

Many neurological manifestations of parathyroid disease result from associated hypercalcemia or hypocalcemia, as

discussed in Chapter 124. However, the myopathic features of hyperparathyroidism may not be related directly to disturbed calcium metabolism.

Hyperparathyroidism

Primary hyperparathyroidism most commonly accompanies hypersecretion of parathyroid hormone by a solitary parathyroid adenoma. Fatigue and subjective weakness are common symptoms. The ease of obtaining serum calcium levels has made the triad of nephrolithiasis, osteitis and peptic ulcer disease ('stones, bones, and abdominal groans'), which characterizes advanced primary hyperparathyroidism relatively uncommon (Heath, 1989).

Cerebral and spinal symptoms

Diverse neuropsychiatric symptoms have been described including irritability, anxiety, personality changes, cognitive impairment, and psychosis (Tonner & Schlechte, 1993). There have been reports of parkinsonism, which improved after parathyroidectomy (Kovacs et al., 1993). Myelopathy may develop when osteoclastic lytic lesions or 'brown tumours' involve the vertebrae and compress the spinal cord (Ganesh et al., 1981; Daras et al., 1990). Compressive myelopathy from brown tumour also has been described in secondary hyperparathyroidism in association with renal disease (Bohlman et al., 1986)

Neuromuscular disease

Neuromuscular symptoms include proximal weakness, myalgia, muscle stiffness, and paresthesiae. About 2–4% of patients with florid primary hyperparathyroidism develop proximal muscle weakness and atrophy with normal muscle enzymes, myopathic features without fibrillations on electromyogram (EMG), and type 2 fibre atrophy on muscle biopsy (Patten et al., 1974). This myopathic syndrome may be even less common with modern earlier diagnosis of primary hyperparathyroidism (Turken et al., 1989). Parathyroidectomy relieves neurological and systemic symptoms in both mild and severe disease (Silverberg et al, 1999; Toft, 2000). A similar myopathic syndrome develops in secondary hyperparathyroidism (Mallette et al., 1975).

Hypoparathyroidism

Seizures and tetany, reflecting central and peripheral neuronal irritability, are classic clinical features (Shulian et al., 1984). Other cerebral manifestations include cognitive impairment, psychosis, and extrapyramidal syndromes. CT may reveal calcification, usually asymptomatic, in basal ganglia, cortex, brainstem or cerebellum (Illum & Dupont, 1985). Less common neurologic syndromes include sensorineural hearing loss, myopathy, and idiopathic intracranial hypertension (Tonner & Schlechte, 1993; Mor & Wysenbeek, 1988). Neuropsychiatric manifestations may not completely reverse with correction of hypocalcemia.

Neurological complications of adrenal disease

Hyperadrenalism (Cushing's syndrome)

Excessive amounts of adrenocortical hormones cause Cushing's syndrome, with its familiar somatic manifestations. Hypercortisolism may be exogenous, from glucocorticoid administration, or endogenous, from excessive pituitary ACTH secretion (Cushing's Disease), adrenal steroid secretion or ectopic adrenocorticotropic hormone secretion.

Cerebral symptoms

Affective disturbances, delirium, and acute psychosis, are common in Cushing's syndrome, and may antedate somatic signs and symptoms (Cohen, 1980, Kelly et al., 1996). Memory impairment is also common (Mauri et al., 1993). These neuropsychiatric manifestations resolve completely after effective endocrine therapy. Idiopathic intracranial hypertension has been described in association with Cushing's syndrome, particularly with steroid withdrawal in exogenous cases or after resection of a pituitary adenoma in Cushing's disease (Neville & Wilson, 1970; Parfitt et al., 1994).

Cranial nerve abnormalities

Over 90% of ACTH-secreting pituitary tumours are microadenomas (less than 1 cm in size), because the distinctive systemic features usually lead to early detection of the tumour (Shimon and Melmed, 1998). Patients with macroadenomas may develop bitemporal hemianopic or superior quadrantic visual field deficits from chiasmal compression or central or junctional scotomata from optic nerve compromise (Melen, 1987). Large tumours may invade the cavernous sinus, causing dysfunction of cranial nerves 3, 4, or 6. Transphenoidal surgery and modern pharmacological management have decreased the necessity for bilateral adrenalectomy. This procedure was complicated, in up to 30% of cases, by rapid expansion of the pituitary tumour (Nelson's syndrome), due to loss of corticosteroid inhibition (Miller & Crapo, 1993).

Spinal cord disorders

Patients with hypercortisolism occasionally develop compressive myelopathy due to epidural lipomatosis (Sivakumar et al. 1995). Epidural lipomatosis may also cause compressive radiculopathy or cauda equina syndrome (Lipson et al., 1980).

Neuromuscular disorders

By far the most common neuromuscular complication of hypercortisolism is myopathy. Fatigue and subjective weakness are common complaints, accompanied in many patients by true proximal weakness, or steroid myopathy (Anagnos et al., 1997). On physical exam, there is proximal atrophy and weakness beginning in hip and thigh muscles, and later in neck flexors and proximal arms. Tendon reflexes are usually preserved, and muscle enzymes are normal. The severity of weakness does not necessarily correlate with the degree of hypercortisolism. The EMG shows myopathic changes, but may be normal in mild cases. Typically, there is no suggestion of muscle fibre irritability, although complex repetitive discharges and increased insertional activity have been described (Lacomis et al., 1993; Olafsson et al., 1994). Muscle biopsy shows type 2 fibre atrophy, but these changes may also be seen in steroid-treated patients without clinical myopathy. Exercise training may partially prevent weakness in patients taking steroid therapy (Horber et al., 1985). Weakness usually improves when the steroid dose is reduced and complete recovery occurs within a few months after steroid levels return to normal.

Hypoadrenalism (Addison's disease)

Cerebral symptoms

Patients with adrenal failure are frequently fatigued or apathetic and personality changes are common (Werbel & Ober, 1993). Insomnia is common. Frank psychosis and dementia occur rarely and there can be a general enfeeblement of all mental processes. The electroencephalogram often shows lowered voltages and generalized slowing, which resolve after steroid therapy.

In acute or severe adrenal failure, delirium or seizures may develop, usually due to associated hypoglycemia, hyponatremia, or both. It has been observed that patients with Addison's disease have signs and symptoms of hypoglycemia at higher glucose levels than normal individuals. Untreated, delirium or confusion can rapidly progress to coma.

Idiopathic intracranial hypertension has been described in association with Addison's disease (Leggio et al., 1995; Condulis et al., 1997), as well as with steroid withdrawal in hypercortisolism (see above). Headaches are common even in the absence of increased intracranial pressure.

Spinal cord disorders

Adrenal insufficiency accompanying spastic paraparesis, or occurring in a patient with a family history of either adrenal or spinal cord disease, suggests a diagnosis of adrenoleukodystrophy or adrenomyeloneuropathy. These are genetic X-linked disorders (Moser, 1997). Adrenal insufficiency may precede neurologic manifestations and thus the diagnosis should be considered in young men with Addison's disease (Carey, 1997).

Neuromuscular disease

Occasional reports of Addison's disease and Guillain–Barré syndrome have appeared, but the association is probably coincidental (Abbas et al., 1977). Patients may note areas of decreased sensation or paresthesiae over hyperpigmented skin areas. Neuralgic pains in lumbar and epigastric regions are common, as are joint pains.

Hyperkalemic periodic paralysis develops in occasional patients and resembles familial hyperkalemic paralysis (Anagnos et al., 1997). Ascending paralysis evolves over several hours, often associated with paresthesiae, distal sensory loss, and areflexia. Acute respiratory failure may result. The clinical picture suggests a neuropathic, rather than myopathic mechanism, but electrophysiological studies are lacking. Acute treatment to lower serum potassium, including intravenous hydrocortisone, glucose and insulin, is necessary due to the danger of cardiac arrest.

Muscle cramps and stiffness may occur with adrenal insufficiency, but overt proximal weakness is uncommon. The clinical picture can resemble stiff-person syndrome, with painful muscle stiffness and reflex muscle spasms, mainly affecting the abdomen and legs in patients with Addison's disease (George et al., 1984). Stiff-person syndrome is associated with a variety of autoimmune endocrinopathies, including adrenalitis (McEvoy, 1991).

Hyperaldosteronism

The neurologic features of primary and secondary hyperaldosteronism are related to potassium depletion, alkalosis, and hypertension. Hypertension and headaches are common presenting features. Vertigo may be caused by abrupt fluid and electrolyte shifts. Tetany, due to alkalosis, and hypokalemic periodic paralysis occurs in about 20% of cases (Conn, 1963). Potassium depletion may also cause a necrotizing, vacuolar myopathy (Atsumi et al., 1979).

Phaeochromocytoma

The neurological complications of these tumours derived from chromaffin cells appear to result from high circulating levels of epinephrine and norepinephrine (Young, 1997). Most phaeochromocytomas develop sporadically, but they also occur in association with type 1 neurofibromatosis, von Hippel–Lindau disease, tuberous sclerosis, and Sturge–Weber syndrome (Werbel & Ober, 1995). Hypertension, either sustained or paroxysmal, is a feature in nearly all cases. Hypertensive paroxysms may be accompanied by headache or subarachnoid or parenchymal intracerebral hemorrhage (Redman et al., 1983). Other acute manifestations include hypertensive encephalopathy and seizures. Elevated catecholamines can cause exaggerated physiologic tremor, which is typically distal, high frequency (7–12 Hz), and most prominent with posture or movement.

Acknowledgement

This chapter is a revision of Chapter 116, written by Dr Robert B. Layzer in the second edition of this book.

Neurological manifestations of hematological diseases

Martin A. Samuels

Department of Neurology, Brigham and Women's Hospital, Boston, Massachusetts, USA

Anemia

General issues

Anemia is present when the concentration of hemoglobin in the peripheral blood is below the normal range for the patient's age and sex (i.e. 14 ± 2 gm/dl for women, 16 ± 2 gm/dl for men and 12 ± 2 gm/dl for children). When anemia is present, the red blood cell population is usually reduced. The normal red blood cell count is $4.8 \pm 0.6 \times 10^6/mm^3$ for women and $5.4 \pm 0.9 \times 10^6/mm^3$ for men. The hematocrit indicates the proportion of red blood cells in the blood. Greater than 40% for men and 37% for women is considered normal. The major red blood cell indices, which may be helpful in the differential diagnosis of anemia are: the mean corpuscular volume (MCV) which is the average red blood cell size (normal is $87 \pm 5u^3$); the mean corpuscular hemoglobin (MCH) which is the amount of hemoglobin per cell (normal is 29 ± 2 pg of hemoglobin/cell); and the mean corpuscular hemoglobin concentration (MCHC) which is the average concentration of hemoglobin per cell (normal is $34 \pm 2\%$).

These erythrocyte indices may be useful but it should be emphasized that they are averages and complete evaluation requires microscopic examination of the peripheral blood smear which will reveal evidence of red blood cell size (macrocytosis, microcytosis) and shape as well as evidence of the degree of maturity of the red blood cells (i.e. presence of reticulocytes or nucleated cells), the intensity of hemoglobin staining (hypochromia, normochromia or hyperchromia), or the presence of macrocytes, target cells, spherocytes, schistocytes or other abnormally shaped cells. In some situations, automated analysis of erythrocyte indices may reveal normal range results, but direct observation of the peripheral blood smear shows evidence of a dimorphic anemia (e.g. iron deficiency plus megaloblastic anemia) in which some cells are clearly microcytic and hypochromic and others are macrocytic, accounting for the normal indices which reflect an automated average of the two abnormalities. No analysis of anemia is complete without a direct observation of the peripheral blood smear by an experienced observer

Neurological aspects of the anemias

Non-specific neurologic effects of anemia

There are very few neurological effects of anemia *per se*. Headache and lightheadedness may occur in severe anemias but these symptoms usually require that the hemoglobin concentration be reduced by at least one-half. In slowly developing anemias, many patients may have little or no neurological symptoms with hemoglobin concentrations as low as one-tenth normal. The most easily examinable part of the nervous system which reflects the effect of anemia itself is the eye. The retina, optic nerve head and their vascular supply are easily observed with the ophthalmoscope and probably reflect similar changes in the rest of the brain. The reddish colour of the fundus is the result of the light from the ophthalmoscope reflected by the choroidal blood altered to a pink colour by the pigment content of the retinal epithelium. As the hemoglobin concentration falls, the reddish colour of the fundus pales. The optic disc also becomes paler with a reduction in the colour contrast normally seen between arteries and veins.

Aside from pallor of the optic fundus, the most common ocular lesion in anemia is retinal hemorrhage, which is usually small and spindle shaped and occasionally associated with a cotton wool exudate. The presence of hemorrhage correlates with the degree of anemia. It is very unusual to see a retinal hemorrhage when the hemoglobin concentration is greater than 50% of normal. It is believed

that blood escapes from the capillaries by diapedesis and that the exudates are composed of fibrin. Both the hemorrhages and the exudates seen in anemia are transient. In severe anemia (i.e. hemoglobin concentration below 6 gm/dl) a minor degree of edema of the optic disc and adjoining retina may be observed. This is not too surprising since the oxygenation of the optic nerve head depends not only on local blood flow but also upon oxygen carrying capacity of the blood. The retinal vessels appear to be of different calibre than normal in anemic patients. The arteries are widened and the usual width relationship between arteries and veins of 2: 3 approaches 1: 1.

There have been rare reports of patients with moderately severe chronic anemia (i.e. hemoglobin less then 10 gm/dl) due to blood loss who presented with focal cerebral symptoms, which resolved upon transfusion. Whether the symptoms reflected an unmasking of underlying previously asymptomatic occlusive vascular disease is not clear, but it is certain that focal cerebral symptomatology is a very rare manifestation of anemia *per se*. Aside from these few general features, anemia itself has little neurological expression. The following sections review the specific neurologic effects of particular anemias, namely: iron deficiency anemia, megaloblastic anemias (B_{12} and folate deficiency) and hemoglobinopathies (sickle cell anemia and thalassemia).

Iron deficiency anemia

Iron deficiency from chronic blood loss remains the most common form of anemia. Iron deficiency in the absence of anemia (sideropenia) may decrease the deformability of red blood cells leading to ischemia in the distribution of small cerebral vessels. This mechanism is particularly important in the context of polycythemia (either primary or secondary) in which there are increased numbers of red blood cells each one of which may be iron deficient. Both the polycythemia and the relative sideropenia lead to increased blood viscosity with associated neurological symptoms and signs (see the section on hyperviscosity below). Iron deficiency causes a microcytic, hypochronic anemia.

Iron deficiency (usually but not always with anemia) is associated with obsessive–compulsive behaviours which fall into two categories: compulsive eating (pica) and compulsive moving of the limbs, usually the legs (restless legs). Common pica behaviours include the eating of starch, paint chips, clay (terra sigillata), earth (geophagia) and ice (pagophagia). The relationship between the iron deficiency and pica is unknown. It is clear that it does not represent replacement of iron since ice eating, the most common pica behaviour, usually does nothing in this regard and many clays contain substances that actually chelate iron, thereby worsening the problem. It seems more likely that pica represents some form of compulsive behaviour akin to a tic.

The restless legs syndrome is a very common cause of insomnia. It consists of an unpleasant creeping sensation which occurs deep in the legs (and occasionally in the arms), when the person is at rest. The person feels compelled to move the legs to avoid the unpleasant feeling. Most sufferers are women, who pace the floors at night, and complain of insomnia. Polysomnographic studies often reveal nocturnal myoclonus (periodic movements of sleep). It is likely that restless legs, nocturnal myoclonus and akathisia represent various fragments of a single disorder, sometimes called the Ekbom syndrome (Ekbom, 1970). It is known that the basal ganglia are rich in iron and that this may predispose to oxidative stress injury in these locations. Many of the movement disorders associated with iron deficiency anemia are reminiscent of those associated with basal ganglia diseases, but the precise relationship between systemic iron deficiency and these movement disorders is cryptic. Many such patients are iron deficient, as judged by serum iron, total iron binding capacity as well as serum and spinal fluid ferritin levels. In this case the symptoms respond to iron replacement. The rest are treated, usually very successfully, with benzodiazepines, L-dopa, pramipexole, clonidine, or clomipramine. When iron deficiency anemia is diagnosed, a search for blood loss should be initiated; including several tests of stool for occult blood.

Megaloblastic anemias

General issues

The term megaloblastic anemia refers to a characteristic pattern of morphological abnormality in the blood and bone marrow which probably arises from impaired DNA synthesis. Clinically, this is usually the result of a deficiency of one of two factors, cobalamin (vitamin B_{12}) or folic acid, both of which are essential to the formation of the deoxyribosyl precursors of DNA. This deficiency results in abnormal development of erythroblasts in the marrow such that there is intramedullary hemolysis resulting in anemia. The peripheral blood contains macrocytic erythrocytes. The disordered DNA metabolism also affects the maturation of granulocytes resulting in hypersegmented polymorphonuclear leukocytes in the peripheral blood.

This disordered DNA metabolism is clearly not confined to the blood cells, since giant epithelial cells are found in many other organs including the mouth, stomach and skin. The neurologic effects of the megaloblastic anemias are probably due to a primary metabolic derangement in neural tissue and are clearly not directly related to the anemia *per se*. Since the blood-forming organs are particularly sensitive to the effects of cobalamin or folate deficiency, it is unusual to find the neurologic effects in patients in whom no disorders of the blood are found. Anemia is, however, only one and probably a relatively late sign of cobalamin or folate deficiency, so it is possible to find a clear example of the neurologic effects of cobalamin or folate deficiency without anemia. It is distinctly rare, however, to find no hematological signs of cobalamin or folate deficiency in a patient with proved neurological effects of these vitamin deficiencies. Some patients of this kind have been reported, but the degree of completeness of the hematological evaluation or the precise nature of the neurological lesions is often questioned in analysing these rare case reports. Some of these cases may represent other forms of degenerative spinal cord disease in which the lateral and posterior column lesions are unassociated with vitamin B_{12} deficiency. Such may be seen with cervical spondylosis or with multiple sclerosis.

Cobalamin (vitamin B_{12}) deficiency

This may be due to a number of causes summarized as follows:

1. Defective diet (low in animal or bacterial products)
2. Defective absorption
   (a) Deficiency of intrinsic factor
      (i) Pernicious anemia
      (ii) Gastrectomy
   (b) Intestinal disease
      (i) Malabsorption (sprue; resection, bypass or disease of terminal ileum)
      (ii) Blind loop syndrome
      (iii) Fish tapeworm infestation
3. Deranged metabolism or increased requirement (thyrotoxicosis, pregnancy, neoplasia).

Of these, the most prevalent form of cobalamin deficiency is pernicious anemia (or Addisonian anemia, Biermer's anemia, Primary anemia). It arises from failure of the gastric fundus to secrete adequate amounts of intrinsic factor to insure intestinal absorption of vitamin B_{12}. This failure of secretion of the mucoprotein intrinsic factor is due to atrophy of the fundic glandular mucosa, a process which is usually an immune-mediated gastritis, but may be familial or result from gastric neoplasia. Patients with autoimmune pernicious anemia often have anti-intrinsic factor and antiparietal cell antibodies as well as clinical and laboratory evidence of other conditions characterized by autoimmunity such as vitiligo and thyroiditis. Serum B_{12} levels have occasionally been measured to be erroneously normal in documented cases so it is now routine to assess intracellular function by directly measuring serum homocysteine and methylmalonic acid (Toh et al., 1997). Cobalamin (vitamin B_{12} or extrinsic factor) exists in two forms, methylcobalamin and adenosylcobalamin, each of which acts as an important cofactor in reactions vital to cellular function. The methylcobalamin system acts to transfer methyl groups from methyltetrahydrofolate to homocysteine, thereby creating tetrahydrofolate, which is required for DNA synthesis, and methionine. Failure of this system results in impaired DNA synthesis and accumulation of homocysteine. Nitrous oxide, an inhibitor of methyl transferase, causes the syndrome of subacute combined degeneration of the nervous system, a fact which argues that DNA synthesis failure can cause neurological disease even though neurons are postmitotic and therefore are themselves resistant to such a toxin. It is likely that this toxicity acts on oligodendrocytes, resulting in the demylinating lesion that is characteristic of subacute combined degeneration. Acute exposure to nitrous oxide in the form of general anesthesia may precipitate acute deterioration (anesthesia paresthetica) in patients with an otherwise mild or asymptomatic case of cobalamin deficiency (Kinsella & Green, 1995).

The adenosyl cobalamin system acts to metabolize propionic acid by converting methylmalonyl CoA to succinyl CoA which then enters the Krebs cycle. Failure of this system results in an accumulation of methylmalonic acid which is toxic to the nervous system by promoting the formation of long chain fatty acids with odd numbers of carbon atoms. Normal long chain fatty acids that contain even numbers of carbon atoms, are formed using malonic acid. Thus, when methylmalonic acid replaces malonic acid, an extra methyl group leads to odd numbers of carbon atoms and an unstable myelin.

Thus, serum homocysteine and methylmalonic acid levels are elevated when there is intracellular failure of the two cobalamin related chemical reactions, making measurement of these levels the most sensitive test for vitamin B_{12} deficiency.

Since vitamin B_{12} is stored in various tissue in large amounts, the appearance of cobalamin deficiency after the cessation of B_{12} absorption or intake is delayed by at least 3 years. Despite the fact that pernicious anemia is the most common cause of cobalamin deficiency, it seems clear that vitamin B_{12} deficiency of any of the above listed causes may

result in the identical clinical picture. The three neurologic manifestations of vitamin B_{12} deficiency are subacute combined degeneration of the spinal cord, mental changes and optic neuropathy.

Subacute combined degeneration of the spinal cord (or subacute combined sclerosis, posterolateral sclerosis)

This is the term used to designate the spinal cord disease due to cobalamin deficiency. The inaccurate term 'combined systems disease' should be avoided. The patients tend to complain of generalized weakness and paresthesias which usually begin distally in the arms. As these symptoms progress, stiffness and weakness in the limbs develops. Loss of vibration sense is the most profound sign often joined later in the course by joint position sense loss as well. The Romberg sign is positive and the gait is unsteady and awkward primarily because of propriceptive loss (pseudotabetic gait). Weakness and spasticity are usually worse in the legs than the arms and may progress to a spastic paraplegia if untreated. Babinski signs are present, but the deep tendon reflexes are variable. They may be grossly increased with clonus, absent, or show any intermediate degree of activity. If a sensory level is found on the trunk implicating the spinothalamic tracts, this should always be viewed with the greatest scepticism and lead one to exhaustively exclude other causes of spinal cord disease. All of the findings of pure vitamin B_{12} deficiency may be attributable to myelopathy alone and there is no convincing evidence that B_{12} deficiency itself causes a neuropathy. However, in practice, the frequent concomitant existence of folate and other vitamin deficiencies, makes it difficult to be sure of this point. Many patients with vitamin B_{12} deficiency have distal symmetrical impairment of cutaneous sensation, absent deep tendon reflexes and even slowed nerve conduction velocities suggesting a neuropathic component. This is probably due to concomitant folate deficiency, but the outside chance that vitamin B_{12} deficiency itself may cause a peripheral neuropathy cannot be rigorously excluded. Pathologically the lesion in the nervous system is a degeneration of white matter in the spinal cord and occasionally the brain. The myelin sheaths and axis cylinders are both involved, the former more profoundly than the latter. These changes begin in the posterior columns of the lower cervical and upper thoracic segments and spread from there up and down and also laterally in the cord to involve the lateral columns. This pathology can often be visualized using magnetic resonance imaging in which a bright lesion can be seen on T_2-weighted images. On microscopic study, early changes consist of swelling and destruction of myelin sheath with subsequent axonal destruction. Later, a cribriform appearance develops. Eventually, white matter is lost and is replaced by gliosis. The focal lesions have a rough but not absolute symmetry, and they extend caudally and rostrally so that ultimately the entire area of the dorsal columns is involved. In the meantime, the lesions have begun in the lateral columns and extend into the other long tracts. The grey matter is spared. Similar changes can be seen in the cerebral hemispheres and optic nerves. The myelin of peripheral nerves may also be involved but axons have not been shown to be unequivocally affected.

Mental changes

These are frequent in patients with vitamin B_{12} deficiency. In most cases these changes reflect abnormalities in level of consciousness with inattention, confusion, somnolence, apathy and delirium being the cardinal features. True dementia, defined as intellectual impairment in the absence of a disorder of level of consciousness, is certainly a relatively rare manifestation of pure vitamin B_{12} deficiency. Pure mental change as the only manifestation of vitamin B_{12} deficiency is exquisitely uncommon. Case reports of true dementia and pure mental change as manifestations of vitamin B_{12} deficiency are contaminated with concomitant causes of dementia and disordered mental status.

Optic neuropathy

This is the third and last major neurologic complication of vitamin B_{12} deficiency. It is characterized by bilateral involvement of the optic nerves resulting in loss of central visual acuity and depressed sensitivity greater for colour than for white in the centrocecal area of the field of vision. This is the rarest of the three neurologic manifestations of vitamin B_{12} deficiency, but may be the only or presenting manifestation of the syndrome. It may be subclinically present in many more cases than previously believed if one uses a very sensitive measurement of optic nerve function such as visual evoked responses. This syndrome is clinically similar to a number of other bilateral optic neuropathy syndromes including the so-called tobacco–alcohol amblyopia, diabetic optic neuritis, Leber's hereditary optic atrophy, and tropical ataxic neuropathy. Some feel that the etiology of all of these syndromes including vitamin B_{12} deficiency optic neuropathy is linked to an abnormality in cyanide metabolism due to a shortage of sulfur donating amino acids. In recent years there was an epidemic of optic neuropathy and myelopathy in Cuba, which was thought to be due to multiple B vitamin deficiency due to malnutrition combined with alcohol and cyanide from cigar smoking and cassava consumption. The epidemic was

terminated by vitamin supplementation (Roman, 1995.) The suspicion that people who became symptomatic in the face of severe vitamin malnutrition harboured an otherwise asymptomatic mutation in the mitochondrial genome akin to the one known to cause Leber's hereditary optic neuropathy is interesting but has not been demonstrated.

Folic acid (folate)

This deficiency accounts for nearly all of the cases of megaloblastic anemia not due to vitamin B_{12} deficiency. The causes of folate deficiency may be summarized as follows:

1. defective diet (low in vegetables and liver)
2. defective absorption
   (a) intestinal malabsorption (sprue; steatorrhea, massive diverticulosis, short circuits of gastrointestinal tract).
   (b) 'blind loop' syndrome
3. deranged metabolism
   (a) increased requirement (hemolytic anemia, pregnancy, neoplasia).
   (b) impaired utilization (liver disease, administration of folic acid antagonists or anticonvulsants).

Unlike vitamin B_{12}, the bodily stores of folic acid are quite limited. A folate deficiency syndrome may commence within several months of dietary deprivation, making it a much more common problem among the malnourished than is vitamin B_{12} deficiency. Folate, once absorbed through the entire small intestine, is reduced by specific liver enzymes to tetrahydrofolic acid, a compound that plays a major role in the metabolism of one-carbon fragments by its synthesis and transfer of methyl groups. Via this mechanism folate is vital for the conversion of deoxyuridate to thymidylate, a precursor needed for DNA synthesis. Thus, tetrahydrofolate derivations are closely linked to vitamin B_{12}-dependent reactions, and the hematologic alterations in vitamin B_{12} and folate deficiency are indistinguishable. Deficiencies of the two vitamins have very similar effects and a deficiency of one may lead to faulty utilization of the other. For example, patients with vitamin B_{12} deficiency may have an initially elevated serum folate, which will plummet rapidly when vitamin B_{12} is administered, thus requiring concomitant treatment with folate lest a folate deficiency state, previously masked by the vitamin B_{12} deficiency, should become clinically significant. Many patients with vitamin B_{12} deficiency have concomitant folate deficiency, but the vast majority of those with the overwhelmingly more common folate deficiency state will have no vitamin B_{12} deficiency. Folic acid deficiency is almost never pure. Since it accompanies malnutrition it is nearly always associated with multiple vitamin deficiencies. The most common neurological manifestation of this multivitamin deficiency state is a polyneuropathy.

The symptomatology of nutritional polyneuropathy includes distal paresthesias, burning and weakness. On examination, there is a distal loss of reflexes and sensation. The essential pathological change is an axonal degeneration with 'dying-back' of the axons according to length. Some minor degrees of segmental demyelination may also occur usually due to entrapment of metabolically weakened nerves. The common entrapment neuropathies (e.g. carpal tunnel syndrome; meralgia paresthetica; peroneal palsy; ulnar palsy) are all more frequent in patients with an underlying metabolic axonopathy such as that due to vitamin deficiency. In circumstances in which the major vitamin deficiency is likely to be folic acid (i.e. when folate antagonists have been given), a mild polyneuropathy of the type described above occurs but even in these patients, the concomitant existence of other vitamin deficiency and/or neurotoxic substances cannot be rigorously excluded. Folate is important to normal nervous system development in that folate deficiency during pregnancy heightens the risk of neural tube disorders in the fetus.

Hemoglobinopathies and thalassemia

General issues

In normal people, variations in the concentrations of the three normal varieties of hemoglobin (A, A_2 and F) are known to take place with maturation. Disorders in which the presence of a structurally abnormal hemoglobin is considered to play a primary pathological role are referred to as hemoglobinopathies. Disturbances involving alterations in the percentages of normal forms of hemoglobin are designated by individual terms, such as thalassemia. Hemoglobin consists of four coiled polypeptide chains. The four chains are of two varieties so that two of each type are present. There are four normal polypeptide sequences designated alpha, beta, gamma and delta. Hemoglobin A consists of two alpha and two beta chains designated $\alpha_2\beta_2$. HbA_2 consists of $\alpha_2\delta_2$ and HbF consists of $\alpha_2\gamma_2$. Several mechanisms that result in abnormal hemoglobin are known. Many examples of abnormal hemoglobins have been defined in which a single amino acid substitution has occurred in one of the two pairs of polypeptide chains. Other abnormal hemoglobins result from crossing over of the adjacent structural genes for the beta, gamma and delta polypeptides. Hemoglobins consisting of a single

variety of polypeptide rather than the normal two have been described, and abnormalities resulting in the switch from fetal to adult hemoglobin are known. Finally, abnormalities in the mechanism controlling the rate of release or synthesis of various polypeptide chains are thought to result in the thalassemia group of disorders. Most of the abnormal hemoglobins cause no hematologic difficulty. However, some diseases are directly attributable to changes in hemoglobin structure which lead to a variety of steric changes in the molecule. Sickle hemoglobin forms insoluble polymers when deoxygenated; the HbM variants lead to excessive levels of methemoglobin. HgM combines irreversibly with oxygen while other types such as HbQ are easily denatured and precipitate within the erythrocytes to form Heinz bodies.

A person homozygous for a structural mutation involving one of the polypeptide chains of HbA will produce only a single abnormal adult variety of hemoglobin. Three examples of such a disease are HbS, HbC, and HbE. Of these, the most important is HbS which causes sickle cell anemia. HbC and HbE diseases are generally mild and have no known neurologic complications.

Sickle cell anemia (HbS disease)

Most of the manifestations of sickle cell anemia are related to the characteristic property of HbS to crystalize under conditions of reduced oxygen tension. This leads to sickled erythrocytes becoming trapped in terminal arterioles and capillaries which results in more hypoxia, increased sickling, thrombosis and infarction. Tissues that normally contain blood at low oxygen tensions such as renal medulla and pulmonary arterioles are at greatest risk but sickling may occur in other organs including the relatively well oxygenated brain and spinal cord. The hemolysis results largely from the fact that the sickled erythrocytes are mechanically rigid, less flexible and more fragile than normal cells.

The neurological complications of sickle cell anemia may be divided into four categories: painful crises, vascular disease, infection and fat embolism.

Painful crises are among the most common clinical problems in the management of patients with sickle cell anemia. The abdominal and bone pain so common in this disease is probably ischemic pain related to the sickling phenomenon as described above. The treatment consists of hydration, bed rest and analgesia.

Vascular disease is the more serious neurological aspect of this disorder and probably contributes in a major way to the decreased life expectancy in patients with sickle cell anemia. The prevalence of overt strokes is about 20% among patients with sickle cell anemia, obviously a massive increase over other patients of similar age. Most of the strokes are due to small vessel occlusions, often resulting in seizures at the onset of the stroke. In some cases, progressive small vessel occlusions with recurrent development of collaterals can lead to a bizarre angiographic picture similar to that seen in moyamoya disease. Hemorrhages may occur due to rupture of these fragile collateral vessels leading to intracerebral, subarachnoid, spinal and retinal hemorrhagic strokes in patients with sickle cell disease. The progressive stenosis of the supraclinoid internal carotid artery that leads to the development of the moyamoya pattern may be detected non-invasively using transcranial Doppler ultrasound (Adams et al., 1997). Stroke risk is reduced dramatically using prophylactic transfusions in patients in whom transcranial Doppler examinations show the time-averaged mean blood velocity in the internal carotid or middle cerebral artery is 200cm per second or higher (Adams et al., 1998). Among children under the age of 15 years, sickle cell anemia is present in 7% of patients with strokes making it an important cause of stroke in childhood. Spinal cord infarction is also seen in patients with sickle cell anemia much more commonly than in the general population. Massive intracranial hemorrhage is a rare but devastating complication of sickle cell anemia. However, most of the literature comes from the pre-CT scan era and it is not clear whether the incidence of intracranial hemorrhage in patients with sickle cell anemia is higher than a matched control population. Large vessel occlusions have also been reported to occur in patients with sickle cell anemia. The supraclinoid carotid has been the site of predeliction. The mechanism for large vessel disease in this circumstance is unclear. Some believe that a hyperdynamic circulation leads to endothelial damage. Others hold that chronic stasis leads to diminished blood volume and thrombosis while others have postulated that sickled erythrocytes occlude the vasa vasorum of large vessels that causes ischemic damage to the vessel wall leading to thrombosis. The moyamoya phenomenon may be treated with extracranial – intracranial arterial bypass grafting or with temporal-pial synangiosis, hoping to reduce the likelihood of rupture of the fragile moyamoya vessels.

Sepsis is the most common cause of death in patients with sickle cell anemia and bacterial infection is the reason for as many as one-half of all hospitalizations in these patients. Of all the infections, meningitis is particularly important accounting for 20% of the deaths from sepsis. Some older children and adults with meningitis have been reported but most of the patients are under three years of age. *S. pneumonia* is an unusually common organism in these patients accounting for about three-quarters of the

cases of meningitis most of whom were patients under three years old, whereas, other children in this age group with meningitis tended to show *H. influenza* type B as the leading cause of infection. This group of patients have a peculiarly malignant course often leading to death within a few hours. Recurrent meningitis seems also to be unusually common in these patients. The unusual susceptibility of patients with sickle cell anemia to infection is not totally understood, but the factors which are believed to be most important include their functional asplenia and an opsonizing defect which causes leukocyte malfunction.

Fat embolism in sickle cell anemia patients occurs with higher than expected frequency and the brain is involved in greater than 80% of the patients in whom it is examined. Bone pain, fever and changes in mental status, are the major presenting features. Treatment is controversial but most advocate systemic anticoagulation and exchange transfusion.

Heterozygous hemoglobin states and complex hemoglobin combinations

Only the presence of some amount of HbS leads to the risk of a neurologic problem. Sickle cell trait is occasionally associated with neurologic complications especially when patients at risk are exposed to an extremely low oxygen tension (e.g. high altitude flying, anesthesia). The HbSC; HbSD; HbSF; and HbS-thalassemia syndromes are all situations in which there is a risk of neurological complications similar to those mentioned above for homozygous HbS disease. However, there are fewer neurological problems in these combined hemoglobin disorders than in the pure sickle cell disease.

Thalassemia

The genetic defect underlying thalassemia involves rates of synthesis of the individual polypeptide chains. Two major varieties of thalassemia exist: one involving defective alpha chain synthesis, the other involving beta chain synthesis. The more common beta-thalassemia may occur in the heterozygous or homozygous form to produce the syndromes of thalassemia trait or Cooley's anemia (thalassemia major) respectively. Heterozygosity for alpha thalassemia results in a very mild condition and may require an associated hemoglobin abnormality for clinical expression (thalassemia minor). Homozygous alpha thalassemia is thought to be incompatible with normal fetal development. The neurologic dysfunction seen in the thalassemias may be divided into three distinct categories: meningitis following splenectomy (discussed above under sickle cell anemia), spinal cord compression due to extramedullary hematopoiesis, and a mixed group of neuromuscular disorders.

The susceptibility to infection seen in thalassemia corresponds to that seen in sickle cell anemia, but is confined to those patients who have undergone splenectomy for control of their hemolysis.

About a third of patients with myelopathy due to extramedullary hematopoiesis have thalassemia as their underlying disease. When extramedullary hematopoiesis exists in the presence of a hemolytic anemia, it is believed to be produced as a compensatory mechanism by totipotential cells in various locations. The usual location for extramedullary hematopoiesis is various parts of the reticuloendothelial system, particularly the liver, spleen and lymph nodes. However, the spinal epidural space, and rarely the intracranial subdural space, may be involved with consequent compression of the spinal cord, and/or brain. Nearly all spinal cases have involved the thoracic spinal segments posteriorly, usually over multiple levels and treatment with surgical decompression and/or radiotherapy has lead to dramatic and sometimes prolonged remissions of myelopathic symptoms and signs.

In addition to the complications of infection and extramedullary hematopoiesis, a large number of other less well defined syndromes may exist in thalassemia. Logethetis and colleagues reported on 138 patients from their own experience with thalassemia major. Twenty per cent had transient episodes of dizziness, blurred vision and fainting, which improved following transfusion. Two strokes occurred. One had convulsions followed by an acute transient hemiparesis four days following splenectomy, and the other had headaches and visual blurring followed by a right hemiparesis two days after a transfusion. Major motor seizures were observed in 7%, and 49% had absent or diminished deep tendon reflexes. Muscular wasting was prominent in 23%, muscle cramps in 4% and muscle wasting in 32%. Nineteen per cent had a myopathic syndrome, eleven of which had a myopathic electrophysiologic study. The possible pathophysiological mechanism for this myopathic syndrome is totally unexplained.

Myeloproliferative disorders

The myeloproliferative disorders include polycythemia rubra vera, myelofibrosis with myeloid metaplasia, chronic myelogenous leukemia, and essential thrombocythemia. The proliferation in all of these diseases originates in the bone marrow or in the liver or spleen where extramedullary

blood formation may occur. The growth is self-perpetuating and involves all cell lines although in each syndrome one line may predominate. This proliferation may be confined to a single cell form or may involve several different strains of cells simultaneously or at separate times. Since overlap syndromes occur so frequently, precise diagnosis in a given patient is often difficult and perhaps fruitless.

The neurological manifestations of these conditions depend primarily on the tendency to thrombosis, hyperviscosity or the effects of extramedullary hematopoiesis.

Strokes are the most common neurologic complication seen in polycythemia vera occurring in 15–32% of the patients. As many as 15% of patients with polycythemia vera die of a stroke, five times that of an age-matched control population. Headache which occurs in nearly half the patients and dizziness and vertigo, which occurs in about a third of the patients, are the most frequent neurologic symptoms.

Several cases of sudden unilateral or bilateral chorea have been described. Pathogenesis is presumed to be vascular, but the precise location of the lesions has been variable in different case reports; most involve the subthalamic nuclei, cerebral cortex and corpus striatum bilaterally in various combinations.

Extramedullary hematopoiesis is a common manifestation of the myeloproliferative disorders but neurologic complications due to extramedullary hematopoiesis are rare. A few cases of intracranial dura matter involvement by extramedullary hematopoiesis have been recorded, but all were asymptomatic and only found incidentally at autopsy or by imaging techniques. About half of the cases of extramedullary hematopoiesis are associated with a myeloproliferative disorder; the rest secondary to various hemolytic anemias, the most frequent of which was thalassemia.

Polycythemia may rarely be due to an erythropoietin-secreting cerebellar hemangioblastoma.

Hemorrhagic diathesis

Hemophilia

This may be defined as an inherited hemorrhagic diathesis, characterized by impairment of the first stage of coagulation, the production of thromboplastin from the interaction of platelets and three or more plasma factors. Among the factors necessary for thromplastin formation are antihemophiliac globulin (AHG, or Factor VIII), plasma thromboplastin component (PTC or Factor IX or Christmas factor) and plasma thromboplastin antecedent (PTA or Factor XI). Factor VIII deficiency is responsible for 75–90%, Factor IX deficiency for 10–20% and Factor XI deficiency for 1–5% of hemophiliacs. Factor VIII and IX deficienty are X-linked recessive disorders and therefore are seen almost exclusively in males. Factor XI deficiency is inherited as an autosomal dominant trait and is thus seen equally in men and women, primarily of Ashkenazy Jewish descent. It is now possible to determine specifically the deficient factor in the patient's plasma and, with the exceptions of hemophiliacs who have circulating antibodies to specific factors, produce normal hemostasis by factor replacement. One may classify the hemorrhagic diathesis as mild (7–15% of normal factor levels), moderate 1–6%, and severe (<1%). Neurologic complications of hemophilia may be divided into those affecting the peripheral nervous system and those affecting the central nervous system.

Peripheral nervous system complications of hemophilia

The major problem with respect to the peripheral nervous system results from intramuscular hemorrhages which may expand muscle tissue or extend into fascial planes and compress peripheral nerves. This most commonly occurs with the femoral or ulnar nerves but cases involving the sciatic, peroneal, median and even facial nerves have been reported. Actual intraneural hemorrhages have been postulated but never proved. Most patients with peripheral nerve compressions may be managed with factor replacement alone, but some may require fasciotomy as well.

Central nervous system complications of hemophilia

Intracranial hemorrhage is becoming increasingly common in patients with hemophilia possibly because of the more active lives permitted by vigorous replacement therapy for intra-articular hemorrhages. Intracranial hemorrhage is an important cause of death in hemophiliacs, possibly the largest hemophilia-related mortality factor other than AIDS. Bleeding may be intracerebral, subarachnoid, subdural and epidural. Before 1970, the mortality rate from intracranial bleeding was 70%. It is now about 30%. In mild cases (7–15% of normal factor levels), intracranial bleeding only occurs after significant trauma. Patients with moderate cases (1–6%) require only minor trauma and severe cases (<1% normal levels) no trauma at all. The best method for accurate diagnosis of intracranial hemorrhage in this setting is the CT scan or MRI.

Subarachnoid hemorrhage may be treated successfully with factor replacement alone, although a ventricular catheter may be required to treat hydrocephalus.

Subdural, and epidural hemorrhages will usually not respond to factor replacement alone and ordinarily require surgical therapy. Surgical evacuation of the hematoma may be safely accomplished after factor replacement. Intracerebral hemorrhages are the most difficult to treat. Some patients have been successfully managed with medical therapy alone or with medical therapy plus a ventricular cannula for measurement and control of intracranial pressure. However, if the hematoma is accessible, surgical resection may lead to higher rates of recovery. General guidelines for the management of head trauma in hemophiliacs are as follows. In patients with mild head trauma and a normal neurologic examination, one would suggest factor infusion to a measured post-infusion level of 70% of normal. In patients with more severe head trauma and/or abnormal neurologic examination, an emergency CT scan should be obtained. If normal, then 48 hours of 30–70% factor levels should be maintained by factor infusion. If the CT scan shows a hemorrhage, then factor infusions should continue for 7–10 days after the bleeding has stopped or 14 days after the neurosurgical procedure, whichever is longer.

Thrombocytopenia and other purpuras

Thrombocytopenia is usually an acquired reduction in the number of platelets due to either diminished production or increased peripheral destruction. Thrombocytopenia due to diminished production is seen from drug effects on the bone marrow, myelophthisic phenomena and ineffective thrombopoiesis. Thrombocytopenia due to increased peripheral destruction of platelets may be due to mechanical factors such as a prosthetic device or vasculitis, disseminated intravascular coagulation, or thrombotic thrombocytopenic purpura. Thrombocytopenia not of mechanical origin but due to peripheral destruction of platelets has been called immune thrombocytopenic purpura. Immune thrombocytopenic purpura may be subdivided into the secondary forms due to drugs (e.g. heparin induced thrombocytopenia), virus, lymphoproliferative disorders and collagen vascular diseases and the primary or idiopathic thrombocytopenic purpura (ITP). Splenomegaly, while it does not shorten platelet lifespan, increases the size of the sequestered platelet pool and causes thrombocytopenia.

The neurologic complications of thrombocytopenia revolve around intracranial bleeding, the severity and frequency of which is dependent on the severity of the thrombocytopenia rather than the underlying diseases. There are a few exceptions to this rule in which the underlying disease affects the neurological picture apart from the thrombocytopenia itself. Those are: lupus erythematosus, thrombotic thrombocytopenic purpura (see succeeding section in this chapter) and leukemia, in which the leukemic infiltrates in the brain add to the tendency for intracranial hemorrhage.

The incidence of intracranial bleeding in thrombocytopenia is substantial ranging to as high as 26% in older work to figures around 1.5% in more recent surveys. This wide variation is partly due to improvement in treatment, but also reflects the definition of cases said to have intracranial hemorrhage. The more recent surveys generally refer only to true intracerebral hemorrhage and exclude cases in which hemorrhagic spinal fluid is found in the absence of signs of an intraparenchymal hemorrhage. The CT scan has now made this an easy differential point, since only large intracerebral hemorrhages would be seen by this technique whereas episodes of brain purpura (see below) with hemorrhagic spinal fluid would not likely yield a positive CT scan. Intracerebral hemorrhage is one of the most common causes of death directly attributable to thrombocytopenia.

Intracranial bleeding in thrombocytopenia can be in the form of multiple small punctate or petechial hemorrhages due to capillary bleeding. This ‘brain purpura’ consists of small ring-shaped hemorrhages in both the grey and white matter of the brain. The basic pathophysiology of cerebral hemorrhage in thrombocytopenia is probably capillary bleeding which may become confluent with continued bleeding in severe cases, leading to frank intracerebral hemorrhages. This intracerebral source of bleeding probably explains the sparsity of subdural, subarachnoid and epidural hematomas seen in the thrombocytopenias compared with the frequency of intracerebral hemorrhages. Peripheral nerve involvement with hemorrhage and spinal cord hemorrhage are both rare in the thrombocytopenias. The symptom complex associated with ‘brain purpura’ is not known. It is probable that most of these petechiae are asymptomatic.

Treatment depends on the etiology of the thrombocytopenia. Platelet transfusions are useful in situations in which decreased production is the difficulty. When increased platelet destruction or splenic sequestration is an important factor, therapy may require splenectomy, corticosteroids, intravenous immunoglobulin (IVIg) and platelet transfusions. In the presence of central nervous system bleeding, corticosteroids, IVIg and platelet transfusions may be administered. Emergency splenectomy has been advocated when intracerebral hemorrhage is suspected in a patient with immune thrombocytopenia even before a full evaluation of the intracerebral hemorrhage is carried out. This should be accompanied by corticosteroid

and platelet administration followed by neurosurgical evacuation of the hemorrhage if technically possible. The efficacy of IVIg, which can transiently raise the platelet count in patients with ITP, may alter this practice. When heparin-induced thrombocytopenia is recognized, the patient is switched to another drug, such as danaparoid or hirudin. In the case of the heparin-induced thrombocytopenia (HIT), there are antibodies (usually IgG) directed against a complex of heparin and platelet proteins (usually platelet factor 4) which activate platelets resulting in thrombocytopenia and thrombosis (Warkentin et al., 1998). Thus, the neurological consequences of HIT are thrombotic rather hemorrhagic. Low molecular weight heparin is usually ineffective.

Thrombotic thrombocytopenic purpura (Moschcowitz disease)

This is usually considered a triad of thrombocytopenic purpura, hemolytic anemia and neurological manifestations. Fever and evidence of renal disease are also almost invariably present. The diagnosis requires histological demonstration of the characteristic pathological lesion consisting of widespread hyaline occlusion of terminal arterioles and capillaries. This can be accomplished using many tissues, the most accessible of which are lymph node, bone marrow, skin and spleen. The blood smear often shows a microangiopathic hemolytic anemia. The most important pathological changes in the nervous system are a striking increase in the cellularity of the walls of arterioles and capillaries and platelet thrombi associated with multiple small foci of parenchymal necrosis and petechial hemorrhages. These changes are identical to those seen in other organs and thus are considered part of a systemic disease. Grey matter is affected to a greater extent than white matter. The neurologic manifestations of the disease reflect the widespread grey matter involvement. The most common are headache, mental change including altered states of consciousness, agitation, confusion, delirium, hemiparesis, aphasia, syncope, visual changes, dysarthria, seizures, coma, cranial nerve palsies, paresthesias and vertigo.

The pathogenesis of thrombotic thrombocytopenic purpura remains obscure. Multiple theories including toxins, drug sensitivity, bacterial infections, autoimmune reactions, collagen disease, abnormality of serum lipids, intravascular thrombosis and hemolysis as related to intravascular thrombosis all have been postulated. At present most arguments favour an immunologically mediated phenomenon. The disorder has occurred in association with an immune response (triggered by vaccination, medication or infection) often in the setting of certain autoimmune disease such as systemic lupus erythematosus. Subnormal levels of serum complement and immunoglobulins in the vascular lesions, elevated levels of platelet bound immunoglobulins and the presence in serum of antibodies directed against fragments of Von Willebrand factor have been reported. The hemolytic uremic syndrome, a childhood disorder similar in many respects to thrombotic thrombocytopenic purpura may be triggered by immune complexes. The same can be said for the HELLP (hemolytic anemia, elevated liver function tests, low platelets) syndrome seen in peripartum patients. Exchange transfusion has been reported to dramatically reverse the syndrome. It has also been noted that remission can be induced with fresh frozen plasma but not albumen. If there were an unusual class of immune complex active against vascular tissue and perhaps platelets which provoked thrombotic thrombocytopenic purpura, this would explain the effectiveness of exchange transfusions. Furthermore, normal plasma might promote clearing of these presumptive immune complexes if, fortuitously, it contained an antibody with high affinity for their antigenic component. These postulated immune complexes have, however, not yet been identified. Other treatments for thrombotic thrombocytopenic purpura have included heparin, antiplatelet agents, corticosteroids, dextran and splenectomy, all aimed at various parts of the syndrome. The prognosis is poor and mortality in most series is about 50% though better results have been reported in groups using exchange transfusions with whole blood or plasmapheresis.

Hereditary hemorrhagic telangiectasia (Osler–Weber–Rendu disease)

This is an autosomal dominant disease involving several systems. The neurological manifestations may be produced by vascular malformations of the central nervous system or by complications of pulmonary arteriovenous malformations.

Pulmonary arteriovenous malformations are the most common large visceral vascular anomalies in hereditary hemorrhagic telangiectasia. Several mechanisms may cause the development of neurogenic symptoms: erythrocytosis may induce cerebral thrombosis; cerebral air embolism may follow hemoptysis; thrombosis may develop in the pulmonary malformation with subsequent cerebral embolism and the right to left extracardiac shunt, which allows bacteria and septic microemboli to bypass the pulmonary filter, predisposes to the development of brain abscess. Multiple and

solitary abscesses have been described as occurring anywhere in the brain.

In addition, the brain, spinal cord or meninges may be the site of telangiectasias or larger vascular malformation. Seizures, headaches, progressive neurologic deficits or spontaneous subarachnoid or intracerebral hemorrhage are the typical clinical presentations.

Henoch–Schonlein (allergic or anaphylactoid) purpura

This is characterized by serosanguinous effusions into the subcutaneous submucous and subserous tissues. The pathogenesis of the disorder is obscure but much indirect evidence suggests an allergic etiology. The disorder is most common in children and young adults. The skin lesions are variable in appearance but the purpura is usually associated with one of the manifestations of allergy such as erythema or urticaria. Effusions into joints or viscera may produce various localized symptoms such as joint pain or abdominal pain. Involvement of the nervous system is rare, but cerebral hemorrhages and peripheral nerve involvement have been reported. Treatment is largely symptomatic. Corticosteroids have been used but with questionable success.

Disseminated intravascular coagulation (DIC)

This is a relatively common acquired hemorrhagic thrombotic syndrome, which occurs as a result of the presence of thrombin in the systemic circulation. The syndrome follows other disease states such as viral infections, bacterial infections, obstetrical and surgical complications, neoplasms, fat embolism, diabetic ketoacidosis, head injury and others. DIC causes thrombosis and bleeding at multiple sites including the nervous system. The essential neuropathologic changes are multiple infarctions, petechial hemorrhages, and occasional small subdural and subarachnoid hemorrhages. Fibrin thrombi are found in the cerebral vessels. The clinical syndrome depends upon the particular pathology but may include seizures, mental changes and focal findings. Most patients with DIC show xanthochromic cerebrospinal fluid and angiographic abnormalities consistent with multiple small vessel occlusions. The treatment of subacute or chronic DIC with heparin has been effective, particularly in patients with thrombotic complications. However, no specific treatment apart from removal of the underlying cause (e.g. evacuation of the uterus in cases of abruptio placentae) is useful in acute DIC (also see section on hypercoagulable states related to underlying malignancy).

Anticoagulants

Hypoprothrombinemia is a common cause of clinical bleeding. The rare causes include congenital (vitamin K resistant) and idiopathic (vitamin K responsive) hypoprothrombinemia, hemorrhagic disease of the newborn as yet unable to provide its own vitamin K; diseases that interfere with vitamin K absorption (e.g. sprue, steatorrhea, surgical resection); disorders that interfere with bile access to the vitamin K in the gut (biliary obstruction); liver diseases which interfere with prothrombin production, and salicylate therapy. However, by far the most important and frequent cause of hypoprothrombinemia is anticoagulant drugs. The neurologic complications of anticoagulant drug usage are related to the presence of hypoprothrombinemia. Any other cause of hypoprothrombinemia as listed above can result in the same spectrum of disorders. In addition, the following discussion will include the neurologic complications of heparin therapy, a drug which inactivates thrombin, inhibits the conversion of prothrombin to thrombin and prevents the agglutination of platelets. Its complication spectrum is similar to that of the agents which lower the prothrombin content of the blood by acting as a metabolic antagonist to vitamin K (e.g. coumarin and related agents).

Nervous system hemorrhage in patients on anticoagulants may involve numerous locations including intracerebral, subarachnoid, subdural, cranial epidural, spinal epidural and spinal intramedullary. In addition, roots, plexus and peripheral nerves may also be compressed by bleeding of this type. Before the advent of CT scanning, lumbar punctures were used to diagnose nervous system bleeding of this type. However, lumbar puncture itself may be dangerous in the presence of a hemorrhagic diathesis and has led to epidural and cauda equina compression syndromes. When CT scanning is not available, every effort should be made to correct the coagulation defect before the lumbar puncture is performed, though this process should not be permitted to delay a lumar puncture too long if an infection is being considered. In general the incidence of serious neurological hemorrhage rises above the benefit of anticoagulation when the international normalized ratio (INR) exceeds 3.0. For neurological purposes, the target INR is 2.0–3.0 for all conditions except antiphopholipid antibody syndrome and mechanical heart valves.

Paraproteinemias

Paraparoteinemias may be seen in many conditions including connective tissue diseases, multiple types of

malignancy and even in the absence of any known underlying disease. The most important group of disorders associated with the production of abnormal proteins are the plasma cell dyscrasias.

Plasma cell dyscrasias

The plasma cell dyscrasias are a group of disorders characterized by the uncontrolled proliferation of cells normally involved in antibody synthesis. This is usually accompanied by the synthesis of a homogeneous immunoglobin or one of its constituent polypeptide chains. These disorders are often classified according to type of protein that is produced. Thus, they fall into three major categories: (i) multiple myeloma: IgG, A, D and E; (ii) macroglobulinemia: IgM; and (iii) heavy-chain diseases: gamma, alpha, and mu.

Multiple myeloma

This is the most common plasma cell dyscrasia and is characterized by infiltration of the bone marrow with neoplastic plasma cells. Characteristic 'punched-out' bony lesions, often involving the skull and associated with hypercalcemia, may be found but the disease may certainly be present without any bony lesions. The disease may be present in a subclinical form for many years prior to the development of symptomatology, the most characteristic components of which are: (i) frequent and recurrent bacterial infections due to impaired normal antibody synthesis; (ii) chronic renal dysfunction due to several factors including tubular damage secondary to the reabsorption of large amounts of Bence–Jones proteins (light chains) filtered by the glomeruli, secondary amyloid renal disease, hypercalcemic renal damage, recurrent pyelonephritis and hyperuricemia; and (iii) damage to other organs, such as the spinal cord and nerve roots by pathologically fractured vertebrae or local development of plasmacytomas. In about 5–10% of patients with multiple myeloma, symptoms are induced by the presence of the abnormal proteins, the characteristics of which are described below. The peripheral blood smear may show abnormal clumping of erythrocytes in stack of coin-like rows (rouleaux), due to the fact that the normal surface charges that cause red cells to repel each other are coated with the paraprotein.

Macroglobulinemia

This is defined by the presence of an excessive amount of IgM gammaglobin in the serum. It includes a spectrum of disorders ranging from an apparently benign monoclonal gammapathy to progressive malignant lymphoma. Clinically the disease is generally seen in the elderly and resembles a malignant lymphoma with weakness, weight loss, adenopathy and hepatosplenomegaly as the characteristic clinical picture. Bone lesions are rare. Like myeloma, anemia is occasionally seen as a complication. Neurological complications are primarily related to the viscosity of the large abnormal protein or the development of malignant lymphoma.

Heavy-chain diseases

These are defined by the finding of characteristic immunoglobin heavy-chain fragments in the serum or urine. Three of the five possible types of heavy-chain diseases have been recognized. Gamma heavy-chain disease resembles a lymphoma more than a myeloma. Alpha heavy-chain disease is the most common heavy-chain disease and is the almost invariable accompaniment of a malignant lymphoma of the intestine with malabsorption. Mu heavy-chain disease is the rarest of these disorders having been seen in association with chronic lymphocytic leukemia.

Neurological manifestations of the paraproteinemias may be divided into the following categories: hyperviscosity syndrome; cryoglobinemia; cold agglutinin disease; amyloidosis; hemorrhagic diathesis; polyneuropathy; mononeuropathy; paraneoplastic syndromes (e.g. progressive multifocal leukoencephalopathy; cerebellar degeneration); encephalopathy (Bing-Neel syndrome); and infections (fungus, bacteria).

The hyperviscosity syndrome

This refers to the symptom and sign complex of abnormal levels of consciousness (inattention, drowsiness, stupor, coma, delirium), fundoscopic changes characterized by venous engorgement ('sausage veins'), retinal hemorrhages and exudates, blurred vision and headache. The term 'coma paraproteinemia' refers to the encephalopathy of the hyperviscosity syndrome. The syndrome requires that the relative viscosity of the blood as measured by a viscosimeter be greater than 3.0 (normal is less than 2.0). This increase in viscosity may be due to an increased red blood cell mass (as in polycythemia) but more often is due to the presence of large amounts of an abnormal protein, usually a macroglobulin. When abnormal proteins are the cause, treatment consists of plasmapheresis, usually with dramatic relief of the symptoms and signs. When indicated, treatment must then be directed toward the underlying disease (e.g. plasma cell dyscrasia, polycythemia).

Cryoglobulinemia

This refers to the presence in the serum of proteins that precipitate in the cold and redissolve on warming. These

proteins are most often associated with hepatitis C infection, myeloma and macroglobulinemia, but may be seen as part of a connective tissue disease or as an isolated finding in the absence of any known underlying cause. About a third of the cryoglobulins are myeloma IgG proteins (Type I), a third are IgM macroglobulins (Type II) and a third a mixture of IgM and IgG molecules (Type III). Many cryoglobulins may actually be antibodies against gamma globulins. The mechanism of the cryoprecipitation is not known and there is not a direct relationship between the amount of cryoglobulin or the temperature at which precipitation occurs and the symptom complex. The neurological syndrome associated with cryoglobulinemia is most common in the Type III form which is the type most often related to an underlying connective tissue disease. These patients often show purpura and a progressive renal lesion which is suggestive of an antigen-antibody (immune) complex nephritis. The most frequent neurologic syndrome is a sensory motor polyneuropathy, the precise pathology of which is not understood. It may represent a form of mononeuropathy multiplex due to disease of the vasa nervorum or an axonal polyneuropathy. There is no clear explanation for the latter possibility. Central nervous system syndromes are poorly described but may represent episodes of brain purpura associated with the bleeding diathesis.

Cold agglutinins

These are an unusual group of macroglobulins which induce red cell agglutination and hemolysis on exposure to cold. Although the phenomenon may be seen transiently in certain infections such as mononucleosis, it rarely causes clinically relevant hemolysis in conditions other than lymphomas and macroglobulinemia. These proteins contain only kappa light chains and are generally directed against the I antigen of erythrocytes. These proteins may also interact with clotting factors or coat platelets thus interfering with the blood coagulation mechanism. This may lead to central nervous system bleeding and the retinal hemorrhages so commonly seen in the paraproteinemic states.

Polyneuropathies

These have been described in cases of paraproteinemias, particularly in myeloma and macroglobulinemia. Most often there is a sensory polyneuropathy manifested by cramps, parasthesias and acral sensory loss. Cranial nerve palsies and an acute demyelinating polyneuropathy (Guillain–Barré-like illness) have been encountered, however the number of such cases is so few that it is difficult to ascribe the polyneuropathy to any particular characteristic of the paraproteinemia state. Some may represent paraneoplastic syndromes while others may be due to more common concomitant causes of peripheral nerve dysfunction such as vitamin deficiency.

Paraneoplastic syndromes

Paraneoplastic syndromes of many types have been recorded in patients with various paraproteinemias including polymyositis, cerebellar degeneration, polyneuropathy and progressive multifocal leukoencephalopathy. The cause of the latter is known to be a viral infection. The etiologies of the other syndromes in this group remain cryptic though an immune-mediated mechanism is most likely.

The Bing–Neel syndrome

This is loosely defined as the central nervous system syndrome seen in macroglobulinemia and was actually described prior to Waldenstrom's naming of the disease in 1944. Central nervous system involvement occurs in about 5–15% of the patients with macroglobulinemia, however, it is clear that many of the manifestations of the syndrome are due to the effects of hyperviscosity. This aspect of the Bing–Neel syndrome is reviewed above in the section on the hyperviscosity syndrome. In addition, however, some patients show a multifocal disease with a rapid downhill course which is uniformly fatal and unresponsive to plasmapheresis. The spinal fluid in these patients is abnormal with some pleocytosis and elevated protein. The pathology consists of infiltration of lymphocytes and plasma cells particularly around veins. Sometimes the pathological appearance is that of a histiocytic lymphoma (formerly called reticulum cell sarcoma or microglioma) of the brain.

Infections

These are common in patients with paraproteinemias probably because of the paucity of normal immunoglobulins associated with the over-production of the abnormal proteins. Since the defect is mainly in the sphere of humoral immunity, the patients are most susceptible to bacterial and fungal infections which may affect the nervous system. The most important of these include fungal and tuberculous meningitis and bacterial meningitis.

POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, skin changes)

This is a multisystem syndrome seen in patients with osteosclerotic myeloma. The mechanism is unknown, but it is likely that it is an immune mediated paraneoplastic syndrome. The polyneuropathy is a subacute or chronic

painful polyneuropathy. There is usually hepatosplenomegaly, sexual impotence and various skin lesions. The M component in the serum is produced by an osteosclerotic myeloma, which when treated, results in improvement in all components of the syndrome.

The hypercoagulable states

General issues

Patients are considered to have hypercoagulable states if they have laboratory abnormalities or clinical conditions that are associated with an increased risk of thrombosis (prethrombotic states) or if they have recurrent thrombosis without recognizable predisposing factors (thrombosis prone). The hypercoagulable states are subdivided into two categories: those in which a clearly identified, specific abnormality in hemostasis can be found (primary hypercoagulable states), and those in which various diverse clinical conditions have been associated with an increased risk of thrombosis (secondary hypercoagulable states). In both circumstances, it is becoming increasingly clear that cerebral thrombosis (venous and arterial) and embolism are important manifestations.

The primary hypercoagulable states

The primary hypercoagulable states are due to failure of one of the three physiologic anticoagulant mechanisms (e.g. antithrombin III, protein C, and the fibrinolytic system) and include antithrombin III deficiency, protein C deficiency, protein C resistance due to factor V Leiden, protein S deficiency, fibrinolytic disorders, dysfibrinogenemia, factor XII deficiency, prekallikrein deficiency, the antiphospholipid antibody syndrome, and the prothrombin gene mutation.

Antithrombin III deficiency

This may be either inherited as an autosomal dominant trait or acquired as a result of urinary excretion of the protein in patients with the nephrotic syndrome or in patients with severe disease of the liver, where much of the protein is produced. Venous is more common than arterial thrombosis and treatment consists of intravenous heparin.

Protein C or S deficiency and protein C resistance

This is inherited as an autosomal dominant trait, and occasionally acquired in patients with severe liver disease or disseminated intravascular coagulation. Protein S acts as a cofactor for the anticoagulant effects of protein C and can be deficient due to autosomal dominant inheritance or in severe liver disease or to DIC. The treatment of people with protein C or protein S deficiency who suffer recurrent thrombosis is chronic warfarin therapy. The factor V Leiden mutation leads to protein C resistance and recurrent usually venous thrombosis which can affect cerebral veins and dural sinuses.

Various fibrinolytic abnormalities

This can lead to defective digestion of fibrin. Some patients with hypercoagulable states have been found to have defective release of plasminogen activator from endothelial cells in the vessel walls. There may also be circulating inhibitors of plasminogen activators. Neurologists and neusosurgeons have ceased using epsilon aminocaproic acid (Amicar) to prevent rebleeding in subarachnoid hemorrhage patients because of the hypercoagulable state that is produced by this drug's inhibition of circulating plasminogen activator. Genetically produced tissue plasminogen activator (tPA) may have a role in treating such patients but the risk of hemorrhage may outweigh the potential benefits.

Dysfibrinogenemia

In a few patients with hypercoagulable states there is formation of a functionally abnormal fibrinogen molecule which forms gels that are extremely rigid and resistant to removal by the fibrolytic system. These dysfibrinogenemias are probably very rare causes of the hypercoagulable state.

Factor XII and prekallikrein deficiency

Patients with autosomal recessively inherited deficiencies of factor XII (Hageman factor) or other factors involved in contact activation of the coagulation cascade (e.g. prekallikrein and high molecular-weight kininogen) have prolonged partial thromboplastin times but paradoxically have an increased tendency to thrombosis, probably because these factors promote blood fluidity by helping to activate the fibrinolytic system and generate vasodilator kinins.

The prothrombin gene mutation

This is a reasonably common cause of a hypercoagulable state usually involving veins more than arteries.

The antiphospholipid antibody syndrome

Two major antiphospholipid syndromes are known: the lupus anticoagulant and the anticardiolipin antibody. The so-called lupus anticoagulant is actually an antibody to phospholipids which interferes with the formation of the

prothrombin activator, a complex of calcium ions, factors Xa, V and a source of phospholipid, usually the platelet membrane in the coagulation cascade. This IgG or IgM antiphospholipid antibody often, but not always, causes prolongation of phospholipid-dependent coagulation tests, such as the activated partial thromboplastin time (aPTT). This antibody is present in about 25% of patients with systemic lupus erythematosus (SLE), and may cross-react with cardiolipin, the antigen commonly used in a blood screening test for syphilis, thus producing a biologic false positive. Despite the prolonged PTT, this antiphospholipid antibody is actually a procoagulant as a consequence of several mechanisms including increased platelet adhesiveness, interference with the production of the vasodilator and antiplatelet aggregator prostacyclin by the endothelial cell, and decreased production of plasminogen activator. The lupus anticoagulant can only be diagnosed using a three-step functional test: (i) screening test such as a PTT; (ii) mixing test to determine that the factor which prolongs the PTT is in the serum and, (iii) phospholipid loading test such as platelet addition or octagonal phase to determine that the plasma factor that prolongs the PTT is an antiphospholipid antibody). It cannot be readily quantified. The anticardiolipin antibody may be quantified using an enzyme linked immunosorbent assay (ELISA). In addition to patients with systemic lupus erythematosus, other people at risk for anticardiolipin antibody include patients on neuroleptic drugs, patients with neoplasms, other autoimmune disorders and some people with no apparent underlying disorders. Those without underlying disease are said to have the primary anticardiolipin antibody syndrome.

The primary antiphospholipid antibody syndrome (Sneddon syndrome) is characterized by recurrent episodes of venous and/or arterial thrombosis, recurrent mid-pregnancy spontaneous abortions and thrombocytopenia. Migraine, mitral valve prolapse and livedo reticularis are also over represented in these patients. Echocardiography frequently reveals the presence of vegetations on the mitral valve, presumably representing foci of Libman–Saks endocarditis. The nervous system is commonly affected with large and small vessel arterial occlusions, venous occlusions and emboli probably arising from non-bacterial thrombotic endocarditis (NBTE) which in turn results from the hypercoagulable state. Many of the neurologic syndromes seen in SLE patients can be conceptualized as being due to either thrombosis *in situ* or emboli from NBTE (known as Libman–Sacks endocarditis in SLE patients). Treatment of patients who have the antiphospholipid antibody and who suffer recurrent thrombosis is long-term, high intensity, warfarin therapy. The precise dose of warfarin is unknown, but it is likely that fairly intense anticoagulation is required (i.e. international normalized ratio of 3.0 – 3.5).

The secondary hypercoagulable states

The secondary hypercoagulable states may be divided into three major groups based on the presumed predominant pathophysiological mechanism: (i) abnormalities of coagulation and fibrinolysis, such as malignancy, pregnancy, use of oral contraceptives, infusion of prothrombin complex concentrates and nephrotic syndrome, (ii) abnormalities of platelets, such as myeloproliferative disorders, paroxysmal nocturnal hemoglobinuria, hyperlipidemia, diabetes mellitus, heparin-induced thrombocytopenia and (iii) abnormalities of blood vessels or rheology, such as conditions promoting venous stasis (e.g. immobilization, obesity, advanced age, post-operative state), artificial surfaces, vasculitis and chronic occlusive arterial disease, homocysteinemia, hyperviscosity (e.g. polycythemia, leukemia, sickle cell disease, leukoagglutination, increased serum viscosity) and thrombotic thrombocytopenia purpura.

Hypercoagulable states related to underlying malignancy

The relationship between increased tendency for thrombosis and malignancy has been known ever since Armand Trousseau described the syndrome that bears his name. Migratory phlebothrombosis, pulmonary emboli and transient or permanent focal neurological deficit is viewed as a paraneoplastic syndrome usually in patients with mucin secreting adenocarcinomas. Some of the neurologic deficits are due to thrombosis *in situ* of cerebral vessels while others are due to emboli arising from non-bacterial thrombotic endocarditis (NBTE), which itself is caused by the paraneoplastic hypercoagulable state. Most data support the concept that this hypercoagulable state is due to a general activation of the clotting system resulting in chronic DIC. This DIC may be initiated by the tumour's production of procoagulant such as a cysteine protease which has been found in malignant cells and is known to activate factor X.

Hypercoagulable states related to pregnancy

Pregnancy increases the risk of thrombosis probably as a consequence of a chronic low grade DIC, which develops normally in pregnancy, presumably in preparation for the hemostatic challenge of placental separation. Cerebral venous thrombosis is the major neurologic complication of this hypercoagulable state, seen primarily in the postpartum period. It takes two major clinical forms: venous sinus occlusion and cortical vein occlusion. Though these two clinical forms often fuse as the illness progresses, venous

sinus thrombosis usually presents with increased intracranial pressure, whereas cortical vein thrombosis usually begins with partial seizures, often very resistant to anticonvulsant therapy. As in any venous occlusions, the resultant infarctions, if any, are hemorrhagic and, as such, are usually easily visible by imaging techniques. The contrast-enhanced CT and MRI have proved particularly useful in demonstrating the characteristic triangular thrombosis (empty delta sign) in the superior saggital sinus even when hemorrhagic infarction is not present. Magnetic resonance venography is now the gold standard neurodiagnostic study when venous occlusive disease is suspected. The treatment for the hypercoagulable state of pregnancy is reserved for patients with demonstrated thrombosis and consists of heparin, since warfarin crosses the placenta and is possibly teratogenic.

Hypercoagulable states related to oral contraceptive use

Oral contraceptives significantly increase the risk of thrombosis in a way similar to that seen in late pregnancy, but unlike in pregnancy, the fibrinolytic response is inappropriately blunted. Epidemiologic studies have suggested that use of an oral contraceptive raises the risk of stroke in young women, particularly in people with a history of migraine. The risk appears to be dose related

Hypercoagulable states related to prothrombin complex infusions

Prothrombin complex concentrates contain the vitamin K-dependent clotting factors II, VII, IX, and X and are used to treat patients with deficiencies of these factors. Transfusion with these concentrates is associated with an increased risk of thrombosis and DIC including stroke, particularly in patients with underlying liver disease. The thrombogenicity of these concentrates may be due to small quantities of activated clotting factors which cannot be adequately cleared by the patient's diseased liver.

Hypercoagulable states related to nephrotic syndrome and other causes of factor loss.

In patients with the nephrotic syndrome, there is an increased risk of stroke probably related in large part to an acquired antithrombin III deficiency, caused by urinary loss of the protein. Factor deficiency also explains the hypercoagulable state seen with L-asparagine therapy for acute lymphocytic leukemia.

Hypercoagulable states related to abnormalities in platelets

Abnormalities in platelet function probably underlie in part the thrombotic tendency seen in patients with myeloproliferative disorders, thrombocytosis, paroxysmal nocturnal hemoglobinuria, hyperlipidemia and heparin-induced thrombocytopenia.

Hypercoagulable states related to abnormalities of blood vessels or rheology

Lastly, many abnormalities in blood vessels and rheology may promote coagulation and thus produce cerebral thrombosis. Of particular importance from a neurologic perspective are artificial surfaces, such as seen in patients placed on extracorporeal circulation, vasculitic conditions, such as giant cell arteritis of the brain and Behçet's disease, homocysteinemia and hyperviscosity of any cause.

Neurocutaneous syndromes

E. Steve Roach

Department of Neurology, University of Texas, Southwestern Medical School, Dallas, TX, USA

Congenital or hereditary conditions which feature lesions of both the skin and the nervous system have been traditionally considered together as neurocutaneous disorders. Selected neurocutaneous disorders are presented in detail, and several other examples are listed in Table 128.1. While each of these conditions has unique clinical manifestations and a distinct pathophysiology, the concept of neurocutaneous syndromes does serve to highlight a group of neurological disorders the identification of which depends predominantly on simple visual diagnosis.

Table 128.1. Selected neurocutaneous syndromes

Ataxia telangiectasia
Ehlers–Danlos syndrome
Epidermal nevus syndrome
Hereditary hemorrhagic telangiectasia
Hypomelanosis of Ito
Neurocutaneous melanosis
Neurofibromatosis type 1
Pseudoxanthoma elasticum
Progeria
Tuberous sclerosis complex
Sturge–Weber syndrome
von Hippel–Lindau disease

Neurofibromatosis

Neurofibromatosis (NF) is actually two separate conditions, each caused by a different gene: neurofibromatosis type 1 (NF1), or von Recklinghausen's disease, and neurofibromatosis type 2 (NF2), which is characterized by bilateral vestibular schwannomas and often leads to other brain or spinal cord tumours (Roach, 1992; Riccardi & Eichner, 1992). The clinical manifestations of both conditions are highly variable (Friedman & Birch, 1997; Martuza & Eldridge, 1988).

Neurofibromatosis type 1 is the most common of the neurocutaneous syndromes, occurring in approximately 1 of every 3000 people (Crowe et al., 1956; Riccardi & Eichner, 1992). About half of the individuals with NF1 result from a spontaneous mutation. In contrast, NF2 occurs in only one in 50 000 people (Listernick & Charrow, 1990).

Cutaneous lesions of NF1

Cutaneous lesions of neurofibromatosis type 1 include cafe-au-lait spots, subcutaneous neurofibromas, and plexiform neurofibromas. Cafe-au-lait spots (Fig. 128.1) are flat, light to medium brown areas which have various shapes and sizes. They are typically seen at birth, but increase in size and number during the first few years. Additional freckle-like lesions, 1 mm to 3 mm in diameter, often occur in the axillae or intertriginous regions.

Neurofibromas are benign tumours arising from peripheral nerves (Fig. 128.1). These tumours are composed predominantly of Schwann cells and fibroblasts, but contain endothelial, pericyte and mast cell components (Riccardi & Eichner, 1992). Neurofibromas can develop at any time, and both the size and number often increase after puberty.

Plexiform neurofibromas are common and often cause substantial deformity (Fig. 128.1). In one series, 68 of 405 (16.8%) patients with NF1 developed one or more plexiform neurofibromas (Waggoner et al., 2000). Another report of 121 patients with plexiform neurofibromas documented tumour progression in 46% of the patients. Patients with plexiform tumours of the head, face, or neck and those who presented before age 10 years were more likely to do poorly (Needle et al. 1997). Plexiform neurofibromas have a 3–5% lifetime risk of malignant degeneration (Gutmann, 1998;

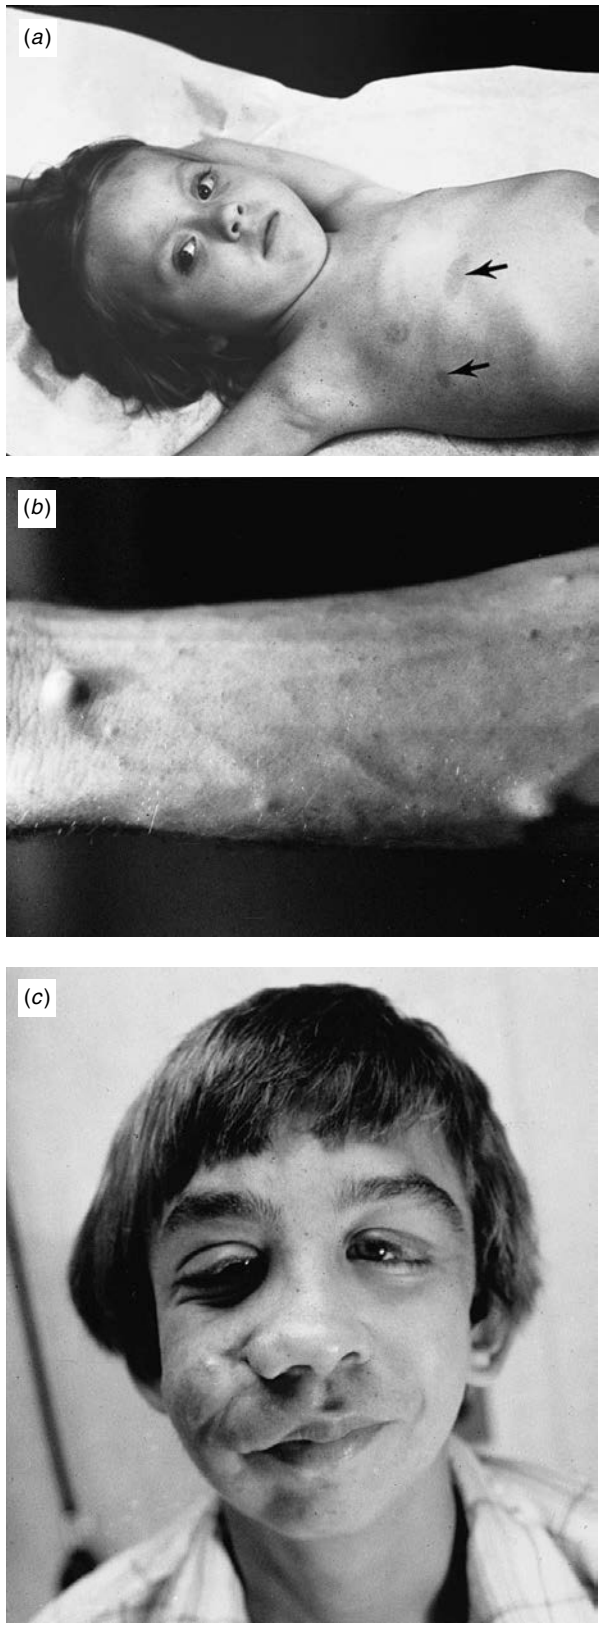

Fig. 128.1. Cutaneous lesions of neurofibromatosis type 1 include: (*a*). café-au-lait spots (arrows); (*b*) subcutaneous neurofibromas; and (*c*) plexiform neurofibromas. (Reprinted from Roach, 1988, with permission.)

Waggoner et al., 2000). Both rapid growth and non-traumatic pain should raise concerns about malignant transformation of a plexiform neurofibroma (Korf, 1999).

Ophthalmologic lesions of NF1

Lisch nodules are pigmented iris hamartomas (Fig. 128.2) which are asymptomatic but help to establish the diagnosis of NF1. Lisch nodules do not occur in all NF1 patients and may not be apparent during early childhood, so their absence does not exclude the diagnosis of NF1. Rare children with NF1 have retinal hamartomas, but these are also asymptomatic in most individuals.

Arterial lesions of NF1

Dysplasia of the renal or carotid arteries occurs in a small percentage of patients with NF1. Renal artery stenosis may lead to systemic hypertension. Another potential cause of hypertension is pheochromocytoma (Walther et al., 1999). Several forms of cerebral artery dysplasia occur, most commonly moyamoya syndrome, which promotes cerebral infarction in children and brain hemorrhage in adults (Rizzo & Lessell, 1994).

Neurologic lesions of NF1

Neurofibromatosis type 1 affects the nervous system in several ways, but the clinical features vary even among affected members of the same family. Tumours occur in the brain, spinal cord, and peripheral nerves, though not as frequently as with NF2 (Riccardi & Eichner, 1992; Thakker et al., 1999). Optic nerve glioma (Fig. 128.3) is the most common central nervous system tumour caused by NF1 (Listernick et al., 1999). About 15% of NF1 patients have either a unilateral or bilateral optic glioma (Gutmann, 1998; Listernick et al., 1999). The rate of growth varies, but optic gliomas tend to behave less aggressively in NF1 patients than in patients without NF1 (Listernick et al., 1995, 1999). Optic atrophy and progressive visual loss are more common than pain or proptosis. Precocious puberty is a common presenting sign of optic nerve tumours in NF1 patients, although occasional children with NF1 present with precocious puberty even in the absence of optic tumours (Listernick et al., 1995).

Ependymomas, meningiomas and astrocytomas of the central nervous system occur in patients with NF1, though less often than in patients with NF2. Neurofibromas and

Fig. 128.2. Lisch nodules (arrows) of the iris in a patient with neurofibromatosis type 1. (Reprinted from Roach, 1992, with permission.)

Fig. 128.3. Computed cranial tomography scan demonstrates bilateral optic nerve gliomas (arrows), larger on the right than the left, in a child with neurofibromatosis type 1. (Reprinted from Roach, 1992, with permission.)

Schwannomas are common but not always symptomatic; they can develop on either cranial nerves or spinal nerve roots. The symptoms from these tumours reflect their size, location and rate of growth.

Most patients with NF1 have high signal lesions of the basal ganglia, thalamus, brainstem, and cerebellum on T_2-weighted MRI sequences (Fig. 128.4), although these findings alone are not very specific (DeBella et al., 2000). Whether these MRI lesions correlate with the likelihood of cognitive impairment has been debated (Joy et al., 1995).

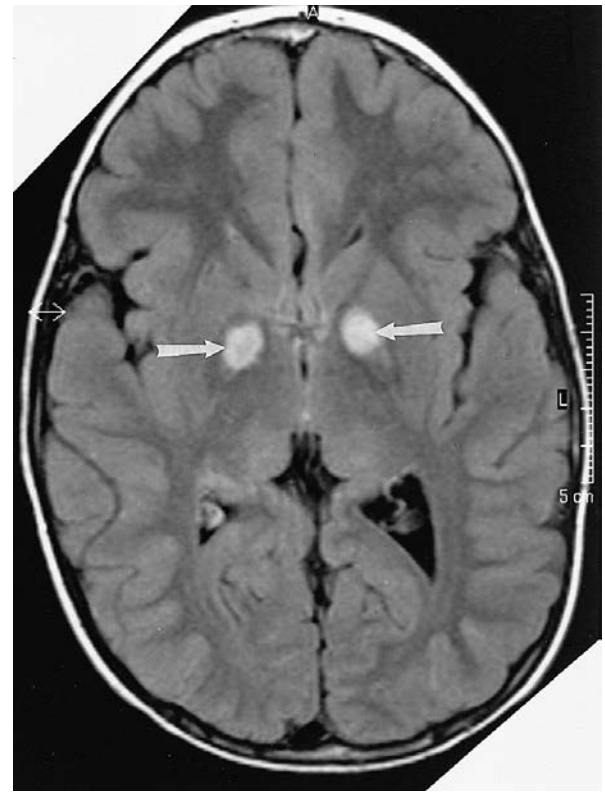

Fig. 128.4. Coronal T_1-weighted magnetic resonance scan shows bilateral high signal lesions in the basal ganglia (arrows), abnormalities typical of neurofibromatosis type 1.

Patients with NF1 often have non-specific cognitive defects such as reduced intelligence, behavioural difficulty, attentional problems and learning disability (Ozonoff, 1999). Intelligence quotient (IQ) scores are typically in the low normal range, and only 4% to 8% of individuals with NF1 are mentally retarded (North et al., 1995; Moore et al., 1994; Hofman et al., 1994). About 40% of NF1 patients have some type of learning disability or behavioural problem (Riccardi & Eichner, 1992).

Clinical features of neurofibromatosis Type 2

Patients with NF2 have few cutaneous lesions but often have multiple tumour types in the central nervous system (thus its occasional characterization as 'central neurofibromatosis'). The frequency of café-au-lait spots is not increased nor are Lisch nodules and subcutaneous neurofibromas typical of NF2. NF1 and NF2 do not occur in

Table 128.2. Diagnostic criteria for neurofibromatosis

Neurofibromatosis type 1 (any two or more)
Six or more cafe-au-lait lesions over 5 mm in diameter before puberty and over 15 mm in diameter afterward
Freckling in the axillary or inguinal areas
Optic glioma
Two or more neurofibromas or one plexiform neurofibroma
A first degree relative with NF1
Two or more Lisch nodules
A characteristic bony lesion (sphenoid dysplasia, thinning of the cortex of long bones, with or without pseudarthrosis)
Neurofibromatosis type 2
Bilateral VIII nerve tumour (shown by MRI, CCT, or histological confirmation)
A first-degree relative with NF2 and a unilateral eight-nerve tumour
A first-degree relative with NF2 and any two of the following lesions: neurofibroma, meningioma, schwannoma, glioma, or juvenile posterior subcapsular lenticular opacity

Source: Data from National Institutes of Health Consensus Development Conference (1988).

different members of the same family, which is not surprising considering that the two conditions are caused by different genes.

Most NF2 patients eventually develop bilateral vestibular schwannomas. In one series, 96% of the patients who met established diagnostic criteria for NF2 (Table 128.2) had vestibular schwannomas, and most of these were bilateral tumours (Mautner et al., 1996). Symptoms of NF2 typically develop in adolescence or early adulthood, although children can also be affected. Common complaints with larger acoustic tumours include hearing loss, tinnitus, vertigo, facial weakness and headache. Unilateral hearing loss is relatively common in the early stages.

Various other tumours of the central nervous system occur, although much less often than acoustic schwannomas (Mautner et al., 1996). The clinical features of these tumours depend primarily on the lesion's location within the brain and spinal cord. Schwannomas of other cranial nerves occur in some patients, and meningiomas, ependymomas and astrocytomas also occur with increased frequency. Patients with NF2 may develop multiple simultaneous tumour types.

Diagnostic criteria for neurofibromatosis

If several characteristics are present, the diagnosis of both NF1 and NF2 is obvious, especially when another family member is also affected. But when the clinical features are not classic and there is no family history, the diagnosis can be difficult. Very young children may have less apparent lesions and definitive diagnosis can be difficult in these children. Diagnostic criteria (Table 128.1) help to resolve some of these questionable cases, but the criteria should eventually be replaced by specific gene testing. Screening for the NF1 gene is technically difficult because of the gene's large size and the numerous different mutations that are known to affect the NF1 gene. This makes it difficult to efficiently exclude every possible mutation, and so the commercially available diagnostic analyses have a 30% false-negative rate.

Genetics of NF1 and NF2

Neurofibromatosis type 1 is caused by a mutation of the 60 exon NF1 gene on chromosome 17.q. The *NF1* gene product, neurofibromin, is partially homologous to GTPase-activating protein (GAP) (Upadhyaya et al., 1997). Multiple mutations of NF1 have been identified in various regions of the gene (Tonsgard et al., 1997; Upadhyaya et al., 1995, 1997).

Several patients have developed a somatic NF1 mutation affecting only a limited region of the body. With this 'segmental' neurofibromatosis, one extremity may have café-au-lait lesions, subcutaneous neurofibromas, and other signs of NF, but rest of the body is unaffected (McFadden et al., 1988; Hager et al., 1997). Similarly, patients with germline mosaicism have been described. These individuals have no outward manifestations of NF1, but can have multiple affected offspring (Lázaro et al., 1994).

Neurofibromatosis type 2 is caused by a mutation of the *NF2* gene on chromosome 22. The NF2 protein product is known as schwannomin. The *NF2* gene suppresses tumour function, and its dysfunction accounts for the common occurrence of central nervous system tumours with NF2 (Gutmann et al., 1998). As with NF1, multiple different mutations of the *NF2* gene have been described (De Klein et al., 1998; Gutmann et al., 1998; Ruttledge et al., 1996; MacCollin et al., 1996). The clinical severity may be related to the nature of the *NF2* mutation: missense mutations which allow some protein function tend to produce milder clinical manifestations, while frameshift and nonsense mutations often cause severe disease (Gutmann et al., 1998; Kluwe et al., 1996; MacCollin et al., 1996).

Tuberous sclerosis complex

Tuberous sclerosis complex (TSC) is a disorder of cellular differentiation and proliferation which affects the brain, skin, kidneys, heart and other organs (Sparagana & Roach,

Table 128.3. Diagnostic criteria for tuberous sclerosis complex

Major features	
1	Facial angiofibromas or forehead plaque
2	Non-traumatic ungual or periungual fibroma
3	Hypomelanotic macules (more than three)
4	Shagreen patch (connective tissue nevus)
5	Cortical tuber[a]
6	Subependymal nodule
7	Subependymal giant cell astrocytoma
8	Multiple retinal nodular hamartomas
9	Cardiac rhabdomyoma, single or multiple
10	Lymphangiomyomatosis[b]
11	Renal angiomyolipoma[b]
Minor features	
1	Multiple randomly distributed pits in dental enamel
2	Hamartomatous rectal polyps[c]
3	Bone cysts[d]
4	Cerebral white matter 'migration tracts'[a, d]
5	Gingival fibromas
6	Non-renal hamartoma[c]
7	Retinal achromic patch
8	'Confetti' skin lesions
9	Multiple renal cysts[c]

Notes:

[a] When cerebral cortical dysplasia and cerebral white matter migration tracts occur together, they should be counted as one rather than two features of tuberous sclerosis.

[b] When both lymphangiomyomatosis and renal angiomyolipomas are present, other features of tuberous sclerosis should be present before a definite diagnosis is assigned.

[c] Histological confirmation is suggested.

[d] Radiographical confirmation is sufficient.

Definite TSC: Either two major features or one major feature plus two minor features.

Probable TSC: One major plus one minor feature.

Suspect TSC: Either one major feature or two or more minor features.

Source: Reprinted with permission from Roach et al. (1998).

2000; Weiner et al., 1998; Gomez, 1988; Roach et al., 1998). Many of the clinical manifestations of TSC result from hamartomas; true neoplasms also occur, particularly in the kidney and brain. Abnormal neuronal migration plays a major additional role in neurologic dysfunction (Roach & Delgado, 1995). The clinical diagnostic criteria were recently revised (Table 128.3) and guidelines for ongoing diagnostic testing were proposed (Roach et al., 1998, 1999).

Population-based studies suggest a prevalence of 1 per 6000 to 9000 individuals (Osborne et al., 1991). However, because of its striking variability of clinical expression and severity, the diagnosis of TSC can be difficult in individuals with subtle findings (Roach et al., 1991b).

General features of tuberous sclerosis complex (TSC)

Skin lesions

The cutaneous lesions of TSC include hypomelanotic macules, the shagreen patch, ungual fibromas, and facial angiofibromas (Roach & Delgado, 1995). Hypomelanotic macules (ash leaf spots) are found in over 90% of patients (Fig. 128.5). The lesions are usually present at birth but may be difficult to see in the newborn without an ultraviolet light. Other pigmentary abnormalities include the 'confetti' lesions (an area with stippled hypopigmentation, typically on the extremities) and poliosis of the scalp hair or eyelids (Fig.128.5). Hypomelanotic macules are not specific for TSC: one or two of these lesions are common in normal individuals (Vanderhooft et al., 1996).

Facial angiofibromas (adenoma sebaceum) are made up of vascular and connective tissue elements. Although these lesions are considered specific for TSC, they are found in only about three-fourths of patients and often appear several years after the diagnosis has been established by other means. The lesions typically become apparent during the preschool years as a few small red papules on the malar region (Roach & Delgado, 1995); they gradually become larger and more numerous, sometimes extending down the nasolabial folds or onto the chin (Fig. 128.5).

The shagreen patch is most often found on the back or flank area; it is an irregularly shaped, slightly raised or textured skin lesion (Fig. 128.5). The lesion is found in less than a third of TSC patients, and even so may not be apparent in young children.

Ungual fibromas are nodular or fleshy lesions that arise adjacent to or from underneath the nails (Fig. 128.5). The lesion is usually considered specific for TSC, although a single lesion occasionally occurs after trauma. Ungual fibromas are seen in only 15–20% of unselected TSC patients, and are more likely to be found in adolescents or adults.

Retinal lesions

The frequency of retinal hamartomas in TSC has varied from almost negligible to 87% of patients, probably reflecting the expertise and technique of the examiner (Kiribuchi et al., 1986). Retinal lesions may be difficult to identify without pupillary dilatation and indirect ophthalmoscopy, particularly in uncooperative children. Retinal lesions vary

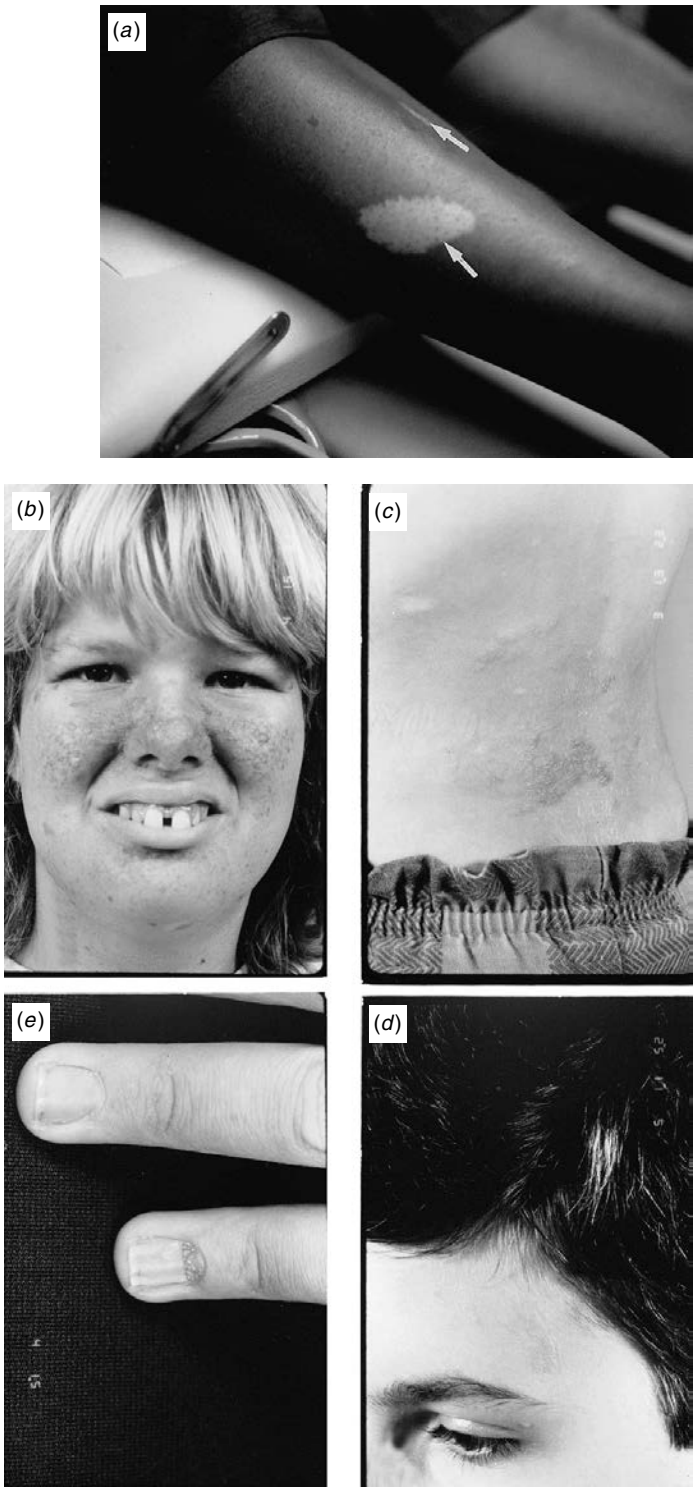

Fig. 128.5. Cutaneous features of tuberous sclerosis include: (*a*) hypomelanotic macule (arrows); (*b*) facial angiofibromas (adenoma sebaceum); (*c*) a shagreen patch; (*d*) poliosis; and (*e*) ungual fibromas. (Part (*a*) reprinted from Roach, 1988; parts (*b*)–(*e*) reprinted from Roach & Delgado, 1995, with permission.)

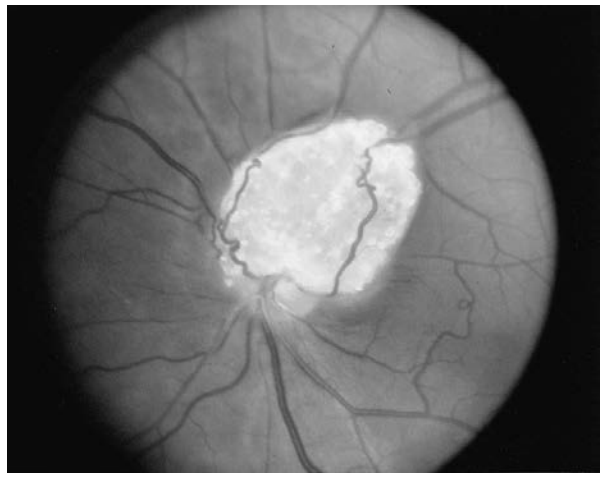

Fig. 128.6. A retinal astrocytoma ('mulberry lesion') adjacent to the optic nerve is typical of those found with tuberous sclerosis. (Reprinted from Roach, 1992, with permission.)

from the classic mulberry lesions adjacent to the optic disc (Fig. 128.6) to the plaque-like hamartoma or depigmented retinal lesions. Most retinal lesions are clinically insignificant, but occasional patients have visual impairment due to a large macular lesion, and rare patients have visual loss due to retinal detachment, vitreous hemorrhage, or hamartoma enlargement. Occasional patients have a pigmentary defect of the iris (Gutman et al., 1982).

Cardiac lesions

About two-thirds of TSC patients have one or more cardiac rhabdomyomas (DiMario et al., 1996), but few of these lesions are clinically important. Cardiac rhabdomyomas are hamartomas; they tend to be multiple, and there is evidence that their frequency diminishes with age (Smith et al., 1989; DiMario et al., 1996). These lesions are sometimes evident on prenatal ultrasound testing, and most of the patients with cardiac dysfunction present soon after birth with heart failure. A few children later develop cardiac arrhythmias or cerebral thromboembolism.

Renal lesions

Renal angiomyolipomas occur in 75–80% of TSC patients; most of these lesions are histologically benign tumours with varying amounts of vascular tissue, fat and smooth muscle. Bilateral tumours or multiple tumours per kidney are typical. The prevalence of renal tumours increases with age, and tumours larger than 4 cm are much more likely to become symptomatic than smaller tumours (Ewalt et al., 1998; Steiner et al., 1993). Renal cell carcinoma or other malignancies are less common (Al-Saleem et al., 1998; Bjornsson et al., 1996).

Pulmonary dysfunction

An estimated 1% of TSC patients develop lung disease. Pulmonary disease is five times more common in females than in males. Spontaneous pneumothorax, dyspnea, cough, and hemoptysis are typical symptoms of pulmonary TSC, although these do not often develop before the third or fourth decade (Scully et al., 1994).

Neurologic dysfunction from TSC

The predominant neurological manifestations of TSC are mental retardation, epileptic seizures, and behavioural abnormalities, although milder forms of the disease with little or no neurologic impairment are common (Roach & Delgado, 1995). Neurological lesions probably result from impaired cellular interaction resulting in disrupted neuronal migration along radial glial fibres and abnormal proliferation of glial elements. Neuropathological lesions of TSC include subependymal nodules, cortical hamartomas, areas of focal cortical hypoplasia and heterotopic grey matter.

Various types of seizures occur in up to 90% of patients. Most mentally retarded patients have epilepsy but there are exceptions. In contrast, many patients have seizures but not mental retardation. The number of subependymal lesions does not correlate with the clinical severity of TSC, but patients with numerous lesions of the cerebral cortex shown by MRI tend to have more cognitive impairment and more difficulty with seizure control (Jambaque et al., 1991; Roach et al., 1987; Goodman et al., 1997). Children with infantile spasms are more likely to exhibit long-term cognitive impairment (Jozwiak et al., 1998), but these patients, in turn, have more cortical lesions demonstrated by MRI (Shepherd et al., 1995).

The likelihood of mental retardation in patients with TSC is probably over estimated. Webb and colleagues, for example, found only ten mentally retarded patients among 26 TSC patients in a population survey (Webb et al., 1991). The severity of intellectual dysfunction ranges from borderline to profound mental retardation.

In addition to frank mental retardation, many children have serious behavioural disorders (Hunt & Dennis, 1987). Autism and various behavioural disturbances including hyperkinesis, aggressiveness and frank psychosis, are sometimes noted, either as isolated problems or in combination with epilepsy or intellectual deficit (Hunt & Shepherd, 1993; Curatolo, 1996; Shepherd & Stephenson, 1992). Prior immunization does not correlate with neurological outcome (Jozwiak et al., 1998).

The calcified subependymal nodules (Fig. 128.7) which characterize TSC are best demonstrated with CCT (Iwasaki et al., 1990). Superficial cerebral lesions can sometimes be seen with CCT but are far more obvious with T_2-weighted MRI (Fig. 128.8) (Roach et al., 1987). Cerebellar anomalies can be demonstrated in over one-fourth of TSC patients (Roach et al., 1987). Nodular subependymal lesions that have not yet calcified produce a high-signal lesion with T_2-weighted scans. Evidence of abnormal neuronal migration can be seen in some patients as a high signal linear lesions running perpendicular to the cortex on T_2-weighted scans (Roach et al., 1991a).

Fig. 128.7. Computed cranial tomography scan from a child with TSC demonstrates typical calcified subependymal nodules; a large calcified parenchymal lesion (curved arrow) and low-density cortical lesions (arrows) are seen as well. (Reprinted from Roach et al., 1991a, with permission.)

Subependymal giant cell astrocytomas (SEGA) develop in 6–14% of TSC patients (Shepherd et al., 1991). Unlike the more common cortical tubers, giant cell astrocytomas can enlarge and cause symptoms of increased intracranial pressure (Torres et al., 1998). Clinical manifestations include new focal neurologic deficits, increased intracranial pressure, unexplained behaviour change, or deterioration of seizure control (Torres et al., 1998). Acute or subacute onset of neurologic dysfunction may result from sudden obstruction of the ventricular system by an intraventricular SEGA. Rarely acute deterioration occurs because of hemorrhage into the tumour itself.

Giant cell tumours are usually benign but locally invasive, and surgery, performed early, can be curative (Torres et al., 1998). Identification of an enlarging SEGA before the onset of symptoms of increased intracranial pressure or

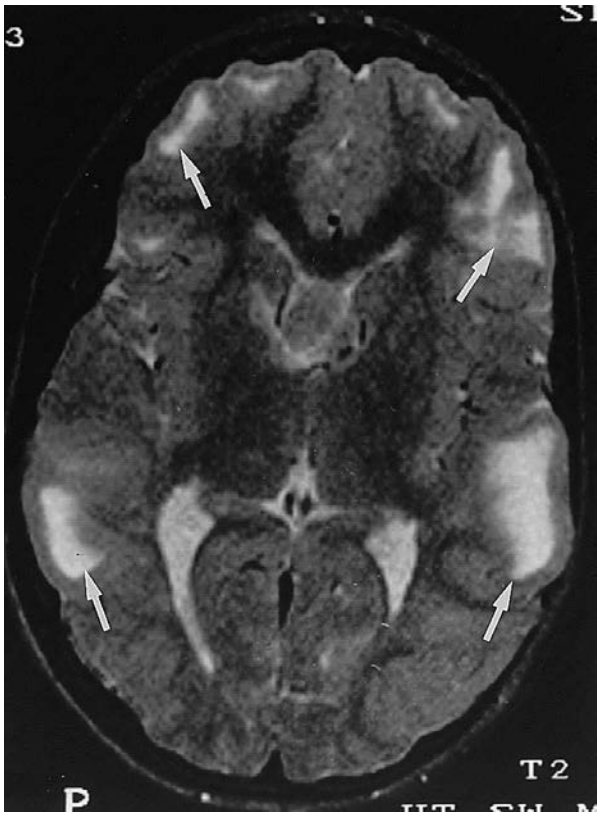

Fig. 128.8. Non-contrast T_2-weighted magnetic resonance scan from a child with tuberous sclerosis demonstrates extensive high-signal cortical lesions (arrows) typical of tuberous sclerosis. (Reprinted from Miller & Roach, 2000, with permission.)

new neurological deficits may improve surgical outcome (Roszkowski et al., 1995; Torres et al., 1998).

Genetics of tuberous sclerosis

Tuberous sclerosis is inherited as an autosomal dominant trait with variable penetrance (Weiner et al., 1998). The estimated spontaneous mutation rate for TSC varies from 66–86%, depending in part on the completeness of investigation of the extended family (Roach et al., 1991b). In addition, germline mosaicism accounts for an estimated 1% to 2% of the patients, making genetic counselling more difficult even when a specific mutation has been identified (Rose et al., 1999; Kwiatkowska et al., 1999; Verhoef et al., 1999; Yates et al., 1997).

Two genes are responsible for TSC. One gene (TSC2) was found adjacent to the gene for adult polycystic kidney disease at chromosome 16p13.3, and the other gene (TSC1) was recently located at chromosome 9q34 (European Chromosome 16 Tuberous Sclerosis Consortium, 1993; van Slegtnenhorst et al., 1997). Multiple mutations have been identified in each gene (Au et al., 1998). Tuberin, the gene product of *TSC2*, has a homologous area with the GTP-ase activating protein of rap1 (Wienecke et al., 1997). Tuberin colocalizes with hamartin, the gene product of *TSC1*, in the Golgi apparatus, suggesting that the two genes cause similar phenotypes because they interact in the same process (Wienecke et al., 1996; van Slegtenhorst et al., 1998).

Unlike neurofibromatosis types 1 and 2, there are no obvious phenotypic differences between *TSC1* and *TSC2*. Multiple mutations have been identified in different regions of both *TSC* genes (Au et al., 1998; Jones et al., 1999). The clinical manifestations cannot be reliably predicted by the specific gene or mutation site, but in general *TSC1* seems to be more likely to account for familial cases and on the whole causes less severe disease than *TSC2* (Jones et al., 1997, 1999).

Sturge–Weber syndrome

Sturge–Weber syndrome (SWS) is characterized by a facial cutaneous angioma (port-wine nevus) and an associated leptomeningeal and brain angioma, typically ipsilateral to the facial lesion. In addition to the facial nevus, classic findings include mental retardation, contralateral hemiparesis and hemiatrophy, and homonymous hemianopia (Roach, 1992; Roach et al., 1999). However, the clinical features are highly variable, and patients with the cutaneous lesion and seizures but with normal intelligence and no focal neurologic deficit are common. The syndrome occurs sporadically and in all races (Roach, 1992).

Cutaneous features of SWS

The nevus classically involves the forehead and upper eyelid, but it often affects both sides of the face and may extend onto the trunk and extremities (Fig. 128.9). Patients whose nevus involves only the trunk, or the maxillary or mandibular area but not the upper face, have little risk of an intracranial angioma (Uram & Zubillaga, 1982; Enjolras et al., 1985; Tallman et al., 1991). The facial angioma is usually obvious at birth, but occasional patients have the characteristic neurological and radiographical features of SWS yet have no skin lesion. More frequently, the typical cutaneous and ophthalmic findings are present without clinical or radiographic evidence of an intracranial lesion. Only 10–20% of children with a port-wine nevus of the forehead have a leptomeningeal angioma (Enjolras et al., 1985). The leptomeningeal angioma is typically ipsilateral to a unilateral facial nevus, but bilateral brain lesions occur

Fig. 128.9. A patient with the classic distribution of the port-wine nevus of Sturge–Weber syndrome on the upper face and eyelid. (Reprinted from Roach, 1989, with permission.)

in at least 15% of patients, including some with a unilateral cutaneous nevus.

Ophthalmologic features of SWS

Glaucoma is the main ophthalmologic problem of patients with SWS (Sullivan et al., 1992; Sujansky & Conradi, 1995a). In one study, 36 of 51 patients (71%) had glaucoma; 26 of these developed glaucoma by age 2 years (Sullivan et al., 1992). The risk of developing glaucoma is highest in the first decade, but young adults occasionally develop glaucoma. Buphthalmos and amblyopia are present in some newborns, evidently due to an anomalous anterior chamber angle (Wagner et al., 1988). In other individuals, glaucoma becomes symptomatic later and, if not treated, causes progressive blindness. Periodic measurement of the intraocular pressure is imperative, especially when the nevus is near the eye.

Neurologic features of SWS

Epileptic seizures, mental retardation, and focal neurological deficits are the principal neurological abnormalities of SWS. Seizures usually start acutely in conjunction with hemiparesis. The age when symptoms begin and the overall clinical severity vary, but onset of seizures prior to age two increases the probability of future mental retardation and refractory epilepsy. Patients with refractory seizures are more likely to be mentally retarded, while patients who have never had seizures are usually normal. Few patients who remain normal past age 3 are destined to have severe intellectual impairment.

Seizures eventually develop in up to 80% of SWS patients with unilateral lesions and in 93% of patients with bihemispheric involvement (Bebin & Gomez, 1988). Seizures can begin anytime from birth to adulthood, but 75% of those with seizures begin during the first year, 86% by age 2, and 95% prior to age 5 (Sujansky & Conradi, 1995a). Thus, the risk of a child developing seizures is highest in the first 2 years and thereafter tends to diminish.

Focal motor seizures or generalized tonic–clonic seizures are most typical of SWS initially, but infantile spasms, myoclonic seizures and atonic seizures occur (Chevrie et al., 1988). The first few seizures are often focal even in patients who later develop generalized tonic–clonic seizures. Older children and adults are more likely to have complex partial seizures or focal motor seizures. Some patients continue to have daily seizures after the initial deterioration in spite of various daily anticonvulsant medications, while others have long seizure-free intervals, sometimes even without medication, punctuated by clusters of seizures (Chevrie et al., 1988).

The neurological deficits due to Sturge–Weber syndrome depend on the location of the intracranial vascular lesion. Because the occipital region is so often involved, visual field deficits are common. Hemiparesis often develops acutely, in conjunction with the initial flurry of seizures. Although often attributed to post-ictal weakness, hemiparesis may be permanent or persist much longer than the few hours typical of a postictal deficit. Some children suddenly develop weakness without seizures, either as repeated episodes of weakness similar to transient ischemic attacks or as a single stroke-like episode with persistent deficit (Garcia et al., 1981). In patients with both hemiparesis and seizures, it is difficult to establish which came first. Not all patients have permanent focal neurological signs.

Early developmental milestones are typically normal, but mild to profound mental deficiency eventually develops in about half of SWS patients (Sujansky & Conradi, 1995b). Only 8% of the patients with bilateral brain involvement are intellectually normal (Bebin & Gomez,

1988). Behavioural abnormalities are often a problem even in patients who are not mentally retarded. The clinical condition eventually stabilizes, leaving a patient who has residual hemiparesis, hemianopia, retardation, and epilepsy but without further deterioration. Intracranial hemorrhage due to SWS is rare.

Resection of the brain containing the vascular abnormality sometimes improves seizure control and promotes intellectual development (Carson et al., 1996; Vining et al., 1997). Despite the general agreement that surgical resection is effective, there is debate about patient selection and about the timing of surgery. Almost one patient in five has bilateral cerebral lesions, limiting the surgical options unless one hemisphere is clearly causing most of the seizures, and there is also reluctance to resect a still functional portion of the brain and cause a new deficit (Arzimanoglou & Aicardi, 1992). Surgery is usually reserved for patients with severe seizures who do not respond to medication and who already have clinical dysfunction of the area to be removed (e.g. hemiparesis or hemianopia), an approach similar to that used in other children with refractory epilepsy (Roach et al., 1994).

Diagnostic studies in Sturge–Weber syndrome (SWS)

Most of the children with facial port-wine nevi do not have an intracranial angioma, and neuroimaging studies and other tests help to distinguish the children with Sturge–Weber syndrome from those with an isolated cutaneous lesion. Although gyral calcification is a classic feature of SWS, the 'trolley track' appearance first described on standard radiographs is uncommon especially in neonates, when the possibility of intracranial vascular anomaly typically arises. Intracranial calcification is best demonstrated with CCT (Fig. 128.10). Extensive cerebral atrophy is apparent even with computed tomography, but subtle atrophy is more readily demonstrated by magnetic resonance imaging (MRI) (Elster & Chen, 1990).

Magnetic resonance imaging with gadolinium contrast (Fig. 128.11) effectively demonstrates the abnormal intracranial vessels in Sturge–Weber patients (Elster & Chen, 1990), and gadolinium contrast MRI is currently the best test to determine intracranial involvement. Magnetic resonance angiography has recently been used to directly image the larger abnormal vessels (Vogl et al., 1993).

Functional imaging with positron emission tomography (PET) demonstrates reduced metabolism of the brain adjacent to the leptomeningeal lesion (Chugani et al., 1989). However, patients with recent onset seizures may have increased cerebral metabolism near the lesion. SPECT (single photon emission tomography) shows reduced perfusion of the affected brain (Chiron et al., 1989). Both PET and SPECT often reveal vascular changes extending well beyond the area of abnormality depicted by CCT (Chugani et al., 1989; Maria et al., 1999). While functional imaging may not be necessary for all patients, these tests may help to initially establish a diagnosis and may help localize the lesion prior to surgery.

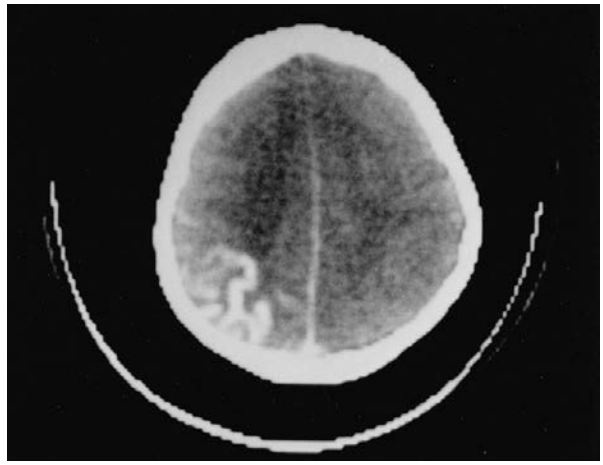

Fig. 128.10. Computed cranial tomography demonstrates an occipital gyriform calcification typical of Sturge–Weber syndrome (Reprinted from Garcia et al., 1981, with permission.)

Cerebral angiography is no longer needed in most patients with SWS, but it is sometimes useful in atypical patients or prior to surgery for epilepsy. The veins are more abnormal than the arteries (Probst, 1980). The subependymal and medullary veins are enlarged and tortuous, and the superficial cortical veins are sparse. Failure of the sagittal sinus to opacify after ipsilateral carotid injection may be secondary to obliteration of the superficial cortical veins by thrombosis (Bentson et al., 1971), and the abnormal deep venous channels probably have a similar origin as they form collateral conduits for nonfunctioning cortical veins (Probst, 1980; Bentson et al., 1971).

Pseudoxanthoma elasticum

Pseudoxanthoma elasticum (PXE) is a hereditary connective tissue disorder with skin, ophthalmic, and vascular manifestations (Carlborg et al., 1959; Viljoen, 1993). The clinical presentation and rate of progression varies considerably even among affected members of the same family (Altman et al., 1974). Both autosomal dominant and autosomal recessive forms of PXE exist (Pope, 1975).

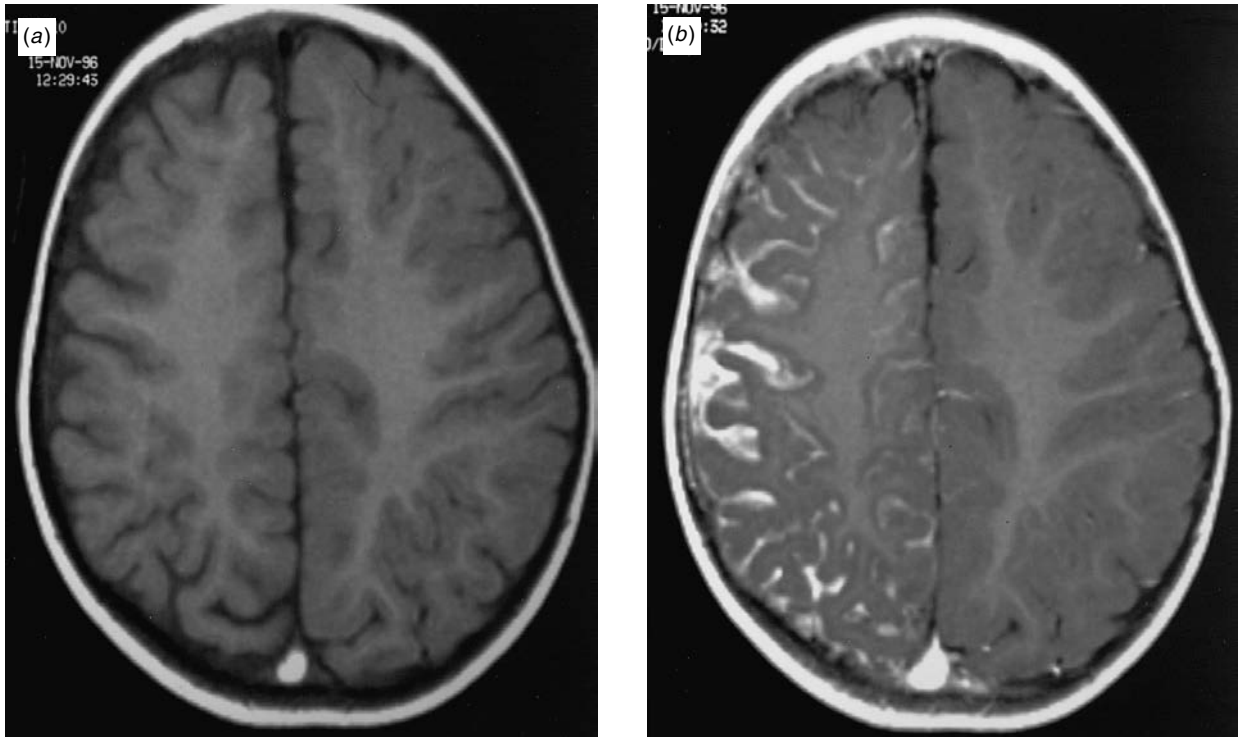

Fig. 128.11. (*a*) Normal T_1-weighted magnetic resonance scan without contrast infusion from a child with Sturge–Weber syndrome; (*b*) On the coronal view with gadolinium, his scan reveals a left frontal leptomeningeal and intraparenchymal angioma. (Reprinted from Roach & Bodensteiner, 1999, with permission.)

Cutaneous lesions of pseudoxanthoma elasticum

Cutaneous signs consist of yellowish plaques or papules of the neck, axilla, abdomen, or the inguinal, decubital or popliteal areas. Similar-looking lesions have been observed in the mucous membranes or intestinal mucosa. Older patients share a facial resemblance due to the lax redundant cutaneous changes of the face and neck. Pregnancy, puberty, and stressful emotional situations may increase the rate of progression of the cutaneous lesions (Reeve et al., 1979). Although the skin lesions of PXE become apparent before age 10 in about half of the patients, occlusive or hemorrhagic vascular complications occur primarily in adults.

Ophthalmic lesions of pseudoxanthoma elasticum

Angioid streaks of the ocular fundus, the result of ruptures of Bruch's membrane, are found in 85% of patients with PXE. These ocular lesions are grey or red irregular lines which radiate away from the optic disc (Secretan et al., 1998). Gradual visual loss may develop from macular degeneration, or visual loss can develop acutely from retinal hemorrhage (Carlborg et al., 1959).

Arterial lesions of pseudoxanthoma elasticum

Most of the systemic complications of PXE result from arterial degeneration and occlusion, but the exact clinical presentation depends largely on which organ system is affected. Progressive occlusion of the large arteries of the limbs may lead to intermittent claudication. Large arteries are sometimes palpably rigid, and radiographs of the extremities sometimes show arterial calcification. Coronary artery disease sometimes occurs in young patients with PXE. Gastrointestinal hemorrhage occurs in both adults and children. Epistaxis, hematuria, and hemoptysis occur but less often than gastrointestinal hemorrhage.

Neurological dysfunction with pseudoxanthoma elasticum

Neurological signs are secondary to vascular compromise. As in other parts of the body, brain dysfunction can result directly from arterial occlusion or rupture or indirectly from systemic hypertension or cardiovascular disease (Munyer & Margulis, 1981). Cerebrovascular lesions due to PXE do not usually manifest until adulthood, when

patients typically present with single or multiple cerebrovascular occlusions resulting from progressive narrowing and then occlusion of an artery (Rios-Montenegro et al., 1972). The angiographic pattern resembles that of severe atherosclerosis, but if the occlusion occurs gradually, sufficient collateral flow may develop to prevent acute neurologic signs (Rios-Montenegro et al., 1972).

Aneurysms of the intracranial carotid artery are common (Munyer & Margulis, 1981), but aneurysms of the other intracranial arteries also occur (Scheie & Hogan, 1957).

Genetics of pseudoxanthoma elasticum

Pseudoxanthoma elasticum results from a mutation of an ABC transporter gene at 16p13.1 (Le Saux et al., 1999, 2000; Bergen et al., 2000; Cai et al., 2000). Both the autosomal dominant and autosomal recessive forms of PXE have been linked to 16p13.1, suggesting that allelic heterogeneity of a single gene accounts for all of the cases (Struk et al., 1997; van Soest et al., 1997).

Ehlers–Danlos syndrome

Several subtypes of Ehlers–Danlos syndrome (EDS) can be defined by clinical manifestations, inheritance patterns, and specific molecular defects (Roach & Zimmerman, 1995; Beighton, 1993; Byers et al., 1979). Together these syndromes are characterized by fragile or hyperelastic skin (Fig. 128.12), hyperextensible joints, vascular lesions, easy bruising and excessive scarring after injuries (Beighton, 1993). About 80% of the patients with EDS have types I, II, or III, and the other subtypes are individually uncommon (Beighton, 1993). Vascular lesions such as aneurysm and arterial dissection are frequent problems in type IV EDS, and these complications often lead to premature death (Pepin et al., 2000). All of the familial Ehlers–Danlos patients with a documented abnormality of type III collagen have displayed autosomal dominant inheritance (Beighton, 1993).

Fig. 128.12. Hyperelasticity of the skin in a patient with Ehlers–Danlos syndrome. (Reproduced from Roach, 1989, with permission.)

Intracranial aneurysm

Rubinstein and Cohen (1964) first reported an adult woman with EDS and aneurysms of both the internal carotid and vertebral arteries. Numerous other individuals with extracranial and intracranial aneurysms have been described, including several people with multiple intracranial aneurysms (Schievink et al., 1990). Most patients became symptomatic in early adulthood, but children and adolescents are occasionally affected.

The internal carotid artery is the most likely intracranial vessel to develop an aneurysm due to EDS type IV (Fig. 128.13). Typically, the aneurysm develops in the cavernous sinus or just as the carotid emerges from the sinus (Rubinstein & Cohen, 1964; Schievink et al., 1990), so aneurysmal rupture often creates a cavernous–carotid fistula. Aneurysms in other intracranial arteries are more likely to present with subarachnoid hemorrhage. In one family, members of three different generations suffered subarachnoid hemorrhage (Schievink et al., 1990).

Unsuspected mutations of the *COLA3A1* gene which causes EDS type IV were not found in a cohort of 58 patients with an intracranial aneurysms or cervical dissections but no other signs of EDS (Kuivaniemi et al., 1993).

Carotid–cavernous fistula

Carotid–cavernous fistula has been reported in several patients with EDS, in some after minor head trauma but most often spontaneously. Intracranial aneurysms and carotid–cavernous fistulae often occur together (Lach et al., 1987). Rupture of an internal carotid artery aneurysm within the cavernous sinus probably causes many of the fistulae (Fox et al., 1988), although spontaneous fistula formation without an aneurysm does occur (Schievink et al., 1991; Halbach et al., 1990). Fragmentation of the internal elastic membrane and fibrosis of portions of the carotid wall are typically found at autopsy (Schoolman & Kepes, 1967).

The vascular fragility of type IV EDS makes both standard angiography and intravascular occlusion of the fistula more difficult (Lach et al., 1987). Nevertheless, intravascular occlusion is sometimes successful (Kashiwagi et al., 1993; Kanner et al., 2000).

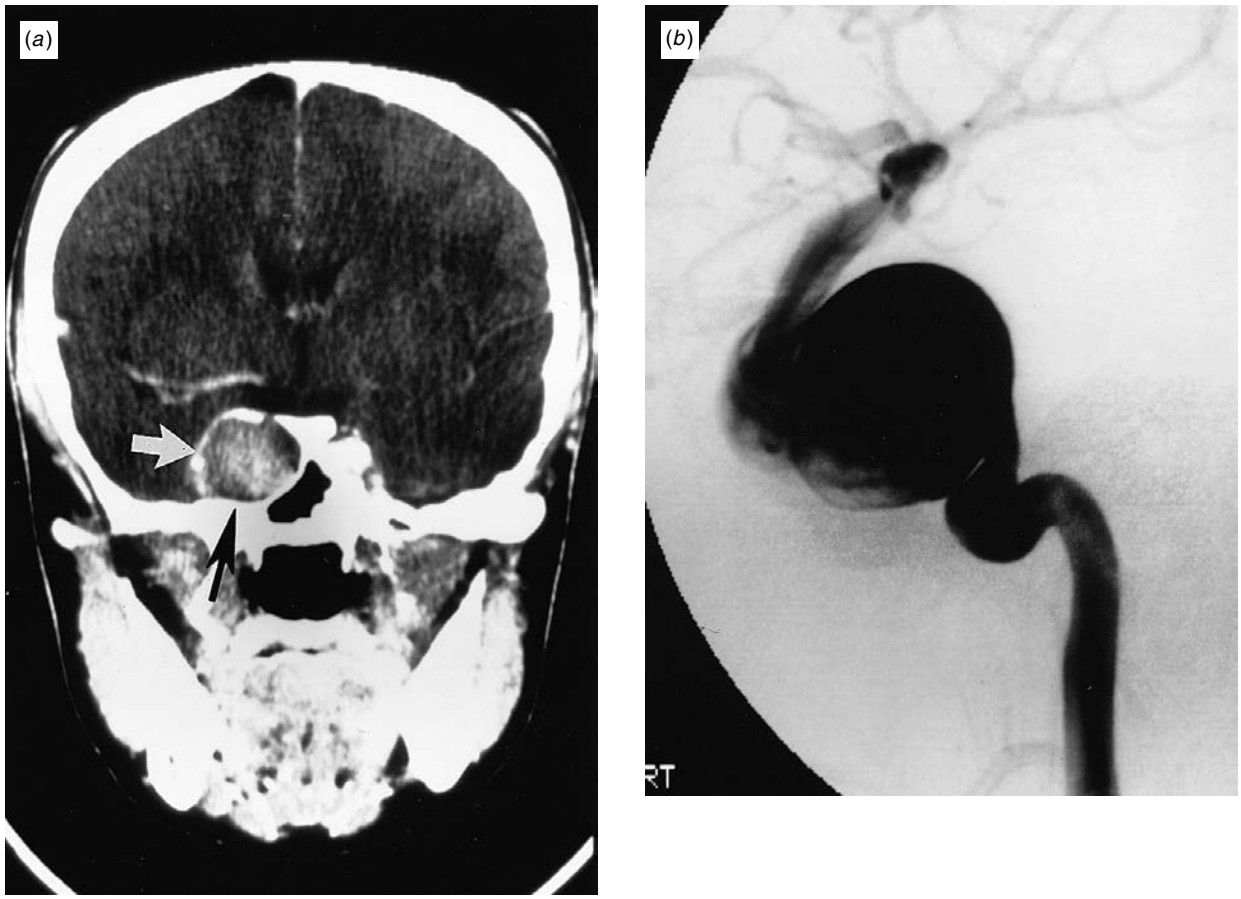

Fig. 128.13. (*a*) Coronal computed tomography with contrast (from an 18-year-old with headaches and a family history of Ehlers–Danlos type IV) reveals a large aneurysm (arrow) of the intracavernous carotid artery. (*b*) Internal carotid angiogram confirms the giant aneurysm of the intracavernous carotid artery. (Reproduced from Roach & Zimmerman, 1995, with permission.)

Arterial dissection

Arterial dissection has been documented in most of the intracranial and extracranial arteries, and the clinical presentation depends primarily on which artery is affected (Pope et al., 1991). One patient with a vertebral dissection developed a painful, pulsatile mass of the neck (Edwards & Taylor, 1969).

Surgery is difficult because the arteries are friable and difficult to suture (Edwards & Taylor, 1969). The arteries fail to hold sutures, and handling the tissue leads to tears of the artery or separation of the arterial layers (Sheiner et al., 1985).

Genetics of Ehlers–Danlos syndrome type IV

Ehlers–Danlos type IV is an autosomal dominant disorder with frequent spontaneous mutations. It results from a mutation of the *COLA3A1* gene on chromosome 2, a gene which codes for the alpha 1 chain of type III collagen, which is expressed in high levels in blood vessels (Gilchrist et al., 1999). Various *COLA3A1* mutations have been identified, but there is no consistent genotype–phenotype correlation (Gilchrist et al., 1999; Kontusaari et al., 1992; Sillence et al., 1991; Tsipouras et al., 1986; Richards et al., 1992; Schwartze et al., 1997).

Hereditary hemorrhagic telangiectasia (HHT)

Hereditary hemorrhagic telangiectasia (Osler–Weber-Rendu disease) is an autosomal dominant disorder which features telangiectasias of the skin, mucous membranes, and various internal organs (Garland & Anning, 1950; Reilly & Nostrant, 1984; Guillen et al., 1991; Shovin et al., 2000). Clinical diagnostic criteria have recently been published

Table 128.4. Diagnostic criteria for hereditary hemorrhagic telangiectasia

Criteria	Explanation
1 Epistaxis	Spontaneous nosebleeds
2 Telangiectases	Multiple lesions at typical sites (lips, mouth, nose, fingers)
3 Visceral lesions	Gastrointestinal telangiectasia (with or without bleeding) or AVMs of the lungs, liver, brain, or spinal cord
4 Family history of HHT	A first-degree relative with HHT by these criteria

Notes:
Definite: meets three criteria.
Possible/suspected: meets two criteria
Unlikely: fewer than two criteria.
Source: Modified from Shovlin et al. (2000), with permission.

(Shovlin et al., 2000; Table 128.4). However, both the clinical manifestations and the age of presentation are variable, and diagnosis may be difficult in younger patients who have not developed the full array of signs (Shovlin et al., 2000).

Cutaneous features of HHT

Cutaneous telangiectasias occur more often on the face, lips, and hands than on the trunk or legs (Bird et al., 1957; Reilly & Nostrant, 1984). Epistaxis due to telangiectasias of the nasal mucosa is often the first indication of HHT (Bean, 1958; Reilly & Nostrant, 1984; Plauchu et al., 1989). About a third of patients have conjunctival telangiectasias and 10% have retinal vascular malformations, although visual loss from these lesions is not common. Telangiectasias are not often prominent during the first decade, but thereafter they tend to enlarge and multiply (Plauchu et al., 1989).

Arterial lesions of HHT

In addition to the vascular lesions affecting the central nervous system, vascular malformations affect the lungs, gastrointestinal tract, or genitourinary system can lead to hemoptysis, hematemesis, melena, or hematuria (Bird et al., 1957; Reilly & Nostrant, 1984; Plauchu et al., 1989).

Neurologic features of HHT

Headache, dizziness, and seizures are common in individuals with HHT (Reagan & Bloom, 1971; Adams et al., 1977). Less common problems include paradoxical embolism with stroke, intraparenchymal or subarachnoid hemorrhage, and meningitis or cerebral abscess.

Paradoxical embolism through a pulmonary arteriovenous fistula leads to cerebral infarction in patients with HHT (Sisel et al., 1970), although rarely a clot may form within the fistula itself before migrating into the arterial circulation. Intermittent symptoms result from repeated small emboli with subsequent improvement. Transient deficits during hemoptysis could result from air embolism via a bleeding pulmonary arteriovenous fistula (Boczko, 1964).

About 1% of patients develop cerebral abscess or meningitis, probably because septic microemboli bypass the normal filtration of the pulmonary circulation via a pulmonary arteriovenous fistula.

Vascular anomalies may be found anywhere in the brain, spinal cord or meninges (Roman et al., 1978; Heffner & Solitare, 1969), and more than one type of lesion may be present in the same patient (Roman et al., 1978). Intracerebral vascular anomalies occur much more often than once suspected. One summary of 90 HHT patients from the literature listed 17 (19%) with arteriovenous malformations and 36 (40%) with telangiectasias or angiomas (Roman et al., 1978). Fulbright and colleagues identified 42 patients with various types of cerebral vascular anomalies among 184 consecutive HHT patients who underwent cranial MRI studies (Fulbright et al., 1998).

Many of these patients remained asymptomatic, and there is some evidence that the intracranial vascular lesions of HHT are less likely to bleed than sporadic arteriovenous malformations (Willemse et al., 2000). Hereditary hemorrhagic telangiectasia should be considered in patients with multiple cerebrovascular malformations (Aesch et al., 1991; Willinsky et al., 1990; Sobel & Norman, 1984; Willemse et al., 2000).

Intracranial aneurysms are much less common in HHT patients than arteriovenous malformations (Grollmus & Hoff, 1973; Roman et al., 1978; Fisher & Zito, 1983). The number of individuals with both HHT and intracranial aneurysm is small enough that the association could be coincidental. The same is true of spontaneous carotid–cavernous fistula.

Genetics of HHT

Hereditary hemorrhagic telangiectasia is an autosomal dominant disorder with variable expressivity and age-related penetrance. Its estimated incidence is 1 in 10 000 individuals (Pece-Barbara et al., 1999). About 30% of the time HHT develops via spontaneous mutation.

Genes on chromosomes 9 and 12 are responsible for HHT1 and HHT2 respectively. The *HHT1* gene at 9q33–34 codes for endoglin, an accessory membrane glycoprotein expressed at high levels in vascular endothelium (Pece-

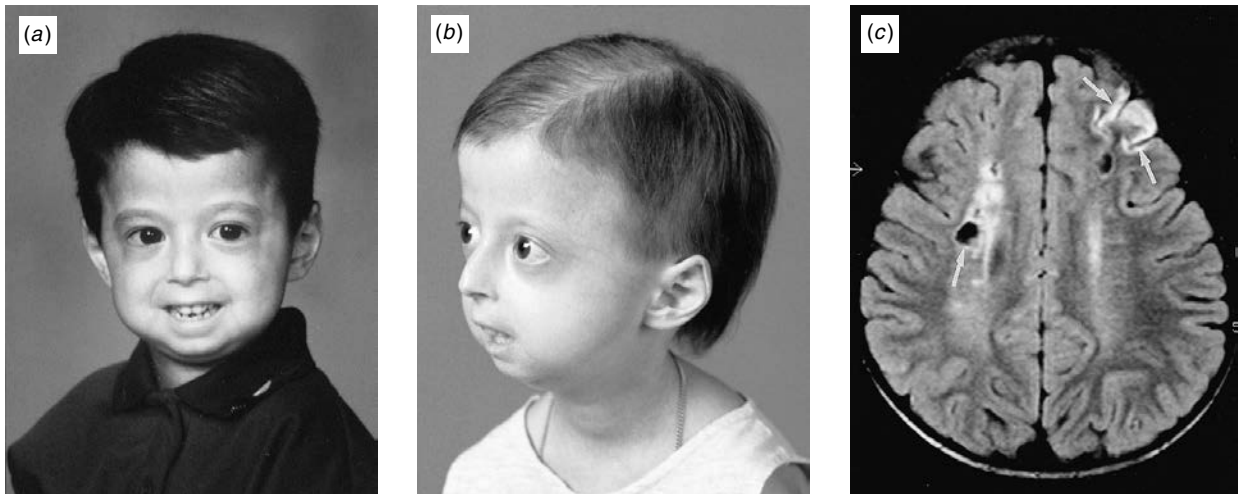

Fig. 128.14. Premature aging in a young boy with multiple ischemic infarctions. (*a*) School portrait prior to the onset of symptoms. (*b*) Later photograph reveals hair loss, stooped posture, and loss of subcutaneous fat. (*c*) Magnetic resonance image shows multiple ischemic infarctions of different ages (arrows). (Reprinted from Miller & Roach, 2000, with permission.)

Barbara et al., 1999). HHT2 results from mutation of the *ALK1* (activin receptor-like kinase-1) gene at 12q13. Like endoglin, ALK1 is expressed at high levels in endothelial cells (Abdalla et al., 2000). Individuals with HHT1 have a greater risk of pulmonary arterial malformations than those with HHT2, while those with HHT2 tend to have a milder phenotype and later onset of symptoms (Pece-Barbara et al., 1999).

Progeria

Hutchinson–Gilford syndrome or progeria (derived from *pro*, before, and *geras*, old age) is a rare condition characterized by premature aging (Fig. 128.14) and the early occurrence of age-related complications. DeBusk estimates that one person in eight million develops progeria (DeBusk, 1972).

Patients with progeria do not reproduce and most do not have affected family members. Some of the children with affected siblings have had atypical features (Viegas et al., 1974), leading to debate about the genetic nature of progeria. Both autosomal dominant and recessive traits have been proposed, but the clinical pattern is perhaps best explained by a dominant trait, usually arising via spontaneous mutation, with occasional instances of germline mosaicism in the families with affected siblings.

The pathogenesis of progeria is not well understood. In one study, cultured fibroblasts derived from a person with progeria reached senescence earlier than control cells, and patient fibroblasts had reduced levels of mRNA coding for the macromolecules of the extracellular matrix (Colige et al., 1991). It is tempting to speculate that progeria could result from an abnormality of telomerase, shown recently to determine the number of cell replications before cellular senescence.

Clinical features of progeria

The signs of progeria usually become apparent during the first 2 years of life. Some features may be subtle or absent initially, then worsen over time. Alopecia, for example, may not be present at first, but is almost universal by adolescence. The most common early features are short stature, decreased subcutaneous fat stores, joint restriction and alopecia (Gilkes et al., 1974; DeBusk, 1972). Skeletal changes include thinning of the bones, coxa valga, and small clavicles; some children have repeated poorly healing fractures. The characteristic physical appearance of progeria results from a combination of postural changes, decreased subcutaneous fat, alopecia, and facial hypoplasia and micrognathia. Children with progeria eventually develop premature atherosclerosis, leading to coronary artery disease or stroke (Fig. 128.14) (Dyck et al., 1987). Heart disease is the chief cause of death in patients with progeria (Dyck et al., 1987). Survival into middle age has been described, but death during the second decade is typical (Dyck et al., 1987).

Several other syndromes also cause signs of premature aging or carotid occlusion with stroke, and these disorders constitute the differential diagnosis of progeria. Werner's

syndrome is an autosomal recessive disorder characterized by cataracts, scleroderma with subcutaneous calcium deposition, a beak-like nose, and the premature appearance of disorders usually associated with aging, such as greying of the hair, senile macular degeneration, osteoporosis, diabetes, malignancies, and atherosclerosis (Gilkes et al., 1974; Epstein et al., 1966). Werner's syndrome has been described as adult progeria (Thannhauser, 1945). Affected individuals often live well into adulthood, and, even so, death from cardiac disease and stroke seem to be less common than in patients with progeria. Mandibuloacral dysplasia is another autosomal recessive disorder which features alopecia and short stature, along with clavicular and mandibular hypoplasia, stiff joints, and persistently open cranial sutures. Whether this is an entirely distinct condition is still in question.

Neurological complications after organ transplantation

Eelco F. M. Wijdicks

Department of Neurology, Mayo Medical School; Neurology–Neurosurgery Intensive Care Unit, and
Department of Neurology, Mayo Clinic and Mayo Foundation; Rochester, MN, USA

The impressive progress of transplantation over the last 20 years has been made possible by surgical advances, the discovery of a superb immunosuppressive agent, cyclosporine, improved postoperative care, and infectious disease surveillance. These advances, however, were not devoid of neurological complications. The risk of such complications is after surgery when the graft may deteriorate in function from vascular complications. An entirely new field of neurological complications, unique to organ transplant recipients, has emerged, but only now are some of the basic mechanisms being unravelled. Neurologists have started to play an integral part in the postoperative evaluation and management of patients after transplantation and are able now to recognize the clinical presentations. We are beginning to understand how immunosuppressive agents can cause neurotoxicity, risks of infections of the central nervous system (CNS), management of seizures, and long-term effects, including demyelinating disorders (Wijdicks, 1995, 1999). This chapter targets the major neurological disorders seen after organ transplantation.

Epidemiology

Estimation of frequency of neurological complications after transplantation is fraught with difficulties. First, most studies have reported a retrospective analysis of surgical series that are probably skewed towards the more severe neurological complications. Neurologists would only be called on when a neurological complication appears to dominate the clinical picture or could invalidate the initial success of grafting. One can also expect that, with further categorization of neurological syndromes and consequently recognition by the transplant team, neurologists will be consulted less often and only when diagnosis and management become more complex or frustrating. Prospective studies may also not capture all of postoperative events, and to be accurate, they would need a neurologist participating in rounds with the transplant team. Neurological complications in organ-transplant recipients are more common after liver and heart transplants, because these surgeries are more prone to hemodynamic instability. Neurological complications in renal transplant recipients usually appear in the years after transplantation and may be due to comorbidity associated with end-stage renal failure and a result of long-term immunosuppression.

It is useful to categorize neurological complications into major complications, such as recurrent seizures, postoperative failure to awaken, neurotoxicity associated with immunosuppressive agents, and acute neuromuscular disorders, and minor manifestations, such as tremors, transient agitation, and confusional states.

The estimated frequency of major neurological manifestations is summarized in Table 129.1. Seizures are particularly common in liver and lung transplantation (Starzl & Demetris, 1990; Wong et al., 1999), and mononeuropathies appear more often in kidney transplantation. Ischemic and hemorrhagic stroke are uncommon occurrences in all transplantations, perhaps reflecting the low incidence of stroke in abdominal operations. Stroke is expected to occur more frequently relative to cardiac transplants, in which multiple vascular reattachments take place. The frequency of immunosuppressive agent neurotoxicity has decreased substantially, because transplant surgeons have become familiar with more appropriate titration of cyclosporine and FK506. Newer drugs, such as an oral microemulsion of cyclosporine (Neoral) and mycophenolate mofetil (Cellcept), which both have a much safer profile, may be responsible for this observation as well. Neurological complications after bone marrow transplantation are more difficult to estimate because of varied

Table 129.1. Estimated incidence of neurological complications

	Incidence (%)				
Type	Coma or stupor	Seizures	Immunosuppression neurotoxicity	Neuromuscular disorders	Stroke[a]
Heart	<1	Sporadic	Sporadic	Sporadic	1–5
Liver	5–10	2–40	10	5	<1
Kidney	<1	Sporadic	5	5–40	<1
Lung	10	20	NR	5	<1
Pancreas	<1	10	NR	NR	<1
Bone marrow	<1	10–15	5	5–20	1–3

Notes:

[a] Includes anoxic–ischemic encephalopathy in some series.

NR, not reported yet.

patient populations, the type of bone marrow transplant, and whether the patient received bone marrow from an alternative donor (patients who receive an allogenic graft from either a human leukocyte antigen [HLA]-matched unrelated donor or an HLA-mismatched related donor). Institutions with a major commitment to transplantation programmes should keep a prospective database to monitor trends over time. With these data we have been able to find a decreasing trend of neurologic complications except for stroke in heart transplantation (Jarquin-Valdivia et al., 1999) and decrease in major complications in patients using cyclosporine (Wijdicks et al., 1999).

Immunosuppression neurotoxicity

Traditional immunosuppressive regimens include cyclosporine or tacrolimus, azathioprine, and corticosteroids, but postoperative protocols are in flux. Novel agents include sirolimus, Neoral, and mycophenolate mofetil. Newer investigational agents are leflunomide (tyrosine kinase inhibitor), and monoclonal antibodies to CD4 on adhesion molecules. Polyclonal antithymocyte globulin or OKT3 is typically used in rejection therapy.

Cyclosporine remains the prime immunosuppressive agent in liver, kidney, and bone marrow transplantation. Cyclosporine is a cyclic oligopeptide composed of 11 amino acids, which are extracted from fungi. Its presumed mechanism of modulating T-cell function is linkage to an intracellular protein called 'cyclophilin', resulting in a complex that subsequently blocks calcineurin activity. Calcineurin regulates the interleukin-2 gene transcription and T-cell lymphocyte proliferation, and thus when blocked, would stop the immunological response to a new graft. T-cell activation, which after differentiation and clonal expansion induces cytokine synthesis, activates a complex cascade of interacting co-stimulatory molecules and will result in rejection. Cyclosporine also inhibits T-cell activation and thus prevents rejection. Nonetheless, it has been estimated that at least 50% of allograft recipients have at least one episode of acute rejection during the post-transplant period. Cyclosporine has a half-life of 8 hours and, like tacrolimus, is metabolized by the cytochrome P-450 microsomal enzyme system. Therefore, antifungal agents, calcium channel blockers, fluoroquinolones, macrolide antibiotics and metoclopramide, which may be used in the postoperative period, may cause cyclosporine toxicity as a result of inhibition of this metabolizing system.

Cyclosporine may cause hypomagnesemia, hyperkalemia, and hypertension, but neurotoxicity is most frequent. Cyclosporine neurotoxicity occurs in 1 of 10 patients with a transplanted liver, but is only found in 1 of 20 patients who receive renal or bone marrow transplants. The clinical spectrum of cyclosporine-associated neurotoxicity has changed dramatically over the years (Table 129.2). In the earlier days of transplantation, cyclosporine neurotoxicity was considered only after patients progressed to coma and status epilepticus. Early recognition and more careful intravenous titration of cyclosporine has reduced the severity of neurotoxicity. With the improved bioavailability of cyclosporine, severe neurotoxicity have become less common, and headache, tremors, and occasional seizures have remained as overwhelming side effects of cyclosporine microemulsion.

Although cyclosporine is highly hydrophobic, it does not permeate the intact blood–brain barrier, owing to tight

Table 129.2. Clinical features of immunosuppression neurotoxicity (increasing severity)

junctions and lack of lipoprotein transport (Begley et al., 1990). Therefore, a damaged blood–brain barrier is pivotal for cyclosporine penetration into the brain. Nonetheless, a recent study documented metabolites of cyclosporine in cerebrospinal fluid (CSF) in 4 of 17 liver transplant recipients. Only patients with high levels of blood urea nitrogen and bilirubin had these metabolites of cyclosporine in the CSF, and it appears that acute renal failure may have enhanced CSF penetration (Bronster et al., 1999).

Cyclosporine neurotoxicity is also associated with low plasma cholesterol. Cyclosporine penetrates the intercellular brain tissue through low-density lipoprotein receptors (de Groen et al., 1987). Hypocholesterolemia results in up-regulation of low-density lipoprotein receptors, which may facilitate transport. It has been documented that only a small percentage of cyclosporine exists in the free or unbound state, and changes in protein binding may result in a significant increase in the therapeutic and toxic effects of the drug. This mechanism cannot explain cyclosporine neurotoxicity in liver transplant patients with normal serum cholesterol levels and in other transplant recipients with cyclosporine neurotoxicity.

Another possibility for cyclosporine to exert its effect on the neuronal structures might be damage of the blood–brain barrier. It has been postulated that cyclosporine may directly damage the endothelium, leading to increased endothelin production and release of thromboxane, resulting in vasoconstriction and microvascular damage. It is possible that the blood–brain barrier may also have become damaged in patients who had an anoxic ischemic injury or in patients with prior hepatic encephalopathy, but none of these factors has consistently increased the risk in cohorts being evaluated for predictive factors for cyclosporine neurotoxicity. Disturbance of the blood–brain barrier may lead to vasogenic edema, and when exposure to the drug is prolonged, apoptosis may occur (Wijdicks, 2001). Other factors related to cyclosporine neurotoxicity are hypomagnesemia, corticosteroids, and hypertension, but whether these risk factors are simply covariants and therefore unrelated is not clear.

Cyclosporine neurotoxicity may produce a posterior leukoencephalopathy on magnetic resonance imaging similar to patterns seen in hypertensive encephalopathy. This suggests that hypertension from cyclosporine toxicity, another major management problem with its use, may be the main final common pathway. However, hypertension from cyclosporine typically occurs several weeks into the treatment. Hypertension is anticipated and aggressively treated by experienced transplant teams, resulting in controlled blood pressures in most patients with cyclosporine neurotoxicity (Wijdicks et al., 1995, 1999).

The clinical features of cyclosporine neurotoxicity typically occur during the intravenous administration phase. An acute psychotic period in a patient who also displays a fine hand tremor is characteristic. This psychotic period may involve bizarre delusions and visual hallucinations commonly with bright coloured lights and also paranoid behaviour, a panic state, or nihilism. Speech becomes rambling and nonsensical but may have other characteristics (Bronster et al., 1995), including mutism (Valldeoriola et al., 1996). Tongue tremors and an action myoclonus speech disorder may be seen in which a patient stutters during rapid speaking but has a normal voice when asked to slow down. Speech abnormalities may progress to mutism and orolingual apraxia, with the patient unable to open the jaw and lips and to move the tongue, often also associated with some degree of generalized hypokinesia (Bird et al., 1990).

Although seizures in transplant recipients can be caused by many triggers, cyclosporine and tacrolimus neurotoxicity are commonly present (Fig. 129.1). Other potential triggers for seizures such as an acute metabolic derangement, drug toxicity, hypoxic–ischemic injury, newly developed cerebral structural lesion, and particularly a rapidly evolving opportunistic infection should be strongly considered and excluded as well. Generalized tonic–clonic seizures may be the only presentation of cyclosporine neurotoxicity (Wijdicks et al., 1996a,b). Status epilepticus is exceptional, often because the earlier manifestation of tremors and confusion followed by a single seizure was recognized by the transplant team and prompted discontinuation of cyclosporine.

Visual manifestations of cyclosporine neurotoxicity may take the dramatic form of cortical blindness but are rare (Rubin & Kang, 1987). Posterior leukoencephalopathy is reversible, but a recent report described a 2-year-old child who, after bone marrow transplantation, developed oculogyric crisis with sustained upward and lateral eye deviation

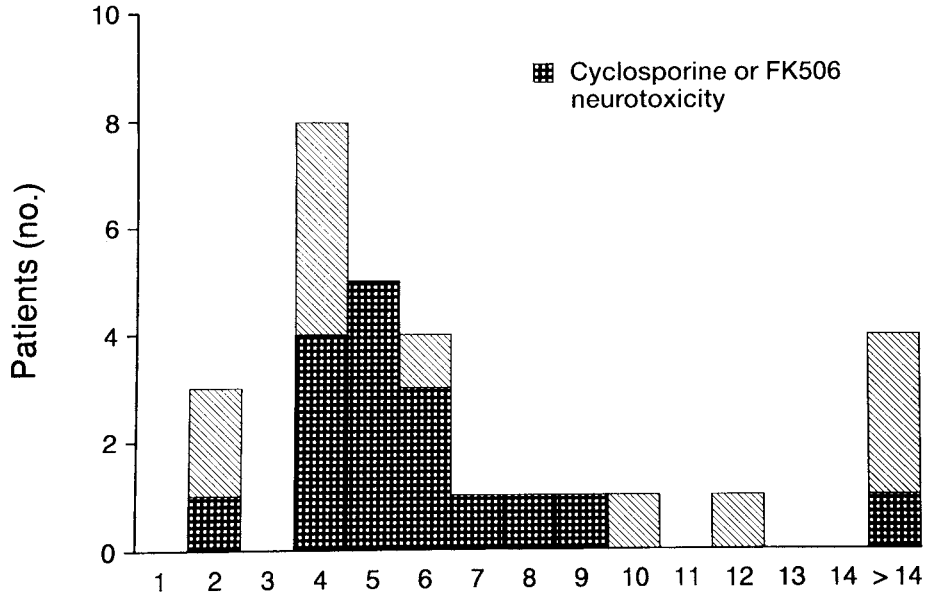

Fig. 129.1. Time of onset (in days) of new-onset seizures after liver transplantation indicates a large proportion of patients with cyclosporine or tacrolimus (formerly known as FK506) neurotoxicity. (From Wijdicks et al., 1996a,b, with permission from the American Academy of Neurology.)

and cortical blindness associated with bioccipital hemorrhagic infarcts (Antunes et al., 1999). Possibly a failure to recognize these dystonic eye movements led to prolonged exposure to cyclosporine neurotoxicity and permanent damage on MRI. More likely, permanent blindness, if it occurs in the setting of cyclosporine toxicity, is due to a retinal lesion (Esterl et al., 1996). In addition, cortical blindness in patients who underwent a heart or lung transplantation may not be related to cyclosporine neurotoxicity but due to hypotension or from cardiac emboli during removal of the diseased dilated myocardium.

Major management difficulties with cyclosporine are headache and insomnia. Headaches are often vascular-type headaches but may be unilateral and may have migraine features, such as nausea, vomiting and photophobia (Steiger et al., 1994; Rozen et al., 1996). We can now estimate that 10% to 20% of patients using cyclosporine in any formulation experience headaches. There is no relationship with the plasma cyclosporine levels, and headaches may persist or suddenly disappear after switching to another immunosuppressive agent, such as tacrolimus. Insomnia has emerged as a major nuisance leading to decreased productivity. Sleep studies are not available and dose adjustments are not always successful. It may be a reason for switching to tacrolimus as well.

Tacrolimus neurotoxicity has a virtually similar clinical profile to cyclosporine, and any of the above-mentioned features have been documented in tacrolimus (Eidelman, et al., 1991; Wijdicks et al., 1994; Small et al., 1996). Tremors, however, remain exceedingly more common, and speech abnormality associated with tacrolimus has more apraxic components characterized by a breathy phonation, imprecise articulation, vowel distortions, and the inability to perform non-speaking tasks, such as whistling and puckering of the lips. Many patients also complain of perioral tingling, hyperesthesias in the hands, and restless leg syndrome, but a polyneuropathy has not been documented clinically or defined electrophysiologically or pathologically in any of the patients.

The diagnosis of cyclosporine or tacrolimus neurotoxicity is based on clinical features alone and remains a tentative diagnosis until symptoms disappear after discontinuation of the drug. MRI scanning may document edema in the subcortical white matter of the occipital and parietal lobes (Fig. 129.2). These MRI changes are highly typical and can be seen in association with intracranial hemorrhage, predominantly subdural hematoma, acute cerebellar edema, and cortical hyperintensity. All of these changes disappear after a resolution of the symptoms. The sensitivity of magnetic resonance imaging in cyclosporine or tacrolimus neurotoxicity is low but increases with seizures and decrease in level of consciousness (Wijdicks, 1995; Wijdicks et al., 1996a,b). Extremely high blood levels of cyclosporine may confirm the clinical diagnosis, but a good clinical and laboratory correlation has not been found.

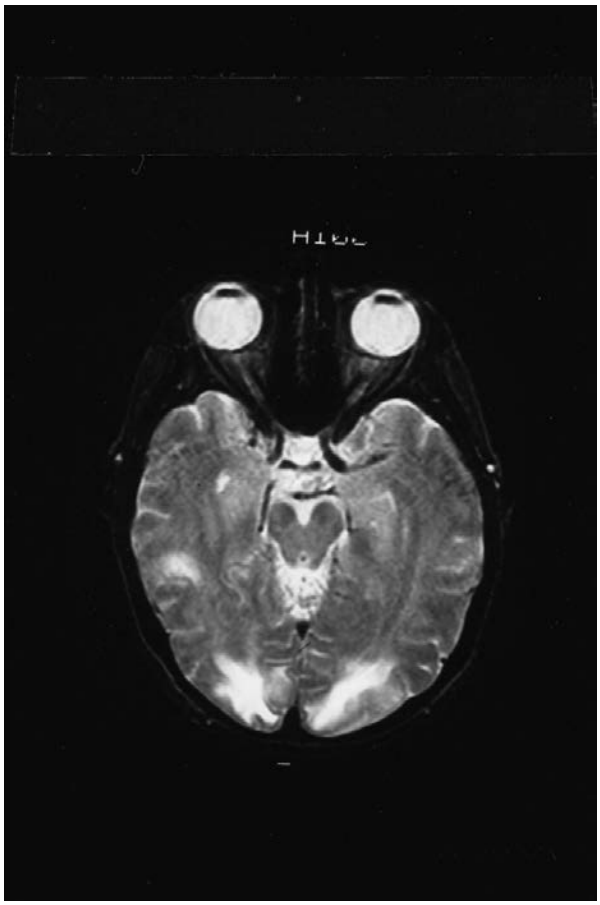

Fig. 129.2. Occipital lesions (posterior leukoencephalopathy) in cyclosporine neurotoxicity. (From Wijdicks, 1999, with permission from Mayo Foundation.)

Sirolimus is a novel immunosuppressive agent with a different target than tacrolimus (despite similarities in name). Neurotoxicity has not been reported yet except for mild headache and insomnia, thrombocytopenia and hyperlipidemia (Hong & Kahan, 2000; Kahan et al., 2000).

OKT3 has been used as a primary immunosuppressive agent in the initial phases in heart and lung transplantation. OKT3 has become part of many cardiac transplantation protocols, but neurotoxicity, after a few incidental reports, is rarely seen. OKT3 is combined with corticosteroids and azathioprine and after 2 weeks is replaced by an oral dose of cyclosporine. OKT3 is a monoclonal antibody targeting T cells and may block the T-cell receptor interaction with major histocompatibility antigens. In the first days of administration, a cytokine release syndrome may occur, leading to fever, headache, pulmonary edema, and deteriorating renal function, all potential contributors to a reduced level of consciousness. Profound headaches may indicate the development of aseptic meningitis and CSF examination documents lymphocytic pleocytosis, usually within the first 3 days after initiation of therapy. Mild headache may progress in exceedingly rare circumstances to brain swelling, bilateral papilledema, and vision loss as a presentation of a rarely seen OKT3 encephalopathy.

Management of immunosuppressive neurotoxicity is discontinuation of the immunosuppressive agent and after several days restarting with an alternative drug. Cyclosporine can be replaced by tacrolimus, surprisingly without much risk of recurrent toxicity, but many transplant teams now use mycophenolate mofetil. When neurotoxicity is associated with significant agitation, haloperidol (2–4 mg) given intravenously every 6 hours and lorazepam (2–4 mg) given intravenously every 4 to 6 hours can be suggested. When headache remains persistent, the dose should be reduced. High-dose aspirin (1 500 mg) is often effective. Drugs such as nicardipine, diltiazem, and verapamil are not advised, because they can significantly increase cyclosporine concentrations and thus have a paradoxical effect and perpetuate headaches.

Central nervous system infections

CNS infections are a lifetime risk after transplantation, and the United Network for Organ Sharing continues to list infections as a major cause of morbidity and mortality (Fishman & Rubin, 1998). These patients are at risk as a result of chronic immunosuppressive therapy, but environmental exposure is essential. An example is exposure to *Aspergillus* species within the hospital, which may be seen during construction and may seriously challenge transplantation wards and cause outbreaks (Massin et al, 1994; Brown et al., 1996). Most of the CNS infections occur 1 month after transplantation and after the perioperative period. Fulminant CNS infections in the early period, however, do occur and should be considered when seizures, fever and a rapid onset of coma are seen in a setting of a systemic infection. Many clinical presentations of CNS infections are attenuated unless the infection is advanced. Clinical symptoms may be vague, and similar symptoms can be due to drug toxicity or rejection. Patients who develop a *Listeria* meningitis may complain of only persistent headache and fever and may have normal results of neuroimaging study and spinal fluid examination until the CSF culture documents the offending organism.

CNS infections are divided into meningitis, cerebritis, and development of multiple cerebral abscesses. *Listeria monocytogenes*, *Cryptococcus neoformans*, and *Aspergillus fumigatus* are the major pathogens causing CNS infections

Table 129.3. Transplant-associated CNS infections

Organism	Time from Tx (mo)	Presentation	CT or MRI	CSF	Diagnosis	Therapy
Listeria monocytogenes	1–6	Headache, stupor (prior abdominal cramps and diarrhea)	Meningeal enhancement only	May be normal	CSF culture	i.v. ampicillin, 10–12 q/day; i.v. gentamicin, 1.0–1.5 mg/kg every 8 hours
Nocardia asteroides	1–6	Localizing findings: headache, stupor	Abscesses (may be solitary)	Pleocytosis	Biopsy, CSF blood culture	Trimethoprim-sulfamethoxazole, 2.5–10.0 mg/kg twice a day
Aspergillus	1–6	Rapidly developing coma, seizures (prior lung infection)	Ring lesion, hemorrhage scattered	Pleocytosis	Biopsy, blood culture	Amphotericin B, 1.0–1.5 mg/kg per day
Cryptococcus neoformans	>6	Unexplained headache, fever, cognitive changes, rarely focal signs	Thalamus, basal ganglia; widespread miliary; no edema	Pleocytosis; may be normal	CSF antigen	Amphotericin B, 1.0–1.5 mg/kg per day
Toxoplasma gondii	>6	Seizures, stupor, rarely focal signs	Multiple lesions, subcortical meninges spared	Pleocytosis; may be normal	Brain biopsy, SPECT	Trimethoprim-sulfamethoxazole, 2.5–10.0 mg/kg twice a day

in organ transplant recipients (Conti & Rubin, 1988; Hall et al., 1989). Details of these infections are found in other chapters of this book. Their clinical presentation, means of diagnosis, and laboratory tests are summarized in Table 129.3.

Transplant recipients are also at risk of Epstein–Barr virus-associated infections that may cause lymphoma or an Epstein–Barr virus-associated post-transplantation lymphoproliferative disease, which can cause seeding along the spinal cord as well as infiltration of the meninges.

Progressive multifocal leukoencephalopathy is caused by JC virus, which is reactivated in 20% of patients after transplantation but does not always lead to a clinical presentation (Worthmann et al., 1994; Coppo et al., 1999). Progressive multifocal leukoencephalopathy progresses fairly rapidly in most cases. Within months of diagnosis a patient may display cognitive decline, focal signs such as hemiparesis, ataxia, and sometimes a more specific frontal lobe dementia syndrome. Magnetic resonance images are fairly characteristic, with a focal white matter lesion that may be localized in any lobe. The JC virus cannot be cultured from spinal fluid examination, and a polymerase chain reaction needs to be performed (Aksamit, 1995). Seventy to ninety per cent of the patients with progressive multifocal leukoencephalopathy have a positive result of polymerase chain reaction, but biopsy is needed to document the enlarged inclusion-bearing oligodendrocytes, followed by in situ hybridization. No treatment for progressive multifocal leukoencephalopathy has been found, and most patients die within the first year after presentation.

Neuromuscular complications

Neuromuscular complications in transplant patients have been reported as mononeuropathy, myopathy, polyneuropathy and neuromuscular junction disorders (Junaid et al., 1993; al-Lozi, et al., 1994; Taylor et al., 1995; Lacomis et al., 1996; Wijdicks et al., 1996a,b). The recognition of these disorders is difficult and they may go undetected in

Table 129.4. Mononeuropathies after transplantation

Mononeuropathy	Proposed mechanisms	Transplants and incidence[a]
Phrenic nerve	Artificial cooling (ice), intraoperative injury	Lung, 3.2–29.0%; liver, up to 44%; (heart)
Brachial plexopathy	Stretch (shoulder hyperabduction), sternal retractors, trauma from cutdown for axillary vein cannulation	Liver, 0–5.8%; (heart, BM)
Ulnar	Compression (intraoperative, blood pressure cuff, or prolonged immobility), heterotopic ossification	Liver, 0.5–4.0%; kidney, up to 43%
Radial	Intraoperative compression	Liver, 0–0.4%
Peroneal	Compression (intraoperative or from prolonged immobility)	Liver, 0.4–1.3%; (heart, BM)
Femoral	Retractors, hematoma, lymphocele, vascular steal	Kidney, 4–11%; liver, 0–0.4%; (heart, BM)
Lumbosacral plexopathy	Hemorrhage	Liver, 0–0.2%; (BM)
Sympathetic nerve	Internal jugular vein cannulation, lower brachial plexus traction (usually from sternal retractors)	Liver, 0.2–2.0%; (heart)
Nerve root or ganglia	Herpes zoster virus reactivation from immunosuppression	BM, 4.5–19.0%; pancreas, 13%; liver, 0–0.3%

Notes:
[a] Incidence is given when reported. Transplant types in parentheses are case reports (see text for references). BM, bone marrow.

the sickest patients. Mononeuropathies after transplantation are typically a result of trauma during surgery, immobilization and invasive procedures. Plexopathy may occur in a few patients after liver and heart transplantation, but almost always has its origin in sternal retractors or hyperabduction of the shoulder during procedures in liver transplantation. Although stretch and interoperative compression may be explanations for a plexopathy (Katirji, 1989; Wijdicks et al., 1996a,b), graft-vs.-host disease has been suggested as a possible mechanism of brachial plexopathy after bone marrow transplantation (Adams et al., 1995). Peroneal mononeuropathy is comparatively common in patients with liver transplants (Wijdicks et al., 1996a,b). It is caused by compression of the fibular head and is prone to occur in patients with end-stage liver disease due to major weight loss.

It has a good outcome and drop feet disappear within 3 months of transplantation (Table 129.4). Acute myopathy may occur after transplantation (Lacomis et al., 1996). A severe quadriplegia has been documented, typically sparing the extraocular musculature. Electrodiagnostic tests document decreased compound muscle action potential amplitudes and relative sparing of the sensory response on nerve conduction studies. An important recent study has shown that direct muscle stimulation decreases the compound muscle action potential, and this is helpful in discriminating between myopathy and neuropathy (Rich et al., 1997). Myopathy after transplantation is associated with corticosteroid use and with histopathological features of type 2 myofibre atrophy (al-Lozi et al., 1994). A causal relationship with cyclosporine seems improbable unless it is combined with lovastatin. Rhabdomyolysis, particularly when patients have survived a sepsis syndrome, should be considered and creatine phosphokinase values may be normalized. Outcome in our experience with a few patients has been good, with functional full recovery.

Acute polyneuropathy with progressive limb weakness over weeks has been described and may be inflammatory in nature. A Guillain–Barré-like syndrome has been reported associated with bone marrow transplantation (Wen et al., 1997) and with liver transplantation (Taylor et al., 1995) (Fig. 129.3). The triggers are not known and may include hepatitis B infection. Treatment with plasma exchange or intravenous immunoglobulin should be offered.

De novo tumours of the central nervous system

There is a three- to fourfold increased incidence of malignancies of all sorts in immunosuppressed organ transplant recipients (Penn & Porat, 1995). The vast majority of CNS tumours are non-Hodgkin lymphomas, followed by gliomas, with equal distribution of glioblastomas and astrocytomas (Table 129.5). CNS lymphomas are frequent with

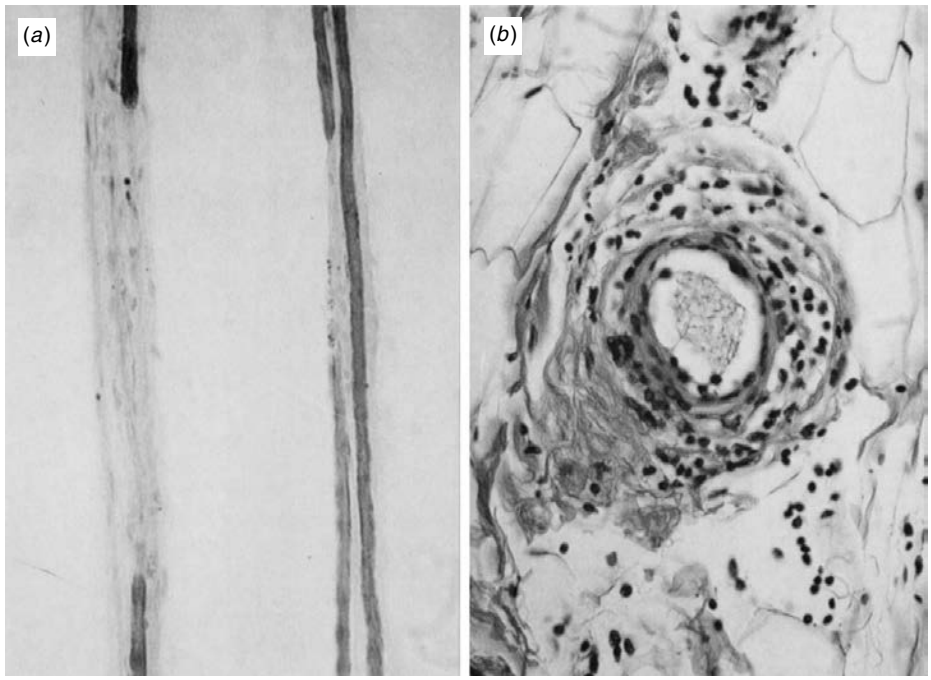

Fig. 129.3. Patient with chronic inflammatory demyelinating polyneuropathy 15 months after orthotopic liver transplantation. (*a*) Segmental demyelination in teased fibre preparation. (*b*) Perivascular lymphocytic infiltration around vasa vasorum. (From Taylor et al., 1995, with permission from the American Neurologic Association.)

Table 129.5. Types of neoplasms in the Cincinnati transplant tumour registry

Tumour	No.
Lymphoma	345
Glioma	44
Meningioma	4
Neuroectodermal	2
Miscellaneous	3

renal transplantation because kidney transplantation is more commonly performed. Most CNS lymphomas occur within the first 12 months after the transplantation but may be seen as early as 3 weeks (Peterson & DeAngelis, 1997). In the Cincinnati registry, however, 18 of all 345 (5%) registered lymphomas occurred 10 years or more after transplantation. CNS lymphoma is largely located in the hemispheres or cerebellum (Fig. 129.4) but may coexist in the spinal cord or be in the spinal cord only. Non-Hodgkin lymphoma may appear as a focal mass, peripherally enhancing and centrally translucent (Fig. 129.4). Meningeal involvement may occur. Often the tumour has significant necrosis, which produces the central translucency (Johnson et al., 1997).

The diagnosis of CNS lymphoma is suspected with new-onset headache, papilledema, and seizures, and because of its common localization in the frontal lobe, personality changes are the first indicators. Evaluation should include stereotactic biopsy of the lesion. Therapy is limited but should include dexamethasone, 16 to 25 g/day, and local radiation therapy (DeAngelis, 1995). Stereotactic biopsy is necessary for the diagnosis, but the Mayo Clinic experience (Phan et al., 2000) involved increased incidence of intracranial hematoma after biopsy. These transplant-associated lymphomas probably are of a different nature than CNS lymphoma in a general population and more hemorrhagic. A complete remission may occur, although residual neurological deficit may persist. Approximately half of the patients with this lymphoma die as a direct result of the malignant disease despite treatment.

In conclusion, neurological complications have been identified since the early days of kidney transplantation. They may be an additional major cause of morbidity. The role of the neurologist in a transplantation programme has

Table 129.6. Neurologic complications after transplantation: classification by neurologic signs and symptoms and common diagnostic considerations

Sign or symptom	Consideration
Failure to awaken	Hypoxic–ischemic encephalopathy, central pontine myelinolysis, anesthetic agents, air embolism, acute uremia, acute graft failure, multiple intracranial abscesses
Loss of consciousness	ICH, fulminant meningitis, seizures, drug toxicity
Confusional state	Immunosuppressive toxicity, acute hypoglycemia, hyperglycemia, corticosteroids, fungal meningitis
Seizures	Cyclosporine or tacrolimus toxicity, ICH, lymphoma, meningitis, chemotherapeutic agents
Mute or stuttering	Cyclosporine or tacrolimus toxicity, cerebral infarct
Cortical blindness	Cardiac arrest, cyclosporine toxicity, cardiac catheterization, hypertensive encephalopathy
Hemiparesis	Brachial plexopathy, ischemic or hemorrhagic stroke, neoplasm, brain abscess
Tremors	Immunosuppressive drugs
Myoclonus	Hypoxic-ischemic encephalopathy, ketamine or penicillin intoxication
Asterixis	Acute liver, renal, or pulmonary disease
Rigidity	Haloperidol overdose, malignant hyperthermia
Muscle weakness	Acute critical illness polyneuropathy, polymyositis, corticosteroids, myopathy, neuromuscular junction blocking agents
Headaches	Fungal meningitis, OKT3 toxicity, cyclosporine or tacrolimus use, lymphoma, astrocytoma

Note: ICH, intracranial hemorrhage.

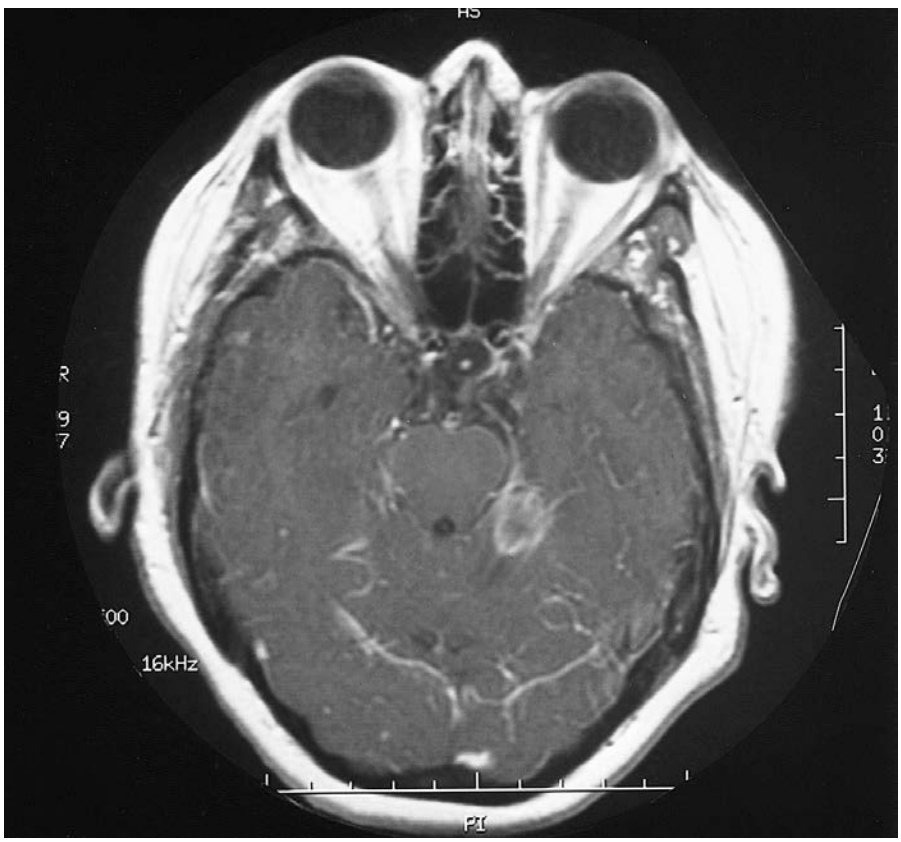

Fig. 129.4. Peripherally enhancing mass in superior cerebellum and peduncle confirmed as lymphoma by biopsy in renal transplant recipient.

been established. The spectrum of consultations seems to have narrowed down to a few major critical problems. For easy reference, the most common reasons for consultation with initial consideration for diagnosis are summarized in Table 129.6.

Abbreviations of conditions used in subheadings (without explanation):
AD Alzheimer's disease
AIDS Acquired immune deficiency syndrome
ALS Amyotrophic lateral sclerosis
CJD Creutzfeldt–Jakob disease
FTD Frontotemporal dementia
HIV Human immunodeficiency virus
HD Huntington's disease
PD Parkinson's disease
SIADH syndrome of inappropriate secretion of antidiuretic hormone

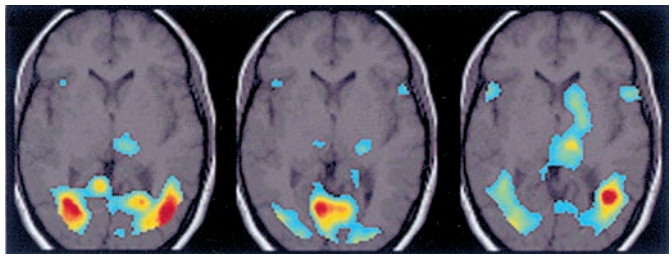

Fig. 1.1. Functional MRI signal changes during performance of a cognitive task. The above images are at the level of the thalamus for three normal controls showing that each of the participants exhibited signal changes in the thalamic hemispheres when they activated an object in memory (Kraut et al., 2001).

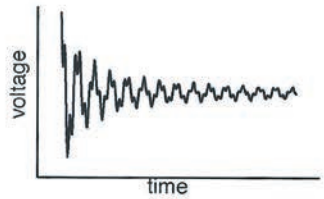
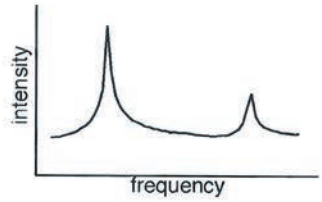
...and imaging

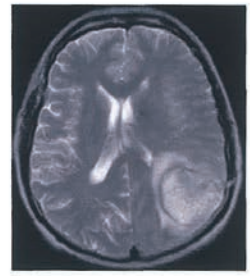
8 A coil in the spectrometer detects the vector in -X as an induced voltage, like this one showing 2 resonant frequencies:



9 Fourier transformation of such a signal into the frequency domain produces a spectrum with two frequency peaks:



10 Anatomical images can be made from large frequency peaks. A magnetic field gradient placed across the sample causes the peak's resonant frequency to assume a different value at each spatial point. If this is done in 2 or 3 dimensions, a computer can reconstruct a 2D or 3D image of the peak's intensity and relaxation properties, both of which vary due to differences in the local microchemical environment across the compartments of biological tissue. These variations provide the anatomical contrast in images like this one (from Fig. 4A), which is a standard T2-weighted MRI scan made from the water proton signal. A glioma and its surrounding edema are visible because they provide microchemical environments for water different from those of normal brain.



11 Several peaks from other compounds are sufficiently intense and well separated from each other to allow mapping of their anatomical distribution by a similar process. This example (Fig. 11.4D) shows the distribution of the signal from choline-containing compounds; signal intensity is color-coded, red high, blue low. The signal is strongest in the region of the glioma, a finding which is characteristic of many brain tumors and may reflect increased membrane synthesis. The map is coarser than the above MRI of the same brain, because the choline signal is several thousand times smaller than the one from water protons. Comparable maps can currently be made from the signals of N-acetyl aspartate, creatine, and lactate (see Figs. 11.4 and 11.5). Methods under development will extend the list to include glutamate, GABA, and other compounds of neurobiological interest.

Fig. 11.2. NMR principles continued.

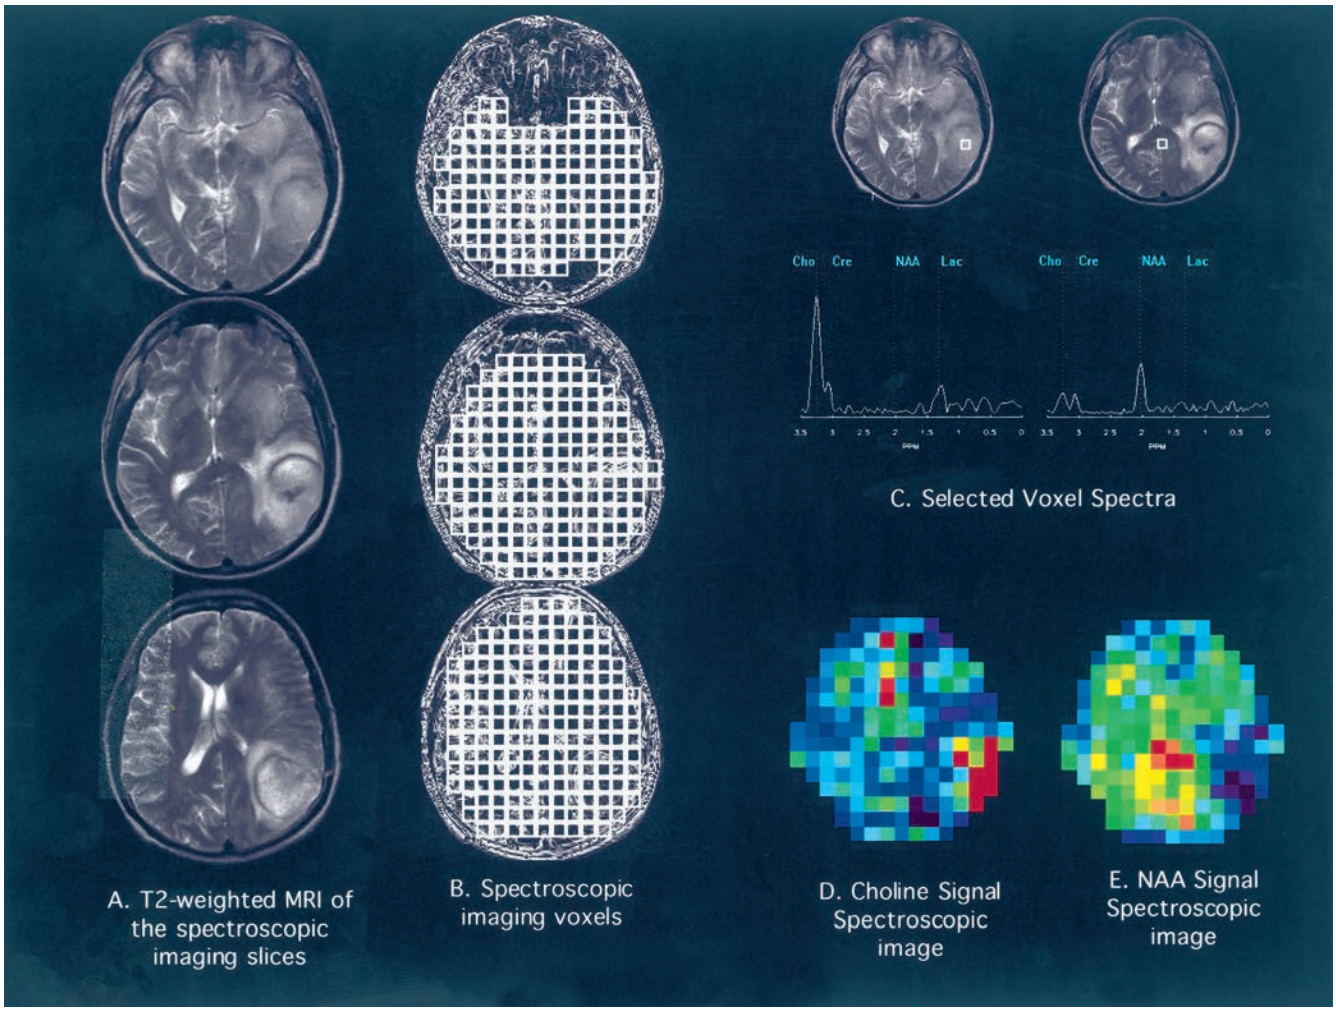


Fig. 11.4. MRI and MRS from a patient later found to have glioblastoma multiforme. (*a*) MRIs at three levels. (*b*) Locations of spectroscopic imaging voxels. (*c*) Images and spectra from voxels in tumour (left) and adjacent normal brain. (*d*), (*e*) Spectroscopic images made from the choline and NAA signals, showing the former elevated in the tumour and the latter depressed.

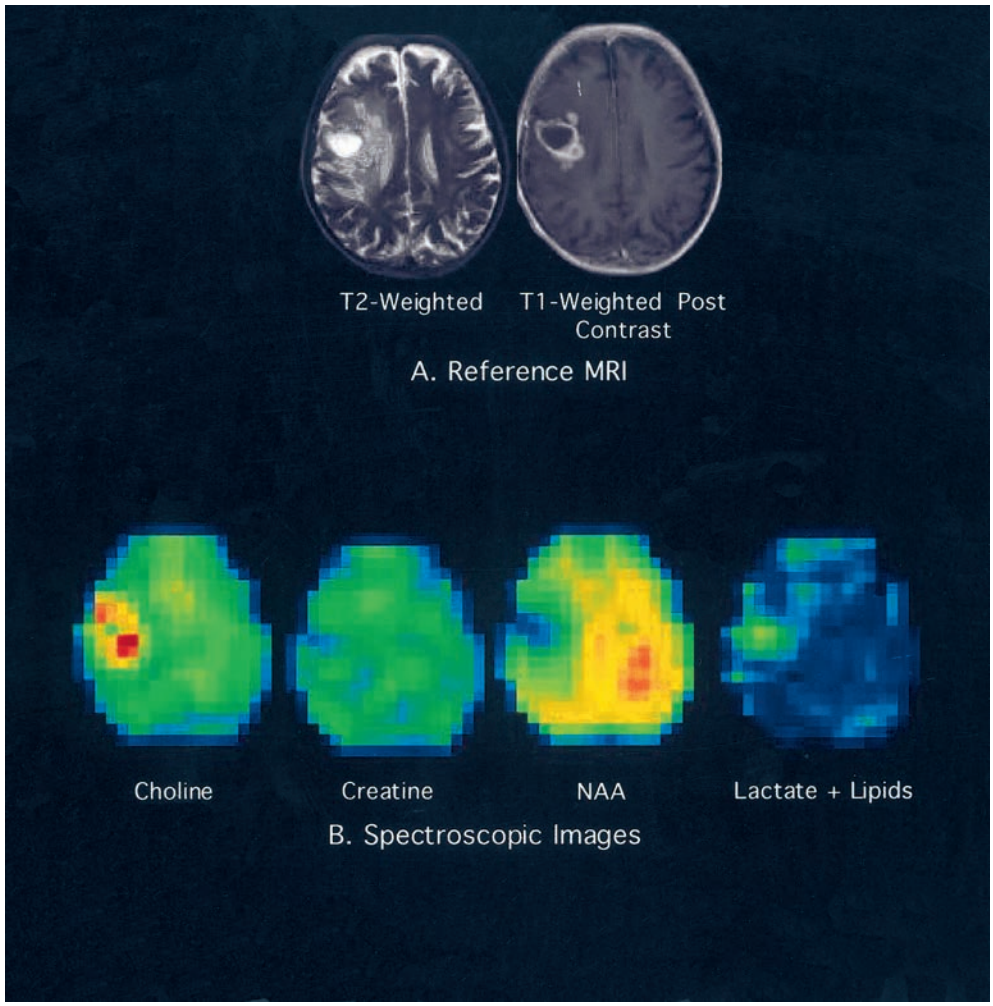

Fig. 11.5. MRI and MRS from a second patient later found to have glioblastoma multiforme. (*a*) MRIs showing the tumour. (*b*) Spectroscopic images showing elevated choline, lactate and lipid signals and depressed creatine and NAA signals associated with the tumour.

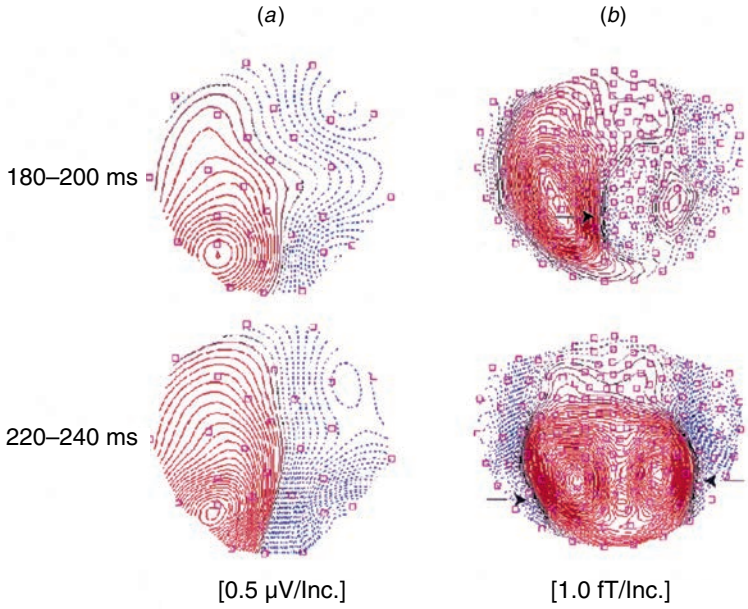

Fig. 12.1. ERP scalp distribution (*a*) and magnetic field distribution (*b*) of the N2pc component in two subsequent time windows (180–200 ms, 220–240 ms). Red lines indicate positive voltage of the potential distribution in (*a*) and magnetic flux leaving the cortex in (*b*). Note, polarities have relative character due to the direction of subtraction (LVF minus RVF targets) that was arbitrarily chosen. Arrows in (*b*) indicate locations of underlying current dipoles.

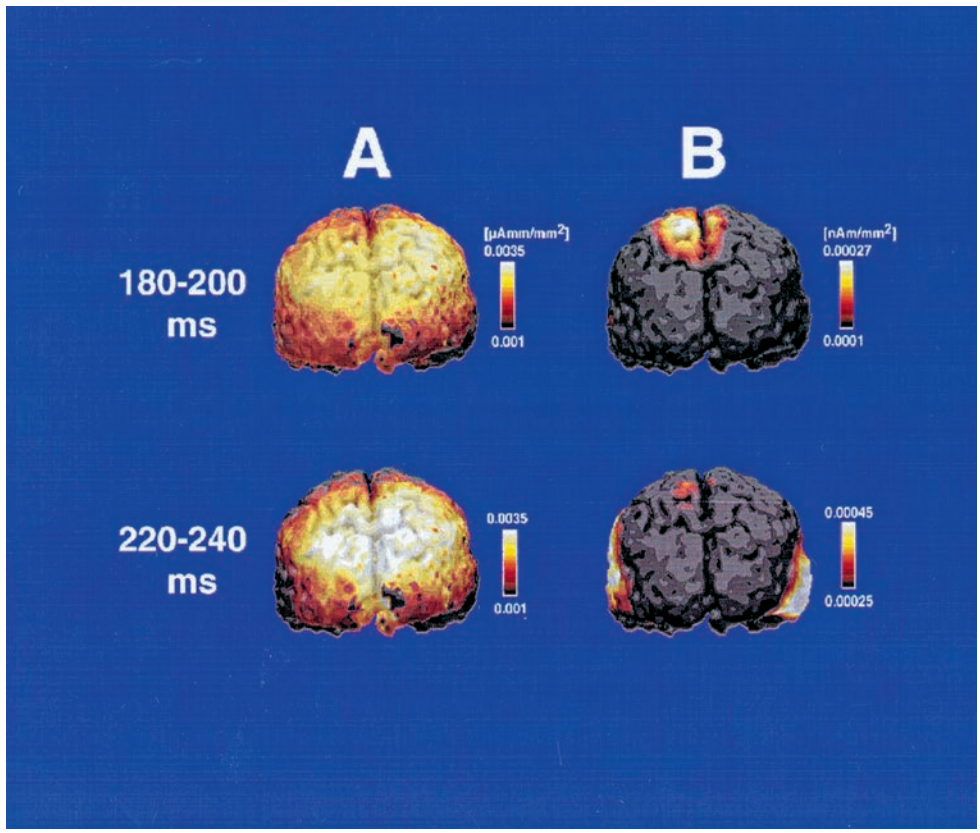

Fig. 12.2. Source density estimates (minimum norm least square) for the N2pc-component based on ERP difference waves (LVF minus RVF targets) (*a*) and MEG difference waves (*b*) in the early (180–200 ms) and late (220–240 ms) time window.

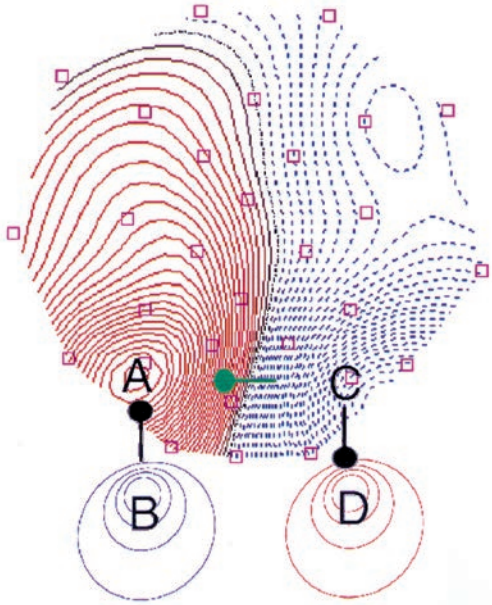

Fig. 12.3. An illustration of the erroneous link between ERP field components that gives rise to the discrepant source density estimates for ERP and MEG data as shown in Fig. 12.2. The measured ERP distribution between 220 and 240 ms is schematically completed by field components (*b*) and (*d*) that could not be picked up with the used electrode array, but are strongly implied by the magnetic field configuration. Specifically, linking field component (*a*) to (*b*) and (*c*) to (*d*) would give rise to source configurations as indicated by black dipoles. In contrast, the green dipole illustrates the potential mislocalization due to erroneous linkage of (*a*) and (*c*).

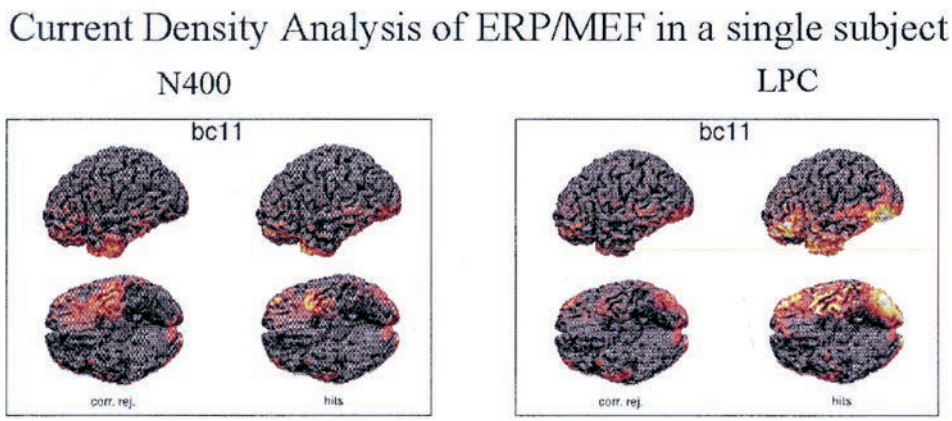

Fig. 12.4. *Upper part:* Single subject current density analysis for hits and correct rejections in the N400 time window and the LPC time window performed by taking into account the subjects 3D MRI. Red colours indicate areas of high current flows on the brain surface that account for the recorded electric and magnetic activity. It can be seen that in the N400 time window, correct rejections induce stronger current flows in the left anterior temporal lobe than hits. In contrast, hits induce stronger current flows in the posterior inferior temporal lobe than correct rejections.

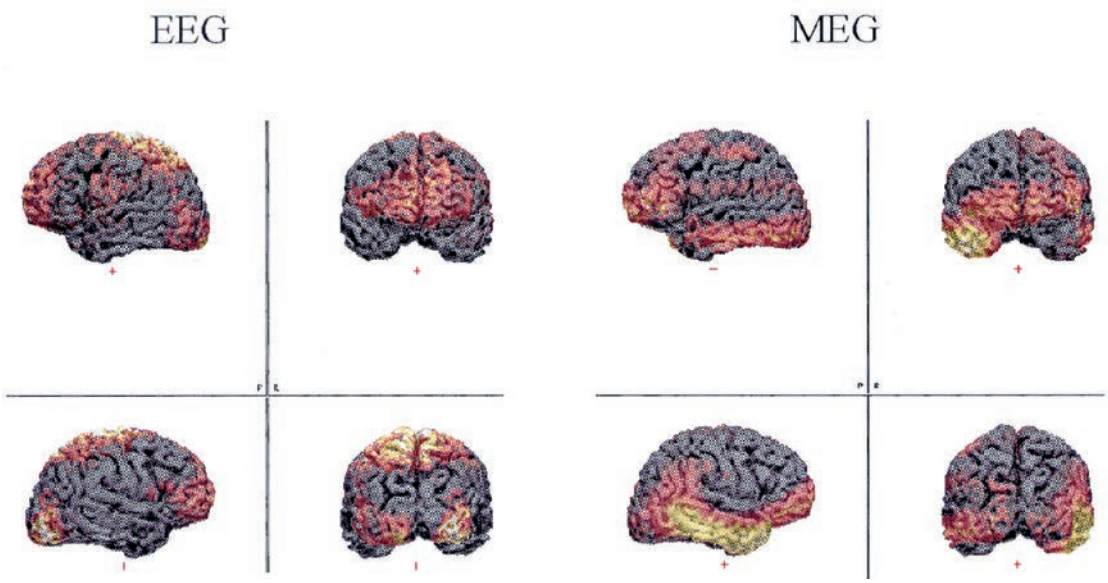

Fig. 12.7. Single subject current density analysis of EEG and MEG measured 200 ms prior to a motor response indicating the completion of a word fragment. While the MEG data reveal, in accord with a concurrent fMRI study, bilateral temporal activity, source analysis based on EEG data alone indicate a prominent parieto-central source.

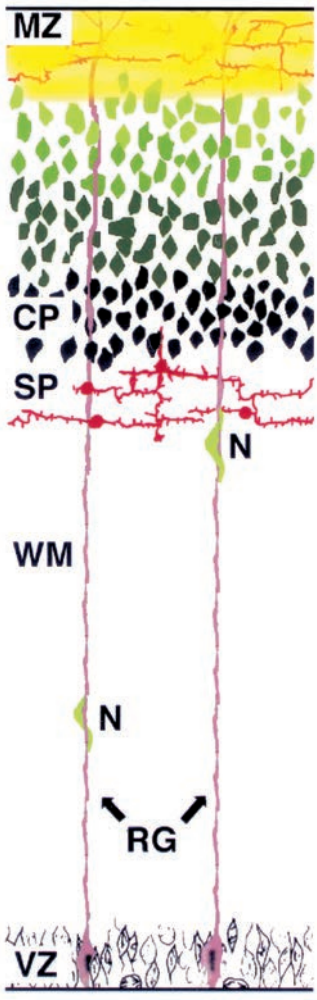

Fig. 13.1. A scheme of glia-guided migration. Postmitotic neurons (N), which are born in the ventricular zone (VZ), migrate along the radial glial fibres (RG) through the developing white matter (WM) and the subplate layer (SP) into the cortical plate (CP). They are added to the cortical plate in an 'inside-out' fashion, and stop immediately underneath the marginal zone (MZ). Reelin protein in the marginal zone (represented by yellow colour) serves as an apparent 'stop signal' for the neurons (see text).

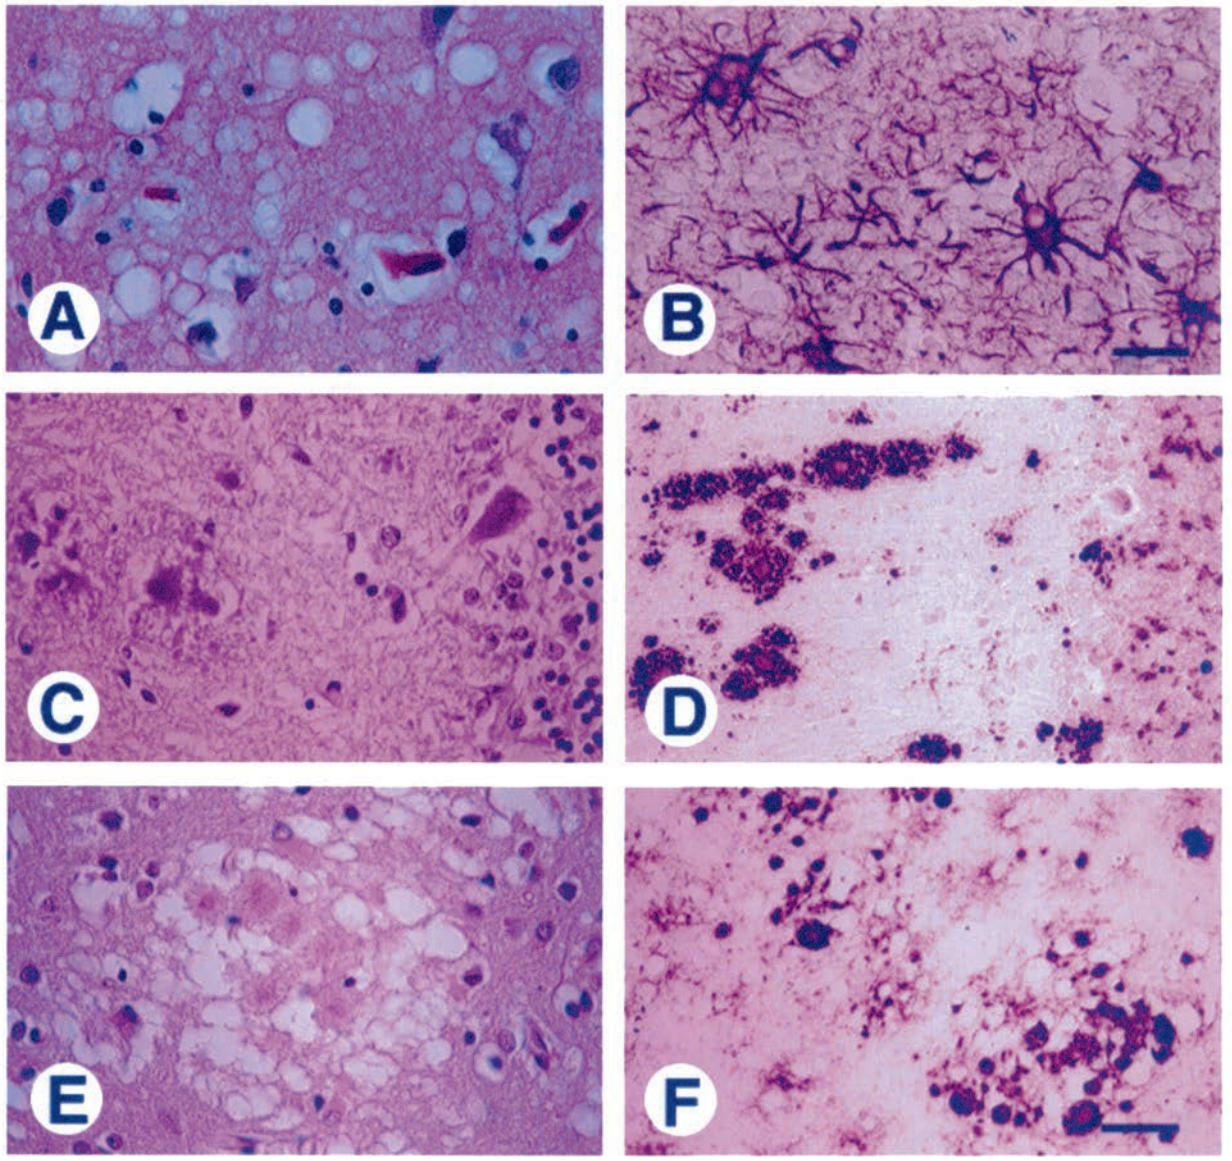

Fig. 15.4. Neuropathology of human prion diseases. Sporadic CJD is characterized by vacuolation of the neuropil of the grey matter, by exuberant reactive astrocytic gliosis, the intensity of which is proportional to the degree of nerve cell loss, and rarely by PrP amyloid plaque formation (not shown). The neuropathology of familial CJD is similar. GSS(P102L), as well as other inherited forms of GSS (not shown), is characterized by numerous deposits of PrP amyloid throughout the CNS. The neuropathological features of nvCJD are unique among CJD cases because of the abundance of PrP amyloid plaques that are often surrounded by a halo of intense vacuolation. (*a*) Sporadic CJD, cerebral cortex stained with hematoxylin and eosin showing widespread spongiform degeneration. (*b*) Sporadic CJD, cerebral cortex immunostained with anti-GFAP antibodies demonstrating the widespread reactive gliosis. (*c*) GSS, cerebellum with most of the GSS-plaques in the molecular layer (left 80% of micrograph), and many but not all are periodic acid Schiff (PAS) reaction positive. Granule cells and a single Purkinje cell are seen in the right 20% of the panel. (*d*) GSS, cerebellum at the same location as panel C with PrP immunohistochemistry after the hydrolytic autoclaving reveals more PrP plaques than seen with the PAS reaction. (*e*) New variant CJD, cerebral cortex stained with hematoxylin and eosin shows the plaque deposits uniquely located within vacuoles. With this histology, these amyloid deposits have been referred to as 'florid plaques'. (*f*) New variant CJD, cerebral cortex stained with PrP immunohistochemistry after hydrolytic autoclaving reveals numerous PrP plaques often occurring in clusters as well as minute PrP deposits surrounding many cortical neurons and their proximal processes. Bar in (*b*) = 50 mm and applies also to panels (*a*), (*c*) and (*e*). Bar in (*f*) is 100 mm and applies also to panel (*d*). Photomicrographs prepared by Stephen DeArmond. (New variant CJD specimens provided by James Ironside, Jeanne Bell, and Robert Will.)

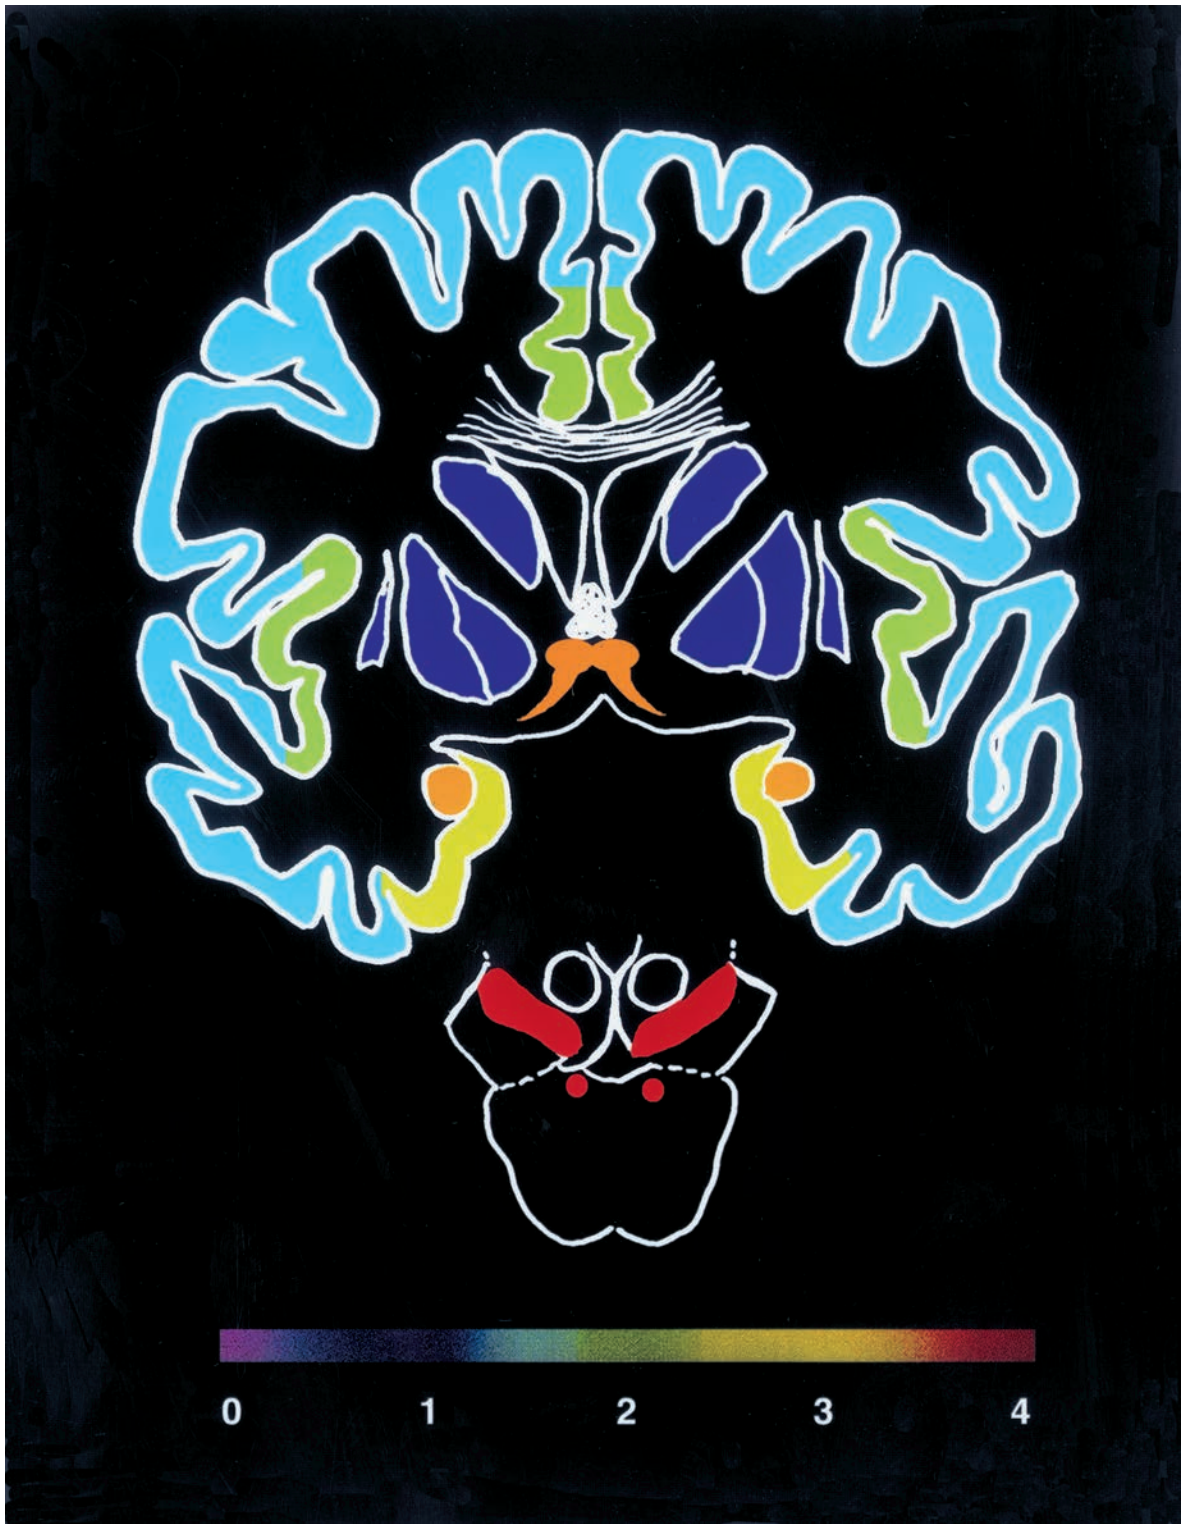

Fig. 18.2. A colour representation of the topography of Lewy bodies plotted onto a coronal human brain section at the level of the amygdala based on Lewy body density data from Gómez-Tortosa et al. (1999). The colour bar indicates red as the greatest quantity and blue as the least.

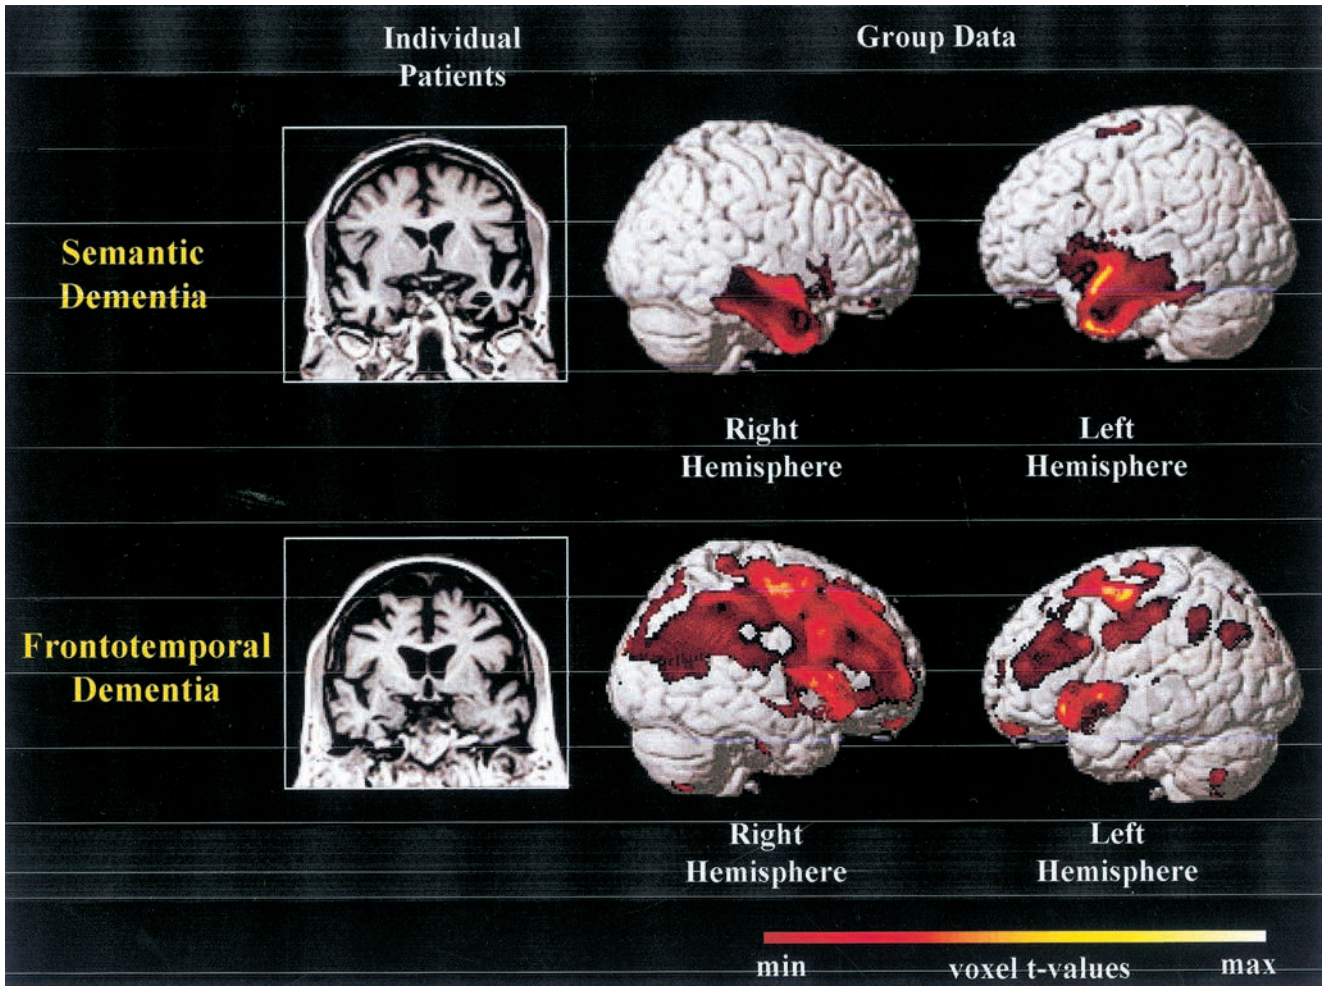

Fig. 19.1. Differing patterns of atrophy in patients with FTD are illustrated. On the left, coronal slices from T1-weighted MRI images in two individual patients are shown. The patient on top shows predominantly frontal atrophy, while the patient on the bottom shows predominantly temporal atrophy, more severe on the left. On the right, group data from a formal analysis of twenty patients with FTD are shown. Twenty patients with FTD were divided into two groups, those with ($N=12$, top) and without ($N=8$, bottom) semantic impairment, and compared with twenty age matched controls subjects. Anatomical analysis was performed using voxel-based morphometry, a technique that allows automated detection of regional atrophy (Ashburner & Friston, 2000). The *t*-values at the regions where atrophy was significant in each group ($P<0.001$) are superimposed on a normal brain. The group with semantic impairment shows atrophy predominantly in the anterior temporal regions, while the group without semantic impairment shows predominantly frontal atrophy. These data illustrate how specific clinical syndromes are associated with specific patterns of cerebral atrophy in FTD.

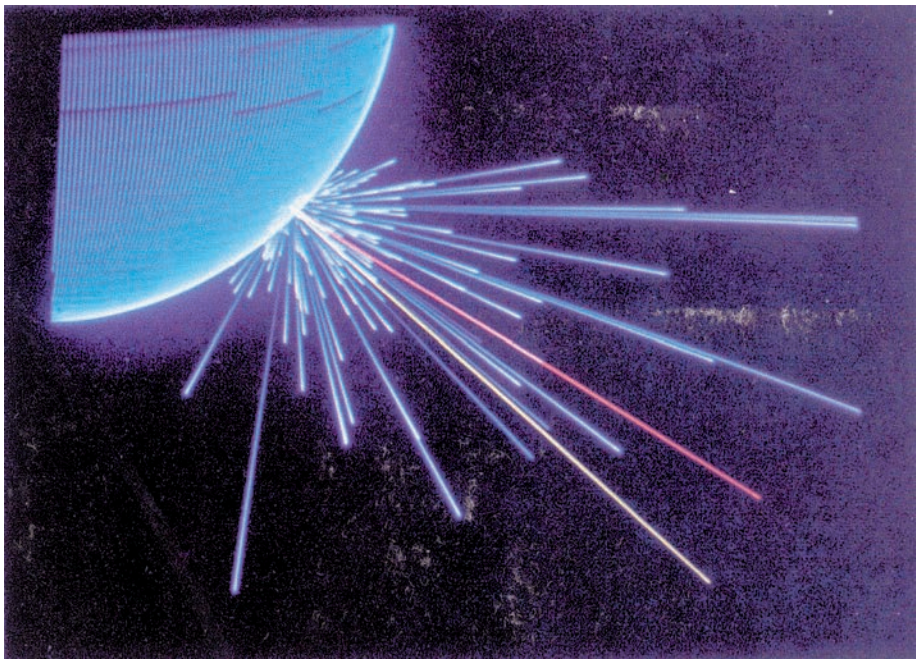

Fig. 31.5. An example of the population coding of movement direction. The blue lines represent the vectorial contribution of individual cells in the population ($N = 475$). The actual movement direction is in yellow and the direction of the population vector is in red. (From Georgopoulos et al., 1986, figure 1.)

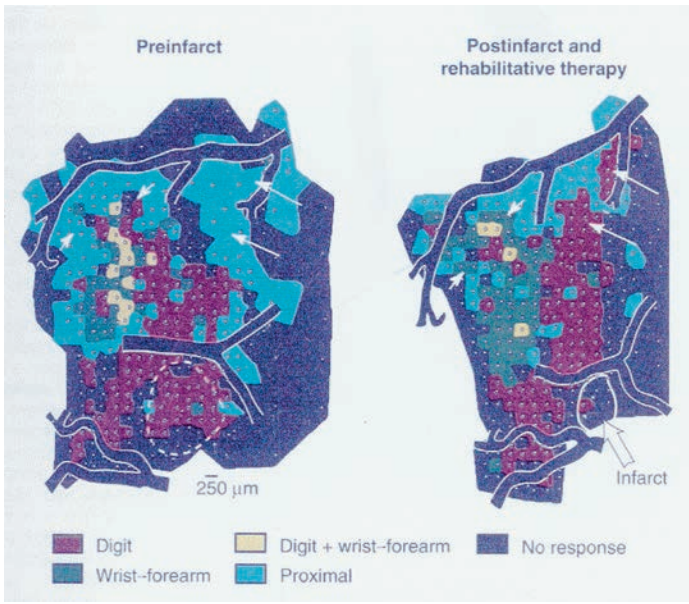

Fig. 31.8. Reorganization of hand representations in the primary motor cortex associated with rehabilitation following ischemic infarct. The volume circumscribed by a dashed line in the preinfarct map shows the area targeted for infarction, the solid line in the postinfarct map indicates the infarcted region. Digit representations all but disappear from the area of the infarct but after rehabilitation have invaded areas of cortex previously occupied by more proximal arm muscles (long thin arrows). In addition, the representation of the wrist–forearm expanded into areas previously occupied by shoulder (short thick arrows). (Adapted from Nudo et al., 1996, figure 3.)

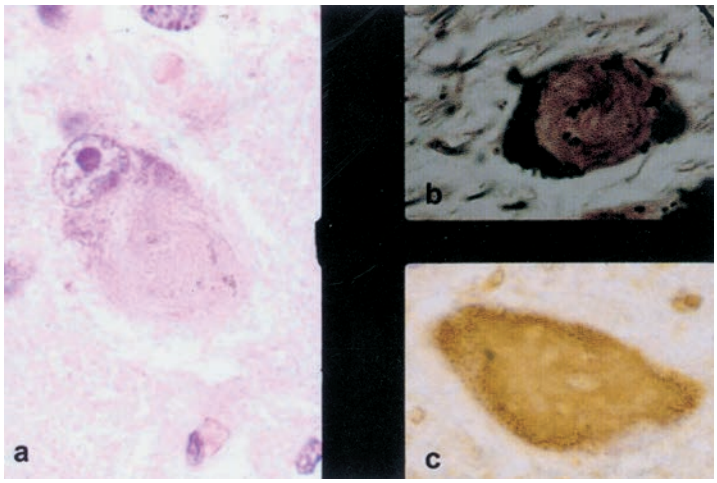

Fig. 34.1. Progressive supranuclear palsy ultrastructural pathology showing a typical globose neurofibrillary tangle in the substantia nigra stained with hematoxylin eosin (*a*); Bieschowsky's silver impregnation (*b*); tau immunohistochemistry (*c*). (Courtesy Dr Tamas Revesz, Dept of Neuropathology, Institute of Neurology, London.)

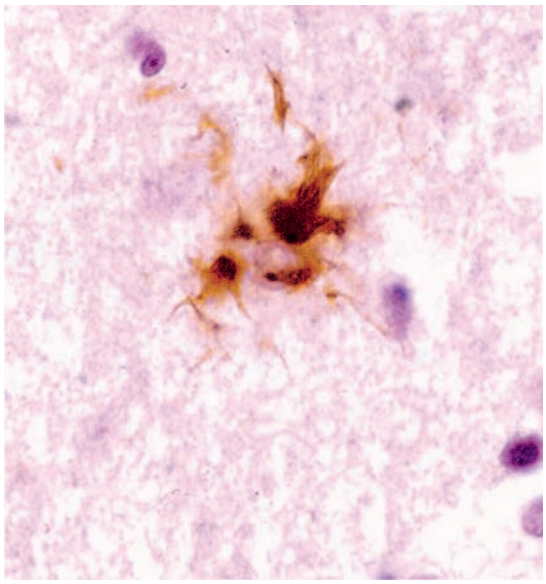

Fig. 34.2. Progressive supranuclear palsy ultrastructural pathology showing a typical tufted astrocyte in the motor cortex. Tau immunohistochemistry. (Courtesy Dr Tamas Revesz, Dept of Neuropathology, Institute of Neurology, London.)

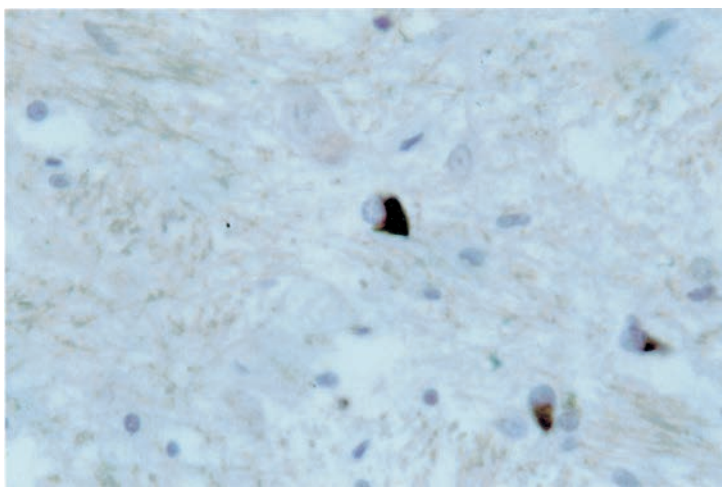

Fig. 34.5. Olgodendroglial inclusion seen in multiple system atrophy. (Gallyas stain). (Courtesy Prof. Francesco Scaravilli Institute of Neurology, London.)

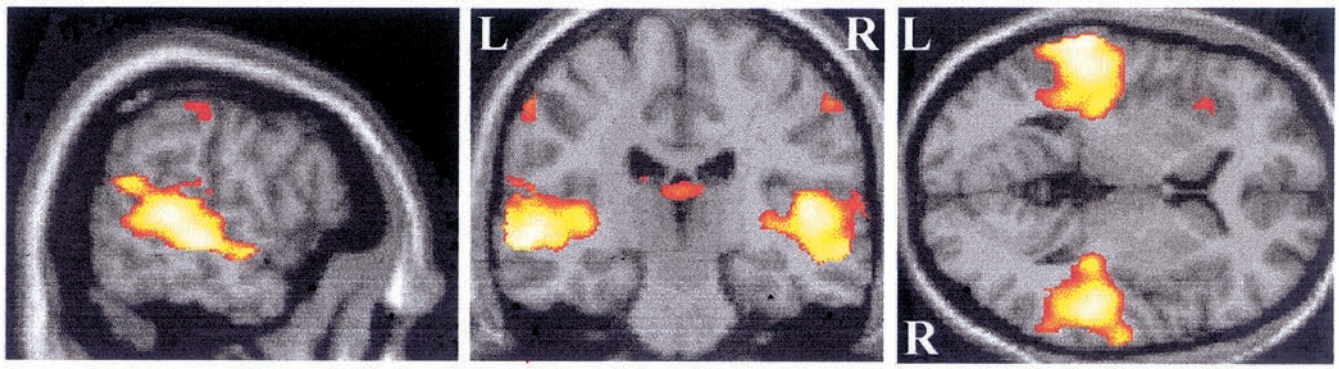

Fig. 45.11. Functional MRI: Activation of temporal cortex during (*a*) passive listening and (*b*) active listening to modulated tones projected into sagittal, coronal and axial planes; both A and B show that the volume of temporal activation is greater on the left side in both passive and active listening; only active listening produces activation in other areas (in this illustration, bilateral postcentral gyri and left insula cortex). (Hall et al., 2000.)

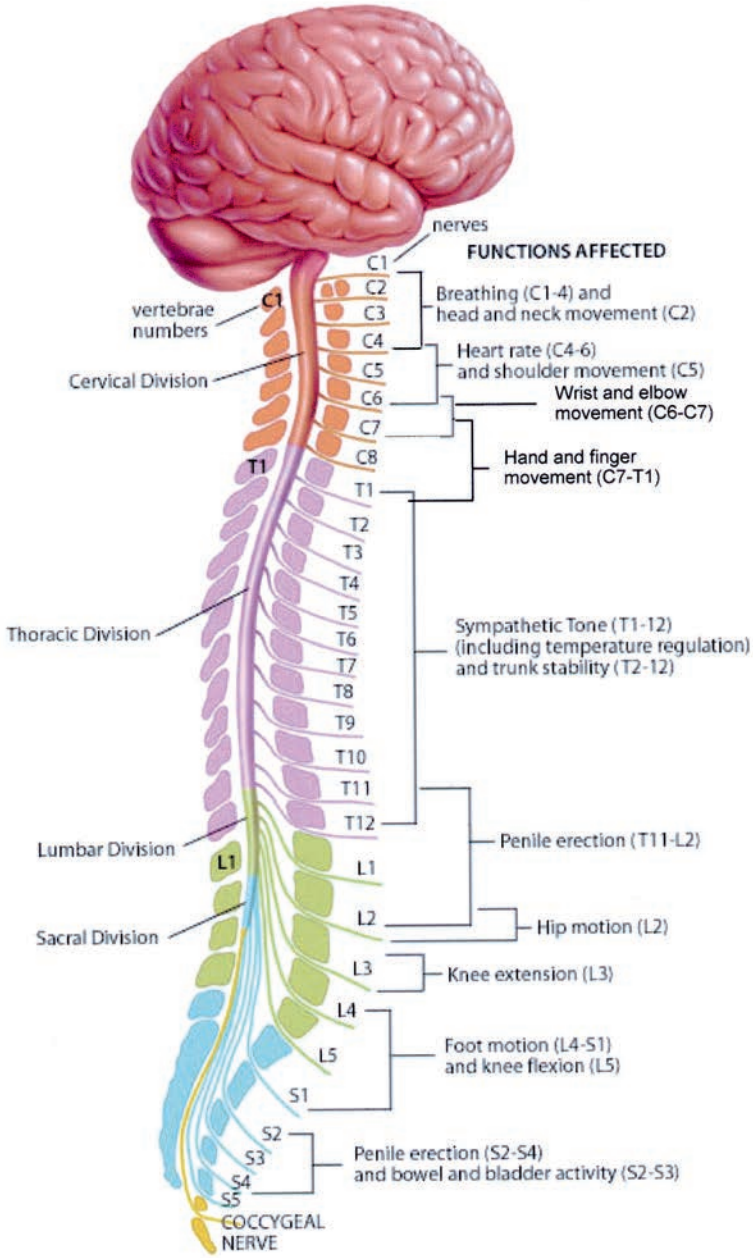

Fig. 47.2. Four divisions of the spinal cord and their associated nerves serve specific areas of the body. In general, the cervical nerves link to the neck, arms and respiratory apparatus; the thoracic nerves control posture and many internal organs; the lumbar nerves work the legs; and the sacral nerves regulate the bladder and bowel and play a role in sexual function.

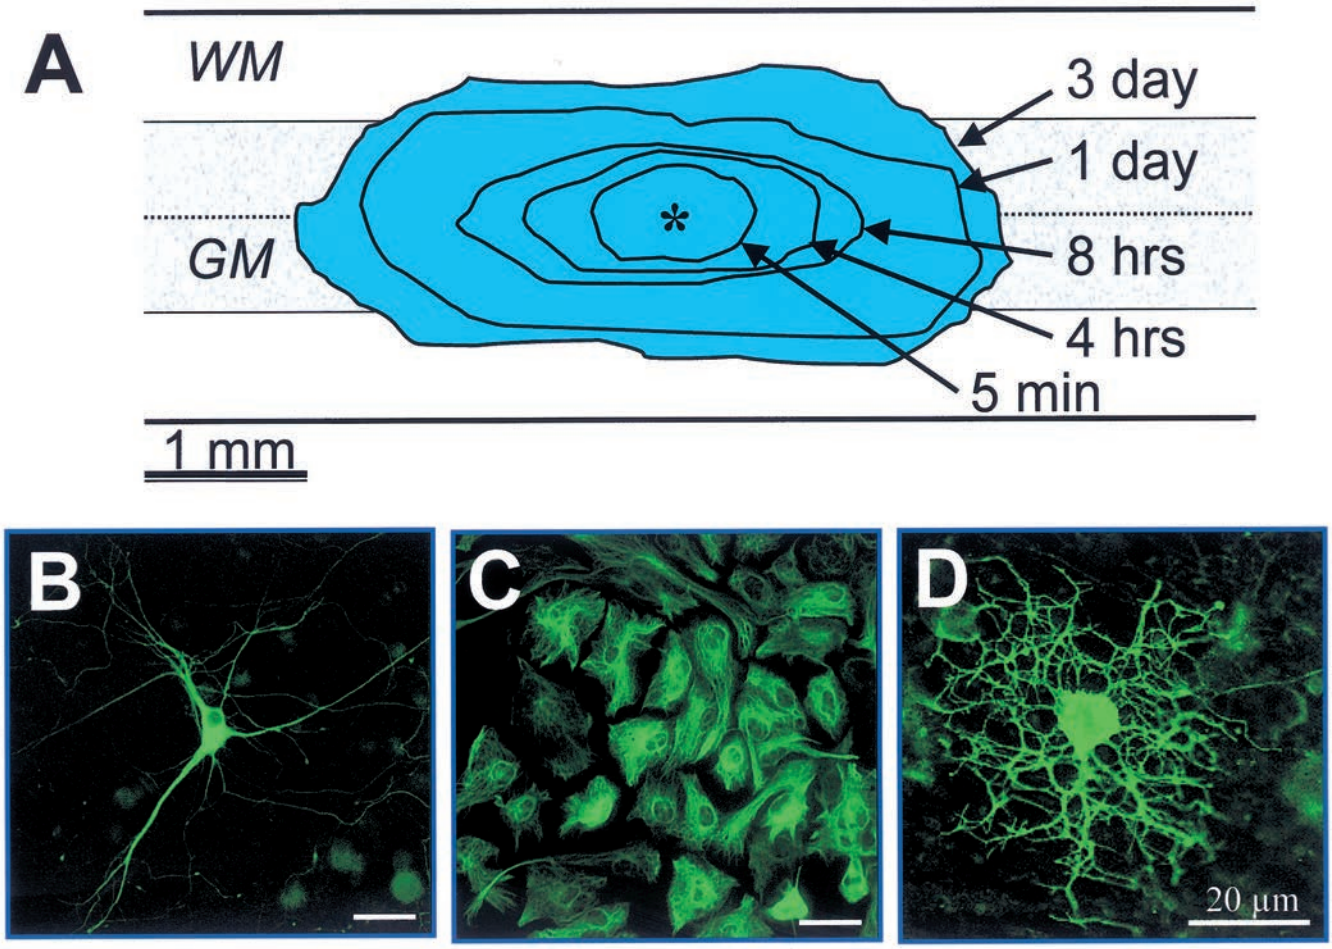

Fig. 47.3. (*a*) Schematic drawing illustrating lesion expansion over time in longitudinal sections through the central canal of rat spinal cords that sustained a moderate contusion injury. The cords were examined at 5 min, 4 and 8 h, and 1 and 3 days after the injury. *WM*, white matter; *GM*, grey matter. * Site of impact. (Adapted from Liu et al., 1997.) Panels (*b*)–(*d*) illustrate the three principal cell types of the central nervous system that are important for function and which are damaged following injury. The (*b*) neuron, (*c*) astrocyte, and (*d*) oligodendrocyte shown were derived from mouse embryonic stem cells, neurally induced with retinoic acid, and grown in culture for 9 days.

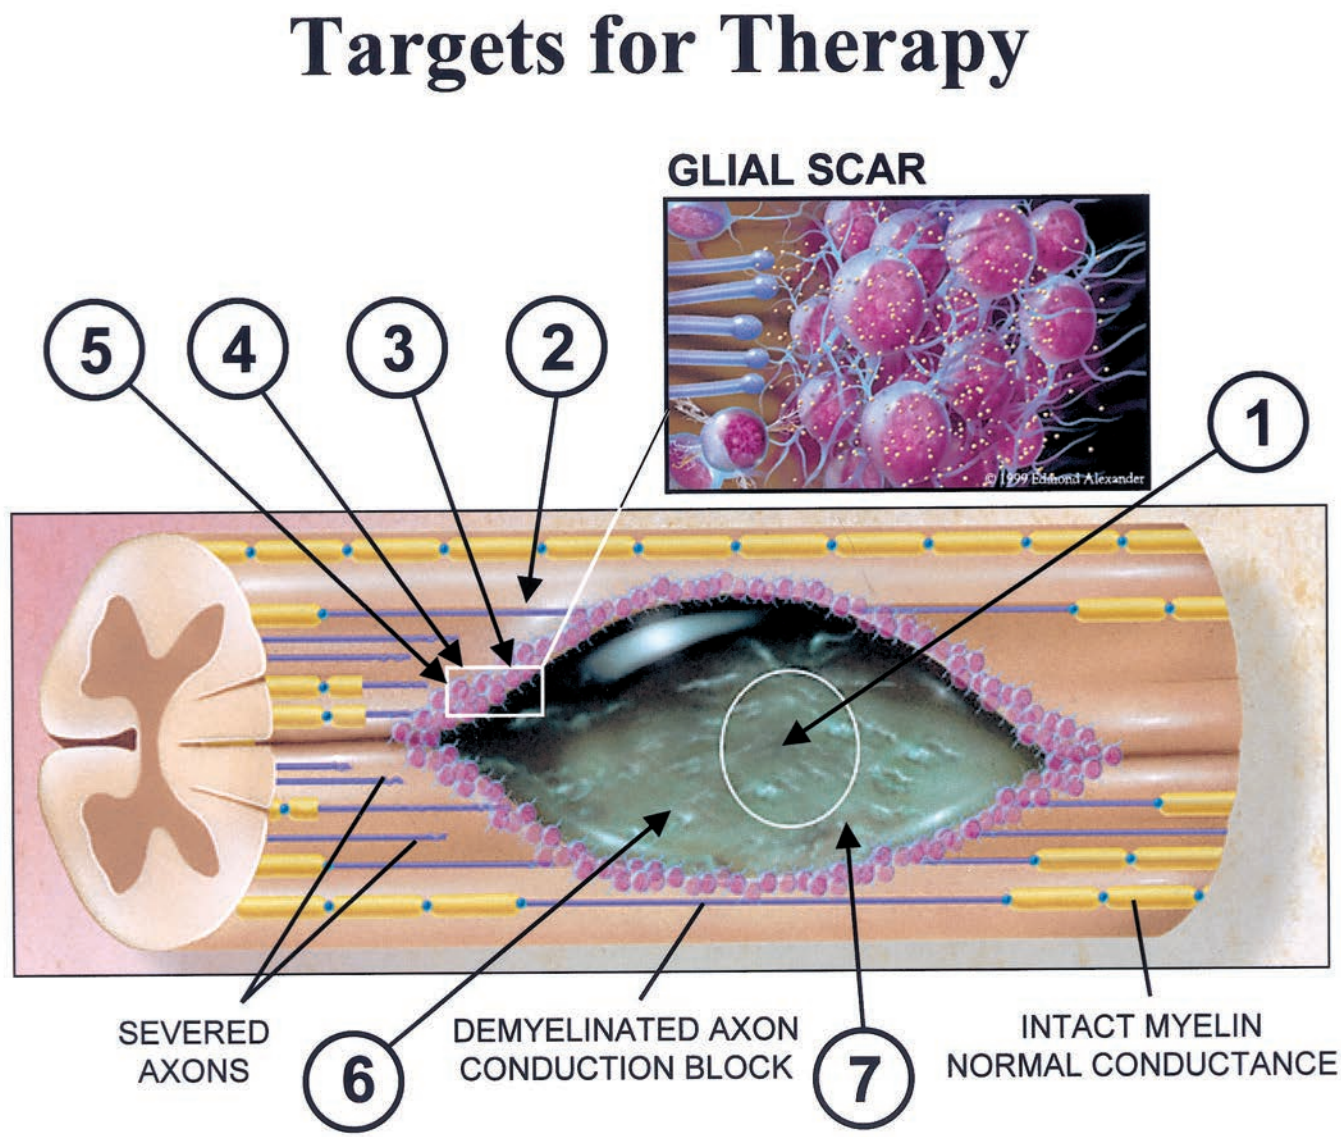

Fig. 47.5. Treatment of spinal cord injury will likely involve several interventions, delivered in an ordered sequence, each with incremental benefits. Illustrated are specific examples representing the different levels of intervention. 1. **Prevent progression of secondary injury**: Prevention of necrotic and apoptotic cell death using anti-excitotoxic drugs (glutamate-receptor blockers) and anti-apoptotic treatments (growth factors such as NT-3, BDNF, and ICE-protease inhibitors). 2. **Compensate for demyelination**: Supply chemicals that prevent action potentials from dissipating at demyelinated areas (prevent conduction block). Provide agents that encourage surviving oligodendrocytes to remyelinate axons. Replenish lost oligodendrocytes. 3. **Overcome inhibition**: Deliver agents that block the actions of natural inhibitors of regeneration (inhibitor neutralizing antibody, IN-1, masks an inhibitory protein) or drugs that down-regulate expression of inhibitory proteins. 4. **Promote axonal regeneration**: Delivery of growth factors that promote regeneration (sprouting) of new axons (e.g. NT-3, BDNF). 5. **Direct axons to proper targets**: Deliver targeting molecules or alter their expression in host cells to guide axons to appropriate targets. 6. **Create bridges**: Implant into the syrinx tissue that can serve as scaffolding for axons and that encourages them to grow (e.g. transplant peripheral nerves or cells competent to support axonal growth, such as ensheathing glia, into the empty syrinx). 7. **Replace lost cells**: Implant cells able to produce all the lost types (e.g. stem cells or ES cells). Deliver substances that can induce undifferentiated cells already in the cord to replace dead cells. In addition to replacing cells, transplanted cells can be used as cellular genetic vectors to deliver regenerative molecules on command (e.g. vectors producing NT-3, bFGF, or PDGF). (Figure reproduced with permission from *Scientific American* (McDonald et al., 1999).)

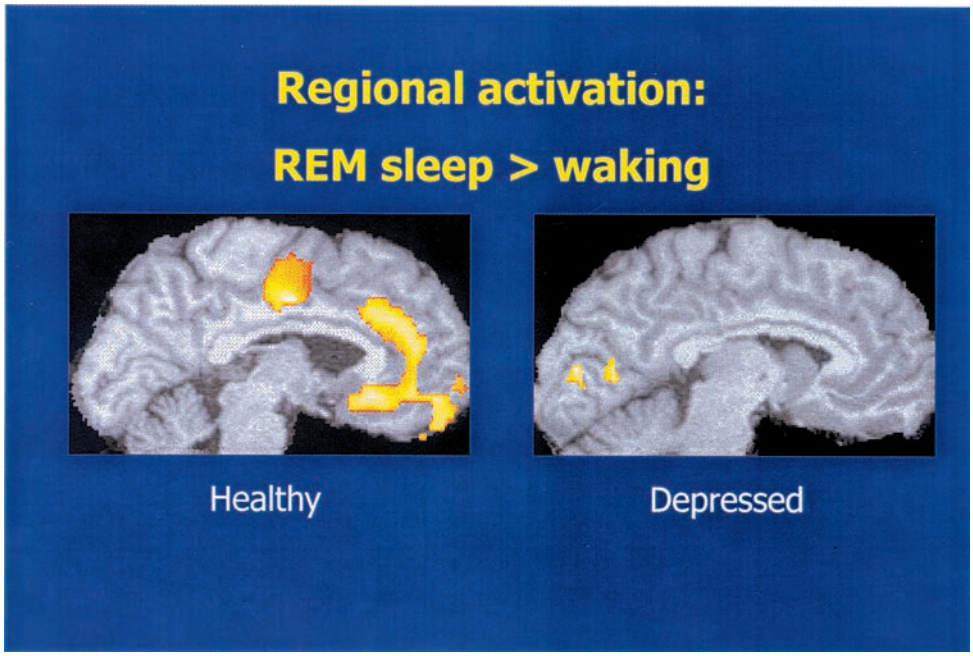

Fig. 55.4. PET studies of REM sleep. See text for description.

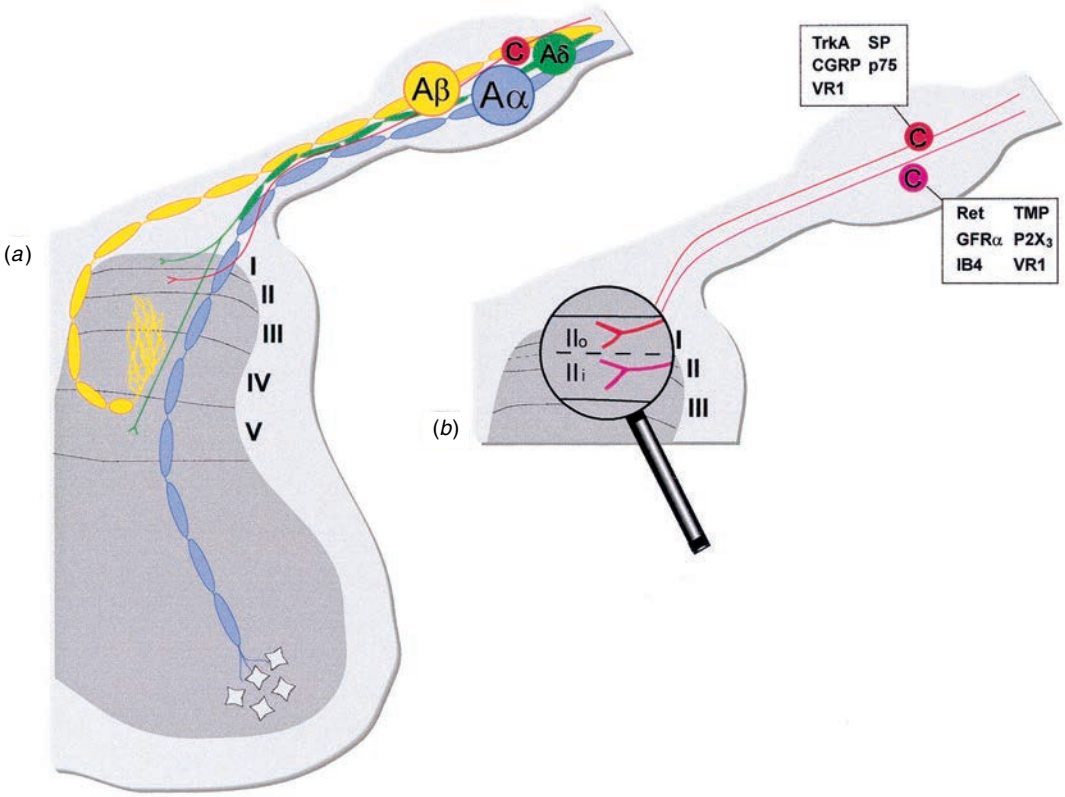

Fig. 58.2. (*a*) Subpopulations of primary sensory neurons synapse in a lamina-specific manner within the dorsal horn. (*b*) Within the C-fibre population of sensory neurons, different chemically defined cells synapse in different parts of lamina II.

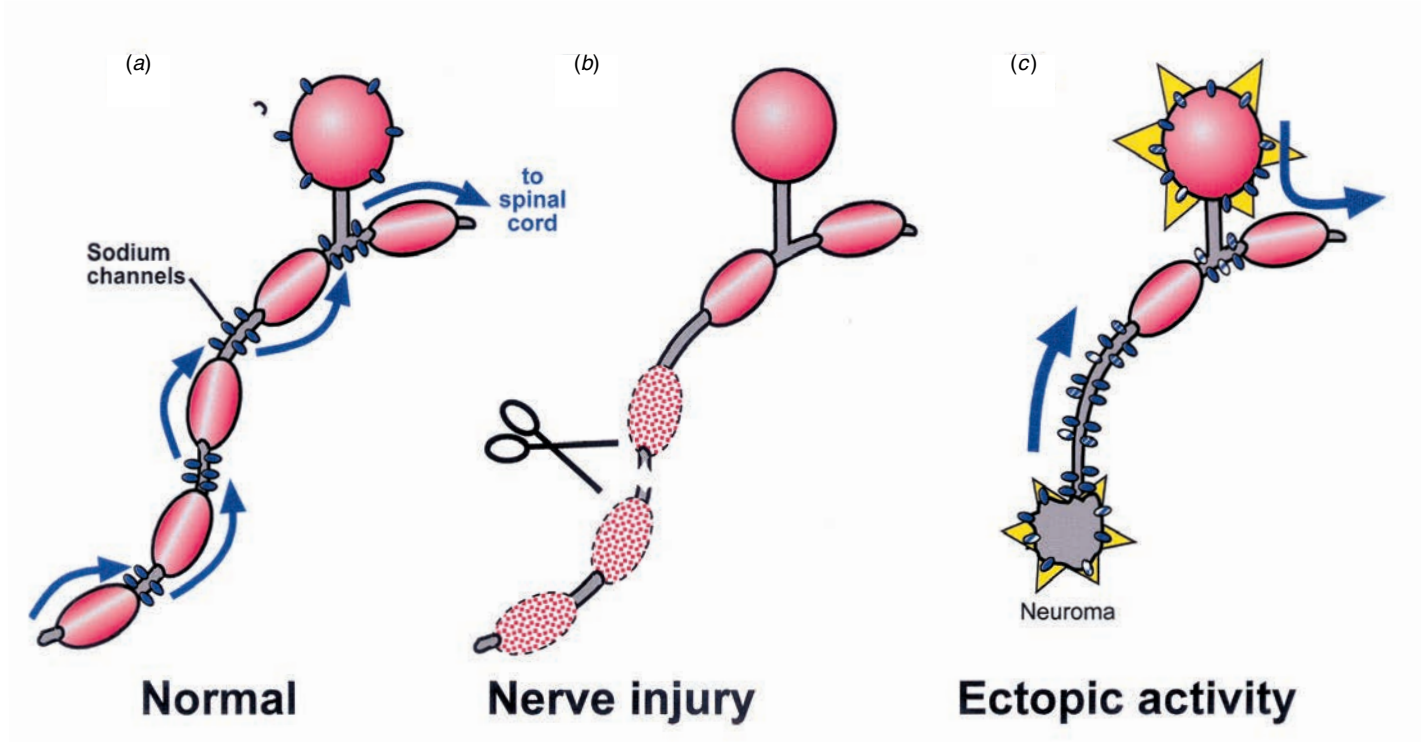

Fig. 58.5. (*a*) In sensory neurons with myelinated axons, fast saltatory conduction of action potentials occurs along the axon at speeds up to 100 metres/second, mediated in part by the expression and discrete localization of voltage gated sodium channels (VGSCs) at the Nodes of Ranvier. (*b*) Following nerve injury, the distal axon segment undergoes Wallerian degeneration, and the Schwann cells lining the end of the proximal axon dedifferentiate and stop producing myelin. (*c*) Injured sensory neurons then display ectopic discharge at the neuroma site, proximally on the axon and from the cell body as a consequence of altered ion channel expression, altered ion channel membrane organization and altered ion channel properties. Note that ectopic activity is also observed in adjacent uninjured fibres following nerve injury.

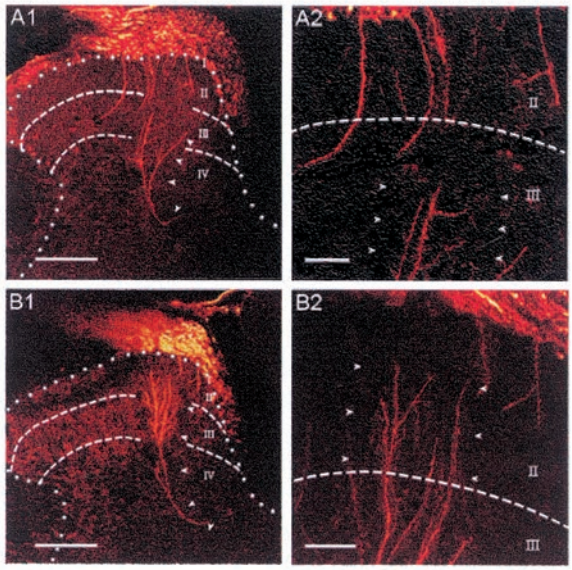

Fig. 58.12. (*a*) Normally, Aβ-fibre central terminals in the ipsilateral dorsal horn synapse within the deeper laminae (II and IV) and those innervating the skin have a characteristic flame shaped central arbour (arrow heads). (*b*) Two weeks after nerve injury in laboratory animals, Aβ-fibre central terminals sprout dorsally into laminae I and II, a region normally innervated only by C-fibres. (Printed with permission from Kohama et al., 2000.)

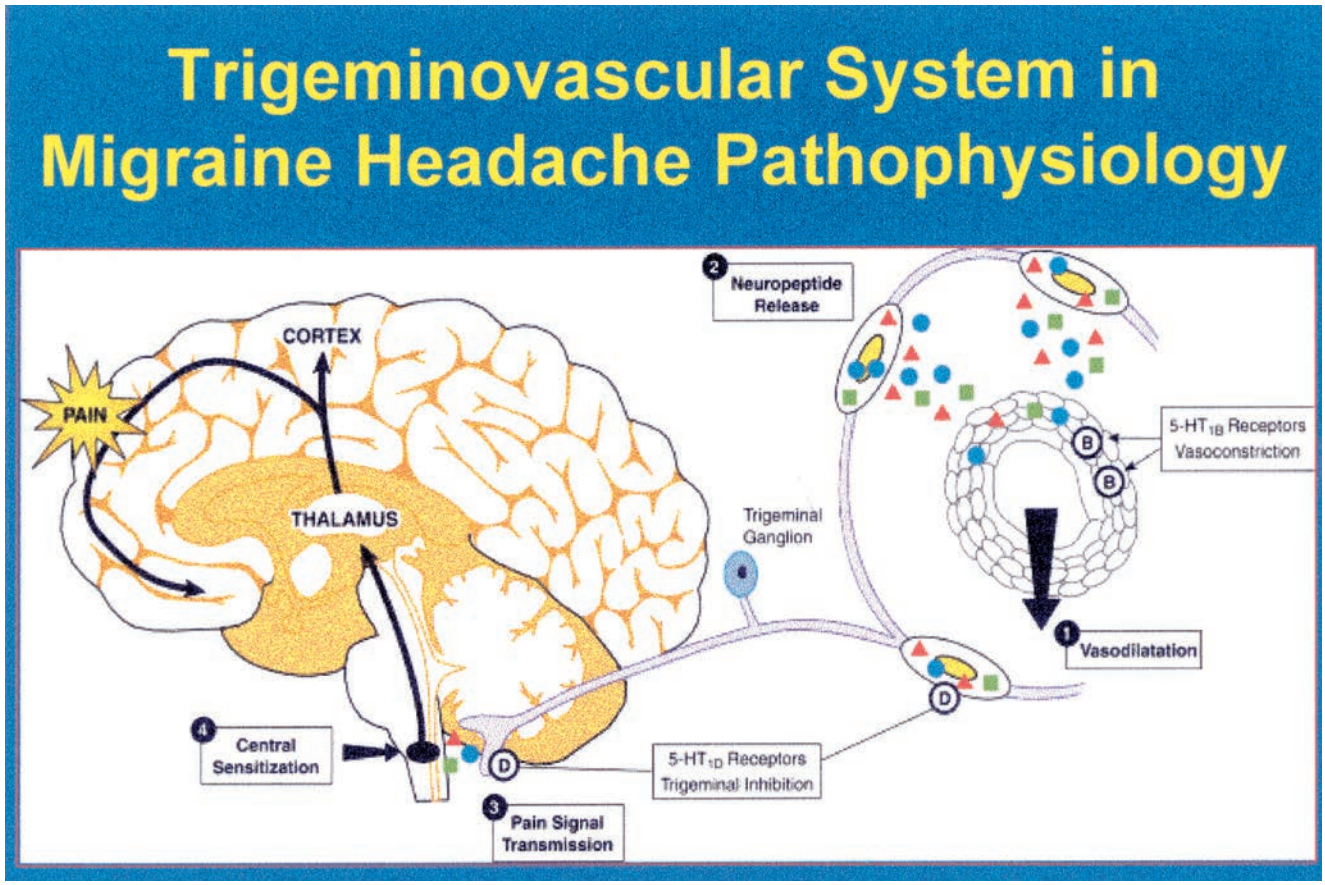

Fig. 61.1. Integrated hypothesis of the pathogenesis of the migraine headache and associated symptoms, and the role of the trigeminovascular system. For explanation, see the various sections in the text.

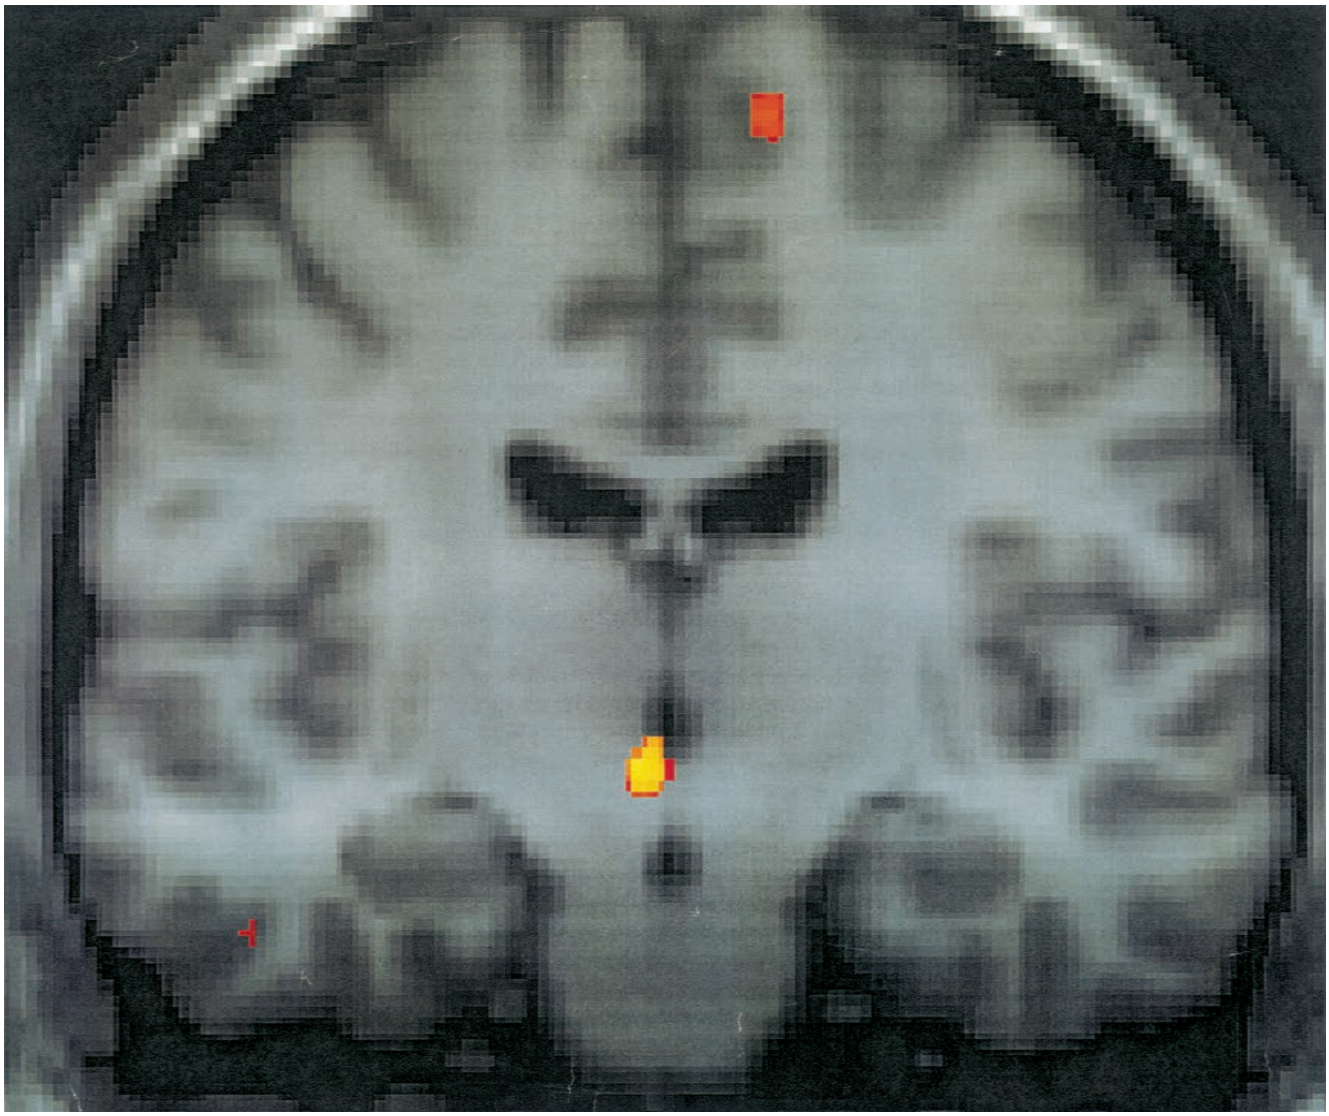

Fig. 62.1. Positron emission tomography (PET) in acute cluster headache illustrating activation in the posterior hypothalamic grey matter. This area is active only in acute cluster headache and not in migraine, nor experimental head pain. It is likely that the crucial neurons responsible for the fundamental pathophysiology of cluster headache are to be found in this region (May et al., 1998).

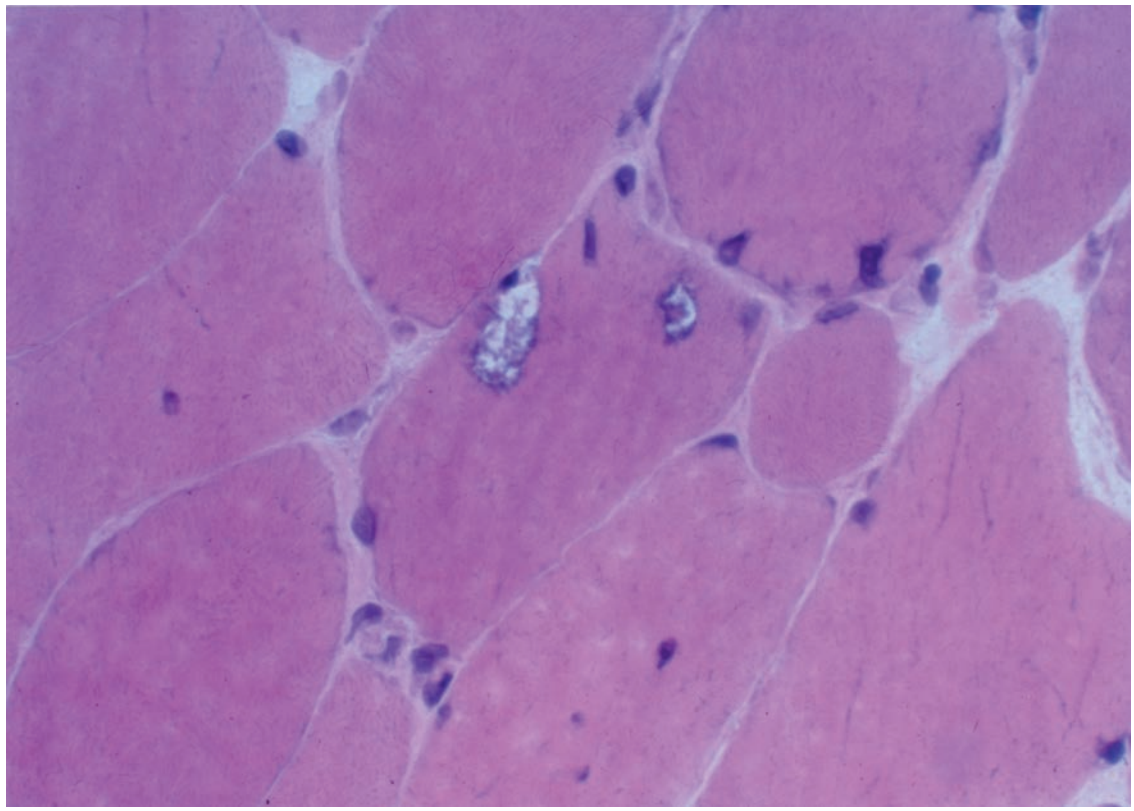

Fig. 70.11. Inclusion body myositis muscle biopsy. Gomori trichrome stain showing characteristic rimmed vacuole. Such vacuoles are not specific for IBM and occur in various other inclusion body myopathies.

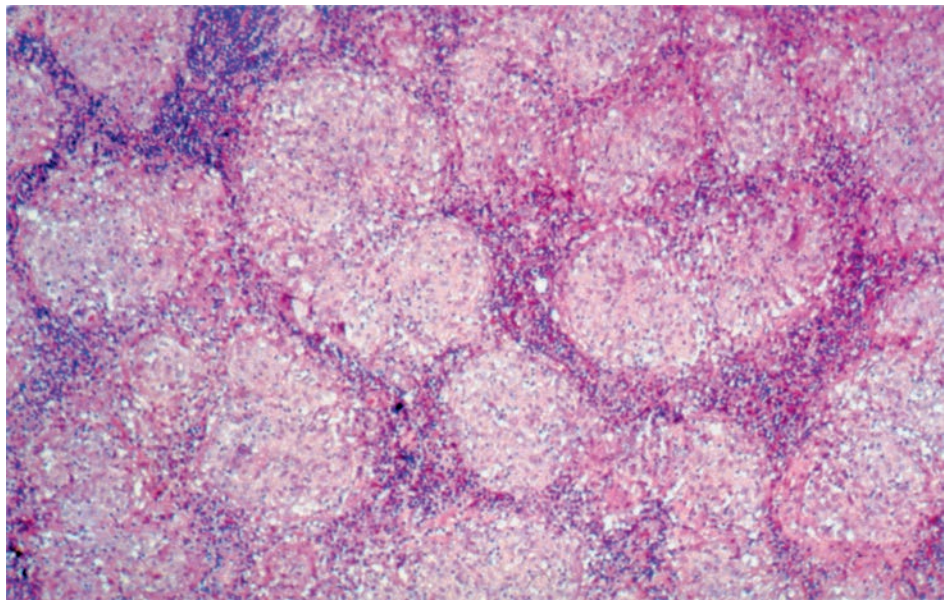

Fig. 95.3. Photomicrograph of mediastinal lymph node biopsy showing numerous non-caseating granulomata. (From Photographic Case Studies in Neurology: Cerenex Pharmaceuticals.)

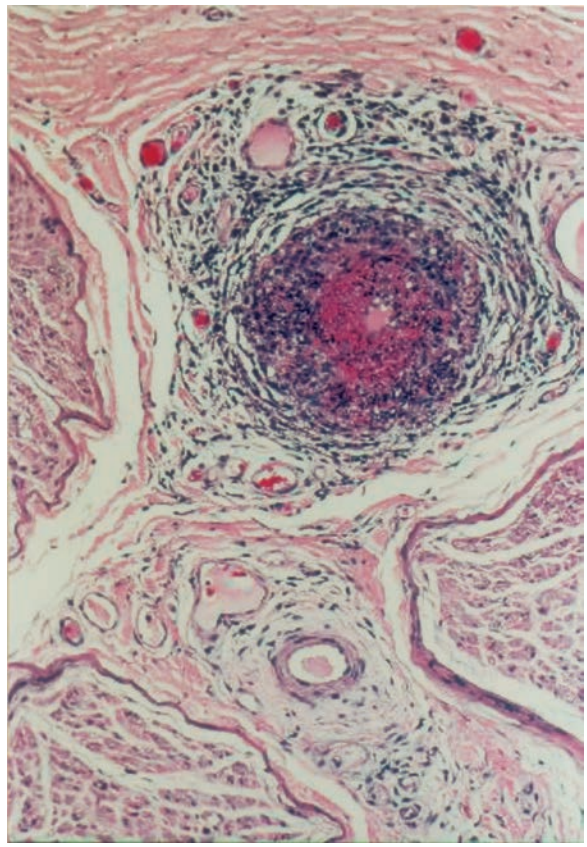

Fig. 96.3. Severe vasculitic neuropathy in polyarteritis nodosa. Inflammation extends through the wall of the blood vessel.

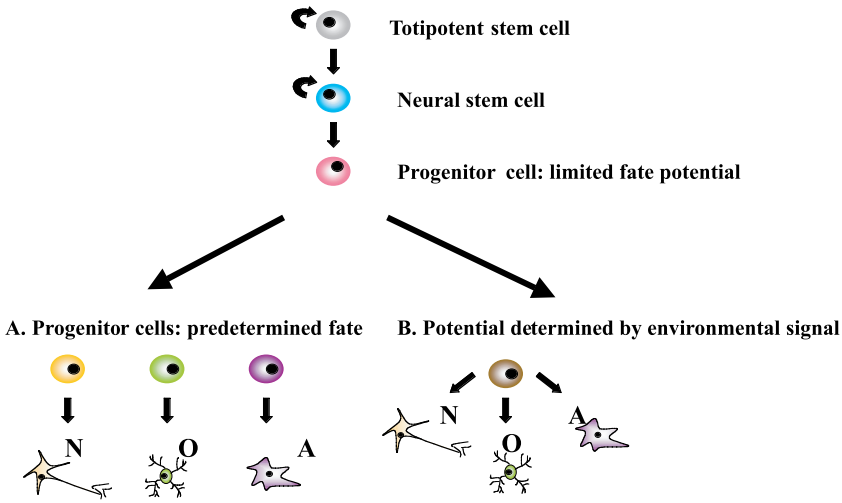

Fig. 97.1. Stem cells self-replicate and generate fate-committed progeny which differentiate into neurons, astrocytes and oligodendrocytes. (Kindly prepared by Dr Siddarthan Chandran.)

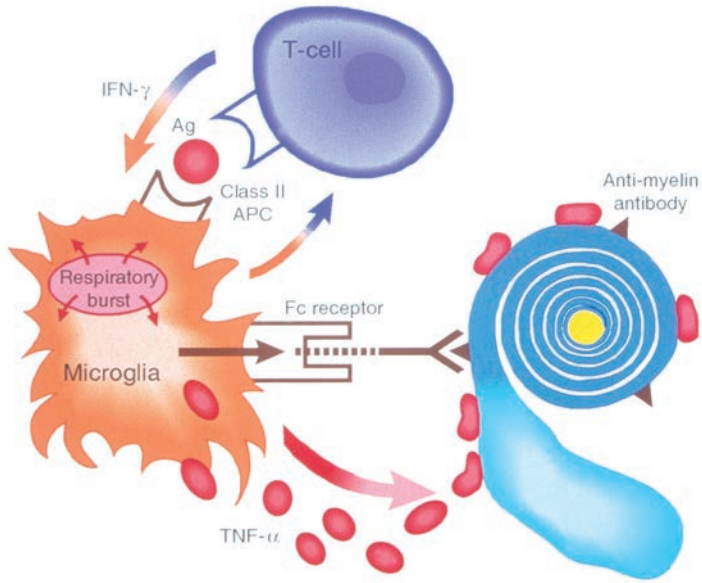

Fig. 97.4. Interaction between T-cells and microglia in the central nervous system. Microglia are activated by T-cell derived IFN-γ; they express class II MHC antigen and function as non-professional antigen-presenting cells, stimulating primed T-cells to secrete additional IFN-γ and recruit naive microglia. Activated microglia secrete proinflammatory cytokines, express Fc and other immune receptors, and damage opsonized oligodendrocytes by cell–cell contact and local production of TNFα. (Reproduced with permission from *McAlpine's Multiple Sclerosis*, 1998, Churchill Livingstone.)

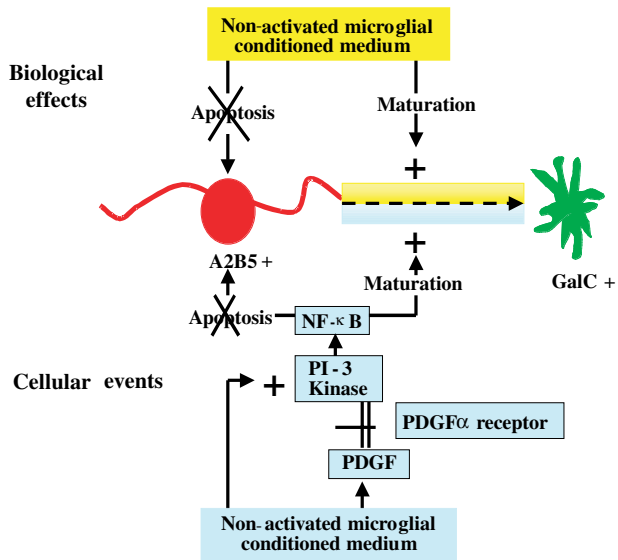

Fig. 97.5. Soluble factors released by non-activated microglia increase oligodendrocyte survival by inhibiting apoptosis and promoting differentiation of their precursors with signalling through the PDGFα receptor activating NF-kB. (Kindly prepared by Dr Richard Nicholas.)

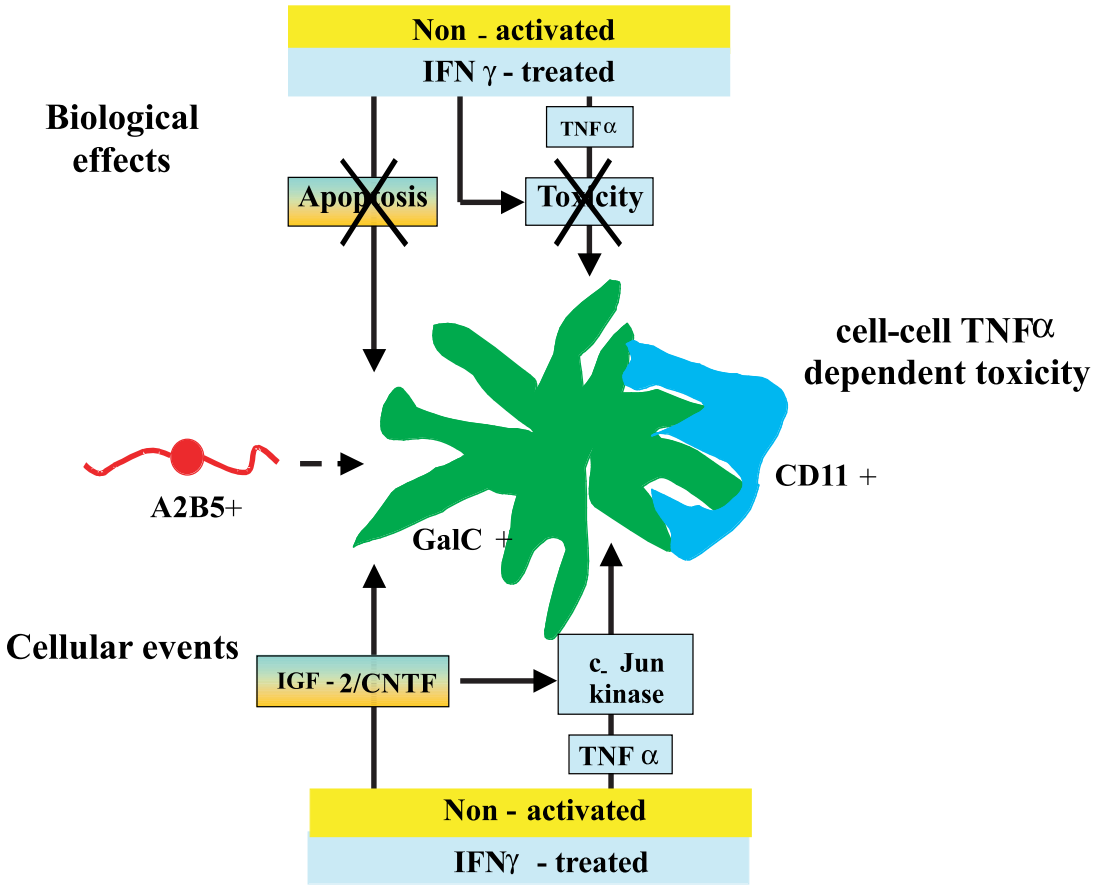

Fig. 97.6. Activated microglia kill opsonized oligodendrocytes by cell–cell contact and local release of TNFα. Oligodendrocytes are only susceptible to soluble TNFα in the absence of IGF-2 and CNTF. These growth factors are produced by microglia and so normally act to inhibit bystander damage of healthy oligodendrocytes. (Kindly prepared by Dr Richard Nicholas.)

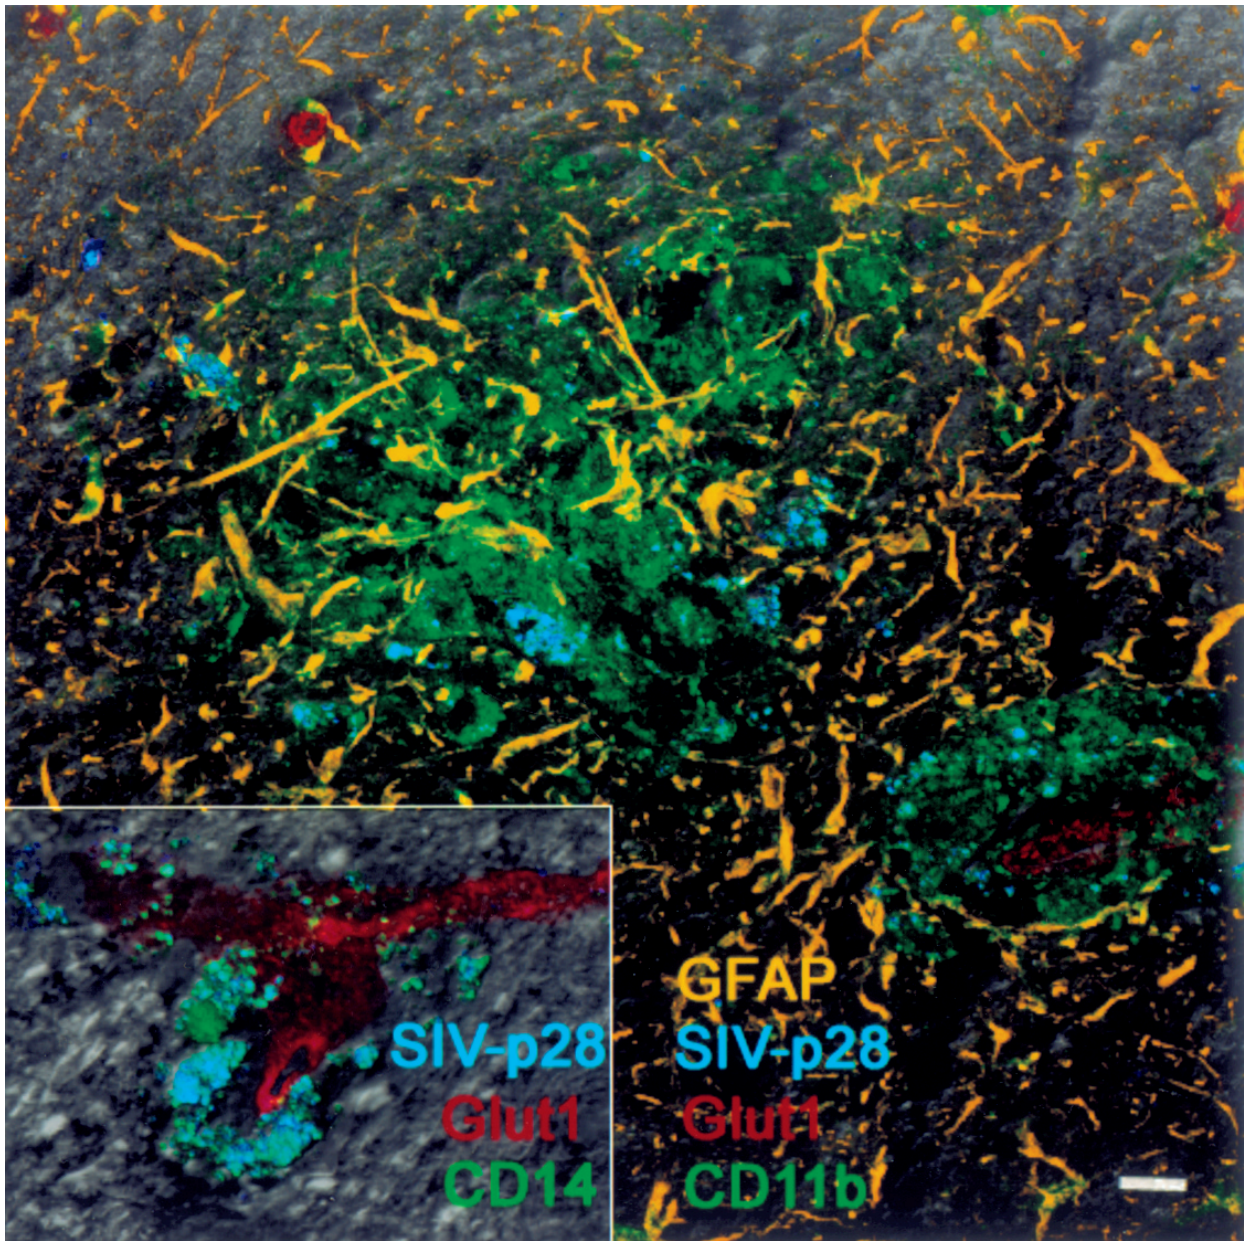

Fig. 103.10. SIV confocal: multilabel confocal microscopy demonstrating perivascular macrophages within the CNS showing that perivascular macrophages are the major cell type infected by SIV. Multilabel confocal microscopy demonstrating astrocytes (GFAP – yellow), SIV viral protein (SIV – blue), endothelial cells (Glut-1 – red), and brain macrophages including microglia and perivascular cells (CD11b – green). There is an accumulation of CD11b macrophages, some of which are SIV-infected as demonstrated by the production of viral proteins. Inset (lower left corner): demonstrates perivascular macrophages (CD14 – green) surrounding CNS endothelial cells (Glut-1 – red), that are productively infected (SIV-p28 – blue). These images demonstrate that CD14+ perivascular macrophages, and not parenchymal microglia, are the major target of SIV, and probably HIV infection. (Courtesy of Dr K. Williams: *Glia*, in press.)

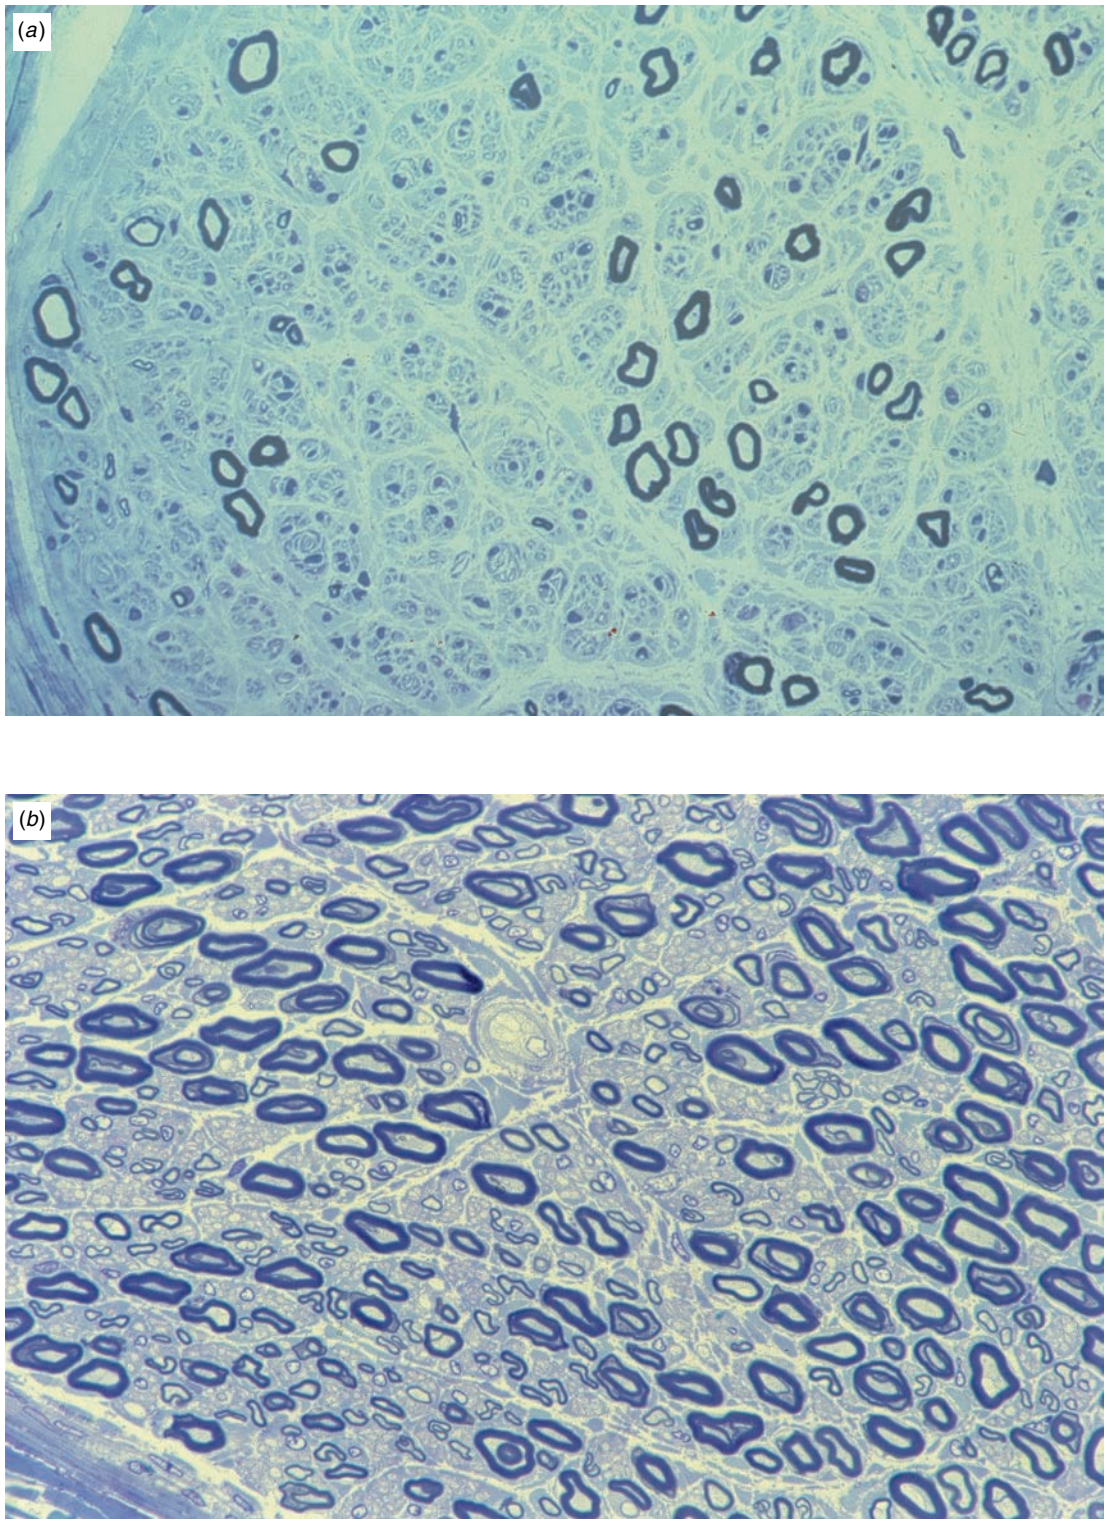

Fig. 103.13. HIV-SN: photomicrograph of sural nerve showing severe myelinated fibre loss in HIV-associated distal sensory polyneuropathy (*a*), compared to control (*b*).

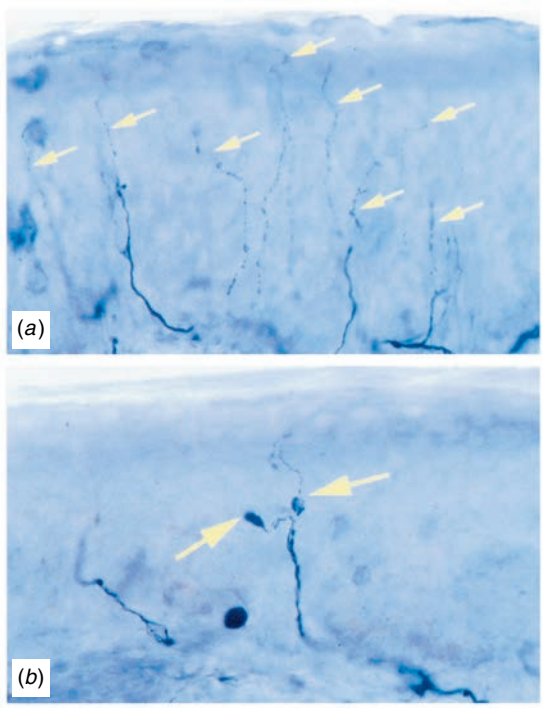

Fig. 103.14. HIV-SN2: Punch skin biopsies immunostained with the pan-axonal marker PGP9.5 to indicate epidermal nerve fibres. In normal region, taken from the thigh (*a*), there is a high density of unmyelinated nerve fibres (arrows). At the ankle, however, the density of fibres is very low, and nerve fibre swelling indicative of degeneration is seen (arrows) (*b*).

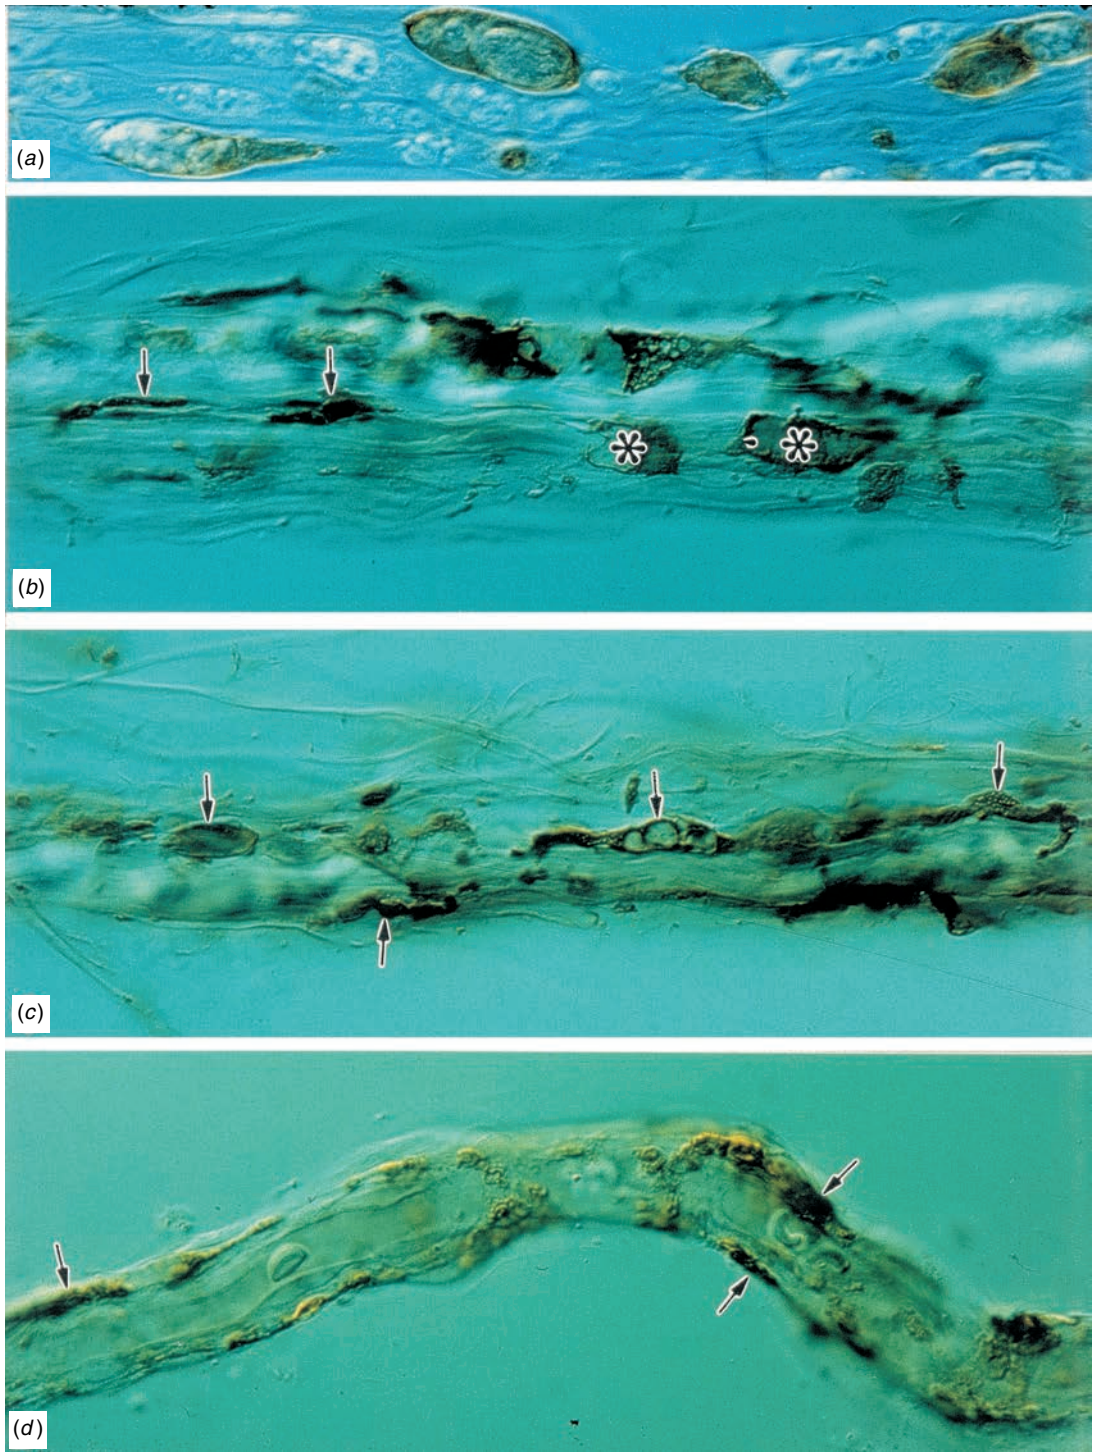

Fig. 103.15. Teased nerve fibres immunostained for various proinflammatory cytokines. In (*a*), macrophages are identifiable arrayed along the nerve fibre, and in (*b*), IL-1, (*c*) TNF-alpha, and (*d*) IL-6 products (arrows) and macrophages (asterisks) are visible with immunocytochemistry. (Courtesy of Dr JW Griffin.)

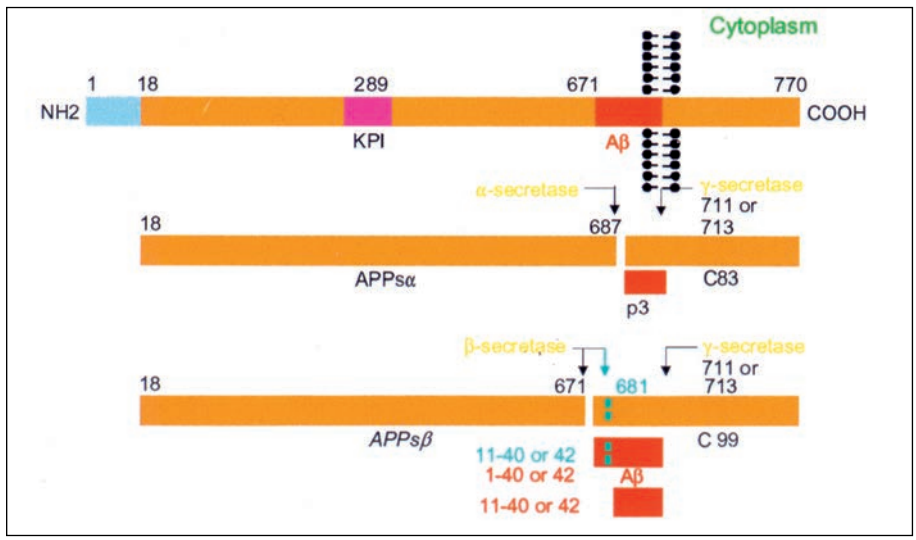

Fig. 115.2. Schematic of APP, a single pass transmembrane protein with a short cytoplasmic C-terminal domain and a large ectodomain. The Aβ peptide is situated partially within the membrane and partially outside the membrane. α-secretase, or tace cleavage, cuts Aβ between residue 16 and 17 and, following δ secretase cleavages, p3 fragments are generated. This cleavage is anti-amyloidogenic. In contrast, BACE1 cleavages at the $+1$ and $+11$ site are followed by γ-secretase cleavages which generate the Aβ peptides that are implicated in the human illness.

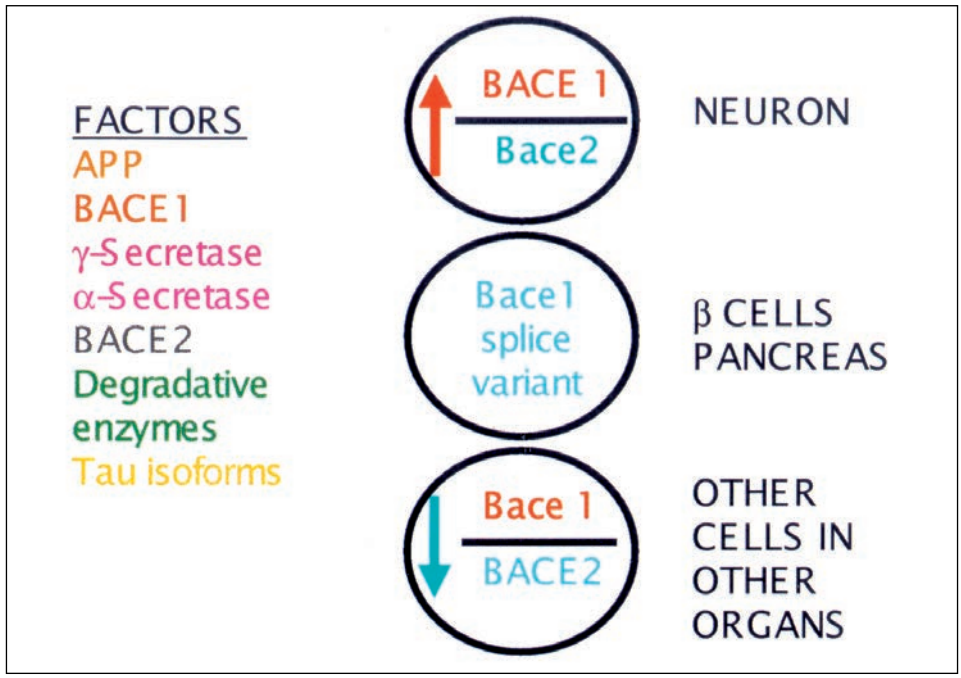

Fig. 115.3. Factors that are important in amyloidogenesis are listed. We have postulated that neurons are vulnerable in Alzheimer's disease because they have relatively high levels of APP and BACE1 and sufficient δ-secretase to generate Aβ. In contrast to other cells, neurons are not protected by α-secretase and BACE2 activities. Other cells have variable levels of APP, but because they have low levels of BACE1 and reasonable levels of BACE2, they are not predisposed to form amyloid. Although a subset of pancreatic cells have relatively high levels of BACE1 MRNA, the MRNAs are alternatively spliced to generate BACE1 isoform that is incapable of cutting APP.

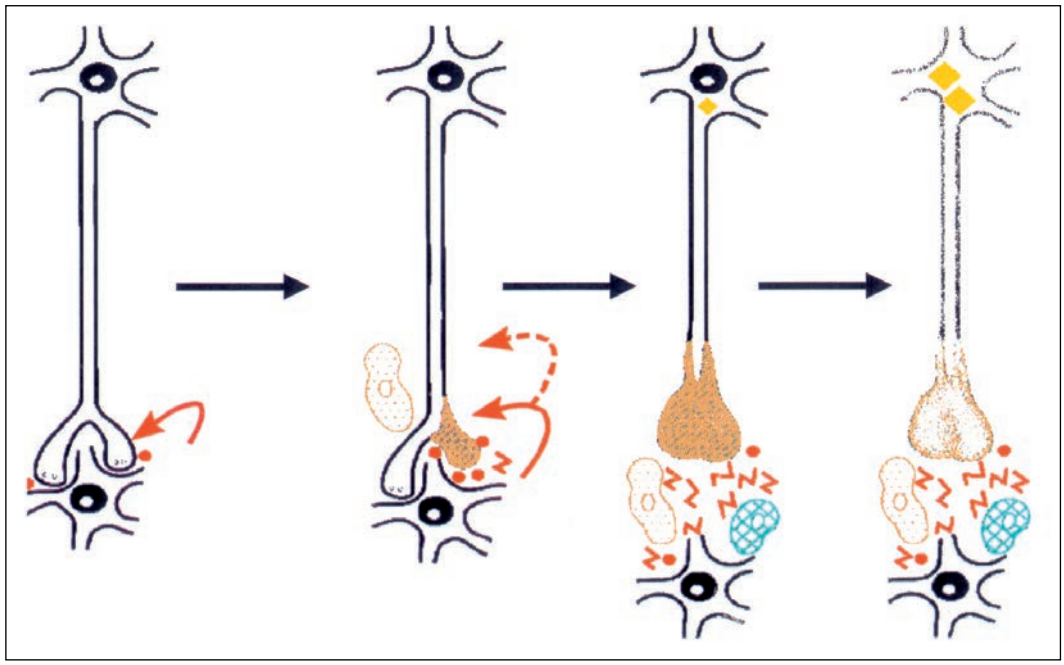

Fig. 115.4. In this model, APP is made in neurons and transported to axon terminals. BACE1 is also present at these sites and cleaves APP to generate C-terminal fragments, which in turn are cleaved by γ-secretase activity to generate small amounts of Aβ. In the presence of mutations, Aβ is generated at higher levels at axon terminals where it appears to be synaptotoxic, probably in the form of Aβ toxic oligomers, to damage synapses which retract from target cells; glial responses begin at this time. In the third image, the parent cell is disconnected from the target. There is a large APP-filled neurite decorated by amyloid deposits (red dots and Zs), astrocytes and microglial cells. Phosphorylated cytoskeletal elements appear in the cell body. It is hypothesized that phosphorylated isoforms of human tau could then begin to form tangles.

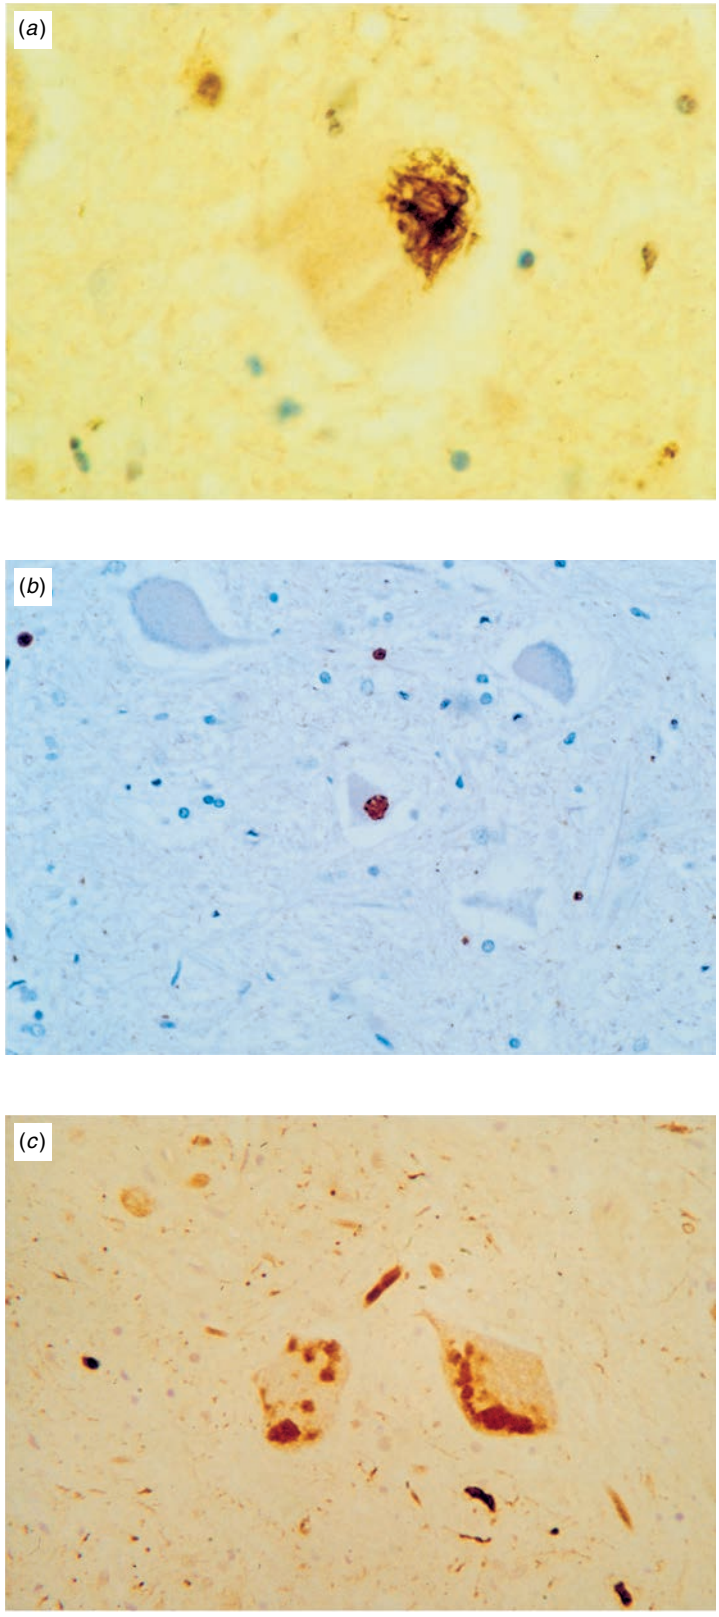

Fig. 116.5. Inclusion bodies in surviving spinal cord motor neurones in ALS patients. (*a*) skein-like ubiquitinated inclusion; (*b*) hyaline ubiquitinated inclusion; (*c*) hyaline conglomerate inclusion showing strong neurofilament immunoreactivity in a patient with SOD1-related familial ALS.

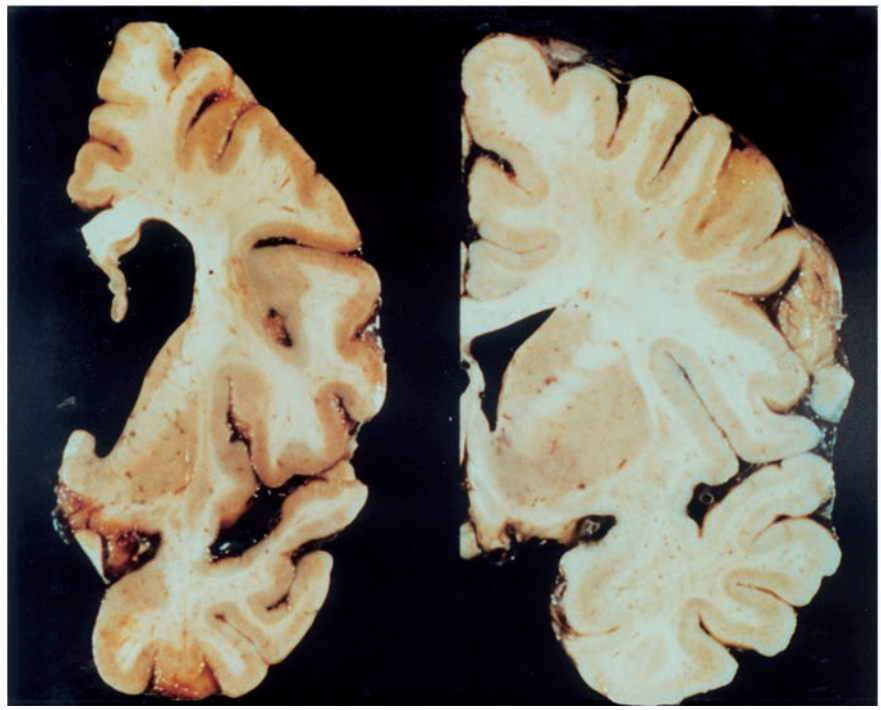

Fig. 118.2. HD gross pathology. Coronal hemisections of brain from HD patient (left) and normal individual (right). Note prominent atrophy of striatum and cerebral cortex, with ventricular enlargement.

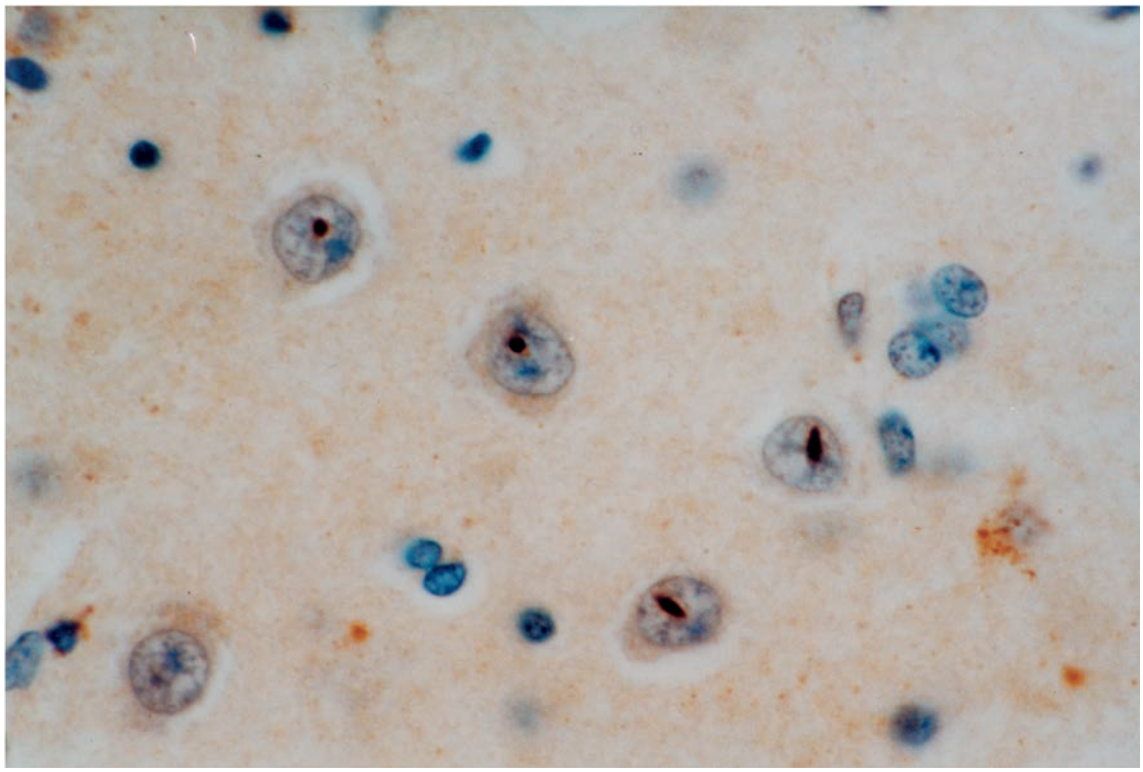

Fig. 118.3. Intranuclear inclusions. Cerebral cortex section from HD-affected brain, immunocytochemically labelled with antiubiquitin antiserum to reveal intranuclear inclusions (orange–brown). Note that the inclusions are limited to neuronal nuclei, and are distinct from the nucleolus.

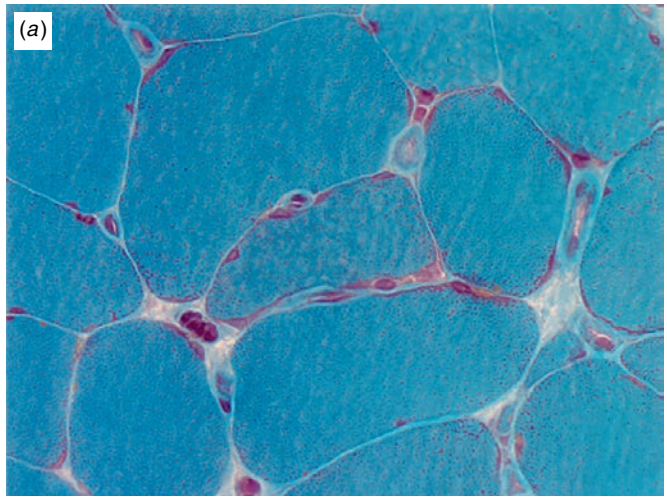

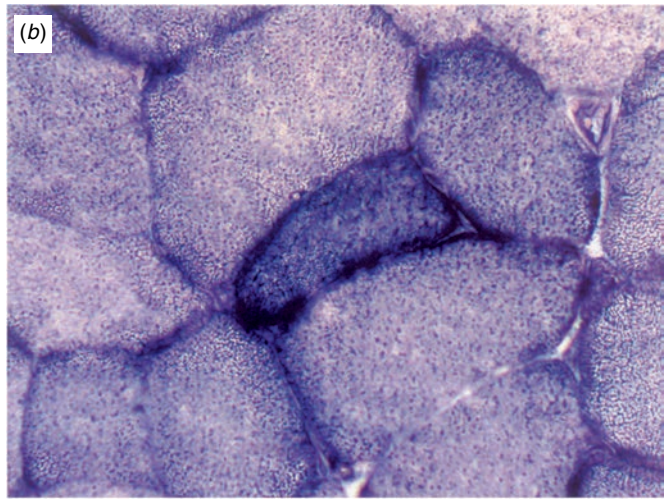

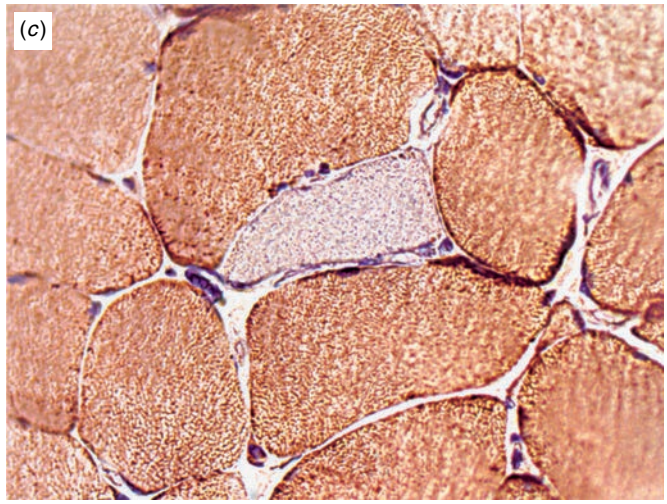

Fig. 120.3. (*a*) Modified Gomori trichrome stain of the muscle biopsy from a patient with CPEO and mitochondrial myopathy. The central fibre is atrophic but in staining shows only very mild and subtle abnormalities and could easily be passed as normal. (*b*) Succinate dehydrogenase staining of a serial section to (*a*). The central, dark staining fibre is now clearly abnormal and confirms the increased sensitivity of this stain in detecting 'ragged red' fibres. (*c*) A further serial section to (*b*) using the cytochrome oxidase (COX) stain. The succinate dehydrogenase positive fibre is COX negative.

Fig. 122.1. Calculating probability of stroke using factors known preoperatively. To find the probability of stroke for any patient, respond yes (+) or no (−) to the following questions: Has the patient had a previous stroke (CVA)? If no, move to the left side of the figure. Does the patient have a carotid bruit (CB)? Does the patient have a history of hypertension (HTN)? Does the patient have diabetes mellitus (DM)? Match this column with the patient's age group (on admission), and you will identify the patient's estimate of stroke risk. Low stroke risks are shown in black, medium stroke risks in blue, and high stroke risks in red.
