Diseases of the Nervous System

Arthur K. Asbury is Van Meter Professor Emeritus of Neurology, Hospital of the University of Pennsylvania, Philadelphia, USA

Guy M. McKhann is Professor of Neurology, The Zanvyl Krieger Mind and Brain Institute, Johns Hopkins University, Baltimore, Maryland, USA

W. Ian McDonald is Professor Emeritus, Institute of Neurology, The National Hospital for Neurology and Neurosurgery, Queen Square, London, UK

Peter J. Goadsby is Professor of Neurology, Institute of Neurology, The National Hospital for Neurology and Neurosurgery, Queen Square, London, UK

Justin C. McArthur is Professor of Neurology and Epidemiology, Johns Hopkins University School of Medicine, Baltimore, Maryland, USA

The third edition of a neurology classic, this two-volume text is the most comprehensive neurology reference available. It encompasses epidemiology, pathology, pathophysiology, and clinical features of the full range of neurological disorders. The basic principles of neurological dysfunction are covered at cellular and molecular level by leading experts in the field. Disease mechanisms are reviewed comprehensively, with particular relevance to the principles of therapy.

Sections cover the general principles of neurological disease, disorders of higher function, motor control, special senses, spine and spinal cord, bodily function, headache and pain, neuromuscular disorders, epilepsy, cerebrovascular disorders, neoplastic disorders, autoimmune disorders, disorders of myelin, infections, trauma and toxic disorders, degenerative disorders, and neurological manifestations of systemic conditions. Each section, under the direction of one of the distinguished editors, is a text-within-a-text, offering the most reliable account of its topic currently available.

Contributors to this work include the leading clinicians and clinical neuroscientists internationally. Current, comprehensive and authoritative, this is the definitive reference for neurologists, neurosurgeons, neuropsychiatrists, indeed everyone with a professional or research interest in the neurosciences.

From reviews of previous editions:

'A scholarly, well-crafted and attractive book . . . *Diseases of the Nervous System* deserves a place in the library of every medical school, neurology department, and neuroscience department'
New England Journal of Medicine

'All clinical neurologists and trainess in neurology will find it invaluable as a reference and a way into the latest scientific literature'
British Medical Journal

'This is a superb book'
Journal of Neurology, Neurosurgery and Psychiatry

Preface

In the 10 years since the second edition of *Diseases of the Nervous System* appeared, extraordinary change has taken place in the field of neurosciences, both basic and clinical. In accordance with what is happening in the neurosciences, major changes have occurred with this third edition. Organization of subject matter and ordering of topics has changed substantially, in some cases dramatically. Of the contributors, a number of the authors for the previous two editions have written again in their special fields of expertise, but overall, more than three-quarters of the contributors are new to these pages. Two new editors have been added, Peter J. Goadsby and Justin C. McArthur; Cambridge University Press is the new publisher; and a new subtitle, *Clinical Neuroscience and Therapeutic Principles* has supplanted the previous one.

Despite these changes, the purpose of these reference volumes remains the same, namely to summarize what the scientific method, as applied to problems of neurological dysfunction, has taught us about the pathophysiology of neurological disorders. To say it differently, our purpose is not to focus on incidence, natural history, phenomenology and semeiology of neurological disorders, although these aspects are touched upon, but rather to focus on the mechanisms of neurological disease and the principles that form the basis for management and therapeutics. In addition to the emphasis on pathophysiology and principles of therapy, three other axioms guided the planning of this edition, just as they did for the previous editions. First, contributors were chosen who brought clinical expertise to bear as well as scientific authoritativeness. Second, we tried to assure that the depth with which each topic covered was relatively uniform from one chapter to the next. There is a corollary to this principle of uniformity. Given that these volumes are a general reference covering the entire field of neurological disorders, each chapter is, by necessity, a relatively brief summary of where matters

stand in that particular disorder or area of interest. This level of detail will be insufficient for some readers. When this is the case, readers are urged to consult the primary literature listed in the references.

The third point has to do with the intended readership. It is assumed that the reader will have a grasp of the terminology of everyday neurology and of the neurological examination, and will have a working knowledge of the basic concepts of nervous system anatomy and physiology. With this proviso, these volumes are designed to be of use to medical students, physicians in training, physicians trained in fields other than the nervous system, and of course to those trained or training in the fields of neurology, psychiatry, neurosurgery and related specialties. Neuroscientists of any background or level of training should have no difficulty using these volumes, and indeed it is this readership whom we particularly have in mind.

A project of this size requires many hands. The editors owe a debt of gratitude to the many who worked so diligently to make these volumes a reality. Particular thanks go to Ms Barbara C. Williams, the overall coordinator, Ms Theresa Daly at the School of Medicine, University of Pennsylvania, Ms Nancy Rosenberg at Johns Hopkins Hospital, Ms Olga Shapeero and Ms Sophie Ryan at the Institute of Neurology Queen Square, and Ms Susan Soohoo at the Krieger Mind-Brain Institute, Johns Hopkins University. Ms Mary Sanders performed the copy editing thoroughly and skilfully. Dr Richard Barling, director of medical and professional publishing at the Cambridge University Press, provided excellent guidance and support. But it is the chapter authors to whom we most deeply indebted, and to whom these volumes are dedicated. The publisher provided the loom, the editors made the design, but it was the 213 contributors who wove the fabric.

Since the last edition of this textbook, the field of Neurology and the Neurosciences has witnessed remarkable advances in the technologies available for the study of the brain and our concepts about the nervous system and its diseases. There has been progress in our ability to modify, prevent or treat these disease processes and to evaluate clinical outcomes, and in the resources available to handle and disperse data. There is, however, always a competition between the advancement of knowledge and the challenges of disease. We face challenges that demand that we put these advances to good use.

This introduction provides a brief, and necessarily incomplete, overview of some of the advances, and the many remaining challenges, for the study and treatment of diseases of the nervous system. A number of new therapeutic strategies have already been developed, and are already impacting on the quality of life of those with neurological disease. Many new treatments, both symptomatic and disease-modifying, are in the developmental pipeline. With the delineation of the human genome in 2001, a particular problem has emerged: the need to delineate protein production (proteomics) and protein modifications on a cellular basis. 'The emerging challenge in understanding the pathogenesis of the neurodegenerative disorders will be to characterize and elucidate aberrant protein interactions in the affected cells' (Martin, 1999). Future efforts will be focused on determining the tertiary structure of proteins which is currently determined using X-ray crystallography and nuclear magnetic resonance. Because of their relatively low through-put, complexity and high cost, these techniques have not generally been used for therapeutic targeting in drug discovery programmes. Recent technological advances, coupled with the information from human genome sequencing, are beginning to enable construction of a database to predict protein structure from sequence, and may be relevant for up to one-third of all gene targets (Christendat et al., 2000).

Global challenges in the developed and developing world

The world's aging population is increasingly affected by both acute and chronic neurological diseases. These include cerebrovascular disease, Alzheimer's disease and other dementias and Parkinson's disease. In the USA, the number of the very old (older than 85) is expected to increase sevenfold, from 2 million in 1990 to 14 million in 2040 and is increasingly vulnerable to chronic neurodegenerative disorders.

Since the original descriptions in the 1870s that microbes caused infections, specifically the discovery by Koch that *Bacillus anthracis* caused anthrax, major neurological complications of systemic infections continue to affect millions annually, particularly in developing nations. These infections include malaria, HIV-1 infection, tuberculosis, and leprosy, as well as 'new' infections that have emerged in previously unaffected areas. Malaria remains a major scourge across the world, with approximately 1.5 million deaths annually, many from cerebral involvement. Until recently, research efforts have been scattered and underfunded, with little coordinated effort for the development of a vaccine. In sub-Saharan Africa, the AIDS epidemic has produced an enormous sociopolitical crisis because it has literally decimated a generation, with seroprevalence rates exceeding 25% of the population, and an estimated 13.2 million 'AIDS orphans' (UNAIDS, 2000). Despite the availability of effective treatment, leprosy remains the commonest cause of peripheral neuropathy worldwide. Increasingly, developed and developing countries are linked by diseases which have spread because of the ease and speed of global travel. As

one recently developing example of 'emerging' infections, the appearance of West Nile encephalitis in the eastern USA in the past few years is thought to reflect the introduction of infected *Anopheles* mosquitoes from increased air travel (Lanciotti et al., 1999).

One of the major challenges facing our society will be how to equitably distribute therapeutic advances, many of which may be both costly and complex, particularly to underserved populations. The AIDS epidemic provides a stark warning of how an inadequate global response can fail to deliver currently available and effective treatments to millions. It serves as an example to avoid as improved pathogenesis-based treatments for neurological diseases such as Alzheimer's are developed (Steinbrook & Drazen, 2001).

The impact of imaging on neurosciences

No technology has changed the practice of the clinical neurosciences more than cranial imaging. Within the past two decades we have witnessed the development first of structural imaging (CT and MRI), then functional imaging (PET and fMRI), and now refined morphological and physiological imaging (diffusion-weighted and perfusion-weighted imaging), and biochemical characterization with magnetic resonance spectroscopy (MRS). Advances in imaging techniques during the past two decades have literally revolutionized our ability to localize pathology within the nervous system, establish diagnoses, and guide therapies. Rather than devalue the role of neuropathology in the clinical neurosciences, the improvements in imaging have facilitated an even closer integration of clinical neurology with pathology. We can now see the brain, ask what part is involved in neural and cognitive processing, evaluate the extent and distribution of injury, and characterize mechanisms of plasticity and recovery.

Of all of the various imaging modalities: computerized tomography, positron emission tomography, angiography, arguably magnetic resonance imaging (MRI) has become the most widely used modality because of its sensitivity, and lack of radiation risk. The field of MRI has now taken on two new functions: (i) magnetic resonance spectroscopy, identifying the biochemical profile of the living brain through the identification of specific chemical spectra and (ii) the development of functional MRI using changes in deoxyhemoglobin to detect regional brain activation. Both of these techniques are non-invasive, repeatable, and involve no radiation risk. Specialized MR techniques such as diffusion-weighted imaging and perfusion-imaging have pushed forward our understanding of cerebrovascular pathophysiology. They allow for the identification of 'vulnerable' brain tissue within the first few hours after onset of stroke. The identification of diffusion–perfusion 'mismatch' can now lead directly to treatment with thrombolytic therapies or induced hypertension.

Table 1.1. Physiologic processes accessible in humans by functional and metabolic imaging

Physiologic processes	Methods
Glucose metabolism	FDG-PET[a]
Blood flow or volume	[^{15}O]H_2O-PET, perfusion MRI
Tissue oxygenation	nitroimidazole-PET, fMRI
Tissue pH	^{31}P-MRS
Protein synthesis	Amino acid-PET
Cell proliferation (mitotic rate)	Thymidine-PET
Receptor concentration or occupancy	PET
Enzyme kinetics	PET
Endogenous metabolite concentration	MRS(I)[a]
Water diffusion	DWI
Tissue anisotropy	DTI
Drug pharmacokinetics/dynamics	PET, MRS
Vascular permeability	Dynamic MR

Notes:
DTI, diffuse tensor imaging; DWI, diffusion-weighted MR imaging; FDG, [^{18}F]fluorodeoxyglucose; fMRI, functional magnetic resonance imaging; MR, magnetic resonance; MRS(I), magnetic resonance spectroscopy–spectroscopic imaging; PET, positron emission tomography. [a] Technique used routinely in clinical practice for oncology.
Source: From Pomper, M.G. (2000). Table 27.3–1, p. 680. Reproduced with permission from the publisher.

These remarkable advances are incomplete. We are still not 'online' with the timing of the brain's processing of information. The dependence of current methods of functional imaging, both PET and fMRI, on changes in blood oxygenation and blood flow associated with neural activity remains a limiting factor. Other imaging techniques based on electrophysiological or magnetophysiological principles may provide further advances. Nonetheless, current physiological imaging as detailed in Table 1.1 can now permit the detection of a variety of metabolic alterations within the living brain, including blood flow, metabolism and perturbations in neurotransmitters (Fig. 1.1, see colour plate section). The recent development of the National Institute of Biomedical Imaging and Bioengineering (NIBIB) at the National Institutes of Health will probably further facilitate and accelerate the progress of imaging research.

Neuropsychiatric disorders have been extensively studied using both structural and functional neuroimaging. Mood disorders have a neurochemical origin, but may also be associated with regionally selective alterations in brain structure. For example, a 40% reduction has been found in grey matter volume in prefrontal cortex in patients with bipolar disorders or familiar recurrent unipolar depression (Drevets et al., 1997). As an example of an investigative approach which combines genetic studies, neuropsychological testing and functional imaging, a specific gene variant in the dopamine-degrading enzyme, catechol-*o*-methyltransferase, is more common in schizophrenics and the prefrontal cortex appears to be metabolically more active (Egan et al., 2001). Positron emission tomography scans during reading tasks showed reduced activity in the left hemisphere in dyslexics from three different countries, suggesting that there is a universal neurocognitive basis for dyslexia (Paulesu et al., 2001). Multidisciplinary studies such as these will become more common and will undoubtedly facilitate an improved understanding of how genetic variation may influence brain behaviour in health and disease.

The genetics of neurological diseases

Over 50% of genetic disorders affect the nervous system and are detailed in the online textbook *Online Mendelian Inheritance in Man (OMIM)*. This database is a catalogue of human genes and genetic disorders authored and edited by Dr Victor A. McKusick and his colleagues at Johns Hopkins and elsewhere, and developed for the World Wide Web by NCBI, the National Center for Biotechnology Information. OMIM contains 12 749 genetic disorders and 9365 established gene locations.

The elucidation of the genetic mechanisms of disease using molecular techniques has advanced rapidly, in large part because most neurogenetic disorders are inherited in a simple Mendelian fashion. Linkage analysis, positional cloning and searches for mutations in candidate genes have led to the identification of mutant genes in more than 50 disorders. The elucidation of the human genome through the Human Genome Project and the surprising observation that the number of identifiable human genes (26 000) is only a few thousand more than the number identified for a much smaller organism, the round worm, sets the stage for a detailed exploration of genes and proteins associated with specific neurological diseases.

Extraordinary progress has been made in identifying specific genes that pose risk factors for many common neurodegenerative disorders and the ways in which proteins coded by these genes are associated with loss of function or gain of adverse properties (Price et al., 1998a; Hardy & Gwinn-Hardy, 1998; Price et al., 1998b). Even before the Human Genome Project was completed in 2001, the mapping and cloning of genes involved in inherited neurological disorders had been performed. It is now anticipated that the genomes of given individuals will be highly variable, as compared to the reference human sequence. Thus, it should be possible to analyse disease genes from studies of a single individual, rather than large kindreds, as has been required up to now. For a number of disorders long considered 'sporadic', the findings from genetics have changed our ways of thinking. Advances in Alzheimer's disease (AD) are illustrative, but we could equally have chosen Parkinson's disease (PD), frontotemporal dementia, or amyotrophic lateral sclerosis. It has been known for some time that rare families existed with an early onset of Alzheimer's disease (under age 60) and an apparently dominant pattern of inheritance. Evaluation of these families has yielded four genetic loci with numerous mutations, all involved in the processing of the protein beta amyloid. These findings not only strengthened the amyloid hypothesis as the underlying mechanism of Alzheimer's disease, but provided information leading to the development of transgenic mouse models. Allelic variation in apo-E appears to act as a time dependent susceptibility gene (Price et al., 1998a).

In an example of a multidisciplinary approach to improve the sensitivity of preventive treatment trials for AD, genetic testing has been combined with functional imaging in an innovative approach to more efficiently test preventive treatments. Positron emission tomography is used in cognitively normal apolipoprotein E4 heterozygotes to identify those with decreased glucose metabolism in several brain regions typically affected in AD. Those with PET abnormalities are considered to be at greatest risk for the development of AD and participate in the clinical trial (Reiman et al., 2001).

Alzheimer's disease also provides an example of the identification of genes associated with an increased risk of disease, rather than disease mechanisms. The first such genotype, Apo-E4, is associated with a fourfold increased risk of late-onset AD and appears to act as a time-dependent susceptibility gene (Price et al., 1998a). Two other genetic loci, A2M and LRPAP1 have also recently been reported as risk-associated genes (Sanchez et al., 2001; Nicosia et al., 2001), and perhaps only operate in selected populations. The concept of risk factor genes has been proposed for some time, but finally there is specific evidence for such a phenomenon. Manipulation of transgenic mice models has suggested therapeutic strategies for the much

larger group of patients with late-onset Alzheimer's disease through manipulation of the secretases involved in processing amyloid, or vaccines aimed against possibly toxic fragments of amyloid. As outlined in Chapter 115, similar strategies have been used to explore the role of the protein alpha synuclein in Parkinson's disease, and the protein tau in frontotemporal dementia.

The mechanisms of cellular injury for most neurogenetic disorders remain uncertain, even when a gene product can be identified. Another genetic abnormality, the triplet repeat mechanism for diseases such as Huntington's disease, fragile X syndrome, and various spinocerebellar ataxias, has focused attention on how proteins determine abnormal cellular function and ultimately cell death. There has been a shift away from thinking about enzymatic abnormalities to abnormalities of protein structure and function. This consideration of proteins as mechanisms of disease applies not only to the triplet repeat diseases, but also to other diseases involving proteins such as prion diseases and neurodegenerative diseases.

Common mechanisms may exist for a number of neurodegenerative diseases, including Alzheimer's disease and Parkinson's disease. Most neurodegenerative diseases have been linked to abnormal protein aggregates interfering with neuronal function and viability. Genetic errors and mutations may produce misfolded proteins which tend to accumulate within neurons and may impair the function of proteasomes, which is normally critical in the ubiquitin proteasome system for breaking down proteins. Further accumulation, over a prolonged period, may lead to additional accumulation and even more proteasomal dysfunction (Bence et al., 2001). In Huntington's disease, polyglutamine expansions in the huntingtin and atrophin-1 proteins can be identified, and have been proposed to lead to neuronal toxicity by interference with gene transcription (Fig. 1.2) (Nucifora, Jr. et al., 2001). Mitochondrial disorders can affect almost every tissue and organ system, typically with maternal transmission. Mitochondrial genetics have become increasingly important since the first descriptions of mutations in mitochondrial DNA in 1988 (Holt et al., 1988). A wide range of systemic and neurological diseases have now been linked to specific mutations, including chronic progressive external ophthalmoplegia (CPEO), Leber's optic atrophy, MELAS and MERRF. In addition, mutations in mtDNA may contribute to aging and neurodegenerative diseases.

The accurate diagnosis of many neurogenetic disorders is now possible; and both antenatal and presymptomatic disease diagnosis is also feasible. Genotypic diagnosis by DNA testing allows for precision in diagnosis, and facilitates genetic counselling and predictive testing. It can also identify patients with specific genetic disorders for natural history studies, and ultimately, for therapeutic interventions. These technological advances bring their own set of ethical concerns, however, including the potential misuse of genetic testing to screen 'at risk' individuals for employment or health insurance.

The field of gene therapy was introduced with tremendous fanfare over a decade ago, and had the potential to introduce functional genes into a diseased cell. There have been persistent technical challenges with the delivery systems used to deliver the genes, and the entire field suffered a major setback following an unanticipated patient death in one gene therapy trial. Nonetheless, the recent demonstration of a non-viral gene-transfer therapy for hemophilia A has generated renewed excitement at the potential to cure selected genetic diseases (Roth et al., 2001).

Ion channels and neurotransmitters in neurological disease

The study of ion channels and their distribution in muscle and nerve has expanded tremendously in the past decade, and has led to an improved understanding of the molecular basis for a collection of disorders termed 'channelopathies', including the familial myotonias and periodic paralyses. In epilepsy, different types of rare seizure disorders are now known to be inherited in either an autosomal dominant or autosomal recessive pattern. Mutations have recently been identified in a widely distributed sodium channel, SCN1A in an inherited form of epilepsy, Generalized Epilepsy with Febrile Seizures Plus type 2 (Escayg et al., 2000). The underlying mechanisms have now been clarified for febrile seizures inherited in an autosomal dominant pattern and have been linked to a point mutation in the beta subunit of voltage-gated sodium channel (Wallace et al., 1998). Identification of the mutant genes underlying rare forms of human epilepsy could facilitate recognition of molecular targets and the development of new treatments, for example, drugs acting on potassium channels to enhance potassium current and inhibit seizures. In other areas, the study of genetically determined dysfunction in ion channels has been productive. Several channelopathies with know genetic alterations have been identified in diseases as phenotypically diverse as familial hemiplegic migraine, episodic ataxia, benign neonatal epilepsy type I, and congenital myotonia. These can affect calcium, potassium or chloride channels, with molecular alterations ranging from point mutations, to prematurely truncated proteins, to pathological expansion of terminal sequences (Nappi et al., 2000).

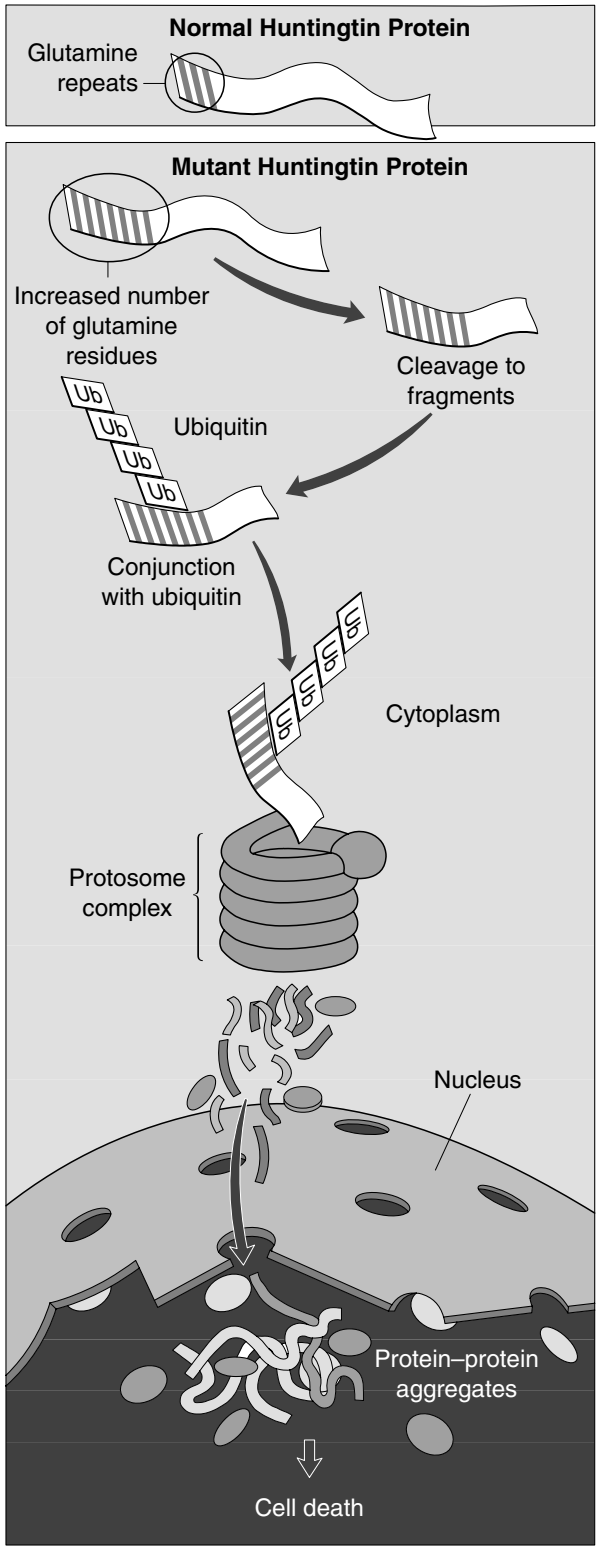

Fig. 1.2. Proposed mechanism of huntingtin-induced death of neuronal cells. The mutant huntingtin protein produced by an increase in the number of CAG repeats in the DH gene is cleaved to fragments that retain the increased number of glutamine residues. These fragments are conjugated with ubiquitin and carried to the proteasome complex. Subsequent cleavage is incomplete, and components of both huntingtin and the proteasome are translocated to the nucleus, where aggregates form, resulting in intranuclear inclusions. Over time, this process leads to cell death. (From Martin, 1999.)

With the description of the neurotoxicity of glutamate in 1957, there has been an explosion in our understanding of the biology of neurotransmitters in the CNS. Much of this work has focused on glutamate, the principal excitatory neurotransmitter, and its inhibitory counterpart gamma-amino butyric acid (GABA). To date, five high-affinity glutamate transporters have been cloned, with differential cellular and anatomical localization. In addition to its neurotoxicity, glutamate plays important roles in synaptic plasticity, learning, and development (Maragakis & Rothstein, 2001).

The molecular pathways underlying learning, memory and drug addiction have begun to converge with the recognition that drugs of abuse can cause long-lasting neural changes in the brain (Nestler, 2001).

The impact of stem cells for neurological diseases

Most of us were brought up with the concept that individuals are born with all of the neurons that they are ever going to have, and that neurons are gradually lost with aging. This concept has now been clearly proven wrong, at least for specific areas of brain such as the hippocampus. The adult brain and spinal cord contain neural stem cells that have the capacity to form neurons, astrocytes, and oligodendrocytes from cells in the ependyma and subventricular zone. Although widely viewed as a 'new' observation, in fact progenitor cells were identified in the periventricular zones in the 1950s. What functional significance this neurogenesis has in later life for the processing of memories or in response to injury remains to be determined. In addition, marrow stroma cells transplanted to the brain are able to generate astrocytes (Kopen et al., 1999). Cell lines developed from pluripotent human fetal or embryonic stem cells have now been developed (Shihabuddin et al., 1999), and successful transplantation has been achieved in animal models of Parkinson's disease, motor neuron disease, and spinal cord injury. The

long-term efficacy of such treatments, particularly in Parkinson's disease, is a particularly active area of investigation. Stem cells are usually derived from aborted fetuses or embryos, and in the USA, ethical concerns have effectively halted the public funding of stem cell research using these embryonic stem cells. The field of stem cell transplant has achieved even greater promise, both scientifically and politically, through the recognition that pluripotential embryonic stems cells can develop into a wide range of differentiated tissues, including neurons and muscle cells. Although embryonic stem cells appear to proliferate much more efficiently than adult stem cells, these cells are being actively developed and may avoid some of the ethical issues of the use of embryonic tissue. There are many questions still to be answered regarding the relative potential of embryonic stem cells and adult-derived progenitor cells. The exciting possibility exists, however, that these cells could be used as therapeutic agents, either as cell transplants, as sources of trophic factors or gene products to modify neurodegenerative processes in the brain or spinal cord. Functional recovery has been achieved in damaged spinal cords with some restoration of neurological function after injury (Kocsis, 1999) and early human trials have been completed in stroke with positive results.

The development of animal models

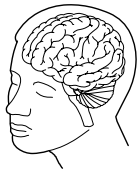
Animal models have, of course, been available for the study of neurological diseases for many years. These models usually occurred spontaneously and were utilized when an astute observer realized their implications for neuroscience research. The development of molecular biological techniques has allowed the insertion and removal of genes at the will of the investigator, particularly in easily manipulated species like the mouse and the fruit fly. This has permitted the development of reproducible animal models of common neurological diseases. Transgenic animals engineered to express human genes linked to Alzheimer's disease, amyotrophic lateral sclerosis and Huntington's disease have produced critically valuable advances in our understanding of the pathophysiological mechanisms. Although the exact pathophysiological mechanisms of Alzheimer's disease remain unclear, several transgenic animal models have already been used to delineate discrete pathways of injury. The application of transgenic technology should allow us to modify tumour-suppressor genes and to test pharmacological, biological, or genetic manipulations to prevent progression or even reverse the neurological disease. Small animal models will also allow for the efficient testing of new therapies for PD and other chronic neurodegenerative disorders. For example, in Parkinson's disease, animal models have been developed in the fly and mouse, which duplicate many of the cardinal features of Parkinson's disease (Fig. 1.3) (Dawson, 2000). Transgenic mice or flies over-expressing alpha synuclein develop pathology within dopamine neurons and age-dependent motor deficits (Masliah et al., 2000; Feany & Bender, 2000). Shimura et al. (2001) showed that the products of two genes, Parkin and alpha-synuclein, functionally interact and may lead to Parkinsonian degeneration.

A genetic model of Tauopathies has been developed by expressing human wild type and mutant Tau in the nervous system of the fruit fly. Transgenic flies die early after developing progressive neurodegeneration, but, at least in this model, show no signs of the large filamentous aggregates of Tau that compose neurofibrillary tangles (Wittmann et al., 2001).

Even more complex functions and neurological disorders can now be evaluated in large animal models. These have traditionally been used for physiological experiments, but are now being developed for the study of neuropsychiatric disorders such as schizophrenia. For example, by disrupting the development of fetal pigs brains chemically with a toxin that impedes cell division, pathological changes can be induced that mimic the abnormalities evident in the brains of some schizophrenics (Anon, 2001).

Mechanisms of cellular injury

Work since the last edition of this book has delineated more clearly how neurons and astrocytes may be injured during neurological diseases. The role of excitotoxic substances including glutamate has been studied extensively and the 'traditional' dichotomous model of two forms of cell death (necrotic or apoptotic) has been challenged. Substantial advances have been made in understanding the pathophysiological mechanisms underlying neuronal cell death in diverse neurological disorders. Great efforts have been made both in dissecting the cellular mechanisms mediating neuronal death, and in developing therapeutic strategies to prevent this, broadly defined as 'neuroprotection'. The two basic mechanisms of neuronal death, necrosis and apoptosis (or programmed cell death), have been extensively researched. In excitotoxic cell death, exposure to exogenous toxic substances, including glutamate, leads to an energy-independent cell destruction. Glutamate exposure can trigger neuronal death within the brain and has been implicated in the pathogenesis of numerous CNS diseases, including ischemic brain injury,



Human	Mouse	Fly
Age-dependent onset with chronic progression	Age-dependent onset – unknown	Age-dependent onset with chronic progression
	Inclusions get larger with age	
Dopamine neuronal cell loss in select brain regions	Dopamine neuronal cell injury	Dopamine neuronal cell loss
Lewy bodies (cytoplasmic inclusions containing α-synuclein and ubiquitin with a core and radiating fibrils)	Cytoplasmic inclusions (containing α-synuclein and some ubiquitin without fibrils); nuclear inclusions	Cytoplasmic inclusions (containing α-synuclein with fibrils; ubiquitin not determined)
Motor deficits	Motor deficits	Motor deficits
Mitochondrial complex 1 deficits	Unknown	Unknown
Increased markers of oxidative stress	Unknown	Unknown

Fig. 1.3. A comparison of animal models of PD. Recent molecular advances have enabled the engineering of mice and flies that carry wild-type or mutant versions of the protein α-synuclein, which is implicated in PD. A comparison of the features of the fly and mouse animal models of PD and how they correlate with the characteristics of the disease in human patients is shown. (From Dawson, 2000.)

amyotrophic lateral sclerosis, trauma, and seizures (Choi, 1988). NMDA receptors appear to be critical in acute glutamate neurotoxicity, for example, in ischemic brain injury. Hypoxic–ischemic brain injury may lead not only to excitotoxic cell death, but also to apoptosis or programmed cell death wherein cells die with negligible inflammation. Lee and Choi (Lee et al., 1999) have proposed that ischemic brain injury most likely represents an 'admixture' of morphologic features of both excitotoxicity and apoptosis. In apoptosis, caspase activation results in cell death through the destruction of critical molecules and the activation of others which mediate an energy-dependent 'suicide programme'. Mediators of apoptosis have been defined and several genes identified, including a family of 'cell death' sustained proteases, the caspases. Activation of caspase1 occurs in diverse models including cerebral ischemia, cerebral trauma, and neurodegenerative diseases such as ALS and Huntington's disease (Hara et al., 1997; Ona et al., 1999). Caspase inhibition may therefore be yet another avenue for targeted therapies, both for acute and chronic neurological disorders. Caspase activation also occurs in cerebral trauma, amyotrophic lateral sclerosis and Huntington's disease. Caspase pathways are activated in territories subjected to moderate hypoxia and lead to apoptotic cell death over a more prolonged period than that occurring with necrotic cell death. The importance of this is that apoptosis can be aborted either by timely reperfusion of the brain or by caspase inhibition (Friedlander, 2000). Despite the clear effectiveness of NMDA antagonists in experimental models of stroke, numerous clinical trials have unfortunately failed to show any clinical efficacy. Rather than being the result of faulty trial design or poor outcome measures, it seems more likely that other forms of cellular injury may play critical roles in ischemic brain injury. These may include AMPA/kainate receptor-mediated toxicity and extracellular zinc.

An important new concept in pathology is the description of the role of inflammation in diseases previously thought not to involve an inflammatory component. For example, in Alzheimer's disease there are now clear descriptions of local microglial activation, cytokine release, reactive astrocytosis and a multiprotein inflammatory response (McGeer & McGeer, 1995; Eikelenboom et al., 1994). Whether these responses are critical, or simply reflect an epiphenomenon, remains to be determined, but

already clinical trials of anti-inflammatory agents are in progress, and their results eagerly awaited.

Multiple sclerosis has traditionally been referred to as an inflammatory demyelinating disease and most of us were taught in medical school that it 'spared CNS axons'. Though degeneration of axons in multiple sclerosis lesions was first recognized by Charcot in 1877, recent elegant work has reinforced the frequency with which axonal transection and both neuronal and axonal loss occurs in multiple sclerosis. Axonal pathology has been identified as a determinant of irreversible disability (Matthews et al., 1998; Davie et al., 1995). This has led directly to change in treatment philosophy, ie, to begin treatment early before there is irreversible axonal injury. Refinement of non-invasive MR-based techniques to quantify underlying pathological lesions in MS will be relevant to the rational development of new treatments.

Plasticity in adult brains

In the past three decades, there has been an increased understanding of the synaptic and molecular basis of plasticity within the adult human brain. Current research indicates that experience-dependent plasticity may not decrease dramatically with age, as had previously been thought. This research may produce effective remediation for neurological impairments following trauma, stroke, or surgery. Functional magnetic resonance imaging has been widely used to examine the neural mechanisms underlying the acquisition of skilled behaviours. In epilepsy, the development of circuitry with recurrent excitatory synapses has emerged as common to numerous experimental models of epilepsy and could potentially occur within the sclerotic hippocampus of humans (McNamara, 1999).

Dendrites may have the capacity to synthesize proteins, thus could modulate the strength of connections between neurons, ultimately influencing neural activities including learning and memory. Protein synthesis occurs in intact dendrites, and this local protein synthesis could facilitate the ability of synapses to make synapse-specific changes (Aakalu et al., 2001).

Information processing and computational neuroscience

The ability to store, integrate and rapidly analyse large amounts of data has been a crucial advance in facilitating the progress in areas such as genomics and imaging. Data management, data handling, and statistics have all advanced to a point where more than adequate computational power is available on the average laptop computer. In addition, the Internet has revolutionized how most neuroscientists access, publish and disperse information, making use of large publicly available databases. One exciting application is the potential for the Internet to enhance remote or long-distance collaborations, without the need for travel or telephone communications. Systems are now in place which can permit the control of experimental equipment remotely in real time. For example, the Great Lakes Regional Center for AIDS Research facilitates telemicroscopy, distance learning, and video conferencing with real-time document and image sharing (Teasley & Wolinsky, 2001).

The objectives of computational neuroscience span the development of alternative test systems to model biological processes to the working of physiological systems, such as explaining how the brain might process information. This field has obviously been advanced by the revolution in affordable computers, which can be applied to produce neural networks and artificial intelligence, or systems which 'learn' how to address a neurobiological problem. The concept of neural networks has increasingly focused on attempts to understand complex human behaviour. For example, complex human memory is likely mediated by assemblies of interconnected neural networks with different components contributing towards memory function and dysfunction. At the same time, our patients and non-scientists have become our partners because they have the potential to tap into the same information sources as clinicians and scientists. In this new era, there is increasing need for clinicians and investigators to be sources of understandable, accurate and unbiased information.

Advances in neuroepidemiology and clinical trials

Here, neurological clinical trials research has advanced on several different fronts. At a national level in the USA, programmes and resources sponsored by the NIH to train and develop well-trained clinical researchers have been expanded. One example of this is the NIH-funded K23 programme, which is designed to foster the career development of clinician–investigators in patient-oriented research. The widespread application of evidence-based neurology in the past two decades has greatly improved clinical practice, the quality of patient-oriented neurology publications and the education of neurologists. Many neurological therapies and interventions have been submitted to rigorous and systematic analyses and meta-

analyses to examine both the efficacy and effectiveness of therapies. Detailed literature reviews and practice guidelines have been developed for most neurological disorders and their treatments through mechanisms such as the *Cochrane Review* and the *American Academy of Neurology*.

The design of clinical trials has improved markedly with the more accurate modelling of sample size calculations to ensure that clinical trials are adequately powered to show statistically significant differences, where they exist. The interactions of neuroscientists and statisticians have led to new strategies to more efficiently test new therapies in controlled clinical trials. As an example, it is now recognized by clinical trialists that even small overestimates in the efficacy of an intervention can lead to a significant reduction in the statistical power of a trial. Cost-effectiveness modelling techniques can be used to better define minimum clinically important differences (Samsa & Matchar, 2001). Finally, new outcome measures have been developed and refined both for the study of central and peripheral nervous system disorders in clinical trials. For example, in multiple sclerosis, clinical trials now routinely incorporate magnetic resonance imaging as one of the important outcome measures. In the study of painful peripheral neuropathies, skin biopsy, a technique originally developed in the 1960s has now been 'rediscovered' and is now being used as an outcome measure in trials of regenerative agents for sensory neuropathies.

Some of the great successes in clinical neurosciences have actually been in prevention with the development of effective vaccines. Thus, we rarely encounter poliomyelitis, postrubella mental retardation, or postinfectious demyelination after measles (at least in the developed world). Recognition of risk factors and changes in life style have led to a significant decline in cardiovascular and cerebrovascular diseases, but strategies for preventing or delaying neurodegenerative diseases are still lacking. Possible protective effects of estrogens, antioxidants, and non-steroidal anti-inflammatory agents for neurodegenerative diseases are promising, but firm recommendations can still not be made.

The ultimate value of deciphering pathophysiological processes at a molecular level will arise in the development of targeted therapies. These should both reduce toxicity and permit a direct attack on disease process. Examples include the development of Herceptin, a 'monoclonal antibody', which has been proved useful for treatment of metastatic breast cancer which has been linked to the over-expression of the HER-2 allele. More recently, a targeted treatment for CML has been approved which blocks the expression of AB-1, a 'tumour promoting gene' (Druker et al., 2001). Gene and cell-based therapies are being developed for stroke, anoxic brain injury and other neurological disorders. In global ischemia models in gerbils, it appears that new neurons are produced within the hippocampus, raising the possibility that recovery after brain ischemia may, in part, reflect neurogenesis (Frank R. Sharp, University of Cincinnati, personal communication 2001). Fetal stem cells have been implanted in rodent models and continue dividing for several weeks. Cell lines in a marmocet model of stroke have restored some functional recovery (Svendsen & Smith, 1999; Ostenfeld et al., 2000).

At the same time, clinical research has come under closer scrutiny. Potential conflicts of interest by investigators, adequacy of informed consent procedures and the adequacy of monitoring of ongoing studies are subjects of concern, not only among investigators, but among the general public as well. As we proceed into the intervention phase of neurologic disease research and care, it is essential that investigators maintain their credibility for accurate, unbiased clinical research trial design, implementation and interpretation.

Therapeutic impact of translational neurosciences research

The concept of translational research, the delivery of laboratory discoveries to patient-oriented applications has many examples in neurological diseases. One increasingly important aspect of translational research is the development of new therapies, focused on pathogenic mechanisms. There are now FDA-approved agents for neurological diseases for which, until recently, we had no therapeutic options. These include Alzheimer's disease, amyotrophic lateral sclerosis, and multiple sclerosis, with agents that, at least for ALS and MS, are truly 'disease modifying', rather than symptomatic. One intervention which has changed clinical practice substantially is the introduction of TPA in appropriately selected patients with acute ischemic stroke. Acute ischemic strokes are now considered, like myocardial infarction, as 'brain attacks' requiring urgent evaluation and consideration for specific treatment. In stroke, the concept of neuroprotection has been tested successfully in ischemic animal models, but has failed to translate successfully to human trials. In fact, the last 15 years have seen a series of failures for a variety of treatments for ischemic stroke. Some of these failures may have been due to underpowered trials, or incorrect estimates of treatment effect (Samsa & Matchar, 2001) In Alzheimer's disease, transgenic models have been used to probe possible effectiveness of disease-modifying therapies, including inhibitors of beta secretase, the enzyme

critical for A-production, vaccination strategies directed against A-beta, neuroprotective strategies with antioxidants or estrogens to protect neurons from the downstream effects of A-beta accumulation, and other strategies. In other neurodegenerative diseases, such as Parkinson's disease, strategies to replace critical neurotransmitters have been attempted. Disappointingly, fetal neuronal grafts into the basal ganglia have as yet produced only modest effect on symptoms of Parkinson's disease with the added concern that dyskinesias developed in a proportion of patients (Freed et al., 2001)

In the tremendous potential of the basic and clinical neurosciences to permit an ever finer dissection of disease processes, we must never lose sight that these same processes affect a person, a family, a mind.

Ask not what disease the person has, rather what person the disease has. ***William Osler, 1889***

Genetics of common neurological disorders

Orest Hurko

Department of Investigational Medicine, GlaxoSmithKline Pharamaceuticals, Neurology Centre for Excellence in Drug Discovery, Harlow, Essex, UK

There is growing appreciation of the influence of genetic constitution on predisposition to disease, even that not usually considered 'genetic'. Approximately 40% of the estimated 30 000 human genes are expressed in the nervous system, the majority of these exclusively (Hurko, 1997; International Human Genome Sequencing Consortium, 2001; Sutcliffe, 1988; Venter et al., 2001). Neurological and psychiatric health might thus be especially susceptible to genetic influence. Furthermore, the nervous system can be uniquely vulnerable to mutations in genes expressed ubiquitously, as with huntingtin (Trottier et al., 1995), and to primary metabolic derangements in non-neural tissue, as with hepatic porphyrias (Strand et al., 1970) or diabetes mellitus. A disproportionate number of single gene disorders manifest as neurological or psychiatric dysfunction (Hurko, 2001).

Many of the successes of human molecular genetics have come from study of neurological disease. Neurological patients suffering from monogenic disorders have thus far only benefited from improved diagnosis. Identification of pathogenic genes has provided powerful reagents, transgenic animals, lessons from homologues in lower organisms and other insights into pathophysiology. These will hasten the development of effective therapies. However, most of these benefits, both realized and anticipated, have been confined to monogenic disorders. Such single gene, or Mendelian, disorders are rare.

Complexity in single gene disorders

Furthermore, even in monogenic disorders the relationship to clinical phenotype is not always straightforward (Estivill 1996). A given phenotype can result from mutation of any of a number of genes. Genetic heterogeneity exists in early-onset Alzheimer's disease (Dartigues & Letenneur, 2000), autosomal dominant spinocerebellar atrophies (Durr & Brice, 2000), limb-girdle muscular dystrophies (Beckmann, 1999; Bushby, 1999; Kissel & Mendell, 1999) and X-linked mental retardation (Toniolo & D'Adamo, 2000), among others.

Allelic heterogeneity

Different mutations within a single gene also contribute complexity. Frame-shift mutations abolish activity of dystrophin, causing Duchenne muscular dystrophy (DMD); mutations that do not shift reading frame compromise function only partially, resulting in milder Becker dystrophy or just subclinical elevation of serum creatine kinase (England et al., 1990; Matsuo et al., 1990). Similarly, variations in the length of triplet repeat expansions underlying Huntington disease (Reddy et al.,1999; Trottier et al., 1994), several of the spinocerebellar atrophies (Cummings & Zoghbi, 2000; Stevanin et al., 2000), fragile-X mental retardation, (Jin & Warren, 2000; Kooy et al., 2000), and myotonic dystrophy (Lieberman & Fischbeck, 2000) determine the severity of the neurological disorder. Allelic differences can be qualitative as well as quantitative. For example, some mutations of the ryanodine receptor result in central core myopathy (Zhang et al., 1993); others confer susceptibility to malignant hyperthermia without clinically evident myopathy (Gillard et al., 1992; McCarthy et al., 2000).

Mosaicism, the presence or expression of more than one genotype in an individual, results either from lyonization in X-linked disorders (Lupski et al., 1991), heteroplasmy in mitochondrial disorders (Hurko, 2001), or somatic mutations, as in tumours. In mosaics, clinical phenotype depends not only on which gene is mutant, but also on distribution and frequency. Parental imprinting adds further complexity. Inheritance of a certain mutation from father results in the Prader–Willi syndrome, whereas inheritance

of a similar mutation from mother causes the very different Angelman syndrome (Fridman & Koiffmann, 2000; Greenstein, 1990; Hulten et al., 1991).

Further complexity results from interaction of a pathogenic gene with the environment and with other genes. Mutation of the ryanodine receptor gene may be inapparent until exposure to halothane; mutations underlying hepatic porphyria inapparent until exposure to barbiturates. No gene is expressed in isolation. 'Monogenic' disorders can be modified by epistatic interactions with other genes (Maestri & Beaty 1992).

Genetically complex disorders

Even more complicated genetic and environmental interactions determine susceptibility to many common neurological and psychiatric disorders. Because of this complexity, delineation of genetic factors for common diseases has lagged behind those of rare Mendelian traits (Risch & Botstein, 1996). Analyses suitable for monogenic disorders are often suboptimal for complex traits. However, recent technical and analytical advances promise identification of susceptibility genes for several common neurological and psychiatric disorders.

Is a disease genetic?

Before turning to specific examples, it is useful to consider the meaning of genetic disorder. All biological phenomena result from complex interactions of thousands of genes and innumerable environmental factors. Diseases are no exception. In a given setting, some factors are more important than others. As a start, it is useful to estimate the relative contribution of genetic and environmental factors.

For many genetic diseases familial grouping is inapparent, particularly given the small size of modern nuclear families. These days, most cases of autosomal recessive disorders, such as metabolic disorders and progressive neurodegenerations of infancy like Tay–Sachs disease, occur as singletons in families with no previous history. Even if 1/100 healthy individuals carry a single copy of recessive mutation, there is only 1/10 000 chance that two such heterozygotes will marry, and only 1/4 of their offspring will fall ill because of homozygosity for the mutant gene. With a typical family size of two children, the overwhelming likelihood is that there will not be additional cases in siblings or in other generations. Only systematic analyses of large populations or consideration of biological data will reveal the genetic nature of such disorders. Similar considerations apply to new autosomal dominant mutations (Rudnik-Schoneborn et al., 1994), mitochondrial disorders like Kearns–Sayre syndrome (Butler & Gadoth, 1976), and chromosomal anomalies like Down's syndrome (Antonarakis, 1993).

Furthermore, not all diseases that 'run in families' are genetic. Members of a family share environmental factors: diet, socioeconomic class, as well as exposure to infectious, physical and chemical pathogens. A classic method for estimating the relative contributions of genetic and environmental factors has been the adoption study. Significantly higher similarity to biological rather than adoptive parents was the seminal indicator of the importance of genetics in schizophrenia (Heston, 1996) and alcoholism (Goodwin et al., 1974). However, the adoption method is limited. It will not detect recessive disorders or new mutations, and it also suffers from selective placement of adopted children into environments similar to those into which they were born. Adoption studies have not been used extensively in the study of neurological diseases.

A useful alternative is the comparison of concordance rates in monozygotic (MZ) and dizygotic (DZ) twins (Hawkes, 1997; Maher & Reik, 2000; Martin et al., 1997). MZ twins share all their genes, whereas DZ twins share only half. Therefore, a higher concordance rate in MZ than DZ twins is evidence of a genetic contribution. The higher the ratio of MZ concordance to DZ concordance, the higher the estimate of heritability. In the simplest case of a genetically determined disease, one would expect that all MZ twins would be perfectly concordant. For complex disorders this is usually not the case, for reasons only partially understood. There may be genetic heterogeneity: some twin pairs may have a highly heritable form of the disease, whereas others have a nonheritable phenocopy. In part, discordance may be an artefact of disease definition: MZ concordance for an expanded definition that includes schizoids is an almost perfect 1.0, twice that for classic schizophrenia. Furthermore, twin discordance has been seen even in well-defined single gene disorders. In X-linked DMD, dramatic discordance between MZ twin carriers is the rule rather than the exception, because of asymmetries in X-inactivation (Lupski et al., 1991). Not only environmental but also other developmental factors such as gene imprinting, may contribute to twin discordance, as has been shown for the Beckwith–Wiedemann tumour and mental retardation syndrome (Maher & Reik, 2000). In theory, the twin method is subject to the possible criticism that MZ twins share more environmental factors both prenatally and postnatally than do DZ twins. However, many of these concerns have proven more apparent than real (Kendler, 1993).

Although not perfect, twin studies have provided useful initial evidence of genetic factors in neurological and

Table 2.1. Comparative heritabilities

Disorder	λ	MZ	DZ	Heritability (%)
Autism	84–210	73%	7%	93
Schizophrenia	11	46%	14%	89
Anorexia nervosa	41			80
Multiple sclerosis	30	25.9%	2.3	
Febrile seizures	6–12	39%	12	
Alzheimer's disease	5			
ADHD	2–4	58%	31%	79
Lacunar stroke volume	2.5	61%	38%	73
Obsessive compulsive disorder				47–68
Bipolar depression	7	62%	8%	59
Migraine		34%	21%	52
Panic disorder	2.4–4.75			35–46
Unipolar depression		40%	17%	21–45
Sciatica		18%	12%	21
Pressure pain threshhold		57%	51%	10

psychiatric diseases, among them, multiple sclerosis (Ebers et al., 1986, 1995; James, 1996), autism (Bailey et al., 1995; Folstein & Rutter, 1977), schizophrenia (Gottesman, 1994), and attention deficit hyperactivity disorder (ADHD) (Sherman et al., 1997; Sutcliffe, 1988).

Other types of segregation analysis consider the relative risk among first-, second- and third-degree relatives of affected probands. The ratio of the risk to each class of relative is compared to the general population risk, expressed as the statistic λ_x. For example, λ_1 of 10 indicates that a first-degree relative of an affected individual has a tenfold higher risk of developing the disorder than does an unrelated individual in the same population. The more heritable the disorder the higher the value of λ_1. The more common the disorder in the general population, the lower is λ_1. This statistic serves as a rough guide to the tractability of a complex disorder for genetic analysis. Modest successes have now been achieved for complex human disorders such as schizophrenia, with λ_1 of about 10 (Table 2.1).

Genetic models

Further evidence of a genetic contribution can be provided by a distinctive pattern of transmission. For example, transmission of DMD from unaffected mothers to half of their sons strongly implicated the X chromosome, long before the dystrophin gene, or, for that matter, anything about DNA or the physical structure of any gene, were known. Identification of genetic patterns of transmission requires an explicit model against which to test data. There are two fundamentally different types of genetic model (Murphy & Chase, 1975). Neurologists are most familiar with the qualitative Mendelian model. An alternative Galtonian model has been used to describe quantitative traits, largely by agricultural and behavioural geneticists. Both models are simplifications, but are demonstrably useful in certain circumstances. Analysis of complex neurological and psychiatric diseases may require a synthesis of the two.

The Mendelian model posits that each phenoype is dichotomous. Either a bean is wrinkled or smooth, green or yellow. In Mendelian disorders, an individual either has the disease or is well. The Mendelian model further posits that each trait is determined exclusively by a single gene represented by two alleles, which can be either identical (homozygous) or different (heterozygous) in a given individual. Each allele is either recessive or dominant with respect to expression of a given trait. Segregation of a mendelian dominant disorder such as Huntington disease can be be modelled by a single coin toss representing the allele a child receives from her affected parent, heads for the wild-type allele, tails for the mutation (Murphy & Chase, 1975). If one scores 1 for heads, there are only two possible outcomes: a score of 1 and she will be healthy, a score of 0 and she will get Huntington disease.

The Galtonian genetic model has been used for metric rather than dichotomous traits. For example, the weight of livestock is more accurately described as a continuum

rather than as a simple dichotomy of heavy or light. Genetic transmission of many metric traits behaves as if there were a large number of genes contributing to the phenotype (Falconer, 1960). An appropriate analogy is a coin tossing game with a hundred equally weighted coins, again scoring 1 for heads and 0 for tails (Murphy & Chase, 1975). In this game there are a large variety of possible outcomes ranging from 0 to 100. The distribution of expected winnings will approximate a normal distribution with a mean of 50. From the score, one is able to tell how many times one flipped heads, but one wouldn't be able to tell which particular coins did so. The agricultural geneticist studying the weight of livestock will be able to estimate the aggregate number of heavy alleles inherited by a given animal, but will be unable to determine in which genes these heavy alleles reside. Some disease states, such as hypertension, are more accurately modelled as a continuum rather than as dichotomous states. Even when diseases can be considered dichotomous, such as stroke, the severity, age of onset and susceptibility may be modelled along a continuum.

For many complex traits, reality is somewhere in between the extreme Mendelian and Galtonian models. Even though multiple genes affect susceptibility, they are unlikely to be of equal effect. A single gene of dominant effect, as occurs in a Mendelian disorder, would be represented by a silver dollar, ten genes of low effect modifying the course of the illness would each be represented by a penny. Possible winnings would be represented by two nonoverlapping normal distributions with means of 5 cents and $1.05. If disease threshold were 50 cents, only the toss of the silver dollar would determine if the person became ill. Furthermore, even though refined measurements might provide an estimate of the total number of modifying genes mutant in an individual, only the presence or absence of mutation in the single gene of major effect could be determined unequivocally.

It is likely that many complex genetic disorders result from alterations of a small number of genes with different degrees of influence. An appropriate analogy is a coin tossing game with pennies, nickels, dimes and quarters. The total score could be determined, but the outcome of any particular toss may be indeterminate. Similarly, mutation of a given susceptibility gene could be present in an unaffected individual or absent in someone affected by virtue of the remainder of the genome. Furthermore, the relative importance of a given gene may vary according to the environment. A gene affecting lipid metabolism may be an importantant determinant of stroke in those consuming a lot of animal fat, but have only negligible significance for vegetarians.

Gene identification

Gene identification in single gene disorders

Definitive proof of monogenic determination requires identification of a gene mutant in affected individuals and normal in those that are healthy. Pathogenic mutations have been identified by one of two general methods: one beginning with biology, the other with genetics. In certain disorders, biochemical definition of abnormal patterns of metabolites or storage products in diseased individuals led to identification of a defective enzyme and subsequent analysis of the encoding gene. This method has been most successful in the delineation of autosomal recessive neurological disorders occurring in infants and children (Online Mendelian Inheritance in Man, 2001).

Many neurological disorders occuring later in life do not leave leave a sufficiently clear biological signature for unambiguous identification of a mutant protein. This calls for an alternative strategy based on identification of the chromosomal location of the mutant gene. This approach of 'reverse genetics' was appropriately renamed 'positional cloning' (Collins, 1990). The favoured method has been linkage analysis in large families segregating the disorder in a Mendelian pattern (Ott, 1985). Naturally occuring variants in the DNA sequence are used as markers. Originally, these markers were polymorphisms of surface antigens or electrophoretic patterns of proteins, then restriction fragment length polymorphisms (RFLPs) (Botstein et al., 1980) and later more ubiquitous microsatellites or short tandem repeats (Bently & Durham, 1995). The chromosomal locations of these markers had previously been determined and assembled into maps. One by one the segregation of these markers is compared to the segregation of the disease phenotype in large families. Unlinked markers are transmitted from affected parent to affected offspring at random, on average, 50% of the time. Those markers in the immediate vicinity of the disease gene are transmitted to affected offspring more often than expected by chance, and are thereby linked.

The observed frequency of recombination, separation of the marker and the disease in offspring, is an estimate of the genetic distance between the two loci. This value is expressed as θ. Because estimates of genetic distance are subject to sampling error, the accuracy of the estimate is given as a likelihood, expressed as a lod score, logarithm of odds. For example, a family study reporting a maximum lod score of 3 for $\theta = 0.04$ to a marker means that it is 1000 times more likely that the true genetic distance between that marker and the pathogenic mutation is 4 centiMorgans (cM), than is the null hypothesis that the two

are unlinked. The larger the number of informative family members observed, the more accurate the estimate.

With current technology, most genome-wide scans are undertaken with about 300 markers, spaced roughly every 10 cM (Brzustowicz et al., 2000; Kehoe et al., 1999b; Morissette et al., 1999; Weeks et al., 2000). Areas of the genome that give positive signals are then re-examined with a denser array of markers confined to that region. In theory, it should be possible to resolve any genetic distance given a sufficient number of observed transmissions and informative meioses. However, there are practical limitations. Accuracy improves by a square of the number of informative meioses sampled. Precise definition of a disease-causing mutation by strictly genetic methods requires analysis of hundreds of thousands of meioses. In actual practice, the accuracy of human linkage studies is limited to about 2–3 cM, roughly 2–3 million base pairs. Current estimates of the total number of human genes have converged on about 30 000 (International Human Genome Sequencing Consortium, 2001; Venter et al., 2001), having previously ranged from 35 000 to 140 000 (Aparicio, 2000; Liang et al., 2000), distributed over the 3300 cM of the human genome. Therefore linkage analysis on practicable human sample sizes can only resolve down to the 20 to 30 genes within that region. Each of these genes becomes a 'positional candidate'. Sometimes this number can be whittled down further by identification of deletions or translocations, overlaps of which define a narrower critical region. In the absence of such physical rearrangements, biological clues such as tissue distribution and predicted gene function guide a series of guesses until a gene mutant only in affected individuals is found. The majority of monogenic disorders have been resolved by a combination of genetic and biological information.

When large families are unavailable, multiple smaller kinships are analysed under the assumption that the gene responsible for the disorder is the same in each family. This assumption proved valid for many neurological disorders, a tribute to the diagnostic precision afforded by clinical neurology. However, for many others, the assumption does not hold. Notably, the demyelinating forms of Charcot Marie Tooth disease, the limb–girdle muscular dystrophies, the adult-onset spinocerebellar degenerations as well as many other Mendelian neurological disorders proved to be genetically heterogeneous (Online Mendelian Inheritance in Man, 2001). Results from linkage data from several small families each segregating a phenotypically indistinguishable but genetically distinct spinocerebellar atrophy would cancel each other out. Ideally, this problem is avoided by the use of a single large family. However, if only small families are available, allowances for heterogeneity can be made, but only by increasing sample size (Lander & Botstein, 1986). Allowances also have to be made for age-dependent penetrance, with care taken not to score individuals as unaffected if below likely age of onset. These considerations, and others, also apply to complex disorders.

Gene identification in complex disorders

Linkage approaches similar to those for monogenic disorders have also been applied to genetically complex diseases, chiefly diabetes, asthma and psychiatric disorders (Brzustowicz et al., 2000; Morissette et al., 1999). However, despite many successes with monogenics, linkage analysis of complex traits has proven much more difficult. Even with strict diagnostic criteria and large samples, most of these linkage analyses have yielded only weak and irreproducible findings (Risch & Botstein, 1996). This failure could mean that even highly heritable common disorders are influenced by a very large number of genes, each of small effect, approaching a Galtonian model. If so, then their identification would be impossible by any feasible linkage study. However, the failures may simply be methodological.

If most of the susceptibility for a given disease results from a small number of genes with large or moderate effect, modifications of the linkage approach may prove successful. One such modification is a non-parametric technique, not requiring specification of a pattern of inheritance (Kruglyak et al., 1996). In the standard parametric linkage analyses used for monogenic disorders, one must specify whether the disease mutation segregates as a dominant or a recessive. In many complex disorders, this is not known. Furthermore, many gene effects are semidominant, a heterozygote is phenotypically distinguishable from either homozygote, unlike the classic Mendelian model (Falconer, 1960). One nonparametric linkage approach is the method of affected sibling pairs. Regardless of mode of inheritance, any marker shared by affected siblings more often than expected by chance must be linked to a susceptibility gene. The closer the marker to the disease gene, the more frequently will it be shared by affected individuals in a given family. The utility of this approach depends not only on the distance between the marker and the disease gene but also on the frequency of the disease allele in the population and the magnitude of its effect on disease susceptibility. In a favourable situation, for example, if individuals with a copy of a susceptibility allele were at four-fold or greater risk of developing

the disorder than were those without that allele, then several hundred sibling pairs are sufficient to establish linkage in a genome-wide search (Risch & Merikangas, 1996).

However, if the disease allele confers less susceptibility or is unusually rare or frequent in the population, linkage can only be established by analysis of tens or hundreds of thousands of sibling pairs. For this reason, alternatives to linkage analysis have to be considered.

The major alternative to linkage analysis in families is allelic association in populations: the presence of a marker allele more frequently in affected individuals than in matched controls from the same population. In properly designed studies, allelic association is more powerful than linkage analysis, detecting associations with genes of only modest effect (genotype relative risk of 1.5) in samples of only a few hundred individuals. In an association study, the goal is to find linkage disequilibrium (not to be confused with linkage analysis) between a marker and a disease-susceptibility gene. Linkage disquilibrium is based on the assumption that a significant proportion of disease susceptibility attributable to a given gene results from an ancestral mutation in a single individual (Jorde, 1995; Kruglyak, 1997). Markers are usually nucleotide polymorphisms in the immediate vicinity of an ancestral mutation, rather than the pathogenic mutation itself. Such markers are transmitted together with the disease allele until separated by recombination. Unless the marker happens to be a unique disease susceptibility mutation, the correlation between it and disease would not be perfect in present-day populations.

In present-day populations, some unaffected individuals with the marker will be descendants of the diseased ancestor, but will have had the marker and disease allele separated by recombination. Such an event can be recognised by the use of multiple markers arranged in a haplotype that brackets the disease susceptibility locus. Other unaffected individuals will have inherited the marker not from the diseased ancestor but from her unaffected sibling. Some affected individuals may not have the marker, either because of recombination or by virtue of having inherited a disease allele from another ancestor with a different background set of markers. For these reasons, the success of association studies depends not only on the proximity of the markers to the actual disease susceptibility locus, but also on the history of the population.

There are two major limitations to association studies, population stratification and the inability to survey beyond the immediate vicinity of the marker. Spurious associations can arise if the ethnicity of affected and control individuals is not matched carefully. For example, both sickle cell anemia and G6PD deficiency are more common in individuals of African and Mediterranean descent than they are in Northern Europeans. In a sample that included both Europeans and Africans, a G6PD marker would show a strong association with sickle cell disease even though the genes are on separate chromosomes. In such a case, allelic association is not an indication of linkage disquilbrium. An identical association study in sub-Saharan Africa would show no association.

A number of methods have been suggested to guard against spurious associations from population stratification (Pritchard & Rosenberg, 1999). However, their utility in population-based case control studies of allelic association of complex disorders resulting from genes of small to modest effect is still untested. An alternative to case-controlled population-based allelic association studies is the transmission/disequilibrium test (TDT) (Spielman et al., 1993), which is immune to errors of population stratification. In this test, nonrandom distribution of a marker from heterozygous parents to an affected offspring provides robust evidence of linkage disequilibrium to a disease susceptibility gene. A thousand trios of affected offspring with both parents should be sufficient in a genome-wide scan to identify markers in linkage disequilibrium with genes of modest effect (Risch & Merikangas, 1996).

The remaining limitation of TDT, as of all association studies, is that in most populations, linkage disquilibrium only extends for very short distances, tens of thousands of bases. Linkage analysis can be undertaken with markers separated by tens of centiMorgans, tens of millions of base pairs, from the disease locus, because the experiment only requires detection of cross-overs in a few generations. A complete linkage scan can therefore be accomplished with 300 markers. In contrast, association studies for linkage disequilibrium depend on the absence of recombination between marker and disease loci in the many generations that separate the study population from the ancestral mutation (Kruglyak, 1997). Thus, even a marker within the same gene but 100 kilobases distant from a pathogenic mutation may fail to show an association. A complete survey of the human genome by association might require testing of as many as 1 000 000 markers (Risch & Merikangas, 1996). The technology to accomplish this will likely require the use of a different type of marker, the single nucleotide polymorphism [SNP], detection of which is amenable to automation. A consortium to develop the necessary SNP markers is already under way (Gray et al., 2000). The technical and statistical problems posed by this

number of assays on hundreds of individuals are formidable, but soluble. Pooling of DNA from affected and unaffected individuals in case control studies followed by quantitation of allele frequencies in each of the two pools requires that an assay need only be done twice, rather than separately for each of hundreds of individuals (Germer et al., 2000; Shaw et al., 1998) Genotyping using dense oligonucleotide arrays on solid supports or other technologies will significantly increase throughput and reduce costs (Fan et al., 2000).

Presently, association studies are limited to analysis of a few candidate genes, selected because of a biological rationale. Many association studies will be mentioned in the sections on specific neurological diseases, but most of them have used single markers and a case-control rather than TDT design. Both negative and positive studies are thus suspect. Ideally, association studies should use TDT with a dense array of multiple markers spanning the gene of interest, something not yet done in most neurological studies. An excellent example of the candidate gene TDT approach has been the robust demonstration of association of ADHD with polymorphisms in the dopamine D4 gene (Muglia et al., 2000; Smalley et al., 1998; Tahir et al., 2000). The recent completion of a first rough draft of the human genome (Bentley, 2000; Butler & Smaglik, 2000; International Human Genome Sequencing Consortium, 2001; Venter et al., 2001) and increased understanding of pathophysiology of neurological diseases will aid in the selection of candidates for allelic association studies as will reference to tissue- or disease-specific patterns of gene expression made possible by high-density nucleotide arrays (Gaasterland & Bekiranov, 2000; Lee et al., 2000).

In addition to the top-down allelic association methods used in case-controlled population studies and TDT, the bottom-up approach of cladistic analysis may prove useful (Haviland et al., 1997; Templeton et al., 1987). In this approach, haplotypes constructed for a randomly selected population sample are used to construct trees, where each branchpoint represents an alteration of one marker. Comparisons of disease frequency are then made on either side of each branchpoint. A significant difference implies that the individuals on either side of the branchpoint must differ by the presence of a mutation affecting susceptibility. Although this method is mathematically more powerful than conventional association studies, it has not been used widely, in part because of the difficulties with accurate estimation of haplotypes and the use of population-based samples in which only a minority of individuals have a clinical phenotype of interest. However, cladistics may prove useful in very common neurological disorders such as stroke or migraine.

Neurological disorders with complex inheritance

In contrast to psychiatric and autoimmune disorders, the emphasis on neurological genetics has been on monogenic disorders. In the last two decades, in excess of 650 monogenic neurological disorders have been mapped. Of these, the responsible gene has been identified for over 460 (Hurko, 2001; Online Mendelian Inheritance in Man, 2001). Over two-thirds of these mapped disorders present in childhood, many of them autosomal recessive disorders such as Tay–Sachs disease for which biochemical analysis revealed an a enzymatic deficiency that was subsequently confirmed by sequencing of a mapped gene in affected individuals. Since homozygosity for many of these mutations precludes reproduction, the mutant alleles survive in the gene pool in the much larger reservoir of asymptomatic heterozygous carriers. Although the total burden of heritable neurological disease in children is low compared to that of adults, the number of discrete diagnoses is considerably higher (Childs, 1998).

In both single-gene and complex disorders, deleterious alleles can survive in the gene pool as dominants if serious disease only becomes manifest after child-bearing years. In contrast to the many rare, single-gene, autosomal recessive neurological diseases in childhood, the number of neurological diagnoses are in adults are fewer even though the total burden of neurological disease is higher. The genetic propensity for most of these diseases is complex. Some neurological diseases are grouped under the same diagnosis, such as Alzheimer's disease, even though they may result from any of a number of distinct genetic abnormalities.

As a general rule, genetic diseases of chidhood are rare, many and monogenic, those of adults are common, few and polygenic (Childs, 1998).

Adult-onset dementias

Some of the heterogeneity of adult-onset dementia is readily apparent clinically, as with multi-infarct dementia, vitamin B12 deficiency, hypothyroidism, Creutzfeld–Jacob disease or late syphilis. More careful clinical and pathological analysis further subdivides late-onset dementia into frontotemporal dementia, Lewy body dementia, Alzheimer's disease, and multiple rarer disorders. The genetic contribution to each of these disorders ranges from negligible to major. As shown in Table 2.2 several of these segregate as single-gene disorders. Allelic heterogeneity has been demonstrated for the amyloid precursor protein and tau genes, mutations of which can cause a variety of clinical phenotypes (Table 2.2).

Table 2.2. Single-gene adult-onset dementias

Disorder	MIM	Location	Gene product
(Early-onset) Alzheimer's disease 1, APP related	104300	21q21.3–q22.05	amyloid beta 4 precursor
Dementia, presenile, and cerebroarterial amyloidosis	104760 0.0005	21q21.3–q22.05	amyloid beta A4 precursor
Amyloid angiopathy (Dutch)	104760	21q21.3–q22.05	amyloid beta A4 precursor
(Early-onset) Alzheimer's disease 3	104311	14q24.3	presenilin-1, seven transmembrane domain protein
Alzheimer's disease, familial, with spastic paraparesis and unusual plaques	104311 0.0017	14q24.3	presenilin-1, seven transmembrane domain protein
(Early-onset) Alzheimer's disease 4	600759	1q31–q42	presenilin-2, seven transmembrane domain protein
Alzheimer's disease, familial, Type 5	602096	12p11.23–q13.12	association with transcription factor CP2; TFCP2 (189889)
Alzheimer's disease without neurofibrillary tangles	604154	3	
Hereditary frontotemporal dementia (FTD)	601630	17q21–q22	microtubule-associated protein tau; MAPT (157140)
Disinhibition–dementia–Parkinsonism–amyotrophy complex (DDPAC)	600274	17q21–q22	tau
Progressive subcortical gliosis (PSG) of Neumann	221820	17q21–q22	?

Autosomal dominant Alzheimer's disease is rare, accounting for only 0.3% of cases (Campion et al., 1999). Mutations of any of three genes account for the majority of these autosomal dominant cases (Table 2.2). All of these lead to early onset, by age 60 (Dartigues & Letenneur, 2000). The prevalence of early-onset Alzheimer's disease has been estimated to be 41.2/100 000 of which only 12.9% were autosomal dominant. In the same population survey, 56% of these autosomal dominant families were found to have a mutation of presenilin-1, and another 15% to have a mutation in amyloid precursor protein APP. Although the vast majority of Alzheimer cases have not been associated with mutations in either presenilins-1, -2 or APP, these rare families have

had great heuristic value in supporting a primary role for amyloid pathology.

In contrast, no simple inheritance pattern is evident in the more common late-onset Alzheimer's disease (AD). That notwithstanding, genetic factors play a major role in predisposition to AD, which has a λ_1 of 5. The only major susceptibility gene unequivocally identified to date is apolipoprotein E, with the presence of the E4 allele increasing the relative risk for AD by a factor of 4.5 in the heterozygous state (Scott et al., 1999). Although this was discovered in the course of linkage analysis, the positive marker was in linkage disquilibrium with apoE, and might not have been detected had a slightly more distant marker been used (Martin et al., 2000; Risch & Merikangas, 1997). However, the E4 allele is neither necessary nor sufficient for Alzheimer's disease: most apoE4 carriers do not dement and about one-half of Alzheimer's disease is not associated with apoE4 (Myers et al., 1996).

Furthermore, the effect of apoE is not specific for Alzheimer's disease, associations with ApoE 4 having been observed for susceptibility to Creutzfeld–Jakob disease (Amouyel et al., 1994), age of onset and susceptibility to Pick's disease (Farrer et al., 1995), susceptibility to schizophrenia (Harrington et al., 1995), age of onset of Huntington's disease in males (Kehoe et al., 1999a) though not disease susceptibility (Kalman et al., 2000), as well as poor outcomes after head trauma and intracerebral hemorrhage (Friedman et al., 1999; Horsburgh et al., 2000).

Although the total λ_1 for AD is 5, the gene-specific λ_1 for apoE is only 2, implying that a substantial part the genetic risk for AD results from other genes. It appears likely that there may be as many as 4 additional susceptibility genes for late-onset AD with effect comparable or greater than that of apoE (Martinez et al., 1998; Warwick Daw et al., 2000). Candidates include an alpha-2-macroglublin in 12p13.3–p12.3, supported in some studies (Blacker et al., 1998; Liao et al., 1998), but not others (Shibata et al., 2000); a perhaps unrelated gene in 12p11.23–q13.12 (Scott et al., 2000); very low density lipoprotein receptor encoded on 9p24 (Okuizumi et al., 1995); bleomycin hydrolase on 17q11.2 (Papassotiropoulos et al., 2000); interleukin 1α (Du et al., 2000); and certain variations of the mitochondrial genome (Hutchin & Cortopassi, 1995). Genetic studies with these candidates have either given mixed results or await confirmation.

Multiple sclerosis

Unlike the adult-onset dementias, no monogenic forms of multiple sclerosis have been reported. Although there may be initial diagnostic confusion presented by the clinical features of adult-onset spinocerebellar atrophies and hereditary spastic paraplegias (Durr & Brice, 2000) or with the radiographic appearance of CADASIL or some of the leukodystrophies, routine clinical evaluation easily distinguishes these Mendelian disorders from multiple sclerosis (Hutchin & Cortopassi, 1995).

Neverthess, this disorder is highly heritable, with a λ_1 of 30, five times that of late-onset Alzheimer's disease. Six per cent of MS probands have an affected first-degree relative, considerably in excess of that predicted by a population frequency of 3/10000. Monozygotic twins have a concordance rate of 25.9% compared to a 2.3% concordance rate in dizygotic twins, suggesting polygenic inheritance. The number of concordant twins in these studies is low, however, and the twin data need to be viewed with some circumspection (Ebers et al., 1995). Despite this apparently high heritability, three recently completed genome-wide linkage scans have failed to identify a susceptibility locus unequivocally (Ebers et al., 1995; Multiple Sclerosis Genetics Group, 1996; Sawcer et al., 1996). The strongest signals from these linkage studies clustered around the HLA region on chromosome 6p21. Even though the HLA locus contributes little to overall susceptibility, it has been clearly identified in a number of case-controlled and TDT studies that have demonstrated an association with HLA-DR2 alleles (Haines et al., 1998).

Weaker positive associations have been observed with interferon gamma in patients at low risk because of their HLA status (Goris et al., 1999; Vandenbroeck et al., 1998) and the I-cell adhesion molecule (Mycko et al., 1998). Severity of but not susceptibility to MS (Reboul et al., 2000) has been reported to be associated with a certain combination of interleukin-1beta and interleukin-1 receptor antagonist genes. An association has been reported with TNF-α, independent of the association with the nearby HLA region (Fernandez-Arquero et al., 1999) as has an association with the immunogobulin heavy chain region (Walter et al., 1991). Association studies with myelin basic protein (Wood et al., 1994) and complement factors 6 and 7 (Chataway et al., 1999) have been negative. Both the negative and positive associations deserve to be re-examined and other regions of the genome examined in larger populations with denser marker arrays. However, at present, there is no strong evidence to support the existence of any susceptibility genes of moderate or major effect other than HLA.

Parkinson's disease

Although there is little evidence for substantial genetic contribution to typical late-onset Parkinson's disease,

some early-onset disease is attributable to either monogenic or polygenic disorders. A rare autosomal dominant form of parkinsonism associated with dysautonomia and dementia has been associated with mutations of the alpha-synuclein gene (Polymeropoulos et al., 1996). An autosomal recessive juvenile-onset parkinsonian syndrome with atypical clinical features has been associated with mutations in the parkin gene (Kitada et al., 1998). Parkinsonian features can sometimes be seen in several other Mendelian disorders, including some of the dominantly inherited spinocerebellar atrophies associated with triplet repeat expansions (Durr & Brice, 2000); the X-linked Segawa syndrome resulting from mutations in GTP cyclohydrolase (Ischinose et al., 1994; Nygaard & Duvoisin, 1986); Filipino dystonia syndrome (Muller et al., 1990); as part of the phenotype of a single infant with tyrosine hydroxylase deficiency (Ludecke et al., 1996); in several of the syndromes associated with mutations in the microtubule tau gene (Lynch et al., 1994; Wijker et al., 1996); and in the X-linked Waisman syndrome of early-onset parkinsonism, megaencephaly and seizures (Gregg et al., 1991).

However, these rare Mendelian disorders can be distinguished readily from classic Parkinson's disease, a common disorder of late adult life with incidence of about 1/10000 (Bower et al., 1999; Tanner et al., 1999). A large twin study demonstrated no difference in concordance for monozygotic or dizygotic twins with late-onset Parkinson's disease (Tanner et al., 1999). The same study demonstrated a sixfold higher monozygotic concordance rate in those twins for whom disease onset was before age 50. These data imply that there is a significant genetic risk for early-onset disease, but none for typical late-onset Parkinson's disease. Segregation analysis has ruled out Mendelian inheritance as an explanation for occasional familial clustering of Parkinson's disease (Zareparsi et al., 1998). Biochemical and cell fusion studies have suggested that a non-Mendelian susceptibility factor might be mitochondrial DNA (Swerdlow et al., 1996), a plausible hypothesis for which the evidence remains inconclusive.

Epilepsy

Although described by Hippocrates as a familial disease, epilepsy is present in siblings in only a minority of families (Baraitser, 1982). Heritability differs by seizure type and age of onset. For idiopathic grand mal epilepsy beginning before age 35, the concordance rate for MZ twins is 0.30 and for DZ twins it is only 0.13 (Miller et al., 1999) whereas for late-onset cases there is no significant difference. Overall, the frequency in close relatives ranges from 3 to 6%, compared to a general population risk of 0.5% (Alstrom, 1950). Febrile seizures have a recurrence rate of 0.39 in MZ twins and 0.12 in DZ twins, indicating significant heritability. The frequency of febrile seizures in siblings is 20% (Frantzen et al., 1970), compared to a general population risk of 3% (Baraitser, 1982). Other studies suggest common genetic factors for febrile convulsions, temporal lobe epilepsy and early status epilepticus (Baraitser, 1982).

Some of this familial clustering results from rare monogenic disorders that segregate as simple Mendelian traits (Table 2.3). However, a larger number of cases appear to result from multigenic inheritance. Susceptibility loci have been mapped, but genes not yet identified. (Table 2.4). In some types of epilepsy, there are a few genes of major effect, none of which is either necessary or sufficient to cause the disorder. In nocturnal frontal lobe epilepsy the effects of two single genes were so strong that they were located with a modified Mendelian model, with allowances for low penetrance (Phillips et al., 1995) (Table 2.3). In contrast juvenile myoclonic epilepsy proved more difficult to map using a Mendelian model, but more tractable using a complex genetic model (Elmslie et al., 1997; Greenberg et al., 2000) using which, two susceptibility loci have been identified. Reduced penetrance in a Mendelian model and complex genetics can simply be different ways of modelling the same reality.

Migraine

The genetics of migraine has proven difficult in part because of the high prevalence of this disorder, with a lifetime incidence of 33% in women and 13.3% in men (Launer et al., 1999). Studies in monozygotic and dizygotic twins raised either together or apart, have yielded heritability estimates of 52% (Ziegler et al., 1998). Twin studies of migraine with aura show a concordance rate of 34% in MZ twins and only 21% in DZ twins, similar to that of non-twin siblings (Ulrich et al., 2000). In migraine without aura, the concordance ratios were similar: 28% in MZ and 18% in DZ twin pairs (Gervil et al., 1999). Although many MZ twin migraineurs are concordant for the presence or absence of aura, a significant proportion are not (Kallela et al., 1999). Rare severe forms of migraine with aura, familial hemiplegic migraine, have been shown to be monogenic disorders. Fifty per cent of these families have mutations of the CACNL1A4 gene on chromosome 19p13 (Ophoff et al., 1996). The same locus appears to contribute to some cases of non-hemiplegic migraine, either with or without aura. There are at least two other monogenic forms of hemiplegic migraine, one of which has been mapped to chromosome 1q31 (Gardner et al., 1997). There is evidence

Table 2.3. 'Monogenic' epilepsy syndromes

Disorder	OMIM	Locus	Gene
Benign adult familial myoclonus epilepsy (BAFME; FAME) (autosomal dominant)	601068	8q23.3–q24.11	
Benign neonatal convulsions, type I (BFNC1) (autosomal dominant)	121200	20q13.3	potassium channel, voltage-gated, subfamily Q, member 2; KCNQ2 (602235)
Benign neonatal convulsions, type II (EBN2; BFNC2) (autosomal dominant)	121201	8q24	potassium channel, voltage-gated, subfamily Q, member 3 KCNQ3 gene (602232
Idiopathic generalized epilepsy (EGI)	600669	8q24	? allelic to EBN2
Benign familial infantile convulsions BFIC (autosomal dominant)	601764	19q	
Benign Rolandic epilepsy; Centrotemporal epilepsy	117100		(mouse gene found on 9)
Childhood Absence Epilepsy 1 (ECA1)	600131	8q24	
Childhood Absence Epilepsy 2 (ECA2)	600131	5q31.1–q33.1	gamma-aminobutyric acid receptor, gamma-2 (GABRG2) (137164)
Febrile convulsions, familial, 1 FEB1 (autosomal dominant, penetrance 60%)	602476	8q13–q21	
Febrile convulsions, familial, 2 FEB2 (autosomal dominant)	602477	19p13.3	
Febrile convulsions, familial, 3 FEB3 (autosomal dominant)	604403	2q23–q24	
Generalized epilepsy with febrile seizures plus; GEFS+, TYPE 1 (autosomal dominant)	604236	19q13	voltage-gated sodium channel beta-1 subunit gene (SCN1B) (600235)
Generalized epilepsy with febrile seizures plus, type 2; GEFS+, TYPE 2 (GEFSP2)(autosomal dominant)	604233	2q21–q33	alpha-subunit voltage-gated sodium channels (SCN1A)(182389)
Generalized epilepsy with febrile seizures plus, type 3; GEFS+, TYPE 3 (GEFSP3)	614233	5q31.1–q33.1	gamma-aminobutyric acid receptor, gamma-2 (GABRG2) (137164)
Nocturnal frontal lobe epilepsy ENFL 1 (autosomal dominant, low penetrance)	600513	20q13.2	neuronal nicotinic acetylcholine receptor, alpha polypeptide 4 (CHRNA4) (118504)
Nocturnal frontal lobe epilepsy ENFL 2 (autosomal dominant, low penetrance)	603204	15q24	close to the CHRNA3 (118503)/CHRNA5 (118505)/CHRNB4 (118509) cluster.
Nocturnal frontal lobe epilepsy ENFL 3 (autosomal dominant, low penetrance)	605375	1p21	Acetylcholine receptor, neuronal nicotinic, beta-2 subunit (CHRNB2) (118507)
Partial epilepsy (autosomal dominant)	600512	10q23.3–q24.1	
Reading epilepsy	132300		
Rolandic epilepsy and speech dyspraxia	601085		

Table 2.4. Susceptibility loci for epilepsy

Disorder	Susceptibility locus
Febrile convulsions, familial, 4 (FEB4)	5q14–q15
Idiopathic generalized epilepsy EGI	8q24
Idiopathic generalized epilepsy EGI	2q22–q23
Juvenile myoclonic epilepsy EJM1, Janz syndrome	6p
Juvenile myoclonic epilepsy EJM2	15q14

Table 2.5. Heritability of stroke

Aneurysm/SAH	$\lambda = 4.2$	(2.2–8.0)
Intraparenchymal hemorrhage	$\lambda = 2.39$	
Dissection	$\lambda = 6.3$	(2.2–18.3)
All ischemic	$\lambda = 1.4$	(1.1–2.0)
Large artery	$\lambda = 1.85$	
Lacunar	$\lambda = 2.53$	
heritability = 73%		
twin concordance = 61% MZ, 38% DZ		

for susceptibility loci on the X chromosome and elsewhere for non-hemiplegic migraine (Nyholt et al., 1998)

Genetic analyses have been undertaken not only for susceptibility but also for specific characteristics of the migraine syndrome. For example, preliminary observations suggest that predisposition to aura in migraineurs may be influenced by a locus on chromosome 6p (Gardner et al., 1997), predisposition to migraine-related strokes by variations in the mitochondrial genome (Nyholt et al., 1998), and the frequency of migraine attacks by a gene in the vicinity of angiotensin-converting enzyme (Martelletti et al., 1999).

Stroke

Although individually rare, there are a large number of Mendelian disorders associated with stroke, which have been reviewed extensively (Hassan & Markus, 2000; Natowicz & Kelley, 1987). Of particular interest is CADASIL, resulting from mutations of the notch3 gene (Viitanen & Kalimo, 2000) and homocystinuria, which can result from deficiency of any of several enzymes (Mudd et al., 1998). Although homozygotes for classic homocystinuria are very rare, heterozygotes are relatively common. An elevated plasma level of homocystine is a significant risk factor for stroke in the general population (Giles et al., 1998) but the relationship to specific genes has not yet been established (Kiely et al., 1993).

Except for these rare Mendelian disorders it is difficult to demonstrate a significant degree of heritability for stroke, in large part because of the high incidence in the general population. The sex-averaged relative risk of having a stroke by virtue of having an affected parent is only 1.9 (Kiely et al., 1993). Population studies demonstrate ethnic differences, which could either be genetic or environmental (Kiely et al., 1993; Reed, 1993). Although a twin concordance study has suggested an influence of genetic factors, generalizations from this small sample must be made with caution (Howard et al., 1994).

However, if stroke is subdivided by type, certain groupings appear to have a higher heritability than others (Table 2.5). A large number of association studies have been undertaken in an effort to identify susceptibility genes underlying ischemic stroke in the general population. Of these, studies with the fibrinogen gene have been positive, showing a modest but consistent effect, whereas studies with genes encoding other clotting factors have been either negative or irreproducible (Hassan & Markus, 2000). Complex genetic analyses of the stroke-prone spontaneously hypertensive rat have identified three distinct quantitative trait loci that account for most of the variance in incidence and severity of stroke (Jeffs et al., 1997; Rubattu et al., 1996) in these laboratory strains. The genes underlying such susceptibility remain to be identified, as does its relevance to human disease (Rubattu et al., 1999).

Myasthenia gravis

About 4% of myasthenics have an affected relative, higher than would be expected from a population prevalence of 2 to 4/100000. There is a sharp dichotomy in heritability between early- and late-onset forms (Online Mendelian Inheritance in Man, 2001). Forty-two per cent of familial cases have onset before 2 years of age, and perhaps are more appropriately described as myasthenic syndromes. Some of this familial clustering is not genetic, but results from maternal transmission of antibody, whereas others result from rare mutations affecting end-plate acetylcholinesterase or the alpha, beta or gamma subunit of nicotinic receptor. Infantile cases only account for 1% of all myasthenics.

Genetic susceptibility to the more common adult-onset form is complex. Some of this genetic susceptibility resides in the HLA region, particularly HLA-DR3 and -B8 (Janer et al., 1999), especially for females. The predisposing haplotypes are the same as for juvenile-onset diabetes mellitus, systemic lupus erythematosus and susceptibility to HIV

(Price et al., 1999). Other HLA associations have been reported for polymyositis and dermatomyositis (Rider et al., 1998). An association with myasthenia gravis has also been reported for the beta-adrenergic receptor (Xu et al., 2000). Although there has been no association independent of HLA between TNFβ and myasthenia (Manz et al., 1998), differences in this site may discriminate myasthenics with thymic hyperplasia from those with thymomas (Zelano et al., 1998). Similarly, there may be an allelic association between interleukin-10 and levels of circulating antinicotinic receptor antibodies in myasthenics but no association with disease susceptibility (Huang et al., 1999).

Pain

Weak associations with the HLA locus have been demonstrated for susceptibility to reflex sympathetic dystrophy (Huang et al., 1999) now renamed the complex regional pain syndrome. Rare instances of monogenic congenital insensitivity to pain have been mapped (Online Mendelian Inheritance in Man, 2001), and, in one instance, the mutant gene identified (Kemler et al., 1999).

However, the heritability of overall pain sensitivity in the general population is a low 10%, with MZ and DZ concordances almost identical. Genetic studies with inbred rodents tested for specific pain mechanisms have shown much higher heritability, attributable in most instances to a small number of genes of major effect (Mogil et al., 1999). Susceptibility to one type of painful stimulus can be either positively or negatively correlated with responses to other stimuli. Genetic analysis of mechanism-based pain susceptibility has yet to be undertaken in humans.

Sleep disorders

Several types of sleep disorder have been described, of which narcolepsy is the best understood. Strong association with the HLA region on chromosome 6 p21.3 has long been known (Mignot et al., 1997). The segregation pattern is complex. Mutations of orexin receptor 2, encoded by a gene on human chromosome 6p21, give rise to a monogenic narcolepsy in dogs (Lin et al., 1999). To date, mutations in the orexin receptor 2 gene have not been reported in humans with narcolepsy although low CSF levels of orexin are common (Nishino et al., 2000). It appears that the proximity of the two genes is fortuitous, and orexin deficiency in most cases of narcolepsy may be the result of immune attack on the hypothalamus. A mutation in the preproorexin gene has been reported in a single case of atypical narcolepsy (Peyron et al., 2000), but this mutation appears exceptional.

Other types of sleep disorder have been shown to segregate as simple Mendelians traits: rare instances of fatal familial insomnia, an autosomal dominant disease resulting from mutations of the prion protein gene (Harder et al., 1999) and a circadian rhythm disturbance (Toh et al., 2000). Genetic definition of other sleep disorders will depend in part on a better definition of phenotype.

Repeat expansion and neurological disease

J. Paul Taylor, Andrew P. Lieberman and Kenneth H. Fischbeck

Neurogenetics Branch, National Institute of Neurological Disorders and Stroke, National Institutes of Health, Bethesda, MD, USA

Repetitive DNA sequences are abundant in the human genome, scattered throughout the regions between genes and, in some cases, within genes. They take the form of minisatellites (repeat sequences ranging in length from tens to hundreds of nucleotides) and microsatellites (repeat sequences consisting of one to several nucleotides in length) and have an intrinsic genetic instability that results in frequent length changes (Charlesworth et al., 1994; Tautz & Schlotterer, 1994). Thus, mini- and microsatellites are highly polymorphic between individuals, a feature which has led to their extensive use in genetic research as markers in positional cloning of genes and also in forensic medicine for DNA-based identification, so-called 'DNA fingerprinting'. While the normal role of these sequences, if any, remains unclear, repeat sequences have gained a great deal of attention over the past decade because of their emerging role in human disease. In particular, expansions of repetitive sequences within genes are increasingly found to underlie hereditary neurological diseases. In this chapter we discuss mechanisms that have been proposed to generate repeat expansion, the relationship between repeat length and disease manifestations, and present a classification scheme for organizing trinucleotide expansion diseases. Finally, we discuss the clinical features, genetics, pathology and molecular pathogenesis of 16 currently recognized trinucleotide expansion diseases.

Anticipation

Neurologists have long recognized the clinical phenomenon of anticipation, the tendency of certain inherited neurological diseases to appear earlier in successive generations, often with more severe clinical manifestations. This phenomenon, which was described as early as 1918 in myotonic dystrophy (Fleischer, 1918) and subsequently observed in other neurodegenerative diseases, was at odds with the classical Mendelian genetic principle that mutations are stably passed on to offspring. Thus, for many years the phenomenon of anticipation was attributed to ascertainment bias. Then, in 1991, spinobulbar muscular atrophy and the fragile X syndrome were found to result from expanded trinucleotide repeats in their respective genes. Furthermore, these expanded repeats were found to be unstable, frequently becoming longer in successive generations. Since longer repeat expansions are generally associated with earlier disease onset and more severe disease, this provided a molecular basis for anticipation. Since then, this dynamic form of genetic mutation has been found to underlie an increasing number of inherited neurological diseases, most of which exhibit anticipation. In general, there is an inverse relationship between age of onset and length of the repeat expansion, and a direct relationship between expansion length and disease severity. In disorders with incomplete penetrance, such as fragile X syndrome, penetrance is also related to length of the expansion.

While anticipation is frequently associated with diseases caused by unstable repeat expansion, it varies markedly in degree, and in some diseases may not occur at all. Anticipation is most pronounced in myotonic dystrophy, but also readily observed in the spinocerebellar ataxias and Huntington's disease. Anticipation is generally not seen in spinobulbar muscular atrophy and oculopharyngeal muscular dystrophy. One feature of anticipation is the 'parent of origin effect'. This is the tendency for anticipation to be observed when the gene is passed on through a specific gender. The tendency may be greater with paternal transmission (e.g. Huntington's disease) or maternal transmission (e.g. myotonic dystrophy), a phenomenon that probably reflects the nature of the expansions underlying the respective diseases.

Mechanisms of repeat expansion

There is an emerging consensus that unusual secondary structures adopted by trinucleotide repeats are responsible for their inherent instability, provoking errors at multiple levels of DNA metabolism (Bowater & Wells, 2000). Errors introduced during DNA replication, DNA repair, and homologous recombination have been implicated as contributing to trinucleotide repeat expansion. The propensity of repetitive DNA sequences to adopt unusual secondary structures (hairpin loops for CAG, CTG, and CGG repeats; triple helices for GAA repeats) provides an explanation for two features of trinucleotide repeat expansion: (i) the threshold effect for repeat instability, and (ii) a greater tendency towards expansion of some trinucleotide repeats than others.

Replication-dependent strand slippage during DNA replication is the mechanism of repeat sequence instability most strongly supported by both in vitro and in vivo evidence. Strand slippage is believed to occur when transient dissociation of the primer and template strands is followed by misaligned reassociation of the complementary strands, resulting in 'slippage' of the nascent DNA to a new position on the template (Wells, 1996). Unusual secondary structures promote primer/template dissociation, probably by causing the DNA replication complex to pause in the vicinity of repeat sequences (Kang et al., 1995).

Nucleotide excision repair systems recognize DNA damage by sensing distortion of helical structure (Wood, 1996). The unusual secondary structures adopted by some trinucleotide repeat sequences are likely to induce this repair pathway. In addition, these structures may be recognized by the mismatch repair system (Modrich & Lahue, 1996). Studies carried out in prokaryotic systems provide evidence that these pathways may contribute to trinucleotide repeat instability (Bowater & Wells, 2000).

An additional mechanism that may contribute to repeat instability is the introduction of errors during homologous recombination. Several human haplotype studies implicated gene conversion and unequal crossing-over as mechanisms that may contribute to the expansions and contractions of CTG trinucleotide repeats observed in myotonic dystrophy (Tsilfidis et al., 1992; O'Hoy et al., 1993; Tishkoff et al., 1998). Three studies investigating the loss of a fragile X mutation between parent and offspring concluded that gene conversion was responsible, suggesting that CGG repeats may also promote errors in homologous recombination (Van den Ouweland et al., 1994; Losekoot et al., 1997; Brown et al., 1996).

Classification of repeat expansion diseases

Trinucleotide repeat expansion disorders may be divided into two types based on the location of the mutation within their respective genes (Paulson & Fischbeck, 1996; see Fig. 3.1). This classification is useful because the location of the mutation may have implications regarding the mechanism of pathogenesis. Type I disorders are those in which the expansion occurs in-frame within the coding region and results in an expanded stretch of amino acids within the gene product. Type II disorders are those in which the expansion occurs outside the coding region: either upstream of the coding sequence, downstream of the coding sequence, or within an intron.

In type I disorders the mutant gene is transcribed and translated normally but leads to production of a protein harboring an expanded repeat of a particular amino acid. The trinucleotide expansions in type I disorders tend to be modest, with a similar threshold for disease (36–40 trinucleotide repeats, with limited exceptions). To date, nine type I diseases have been identified, and in each case the mutant protein is endowed with a toxic 'gain of function'. In general, type I diseases are dominantly inherited (except spinobulbar muscular atrophy), tend to be of late onset, and manifestations are mostly limited to the nervous system.

Conversely, in type II disorders, the coding sequence remains unchanged and the protein product is normal, yet mutations in untranslated regions of the gene lead to abnormal transcription or RNA processing, often resulting in altered levels of gene expression. The trinucleotide expansions leading to type II disorders tend to be large, with hundreds to over one thousand trinucleotides. These mutations often result in 'loss of function' of the relevant gene. To date, seven type II disorders have been identified; most are multisystem disorders and tend to have younger ages of onset than type I disorders.

Type I trinucleotide expansion disorders

Polyglutamine diseases

We currently recognize nine neurodegenerative disorders that result from the same kind of mutation: expansion of a CAG trinuceotide repeat within the coding region of the disease gene. Since CAG is the codon for glutamine, the proteins encoded by these genes carry an expanded polyglutamine tract; thus, these nine disorders are known as the polyglutamine diseases. This list includes Huntington's disease (HD), dentatorubro-pallidoluysian

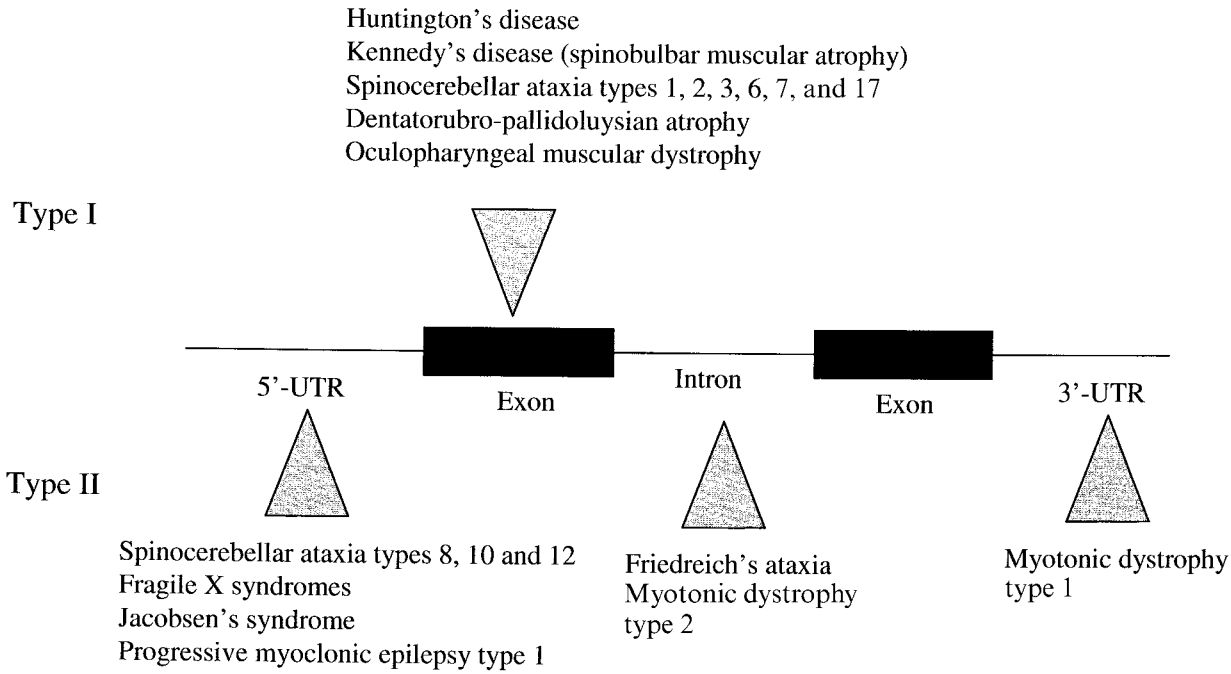

Fig. 3.1. Type I and type II repeat expansion diseases. In type I diseases, the expansion occurs within the coding region (exons) and results in an expanded stretch of amino acids in the mutant protein. In type II diseases, the expansion occurs outside of the coding region in introns, 3′ untranslated, or 5′ untranslated regions. (Adapted from Paulson & Fischbeck, 1996.)

atrophy (DRPLA), Kennedy's disease (also known as spinobulbar muscular atrophy, SBMA), and six spinocerebellar ataxias (SCAs 1, 2, 3, 6, 7 and 17). Evidence indicates that these eight diseases share a common pathogenic mechanism involving a toxic gain of function by the mutant gene product. Below, we present the clinical features and genetic basis of each of these disorders, followed by a general discussion of polyglutamine disease pathogenesis. The clinical features of HD and the SCAs are covered elsewhere in this book.

Huntington's disease

Huntington's disease (HD) is an autosomal dominant, progressive neurodegenerative disease characterized by disordered movement, intellectual impairment, and emotional disturbance. HD is typically a late-onset illness, and it is invariably fatal (Myers et al., 1988). HD was the first autosomal disorder in which the gene was mapped using polymorphic DNA markers. The initial mapping to chromosome 4p16 was followed by a decade of intensive collaborative research that culminated in the identification of a novel gene (*IT15*, for 'interesting transcript 15') of unknown function containing a CAG trinucleotide repeat sequence in the first exon (Huntington's Disease Collaborative Research Group, 1993). The length of this CAG repeat sequence is polymorphic, with 6 to 35 CAGs in normal individuals, and 36 to 121 CAGs in individuals affected by HD. Examination of a large number of individuals carrying 30–40 repeats within *IT15* demonstrated that rare individuals become symptomatic with as few as 36 repeats while others show no sign of disease despite two alleles with 40 repeats (Rubinstein et al., 1996). This evidence demonstrates the incomplete penetrance of HD in the range of 35–40 repeats, while repeat lengths greater than 40 are invariably associated with disease.

Huntington's disease frequently demonstrates anticipation, with successive generations experiencing earlier age of onset and more severe disease than their parents. Anticipation is a consequence of intergenerational instability leading to further expansion of CAG repeat in *IT15* and is particularly associated with paternal transmission. Eighty per cent of patients with juvenile-onset HD, generally associated with alleles of more than 70 repeats, inherit the mutant gene from their father. A likely explanation for greater repeat instability associated with paternal transmission is the larger number of cellular divisions that take place during spermatogenesis.

Ultrastructural studies of HD brain tissue demonstrate both cytoplasmic and nuclear abnormalities in neurons.

The most notable features are ubiquitinated inclusions that are present in neuronal nuclei and dystrophic neurites throughout the brain regions most affected in HD, including the cortex and neostriatum but not in unaffected regions such as the globus pallidus or cerebellum (DiFiglia et al., 1997). These neuronal inclusions stain with antibodies directed to the amino-terminal portion of huntingtin, the protein product of *IT15*, but not with antibodies to the carboxy-terminus. Moreover, an amino terminal fragment of huntingtin of about 40 kD is detectable in nuclear extracts from patient brain and not in an extract prepared from normal brain (DiFiglia et al., 1997). Huntingtin is cleaved by caspases, cysteine proteases that play a significant role in mediating apoptosis. This observation led to the suggestion that low-grade caspase activation may generate toxic, amino-terminal fragments of mutant huntingtin that aggregate in the nucleus (Wellington et al., 2000).

Dentatorubro-pallidoluysian atrophy

In 1958, Smith et al., described a syndrome of progressive myoclonic epilepsy, ataxia, choreoathetosis, and dementia. They used the term 'dentatorubro-pallidoluysian atrophy' (DRPLA) to describe the most prominent neuropathological features; namely, extensive degeneration of the dentate nucleus, red nucleus, globus pallidus, and subthalamic nucleus of Luys. Rare in most parts of the world, a pocket of relatively high incidence of DRPLA is found in Japan (Naito & Oyanagi, 1982). The gene responsible for DRPLA was mapped to chromosome 12p by linkage analysis. Subsequently, because of phenotypic similarities to HD, genes from chromosome 12 were screened for CAG repeat expansions, a novel approach that culminated in identification of the *DRPLA* gene (Li et al., 1993; Koide et al., 1994; Nagafuchi et al., 1994).

Normal *DRPLA* alleles have 6–36 CAGs, while expanded alleles with 49–84 CAGs have been identified in symptomatic patients. Like Huntington's disease, intergenerational instability is more pronounced with paternal transmission (Koide et al., 1994). The product of the DRPLA gene is a widely expressed protein of approximately 190 kD named 'atrophin-1'. Atrophin-1 shares no homology with other known proteins, and its normal function remains unclear. Like huntingtin, atrophin-1 is cleaved by caspases, producing an amino-terminal fragment. Atrophin-1 is distributed through the cytoplasm in neurons and peripheral tissues of both unaffected and affected individuals (Knight et al., 1997; Yazawa et al., 1995). In addition, nuclear inclusions containing mutant atrophin-1 are found in neurons and glia of affected individuals, especially in degenerating regions of the brain (Hayashi et al., 1998; Igarashi et al., 1998).

Spinobulbar muscular atrophy

Spinobulbar muscular atrophy (SBMA), also known as Kennedy's disease, is an X-linked, slowly progressive disorder resulting from degeneration of motor neurons of the brainstem and spinal cord. Patients with SBMA also frequently exhibit mild signs of feminization (Arbizu et al., 1983). Gynecomastia is present in about half of patients, and some degree of infertility may occur. Pathologically, SBMA is characterized by degeneration of motor neurons in the anterior horn of the spinal cord and lower brainstem motor nuclei. Additionally, there is degeneration of sensory neurons in the dorsal root ganglia. Electrophysiological studies on SBMA patients demonstrate sensory neuropathy as well as neurogenic atrophy with fibrillations and fasciculations. Muscle biopsies show evidence of chronic denervation, often with collateral reinervation (Sobue et al., 1981, 1989; Harding et al., 1982).

In 1991, the cause of SBMA was found to be CAG trinucleotide repeat expansion within the first exon of the androgen receptor (AR) gene (La Spada et al., 1991). Normal alleles exhibit polymorphism with repeat length ranging from 9 to 36, while patients with SBMA have been identified with repeat sizes ranging from 40 to 62. In SBMA, anticipation is usually not observed. There is a correlation between repeat length and clinical manifestations, although as with other repeat expansion diseases, repeat length is not a reliable indicator of age of onset and disease severity (Doyu et al., 1992).

The AR is a member of the nuclear receptor superfamily. Like other steroid hormone receptors, it contains distinct domains for hormone and DNA binding. Upon binding of androgen in the cytoplasm, the receptor/ligand complex is transported to the nucleus where it activates the transcription of hormone responsive genes (Zhou et al., 1994). The AR is expressed widely in the brain, but most extensively in motor neurons of the spinal cord and brainstem where it may mediate a neurotrophic response to androgen (Ogata et al., 1994).

The polyglutamine tract is located at the amino-terminus of AR in a region distinct from the hormone and DNA binding regions. The function of the polyglutamine tract is not known, and it is dispensable for transactivation of hormone responsive genes (Jenster et al., 1991). Expansion of the polyglutamine tract may cause partial loss of receptor function and perhaps underlies the mild androgen insensitivity observed in SBMA. However, loss of function alone cannot account for the neurological features of SBMA, because complete absence of AR leads to androgen insensitivity (testicular feminization) syndrome, with no weakness or motor neuron degeneration. This

observation contributes to the argument that SBMA results from a toxic gain of function by mutant AR due to polyglutamine expansion. Heterozygous females carrying a single expanded allele sometimes report mild weakness or muscle cramps and may have subclinical electrophysiological abnormalities. These female carriers may be protected by low androgen levels (if the toxic effect is ligand dependent) or by X-inactivation. Similar to the observations in HD and DRPLA, intranuclear inclusions of mutant AR are found in motor neurons within regions affected by SBMA (Li et al., 1998).

Autosomal dominant spinocerebellar ataxia

The spinocerebellar ataxias (SCAs) are a genetically heterogeneous group of disorders that exhibit substantial overlap in clinical and neuropathological features. We currently recognize 14 genetically distinct forms of autosomal dominant spinocerebellar ataxia (SCA), five of which are caused by CAG repeat expansion and discussed in this section. SCA types 8, 10 and 12 are type II trinucleotide repeat disorders and are presented below. At least five additional genetic loci associated with the SCA phenotype have been identified (SCAs 4, 5, 11, 13 and 14), but the genes and their mutations remain to be determined. The designation SCA 9 remains unassigned.

Degeneration of the cerebellum and brainstem is common to all of the SCAs; consequently, cerebellar ataxia and dysarthria are the hallmark clinical features of these diseases (Zoghbi & Orr, 2000). Additional, variable features may lead the clinician to suspect a particular SCA subtype. For example, SCA1 patients show hyperreflexia, extensor plantar responses, and an increased amplitude of saccadic eye movements, while SCA2 is characterized by reduced saccadic eye movements and depressed or absent reflexes. Protuberant eyes, faciolingual fasciculations, and extrapyramidal signs are features of SCA type 3 (Durr et al., 1996a). SCA type 6 is generally a late-onset, pure cerebellar ataxia. SCA type 7 typically features a pigmentary macular degeneration that accompanies spinocerebellar degeneration. Nevertheless, definitive diagnosis of a particular SCA subtype requires genetic confirmation.

Spinocerebellar ataxia type 1

The SCA1 locus was narrowed by linkage analysis to 6p22–p23 (Zoghbi et al., 1991). When subsequently identified, the *SCA1* gene was found to contain a polymorphic CAG trinucleotide repeat within its coding region (Orr et al., 1993). Normal *SCA1* alleles carry from 6 to as many as 44 CAGs, but those with greater than 20 are interrupted by several repeats of CAT (Chung et al., 1993). Disease alleles, in contrast, contain longer CAG repeat stretches (39–82) and are uninterrupted by CAT sequences (Goldfarb et al., 1996). Marked intergenerational instability is observed, with paternal transmissions tending to produce expansions, whereas maternal transmissions actually tend to show contractions (Chung et al., 1993; Jodice et al., 1994; Ranum et al., 1994).

The *SCA1* gene encodes a ubiquitously expressed protein named 'ataxin-1' that shares no homology with other known proteins and is normally found in the nucleus and the cytoplasm. Ataxin-1 is highly expressed in the central nervous system including Purkinje cells and brain stem nuclei (Servadio et al., 1995). In SCA1 patients, mutant ataxin-1 localizes to large, solitary, nuclear inclusions in Purkinje cells and brainstem neurons (Skinner et al., 1997; Cummings et al., 1998). These inclusions stain positively for ubiquitin, components of the proteasome, and the molecular chaperone HDJ-2/HSDJ. Ataxin-1 likely plays a role in synaptic plasticity, because mice in which the *SCA1* gene has been disrupted have impaired spatial and motor learning, and decreased paired-pulse facilitation in the CA1 area of the hippocampus (Matilla et al., 1998). These *SCA1* 'knockout' mice do not develop ataxia, supporting the contention that *SCA1* is not caused by loss of normal ataxin-1 function. In an analogous observation in humans, large deletions spanning the *SCA1* gene lead to a syndrome of mental retardation and seizures, but do not result in an ataxic phenotype (Davies et al., 1999).

Spinocerebellar ataxia type 2

The *SCA2* gene was mapped by linkage analysis to chromosome 12q23–24.1 (Gispert et al., 1993), and the gene was subsequently identified by three independent groups and found to contain a CAG repeat (Pulst et al., 1996; Imbert et al., 1996; Sanpei et al., 1996). The CAG repeat in *SCA2* is less polymorphic than in the other genes that are involved in polyglutamine disease. Normal *SCA2* alleles have 15–31 CAGs, but 94% of alleles have 22 CAGs. *SCA2* disease alleles have 36–63 CAGs.

SCA2 encodes a widely expressed protein named 'ataxin-2' of approximately 140 kD that shares no homology with proteins of known function, although an ataxin-2– related protein has been identified (Pulst et al., 1996). Immunostaining of SCA2 brain specimens reveals cytoplasmic inclusions containing the mutant protein in Purkinje cells and dentate neurons, an observation that has also been made in a transgenic mouse model (Huynh et al., 2000).

Spinocerebellar ataxia type 3

Spinocerebellar ataxia type 3 (SCA3), also known as Machado–Joseph disease, was initially described among Portuguese–Azorean emigrants who settled in New England. Since then, this disease has been found worldwide in a variety of ethnic backgrounds, but it is especially prevalent in two islands in the Portuguese Azores (Nakano et al., 1972). The presence of SCA3 in regions with historically active sea-trade such as India, China, and Japan led to speculation that the worldwide distribution of the disease may be attributed to the travels of Azorean sailors in the late fifteenth and sixteenth centuries. In support of this suggestion, a worldwide haplotype study has demonstrated a founder effect, with the majority of non-Portuguese families sharing a disease haplotype with families from one Azorean island (Gaspar et al., 2001).

The *MJD1* gene was mapped to chromosome 14q (Takiyama et al., 1993) and subsequently identified by scanning a human brain library using an oligonucleotide probe designed to detect expanded CAG repeats (Kawaguchi et al., 1994). In normal alleles, the CAG repeat length ranges from 12 to 41, while disease alleles have 62 to 84 CAGs (Durr et al., 1996a; Maruyama et al., 1995). *MJD1* is somewhat unusual among the polyglutamine disease genes in that there is a distinct gap between normal and affected repeat sizes. Intergenerational instability is common and more pronounced with paternal transmission.

The *MJD1* gene encodes an approximately 42 kD protein of unknown function named 'ataxin-3' (Kawaguchi et al., 1994). Ataxin-3 is widely expressed in the brain, and regions of greatest susceptibility to degeneration do not show significantly higher ataxin-3 expression. In SCA3 brain specimens, ataxin-3 localizes to ubiquitinated nuclear inclusions in neurons from affected brain regions (Paulson et al., 1997). In addition, these inclusions are found to colocalize with components of the proteasome and cellular chaperones (Chai et al., 1999).

Spinocerebellar ataxia type 6

The mutation responsible for SCA6 is CAG repeat expansion in the *CACNA14* gene, which encodes the α_{1a}-voltage-dependent Ca^{2+} channel (Zhuchenko et al., 1997). The calcium channels formed by α_{1a} are abundant in the central nervous system, with highest levels in the cerebellum (Fletcher et al., 1996). While the seven other known polyglutamine diseases are associated with expansion beyond 36–40 CAGs, SCA6 has a lower disease threshold. Normal alleles of the *CACNA14* gene have 6–18 CAGs, and disease alleles have 21–33 CAGs (Matsuyama et al., 1997; Zoghbi 1997). SCA6 also differs from the other polyglutamine diseases in that the repeat expansion shows little intergenerational instability and anticipation is not observed.

Other mutations in the *CACNA14* gene are associated with two paroxysmal neurological disorders, episodic ataxia type 2 (EA2) and familial hemiplegic migraine (FHM) (Ophoff et al., 1996). Interestingly, both EA2 and FHM are sometimes associated with persistant, slowly progressive ataxia. In addition, naturally occurring mouse mutants known as *tottering* and *leaner*, which exhibit cerebellar atrophy, ataxia and seizures, have point mutations in the orthologous mouse *Cacna1a* gene (Fletcher et al., 1996). The autosomal dominant nature of these disorders suggests that a toxic gain of function may be responsible, but the mechanistic relationship of these disorders to SCA6 remains to be determined. It is also unclear whether altered function of the voltage-gated Ca^{2+} channel contributes to the pathogenesis.

Spinocerebellar ataxia type 7

Using a technique called 'repeat expansion detection' (RED) in which the polymerase chain reaction is used to scan genomic DNA for large trinucleotide repeats, a candidate region for SCA7 was located at chromosome 3p21.1–p12 (Lindblad et al., 1996). Subsequent positional cloning revealed the genetic basis of SCA7 to be expansion of a CAG repeat in a gene of unknown function (David et al., 1997). In normal *SCA7* alleles, CAG repeat lengths range from 7 to 35; and mutant alleles carry 38–200 CAGs (David et al., 1997; Johansson et al., 1998). SCA7 shows anticipation, with greater genetic instability associated with paternal transmission (Johansson et al., 1998). The protein encoded by the *SCA7* gene has been designated 'ataxin-7' and normally consists of 890 amino acids with a nuclear localization motif. Ataxin-7 is widely expressed in the brain and some peripheral tissues, but it is particularly enriched in regions susceptible to degeneration in SCA7 (Cancel et al., 2000; Lindenberg et al., 2000). Two studies have reported ubiquitinated neuronal intranuclear inclusions in the brain and retina of SCA7 patients (Holmberg et al., 1998; Mauger et al., 1999).

Polyglutamine expansion in TATA-binding protein (*SCA17*)

In addition to the eight genes responsible for the polyglutamine diseases listed above, a number of other human genes are known to contain polymorphic stretches of CAG

within the coding region. Many of these genes encode transcription factors in which the polyglutamine tract may mediate protein–protein interactions. The recognition that expanded stretches of polyglutamine can cause neurodegeneration has prompted examination of these genes in otherwise unexplained neurodegenerative disorders. In one Japanese patient, a young girl with progressive cerebellar ataxia, hyperreflexia, extensor plantar responses, atypical absence seizures and intellectual impairment, an expanded series of CAG and CAA repeats was identified in the gene encoding TATA-binding protein (Koide et al., 1999). The mutant allele from this patient encodes a stretch of 63 glutamines. In contrast, the patient's parents, who were neurologically normal, carried alleles encoding 35–39 glutamines. This disorder has now been identified in additional families and has been given the designation *SCA17* (Nakamura et al., 2001).

The molecular pathogenesis of polyglutamine disease

A common mechanism?

Four major lines of evidence suggest that the polyglutamine diseases share a common pathogenesis resulting from gain of function in the disease gene product, i.e. that the expanded polyglutamine confers upon the mutant protein a new property that is toxic to neurons. (i) The expanded polyglutamine tract is the only common feature among the genes responsible for these diseases. They share no other sequence homology, no common subcellular localization, and appear to be functionally unrelated. Yet, the phenotype of each disease is characterized by late-onset, slowly progressive neurodegeneration with clinical overlap. Furthermore, they share common pathological features, most notably ubiquitinated neuronal inclusions containing the mutant protein in brain regions susceptible to neurodegeneration. (ii) With the exception of SBMA, which is X-linked, all of these diseases exhibit dominant inheritance. In SBMA, female carriers may complain of cramps and be found to manifest subclinical electrophysiogical abnormalities suggestive of mild motor neuron disease. As mentioned above, female carriers of SBMA may be protected by X chromosome inactivation or low levels of androgen. (iii) A wide array of model systems has been developed, including cell culture and transgenic animal models, in which expression of the disease genes with repeat expansion recapitulates features of the diseases. Furthermore, transgenic expression of expanded polyglutamine in an unrelated protein (hypoxanthine phosphoribosyl-transferase) also results in neurodegeneration (Ordway et al., 1997). (iv) Naturally occurring and experimentally introduced mutations that cause loss of function in these genes do not recapitulate features of the diseases.

Targets of expanded polyglutamine

Examination of patient tissue, animal models, and in vitro systems has revealed a variety of biochemical pathways and cellular functions that may be altered by expanded polyglutamine (Fig. 3.2). A major challenge is to distinguish primary biochemical derangements caused by expanded polyglutamine from the secondary effects that surely follow. An added difficulty is to discern which alterations are fundamentally related to neuronal dysfunction and death. A primary molecular target of polyglutamine toxicity would be expected to have a novel or altered interaction with the mutant protein, due to altered physical properties resulting from the expanded polyglutamine. Two cellular processes stand out as particular candidates for primary disruption by expanded polyglutamine: transcription and the ubiquitin-proteasome pathway.

The inclusions formed by expanded polyglutamine recruit and sequester additional proteins, particularly proteins that normally contain polyglutamine tracts. One appealing hypothesis suggests that inclusions in the nucleus sequester and deplete factors critical to neuronal function and survival. Candidate targets in this model are transcription factors that are present in limiting quantities and contain polyglutamine tracts. Various transcription factors have been found to colocalize with nuclear inclusions, including CREB-binding protein (CBP), p53, TATA-binding protein, and nuclear receptor co-repressors (Perez et al., 1998; Boutell et al., 1999; McCampbell et al., 2000; Steffan et al., 2000). Furthermore, cell culture studies suggest that sequestration of CBP and p53 has functional consequences on transcriptional regulation. Depletion or altered function of transcription factors in human disease or animal models has yet to be demonstrated directly. Nonetheless, expression-profiling studies on brain tissue from HD and SCA1 mice suggest that altered transcription is an early event in polyglutamine pathogenesis (Luthi-Carter et al., 2000; Lin et al., 2000).

The ubiquitin–proteasome pathway is the primary biochemical means by which cells eliminate unwanted proteins. Proteins are targeted for degradation by covalent linkage to ubiquitin. Ubiquitination is the molecular signature enabling recognition by a family of chaperone proteins which facilitate the targeted protein's access to, and degra-

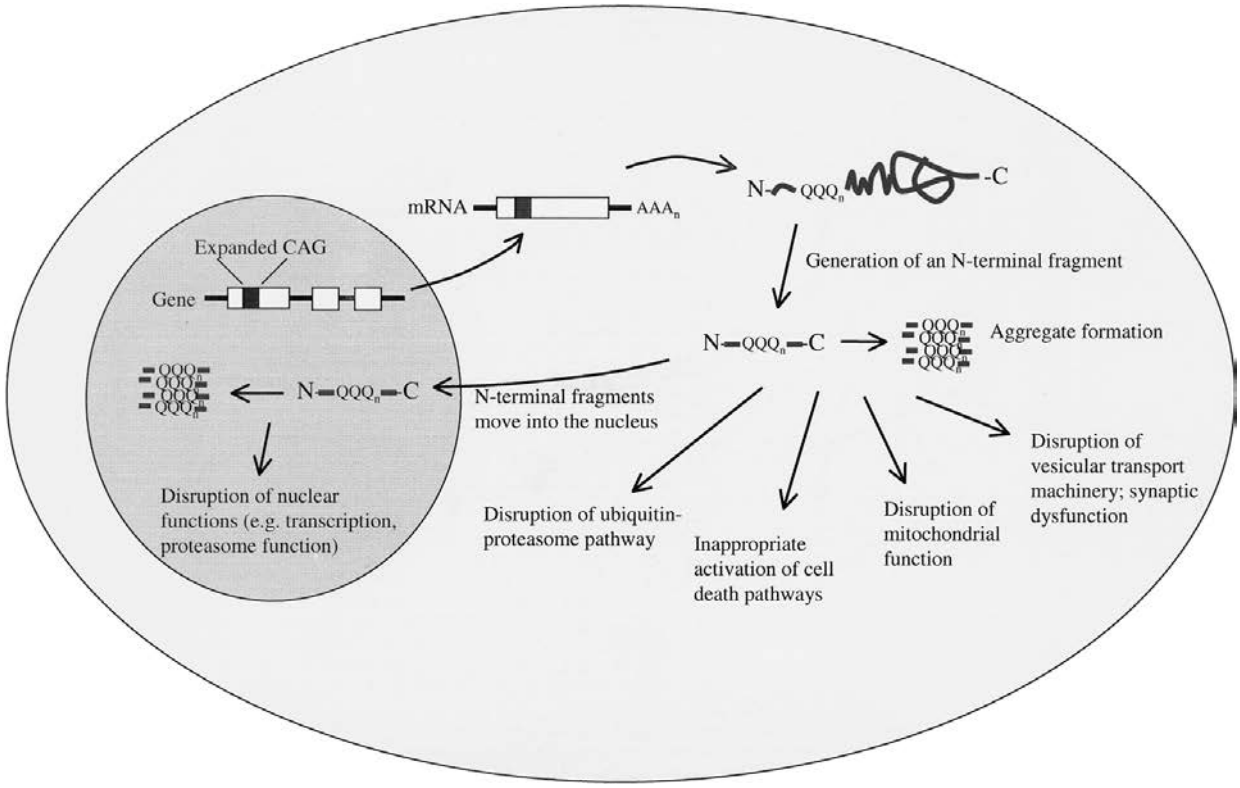

Fig. 3.2. Molecular pathogenesis of polyglutamine disease. The mutant gene with an expanded stretch of CAGs undergoes normal transcription and translation. The mutant gene product contains an expanded polyglutamine tract that confers a toxic gain of function. The mutant protein is susceptible to cleavage, releasing a polyglutamine-containing fragment. The polyglutamine-containing fragments form intracellular aggregates in the cytoplasm and nucleus. It remains unclear whether polyglutamine is toxic as full-length protein, as monomeric fragments, or as aggregate. An array of possible cellular targets is shown and discussed in the text.

dation by, the proteasome, a large macromolecular proteolytic apparatus (Ciechanover, 1997). Normal function of the ubiquitin–proteasome pathway is critical to determining the steady-state levels of many proteins. Additionally, this pathway is charged with rapidly eliminating nascent proteins that fail to adopt their correct structure, thereby protecting the cell from deleterious effects of misfolded proteins. Polyglutamine inclusions in brain specimens from human disease and animal models stain positively for components of the ubiquitin-proteasome pathway, including ubiquitin, chaperone proteins, and proteasome subunits (Paulson et al., 1997; Davies et al., 1997; Hackam et al., 1998). It remains unclear which components of the inclusions are ubiquitinated. The mutant proteins themselves may be ubiquitinated, but resist degradation because of a particular conformation adopted by expanded polyglutamine. Expanded polyglutamine may inhibit the proteasome, resulting in a global accumulation of ubiquitinated substrate with dire consequences for the cell. Neurons may be particularly susceptible to proteasome dysfunction because they are limited in their ability to dilute accumulating toxic proteins with cell division. Experimental evidence supporting a role for the ubiquitin–proteasome pathway in polyglutamine disease comes from a transgenic mouse study of SCA1. A genetic cross between a SCA1 mouse and a mouse with dysfunctional E6–AP ubiquitin ligase, and impairment of the ubiquitin–proteasome pathway, resulted in exacerbation of the neurodegeneration despite fewer inclusions (Cummings et al., 1999). There are precedents for neurological disease resulting from disruption to the ubiquitin–proteasome pathway: juvenile-onset Parkinson's disease, an autosomal recessive disease, is caused by mutations in the gene for parkin, an E3 ubiquitin ligase (Polymeropoulos, 2000). Angelman's syndrome, a developmental disorder that is characterized by motor and intellectual retardation, ataxia, hypotonia, epilepsy, and dysmorphic features, results from mutation in the gene for E6–AP, which is also an E3 ubiquitin ligase.

Other targets have been proposed for expanded polyglutamine. Ultrastructural examination of brain tissue from Huntington's patients shows mitochondrial abnormalities, and patients with HD have altered energy metabolism in brain and muscle, suggesting a role for mitochondrial dysfunction in this disease (Murphy et al., 2000). Mutant huntingtin has been found to associate with synaptic vesicles and vesicular transport machinery, implicating vesicular transport as a potential target of polyglutamine toxicity (Li et al., 2000). Electrophysiological studies of neurons from HD mice demonstrate abnormalities in synaptic transmission (Murphy et al., 2000). Much attention has focused on the potential role of apoptosis in mediating polyglutamine toxicity. Aside from a single report suggesting that mutant huntingtin activates caspase-8 (Sanchez et al., 1999), evidence is scant that components of the apoptotic machinery serve as a primary target for expanded polyglutamine. On the other hand, evidence is accumulating that caspases may play a role in mediating early events in toxicity. Many of the disease proteins contain consensus caspase cleavage sites. Evidence suggests that an important step in the pathogenesis of HD, SBMA, and DRPLA is caspase-mediated generation of polyglutamine-containing fragments that are more toxic than the parent protein (Ellerby et al., 1999; Wellington et al., 2000).

The deposition of misfolded proteins into neuronal inclusions is a central feature of many neurodegenerative diseases, including Alzheimer's disease, Parkinson's disease, amyotrophic lateral sclerosis and the prion diseases. The importance of aggregation in these disorders has been underscored by the identification of three additional dominantly inherited neurodegenerative disorders that are characterized by intracellular aggregation of mutant α-synuclein (Polymeropoulos, 2000), neuroserpin (Davis et al., 1999), and tau proteins (Lee & Trojanowski, 1999). Deposition of misfolded protein in neuronal inclusions has emerged as a common theme in neurodegenerative diseases, perhaps indicating that these diseases also share common mechanisms.

What is the role of aggregation in the polyglutamine diseases?

One pathological feature shared by the polyglutamine diseases is the presence of intraneuronal, ubiquitinated inclusions in brain regions susceptible to degeneration. At the subcellular level, inclusions may be found in the nucleus (e.g. SCA1), cytoplasm (e.g. SCA2), or both (e.g. Huntington's disease). These inclusions consist of insoluble aggregates of polyglutamine-containing fragments in association with a host of additional proteins. Tracts of polyglutamine aggregate as antiparallel ß-strands linked by additional hydrogen bonding: so-called 'polar zipper' formation. There is a remarkable correlation between the threshold polyglutamine length for aggregation in experimental systems and the CAG repeat length that leads to human disease. These observations form the basis of the argument that self-aggregation by expanded polyglutamine is the acquired property underlying neurodegeneration (Perutz et al., 1994).

But are the inclusions themselves toxic? The dissociation of toxicity from inclusion formation observed in cell culture suggests that they are not (Saudou et al., 1998). A dissociation between inclusion formation and the development of pathology has also been demonstrated in transgenic mice (Klement et al., 1998; Leavitt et al., 1999). Some have suggested that inclusion formation may be a protective mechanism employed by the cell to cope with excess, misfolded polyglutamine, perhaps analogous to so-called 'aggresomes' which form in vitro in response to overexpression of misfolded protein (Johnston et al., 1998).

Oculopharyngeal muscular dystrophy

Oculopharyngeal muscular dystrophy (OPMD) has been recognized as a distinct entity since a report by Victor et al., in 1962, although case reports can be found in the literature dating from the early twentieth century. OPMD is an inherited myopathy that shares with the CAG repeat expansion diseases a similar type of genetic mutation and certain pathologic features. OPMD is inherited as an autosomal dominant disease of late onset. It occurs worldwide, although it is particularly prevalent among French Canadians. Patients typically present in the fifth or sixth decade with bilateral ptosis and dysphagia (Tome & Fardeau, 1994). In an attempt to compensate for severe ptosis, patients may contract the frontalis muscle and throw their head back, a position known as Hutchinson's or astrologist's posture. Unfortunately, this posture often has the unwanted affect of worsening the dysphagia. In late stages of the disease, the eyelids are very thin and transparent, the eyebrows are raised, and the supraorbital ridges are prominent. The disease is slowly progressive, and may eventually impair eye movements, occasionally causing diplopia. Instrinsic eye muscles are always spared. Along with dysphagia, patients may experience decreased palatal mobility, an impaired gag reflex, and laryngeal weakness with dysphonia. Skeletal muscles of the extremities may be affected by the disease, often resulting in shoulder-girdle weakness and atrophy. Involvement of limb muscles is symmetric and is not associated with fasciculations.

Tendon reflexes are typically decreased. Dysphagia predisposes patients to malnutrition and aspiration pneumonia.

The pathologic changes in skeletal muscle are progressive, and parallel the worsening clinical features. Biopsy reveals myopathic features, including increased variation in fibre size, internal nuclei, and interstitial fibrosis. There are often scattered small, angulated fibres that are strongly NADH positive. Two pathologic features help distinguish OPMD. Rimmed vacuoles, first described by Dubowitz and Brooke in 1973, appear as clear spaces lined by a granular basophilic rim. While these spaces are not membrane bound, they are likely derived from autophagic vacuoles. Ultrastructural examination has also revealed the presence of intranuclear inclusions (Tome & Fardeau, 1980). These inclusions are composed of aggregated tubular filaments that measure 8.5 nm in outer diameter and up to 0.25 μm in length. They contain the poly(A)-binding protein 2, the protein mutated in the disease (see below), and sequestered poly(A) RNA (Becher et al., 2000; Calado et al., 2000).

The French Canadian population provided a rich source of OPMD families that was important for the identification of the defective gene. After studying these families, Andre Barbeau concluded that the causative mutation was likely introduced into Quebec by ancestors who emigrated from France in 1634 (Barbeau, 1969). A genome-wide scan pointed to a critical region on 14q11 (Brais et al., 1995), which was further narrowed to a 0.26 cM candidate interval (Brais et al., 1998). Within this interval is the gene encoding poly(A)-binding protein 2 (PABP2), a nuclear protein that increases the efficiency of polyadenylation and specifies the length of the mRNA poly(A) tail (Barabino & Keller, 1999). The first exon of the PABP2 gene encodes a stretch of ten alanines, the first six of which are encoded by a GCG repeat. Rouleau and colleagues (Brais et al., 1998) demonstrated an expansion of this repeat in 144 families with OPMD, with the mutated tract containing 8 to 13 GCG triplets. This group of families came from 15 different countries, indicating that cases of OPMD occurring worldwide are caused by the same genetic mutation. Rare cases with two pathologically expanded alleles presented with an earlier onset of the disease (Blumen et al., 1999). This short repeat expansion differs from the longer CAG expansions in SBMA and other polyglutamine diseases in that it is meiotically stable, and therefore families with OPMD do not show genetic anticipation.

Two per cent of the French Canadian population carry a $(GCG)_7$ allele. This allele acts as a modifier of the disease phenotype by worsening symptoms in heterozygotes carrying one pathologically expanded allele. The $(GCG)_7$ allele also functions as a recessive mutation, causing late-onset disease in homozygotes (Brais et al., 1998). Thus, changes in GCG repeat length in the PABP2 gene account for cases of OPMD that are inherited in both a dominant and a recessive fashion.

The mechanism by which an expanded alanine tract leads to OPMD is unknown. One attractive hypothesis is that the mutated protein is prone to form insoluble aggregates, particularly in the nucleus where PABP2 is normally located. These aggregates may then disrupt cell function by mechanisms similar to those proposed for the polyglutamine disorders. Alternatively, as with the polyglutamine disorders, these intranuclear aggregates may be markers of disease that are not mechanistically related to cell injury. It may be that dominantly inherited cases of OPMD are due to haploinsufficiency. Intranuclear aggregates and rimmed vacuoles are also present in other muscle diseases that occur without a GCG expansion in the PABP2 gene, such as inclusion body myositis (Mezei et al., 1999). This may indicate that similar pathways leading to muscle injury are triggered in these diseases, although further studies are required to define this relationship.

Type II repeat expansion disorders

We currently recognize seven type II trinucleotide expansion disorders (see Table 3.1). These are inherited neurological diseases in which a trinucleotide repeat expansion occurs outside the coding region of the mutated gene. The expansions in this diverse group tend to be longer than those observed in the Type 1 diseases. Most often, these repeat expansions lead to reduced expression of the affected genes resulting in loss of gene function and a recessively inherited phenotype that may present early in life. In other instances, the disease phenotype is dominantly inherited, likely reflecting a toxic gain of function. The molecular mechanisms by which these expansions exert their effects are varied and complex.

Myotonic dystrophy

Myotonic dystrophy (DM) is a dominantly inherited multisystem disorder that was first described in the early twentieth century. It has a prevalence of approximately 1 in 8000 worldwide. The clinical presentation is highly variable, reflecting the diverse effects that the underlying mutation has on gene expression. Adult patients with DM often present in the second or third decade with slowly progressive disease. Typical cases are characterized by muscle weakness and wasting particularly involving the face and distal limbs, and by myotonia. Patients may have

Table 3.1. Trinucleotide repeat expansion diseases

Disorder	Gene/locus	Chromosomal location	Protein	Repeat Sequence	Repeat location	Inheritance
Type I						
Huntington's disease	IT15	4p16.3	Huntingtin	CAG	Coding	AD
Dentatorubro-pallidoluysian atrophy	DRPLA	12p13.31	Atrophin-1	CAG	Coding	AD
Spinobulbar muscular Atrophy (Kennedy's disease)	AR	Xq13–21	Androgen receptor	CAG	Coding	X-linked
Spinocerebellar ataxia Type 1	SCA1	6p23	Ataxin-1	CAG	Coding	AD
Spinocerebellar ataxia Type 2	SCA2	12.24.1	Ataxin-2	CAG	Coding	AD
Spinocerebellar ataxia Type 3	SCA3/MJD1	14q32.1	Ataxin-3	CAG	Coding	AD
Spinocerebellar ataxia Type 6	CACNA14	19p13	α_{1A} Subunit of voltage-dependent calcium channel	CAG	Coding	AD
Spinocerebellar ataxia Type 7	SCA7	3p12–13	Ataxin-7	CAG	Coding	AD
Spinocerebellar ataxis Type 17	SCA17	6q27	TATA binding protein	CAG	Coding	AD
Oculopharyngeal dystrophy	PABP2	14q11	Poly-A binding protein	GCG	Coding	AD
Type II						
Fragile X syndrome	FMR1 (FRAXA)	Xq27.3	FMRP	CGG	5′-UTR	X-linked
Fragile XE mental retardation	FMR2 (FRAXE)	Xq28	FMR2	GCC	5′-UTR	X-linked
Spinocerebellar ataxia Type 8	SCA8	13q21	KLH1	CTG	5′-UTR	AD
Spinocerebellar ataxia Type 10	SCA10	22q13	Ataxin-10	ATTCT	9th intron	AD
Spinocerebellar ataxia Type 12	PPP2R2B	5q31–33	PP2A regulatory protein	CAG	5′-UTR	AD
Friedreich's ataxia	X25	9q13–21.1	Frataxin	GAA	1st intron	AR
Myotonic dystrophy	DMPK	19q13.3	Myotonic dystrophy protein kinase	CTG	3′-UTR	AD
Myotonic dystrophy Type 2	ZNF9	3q13–24	Zinc finger protein 9	CCTG	1st intron	AD

a characteristic facial appearance due to atrophy of the masseters, sternocleidomastiods, and temporalis muscle, with involvement of the extraocular muscles that produces ptosis, weakness of eyelid closure, and limited extraocular movements. In addition, the disease often has systemic manifestations, including cataracts, cardiac conduction defects, male frontal balding, testicular atrophy, insulin resistance, pilomatrixomas, and intellectual impairment. Congenital myotonic dystrophy has a more severe presentation with profound hypotonia and weakness from birth, poor feeding and respiratory distress. Cataracts and clinical myotonia are not evident at presentation. Congenital cases typically occur in the setting of maternal transmission from mildly to moderately affected female patients (Harper & Rudel, 1994). Muscle biopsies show an increased number of internal nuclei that are often arrayed in chains, sarcoplasmic masses, ring fibres, and type 1 fibre atrophy. Other myopathic changes may be present, especially in biopsies from patients with advanced disease.

DM is caused by a CTG repeat expansion in the 3′ untranslated region of a cAMP-dependent serine–threonine protein kinase, named 'DM protein kinase' (DMPK) or 'myotonin', one of several genes found at the disease locus 19q13.3 (Brook et al., 1992; Buxton et al., 1992; Fu et al., 1993; Mahadevan et al., 1992). The CTG repeat length is polymorphic in the normal population, varying between 5 and 37 CTGs. Patients with DM have between 50 and several thousand CTGs. The age of onset is inversely correlated with repeat length (Brook et al., 1992; Harley et al., 1992; Hunter et al., 1992; Mahadevan et al., 1992).

The mechanism by which this repeat expansion leads to disease is complex. It was initially hypothesized that loss of DMPK function led to DM, but mice with null mutations in the *DMPK* gene did not replicate the disease phenotype (Jansen et al., 1996; Reddy et al., 1996). When knockout mice were bred to homozygosity, complete loss of expression did result in a mild myopathy and cardiac conduction abnormalities, but not other features of DM, such as the hallmark myotonia (Berul et al., 1999). Several studies have found that expression levels of DMPK protein and mRNA are also decreased in patient muscle (Carango et al., 1993; Fu et al., 1992; Hofmann-Radvanyi et al., 1993). These data suggest that loss of DMPK function contributes to the disease, but is insufficient to account for the full spectrum of clinical manifestations observed in DM.

In addition to loss of DMPK function, the CTG repeat expansion alters the expression of other genes by various mechanisms, including disruption of RNA processing. *DMPK* transcripts that harbour expanded repeats accumulate in intranuclear clusters (Davis et al., 1997; Hamshere et al., 1997; Taneja et al., 1995). This abnormal retention of transcripts is associated with decreased DMPK RNA splicing and polyadenylation (Hamshere et al., 1997; Krahe et al., 1995; Wang et al., 1995). Defects in RNA processing may be caused by altered function of RNA-binding proteins that normally recognize CUG repeats. Several CUG-binding proteins have been identified (Timchenko et al., 1996). One of these proteins, CUGBP1, is involved in pre-mRNA splicing and has altered function in DM (Philips et al., 1998). Sequestration of this, or other RNA-binding proteins, may have widespread effects on gene expression, possibly contributing to the varied manifestations of the disease. In support of this RNA gain of function model, mice in which an untranslated CUG repeat is expressed as a transgene develop certain features of DM, including myotonia and myopathy (Mankodi et al., 2000).

The CTG expansion may also interfere with expression of genes near *DMPK* on chromosome 19. DM-locus-associated homeodomain protein (DMAHP/Six5) is a homeobox gene located close to the expanded repeat in exon 15 of the *DMPK* gene. DMAHP/Six5 mRNA expression in fibroblasts and myoblasts from DM patients is significantly decreased (Klesert et al., 1997; Thornton et al., 1997). This decreased expression may be mediated by methylation of a CpG island adjacent to the expanded repeat (Steinbach et al., 1998). Mice in which the *DMAHP/Six5* gene is disrupted develop cataracts but no apparent skeletal muscle abnormalities (Klesert et al., 2000; Sarkar et al., 2000), suggesting that DM is a contiguous gene disorder caused by altered expression of more than one gene. The CTG repeat expansion may also influence the expression of other nearby genes, including *DMR-N9/59*, a WD-repeat gene located telomeric to *DMPK* (Alwazzan et al., 1999; Jansen et al., 1995).

A phenocopy of myotonic dystrophy was described in a large family that lacks a CTG expansion in the *DMPK* gene (David et al., 1997; Ranum et al., 1998). This disease locus, called DM2, maps to chromosome 3q. Other patients with disease manifestations similar to DM but lacking an expansion in the *DMPK* gene also have been described (Ricker et al., 1994; Thornton et al., 1994). Some of these patients have been classified as having proximal myotonic myopathy (PROMM) to highlight clinical differences with DM (Ricker et al., 1994). The gene mutated in this disorder was recently identified as the zinc finger protein 9 gene (Liquori et al., 2001). The responsible mutation is an intronic tetranucleotide CCTG repeat expansion that results in RNA sequestration, consistent with a messenger RNA gain of function mechanism for both DM and DM2.

Fragile X syndrome

Fragile X syndrome, one of the most common forms of inherited mental retardation, has an estimated incidence of 1 in 4000 males and 1 in 8000 females (Warren & Nelson, 1994). It is inherited as an X-linked dominant trait with reduced penetrance. Those affected have mild to moderate mental retardation, with IQ scores ranging as low as 20 to 60. Clinical features may include hyperkinetic behaviour and concentration problems, and systemic manifestations such as macro-orchidism in males, and abnormal facial features with large ears and a prominent jaw.

Fragile X syndrome is associated with a folate sensitive fragile site at Xq27.3 (Giraud et al., 1976; Harvey et al., 1977; Sutherland, 1977). This cytogenetically defined alteration is caused by an expansion of a CGG trinucleotide repeat. The repeat falls within the 5′ untranslated region of the gene *fragile X mental retardation-1* (*FMR1*) (Kremer et al., 1991; Yu et al., 1991; Verkerk et al., 1991; Oberle et al., 1991). The *FMR1* gene, encompassing 17 exons and spanning

approximately 38 kb of DNA, is widely expressed in mammalian tissues (Ashley et al, 1993; Eichler et al., 1994b). In the normal population, the CGG repeat is polymorphic both in length, ranging from seven to 60 triplets, and in content, as it is variably punctuated by AGG triplets. These AGG interruptions contribute to the stability of the CGG repeat length, and their loss is associated with tracts that are prone to expansion (Fu et al., 1991; Eichler et al., 1994a, b; Kunst & Warren, 1994; Snow et al., 1993, 1994).

Full mutations in patients with fragile X syndrome contain over 230 CGG triplets. These large expansions are associated with DNA hypermethylation and decreased expression of the *FMR1* gene. Somatic mosaicism may affect both repeat length and methylation status. That loss of FMR1 protein (FMRP) is causative of fragile X syndrome is supported by the identification of patients who lack a cytogenetically identified fragile site, and who have deletions or point mutations in the *FMR1* gene (De Boulle et al., 1993; Wohrle et al., 1992). Full mutations are generally inherited through maternal transmission and arise from expansion of an unstable premutation that contains 60 to 230 repeats. These premutations expand during gametogenesis or very early embryonic development (Malter et al., 1997). In carrier females, premutations are unmethylated and give rise to normal levels of *FMR1* transcript and protein. The risk of premutation expansion to full mutation increases exponentially as the number of repeats increases from 65 to 100. Males with full mutations do not, as a rule, transmit alleles with very long expansions, and sperm from these patients have premutation length repeat expansions. These unusual genetics provide a mechanistic explanation of the Sherman paradox (Sherman et al., 1984, 1985; Fu et al., 1991), which states that fragile X transmission occurs through normal males, that their heterozygous daughters are not mentally retarded and have few or no fragile sites, but that by the next generation, a third of heterozygous females are mentally subnormal and contain fragile sites.

Loss of FMRP causes fragile X syndrome in humans, and its targeted deletion causes macro-orchidism and subtle learning and memory deficits in mice (Dutch–Belgian Fragile X Consortium, 1994). FMRP is located primarily in the cytoplasm, but it contains both a nuclear localization signal and a nuclear export signal, suggesting that it shuttles between these two compartments (Eberhart et al., 1996). The protein contains two types of RNA-binding protein motifs, two ribonucleotide K homology domains (KH domains), and clusters of arginine and glycine residues known as RGG boxes (Ashley et al., 1993; Siomi et al., 1993). These RNA-binding domains enable the binding of FMRP to RNA, as demonstrated by in vitro assays where it preferentially associates with poly(G) or poly(U). Its in vivo binding specificity and native targets remain unknown.

FMRP associates with ribosomes as a component of messenger ribonucleoprotein (mRNP) particles. Additional components of these mRNP particles include two autosomal homologues of FMRP, designated FXR1P and FXR2P, nucleolin, and at least three other proteins (Siomi et al, 1995; Zhang et al., 1995). In this context, FMRP may play a role in the export of specific mRNAs from the nucleus to the cytoplasm. Alternatively, FMRP may regulate the stability or translation of the mRNAs with which it associates. In either case, FMRP likely plays an important role in protein synthesis, and its loss may severely impact neuronal function during development and learning.

FRAXE, FRAXF, and Jacobsen syndrome

In addition to the folate-sensitive fragile site associated with fragile X syndrome (FRAXA), two other fragile sites are present distally on Xq. FRAXE at Xq28 is caused by amplification of a CCG repeat (Knight et al., 1993). In normal individuals, this region contains 6 to 25 triplets, whereas in FRAXE-positive mentally retarded patients there are more than 200 triplets. The expansion is associated with methylation of a nearby CpG island, and decreased expression of a putative transcription factor, designated FMR2 (Gu et al., 1996; Gecz et al., 1996). Distal to both FRAXA and FRAXE is a third folate-sensitive fragile site, designated FRAXF (Hirst et al., 1993). This site results from the expansion of a GCC repeat that is polymorphic in the normal population, ranging from 6 to 29 triplets (Parrish et al., 1994). Rarely, an expansion to several hundred triplets has been associated with developmental delay (Ritchie et al., 1994), but there is not a well-established correlation between FRAXF and human disease.

Mental retardation may be associated with fragile sites on autosomes as well. One such example is Jacobsen syndrome, a clinically complex disorder with manifestations that include psychomotor retardation and trigonocephaly (Jacobsen et al., 1973). The disorder is due to deletions of the long arm of chromosome 11, typically from 11q23 to the telomere, with subsequent loss of numerous genes. Jacobsen syndrome is associated with a folate-sensitive fragile site at 11q23.3, designated FRA11B. As with other fragile sites, this cytogenetic abnormality is caused by the expansion and hypermethylation of CCG repeats. For Jacobsen syndrome, the triplets fall within the 5′ end of the gene encoding the proto-oncogene *CBL2* (Jones et al., 1995). Here, the fragile site may predispose to chromosome breakage, resulting in profound clinical consequences.

Progressive myoclonus epilepsy type 1

Progressive myoclonus epilepsy type 1 (EPM1), also known as Unverricht–Lundborg disease or Baltic myoclonus, was separately described by Unverricht and Lundborg in cases from Estonia and Sweden, respectively, near the turn of the last century. It is an autosomal recessive disorder that occurs worldwide, but is particularly prevalent in the Baltic and western Mediterranean regions. EPM1 is also the major cause of progressive myoclonus epilepsy in North America (Lehesjoki & Koskiniemi, 1998).

EPM1 has its onset in childhood, typically between the ages of 6 and 13 years (Lehesjoki & Koskiniemi, 1998). The myoclonus may generalize to shaking attacks and usually progresses to tonic–clonic seizures. Later in the course of the disease, patients may exhibit ataxia, intention tremor, and dysarthria. A slow cognitive decline and emotional lability are often seen. EEG abnormalities are present in patients even before the onset of symptoms, and characteristically manifest as symmetric, generalized and high-voltage spike and wave and polyspike and wave paroxysms. Other laboratory tests are generally unrevealing, except for increased urinary excretion of indican.

EPM1 is associated with severe diffuse Purkinje cell loss and Bergmann's gliosis (Hanovar & Meldrum, 1997). Surviving Purkinje cells are swollen and vacuolated. Mild to moderate neuron loss also occurs in the cerebral cortex, striatum, medial thalamic nucleus, brainstem nuclei, and spinal motor neurons. No Lafora bodies are present, indicating that EPM1 and Lafora disease are both pathologically and genetically distinct (Labauge et al., 1995).

EPM1 is caused by mutations in the *CSTB* gene, which encodes cystatin B, a cysteine protease inhibitor. Uncommonly, point mutations in the coding region result in protein truncation (Pennacchio et al., 1996). More often, expansions of a 12-nucleotide repeat in the 5′ untranslated region result in reduced mRNA expression (Lalioti et al., 1997; Lefreniere et al., 1997, Virtaneva et al., 1997). While normal alleles contain two to three copies of this 12-mer repeat unit, mutant alleles contain more than 60 copies. Unstable premutations containing 12–17 repeats are prone to expansion but do not cause clinical symptoms. That EPM1 is caused by the loss of cystatin B expression is further supported by the targeted disruption of this gene in mice, which causes progressive ataxia and myclonic epilepsy (Pennacchio et al., 1998).

Spinocerebellar ataxia type 8

The spinocerebellar ataxia type 8 (SCA8) locus at 13q21 was identified in a family with an undefined form of adult-onset, autosomal dominant spinocerebellar ataxia (Koob et al., 1998, 1999). The identified expansion consisted of 80 CAG triplets followed by 11 TAG triplets. DNA from a collection of ataxia families was then screened, leading to the identification of seven other affected kindreds carrying this expansion. The largest of these families, with 7 generations and 84 members, was evaluated clinically and genetically. All affected family members were found to have the expansion, yielding a maximum lod score for linkage between ataxia and the expansion of 6.8 at $\theta = 0.00$. In this and other kindreds (Ikeda et al., 2000), disease onset was in adulthood, ranging from 18 to 73 years, with symptoms including limb and truncal ataxia, ataxic dysarthria, and horizontal nystagmus. Disease manifestations were slowly progressive, and only severely affected individuals were non-ambulatory by the fourth to sixth decades. MRI scans revealed marked cerebellar atrophy.

Characterization of transcripts from the SCA8 locus indicate that the repeat expansion is near the 3′ end of an RNA that lacks an extended open reading frame (Nemes et al., 2000). The expansion is transcribed in the CTG orientation, complementary to the CAG repeat found in other spinocerebellar ataxias and reminiscent of the expansion in myotonic dystrophy (Koob et al., 1999). The 5′ exon of the SCA8 transcript is complementary to the first exon of another gene that is transcribed in the opposite orientation. This gene encodes a novel actin-binding protein that is primarily expressed in brain, named Kelch-like 1 (KLH1). The arrangement of these two genes suggests that the SCA8 transcript may be an endogenous antisense RNA that regulates the expression of KLH1.

Caution should be observed in interpreting whether expansion at the SCA8 locus is causative for the disease. In the large SCA8 kindred originally described, both the CTG and adjacent CTA repeats were polymorphic, and were expanded to 110–130 combined repeats in affected individuals. Normal alleles were found to carry 16–91 combined repeats. Several studies (Stevanin et al., 2000; Worth et al., 2000; Vincent et al., 2000) have since confirmed that the vast majority of control alleles (over 97%) have a small combined CTG/CTA repeat length, ranging from 3–31. However, in each of these studies, rare expanded alleles were also identified in the control population and in patients with other neurologic disorders. Very large expansions to hundreds of repeats were also observed in unaffected members of SCA8 kindreds and in a CEPH reference family. These data have raised the question whether the repeat expansion is causative for the disease or only linked to the causative mutation. If the expansion is involved in disease pathogenesis, then the reduced penetrance of the SCA8 phenotype and ranges for normal and pathologic expansions need to be explained.

Spinocerebellar ataxia type 10

Spinocerebellar ataxia type 10 (SCA10) is an autosomal dominant form of spinocerebellar ataxia associated with seizures. The disease locus was originally mapped to a 15 cM region at 22q13 (Zu et al., 1999). Matsuura et al., (2000) identified large expansions of an ATTCT pentanucleotide repeat in five Mexican SCA10 families. This pentanucleotide repeat is polymorphic in normal controls of European, Japanese and Mexican descent, and ranges in length from 10 to 22. In patients with the disease, there is a marked expansion to upwards of 4500 repeats. The pentanucleotide repeat is present within intron 9 of a gene of unknown function, designated *SCA10*, that is widely expressed within the mammalian brain. The mechanism by which the repeat expansion causes the diseases is unknown, and the possibility that it represents a rare polymorphism in linkage disequilibrium to the true pathogenic mutation has not been formally excluded.

Spinocerebellar ataxia type 12

Spinocerebellar ataxia type 12 (SCA12) is an autosomal dominant form of spinocerebellar ataxia identified in a single, large pedigree of German descent (Holmes et al., 1999). Clinical onset ranged from 8 to 55 years. Most patients presented in the fourth decade with a slowly progressive illness initially characterized by upper extremity tremor. The disease typically progressed to include head tremor, gait ataxia, dysmetria, dysdiadokinesis, hyperreflexia, paucity of movement, abnormal eye movements, and, in the oldest patients, dementia. MRI and CT scans of five cases revealed cortical and cerebellar atrophy. No pathological studies have been reported.

Like other autosomal dominant spinocerebellar ataxias, SCA12 is defined based on the involvement of a distinct genetic locus. Using a PCR-based strategy (Schalling et al., 1993; Koob et al., 1998; Holmes et al., 1999), a novel CAG repeat expansion was identified in the proband and other affected family members of the German pedigree. The range of expansion was relatively narrow (66–78 CAGs), and distinct from that observed in 394 normal subjects and 1099 disease controls (7–28 CAGs). In affected individuals, there was no apparent correlation between repeat length and age of onset, although the precise age of onset was often difficult to define and the expansion range in this pedigree was narrow.

The SCA12 CAG repeat is located 133 nucleotides 5′ of the apparent transcriptional start site of the gene encoding a brain-specific regulatory subunit of protein phosphatase PP2A, known as *PPP2R2B*, which has been mapped to 5q31–5q33. The use of an alternative transcriptional start site 5′ of the CAG repeat was suggested by the identification of a mouse brain EST derived from this region, and by the identification of promoter elements upstream of the repeat. As such, the repeat expansion may affect expression of this PP2A regulatory subunit, thereby altering PP2A function in the brain. Alternatively, the repeat may lie within an as yet unidentified overlapping or adjacent gene, or it may be in linkage disequilibrium with the causative mutation.

Friedreich's ataxia

Friedreich's ataxia (FRDA) is an autosomal recessive, multisystem degenerative disorder affecting approximately 1 in 40 000 individuals in the United States. The principal feature of FRDA is progressive gait and limb ataxia (Harding, 1981). Other commonly associated neurological features include cerebellar dysarthria, sensory loss, distal weakness, pyramidal signs, and absent reflexes in the lower limbs (Durr et al., 1996b). Disease onset is usually before age 25, and the symptoms are progressive. Skeletal deformities, diabetes, and progressive hypertrophic cardiomyopathy are found in many patients (Sanchez-Casis et al., 1977). This later aspect of the disease often contributes to mortality.

The neurological manifestations of FRDA reflect the distribution of pathology within the nervous system. FRDA is characterized by widespread neuronal degeneration within the central nervous system, but the hallmarks are atrophy of the posterior columns of the spinal cord, loss of deep cerebellar nuclei and efferent cerebellar pathways and degeneration of distal corticospinal tracts. In the peripheral nervous system, loss of sensory neurons is observed in the dorsal root ganglia (Hewer, 1968; Lamarche et al., 1993).

FRDA results from mutations causing loss of function of the *FRDA* gene at chromosome 9q13 (Campuzano et al., 1996). The vast majority of these mutations (more than 95%) are expansions of a guanine–adenine–adenine (GAA) trinucleotide repeat in the first intron of *FRDA*. The causative nature of *FRDA* mutations was verified by the identification of patients carrying one expanded allele and one allele with a point mutation (Campuzano et al., 1996; Durr et al., 1996b). No patients with point mutations in both alleles have yet been reported. The length of the GAA trinucleotide repeat in the *FRDA* gene is polymorphic, with normal chromosomes carrying fewer than 42 triplets (Cossee et al., 1997). FRDA chromosomes, in contrast,

carry from 80 up to 1200 GAA repeats. Through a mechanism that remains unclear, but which likely involves defective transcriptional elongation, the expanded GAA repeat results in reduced *FRDA* expression.

The *FRDA* gene encodes a widely expressed 210-amino acid protein, frataxin, which localizes to the mitochondria (Campuzano et al., 1996, 1997) and likely contributes to iron homeostasis (Koutnikova et al., 1997; Babcock et al., 1997). In model systems, loss of frataxin results in overload of mitochondrial iron accompanied by reduced activity of key mitochondrial enzymes, hypersensitivity to oxidative stress, and defective oxidative phosphorylation (Wilson & Roof, 1997; Babcock et al., 1997; Rotig, 1997; Radisky et al., 1999). Mitochondria are a major source of reactive oxygen species, catalysed by iron via the Fenton reaction. These reactive oxygen species are believed to be the principal mediators of mitochondrial injury.

In patients with FRDA, loss of frataxin expression and function also results in accumulation of iron within mitochondria. This iron overload is especially pronounced in the tissues that are most severely affected in FRDA, including cardiac muscle, pancreatic islet cells, and the nervous system (Sanchez-Casis et al., 1977; Campuzano et al., 1997). Examination of tissues from patients with FRDA confirms that excess iron accumulation is associated with a reduction in mitochondrial enzyme function, increased susceptibility to oxidative stress, and defective oxidative phosphorylation (Lamarche et al., 1993; Waldvogel et al., 1999; Lodi et al., 1999; Delatycki et al., 1999; Rotig, 1999). Iron-induced injury in FRDA tissues is diminished by free radical scavengers such as ubiquinone (coenzyme Q_{10}) and idebenone, supporting the contention that the injury is mediated by reactive oxygen species (Wong et al., 1999). Elevated levels of urinary 8-hydroxy-2′-deoxyguanosine (a byproduct of oxidative damage to DNA) and plasma malondialdehyde (a byproduct of lipid peroxidation) are found in patients with FRDA, lending further support to the hypothesis that iron overload is associated with oxidative injury (Schultz et al., 2000; Edmond et al., 2000). The emerging consensus regarding the pathogenesis of FRDA is that loss of frataxin expression leads to a loss of iron homeostasis. The resulting overload of iron in mitochondria, in turn, results in increased steady-state levels of reactive oxygen species which cause oxidative damage and decreased ATP production causing injury to tissues – particularly those with a high energy demand (Beal, 2000).

In conclusion, the last decade of research in neurology has resulted in recognition of an entirely new class of hereditary disease. Progress in understanding these diseases will probably proceed hand in hand with a better understanding of underlying biochemical and cellular processes. Beyond the specific mechanisms at work in each of these disorders, there are a number of shared characteristics. First, all known repeat expansion diseases affect the nervous system. This may be related to specific molecular targets that are expressed only in neurons, or to a deficiency in some compensatory mechanism relative to non-neuronal cells. That neurons are long-lived cells with limited regenerative capacity probably contributes to their selective vulnerability. Secondly, naturally occurring repeat expansion diseases have thus far only been found in humans. Perhaps this is related to the long duration between birth and age of procreation in humans, which allows a large numbers of cell divisions in spermatogenesis, resulting in a greater opportunity for these dynamic mutations to occur. Also, since many of these diseases appear late in life, it is likely that the long lifespan of humans favours a higher incidence of disease. Ascertainment probably also plays a role. Finally, the repeat expansion diseases may be related to other non-expansion neurodegenerative diseases. Parallels exist between the polyglutamine diseases and more common neurodegenerative proteinopathies such as Parkinson's disease, Alzheimer's disease, prion diseases and amyotrophic lateral sclerosis. It is possible that protein deposition is an epiphenomenon representative of a morbid state in neurons. But the recent recognition of additional dominantly inherited neurodegenerative disorders that are characterized by intraneuronal aggregation of the mutant gene product, and the emerging evidence that defects in the ubiquitin–proteasome pathway may underlie neurodegenerative disease, argue that many of these diseases share a common pathogenesis. If the next decade of neurological research is as productive as the last, then a better understanding of this pathogenesis may lead to effective treatment for these disorders.

Formation of the neural tube and control of cell fate by dorsal–ventral signalling centres

One of the most remarkable features of mammalian neural development is the production of the complicated end product, the brain, spinal cord and peripheral nervous system, from a simple one-cell layer thick sheet of neuroepithelial cells. The first step in this process is the formation and patterning of the neural tube through a process termed neural induction (Kandel et al., 2000). This involves the formation of a specialized region of columnar epithelium, called the neural plate, from the embryonic dorsal ectoderm. Soon after its formation the neural plate folds and becomes a tube (Fig. 4.1). In this process the most medial regions of the neural plate form the ventral neural tube and the more lateral regions of the neural plate form the dorsal neural tube. At the neural plate stage, signals from the mesoderm underlying it pattern the neural plate so that there are molecular differences between the rostral and caudal regions of the neural plate. Therefore, these early patterning events are fundamental to the later production of specialized regions and cells of the nervous system from the neural tube.

Neural induction is not completely understood at the molecular level but significant recent progress has been made (Harland, 2000). Current thinking is that the ectoderm at this stage of embryogenesis has a default neural fate except that the action of bone morphogenetic proteins (BMPs) and Wnts (a family of secreted glycoproteins similar to the *wingless* gene in *Drosophila*) expressed widely in the embryo suppress the acquisition of neural fate. Neural induction then occurs in the neural plate because of the release of soluble BMP and Wnt inhibitors from the underlying mesoderm. The inhibition of BMP and Wnt effects allows the default neural fate pathway to operate and the neural plate forms. The rostral–caudal patterning of the neural plate is further affected by the actions of molecules such as retinoic acid (which induces a caudal neural pattern).

After the neural tube forms, the rostral–caudal subdivisions (that will become the telencephalon, diencephalon, mesencephalon, metencephalon and spinal cord) become visible anatomically. At this stage, at each level from rostral to caudal, the fate of individual neural precursors begins to be controlled by dorsal and ventral signalling centres present in the neural tube called the roofplate and the floorplate, respectively. The roofplate produces a variety of molecules in the Wnt and BMP families, while the floorplate produces sonic hedgehog (SHH). There is now persuasive evidence that signaling by BMPs and Wnts regulates the proliferation, differentiation and migration of derivatives of the dorsal neural tube (Lee & Jessell, 1999). These include dorsal spinal interneurons and neural crest cells, which go on to generate the entire peripheral nervous system. Similarly, the differentiation of spinal motor neurons and ventral spinal interneurons is directly controlled by SHH secreted from the floorplate (Kandel et al., 2000). The roofplate and floorplate also secrete a host of other factors that regulate later events such as axon guidance decisions made by cells at all levels of the developing nervous system. Structures analogous to the roofplate and floorplate are present at rostral levels of the nervous system as well but their role in differentiation is much less completely understood in these more morphologically complex regions. Failure of the proper dorsal–ventral patterning events in the developing prosencephalon leads to major brain malformations such as holoprosencephaly. A number of hereditary cases of this syndrome have been linked to genes involved in dorsal–ventral patterning, including mutations in SHH itself (Wallis & Muenke, 2000). Cyclopamine, a teratogenic chemical, appears to cause holoprosencephaly by interfering with SHH signalling (Cooper et al., 1998).

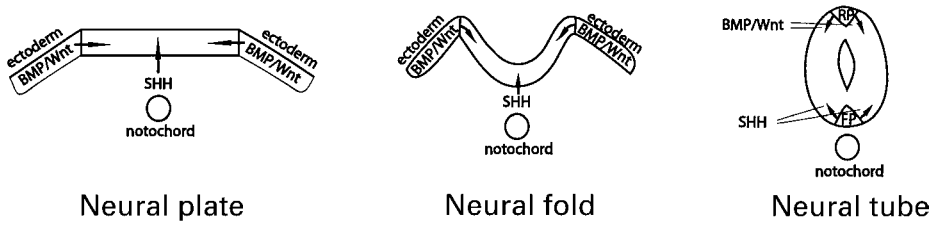

Fig. 4.1. Schematic diagram of the stages of formation of the neural tube from the neural plate. Initially the neuroectoderm is specified from the ectoderm and is a flat sheet of epithelial cells. It begins to fold and finally forms a tube. During this entire time the medial neural plate (which becomes the ventral neural tube) and the lateral neural plate (which becomes the dorsal neural tube) are patterned by secreted molecules. Abbreviations – SHH = sonic hedgehog, RP = roofplate; FP = floorplate.

Cellular and molecular correlates of neurogenesis and gliogenesis during development

Once the neural tube forms and the actions of the dorsal–ventral signalling centres have had their initial effects on the patterning of the neural tube, the process of cellular differentiation begins. Within the ventricular zone, mitotic multipotential cells begin to produce differentiated neuronal and glial cell types following a sequential programme. This process is best understood in the six-layered neocortex. Initially, mitotic stem cells undergo repeated cycles of so-called 'symmetric' cell divisions that yield two daughter cells with the same potential as the parent cell (Lu et al., 2000). These mitoses occur in a characteristic to-and-fro migratory pattern termed interkinetic migration. In this pattern stem cells have cellular processes that span the cortical wall from ventricular to pial surface, and their soma is in an intermediate position. As the stem cell prepares to divide, its cell body descends to the ventricular surface where mitosis occurs. At the appropriate stage of development for the production of differentiated neurons, neural stem cells begin to undergo 'asymmetric' cell divisions that yield a daughter cell that goes on to further differentiate and a daughter cell that remains a stem cell (Lu et al., 2000). The differentiated daughter cell then migrates radially into the cortical plate. As development goes on, progressively more cell divisions are asymmetric and waves of differentiated cells are produced, and less and less stem cells remain in the ventricular zone. Disorders such as tuberous sclerosis and focal cortical dysplasia may arise because of dysfunction in the processes regulating the decision whether to adopt a neuronal or glial fate within the ventricular zone (Walsh, 1999).

In the ventricular zone, neurons with particular laminar fates are produced in a characteristic 'inside-out' manner so that cells destined for the deeper cortical layers are born first and cells destined for superficial cortical layers are born later and migrate past the earlier born cells. The migrating of cells from the ventricular zone using radial glial cells as the scaffolding to reach their final laminar position in a so-called radial pattern of migration. Lissencephalies, periventricular nodular heterotopias and periventricular band heterotopias are all disorders of this process of radial migration and are caused by mutations in genes controlling various steps of migration (Walsh, 1999; Gleeson & Walsh, 2000).

The molecular regulation of the events occurring in the ventricular zone during this period is starting to be elucidated. The decisions made by neural stem cells are controlled in part by the actions of the Notch family of transmembrane receptors. These receptors interact with their ligands, the Delta and Jagged proteins, in a cell contact-dependent manner. Activation of the Notch receptor leads to a decision to remain an undifferentiated stem cell or to become a radial glial cell (Lu et al., 2000). Inhibition of Notch signalling occurs in part by the inheritance of a protein called Numb that is asymmetrically distributed between daughter cells of asymmetric cell divisions. Numb blocks the downstream effects of the Notch receptor and releases the cell to differentiate into a neuron (Lu et al., 2000).

The differentiation of glial progenitors to mature oligodendroglia and astroglia in the developing CNS is also subject to extrinsic regulation. Basic fibroblast growth factor (bFGF) inhibits maturation of glial progenitors to either oligodendroglia or astroglia (McKinnon et al., 1990; Grinspan et al., 2000). Platelet-derived growth factor-alpha (PDGFα) drives recruitment into the oligodendroglial lineage (Fruttiger et al, 1999), whereas the BMPs enhance differentiation of glial progenitors to glial fibrillary acidic protein (GFAP) positive astroglia (Grinspan et al., 2000).

Apoptosis during normal brain development

Immature animals remodel CNS and other tissues by apoptotic removal of redundant cells. Morphological features of apoptosis include nuclear fragmentation, cell shrinkage, membrane blebbing, and phagocytosis by macrophages. Apoptosis is triggered by activation of target cell plasma membrane death receptors (e.g. CD95, the tumor necrosis factor (TNF) receptors, and the low affinity neurotrophin receptor, p75NTR), by unsuccessful competition of the target cell for critical survival factors, or by inability of the target cell to establish and maintain contact with critical extracellular matrix constituents ('anoikis') (Savill & Fadok, 2000; Meier et al., 2000).

A superfamily of cysteine proteases, the caspases, are responsible for apoptotic execution. These proteins are synthesized as procaspases, which require proteolytic clipping in order to activate their catalytic sites. This activation can be initiated by their aggregation with a plasma membrane death receptor or with proteins (cytochrome c and Apaf-1) released through mitochondrial membrane pores. Once begun, a chain reaction of proteolytic caspase activation follows. The caspases cleave target proteins at aspartate residues. In some instances, this cleavage results in protein activation (e.g. other members of the caspase family, and interleukin-1). More commonly, the target protein (e.g. gelsolin, and an inhibitor of a nuclease capable of intranuclear double-stranded DNA nicking) is inactivated. Together, these proteolytic events are responsible for the DNA nicking and cytoplasmic and plasma membrane remodelling that characterize apoptosis, and culminate in cell digestion by macrophages (Hengartner, 2000).

The Bcl-2 family of proteins modulate caspase activation. Pro-apoptotic members of this family (e.g. Bax and Bak) facilitate release of cytochrome c and Apaf-1 from target cell mitochondria, whereas anti-apoptotic members (e.g. Bcl-2 and Bcl-x_L) inhibit this release. Expression of this Bcl-2 family of proteins is developmentally regulated in the CNS (Kelekar & Thompson, 1998; Hengarter, 2000).

Apoptosis is prominent in both neuronal and macroglial lineages in the CNS. In the cat retina, for example, more than 80% of the ganglion cells do not survive long after birth (Meier et al., 2000), and more than 50% of the late oligodendroglial progenitors formed in perinatal rat optic nerve do not survive to maturity (Barres & Raff, 1994). This apoptotic culling of neural cells unable to obtain the survival factors they require provides a powerful and precise means by which normal CNS tissue structure and function can be ensured. An illuminating example of this is provided by examination of transgenic mice that overexpress $PDGF_{AA}$ in CNS. $PDGF_{AA}$ is a growth factor for oligodendroglial progenitors, and these mice accumulate many more oligodendroglial progenitors in the perinatal period than do their normal littermates. Yet, as these transgenic mice mature, the numbers of oligodendroglia and their levels of myelination in the CNS are normal (Calver et al., 1998). Conversely, in mice in which CNS apoptosis is prevented by knocking out caspase-9 or caspase-3, there are ectopic accumulations of supernumerary neurons (Yuan & Yankner, 2000).

Neurogenesis in the normal adult brain

Up to this point only the mechanisms of developmental production of cells have been discussed. It has been known for many years that continued production of glial cells occurs in the adult brain. Most of these are thought to be generated from the striatal and cortical subventricular zones. What has been less widely appreciated, although also well established in the 1960s, is that there is continued production of neurons in the adult brain of mammals in two locations, the dentate gyrus and olfactory bulb (Gage, 2000).

In the dentate gyrus of the hippocampal formation there is a layer of mitotically active cells at the border of the hilus and dentate granule cell layers that has been proven to produce new neurons throughout life in both rodents and primates (Gage, 2000) (Fig. 4.2). The function of the newly born granule cells is unknown, but it is known that at least some of these cells extend axons that integrate into the normal circuitry of the hippocampus. Recent studies have shown that environmental stimuli, including visuospatial learning and physical activity, can have substantial effects on the birth and survival of new dentate granule cells in adult rodents (Kempermann et al., 1997a; Gould et al., 1999a, b; van Praag et al., 1999). Also, there is an age-related decrease in the production of new neurons in the dentate gyrus (Kuhn et al., 1996).

The phenomenon of dentate granule neurogenesis in the adult is being intensively studied since it is a paradigm for the regulation of new neuron production in adult mammals. Many studies have addressed exogenous influences that regulate the rate of proliferation of granule cell precursors, and have shown that granule cell neurogenesis is inhibited by excess glucocorticoids and by excitotoxins (Cameron & Gould, 1994; Cameron et al., 1995). A particularly interesting set of studies has characterized the balance of cell production and granule cell number in inbred strains of mice. These studies demonstrated that various inbred strains of mice may have a low or high basal

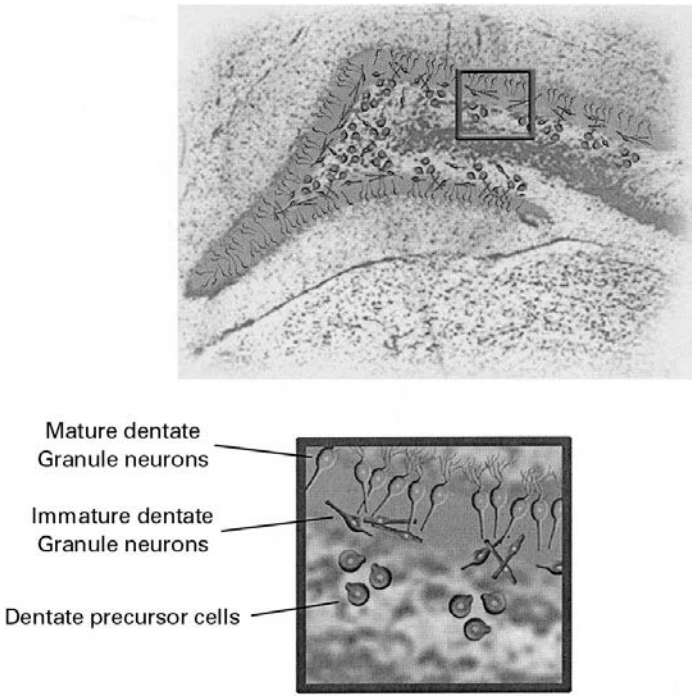

Fig. 4.2. Schematic diagram showing the organization of neurogenesis in the adult dentate gyrus. Mitotic dentate precursor cells are located in the zone just under the granule cell layer. Newborn immature cells are at the inner border and more mature granule cells are in the outer domains of the granule cell layer. (Artwork by Erin Browne.)

rate of new granule cell production (Kempermann et al., 1997b). Some strains have basal rates of granule cell death that match the production of granule cells very closely, while others have a lower rate of death leading to an increasing number of granule neurons as the animals mature (Kempermann et al., 1997b).

The granule and periglomerular interneurons of the olfactory bulb are also produced in adult mammals. These cells are generated in a small region of the anterior subventricular zone. They reach the olfactory bulb by migrating long distances in a direction tangential to the radial migration seen during development (Gage, 2000). Once in the bulb, they appose themselves to radial glial-like cells and migrate radially to take up their final position. What functional role the production of new neurons has in the olfactory bulb is currently unknown. In non-human primates, a recent controversial study demonstrated ongoing neurogenesis from the subventricular zone of neurons that migrated to association areas of neocortex (Gould et al., 1999b). This type of adult neurogenesis has never been seen in rodents and thus may be a primate specialization. Again, the function of these new cells is unknown presently but, if this type of neurogenesis is ongoing in humans, it may have important implications for plasticity of higher cortical functions.

Neurogenesis and gliogenesis in pathologic states

The production of neurons from the dentate subgranular zone and the subventricular zone in the adult nervous system of rodents has been studied in a number of pathologic contexts. The most extensively studied of these is following status epilepticus (Bengzon et al., 1997; Parent et al., 1997). In rodent models of status epilepticus following systemic administration of pilocarpine or kainic acid, there is a dramatic up-regulation of granule cell neurogenesis starting several days after the prolonged seizure and continuing for about 2 weeks. Similar increases in neurogenesis have been seen in the dentate gyrus following transient global ischemia in gerbils (Liu et al., 1998). The functional significance of this response is unclear, but there is some reason to believe that the increased neurogenesis is somehow coupled to increased cell death of granule cells following the same insults (Bengzon et al., 1997). If there is a mechanism for linking the birth of new neurons in the dentate gyrus to cell death, it may also be possible to activate this mechanism in other brain regions that suffer extensive cell death in response to pathologic stimuli like excitotoxicity or neurodegenerative processes. This might serve as a basis for novel therapeutic strategies to help repair the effects of these pathologic insults.

Focal traumatic lesions in the cortex have been shown to up-regulate the rate of proliferation of astrocyte precursors in the subventricular zone. It is possible that this represents the main source of cells contributing to gliosis in the cortex following focal or diffuse injuries (Szele & Chesselet, 1996). In the subventricular zone, increased cell birth of cells with properties of glial cells has been demonstrated in response to experimental allergic encephalomyelitis (Calza et al., 1998). Oligodendroglial progenitors are also identifiable in chronic multiple sclerosis plaques, but often have exited the mitotic cycle (Wolswijk, 1998). Treatment strategies need to be developed that enhance proliferation of these progenitors, and their differentiation to myelin-forming oligodendroglia.

Apoptosis and necrosis in pathologic states

The death of neurons and macroglia caused by deprivation of oxygen and glucose (e.g. in an ischemic infarction)

occurs by two apparently distinct mechanisms. Where oxygen/glucose deprivation is most severe, ATP generation is blocked, and the cells lose the capacity to regulate intracellular Ca^{2+} and Na^{+} concentrations. Cell necrosis results, characterized by perikaryal swelling, loss of plasma membrane integrity, and cell fragmentation. Ionotropic glutamate receptors (GluR), activated by increased extracellular glutamate concentrations, are of central importance in the pathophysiology of ischemic necrosis of neurons and oligodendroglia, and inhibitors of these GluR minimize the extent of ischemic necrosis (Dugan & Choi, 1999). Where oxygen/glucose deprivation is less severe (e.g. in the 'ischemic penumbra'), neurons and macroglia die by apoptosis, and can be rescued by caspase inhibitors (Yuan & Yankner, 2000).

The contribution of apoptosis to neural cell loss in chronic neurological diseases is less clearcut. While cells undergoing apoptosis are common in active multiple sclerosis plaques, most are lymphocytes rather than cells of the oligodendroglial lineage (Bonetti & Raine, 1997). In respect of Alzheimer's disease, amyloid-β can activate neuronal caspases, but most degenerating neurons in this disorder do not show apoptotic features. In mice expressing the human mutant superoxide dismutase-1 gene that causes a familial form of amyotrophic lateral sclerosis (ALS), inhibition of caspase-1 or overexpression of Bcl-2 delays disease progression, and caspase inhibition also delays disease progression in a transgenic model of human Huntington's disease, but neuronal apoptosis is difficult to demonstrate morphologically in these mouse models (Yuan & Yankner, 2000)

Stem cells in the adult brain

The existence of neurogenesis and gliogenesis in the subventricular zone and dentate gyrus of adult animals implies that there must be precursors for these cells (Gage, 2000). The usual terminology applied to progenitor cells for neurons and glia divides them into stem cells and committed precursor cells. A stem cell is multipotential and capable of numerous self-renewing mitoses. A committed precursor cell will be limited to one or a small number of ultimate fates and has a limited capacity for self-renewal. The clear presence of neurogenesis and gliogenesis and the in situ and in vitro demonstration of dividing precursor cells have led to the search for the elusive multipotential neural stem cells that are assumed to be present in the adult nervous system.

In the early 1990s, several cell culture systems that are capable of maintaining multipotential (cells capable of making neurons and glia) stem cells were described. Following these initial studies, there have been a great number of studies that have demonstrated the properties of these cells and their requirements for trophic factors and mitotic factors (such as basic FGF and epidermal growth factor (EGF)) to be maintained in culture (Gage, 2000). Other studies have demonstrated that treating these cultures with factors like retinoic acid can force these cells into producing neurons, while serum and ciliary neurotrophic factor (CNTF) induce the cells to become astrocytes (Gage, 2000). The use of these culture systems has demonstrated that there are quiescent stem cells in all regions of the nervous system rather that just in the areas known to produce new neurons (Gage, 2000). Are these cells placed in a distributed manner in order to produce new glial cells in areas away from the germinative zones? Are there ways to induce them to become neurons in situ and replace neurons killed or injured by pathologic insults?

The scientific question of the location and identity of the neural stem cells in vivo has recently been addressed. Several laboratories have reported that either the ependymal cells lining the adult ventricles or astrocyte-like glial cells adjacent to them are likely to be the in vivo stem cells responsible for the production of olfactory interneurons and glial cells in the adult subventricular zone (Doetsch et al., 1999; Johansson et al., 1999). The relationship of these two populations of stem cells to each other (e.g. are they transitional forms of the same population?), and their relationship to the multipotential cells in the dentate gyrus and elsewhere in the CNS are unknown.

Until recently it was believed that neural stem cells were capable of producing exclusively neurons and glia. Recent exciting experiments have shown that this view may be too limited. In one set of studies, investigators transplanted mouse neural stem cells that were marked with an enzymatic tag to other mice whose bone marrow had been destroyed by irradiation. In these mice, amazingly, the neural stem cells were able to generate hematopoetic stem cells that populated the bone marrow and produced differentiated blood elements and immune cells that expressed the enzymatic tag (Bjornson et al., 1999). Another, even more startling result was obtained when neural stem cells were injected into mouse blastocysts and were able to contribute differentiated cells to all three germ layers of the developing embryo, albeit less efficiently than true embryonic stem cells (Clarke et al., 2000). These experiments blur the distinctions between neural stem cells and other stem cells in the body and perhaps imply that the immediate molecular milieu may be as important as any developmental history in contributing to the multipotentiality of stem cells.

Therapeutic approaches based on neurogenesis

How can we utilize the new understanding of neurogenesis and gliogenesis in the nervous system to treat neurological diseases? One approach is to generate cells for therapeutic purposes in vitro and transplant them into the diseased host (Bjorklund & Lindvall, 2000a). The other approach is to attempt to harness the regenerative capacity of the nervous system to facilitate functional recovery from insults (Lowenstein & Parent, 1999; Bjorklund & Lindvall, 2000b). In the future it is likely that both approaches will be useful.

The approaches that are based on the in vitro production of neural cells are being investigated most intensively for the treatment of Parkinson's disease, Huntington's disease, stroke and epilepsy (Bjorklund & Lindvall, 2000a). In each of these cases the approach depends on the ability to culture pure populations of the appropriate neurons from identified sources. The sources being investigated include xenografts from porcine sources, expanded human neural stem cells, human bone marrow stromal stem cells, and immortalized human cell lines (Bjorklund & Lindvall, 2000a). Each of these sources has its own perils and promises. Xenotransplants may have a higher potential for rejection or infection with zoonotic organisms. Expanded human neural stem cells are still incapable of producing sufficient quantities of pure cells to meet clinical needs. All immortalized cell lines have the potential to lead to neoplasm. The next 10 years will almost certainly lead to solutions to these problems and will allow the clinical efficacy of these treatments to be tested.

The potential for harnessing the native regenerative capacity of the nervous system is perhaps the most exciting future possibility. A recent series of experiments utilizing a clever technique to deliver focal cell type specific injury to the nervous system has emphasized the heretofore unrecognized ability of the nervous system to replace certain types of cells (Snyder et al., 1997). This technique allows the selective photoablation of cells in the cortex in a layer specific manner. These experiments reveal that, after the selective ablation of cortical pyramidal neurons, the rodent brain is capable of using endogenous precursors to replace these cells, despite the fact that these cells are never normally produced in the adult animal (Magavi et al., 2000). If we can understand the cues that regulate these events then these signals may allow regulatable repairs to be performed in the nervous system (Lowenstein & Parent, 1999; Bjorklund & Lindvall, 2000b).

Neuroprotection in cerebral ischemia

Jin-Moo Lee[1] and Dennis W. Choi[2]

[1] Washington University School of Medicine, St Louis, MO, USA
[2] Department of Neurosciences, Merck Research Laboratories, West Point, PA, USA

Ischemic stroke is a consequence of transient or permanent reduction of blood flow to a focal region of the brain, usually caused by the occlusion of an artery by an embolus or thrombus. Cerebral ischemia may also occur globally in the setting of cardiac arrest and resuscitation. While historically brain damage has been considered to be an inexorable consequence of focal or global ischemic insults, in recent years a growing understanding of the underlying mechanisms responsible for brain cell death has led to the identification of new therapeutic approaches. Two main approaches have emerged. The first aims to restore lost blood flow by dissolving the thrombus responsible for cerebral artery obstruction (in ischemic stroke). Thrombolysis has become an established treatment for ischemic stroke after the efficacy of intravenous tissue plasminogen activator (tPA) was demonstrated in a landmark study (The NINDS rt-PA Stroke Study Group, 1995). Promising results have also been reported for the thrombolytic agent pro-urokinase, delivered by intra-arterial catheter directly to the site of intravascular thrombus (Furlan et al., 1999). The second approach, neuroprotection, aims to reduce the intrinsic vulnerability of brain tissue to ischemia; it will be the topic of this chapter.

Mechanisms of ischemic neuronal death

The brain is more vulnerable to ischemia than many other tissues, so it seems plausible that the cellular mechanisms of this heightened vulnerability could be delineated and blocked. Over the last 15 years evidence has accumulated indicating that normal brain signaling and immune defense mechanisms may become harmful after ischemic insults (Rothman & Olney, 1986; Choi, 1988; del Zoppo et al., 2000). In particular, substantial evidence now implicates excitotoxicity, programmed cell death, and inflammation in the pathogenesis of ischemic neuronal death.

Excitotoxicity

The excitatory transmitter glutamate normally mediates most fast synaptic transmission throughout the CNS, but it also has a surprising ability to trigger central neuronal death upon prolonged exposure, a phenomenon called 'excitotoxicity' by Olney (1969). Excitotoxicity now appears to be involved in the pathogenesis of several CNS diseases including ischemic brain injury (Rothman & Olney, 1986; Choi, 1988). Under ischemic conditions, neurons deprived of oxygen and glucose rapidly lose ATP and become depolarized, leading to abnormally high levels of glutamate release (initially mediated by vesicular release from nerve terminals, and later by reverse transport from astrocytes). Once in the extracellular space, glutamate activates three major families of ionophore-linked receptors identified by their preferred agonists: *N*-methyl-D-aspartate (NMDA) alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) and kainate. The channels gated by all three receptors subtypes are permeable to both Na^+ and K^+. Channels gated by NMDA receptors, but only a small number of channels gated by AMPA or kainate receptors (see below), additionally possess high permeability to Ca^{2+}. Marked neuronal cell body and dendrite swelling occur, as Na^+ and Ca^{2+} enters the cell joined by the influx of Cl^- and water. Excessive Ca^{2+} influx mediated predominately by NMDA receptors (but also triggered secondarily by Na^+ influx through AMPA-, kainate-, and NMDA-receptor-gated channels via activation of voltage-gated Ca^{2+} channels and reverse operation of the Na^+/Ca^{2+} exchanger), leads to elevated intracellular free Ca^{2+} concentrations and lethal metabolic derangements (Choi, 1988; Kim et al., 2001).

In neuronal cultures, selective NMDA-receptor blockade prevents most of the Ca^{2+} influx and cell death induced by brief intense glutamate exposures, and also markedly attenuates the death of cultured neurons subjected to oxygen and/or glucose deprivation. These observations are consistent with studies conducted with selective agonists: exposure to NMDA for as little as 3–5 minutes triggers widespread necrosis of cultured cortical neurons ('rapidly triggered excitotoxicity'), whereas exposure to high concentrations of kainate typically requires hours to do the same ('slowly triggered excitotoxicity'). NMDA antagonists are also highly neuroprotective in animal models of focal brain ischemia (Albers et al., 1992), but not consistently in models of transient global ischemia (Buchan, 1990).

Profoundly elevated intracellular Ca^{2+} concentrations, resulting from ischemia and excitotoxicity, are thought to initiate many potentially lethal derangements in cellular processes. Work in recent years has assigned particular responsibility for ensuing cellular death to the Ca^{2+}-dependent activation of catabolic enzymes, generation of free radicals including nitric oxide (NO), impairment of mitochondrial function, and excessive utilization of energy by the DNA repair enzyme poly(ADP–ribose) polymerase (PARP) (see below).

Ca^{2+} may not be the only divalent cation whose excessive entry mediates excitotoxic neuronal death after ischemic insults. The excessive influx of Mg^{2+} through NMDA–receptor-gated channels and its toxic intracellular accumulation has been proposed as a potential component of excitotoxic injury (Hartnett et al., 1997). Furthermore, growing evidence suggests that glutamate receptor overactivation may promote the toxicity of neurotransmitter Zn^{2+} (Choi & Koh, 1998). Zn^{2+} is concentrated in synaptic vesicles at excitatory terminals throughout the forebrain and is released upon neuronal stimulation; it can alter the behaviour of several transmitter receptors and voltage-gated channels, including the NMDA receptor (Frederickson, 1989). Cell culture experiments showed that exposure to concentrations of extracellular Zn^{2+} plausibly attained in the ischemic brain could kill central neurons, especially if the neurons were depolarized. Subsequent studies have indicated that the first step in Zn^{2+}-mediated neuronal death, like Ca^{2+}-mediated neuronal death, is excess entry across the plasma membrane, facilitated by membrane depolarization and consequently enhanced influx through several routes, in particular, voltage-gated Ca^{2+} channels (see below). The idea that Zn^{2+} neurotoxicity might contribute specifically to ischemic brain damage was raised by Tonder et al. (1990), who showed that transient global ischemia in rats was associated with depletion of Zn^{2+} from hippocampal mossy fibres, and the abnormal appearance of Zn^{2+} in the cell bodies of degenerating target CA3 or hilar neurons (dubbed 'zinc translocation', Frederickson et al., 1989). This idea was strengthened by the observation that Zn^{2+} translocated into selectively vulnerable postsynaptic neuronal cell bodies throughout the forebrain, and did so prior to neuronal degeneration. Furthermore, intracerebroventricular injection of the membrane-impermeant chelator CaEDTA (EDTA saturated with equimolar Ca^{2+}, so that it does not affect extracellular Ca^{2+} or Mg^{2+} but still avidly binds Zn^{2+}) before transient global ischemia in rats markedly reduced Zn^{2+} translocation into selectively vulnerable neurons throughout the hippocampus, cortex, thalamus and amygdala, and also reduced the delayed death of these neurons (Koh et al., 1996).

Recently, the idea that toxic Zn^{2+} originates primarily from synaptic vesicles has been challenged by intriguing observations suggesting that Zn^{2+}-mediated neuronal death may still occur after kainate-induced seizures in Zn^{2+} transporter 3 gene (*znt-3*)-null mice, which lack histochemically reactive vesicular Zn^{2+} in nerve terminals (Lee et al., 2000; Cole et al., 1999). These observations raise the possibility that at least some of the toxic Zn^{2+} may originate from intracellular sources, perhaps released from protein binding sites by oxidative stress (Aizenman et al., 2000).

The morphology of cells dying after intense glutamate receptor overactivation and Ca^{2+} and/or Zn^{2+} influx typically has characteristics of necrosis, a fulminant form of cell death associated with failure of the plasma membrane and swelling of both the cell and internal organelles. However, milder levels of toxic glutamate receptor stimulation on cells with preserved energy metabolism may lead to an alternative, more orderly death: apoptosis (Ankarcrona et al., 1995).

Apoptosis

Cerebral ischemia seems an obvious example of a violent 'environmental perturbation' capable of producing necrosis; however, growing evidence indicates that many brain cells undergo apoptosis after ischemic insults (Choi, 1996; Dirnagl et al., 1999). Apoptosis is the end result of a genetically regulated program that induces cells to die in an 'altruistic' fashion, with minimal release of genetic material and other proinflammatory intracellular constituents (Kondo, 1988). In normal physiological settings such as during development, apoptosis has a characteristic morphological appearance, featuring chromatin condensation and aggregation to the nuclear margin, cell and internal organelle shrinkage, and fragmentation of the

nucleus and cytoplasm into membrane-bound vesicles (apoptotic bodies, Kerr et al., 1972). In the past, it has been characterized biochemically by internucleosomal fragmentation of genomic DNA in 185–200 base pair intervals, resulting in 'DNA laddering' detected on agarose gel electrophoresis, or by TdT-mediated biotinylated dUTP nick end-labeling (TUNEL) of nuclei. It is now becoming clear that DNA fragmentation and TUNEL of nuclei also occurs in cells undergoing necrosis, and thus cannot be the sole criterion for identifying apoptosis.

Recent investigations have yielded insights into the molecular mechanisms underlying programmed cell death. It is now apparent that this process is under tight regulatory control at several checkpoints. One checkpoint occurs on the outer membrane of mitochondria and is regulated by a group of proteins belonging to the bcl-2 family, composed of three groups based on structural and functional similarities. Members of group 1 (including bcl-2 and bcl-x_L) which share four conserved bcl-2 homology domains (BH) BH1–4 and a C-terminal hydrophobic tail (anchoring the protein to the outer mitochondrial membrane), are anti-apoptotic, whereas members of group 2 (including bax and bak), which contain BH1–3 and the hydrophobic tail, are proapoptotic. Members of group 3, which share only the BH3 domain, are pro-apoptotic and include bid and bik (Adams & Cory, 1998). Through a process that is currently poorly understood, pro- and anti-apoptotic members of the bcl-2 family interact on the outer mitochondrial membrane to regulate the release of the electron carrier cytochrome c from the intramembranous compartment (Jurgensmeier et al., 1998). Once in the cytoplasm, cytochrome c binds with another apoptosis regulator, Apaf-1, and dATP to form part of the 'apoptosome' (Cecconi, 1999), which activates the effector arm of programmed cell death carried out by a class of cysteine proteases, termed caspases. Caspases can also be activated by cell surface death receptors such as TNF receptors via caspase-8 (see below). Evidence is also emerging for a caspase-independent pathway of mammalian cell apoptosis, mediated by the mitochondrial release of apoptosis-inducing factor (Joza et al., 2001).

Highly conserved through evolution, more than a dozen caspases have been identified; a majority appear to participate in apoptosis, while others are responsible for the proteolytic activation of proinflammatory cytokines. Caspases are activated by proteolytic cleavage at caspase recognition sites. Thus, activation can occur autocatalytically, or through proteolysis by another caspase family member (Thornberry & Lazebnik, 1998). The apoptosome complex provides the initial stimulus for the autocatalytic activation of apical caspase-9, which subsequently cleaves and activates other downstream caspases including caspase-3, -6, and -7; these in turn cleave several proteins vital to survival (Slee et al., 1999). For example, caspase-3-mediated cleavage of the inhibitory subunit of caspase-activated DNase (CAD) results in internucleosomal DNA cleavage and 'DNA laddering' (Nagata, 2000). In addition, cleavage of nuclear lamins results in nuclear shrinking and budding (Buendia et al., 1999), and cleavage of cytoskeletal proteins such as fodrin and gelsolin result in loss of overall cell shape (Kothakota et al., 1997), characteristic of apoptotic cellular morphology.

Potassium efflux and resultant cell shrinkage may also play an important role in apoptosis. It is well established that raising extracellular K^+ inhibits neuronal apoptosis in vitro, an observation attributed historically to the activation of voltage-gated Ca^{2+} channels (Johnson & Deckwerth, 1993). However, the protective effect of raising extracellular K^+ against cortical neuronal apoptosis induced by staurosporine or serum deprivation was not eliminated by blocking voltage gate Ca^{2+} channels and associated increases in intracellular Ca^{2+} concentrations (Yu et al., 1997). Furthermore, these forms of neuronal apoptosis were associated with an early enhancement of the delayed rectifier current I_K, and depletion of cellular K^+ content; and blocking I_K with tetraethylammonium (TEA) attenuated subsequent neurodegeneration (Yu et al., 1997). Similarly, lymphocytes undergoing apoptosis were found to have intracellular K^+ concentrations of 50 mM (normally 140 mM), and blockade of K^+ efflux by raising extracellular K^+ inhibited apoptosis in these cells (Hughes et al., 1997). Such reductions in the concentration of intracellular K^+ may promote apoptosis by facilitating the proteolytic activation of caspase-3 and Ca^{2+}-activated endonuclease (Bortner et al., 1997).

Early evidence implicating apoptosis in the pathogenesis of brain damage after ischemic insults included findings of condensed nuclei with sharply delineated chromatin, apoptotic bodies, and evidence of internucleosomal DNA fragmentation (Li et al., 1995; Linnik et al., 1993; MacManus et al., 1993). While the precise morphology of ischemic neuronal death does not correspond exactly to that of pure apoptosis, for example, seen during development, it is quite plausible that contributions from excitotoxicity and other concurrent pathogenic events would lead to mixed morphological patterns. More recently, specific molecular markers of apoptosis have been identified in ischemic brain tissue. For example, increased expression of anti-apoptotic regulators bcl-2, bcl-x and bcl-w was shown in neurons that survived focal ischemia (Chen et al., 1995; Isenmann et al., 1998; Minami et al., 2000), while proapoptotic bax expression was

increased selectively in vulnerable CA1 neurons following transient global ischemia (Krajewski et al., 1995). The activation of caspase-3 was demonstrated in cortical neurons several hours after a focal ischemic insult (Namura et al., 1998) and after transient global ischemia (Chen et al., 1998). Furthermore, as will be discussed further below, genetic or pharmacological interventions designed to block apoptosis can reduce cell death in cell culture or animal models of brain ischemia.

Inflammation

Cerebral ischemia induces an inflammatory reaction that may exacerbate initial levels of tissue injury in the hours to days after the initial insult. Within hours after transient global ischemia in gerbils, the expression of several proinflammatory cytokines is increased within the hippocampus and thalamus, including tumor necrosis factor (TNF)-α, primarily secreted by microglia, and IL-1β, primarily released from astrocytes. Mounting evidence suggests that the acute expression of these cytokines contributes to brain injury after ischemia, as blockade of their receptors or neutralization with antibodies reduces infarct volumes in rodent models of focal ischemia (for review see Barone & Feuerstein, 1999, and see below). Several actions of TNF-α may contribute to its deleterious effects in the ischemic brain, including a constrictive effect on pial arteries that can exacerbate ischemia, stimulation of matrix-degrading metalloproteinase activity, oligodendrocyte toxicity, and activation of leukocytes (Beutler & Cerami, 1987). However, the effects of TNF-α following cerebral ischemia are not all injurious, as rather surprisingly, mice lacking TNF receptors developed larger infarcts than wild-type controls (Bruce et al., 1996). It has been proposed that this cytokine has dual roles in brain injury, exacerbating toxicity at early time points, but promoting recovery at later times (Shohami et al., 1999).

TNF-α belongs to a family of ligands that activate the TNF superfamily of receptors (so called death receptors), which includes fas ligand (fasL, aka CD-95–L or APO-1–L) and TNF-related apoptosis-inducing ligand (TRAIL). In some cell-types, activation of these death receptors leads to the cleavage and activation of apical pro-caspase-8 (Ashkenazi & Dixit, 1998), which then can activate downstream effector caspases including caspase-3, leading to apoptosis independent of bcl-2-regulated cytochrome c release (Srinivasula et al., 1996). Recent evidence implicates this death receptor pathway of apoptosis in ischemic neuronal death, as fasL and TRAIL were found to be upregulated after transient focal ischemia. Furthermore, *lpr* mice expressing dysfunctional fasL receptors (fas) had smaller infarct volumes than wild-type animals after transient focal ischemia (Martin-Villalba et al., 1999).

TNF-α and IL-1 also have important effects on leukocyte infiltration. Both cytokines 'prime' endothelium for cellular adherence, probably by increasing the expression of adhesion molecules (e.g. intercellular adhesion molecule 1 [ICAM-1], P-selectins, and E-selectins), enhancing neutrophil adhesion and subsequent infiltration (Barone & Feuerstein, 1999). Macrophages and monocytes follow, guided by chemokines such as IL-8, monocyte chemoattractant protein-1 (MCP-1), and interferon inducible protein-10 (IP-10), which are upregulated in the ischemic brain (del Zoppo et al., 2000). The infiltrating leukocytes probably contribute to ischemic brain injury through several mechanisms, including microvascular occlusion and release of cytotoxic products. One particularly damaging product of infiltrating macrophages is nitric oxide (NO), synthesized inside these cells by inducible NO synthase (iNOS or type II NOS). Under ischemic conditions NO can react with superoxide anion to form the powerfully destructrive free radical, peroxynitrite. Other deleterious consequences of NO production include DNA damage (and subsequent activation of PARP, with resultant energy failure), and inhibition of DNA synthesis; both apoptosis and excitotoxic necrosis may be enhanced as a result (Iadecola, 1997; Hewett et al., 1994). Neuronal NOS (nNOS or type I NOS), a second isoform of NOS which is activated by elevated intracellular Ca^{2+}, may be a major mediator of brain cell death following ischemia (see below). In contrast, NO synthesized by a third isoform of NOS in endothelial cells (eNOS or type III NOS) may play a protective role early after ischemia onset, relaxing vascular smooth muscle cells and helping to preserve blood flow (Samdani et al., 1997).

Postischemic inflammation is further augmented by the excessive activation of the Ca^{2+}-activated catabolic enzymes, phospholipase A2 and C (PLA2 and PLC) in neurons, endothelial cells and leukocytes, which promote membrane phospholipid breakdown, producing platelet activating factor (PAF) and arachidonic acid. PAF exerts a variety of deleterious actions in ischemic brain including platelet and leukocyte activation, breakdown of the blood–brain barrier with resultant edema, and direct neurotoxicity at high concentrations (Stanimirovic & Satoh, 2000). Cyclooxygenase-2 (COX-2) is also upregulated following ischemia in close proximity to cells expressing iNOS, probably stimulated by NO (Nogawa et al., 1998), and further metabolizes arachidonic acid to a variety of toxic prostanoids; free radicals are also produced by arachidonic acid metabolism.

Neuroprotective interventions

Antiexcitotoxic approaches

Reducing extracellular glutamate

One approach to decreasing ischemic injury may be to reduce glutamate efflux from presynaptic nerve terminals and astrocytes. The most powerful method of accomplishing this so far may be mild hypothermia, which sharply limits the build-up of extracellular glutamate induced by ischemia (Busto et al., 1989). Both intra- and postischemic hypothermia produce lasting neuroprotective effects in animal cerebral ischemia studies (Barone et al., 1997b). At present, the clinical use of hypothermia is limited to surgical procedures that require concomitant cardiac arrest and neurosurgical procedures such as cerebral aneurysm clipping (Tommasino & Picozzi, 1998). Although hypothermia in patients with traumatic brain injury has been reported to improve outcomes in small clinical studies, a recent randomized trial of hypothermia after acute brain injury initiated within 6 hours did not demonstrate improved outcomes (Clifton et al., 2001).

Neurotransmitters (other than glutamate) released to the extracellular space during ischemia can also influence resultant brain injury, in part by altering circuit excitability and vesicular glutamate release from nerve terminals. GABA is the major inhibitory neurotransmitter in the mammalian brain; agonists at postsynaptic GABA receptors activating Cl^- channels ($GABA_A$ receptors) such as muscimol or benzodiazepines attenuate brain injury in rodent models (Sternau et al., 1989; Lyden & Hedges, 1992; Schwartz-Bloom et al., 1998). However, a phase III trial of the GABA agonist, clomethiazole, failed to show efficacy in patients with acute ischemic stroke (Lyden et al., 2002). One possible explanation for this disappointment might be a surprising ability of $GABA_A$ receptor activation to promote neuronal death induced by oxygen-glucose deprivation, perhaps because it hyperpolarizes neuronal cell membranes and thus enhances the voltage gradient for Ca^{2+} entry (Muir et al., 1996). In addition, it may well be that much of the glutamate accumulating in the extracellular space after ischemic insults is not mediated by circuit activation and vesicular release, but rather by transport from tonically de-energized and depolarized astrocytes (Szatkowski et al., 1990). Agonists of the $5\text{-}HT_{1A}$ serotonin receptor subtype have also been reported to reduce brain injury in rodent models of focal and global ischemia (Prehn et al., 1993; Piera et al., 1995), and a phase III clinical trial of the agonist, Bay x 3702, is currently under way (Goldberg, 2001).

A second general approach to reducing membrane excitability and vesicular glutamate release would be to manipulate various membrane ion channels. For example, several K^+ channel openers reduced endogenous glutamate release following brief ischemia in hippocampal slices (Zini et al., 1993) and have shown some promising effects in animal studies (Takaba et al., 1997; Heurteaux et al., 1993). However, BMS-204352, an opener of large-conductance Ca^{2+}-activated K^+ channels (BK channels) failed to show efficacy in a clinical trial for acute ischemic stroke (Goldberg, 2001). A possible explanation for this failure is raised by the potential of K^+ efflux to promote apoptosis (see above). Blocking voltage-gated Na^+ channels may provide another strategy to reduce circuit excitation. Na^+ channel blockers such as tetrodotoxin, phenytoin, and riluzole exhibit neuroprotective effects in vitro against both excitotoxic neuronal cell death (Lustig et al., 1992) and axonal damage (see below), as well as in vivo in both focal and global ischemia models (Yamasaki et al., 1991; Cullen et al., 1979; Pratt et al., 1992), but a recent clinical trial of fosphenytoin failed (Goldberg, 2001). Newer Na^+ channel blockers such as BIII 890 CL, that demonstrate increased activity in depolarized tissue and reduced interference with normal physiologic function, remain promising (Carter et al., 2000). Lastly, blocking voltage-gated Ca^{2+} channels would be a way to reduce glutamate release, as well as postsynaptic Ca^{2+} or Zn^{2+} influx, although more postsynaptic Ca^{2+} influx into neurons is probably mediated by NMDA receptors, and there might also be risk of potentiating apoptosis (see below). In any case, clinical trials with dihydropyridines in ischemic stroke have so far not been encouraging (American Nimodipine Study Group, 1992; Horn et al., 2001).

Manipulating glutamate receptors

Once released into the extracellular space, glutamate activates its ionophore-linked receptors, in addition to a family of metabotropic receptors linked to second messenger systems. These different glutamate receptors subtypes do not participate equally in excitotoxicity, but several receptor subtypes may be manipulated to reduce glutamate-induced Ca^{2+} overload in the ischemic brain.

Consistent with the prominent role of NMDA receptors in mediating glutamate-induced Ca^{2+} overload and rapidly triggered excitotoxic neurodegeneration in vitro, NMDA antagonists can reduce the death of cultured cortical neurons induced by hypoxia and glucose deprivation (Choi, 1992), and a substantial literature indicates that NMDA antagonists can reduce neuronal death in ischemic brain injury in vivo (Simon et al., 1984; McCulloch, 1992). Unfortunately, several recent clinical trials of NMDA antagonists in stroke patients have been disappointing (see Table 5.1); side effects including hallucinations, ataxia, or hypertension were prominent with several drugs (Lees,

Table 5.1. Agents recently tested as acute treatments for brain ischemia

Drug Category	Mechanism	Drug Name	Trial Status
Manipulate glutamate receptors			
Glutamate antagonists	AMPA antagonists	YM872	Phase III: ongoing
		ZK-200775 (MPQX)	Phase IIa: abandoned
	Competitive NMDA antagonists	CGS 19755 (Selfotel®)	Phase III: no efficacy
	NMDA channel blockers	aptiganel (Cerestat®)	Phase III: no efficacy
		dextrorphan	Phase II: abandoned
		dextromethorphan	abandoned
		magnesium	Phase III: ongoing
		NPS 1506	Phase Ib/IIa: suspended
		remacemide	Phase III in cardiopulmonary bypass: borderline efficacy
	NMDA glycine site antagonist	ACEA 1021 (Licostinel®)	Phase I: abandoned
		GV 150526	Phase III: no efficacy
	NMDA polyamine site antagonist	SL 82-0715 (eliprodil)	Phase III: abandoned
Reduce extracellular glutamate			
GABA agonists	↓ excitation, ↓ glutamate release	clomethiazole (Zendra®)	Phase III: no efficacy
Opiate antagonists		nalmefene (Cervene®)	Phase III: no efficacy
Serotonin agonists		Bay x 3702 (Repinotan®)	Phase III: ongoing
Sodium channel antagonists		Fosphenytoin (Cerebryx®)	Phase III: no efficacy
		BW619C89	Phase II: abandoned
Voltage-gated calcium channel antagonists	↓ Ca^{2+} influx, ↓ glutamate release	nimodipine (Nimotop®)	Phase III: no efficacy
		flunarizine (Sibelium®)	Phase III: no efficacy
Voltage-dependent potassium channel agonists		BMS-204352	Phase III: no efficacy
Unknown	↓ glutamate release, ↓ neuronal excitability, or ↓ NO-mediated injury	lubeluzole (Prosynap®)	Phase III: no efficacy
Block downstream mediators			
Free radical scavengers	↓ free radical-mediated injury	tirilazad mesylate (Freedox®)	Phase III: abandoned
		ebselen	Phase III: borderline efficacy
Phosphatidylcholine precursor	Membrane stabilizer	citicoline (Ceraxon®)	Phase III: no efficacy
Anti-apoptotic			
Growth factor	Anti-apoptotic?, ↑ NMDA receptor inactivation	Fibroblast growth factor (Fiblast®)	Phase II / III: abandoned
Anti-inflammatory			
Leukocyte adhesion inhibitor	Reduction of leukocyte infiltration	anti-ICAM antibody (Enlimomab®)	Phase III: no efficacy
		Hu23F2G	Phase III: no efficacy

Source: From Goldberg (2001).

1997). It remains to be seen whether efficacy can be established with this strategy, perhaps with the aid of enhancements in dosage regimens or drug characteristics, or whether utility in human stroke will prove to be fundamentally constrained (see below).

NMDA receptor blockade can be achieved in a variety of ways, using agents that act at distinct molecular sites within the receptor complex. Competitive antagonists bind the glutamate recognition site; channel blockers (or uncompetitive antagonists), bind sites within the channel pore; glycine antagonists bind the glycine recognition site; and noncompetitive antagonists bind other sites on NMDA receptors (e.g. polyamines, Zn^{2+}, redox site), downmodulating receptor activation via remote actions, for example, via allosteric changes. One might envision trying to improve the therapeutic index of NMDA antagonists in several ways. One strategy might be to find compounds capable of preferentially blocking overactivated NMDA receptors relative to physiologically activated receptors. Memantine, such an activity-dependent NMDA channel blocker, has shown promise in attenuating excitotoxic neuronal loss in vitro as well as brain damage in a rodent model of stroke, at potentially tolerable concentrations (Chen et al., 1992). Another approach might be to limit antagonism with partial antagonists, such as cycloserine (Hood et al., 1989), or by partial reduction in the endogenous glycine-site agonist D-serine (Snyder & Kim, 2000). A third approach might be to develop NMDA receptor subunit-selective antagonists along the lines of ifenprodil, an NR2B-selective antagonist with neuroprotective efficacy in vivo against focal ischemia (Gotti et al., 1988; Kemp et al., 1999). NR2B-containing NMDA receptors are expressed preferentially in the adult forebrain, so blocking these may give adequate neuroprotection against forebrain ischemia with relatively fewer side effects mediated by antagonism of hindbrain receptors. A novel approach to NMDA receptor antagonism was explored using an oral adeno-associated virus vaccine against the NR1 subunit; strong neuroprotection was demonstrated against focal ischemia-induced injury after a single-dose vaccine (During et al., 2000). This strategy could presumably be adapted to yield subtype-selective NMDA receptor blockade; but on the other hand, the resulting blockade cannot be easily controlled, and there is a risk of developing compensatory changes in the NMDA receptor system.

While NMDA antagonists may reduce the toxic influx of Ca^{2+} following cerebral ischemia in certain neurons, there is a risk that NMDA blockade may concurrently increase the likelihood of apoptosis in other neurons (Lee et al., 1999). Several studies have indicated that there can be an inverse relationship between intracellular Ca^{2+} concentration and the propensity to undergo apoptosis (Ca^{2+} set-point hypothesis, Koike & Tanaka, 1991). One unsettling corollary of this hypothesis is that NMDA-antagonist drugs may act as double-edged swords, attenuating excitotoxic necrosis in cells that are in a state of relative Ca^{2+} overload, but promoting apoptosis in Ca^{2+}-starved neurons. While Ca^{2+} overload and Ca^{2+} starvation are opposite states, both could be triggered by the same ischemic event, separated in space or time: for example, excitotoxic Ca^{2+} overload might predominate acutely, close to the ischemic core, whereas at later time intervals and further from the core, Ca^{2+} starvation and apoptosis might predominate. Supporting this idea is the recent observation that NMDA antagonists reduced primary excitotoxic injury in a rodent head trauma model at the impact site, but increased the severity of secondary apoptotic injury at distant sites (Pohl et al., 1999).

As discussed above, AMPA/kainate receptors can directly mediate excitotoxic cell death, albeit less powerfully than NMDA receptors. Besides promoting toxic Ca^{2+} entry, depolarization mediated by AMPA/kainate receptor activation may be a key factor promoting toxic levels of Zn^{2+} entry (see above). The competitive AMPA/kainate receptor antagonist NBQX is effective in reducing neuronal loss following both global (Sheardown et al., 1990) and focal (Buchan et al., 1991) cerebral ischemia. Likewise, the noncompetitive antagonist GYKI-52466 has also exhibited neuroprotective effects in studies of global (Le-Peillet et al., 1992) or focal (Smith & Meldrum, 1992) ischemia. Several factors that operate in the ischemic brain, in particular a shift towards acid pH due to buildup of lactic acid, may attenuate NMDA-receptor function and so reduce the prominence of NMDA-receptor-mediated neurotoxicity relative to AMPA- or kainate-receptor-mediated neurotoxicity. Acid pH may also enhance AMPA receptor-mediated neurotoxicity, perhaps by slowing recovery of cellular calcium homeostasis (McDonald et al., 1998b).

Another mechanism that has been proposed to enhance the contribution of AMPA/kainate receptor-mediated toxicity to ischemic neuronal death is an ischemia-induced enhancement of the expression of Ca^{2+} (and Zn^{2+}) permeable AMPA receptors, due to an alteration in subunit composition (reduced expression of AMPA receptor subunit GluR2/GluR-B (Pellegrini-Giampietro et al., 1997). However, on the downside, AMPA/kainate receptor blockade may be inadequate to reduce calcium overload on neurons where NMDA receptors have been strongly activated, and conversely, AMPA/kainate receptor blockade also has some potential to enhance apoptosis in the setting

of relative calcium starvation. Will the strategy work? A phase III trial of the AMPA antagonist YM872 in acute ischemic stroke is currently ongoing.

Although not directly mediating excitotoxicity, the metabotropic glutamate receptors can modify excitotoxicity and thus may be useful targets for therapeutic manipulation. These receptors, which are linked to G-proteins rather than ion channels, have been identified and segregated into three groups based on sequence similarity and mechanisms of signal transduction (Nakanishi & Masu, 1994; Conn & Pin, 1997). The first clue to neuroprotective actions was the demonstration that the nonselective mGluR agonist, trans-1-aminocyclopentane-1, 3-dicarboxylic acid (tACPD), could attenuate glutamate-induced neuronal death (Koh et al., 1991); non-selective activation of mGluRs also reduced infarct volume in vivo after focal ischemia (Chiamulera et al., 1992). Growing evidence suggests that activation of mGluR group II and III receptors, which typically have inhibitory effects on circuit excitation and glutamate release (Conn & Pin, 1997; Cartmell & Schoepp, 2000), may have more powerful antiexcitotoxic effects than non-selective agonists. A recent study suggests that the excitatory effects of group I mGluR activation may be harnessed to reduce neuronal apoptosis (Allen et al., 2000).

Blocking downstream mediators

Many enzymes including proteases, endonucleases, kinases, and phosphatases are activated directly or indirectly by increases in intracellular Ca^{2+} concentration and may contribute to cellular damage after ischemic insult. Compared with glutamate-receptor antagonists, interventions directed at blocking the downstream intracellular mediators of excitotoxicity may have a longer therapeutic window. For example, calpain inhibition by MDL 28170 decreased infarct volume after transient focal ischemia even when administered 6 hours after ischemia onset (Markgraf et al., 1998). Cytoplasmic phospholipase A2 ($cPLA_2$) is activated following NMDA receptor stimulation and promotes membrane phospholipid breakdown, liberating arachidonic acid (Dumuis et al., 1988) and producing free radicals. Pharmacological inhibition (Phillis, 1996) or genetic ablation (Bonventre et al., 1997) of $cPLA_2$ reduced brain injury in animal models of cerebral ischemia. Blocking PAF, a product of phospholipid breakdown, with gingkolide B or BN 52021 also reduced ischemic injury (Lindsberg et al., 1991).

Adding to the injury occurring during a given ischemic insult, postischemic reperfusion induces further tissue damage in the brain, probably mediated by the accelerated formation of several reactive oxygen species including superoxide, hydroxyl, and NO radicals (Kuroda & Siesjo, 1997). Free radical production is likely a specific downstream mediator of glutamate-induced neuronal death. As noted above, nNOS which is activated by elevated intracellular Ca^{2+} forms the weak oxidant, NO (Dawson & Snyder, 1994), but in the presence of superoxide anion can be converted to peroxynitrite (Beckman & Koppenol, 1996). Inhibiting nNOS either pharmacologically or genetically (via gene deletion) renders cultured neurons resistant to NMDA-induced death, and also reduces infarct volume in rodent models of transient focal ischemia (Samdani et al., 1997). Blockade of iNOS in inflammatory cells after ischemia will be discussed below. COX-mediated metabolism of arachidonic acid to a prostaglandin intermediate can also lead to the production of toxic superoxide anion (Chan et al., 1985). In cortical neuronal cultures, NMDA-induced excitotoxicity was decreased by a specific COX-2 inhibitor (Hewett et al., 2000) which also afforded neuroprotection against focal ischemia when administered to rats post-occlusion (Nogawa et al., 1997). Another link between excitotoxicity and free radicals is through excessive Ca^{2+} accumulation in mitochondria which uncouples energy production from electron transport and the formation of toxic levels of free radicals (Dugan et al., 1995; Reynolds & Hastings, 1995).

Beneficial results have been obtained with several free radical scavenger drugs in animal studies of ischemic or traumatic brain injury (Clemens et al., 1994), although the magnitude of neuroprotection observed has typically not been very large. Two phase III clinical trials involving free radical scavengers in acute ischemic stroke were conducted recently. One trial testing the lipid peroxidation inhibitor tirilazad mesylate was prematurely terminated due to concerns about the safety of the drug (Haley, 1998). The second trial involved treatment with ebselen, a selenoorganic compound with antioxidant activity, and did not demonstrate definitive efficacy (Yamaguchi et al., 1998). It is possible that more powerful antioxidant agents may yield greater therapeutic benefits. The spin trapping agent α-phenyl-*N*-tert-butyl nitrone (PBN) reduced infarct volume following focal ischemia in rats even when administered up to 3 hours after ischemia onset (Zhao et al., 1994).

One especially important consequence of reactive oxygen species formation may be single-stranded DNA breakage, leading to activation of the repair enzyme, PARP, and consequent depletion of cellular NAD^+ and energy stores (Szabo & Dawson, 1998). Pharmacological inhibition or gene deletion of PARP attenuated neuronal death induced by glutamate receptor agonists in vitro (Zhang et al., 1994; Eliasson et al., 1997), and decreased infarct size in

rodent focal ischemia studies (Zhang et al., 1994; Eliasson et al., 1997; Endres et al., 1997).

Antiapoptotic strategies

As noted above, accumulating evidence suggests that many brain cells undergo apoptosis following ischemic insults, including evidence that blocking apoptosis reduces ischemic brain damage in vivo or in vitro. Transgenic overexpression of *bcl-2* (Martinou et al., 1994) or its delivery via herpes virus vector (Linnik et al., 1995) were both found to reduce infarct volume in mice subjected to focal ischemia; and the survival of hippocampal CA1 neurons after transient global ischemia was enhanced in transgenic mice overexpressing bcl-2 (Kitagawa et al., 1998). Likewise, overexpression of *bcl-*x_L in transgenic mice reduced infarct volume following permanent focal ischemia (Wiessner et al., 1999). In experiments in our laboratory, mice lacking the *bax* gene exhibited reduced infarct volumes after transient focal ischemia (F. Gottron & D.W.C., unpublished data). While genetic manipulation of the Bcl-2 family of genes may not be a practical approach to antiapoptotic therapy in the human, future development of strategies to suppress or enhance this family of proteins (e.g. using antisense oligonucleotides) or to disrupt interactions between family members may prove beneficial (Nicholson, 2000).

A more immediately viable approach to antiapoptotic therapy might be via pharmacological caspase inhibitors. Intracerebroventricular (icv) infusion of the relatively non-specific caspase-3 inhibitor (*N*-benzyloxycarbonyl-Asp(OMe)-Glu(OMe)-Val-Asp(OMe)-fluoromethylketone or z-DEVD.FMK) decreased infarct size after transient focal ischemia (Hara et al., 1997) and reduced hippocampal CA1 cell death in transient global ischemia (Chen et al., 1998). In addition, the pan-caspase inhibitor, boc-aspartyl(OMe)-fluoromethylketone (BAF) given icv or systemically, was markedly neuroprotective in a rat model of neonatal hypoxia-ischemia even when administered 3 hours after the insult (Cheng et al., 1998). It is plausible that non-specific caspase inhibitors may be more effective at stopping the effector arm of apoptosis, owing to the broad-spectrum inhibition of all caspases in the cascade. Several caspases other than effector caspase-3 have been implicated in ischemic brain injury including the upstream caspases, caspase-9 (Krajewski et al., 1999), and caspase-8 which is activated via the death receptor pathway (Martin-Villalba et al., 1999). In addition, recent work suggests that caspase-11, a novel upstream caspase activated only under pathological conditions, is also activated after cerebral ischemia (Kang et al., 2000). Although concerns about the systemic blockade of all caspase activity are warranted, given the importance of apoptosis in normal physiologic processes, short-term administration after acute stroke may be tolerable. Another approach to inhibiting caspases may be modelled by the inhibitor of apoptosis (IAP) family of proteins, which bind and inhibit both initiator and effector caspases (Reed & Tomaselli, 2000). Included in this family is neuronal AIP (NAIP); inactivation by a hereditary mutation underlies motor neuron degeneration in spinal muscular atrophy (Roy et al., 1995). While antiapoptotic caspase inhibitors have not yet reached the clinic, drugs that block caspase-1 (or interleukin-1 converting enzyme, ICE) have recently been introduced for the treatment of rheumatoid arthritis (Nicholson, 2000).

The recent finding that the death receptor-mediated pathway to apoptosis may be involved in ischemic injury opens other potential targets for intervention. Development of means to suppress fasL or to block its receptor fas may be of benefit. The immunosuppressant FK506, a known neuroprotective agent following focal ischemia, suppresses the upregulation of fasL following ischemia (Martin-Villalba et al., 1999). In addition, one might try to mimic or augment the action of a naturally occurring protein known as FLICE-inhibitory protein (FLIP), which blocks the recruitment and activation of caspase-8 (formerly known as FLICE) and inhibits apoptosis induced by several death ligands (Thome et al., 1997).

As outlined above, transmembrane ionic fluxes may play a role in the regulation of programmed cell death, with Ca^{2+} starvation and K^+ efflux promoting apoptosis. Addressing these derangements through therapeutic intervention is plausible, but will have to be done in such a way that death due to excitotoxic calcium overload is not augmented. We have speculatively suggested a 'pull–push' approach to manipulating neuronal calcium homeostasis during ischemic insults: initially reducing calcium influx, with drugs like NMDA antagonists, to reduce excitotoxicity, and then later enhancing calcium influx to reduce calcium starvation and apoptosis (Lee et al., 1999). Similarly, targeting K^+ depletion in cells at risk for apoptosis, for example by augmenting K^+ influx or blocking upregulation of the neuronal delayed rectifier current, has to be accomplished with specificity, as this may also enhance circuit excitability and excitotoxicity.

Growth factors may be valuable in reducing apoptosis following cerebral ischemia. The expression of several growth factors increases in ischemic tissue, likely as a protective response. In addition, exogenous administration of growth factors including nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), neurotrophins 4/5 (NT-4/5), basic fibroblast growth factor (bFGF), and type-1

insulin-like growth factor (IGF-1) reduces brain damage in rats subjected to cerebral ischemia (Hefti, 1997). Some growth factors may also enhance nerve fibre sprouting and synapse formation after ischemic injury, thereby promoting functional recovery. Delivery issues are substantial obstacles to practical use, but may be surmountable through the development of small-molecule agonists that bind immunophilins, and have neurotrophic and neuroprotective actions that can be separated from immunosuppressant effects (Snyder et al., 1998). Unfortunately, the first trial of a growth factor for treatment of ischemia, bFGF in acute ischemic stroke, was unsuccessful (Goldberg, 2001). In addition, in a fashion akin to the situation with manipulation of calcium homeostasis, a downside risk of at least the neurotrophins and IGF-1 may be the enhancement of excitotoxic necrosis (Koh et al., 1995).

Anti-inflammatory approaches

Interference with inflammatory cascades is another general approach likely to aid neural cell survival. A key early event amenable to therapeutic intervention may be the suppression of key cytokines which are induced shortly after ischemia onset. For example, delivery of the IL-1 receptor antagonist (IL-1ra, which is a naturally occurring inhibitor in the brain) by intracerebroventricular injection (Loddick & Rothwell, 1996) or by adenoviral vector (Betz et al., 1995) reduced brain injury following focal ischemia in rats. Although clinically impractical, these interventions underscore the potential of this pathway as a target for neuroprotection. The peripheral administration of IL-1ra (a more clinically relevant route) reduced infarct volume in a rodent focal ischemia model (Relton et al., 1996). Likewise, interfering with TNF-α signalling using an anti-TNF-α monoclonal antibody or soluble TNF-α receptor I (which acts by competing with membrane receptors) resulted in attenuation of brain injury after focal ischemia (Barone et al., 1997a), likely by improving microvascular perfusion in ischemic cortex (Dawson et al., 1996). These effects must be interpreted with caution, as cerebral ischemia in mice lacking TNF receptors demonstrated larger infarct volumes than their wild-type counterparts (Bruce et al., 1996).

One of the detrimental effects of TNF-α is the upregulation of endothelial cell adhesion molecules and leukocyte adherence to blood vessels, another potential target for intervention. Administration of antibodies to either ICAM-1 or the β-integrins (CD11a/CD18) expressed on leukocytes decreased infarct size in rodent transient (Chopp et al., 1996), but not permanent focal ischemia (Zhang et al., 1995). In addition, mice lacking the ICAM-1 gene were less susceptible to ischemia-reperfusion injury (Connolly et al., 1996). A phase III clinical trial using anti-ICAM antibodies failed, possibly due to murine antibody-induced complications; however, another trial using humanized antibodies directed against CD11/CD18 also failed to show efficacy in patients with acute ischemic stroke (Enlimomab Acute Stroke Trial Investigators and Sherman, 1997; Goldberg, 2001).

Following cerebral ischemia infiltrating leukocytes increase expression of iNOS, peaking 12–48 hours after ischemia onset (del Zoppo et al., 2000). The relatively selective iNOS inhibitor, aminoguanidine, reduced infarct volume following focal ischemia even if given 24 hours after MCA occlusion (Nagayama et al., 1998). Confirming the pharmacological effect, mice lacking the iNOS gene also had smaller infarcts than their wild-type littermates (Iadecola et al., 1997). The delayed expression of iNOS following cerebral ischemia makes it an attractive target for intervention in human stroke with a potentially long therapeutic window.

The secretion of vasoactive mediators by endothelial cells is another consequence of ischemia-induced inflammation, and may lead to vasoconstriction and microvascular thrombosis, resulting in further exacerbation of ischemic damage (del Zoppo et al., 2000). Two classes of agents, attractive because they are currently in clinical use, may be able to reduce ischemic brain damage by altering vasoactive mediators. The cholesterol-lowering agents, 3-hydroxy-3-methylglutaryl (HMG)-CoA reductase inhibitors (or statins) decreased cerebral infarct size in mice by upregulating eNOS, resulting in increased cerebral blood flow (CBF) during ischemia (Endres et al., 1998). In addition, the estrogens have been shown to have neuroprotective properties in rodent cerebral ischemia models. Although the mechanism of action is not as well defined as that of the statins, it is believed that improvement in CBF may contribute, in part by up-regulation of NOS. Other proposed neuroprotective mechanisms include antioxidant actions, induction of *bcl-2* and neurotrophic factors, and modulation of excitotoxicity (Hurn & Macrae, 2000).

White matter injury

While much of the current work in neuroprotection has focused on blocking injury mechanisms relevant to dendrites and neuronal perikarya (grey matter), myelinated fibre tracts (white matter) are also damaged by ischemic insults and could benefit from targeted neuroprotective approaches. Many antiexcitotoxic treatments, such as NMDA receptor antagonists, would not be expected to

protect white matter. Experiments using isolated rat optic nerve as an in vitro model for myelinated CNS tracts have revealed that compound action potentials disappear after 8–10 minutes of anoxia, evidence that white matter tracts are critically dependent on oxidative metabolism to maintain energy for excitability (Waxman et al., 1991). Hypoxic–ischemic energy depletion leads to failure of the membrane Na^+–K^+-ATPase, leading to membrane depolarization and accumulation of axoplasmic free Na^+, largely due to influx through tetrodotoxin-sensitive, voltage-gated Na^+ channels subserving action potentials. This elevation in axonal $[Na^+]_i$ stimulates the Na^+/Ca^{2+} exchanger, resulting in Ca^{2+} influx and toxic elevations in $[Ca^{2+}]_i$ (Stys, 1998), leading to consequences presumably similar to those outlined in studies of cultured neurons. Agents that block voltage-gated Na^+ channels, including local anesthetics, antiarrhythmics and certain anticonvulsants, are protective in the optic nerve anoxia model, as are the Na^+/Ca^{2+} exchange inhibitors, bepridil and benzamil (Stys, 1998).

Oligodendrocytes, responsible for myelinating nerve fibres in the CNS, express Ca^{2+}-permeable AMPA receptors and are highly vulnerable to AMPA-receptor-mediated injury in vitro (Matute et al., 1997). In addition, cultured oligodendrocytes deprived of oxygen and glucose were protected by an AMPA receptor antagonist, and injection of AMPA into rat brain white matter induced widespread oligodendrocyte death (McDonald et al., 1998a). Although most oligodendrocytes are remote from synapses, they may be exposed to excess extracellular glutamate, released by adjacent neurons or astrocytes following ischemic insults. Glutamate may also be released along axons through a non-synaptic process mediated by reversal of the Na^+/K^+-glutamate transporter (Nicholls & Attwell, 1990).

Clinical trials and future directions

Despite the wealth of preclinical data supporting the efficacy of many neuroprotective agents, why have these agents failed so far in human trials? The answer to this vexing question probably lies partly in the difficulty of conducting human clinical trials of neuroprotective agents, and partly in limitations of neuroprotective efficacy in the agents tested to date. Clinical trials have many more variables than studies with experimental animals in controlled laboratory settings. While most laboratory investigations are conducted on young healthy animals, patients suffering strokes or cardiac arrest typically are elderly and have concomitant diseases such as hypertension or diabetes; etiology, severity, and lesion location (cortical vs. subcortical infarction) typically vary widely. The endpoint used to determine efficacy is another important difference between human and experimental studies: most animal studies have utilized lesion size measured hours to days after ischemia, whereas human clinical studies have relied upon functional outcome as measured by clinical assessment scales (Barthel Index, Rankin Score, etc.) usually several months after ischemia. A drug that reduces lesion size may or may not produce a detectable improvement in functional outcome, depending upon multiple other factors, in particular lesion location. In the future, enhanced neuroimaging techniques may be able to provide sufficient quantitation of lesion volume to be able to serve as surrogate outcome measures for assessing neuroprotective interventions. Furthermore, techniques for imaging at-risk tissue, such as diffusion- and perfusion-weighted magnetic resonance imaging, may permit each patient to serve as his/her own control (comparing the brain volume initially at risk, to the volume of damage that ultimately evolves with or without intervention).

Most clinical trials of neuroprotective agents to date share, at least in part, a common rationale of reducing excitotoxicity. The future of neuroprotective approaches for brain ischemia will likely lie in broader aims, specifically encompassing strategies to limit ischemic apoptosis and post-ischemic inflammation. Indeed, as discussed above, the postulate that the prominence of apoptosis in the brain after ischemic insults approximates that of excitotoxicity, supported by substantial emerging evidence, places many anti-excitotoxic treatments on a dangerous balance point (Fig. 5.1). Many approaches useful in limiting excitotoxicity, reducing circuit activation, glutamate release, membrane depolarization, calcium entry, etc., may have a downside, enhancement of apoptosis. Perhaps the key difference between experimental studies, for the most part conducted with lissencephalic rodent brains and sharply controlled ischemic insults, and human stroke, involving a gyrencephalic brain and sometimes fluctuating levels of ischemia, is a greater prominence of mild ischemia and apoptosis in the latter setting.

One path ahead may thus be to combine approaches, so that excitotoxicity and apoptosis might be simultaneously reduced. Two experimental studies have so far tested the concurrent administration of NMDA antagonists and inhibitors of apoptosis. Coadministration of dextrorphan and cycloheximide produced greater than 80% reduction of infarct volume after transient focal ischemia in rats, better than the effect of optimal doses of either agent alone (Du et al., 1996). Furthermore, the combination of MK-801 and z-VAD.fmk demonstrated neuroprotective synergy in reducing infarction, and an extended therapeu-

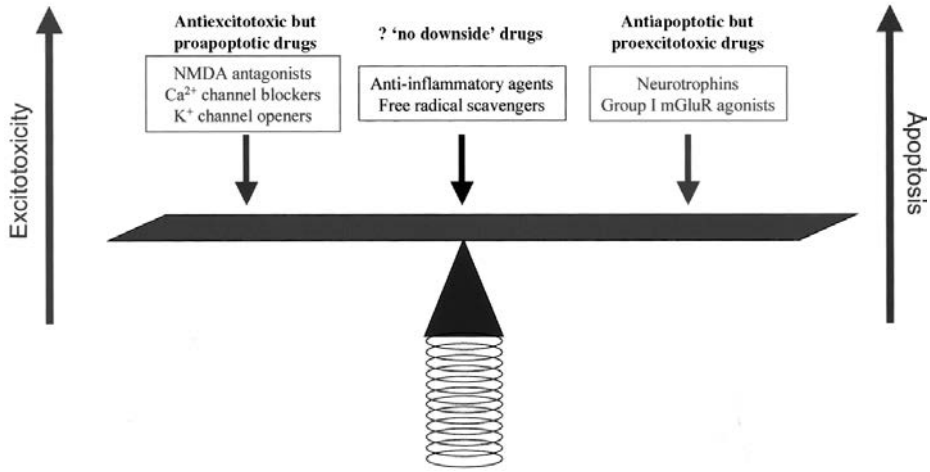

Fig. 5.1. Balancing antiexcitotoxic and antiapoptotic approaches to neuroprotection in the ischemic brain. Speculative diagram depicting the possibility that some approaches may reduce excitotoxicity but enhance apoptosis, or vice-versa; whereas some 'no downside' approaches may reduce both forms of death (or at least reduce one without enhancing the other).

tic window compared to that of either drug alone (Ma et al., 1998).

Alternatively, it may be possible to target antiexcitotoxic and anti- apoptotic approaches in time or space to maximize benefits and minimize deleterious consequences. With progressive enhancements in brain imaging, both in terms of resolution and in terms of yielding information about functional state, one can envision a time when imaging techniques are used to select and direct the optimal neuroprotective strategies for a given specific clinical situation. For example, the development of methods for identifying the early activation of the apoptosis cascades, or levels of intracellular free calcium, might enable clinicians to know when to stop delivery of acutely initiated NMDA antagonist drugs, and begin treatment with caspase inhibitors or neurotrophins.

A third path ahead might be to prioritize the deployment of 'no downside' drugs: capable of limiting excitotoxicity or apoptosis, but lacking concurrent ability to enhance the other form of death. Examples of such drugs might be PARP inhibitors for excitotoxicity or caspase inhibitors for apoptosis; antioxidants or anti-inflammatory drugs might be able to reduce both forms of death (Fig. 5.1).

Promoting recovery of neurological function

Ted Abel[1] and Michael E. Selzer[2]

Department of [1]Biology and [2]Neurology, University of Pennsylvania, Philadelphia, PA, USA

This chapter focuses on the biologically driven strategies that are being developed to enhance that recovery following neural injury. It is beyond the scope of this chapter to review the entire field of neurologic rehabilitation, much of which involves orthotic, prosthetic, behavioural, psychological and sociological approaches. Many of these approaches are accumulating substantial evidence for their effectiveness and their omission here should not be interpreted as an indication of lack of importance. Several recent monographs on neurologic rehabilitation cover them in greater detail (Dobkin, 1996; Lazar, 1998; Ozer, 2000). Here, the behavioural, physiological and structural mechanisms by which the nervous system adapts spontaneously to injury will be reviewed. Then some promising current approaches to optimizing recovery by utilizing the nervous system's own adaptive processes will be discussed. Finally the mechanisms that limit the ability of the nervous system to reconstitute the lost neural circuitry will be examined, and strategies that are being developed to overcome these limitations will be summarized.

Mechanisms of spontaneous recovery

Following injury to the nervous system, it is usual for patients to recover to a variable degree. This is a consequence of three processes. First, depending on the type of injury, an ischemic/traumatic penumbra (Heiss & Graf, 1994; Tator, 1995) results in temporary dysfunction of neuronal elements due to pressure from edema, excitotoxicity with intracellular (intramitochondrial) calcium accumulation (Stout et al., 1998), extracellular accumulation of potassium and magnesium, and inflammation (Carlson et al., 1998) (Fig. 6.1). If they do not kill the neurons, these changes eventually resolve and neuronal function is restored. Secondly, patients can employ a variety of behavioural adaptations to restore equivalent functions to those lost as a consequence of the structural and physiological alterations brought about by the injury. Thirdly, physiological changes and short distance anatomic rearrangements in spared neural pathways may result in compensatory enhancement in transmission through those pathways to reproduce or substitute for lost functions. A fourth mechanism, frank regeneration of injured axons and replacement of lost neurons to reconstitute the interrupted synaptic circuits, is currently believed not to occur to a significant degree in the mammalian CNS. Strategies to promote such neural repair are discussed later in the chapter.

Behavioural adaptation

Behavioural adaptation refers to the conscious substitution of behaviours, based on spared physiological functions for the lost more natural or commonly utilized functions, aimed at producing the same desired result. For example, a right-handed person who has suffered a left hemispheric stroke might begin using his left hand to perform functions previously performed with the right hand. To a large extent, occupational therapy is involved in teaching patients to utilize effective behavioural adaptations (see below). To the extent that the newly acquired behaviours must be learned and learning involves physiological plasticity, most behavioural adaptations involve physiological plasticity as well.

Cortical remodelling

Experiments utilizing electrophysiological, stimulation and imaging techniques have demonstrated that injuries to both the peripheral and central nervous systems result in alterations in the central representations of sensory and motor functions in such a way as to suggest effective

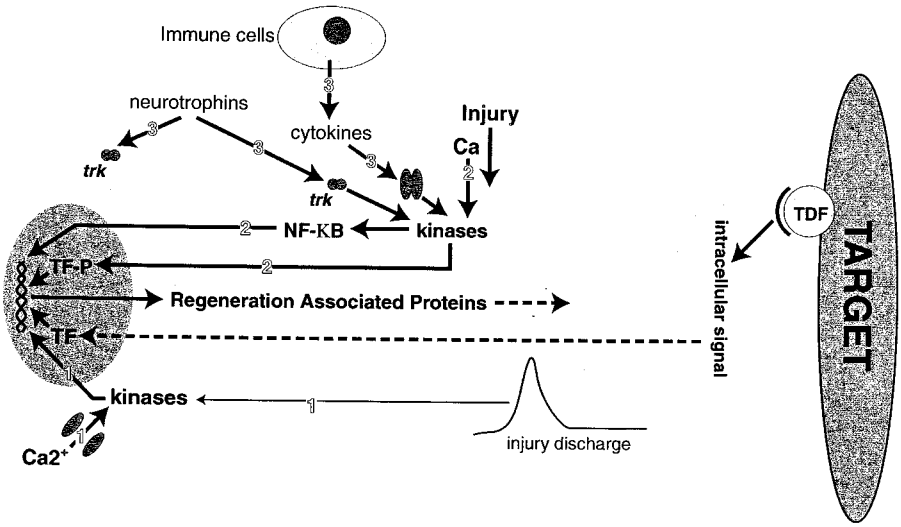

Fig. 6.1. Molecular responses to axon injury leading to regeneration. Neural injury gives rise to an injury-related discharge (1) that back-propagates towards the cell body where it leads to the opening of voltage-dependent calcium channels. This calcium influx activates kinases, including CaMKII, PKA, PKA and MAP kinase, that phosphorylate a variety of target proteins. Especially important targets of these kinases are transcription factors such as CREB and NF-κB. These transcription factors induce the expression of regeneration-associated proteins such as GAP-43, CAP-23 and several cytoskeletal proteins. Injury also results in bulk calcium influx at the site of injury (2). The longer-term response to injury involves the release of neurotrophins (NGF, BDNF, NT-3, NT-4/5) and cytokines (CNTF, LIF, IGF, IL-6) that activate intracellular signalling pathways via specific receptors (3).

compensation for the injury. These changes following injury resemble in many ways the cortical changes that are observed following learning or other experiences. A common term used to describe these altered physiological responses following injury and training is 'neural plasticity'. Many plastic processes result from alterations in intracellular signalling cascades but, in many cases, ultrastructural or immunohistological alterations also are observed.

Reorganization of synaptic contacts is especially prevalent in the cortex, where sensory and motor maps undergo extensive reorganization and remapping as a result of experience (Buonomano & Merzenich, 1998). One well-known example of neural plasticity within the cortex is the rearrangement of hand representation in the somatosensory cortex following injury to a peripheral nerve or amputation of a digit. Following such deafferentation, the cortical representation of adjacent regions expands over the surface of the cortex for a distance of approximately 1.5 mm, an area that encompasses the distribution of terminals of thalamocortical neurons (Rausell & Jones, 1995). Because this initial expansion occurs rapidly, it might be the result of the unmasking of formerly inactive synaptic connections that were previously masked by inhibition from the lost afferent pathway (Jones, 1993). At longer recovery times, the area covered by the shifting sensory map increases substantially beyond that covered by the distribution of thalamic afferents (Pons et al., 1991).

Cortical plasticity may contribute to functional recovery following a CNS injury such as stroke. A region of the sensory cortex to which behaviourally important portions of the finger tips project was destroyed by microlesions, the behaviour of monkeys in a learned sensorimotor task at first deteriorated, but then improved (Xerri et al., 1998). Concomitantly, the central projection for those finger tips shifted to neighbouring regions of cortex. These findings are consistent with 'substitution' and 'vicariation' models of recovery from brain damage and stroke. In these models, adaptive reorganization of the cortex takes place following a lesion in such a way that other regions of the cortex that may not have been originally involved in the function of the injured area now directly compensate for the dysfunctional area (Xerri et al., 1998).

Afferent input to the cortex can also be modulated by experience, including environmental enrichment and training. Increases in dendritic arbourization and synaptic contacts in the cerebellar and cerebral cortices have been observed in many environmental enrichment studies and after extensive training (van Praag et al., 2000). These alterations are thought to result from the induction of use-

dependent patterns of neural activity that lead to the selective reshaping of neuronal connections. Whether similar mechanisms act following injury is not known, but the similarity between the two processes suggests that they may share overlapping molecular mechanisms. Repeated sensory overstimulation and training on digital dexterity tasks can increase the receptive fields of the involved digits within the primary somatosensory cortex in primates (Buonomano & Merzenich, 1998). Enlarged representation of relevant movements is also observed in the primary motor cortex after training (Buonomano & Merzenich, 1998). Such remapping results in a much finer representational grain than normal. Thus, for both sensory and motor cortices, experience alters the cortical map in a way that correlates with the behavioural demands of the task.

Using transcranial magnetic stimulation (TMS), functional imaging, magnetoencephalography or high resolution electroencephalography, many examples have been documented of cortical remapping in normal human subjects as well as in patients with peripheral or central nervous system lesions (Classen et al., 1998; Karni et al., 1995). For example, focal stimulation of the motor cortex using TMS was used to evoke thumb movements before and after the practising of thumb movements. Focal TMS more often evoked movements in the recently practised direction than in other directions (Classen et al., 1998). Thus, in humans, training rapidly and transiently induces a change in the cortical network representing the movement of the thumb, thereby encoding the details of the practised movement.

What molecular mechanisms are responsible for this newly emergent representation of sensory information or motor maps within the cortex? There are several mechanisms that might be responsible for the neural plasticity that underlies the long-term alterations in cortical maps that follow injury or training. Two major mechanisms are the restructuring of neuronal morphology and changes in the strength of synaptic connections. It is important to note that these mechanisms may be inter-related. The induction of synaptic plasticity is accompanied by morphological changes in neurons (Segal & Andersen, 2000). Morphological changes might result from the sprouting of collateral axon branches, the extension of dendritic arbours, the creation of dendritic spines, and the creation of new synapses. The expansions of sensory receptive fields produced by long-term alterations in afferent input are probably due to physiological and/or anatomical plastic changes (Buonomano & Merzenich, 1998). Activity-dependent modifications in synaptic strength may play a critical role in cortical remapping, perhaps via NMDA receptor mediated long-term potentiation (Garraghty & Muja, 1996), as has been described for synaptic plasticity in the hippocampus (Bliss & Collingridge, 1993).

To investigate the hypothesis that synaptic plasticity underlies cortical map reorganization, researchers have used pharmacological, electrophysiological and genetic approaches. Recent experiments in humans have used the changes in TMS-evoked thumb movements after training (Classen et al., 1998) to explore the effects of drugs that block synaptic plasticity in the motor cortex in vitro on cortical map plasticity in vivo. An NMDA receptor antagonist, dextromethorphan, and a GABA-A receptor modulator, lorazepam, both of which block the induction of long-term potentiation (LTP) in the motor cortex in vitro, block the use-dependent reorganization of the cortical thumb representation in human subjects (Butefisch et al., 2000). By contrast, lamotrigine, a drug that modifies sodium and calcium channels without altering LTP induction, does not alter cortical map reorganization. Thus, these findings point to a striking similarity between use-dependent cortical plasticity and the cellular mechanisms of LTP, which is thought to underlie learning and memory (Martin et al., 2000; Rioult-Pedotti et al., 2000). Genetic approaches in mice have been used to study plasticity in the barrel (somatosensory) cortex, which receives input from the whiskers. Removal of all facial whiskers (vibrissae) except for one results in the expansion of the spared whisker's functional representation in the somatosensory cortex. Mutant mice with impairments in LTP, including those with alterations in CaMKII or CREB, exhibit impairments in this form of experience dependent cortical plasticity (e.g. Glazewski et al., 2000). Thus, understanding the molecular mechanisms underlying forms of synaptic plasticity, such as LTP, may provide insights into the molecular basis of cortical remodelling following injury.

Physiological plasticity

Since its introduction over a century ago by Santiago Ramón y Cajal, the word 'plasticity' has been used in many ways by neuroscientists studying a variety of processes ranging from recovery from neural injury to learning and memory to drug addiction and psychiatric disorders (Nestler & Hyman, 1999). We will focus our discussion on two broad forms of plasticity: physiological plasticity, in which patterns of use and disuse modify synaptic strength (synaptic plasticity) and modulate neuronal firing (neural plasticity), and anatomical plasticity, which involves structural alterations (e.g. sprouting, pruning, regeneration) following injury or use. Many of these forms of plasticity share

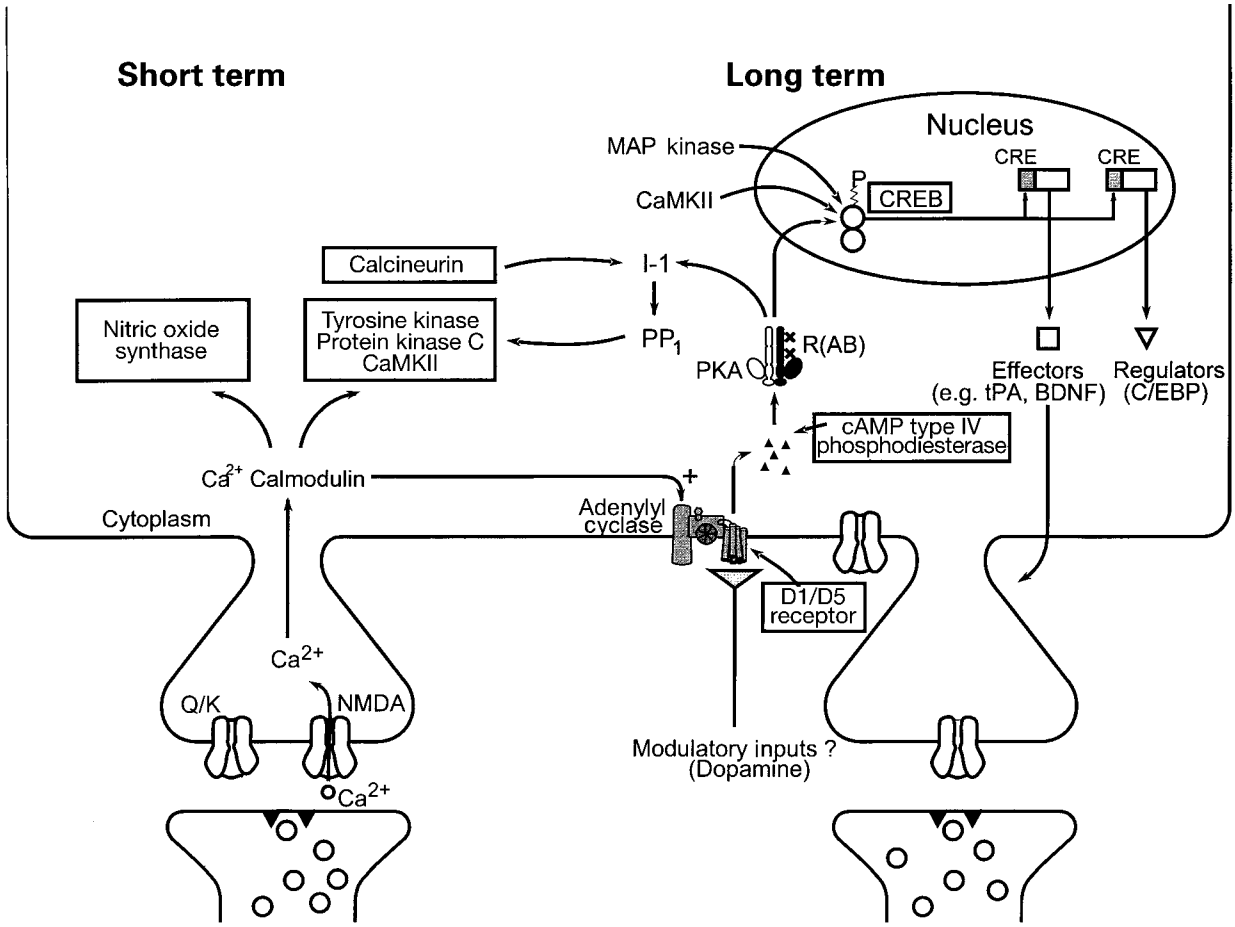

Fig. 6.2. Molecular mechanisms of synaptic plasticity. Studies of long-term potentiation in the hippocampus have revealed the signaling pathways that mediate changes in synaptic strength. Activation of the NMDA type of glutamate receptor leads to calcium influx and the activation of calcium sensitive enzymes such as CaMKII, PKC and calcineurin. Other signaling pathways involved in the early phase of LTP include tyrosine kinases and nitric oxide synthase, which may give rise to a retrograde messenger in the form of the diffusible gas NO. Long-term changes in synaptic strength result from the activation of adenylyl cyclase by calcium or modulatory neurotransmitters that stimulate G protein coupled receptors. This activation of adenylyl cyclase leads to the synthesis of the second messenger cAMP, which, in turn, activates PKA. PKA plays a central role in initiating the events that lead to long-lasting changes in synaptic strength by acting on a variety of targets, including the transcription factor CREB. CREB, which is also the target of other kinases such as CaMKIV and MAP kinase, turns on a variety of effector and regulatory genes whose gene products include tPA and BDNF. (Adapted with permission from Abel et al., 1997.)

common underlying molecular mechanisms mediated by intracellular signal transduction cascades (Girault and Greengard, 1999). The responses of a neuron to neurotransmitters or neuromodulators, or to neural injury are mediated by intracellular signal transduction pathways that include a large variety of protein kinases, protein phosphatases and adapter molecules (Fig. 6.2). Kinases play a particularly important role in signalling cascades that respond to alterations in synaptic input. These kinases include tyrosine kinase receptors that are activated by the binding of a growth factor or a neurotrophic factor such as BDNF or NGF, as well as cytoplasmic Src family tyrosine kinases, such as Fyn. In other cases, serine/threonine kinases, such as protein kinase A (PKA) or protein kinase C (PKC), may be activated by second messenger molecules, such as cAMP or IP_3, respectively. These second messengers are formed when a neurotransmitter (e.g. norepinephrine or dopamine) or hormone (e.g. insulin) binds to a receptor that is linked by a GTP-binding-protein. These G proteins activate enzymes such as adenylyl cyclase or phospholipase C, thus leading to the production of cAMP or IP_3. Calcium is another second messenger molecule that

activates calcium-dependent enzymes, including certain isoforms of adenylyl cyclase and PKC. Once kinases are activated, they modulate the activity of a number of target proteins ranging from ion channels to metabolic enzymes to transcription factors. These transcription factors are potentially important candidates to mediate long-term changes in neural function that might occur following injury and during the recovery from neural injury. Transcription factors bind to DNA and regulate the expression of one or more genes, whose protein products may mediate long-term changes in the physiology and structure of the neuron, including processes such as programmed cell death (apoptosis), increased synthesis and release of neurotransmitter, or the sprouting of extra branches by spared axons.

Although we will consider physiological and anatomical plasticity in separate sections, it is worth noting that there has been a convergence of these two processes in recent years (Squire & Kandel, 1999). Kandel's work on the mollusk *Aplysia* has revealed that long-term memory for sensitization is accompanied by the increased strength of particular synaptic connections as well as the growth of new synaptic connections between neurons mediating the reflex that has undergone sensitization (Abel & Kandel, 1998). These long-term changes in behaviour, neural anatomy and synaptic function are mediated by the activation of genes containing cAMP response elements (CRE) through the phosphorylation of the transcription factor CRE-binding protein (CREB). A critical challenge is to see if such transcription-mediated changes in neural function and structure underlie the recovery from neural injury.

Long-term potentiation

Synaptic plasticity, the use-dependent change in the strength of neuronal connections in the brain, is thought to underlie memory storage and may play a crucial role in a variety of neurological and mental disorders, including Alzheimer's disease, mental retardation, epilepsy and depression. During recovery following neural injury, the changed pattern of activity in the remaining synaptic connections may alter the strength of these connections and perhaps contribute to recovery. Repeated high frequency stimulation of excitatory glutamatergic pathways to the pyramidal cells of the CA1 region of hippocampus results in a large increase in synaptic efficacy of those pathways that may last hours or even days, a phenomenon termed LTP (Martin et al., 2000). LTP has been observed in many locations in the brain, and the cellular mechanism may vary from location to location. Further, some synapses in the brain undergo long-term depression, depending on the pattern and intensity of stimulation (Linden & Connor, 1995). Our discussion will focus on LTP in the CA1 region of the hippocampus because of the extensive knowledge of the signal transduction mechanisms that mediate this form of synaptic plasticity (Fig. 6.2). This form of LTP depends critically on the NMDA subtype of glutamate receptor, a receptor that serves as a 'coincidence detector' because it is activated in response to both neurotransmitter and membrane depolarization. Once activated, the NMDA receptor is permeant to calcium, and thus calcium is a critical second messenger mediating LTP in hippocampal area CA1.

Genetically modified mice have been particularly useful in the study of the molecular basis of hippocampal LTP. The analysis of genetically modified mice provides a way to test whether a particular gene product is important for synaptic plasticity and provides a useful bridge between molecules and synaptic plasticity, on the one hand, and systems of neurons and behaviour, on the other. Many of these studies have focused on an early, transient phase of LTP (E-LTP) that lasts 1 to 2 hours in hippocampal slices. These studies have shown that genetic manipulation of any one of several kinases, including calcium/calmodulin-dependent protein kinase II (CaMKII) and fyn, interferes with E-LTP, and also often results in impaired short-term memory (Fig. 6.2; Martin et al., 2000). The influx of calcium that occurs during the induction of LTP also appears to result in the creation of a retrograde chemical signal directed back to the presynaptic terminal, where it may regulate neurotransmitter release. The nature of the retrograde signal is not known, but both nitric oxide and carbon monoxide have been suggested as candidate retrograde signals (Zhuo et al., 1999).

The study of amnesic patients and experimental animals has revealed, however, that the role of the hippocampus in memory storage extends from weeks to months (Squire & Alvarez, 1995), suggesting that longer lasting forms of hippocampal synaptic plasticity may be required. LTP in the CA1 region of hippocampal slices, like many other forms of synaptic plasticity and memory, has distinct temporal phases (Huang et al., 1996). In contrast to E-LTP, the late phase of LTP (L-LTP) lasts for up to 8 hours in hippocampal slices and for days in the intact animal. Long-term memory storage is sensitive to disruption by inhibitors of protein synthesis, and L-LTP in the CA1 region of hippocampal slices, unlike E-LTP, shares with long-term memory a requirement for translation and transcription (Huang et al., 1996; Silva et al., 1998).

Although extensive information is available about E-LTP and its relation to behaviour, less is known about L-LTP. Pharmacological experiments have suggested that PKA

plays a critical role in L-LTP (Fig. 6.2) (Huang et al., 1996). One of the nuclear targets of PKA is CREB, and CRE-mediated gene expression is induced in response to stimuli that generate L-LTP and long-term memory. Behavioural studies of mice lacking the α and Δ isoforms of CREB have suggested that this transcription factor plays a role in long-term memory storage (Silva et al., 1998). The deficits in long-lasting forms of LTP and in long-term memory observed in transgenic mice with alterations in PKA suggest that this signal transduction pathway plays a role in initiating the molecular events leading to long-lasting changes in neuronal function in mammals (Abel et al., 1997). The importance of the cAMP/PKA pathway is further underscored by recent work examining mutant mice lacking calcium/calmodulin activated isoforms of adenylyl cyclases, AC1 and AC8 (Wong et al., 1999). These mutant mice exhibit deficits in long-lasting forms of LTP and in long-term memory that are strikingly similar to those observed in the R(AB) transgenics.

Alterations in the subunit composition of NMDA receptors in the hippocampus can also modulate synaptic strength and hippocampal function. This is shown by the study of mice overexpressing the 2B subtype of NMDA receptor (Tang et al., 1999). In these transgenic mice, the NMDAR2B subunit is expressed in neurons within the forebrain using the CaMKIIα promoter, resulting in increased activation of the NMDA receptor and increased long-term potentiation. These mice also exhibit increased performance on a number of behavioural tasks. This study has received much attention, both in the scientific literature and in the popular press and it would seem to suggest that the 2B subunit of the NMDA receptor would be an interesting candidate for enhancing neuronal function.

Memory suppressor genes

The study of synaptic plasticity in a number of systems has revealed the existence of proteins that act as inhibitory constraints to block increases in synaptic strength and impede memory storage. These inhibitory constraints have been termed memory suppressor genes by analogy to tumour suppressor genes that restrict cell proliferation (Abel et al., 1998; Cardin & Abel, 1999). The study of memory suppressor genes is important not only for understanding the link between synaptic plasticity and learning, but also for identifying potential targets for future pharmaceuticals to treat memory disorders. In *Aplysia*, memory suppressor gene products act at each step in long-term facilitation: in the cytoplasm to regulate kinase activity, in the nucleus to alter the activity of transcriptional regulatory proteins, and on the cell surface to modulate cell–cell interactions. During long-term facilitation following serotonin treatment, the activity of PKA is constitutively enhanced as a result of the proteasome-mediated degradation of the regulatory subunit of PKA. A cell adhesion molecule, apCAM, is internalized via a MAP kinase-mediated process thus allowing for defasiculation and synaptic growth. In the nucleus, a transcriptional repressor, CREB-2, is inactivated, thus enabling the induced expression of a number of effector genes.

One potential memory suppressor gene product in mammalian systems is cAMP phosphodiesterase. Rolipram, an inhibitor of type IV cAMP phosphodiesterase, induces persistent long-term potentiation in hippocampal area CA1 after a single tetanic train of stimulation, which normally gives rise to a transient potentiation in untreated slices (Barad et al., 1998). Behaviourally, rolipram treatment prior to training increased long-term memory for contextual fear conditioning, without altering short-term memory. Further, rolipram is able to overcome the deficits in synaptic plasticity and spatial memory that are observed with aging in rodents (Bach et al., 1999). Thus, memory suppressor genes may be particularly attractive targets for therapies designed to enhance neural function.

Denervation supersensitivity

Following the loss of a synaptic input, a neuron generally becomes more responsive to that transmitter, a phenomenon termed 'denervation supersensitivity'. This supersensitivity is usually specific to the neurotransmitter at that synapse. At the neuromuscular junction, an increase in the number of extrajunctional acetylcholine receptors is observed due to loss of electrical activity in the muscle (Lomo & Rosenthal, 1972). In the CNS, the depletion of dopamine in the nigra-striatal tract results in supersensitivity to dopamine in the basal ganglia (Rioux et al., 1991). A similar receptor hyperactivity has been observed in some patients with Parkinson's disease and this may explain some of the dyskinesias observed after chronic L-dopa treatment of Parkinson's disease patients (Nguyen et al., 2000). Such changes in receptor responsiveness may also play a role in the response of schizophrenics to neuroleptics (Seeman & Van Tol, 1995). The upregulation of receptors or the signal transduction pathways that they activate may also be the basis for the behavioural changes induced by chronic exposure to drugs of abuse such as cocaine or morphine (Nestler, 1997). Denervation supersensitivity appears to be a widespread phenomenon seen in many neurotransmitter and neuromodulator systems. Thus, it may play a role in the response to injury and the subse-

quent recovery of function. Such supersensitivity of α-adrenergic receptors in peripheral nociceptors has been proposed as a mechanism for the causalgic pain that follows partial nerve injuries (Perl, 1999). Whether supersensitivity plays a role in the hyper-reflexia or functional recovery seen after partial spinal cord injury represents an important direction of future research.

Anatomical plasticity

Some of the molecular mechanisms of neural plasticity result in changes of neuron structure, such as axonal sprouting and dendritic remodelling. These changes are important, not only because they have functional consequences; they may represent a potential for more profound regenerative responses.

Collateral sprouting

Ideally, injured axons would regenerate towards their appropriate targets and form functional synapses, thereby restoring the connection severed by the lesion. This type of regeneration is seen in the CNS of amphibia, fish and lampreys (Cohen et al., 1998), but is not seen in birds and mammals. However, during development and during regeneration of peripheral nerve, the sprouting of collateral branches of axons plays an important role in the establishment and refinement of neuronal circuitry. This sprouting occurs when new motile structures, filopodia and lamellae, form along previously quiescent regions of the axon. In the peripheral nervous system (PNS), partial denervation of muscle is followed by sprouting of neurites from neighbouring spared axons and reinnervation of the denervated muscle fibres by the sprouts (Brown et al., 1981). Collateral sprouting is different in several ways from regenerative growth. First, collateral sprouting occurs from unlesioned axon fibres near the lesioned axons. Secondly, collateral sprouting occurs close to the denervated target cells, so axon fibres do not have to extend over long distances. In this way, collateral sprouting in response to injury is similar to the terminal branching that occurs near the target region during development. Thirdly, the regions near targets are often less myelinated and thus provide less impedance to axon elongation. As discussed below, myelin associated neurite growth inhibitors appear to be present in the CNS. Thus collateral sprouting is increased in rats in which myelination has been suppressed by neonatal X-irradiation (Schwegler et al., 1995). Fourthly, at the neuromuscular junction, Schwann cells that cap degenerated nerve terminals send out processes to adjacent neuromuscular junctions that may also serve to guide sprouts to the denervated muscle and thus help establish a new neuromuscular junction (Son et al., 1996).

Collateral sprouting has been observed in the spinal cord (Liu & Chambers, 1958) and in several locations within the brain, including the septal nucleus, the CA3 region of hippocampus and the dentate gyrus, where it has been studied most extensively. Entorhinal cortical lesions result in sprouting of as much as 2–3 mm within the contralateral entorhinal cortical projection to the dentate gyrus (Steward et al., 1974). Sprouting of the mossy fibre projection from the dentate gyrus to hippocampal area CA3 has been observed following electroconvulsive, pharmacological or kindling induced seizures (McKinney et al., 1997).

The functional role of sprouting remains unclear. In the spinal cord, the time course of sprouting correlates with the development of hyper-reflexia and increased muscle tone following spinal transection, suggesting that sprouting might be of functional benefit in spinal cord injured animals by enhancing their ability to support their weight (Goldberger & Murray, 1974; Murray & Goldberger, 1974). Sprouting in the spinal cord after peripheral nerve lesions may also underlie chronic pain conditions. Here, sprouting often involves the expansion of axons into inappropriate target areas, perhaps leading to severe pain syndromes because sprouting axons derive from low threshold mechanoreceptors (Woolf & Doubell, 1994). In the hippocampus, mossy fibre sprouting develops in parallel with recurrent seizures. It has been suggested that sprouting contributes to post-traumatic epileptogenesis in the hippocampus by eliciting 'reactive synaptogenesis', which may contribute to the formation of a functional excitatory feedback circuit (McKinney et al., 1997). Alternatively, sprouting might be protective against seizures as a result of sprouting mossy fibres synapsing onto inhibitory interneurons.

The molecular mechanisms underlying sprouting in the CNS are not known, but as at the neuromuscular junction, sprouting appears to involve interactions between cells in the region of axon terminal degeneration and the neighbouring spared axons. In addition to inhibitory proteins in myelin, the intrinsic growth potential of the axon also appears to be a determinant of the extent of axonal outgrowth. Axonal sprouting is increased in the peripheral and central nervous system in adult mice that overexpress the growth associated protein GAP-43 (Aigner et al., 1995). Moreover, the neurotrophins nerve growth factor (NGF) and brain derived neurotrophic factor (BDNF) are often up-regulated following seizures (Ernfors et al., 1991) and may provide a signal for collateral sprouting of mossy

fibres (Patel & McNamara, 1995). Neurotrophins promote axon collateral formation in vivo, modulate growth cone morphology in culture and mediate developmental processes involving collateral sprouting (Cohen-Cory & Fraser, 1995). Further, neurotrophins produced by target tissues can modulate axon branching (Hoyle et al., 1993). During regeneration of DRG cell axons, NGF promotes the formation of collateral branches (Diamond et al., 1987). Neurotrophins act directly on the axon of DRG cells to promote the formation of collaterals (Gallo & Letourneau, 1998). This sprouting is mediated by the activation of actin-dependent motility via a phosphoinositide-3 kinase pathway initiated by the trk A receptor. Although neurotrophins can initiate and stabilize branching, other factors may be responsible for stabilizing collaterals and allowing them to mature (Bastmeyer & O'Leary, 1996).

Cell adhesion molecules (CAMs) may also regulate axon outgrowth and synapse formation. In *Aplysia*, long-term memory storage and long-term changes in synaptic strength are accompanied by increases in axonal branching and in the number of synaptic contacts (Abel et al., 1998). This is paralleled by a decrease in the levels of apCAM as a result of endocytosis of this molecule. This downregulation of apCAM suggests that cell adhesion molecules may normally act to block synaptic growth. Thus a CAM may act as a 'memory suppressor' gene product, normally inhibiting memory storage (Abel et al., 1998). The removal of these inhibitory constraints may provide a mechanism to enhance axon outgrowth and new synapse formation during memory storage and recovery from neural injury.

Dendritic remodelling

The loss of input to a postsynaptic neuron leads to changes in neuronal morphology, including the loss of dendritic spines, the simplification of the dendritic arbour and atrophy of the postsynaptic neuron, processes that are termed dendritic pruning. The mechanisms underlying this dendritic plasticity are unknown but changes in intracellular calcium may play a crucial role (Segal, 2001). Calcium may act to regulate protein synthesis within the spines because clusters of polyribosomes have been demonstrated associated with cysternae at the base of dendritic spines (Steward & Reeves, 1988). Denervation results in loss of these polyribosomes, whereas reinnervation is associated with their return (Steward & Fass, 1983). Thus synaptic activity localized to one spine could rapidly influence protein synthesis in that portion of dendrite and thereby affect the size, shape and function of the dendritic tree.

The communication between the dendritic spine, the dendrite itself and the soma are crucial issues. The dendritic spine is often thought of as a relatively isolated environment in which calcium can reach sufficient levels to activate intracellular signal transduction pathways, but this depends critically on spine head and spine neck geometry. Further, the activation of calcium release from intracellular stores can have dramatic effects on calcium levels throughout the cell, leading to the activation of transcriptional processes (Berridge, 1988). This complexity of calcium signalling may potentially explain the many contradictory findings in studies of dendritic morphology (Segal, 2001): at very low calcium levels, spines are eventually eliminated, moderate increases in calcium cause the elongation of spines and the formation of new ones and large increases in calcium, such as occur during trauma or an epileptic seizure, cause the shrinkage and collapse of spines.

A crucial issue is how new dendritic processes form in response to collateral sprouting and axonal outgrowth. The formation of new synapses has been observed after environmental enrichment, learning and long-term potentiation (Segal, 2001). Recent studies have used organotypic cultures of hippocampal slices combined with a local superfusion technique to restrict the site of LTP induction to a small dendritic region. Using two-photon laser scanning microscopy, three-dimensional images of the postsynaptic neuron can be obtained. In these studies, new spines are observed on the postsynaptic dendrite of the CA1 pyramidal cell after the induction of long-term synaptic potentiation (Engert & Bonhoeffer, 1999). No changes in dendritic morphology are observed after short-lasting potentiation or in control regions that were not potentiated. Are such newly formed dendritic spines functional? This is a difficult and important question. Quantal analysis of synaptic transmission does suggest that cAMP-induced long-lasting forms of LTP are accompanied by an increase in the number of quanta released in response to a single presynaptic action potential (Bolshakov et al., 1997). This increase may be due to an increase in the number of sites of synaptic transmission, an idea supported by studies using the fluorescent dye FM 1–43, which suggest that cAMP-induced synaptic potentiation is accompanied by an increase in the number of active presynaptic terminals (Ma et al., 1999).

Although much of the discussion of anatomical plasticity has focused on morphological changes in axonal arbourization or dendritic spines, it is important to note that molecular changes can make previously 'silent' (or, perhaps more precisely, 'deaf') synapses functional. Studies of LTP in hippocampal area CA1 have revealed intracellular trafficking processes in the postsynaptic

neuron by which AMPA receptors are rapidly redistributed after NMDA receptor activation (Shi et al., 1999). The redistribution of AMPA receptors provides a striking mechanism by which synapses may be strengthened.

Therapeutic approaches to recovery

In order to promote recovery from neural injury, it is necessary to optimize the nervous system's own adaptive responses as well as to intervene in those mechanisms that inhibit full neurophysiological restoration. Promising approaches include: (i) teaching patients adaptive behaviours; (ii) harnessing the physiological plasticity of the CNS through cutting edge physical therapies; (iii) promoting regeneration of axons by neutralizing environmental inhibitory influences, upregulating the intraneuronal molecular regeneration program and supplying growth promoting factors; (iv) replacing lost neurons. By using one or a combination of these approaches, researchers have already made progress in eliciting functional recovery in animals, and even in some human patients.

Behavioural adaptation (occupational therapy)

The field of occupational therapy is targeted toward promoting recovery of vocational, recreational and self-care functions by teaching patients adaptive strategies to substitute for lost physiologic functions. The focus is mostly on upper extremity and cognitive/perceptual functions. For example, a person with a homonymous hemianopia can be taught to scan the written page to be certain that she is not ignoring written material on the hemianopic side. Much of conventional practice in occupational therapy has been based on common empirical experience, *a priori* reasoning and theories that have not been subjected to controlled clinical trials. Increasingly, the practices in the field are coming under experimental test. In any case, there is little doubt that retraining of patients with neurological injuries and diseases, by any number of strategies, results in significant functional improvement (Cheung & Broman, 2000). A generalization that can be drawn from a variety of studies is that functional improvement is most likely to occur when the training is task specific. Thus, relearning words after an aphasic injury requires that the words to be learned be repeated. Learning one word has little effect on the ability to learn another word. Similarly, the effect of exercise in improving a particular function is greatest when the exercise task closely resembles the function (Kwakkel et al., 1999; Taub et al., 1999).

Physical therapies

Conventional practice methods

Although there is considerable overlap in the potential roles of occupational therapists and physical therapists in the rehabilitation of patients with neurological impairments, physical therapists tend to be concerned more with issues of gait retraining, strengthening and cardiovascular conditioning. Thus they more often address lower extremity functions than upper extremity functions or cognition. The comments made above regarding occupational therapy are also true for the therapist-assisted, staged retraining of gait following stroke, spinal cord injury and other CNS injuries using parallel bars, walkers, canes and braces. However, specific types of training targeted at inducing plastic changes in the motor output warrant special consideration.

Constraint-induced forced use

In an attempt to test the theory that learned non-use contributes to upper limb disability in stroke patients, Ostendorf and Wolf constrained the unaffected left arm in a sling in a patient 18 months after a right hemiplegic stroke, forcing her to use the affected right arm (Ostendorf & Wolf, 1981). During a 1-week trial, there was no change in the function of the restrained arm but the patient used the affected arm more frequently and more effectively. Subsequently, several studies of patients with chronic hemiparesis due to stroke or head trauma confirmed that constraint-induced, forced use of the impaired arm for a period of 2 weeks or less results in functional improvement of that arm for many months (Miltner et al., 1999; Wolf et al., 1989). A recent randomized, single blind, controlled study of constraint-induced forced use vs. conventional rehabilitation was carried out on 20 patients within 14 days of an ischemic stroke (Dromerick et al., 2000). Measurements during acute inpatient rehabilitation suggested that the constraint technique provides improved recovery on some tests of arm function. How this would affect long-term recovery remains to be determined. Electrophysiological studies have shown that forced use of the limb results in long-lasting plastic changes in the CNS. In four hemiparetic stroke patients, movement-related cortical potentials before and immediately after training and at 3 months follow-up suggested that movement of the affected hand was associated with activation not only of the contralateral hemisphere but also the ipsilateral hemisphere in the absence of mirror movements of the unaffected hand (Kopp et al., 1999). By contrast, TMS before and after a 12-day-period of constraint-induced movement therapy in 13 chronic stroke patients showed an

increase in the motor representation of the test muscle on the affected side and a displacement of the center of the motor output area of that muscle to adjacent cortex (Liepert et al., 2000). As with the changes seen in functional imaging of recovery from stroke, the significance of the shifts, particularly the activation of cortex ipsilateral to the affected arm, is not clear. However, these studies do suggest that functional recovery by application of constraint-induced forced use of a paretic limb is associated with electrophysiological evidence of cortical plasticity.

Partial body weight supported treadmill training

The spinal cord of all vertebrates studied thus far contains intrinsic circuitry, called central pattern generators (CPGs), that produce rhythmic locomotor efferent discharges to synergistic groups of muscles (Cazalets et al., 1995; Grillner, 1975). There is evidence that the spinal CPG is subject to experience-induced plastic changes, i.e. the spinal cord is capable of a form of learning that is now under investigation as a possible means by which impaired locomotion due to stroke or spinal cord injury may be improved (Dobkin, 1999). Experiments in thoracic spinal transected cats indicated that treadmill training with early support of the hindlimbs could permit the animals to develop rhythmic stepping of the previously paralysed hindlimbs, and eventually to do so while supporting their own weight (Barbeau & Rossignol, 1987; Lovely et al., 1986). Although the hindlimb stepping was not coordinated with that of the forelimbs, the hindlimb stepping persisted for 6 weeks after cessation of training, declining by 12 weeks (De Leon et al., 1999a). Retraining resulted in an accelerated acquisition of full weight-bearing stepping. These observations suggest that the spinal cord pattern generator for locomotion is subject to a form of learning. Of interest, training for weight bearing caused a loss of previously attained ability to step. This loss could be reversed immediately by strychnine, suggesting a role for glycinergic inhibition in the ability of locomotor circuits to interpret sensory input to drive stepping (De Leon et al., 1999b).

There is also EMG and visual observation evidence for spinal cord rhythmic motor output in paralysed humans (Bussel et al., 1996; Calancie et al., 1994), suggesting that a locomotor central pattern generator exists in the human lumbosacral enlargement. As in animals, the human pattern generator appears to be subject to modulation by sensory input (Harkema et al., 1997). If so, then the human pattern generating circuitry might also be subject to use-dependent and pharmacological enhancement (Fung et al., 1990). Given the widespread acceptance of the principle of task-specific training, a difficulty with attempting to retrain the central pattern generator in paralysed patients is that weakness in patients' antigravity muscles prevents them from practising the task (locomotion) that is to be recovered. In order to get around this problem patients have been placed in harnesses that partially support their weight, permitting them to practise locomotion on a treadmill. Preliminary clinical trials have suggested that such training can enhance recovery in chronic and acute patients with incomplete spinal cord injury (Dietz et al., 1995; Gazzani et al., 1999; Wernig et al., 1995) and hemiparetic stroke (Hesse et al., 1995; Visintin et al., 1998). In one follow-up study on spinal cord injured patients, improvement persisted for 6 months to 6 years (Wernig et al., 1998). While promising, all these studies have been limited in some degree by small sample size, lack of prospective design, non-randomization of controls, lack of blinding in outcomes measurements or non-uniformity of rehabilitation protocol, including time of intervention after injury (for critical review, see Dobkin, 1999). An NIH-supported, prospective, randomized, multicenter trial of body weight supported treadmill training in spinal cord injured patients is currently under way (Dobkin, 1999).

Promotion of regeneration

Although there is great promise in approaches that harness the endogenous plasticity of the CNS, maximal recovery will require reconstitution of lost neuronal connections. The peripheral and central nervous systems both show evidence for regenerative potential but they have different strengths and limitations in this regard.

Spontaneous axonal regeneration in PNS

Wallerian degeneration

Injury to peripheral nerve results in variable effectiveness of regeneration, depending on the type of injury, the distance from the perikaryon and the distance from the target. Proximal lesions result in faster regeneration (3–6 mm/day) than distal lesions (1 mm/day; reviewed in Selzer, 1987). When an axon is interrupted by physical trauma, a process called 'Wallerian degeneration' ensues (Scherer & Salzer, 2001). This consists of breakdown of the axon distal to the lesion, and the separation of myelin sheaths at the incisures of Schmidt–Lanterman into ovoids that are phagocytosed primarily by macrophages that invade the degenerating nerve. Schwann cells also participate in the phagocytosis and proliferate within the denervated connective tissue sheath, forming linear arrays called 'bands of Büngner'. The molecular signals that trigger the Schwann cell proliferation are not known, but

correlative data suggest involvement of neuregulin-1, a constituent of axons that is a potent Schwann cell mitogen in vitro. Denervated Schwann cells express a receptor for neuregulin 1, consisting of a heterodimer of ErbB2/ErbB3. During Schwann cell proliferation, ErbB2 is activated by phosphorylation (Kwon et al., 1997).

The degenerated distal nerve stump supports regeneration

The bands of Büngner form a particularly fertile environment for regeneration of the peripheral axons. This appears to be due to a combination of complex factors including the nature of the basal lamina sheath, which includes extracellular matrix molecules such as laminin-2, fibronectin and type IV collagen and several others that are excellent substrates for axon elongation in vitro (Fu & Gordon, 1997). Denervated Schwann cells contribute importantly to the regenerative ability of peripheral nerve fibres by synthesizing these extracellular matrix molecules and a variety of cell adhesion molecules, including the Ig-like cell adhesion molecules (CAMs) N-CAM, P_0, L1 and MAG. The axon binds to extracellular matrix molecules by expressing a family of heterodimeric receptors called integrins, which connect the extracellular matrix molecules to the axon cytoskeleton (Helmke et al., 1998; Schmidt et al., 1995) and may mediate activation of intracellular signaling cascades, as suggested primarily by studies in non-neuronal cells (Boudreau & Jones, 1999; Clark & Brugge, 1995). However, the axon growth cone appears to grow along Schwann cells in preference to the basal lamina, when given a choice in vitro (reviewed by Martini, 1994). As with extracellular matrix molecules, CAMs not only provide an adhesive surface for axons to grow along, but also mediate the activation of intracellular signalling pathways (Walsh et al., 1997). In this way, the extracellular matrix and cell adhesion molecules synthesized by denervated Schwann cells may contribute to the elongation and navigation of growing axon tips during regeneration. These conclusions are based primarily on studies of embryonic neurons growing in vitro. The degree to which they apply to regeneration of peripheral nerve in vivo is not clear.

Denervated Schwann cells, together with macrophages and fibroblasts in the denervated nerve, also manufacture a variety of trophic molecules and their receptors, many of which appear to be important for both axonal regeneration and Schwann cell proliferation. Among these factors are the neurotrophins NGF, BDNF, neurotrophin 3 (NT-3) and NT-4, transforming growth factors β (TGF-βs), glial cell line derived neurotrophic factors (GDNFs), the cytokines ciliary neurotrophic factor (CNTF), leukemia inhibitory factor (LIF), interleukin 6 (IL-6), and the insulin-like growth factors (IGFs) and fibroblast growth factors (FGFs). Their possible role in regeneration of peripheral nerve has recently been reviewed (Scherer & Salzer, 2001).

Specificity of regeneration

Although the precise roles of all of these molecules in regeneration are not known, the denervated distal stump of injured peripheral nerve provides an especially welcoming environment for regenerating axons to grow in. Yet, many injuries to peripheral nerve are not followed by regeneration that is adequate to result in satisfactory functional recovery. The distance of regeneration might be further enhanced by the application of extrinsic trophic factors but the main reason for incomplete functional restoration is that the degree to which regenerating axons find their correct targets is limited (Lee & Farel, 1988; Scherer, 1986). The anasthomotic fascicular structure of peripheral nerve is such that the individual axons of a severed nerve do not regenerate to their original destinations unless they find their original endoneurial tubes. Even if the fascicles are matched perfectly by microsurgical repair, the preponderance of experimental evidence (Aldskogius et al., 1987) and clinical experience has indicated that the specificity of reinnervation is still limited. The further the injury from the target, the greater the number of nerve branches the regenerating axons might enter and the more likely that a mismatch will occur between the axon and its eventual target. On the other hand, when the axon is interrupted by a compressive injury that does not interrupt the Schwann cell basal lamina endoneurial sheath, the nerve can regenerate along its original path and innervate its original muscle or sensory target (Brown & Hardman, 1987; Selzer, 1987).

Despite the above observations of inaccuracy in regeneration of severed peripheral nerve, more recent studies suggest that a certain degree of specificity does occur. In tadpoles before the Schwann cells have elaborated a basal lamina tube, severed motor axons tended to reinnervate their correct muscles selectively. It is only after a basal lamina tube is formed that axons are forced to innervate incorrect muscles if the axons enter an incorrect tube (Meeker & Farel, 1993). In neonatal but not adult rats, transection of facial nerve is followed by selective reinnervation of correct muscles (Aldskogius & Thomander, 1986). Even in adult rats, transected nerves reinnervate portions of the serratus anterior and diaphragm muscles in a somatotopically correct, though imperfect way (Laskowski & Sanes, 1988). This positional selectivity may involve the expression of ephrins by muscle fibres (and presumably complementary receptors on the motor axons) (Feng et al., 2000) and competition among regenerating axons for

correct synaptic targets (Laskowski et al., 1998). Thus, in some circumstances, synaptic competition and pruning of incorrectly regenerated axons may compensate for randomness in reinnervation of Schwann cell tubes. A form of secondary pruning also accounts for selective reinnervation of motor and sensory branches by motor and sensory axons respectively, during regeneration of severed rat femoral nerve (Brushart et al., 1998; Madison et al., 1996). Unlike the selectivity in the reinnervation of the serratus anterior, the selectivity of motor vs. sensory nerve reinnervation appears to involve guidance signals associated with the Schwann cells (Martini, 1994). Unfortunately, the specificity in regeneration of some peripheral nerve axons is not absolute but reflects statistical trends that still are not robust enough to result in functional recovery in most cases.

Spontaneous axonal regeneration in CNS

By contrast with the PNS, regeneration is quantitatively much less successful. Paradoxically, where regeneration does occur, it appears much more specific. Thus if ways can be found to enhance the probability and distance of regeneration in CNS, sufficient specificity in pathway selection and synapse formation would occur that the regeneration would yield functional recovery. Some of the molecular mechanisms that block regeneration in CNS and also contribute to its specificity are summarized below. For additional details, see Chapter 47 by J. McDonald.

Extracellular determinants

Growth cone collapsing factors

During regeneration, axons come in contact with molecules in their environment that inhibit their growth. An understanding of this phenomenon requires an understanding of the mechanisms of axon elongation.

Mechanisms of axon growth in the regenerating CNS

The leading edge of axons belonging to embryonic or invertebrate neurons grown on conventional adhesive substrates such as laminin or polo-L-lysine takes the form of a specialized structure, the 'growth cone' (Gordon-Weeks, 1989; Lankford et al., 1990; Lin et al., 1994; Rivas et al., 1992). The proximal flattened portion of the growth cone is the 'lamellipodium', which contains microtubules and short actin and myosin filaments in a relatively disorganized orientation. Extending along the leading edge of the lamellipodium are fine projections called 'filopodia'. These contain bundles of fibrous actin (f-actin) microfilaments and elongate on the extracellular matrix through target activated polymerization of the actin filaments at their distal end (Lin & Forscher, 1993). The elongation of filopodia translates into tension on the more proximal growth cone by actin-myosin linkages to the microtubules (Lin et al., 1996). This results in the rapid (1–3 mm/day) growth that characterizes early embryonic development. While much of the thinking about mechanisms underlying axon regeneration assumes that this mechanism obtains in axonal regeneration in the mature CNS, work in the lamprey suggests that this may not be true (Conti & Selzer, 2000). In this species, the growth cones of cut spinal cord axons lack filopodia (Lurie et al., 1994), have little f-actin (Hall et al., 1997) and regenerate more slowly (Yin & Selzer, 1983) than vertebrate and invertebrate embryonic axons. Observations on the morphology and cytoskeletal contents of growth cones regenerating in the CNS of mammals and other vertebrates in vivo have been scant. Thus it is not known whether the differences between regenerating lamprey growth cones and growth cones of embryonic neurons are due to species differences or to differences between axon development and regeneration.

Myelin associated growth inhibitors

Cells in the mature CNS express several molecules that inhibit axon growth in tissue culture by causing collapse of the growth cone. Because most knowledge concerning axon elongation has been derived from studies in vitro, work on the molecular mechanisms involved in growth inhibition have usually employed tissue culture assays. Perhaps most well known of these growth inhibitors was described by Caroni and Schwab (1988a, b), who observed that neurons can grow long processes when cultured on peripheral myelin fractions but not on fractions of CNS myelin. They identified two molecules with MW 35 000 and 250 000 (NI-35/NI-250) on the surfaces of oligodendrocytes, but not Schwann cells, that cause growth cones to collapse on contact (Caroni & Schwab, 1988b). Both molecules were bound by a single mAb, IN-1 (Caroni & Schwab, 1988a). These molecules appear to cause growth cone collapse by activating a G protein (Igarashi et al., 1993) and releasing calcium from intracellular stores (Bandtlow et al., 1993). The excess calcium might activate breakdown of microtubules and actin microfilaments and thus turn off growth cone motility. For years, the identities of NI-35/250 remained a mystery. However, similar molecules have now been sequenced from rats (Chen et al., 2000) and humans (GrandPre et al., 2000) and renamed 'Nogo'. Three members of the Nogo family have been identified, of which Nogo A appears to be the one responsible for the oligodendrite associated growth inhibition (Chen et

al., 2000). Several lines of in vivo experimentation suggest that neutralizing Nogo with IN-1 can enhance the regenerative capacity of CNS axons but the role of Nogo as the main cause of regenerative failure in the CNS is still debated (see below and Chapter 47 by McDonald).

Myelin-associated glycoprotein (MAG) has also been shown to have neurite outgrowth inhibiting and growth cone collapsing activity in vitro (McKerracher et al., 1994; Mukhopadhyay et al., 1994). This activity can be overcome by prior administration of neurotrophins or dibutyryl cAMP, which is elevated by neurotrophins (Cai et al., 1999). It has been suggested that in the presence of appropriate neurotrophins, cAMP levels in neurons are elevated, activating PKA, which blocks subsequent inhibition of regeneration. MAG activates a Gai protein, which blocks increases in cAMP, thus voiding the neurotrophin effect (Cai et al., 1999). The significance of MAG for regeneration in vivo has been questioned because axon outgrowth was not better on CNS myelin of MAG-deficient mice than on myelin of wild-type mice (Bartsch et al., 1995).

Two chondroitin sulfate proteoglycans, each having neurite growth inhibiting properties, have been demonstrated on the surfaces of bovine spinal cord oligodendrocytes (Niederost et al., 1999). Treatment with beta-xylosides, which inhibited synthesis of both proteoglycans, reversed the growth cone collapse seen during encounters of neurites with oligodendrocytes. Since chondroitin sulfate proteoglycans had previously been suggested to be inhibitors of regeneration associated with glial scars (Bovolenta et al., 1997) (see below), these molecules might also account for part of the regeneration inhibiting effect of CNS myelin.

Another molecule that has neurite growth inhibiting properties in vitro and is produced by oligodendrocytes is tenascin-R. In the salamander, optic nerves regenerate after they are cut, even though the myelinated optic nerve contains tenascin-R and retinal ganglion cells of salamander do not grow on a surface of tenascin-R in vitro. This may be explained by the disappearance of myelin, MAG and tenascin-R from the optic nerve by phagocytosing cells within 8 days after transection (Becker et al., 1999). In rats, optic nerves do not regenerate and tenascin-R is not removed after optic nerve transection (Becker et al., 2000). Thus tenascin-R may be a significant inhibitor of axonal regeneration in CNS, but thus far the evidence is only correlational.

It is not clear how universal the inhibitory effect of oligodendrocytes is. Contact with oligodendrocytes in vitro inhibited the growth of dorsal root ganglion (DRG) cell axons but not those of retinal cells (Kobayashi et al., 1995). Growth cone collapsing activities require not only the presence of an inhibitory molecule but also the presence of receptors on the surfaces of susceptible neurons. It is assumed that axons grow readily during embryogenesis because the late development of myelin delays contact with myelin-associated growth inhibitors. However, embryonic neurons from hippocampus, neocortex and superior colliculus were able to grow long axons when transplanted by atraumatic microinjection into various white matter tracts in the adult mouse (Davies et al., 1994). This may reflect an absence in these immature neurons of receptors for myelin-associated inhibitory molecules. On the other hand, myelin-associated growth inhibitors might not be as potent when encountered by growing axons in vivo as in vitro and other molecules normally introduced at the site of injury might be more important (Davies et al., 1997).

Neuron-associated growth inhibitors

Growth cone collapsing activity is also associated with neuronal membranes (Kapfhammer & Raper, 1987). Axons from the nasal side of the developing retina grow selectively to the posterior part of the optic tectum, while temporal retinal axons grow to the anterior tectum. This is due to a growth cone collapsing activity on cell membranes from the posterior tectum that act only on temporal but not nasal retinal axons (Cox et al., 1990). This is now ascribed to the interaction between ephrins on the surfaces of posterior tectal membranes and Eph receptors on the surfaces of growth cones of temporal retinal neurons (Ciossek et al., 1998). Ephrin signalling may also be involved in the development of the spinal cord (Yue et al., 1999). Re-expression of Eph B3 after spinal cord injury (Miranda et al., 1999) suggests the possibility that ephrin signalling may inhibit regeneration of some spinal cord axons (see section on Specificity of Regeneration below). Similarly, the persistence of netrins and their chemorepellent receptor molecule UNC-5 in the CNS of postembryonic animals suggests that netrin may act as a chemorepellent to some growth cones during regeneration (Shifman & Selzer, 2000).

Astrocyte-derived extracellular matrix molecules

It was long assumed that axons did not regenerate through an astrocytic injury scar because of the scar's hard consistency and other mechanical features. However, although membrane fractions from grey matter support axon growth in vitro, membrane fractions from astrocytic scars do not (Bovolenta et al., 1993). This growth-inhibiting activity appears to be associated with one or more cell surface sulfated glycoproteins, especially chondroitin sulfate proteoglycans. Secretion of proteoglycans by reactive astrocytes is

one proposed mechanism by which the glial scar inhibits axonal regeneration in the CNS (McKeon et al., 1991). Thus adult DRG cells grew long processes when microinjected atraumatically into spinal cord white matter (Davies et al., 1997). In a few cases, the injection was traumatic enough to activate secretion of proteoglycans, and this was associated with failure of axon growth. Such observations have suggested that CNS myelin is not significantly inhibitory to regeneration in vivo, but rather it is the proteoglycans secreted at the site of injury that inhibits regeneration. Until now, it has not been possible to repeat the microinjection experiments with adult neurons other than DRG cells.

Intraneuronal determinants

Within a species, the ability of axons to regenerate decreases with age. For example, spinal axons regenerate in tadpoles, but not in postmetamorphic frogs (Beattie et al., 1990; Clarke et al., 1986; Forehand & Farel, 1982). Fetal spinal cord transplants are more successful in restoring anatomic connectivity and locomotor function to a spinal cord injury when performed in neonatal mammals than in adults (Miya et al., 1997). Most explanations for the failure of regeneration in the mature CNS have focused on the delayed appearance of myelin and its growth inhibiting molecules discussed above. The importance of environmental causes for failure of regeneration may have been overemphasized as a result of the striking observations that some axons of mature CNS can regenerate into peripheral nerve grafts (David & Aguayo, 1981; Richardson et al., 1980; Vidal-Sanz et al., 1987). However, in these and subsequent experiments on retinal ganglion cells, environmental influences were insufficient to explain the decline in regenerative ability in postembryonic mammals. For example, only a minority of injured axons regenerate into peripheral nerve grafts (Villegas-Perez et al., 1988). This issue has been investigated in cocultures of retina and optic tectum in rat (Chen et al., 1995). Embryonic retinal cells were able to extend axons into adult tectum, but postnatal retinas were unable to send axons into embryonic tecta. Thus the age of the neuron rather than that of its host environment most influenced the regenerative ability of axons. Similar conclusions were drawn when cocultures of entorhinal cortex and hippocampus were used to test the influence of postnatal age on regeneration of the entorhino-dentate pathway of rats (Li et al., 1995). Perhaps the most convincing evidence for the importance of intraneuronal factors is the great heterogeneity in regenerative abilities of axons growing in the same part of the CNS in the same animal. Following spinal cord transection in the lamprey, identified reticulospinal neurons vary greatly in their ability to regenerate through the same spinal cord environment (Davis & McClelland, 1994; Jacobs et al., 1997; Yin & Selzer, 1983). The same axons regenerated better following axotomy close to the perikaryon than more distally (Yin & Selzer, 1983). Similarly in the rat, supraspinal axons did not regenerate as well into peripheral nerve grafts inserted into the spinal cord at thoracic or lumbar levels as into cervical levels (Richardson et al., 1984). It is also well known that adult neurons are difficult to grow in culture in the absence of myelin and on the same substrates that support extensive survival and neurite outgrowth in embryonic neurons. Thus neuron intrinsic factors must contribute greatly to the limitations on regeneration in the CNS. Recent therapeutic approaches have attempted to enhance the intrinsic regenerative abilities of neurons through the use of supplemental trophic factors. Several examples of neuron intrinsic influences on regeneration and of the effects of trophic factors are reviewed below.

Conditioning lesion effects

A conditioning axotomy can accelerate regeneration after a second lesion (Lanners & Grafstein, 1980). Although environmental changes at the injury site may contribute, the conditioning lesion effect is attributed mainly to intracellular changes of the injured neuron (Lankford et al., 1998). That this is true can be deduced from experiments using DRG neurons, which have two processes originating from a unipolar axon. One process travels with the peripheral nerve and the second enters the spinal cord with the dorsal root. Injury of the peripheral process initiates a robust metabolic response that leads to regeneration. The regenerative response to injury of the central process in the dorsal root is weaker (Chong et al., 1994; Oblinger & Lasek, 1988). Although the axons regenerate within the dorsal root, they do not penetrate the spinal cord at the dorsal root entry zone (Liuzzi & Lasek, 1987; Pindzola et al., 1993). Nor do the central processes ascending in the dorsal columns regenerate after spinal cord injury. However, regeneration of the central processes of DRG cells can be enhanced by a preceding peripheral nerve injury that boosts the growth-associated metabolic response in the cell body (Neumann & Woolf, 1999; Richardson & Issa, 1984). The conditioning lesion may upregulate the expression of growth-associated genes and decrease the synthesis of receptors for inhibitory molecules within the spinal cord (for review see Chong et al., 1999).

GAP-43

An early strategy to identify molecules that may be important in regeneration was to look for proteins whose con-

centrations are greatly increased in neurons during regeneration of their axon. The best known of these proteins, growth-associated protein of 43 kDa (GAP-43), was discovered in the frog retina during regeneration of the optic nerve (Skene & Willard, 1981). GAP-43 is transported to the growth cone, where it is preferentially concentrated during development and synaptic remodelling (Goslin et al., 1988). Although the precise mechanism is still unknown, GAP-43 may mediate signal transduction for the reorganization of the cytoskeleton in growth cones and synaptic terminals in response to extrinsic stimuli (Igarashi et al., 1995) that activate axon growth and synaptic plasticity, e.g. LTP (Namgung et al., 1997). There is also correlative evidence for a role of GAP-43 in regeneration (Chong et al., 1996; Kobayashi et al., 1997; Ng et al., 1995; Schaden et al., 1994). Direct evidence for a role of GAP-43 in axon regeneration has been difficult to obtain, although a role in axon development has been fairly well supported. Some of the ambiguities concerning the role of GAP-43 in regeneration may ultimately be cleared up by recent studies suggesting that a second growth associated protein, CAP-23, acts in concert with GAP-43 in promoting subplasmalemmal accumulation of actin in the growth cone (Frey et al., 2000). Thus, although overexpressing GAP-43 alone does not enhance regeneration of DRG axons, coexpression of GAP-43 and CAP-23 in DRG cells resulted in enhanced process outgrowth in vitro and increased regeneration of DRG axons after spinal cord injury (Bomze et al., 2001).

Cytoskeletal proteins

The neuronal cytoskeleton consists of three major elements: (i) microtubules, molecularly complex structures that mediate axonal transport of molecules and organelles; (ii) microfilaments, f-actin strands composed of polymers of g-actin; and (iii) intermediate filaments, heteropolymers of three neurofilament subunits NF-L, NF-M and NF-H. Axotomy of motoneurons in peripheral nerve results in decreased synthesis of neurofilament and increased synthesis of actin and tubulin (for review see Bisby & Tetzlaff, 1992; Conti & Selzer, 2000). After the nerve has regenerated to its target, the changes are reversed (Muma et al., 1990; Oblinger & Lasek, 1988), but they are permanent if regeneration is prevented (Tetzlaff et al., 1988). Thus regeneration of peripheral nerve may depend on the transport and assembly of actin and microtubules, while neurofilaments are important to the subsequent maturation and enlargement of the regenerated fibres.

Even less is known about the role of cytoskeletal proteins in regeneration of axons in the CNS. Arguments against the applicability of developmental growth cone mechanisms to regeneration in the CNS have been made in the lamprey, which recover normal appearing swimming and other behaviours after spinal transection (Selzer, 1978). Unlike growth cones of embryonic neurons, the growth cones of regenerating lamprey axons lack lamellipodia and filopodia (Lurie et al., 1994) and contain densely packed neurofilaments (Pijak et al., 1996) but little f-actin (Hall et al., 1997). Moreover, neurons whose axons regenerate well showed only a transient downregulation of neurofilament mRNA expression, while neurons that regenerate poorly showed a permanent downregulation (Jacobs et al., 1997). This has suggested a hypothesis that regeneration involves a protrusive force generated by the transport of cytoskeletal elements such as neurofilaments into the growing tip (Jacobs et al., 1997; Pijak et al., 1996). However, it will be necessary to manipulate expression of cytoskeletal proteins in vivo in order to test any specific hypothesis concerning their roles in regeneration.

Specificity of axonal regeneration

In recent years, substantial progress has been made in understanding how developing axons choose their paths (Goodman, 1996). Much less is known about the degree to which axons are guided during regeneration, the specificity with which they form synapses, or the molecular mechanisms of any specificity that they show. Regeneration in the CNS of several lower vertebrates does appear to be specific to a significant degree. The severed optic nerves of fish and frogs regenerate to their proper target regions of the optic tectum, restoring accurate vision (Gaze & Jacobson, 1963; Sperry, 1948). Retinotectal regeneration in reptiles is much less specific and does not restore correct vision (Dunlop et al., 2000). Cut or crushed dorsal roots in the frog regenerate into the spinal cord and muscle sensory neurons form synaptic contacts selectively with appropriate agonist motoneurons (Sah & Frank, 1984). In the lamprey, axons cut by a spinal transection regenerate selectively in their original paths (Lurie & Selzer, 1991; Yin et al., 1984). During regeneration, these axons behave as if they were following local environmental guidance cues (Mackler et al., 1986). Moreover, they form functioning synapses selectively with correct neurons distal to the lesion (Mackler & Selzer, 1987).

Much less is known about the specificity of axonal regeneration in mammalian CNS. Rat retinal ganglion cell axons regenerate through peripheral nerve grafts into the superior colliculus and terminate in correct layers, forming synapses with normal ultrastructural features (Vidal-Sanz et al., 1991). In similar experiments, peripheral nerve grafts connected the cut optic nerve with the rostral brainstem or diencephalon. In one-third of such animals, retinal axons

had regenerated up to 6 mm within the brainstem, terminating selectively in normally retinorecipient pretectal nuclei, i.e. the nucleus of the optic tract and the olivary pretectal nucleus (Aviles-Trigueros et al., 2000). Thus even in mammals, there is evidence for at least limited specificity in the regeneration of optic nerve when inhibitory effects of the adult CNS environment are circumvented by peripheral nerve grafts.

The molecular mechanisms underlying specificity in CNS axon regeneration are still unknown. Several developmental guidance molecules are expressed in postembryonic CNS of lower vertebrates and mammals (Aubert et al., 1995; Shifman & Selzer, 2001). Expression of some guidance molecules is upregulated in the spinal cord or supraspinal projecting neurons following spinal cord injury. These include: Eph B3 (Miranda et al., 1999), a member of the Eph family of protein tyrosine kinase receptors for the chemorepellent molecules of the ephrin family; netrins (Shifman & Selzer, 2000), molecules that can act as either chemorepellents or chemoattractants, depending on the receptor with which they interact; and the chemorepellent netrin receptor UNC-5 (Shifman & Selzer, 2000). In the lamprey, netrin mRNA expression has been demonstrated widely throughout the spinal cord, while UNC-5 is expressed by some reticulospinal neurons. Following spinal cord transection, UNC-5 may be upregulated selectively in neurons that are bad regenerators, suggesting that netrin signaling might be involved in modulating the regeneration of these axons (Shifman & Selzer, 2000). In adult zebrafish, rostral-low to caudal-high gradients of ephrine-A2 and ephrin-A5b mRNA expression have been found in the tecta of normal animals and during retinotopically correct regeneration of optic nerve (Becker & Becker, 2000). It has not yet been established that the retinal ganglion cells express the corresponding Eph receptors. Thus far, evidence that guidance molecules influence the pathfinding of regenerating axons in the CNS is only correlative.

Potential therapeutic approaches based on repairing the injured nervous system

Substantial progress has been made in developing methods to repair the injured nervous system. These are reviewed briefly below. Additional details may be found in Chapter 47 by McDonald.

Enhance neuronal survival and regenerative capacity

Secondary neuronal death in acute CNS injury

Part of the functional loss that follows CNS injury is attributable to the secondary death of neurons near the site of injury due to a complex interplay among glutamate excitotoxicity, edema, vascular changes and possibly cytokine toxicity (for reviews see Martin et al., 1998; Schwab & Bartholdi, 1996; Tator & Koyanagi, 1997). This is especially problematic in spinal cord injury, where the process of secondary neuronal damage is especially virulent. Despite a large number of interventions that have been successful in reducing excitotoxic and other modes of secondary neuronal injury in experimental animals (Anderson et al., 1985), the only treatment of acute spinal cord injury that has proven successful in humans is high dose methylprednisolone (Bracken et al., 1992), which is thought to act primarily by suppressing lipid peroxidation and opposing the effects of free radicals (Anderson et al., 1988).

Neurotrophic factors

Additional functional loss is attributable to atrophy or apoptotic death of axotomized neurons due to loss of target derived trophic support (Himes & Tessler, 2000; Martin et al., 1998). In addition to eliminating the possible involvement of surviving neurons in compensatory neuronal circuits, neuron death precludes the application of strategies designed to promote regeneration. Thus there is a rationale for developing pharmacological strategies to sustain the viability and vigor of axotomized neurons until a more definitive reparative manipulation can be instituted.

Peripheral nerve bridges

The ability of some CNS axons to regenerate in peripheral nerve grafts has been employed to reconnect transected optic nerve to the superior colliculus (Carter et al., 1989; Vidal-Sanz et al., 1987). Schwann cells in the nerve grafts produce growth-permissive extracellular matrix molecules such as laminin. The grafts also release trophic factors necessary for the survival of the injured neurons, in particular brain-derived neurotrophic factor (BDNF) and neurotrophin 4/5 (NT-4/5) (Cohen et al., 1994; Jelsma et al., 1993; Mansour-Robaey et al., 1994). The neurotrophic effect was enhanced when the nerve grafts predegenerated for 7 days (Golka et al., 2001), presumably because the denervated Schwann cells upregulate their production of trophic factors and extracellular matrix. These nerve grafts were reported to mediate light–dark discrimination in hamsters (Sasaki et al., 1993) and pupillary light reflexes in rats (Whiteley et al., 1998). Peripheral nerve grafts might be used to enhance recovery in spinal cord injury and other cases of interruption of compact long white matter tracts.

However, peripheral nerve grafts attract axons primarily from neurons situated close to the grafts (Richardson et al., 1984), as opposed to axons of supraspinal projection neurons such as the corticospinal or rubrospinal tracts.

Neutralize inhibitory factors

Antibodies directed at oligodendrocyte-associated growth cone collapsing factors have been used to promote regeneration (Schnell & Schwab, 1990). IN-1 secreting hybridomas were transplanted into the parietal lobes of rats, which were then subjected to spinal cord dorsal over-hemisection, interrupting both corticospinal tracts. Corticospinal axons grew up to 15 mm around and beyond the hemisection. Contact placing reflexes were restored in the hindlimbs and stride length was partly normalized (Bregman et al., 1995). In control rats, regeneration did not exceed 1 mm. Similar regeneration has been achieved by infusion of a partially humanized, recombinant Fab fragment derived from IN-1 directly into the injury site (Brosamle et al., 2000). However, in such experiments, only approximately 10% of corticospinal axons regenerate, possibly due to the presence of additional myelin-associated growth inhibitory molecules. A novel approach to dealing with this limitation has been developed by immunizing mice against myelin, using incomplete Freund's adjuvent to avoid the development of experimental allergic encephalomyelitis (Huang et al., 1999). This presumably resulted in neutralizing several inhibitory molecules. Immunized animals showed regeneration of large numbers of corticospinal axons and recovery of hindlimb motor functions after spinal cord dorsal over-hemisection.

Fetal tissue transplants

Transplants of fetal spinal cord can reduce both retrograde death of axotomized neurons (Himes et al., 1994; Shibayama et al., 1998) and the amount of glial scarring that occurs at the site of a spinal cord injury (Houle, 1992). The axons of corticospinal and bulbospinal neurons regenerate through fetal spinal cord transplants and into caudal host spinal cord, where they enhance the development of locomotion and other motor functions in newborn animals (Bregman et al., 1993; Diener & Bregman, 1998; Kim et al., 1999; Miya et al., 1997). By contrast, in adult hosts long axon tracts regenerate poorly through the transplant and regeneration of CNS axons is almost exclusively from neurons close to the transplants. Even these axons do not extend into the distal host spinal cord (Jakeman & Reier, 1991). Administration of exogenous neurotrophic factors increases growth of supraspinal axons into the transplant (Bregman et al., 1997). By combining fetal spinal cord transplants with exogenous neurotrophic factors or with the IN-1 antibody against Nogo, it was possible to increase sprouting adjacent to the transplants, enhance long distance regeneration and promote recovery of hindlimb locomotor function (for review see Bregman et al., 1998).

Modulate intraneuronal factors

As we learn more about the neuron-intrinsic factors that modulate axonal regeneration, it will become possible to manipulate expression of these factors such as growth associated and cytoskeletal proteins, as well as the proteins important for synaptic plasticity. However, intraneuronal growth programs are modulated by environmental factors such as guidance molecules and neurotrophic factors. For the moment, most manipulations of the intrinsic regenerative capacities of neurons has been achieved through extrinsic application of trophic factors, as described above.

Neuronal replacement

Fetal neurons

Embryonic neurons have been used to promote recovery by transplanting them into the brains of patients with neurodegenerative diseases (Bjorklund & Lindvall, 2000). The most extensive experience has been with Parkinson's disease (Lindvall, 1998; Olanow et al., 1996). This approach is reviewed in more detail in chapters on the relevant diseases. Challenges associated with this approach include (i) addressing the ethical and practical difficulties associated with the use of human fetal tissue; (ii) enhancing survival of grafted cells; (iii) enhancing the degree of innervation of the host striatum. Theoretically, the difficulties associated with the use of human fetal tissues can be addressed by the substitution of stem cells and immortalized cell lines. In practice, using xenografts of fetal porcine dopaminergic neurons has already shown promise (Schumacher et al., 2000), with clinical improvement comparable to that reported with human allografts. On the basis of animal studies, survival of the graft may be improved by the use of trophic factors, antiapoptotic drugs, calcium channel blockers and inhibitors of lipid peroxidation (Brundin et al., 2000). Porcine xenografts of striatal cells have now been inserted into several patients with Huntington's disease (Fink et al., 2000). It is too soon to know whether there will be a therapeutic response.

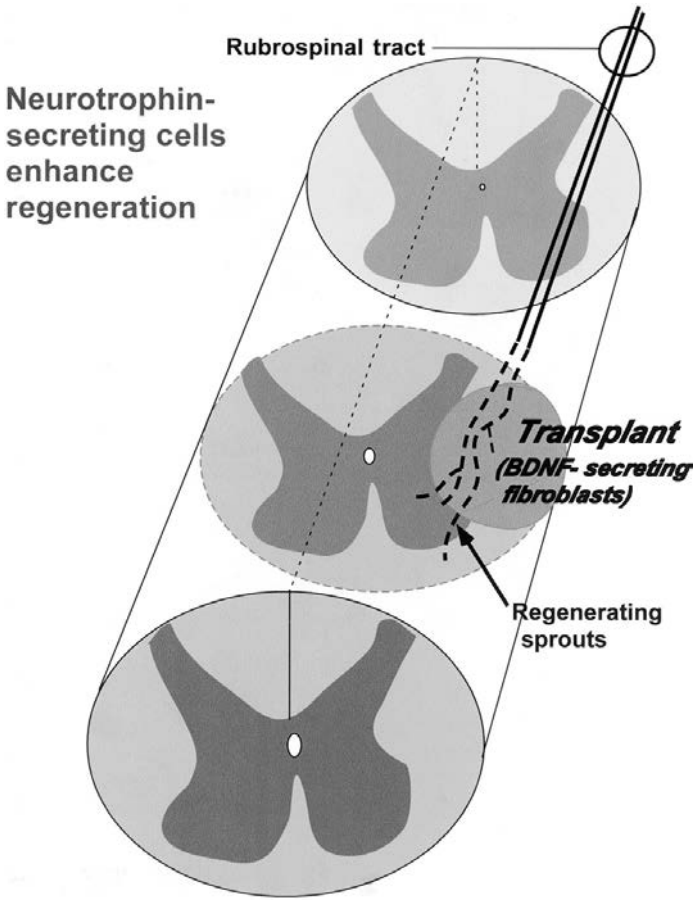

Fig. 6.3. Use of genetically modified cell lines to deliver trophic factors. Fibroblasts can be genetically modified to release molecules that enhance regeneration and clonally expanded (Blesch et al., 1999). This would have the advantage that a patient's own fibroblasts could be used for transplantation into the CNS, thus reducing the risk of immune rejection. An example of this strategy is illustrated in the work of Liu et al. (1999a), who transplanted BDNF-expressing fibroblasts into a spinal hemisection lesion that severed the rubrospinal tract, among others. Anterograde tracing from the red nucleus revealed regeneration of rubrospinal axons through the transplant into the spinal cord caudal to the lesion. This was accompanied by evidence of enhanced functional recovery.

Stem cells, neuronal progenitors and other cell lines

Because of the limited effectiveness of fetal transplants in many circumstances, the limited availability of human fetal tissue and the ethical considerations that their use has raised, alternative sources of neurons have been explored. The most promising approaches are based on cell lines that can be genetically modified to express desirable molecules, such as trophic factors. One attractive approach is to use cells from the patient's own body. Fibroblasts and Schwann cells engineered to synthesize trophic factors have been transplanted in rats to rescue axotomized neurons, promote regeneration and remyelination, and even enhance functional recovery (*c.f.* Blesch et al., 1999; Jin et al., 2000; Liu et al., 1999a; McTigue et al., 1998) (Fig. 6.3).

Neural stem cells and progenitor cells are particularly attractive for use as transplants (McKay, 1997). They have been isolated from the brain and spinal cord of adult as well as developing animals (Gage, 1998), including humans (Eriksson et al., 1998). Neural progenitors can be genetically modified to make neurotrophic factors (Liu et al., 1999b) and may be able to generate neurons to replace those lost to trauma and to furnish oligodendrocytes (Liu et al., 2000) that can remyelinate surviving and regenerating axons.

The olfactory nerve is constantly regenerating in life. Adult olfactory bulb ensheathing glia, which form the environment for this natural regeneration, can be transplanted into the injured spinal cord to promote axonal regeneration (Ramon-Cueto et al., 1998) and even functional recovery (Li et al., 1997).

Combination approaches

It is unlikely that any individual treatment will restore function completely and combinations of therapeutic approaches will probably be required. For example, Schnell and Schwab combined the IN-1 antibody and fetal spinal cord tissue inserted into the lesion to enhance the distance and profusion of regeneration (Schnell & Schwab, 1993). Local injections of NGF, BDNF or NT-3 were effective substitutes for the fetal transplants (Schnell et al., 1994). Olson's group in Sweden combined multiple peripheral nerve grafts, fibrin tissue glue, acidic fibroblast growth factor (aFGF) and compressive wiring of the dorsal spines in dorsiflexion to bridge a gap of 5 mm of spinal cord produced in rats by excision of the T_8 segment. Anterograde tracing demonstrated evidence for anatomic regeneration of ascending and descending pathways (Cheng et al., 1996) and improvement in open-field walking scores and in more elaborate measures of gait coordination (Cheng et al., 1997). These striking observations and other recent experiments suggest that combinations of surgical manipulations, trophic factors and growth inhibitor neutralization measures may be more effective than single therapies. Moreover, as the mechanisms of spontaneous recovery are better understood, new therapeutic approaches will incorporate strategies that optimize these mechanisms into the combination approach.

Measurement of neurological outcomes

Jeremy Hobart[1] and Alan J. Thompson[2]

[1] Department of Neurology, The Peninsula Medical School, Derriford Hospital, Plymouth, Devon, UK and Institute of Neurology, London, UK
[2] Neurological Outcome Measures Unit, Institute of Neurology, Queen Square, London, UK

Increasingly, clinical trials in neurology are using rating scales of patient-based outcomes to evaluate the effectiveness of therapeutic interventions and, therefore, influence patient care and the expenditure of public funds. To justify this important role in research and clinical practice, these measurement methods must demonstrate that they are rigorous indicators of abstract and unobservable variables such as disability and health-related quality of life.

This chapter, divided into five major sections, is about rating scales for measuring health. The first section examines the history underpinning the science of health measurement and psychometrics, demonstrates that the scientific foundations of this new medical discipline are deeply rooted in education and psychology, and discusses how clinical variables can be rigorously measured. Sections two to four discuss frameworks for evaluating, choosing and developing measures. This approach, rather than recommending a list of instruments, has been chosen because the clinical neurologist is often faced with a choice of instruments. No instrument has universal usefulness, it is therefore important to identify the strengths and weaknesses of individual measures. Section five introduces some of the new developments in health measurement.

Health measurement and psychometrics

History

Although health measurement as a distinct discipline emerged in the 1980s (Ware et al., 1980; McDowell & Newell, 1987; Streiner & Norman, 1989), it is derived from well-established theories and methods of measurement in the field of social sciences whose origins can be traced to the mid-1800s. The basic scientific principles of measurement were established by mathematical psychologists interested in the human being as a measuring instrument. By studying how people make subjective judgements about measurable physical stimuli (e.g. length, weight, loudness), they developed the science of psychophysics: the precise and quantitative study of how human judgements are made (Guilford, 1954). The investigation of overt responses to physical stimuli requires precise methods, referred to as psychophysical methods, for presenting the stimuli and for measuring responses (Nunnally, 1959).

The work of psychophysicists seems far removed from health measurement. It established the fundamental principles of subjective measurement which are as equally relevant to judgements about health as to judgements about physical stimuli. The psychophysicists demonstrated that: subjective judgement is a valid approach to measurement; humans make judgements about abstract comparisons in an internally consistent manner; and accurate judgements can be made on ratio rather than simple ordinal scales. It is notable that psychophysical methods are still used in neurology; thermal threshold testing is based on the principle of the just noticeable differences in temperature detection and audiometry on a person's response to different sound frequencies.

Whilst the psychophysicists were measuring subjective judgements about physical stimuli that could be independently and objectively measured and verified, experimental psychologists were attempting to measure human attributes for which there were no independent physical scales of measurement (e.g. intelligence, personality, attitudes) (Nunnally, 1959). Darwin's empirical demonstration of evolution in the *Origin of Species* in 1859 was the impetus behind the study of individual differences in psychology (Rogers, 1995). It was reasoned that, if animals inherit ancestral characteristics, and if individual differences influence their ability to adapt and survive, so individual differences in humans would have functional

significance and could be inherited. Galton, who followed Darwin and believed that the human race could be bettered through controlled mating (eugenics), realized that human characteristics must be measured in a standardized manner before their inheritance could be studied. He coined the term 'mental test' for any measure of a human attribute (this explains why this term appears in the original literature, e.g. Gulliksen (1950), Lord & Novick (1968), and set about the large-scale testing of sensory discrimination and motor function in the belief that people with the most acute senses would be the most gifted and most knowledgeable (Rogers, 1995). However, when Galton's colleague Pearson developed and applied the correlation coefficient, it became clear that results from these simple sensory and motor tests bore almost no relationship to measures of intellectual achievement, such as school grades (Nunnally, 1970). This finding prompted the development of the mental test movement, i.e. the widespread interest in the development and application of mental testing, and the measurement of individual differences.

A major advance in mental testing (Torgerson, 1958) was made when Thurstone demonstrated that psychophysical scaling methods could be used to accurately measure psychological attributes (Thurstone, 1925; Thurstone & Chave, 1929). This finding prompted the development of psychological (or psychometric) scaling methods, which are defined as procedures for constructing scales for the measurement of psychological attributes (Guilford, 1954). Spurred on by the practical need to measure diverse outcomes, the mental test movement flourished between 1930 and 1950 with the spread of standardized testing for assessing educational achievement, measuring attitudes and personality and selecting and screening personnel. In addition, scientific interest in methods of testing led to the development of psychometrics as a prominent discipline within psychology and established the cornerstones of the scientific evaluation of measuring instruments based on reliability and validity testing (Guilford, 1954; Nunnally, 1967).

Thus, when health care evaluation needed methods for measuring patient-oriented outcomes, the technology already existed. Since the 1970s, the focus of health care evaluation has moved to the measurement of function (the ability of patients to perform the daily activities of their lives), how patients feel, and their own personal evaluation of their health in general (Stewart & Ware, 1992). The primary source of this information is standardized surveys (Ware et al., 1980), for which psychometric techniques of scale construction are highly appropriate (Stewart & Ware, 1992). Two studies in the US confirmed the value of psychometric methods for measuring health variables. The Health Insurance Experiment (Brook et al., 1979), a randomized experiment conducted by The RAND Corporation between 1974 and 1981, demonstrated that psychometric methods can be used to generate reliable and valid measures for assessing changes in health status for both adults and children in the general population. Following on from this, the Medical Outcomes Study (Stewart et al., 1989; Stewart & Ware, 1992) demonstrated that psychometric methods of scale construction and data collection were successful for measuring health status in samples of sick and elderly people. This study also demonstrated that psychometrically equivalent short-form measures could be constructed from the original longer-forms (McHorney et al., 1992), thereby reducing respondent and administrative burden and improving measurement efficiency. These two pivotal studies confirmed that psychometric methods, borrowed from the social sciences, generated scientifically sound and clinically useful health measures.

Psychometric methods, however, have been slow to transfer to clinical practice. Perhaps because many clinicians do not have the time to learn about instrument development and evaluation, and the literature, which is directed primarily towards educationalists and psychologists, is incomprehensible (Streiner & Norman, 1995). Consequently, awareness of psychometric methods is limited, despite a rapid expansion of the health measurement literature since the mid-1980s. Although the principles and standards developed in psychology and education are highly applicable to health, it is important to note that they may not be wholly appropriate as measurement of health differs from measurement of psychological and educational constructs (McDowell & Jenkinson, 1996). McDowell and Jenkinson argue that 'as health is based on biological processes it includes a factual element and a consistent internal logical structure that is absent in ratings of political opinions or economic preferences' (McDowell & Jenkinson, 1996, page 238). Important health-specific methodological work is still needed (Hunt, 1997).

Measuring clinical variables

Traditionally, medicine has evaluated the effectiveness of therapeutic interventions using measurements made by machines or by documenting simple clinical end points. For example, studies of interferons in MS have measured MRI abnormalities and relapse rates; studies of interventions in stroke have measured mortality rates, recurrence of stroke rates, and incidence of cerebral haemorrage as a complication of treatments; studies in epilepsy have meas-

0 No increase in tone

1 Slight increase in tone giving a "catch" when the limb is moved in flexion or extension

[1+* Slight increase in tone, manifested by a catch, followed by minimal resistance throughout the remainder (less than half) of the range of movement]

2 More marked increase in tone but the limb easily flexed

3 Considerable increase in tone, passive movement difficult

4 Limb rigid in flexion or extension

* The modified Ashworth scale includes the 1+ rating

Fig. 7.1. Ashworth scale of spasticity.

ured seizure frequency; studies of neurological cancers have measured mortality rates, duration of survival and 5-year survival rates.

Two limitations of traditional outcomes have recently been highlighted. They provide little information about the diverse consequences of disease, and they fail to incorporate the patient perspective. Consequently, there is a need to measure more pertinent but abstract health status concepts such as disability/activities, handicap/participations, and health-related quality of life. As neurology is a specialty with few cures and a large proportion of chronic disorders, this change in focus from measuring quantity of life towards assessing aspects of the quality of life is particularly appropriate. However, this change has brought new challenges because abstract health status concepts, unlike concrete physical entities such as height, weight, and blood pressure, are impossible to measure explicitly because they are unobservable (Bland & Altman, 1997). In the social sciences unobservable variables are know as theoretical constructs or latent variables. Reliable and valid rating scales must be devised to measure these variables. (A construct is a variable that is relatively abstract as opposed to concrete, and is defined or operationalized in terms of observed indicators (Stewart & Ware, 1992)).

Latent variables can be measured indirectly by asking questions intended to capture empirically the essential meaning of the construct. The simplest way to do this is to ask a single straightforward question (item). For example, rate patient X's degree of disability on a scale of 1 (no disability) to 5 (extremely disabled). The Ashworth scale (Fig. 7.1), which grades spasticity from 0 (no increase in tone) to 4 (limb rigid in flexion or extension), is an example of a single item measure (Ashworth, 1964; Bohannon & Smith, 1987). Although single item measures are simple, user friendly, and appropriate for measuring some individual properties, they have a number of scientific limitations when measuring complex clinical variables. Single items are unlikely to represent well the broad scope of a complex theoretical construct and, are likely to interpreted in many different ways by respondents. In addition, single items are imprecise as they cannot discriminate fine degree of an attribute (the Ashworth scale categorises patients into five levels only), and are notoriously unreliable (prone to random error) as they do not produce consistent answers over time (Nunnally, 1978). Finally, it is difficult to estimate the measurement properties of single item measures (McIver & Carmines, 1981).

Multi-item instruments, where each item addresses a different aspect of the same underlying construct, are able to overcome the scientific limitations of single items and are superior methods of measuring latent variables. More items increase the scope of the measure, are less open to variable interpretation, enable better precision, and improve reliability by allowing random errors of measurement to average out (Nunnally, 1978). The Barthel Index (Mahoney & Barthel, 1965) is an example of a multi-item measure. Its ten items measure feeding, grooming, dressing, bathing, walking, transfers, stairs, toilet use, bladder, and bowels. Item scores are summed to generate a total score, which is an estimate of dependency in activities of daily living.

There are many methods, termed scaling models, for combining multiple items into scales depending on the purpose the resulting scale is to serve (Thurstone, 1925; Guttman, 1945; Gulliksen, 1950; Edwards, 1957; Torgerson, 1958). The most widely used scaling model in health measurement is the method of summated rating proposed by

Likert in 1932 (Likert, 1932; Likert et al., 1934). Four characteristics constitute a summated rating scale. First, there are multiple items whose scores are summed, without weighting, to generate a total score. Secondly, each item measures a property that can vary quantitatively (e.g. difficulty walking ranges from none to unable to walk). Thirdly, each item has no right answer. Fourthly, each item in the scale can be rated independently. Examples of Likert scales in health measurement are: the Barthel Index (BI) (Mahoney & Barthel, 1965), functional independence measure (FIM) (Granger et al., 1986), Medical Outcomes Study 36-item Short Form Health Survey (SF-36) (Ware et al., 1993, 1994), General Health Questionnaire (GHQ) (Goldberg, 1978), Hospital Anxiety and Depression Scale (HADS) (Zigmond & Snaith, 1983), and the Parkinson's Disease Questionnaire (PDQ-39) (Peto et al., 1995). Likert scales are popular because they are simple, easy to administer, user friendly, cheap, relatively straightforward to develop, and can be reliable and valid.

Evaluating health rating scales

In this section we discuss the process of evaluating rating scales. We make the assumption that a neurologist has chosen to use a particular scale but there is no published evidence concerning its measurement properties. This is a common scenario…what should be done?

There are two compelling reasons why it is important for clinicians to consider formally evaluating health rating scales. First, the properties of a scale are sample dependent (not simply disease dependent) and, therefore, the performance of a measure in a specific application is more important than its performance generally (McHorney et al., 1994). Secondly, data are only as strong as the instruments used to collect them. Sophisticated statistical methods and advances in study design will do little to overcome the damage done by poor quality measures (Fleiss, 1986; Cone & Foster, 1991), despite opinions to the contrary (Wade, 1999). It is sobering to think that vast amounts of money have been spent evaluating the impact of interferons on disability in MS using a measure, the Expanded Disability Status Scale (Kurtzke, 1983). Prior to these studies there had been limited evaluation of the EDSS using formal psychometric methods. Subsequently, evaluations have demonstrated its limited ability to discriminate between individuals and groups known to differ in their levels of disability and poor responsiveness (Sharrack et al., 1999; Hobart et al., 2000).

The aim of scale evaluation is to determine whether an instrument satisfies criteria for rigorous measurement. Much of this information can be gained from the retrospective analysis of data if they have already have been collected. However, prospective studies are often required. We recommend evaluating five measurement properties: data quality, scaling assumptions, acceptability, reliability, validity and responsiveness.

Data quality

Indicators of data quality, such as percentage item nonresponse and percentage computable scores, determine the extent to which an instrument can be incorporated into a clinical setting. These indicators, like all psychometric properties, vary across samples (McHorney et al., 1994). If the measure is patient report, these indicators reflect respondents' understanding and acceptance of a measure and help to identify items that may be irrelevant, confusing, or upsetting to patients (McHorney et al., 1994). If the measure is clinician report, these indicators reflect the ability to incorporate a measure into a clinical setting. When there are large amounts of missing data for items, scores for scales cannot be reliably estimated.

Scaling assumptions

Tests of scaling assumptions determine whether it is legitimate to generate scores for an instrument using the algorithms proposed by the developers. For example, the Medical Outcomes Study 36-item Short-Form Health Survey (SF-36; Ware et al., 1993), a generic measure of health status, has 36 items grouped into eight scales. A score is generated for each SF-36 scale by summing scores across groups of items. However, few investigators examine whether the assumptions that underpin the summing of items to generate scores are satisfied. Items can be summed without weighting or standardization when they measure at the same point on the scale (have similar mean scores), contribute similarly to the variance of the total score (have similar variances), measure a common underlying construct (the items must be internally consistent), and are correctly grouped into scales (hypothesized item groupings are supported by techniques including factor analysis and examination of item convergent and discriminant validity).

Acceptability

Acceptability is the extent to which the spectrum of health measured by a scale matches the distribution of health in the study sample and is determined simply by examining score distributions (Lohr et al., 1996). Ideally, the observed scores from a sample should span the entire range of the

Table 7.1. Score ranges, means, standard deviations, floor and ceiling effects for EDSS[a], Barthel Index, and FIM[b] ($n = 64$)

	Admission score				
	Range			Floor effect	Ceiling effect
Instrument	Scale	Sample	Mean (SD)	*n* (%)	*n* (%)
EDSS	0–10	5.0–9.0	7.1 (0.9)	0 (0)	0 (0)
Barthel Index	0–20	0–20	12.02 (5.7)	5 (2.5)	10 (5.4)
FIM	18–126	24–122	89.42 (23.6)	0 (0)	0 (0)

Notes:
[a] EDSS = Kurtzke Expanded Disability Status Scale.
[b] FIM = Functional Independence Measure.

scale, the mean score should be near the scale midpoint, and floor and ceiling effects (percentage of the sample having the minimum and maximum score, respectively) should be small. McHorney recommends floor and ceiling effects should be <15% (McHorney & Tarlov, 1995).

Table 7.1 presents results from an unpublished study and illustrates the importance of examining score distributions. Score distributions for 64 MS patients undergoing inpatient neuro-rehabilitation are presented for three disability measures, the EDSS, Barthel Index, and Functional Independence Measure (FIM). Neither scale has floor or ceiling effects. These results indicate that the range of disability in the sample is adequately covered by all three instruments. However, the sample spans the whole range of the Barthel Index and FIM but only 50% of the EDSS scale range. These results indicate that the EDSS covers a greater range of disability than the Barthel and FIM. More importantly, these findings indicate that the EDSS does not discriminate as well as the Barthel Index and FIM between different levels of disability. This is further exemplified by examining Table 7.2, which reports the range of Barthel and FIM scores for each EDSS score in the study sample.

Table 7.2. Barthel Index and FIM score ranges and means for each EDSS score ($n = 311$)

		Barthel Index score		FIM score	
EDSS score	*n*	Range	Mean	Range	Mean
5.0	3	19–20	N/A[a]	114–122	NA
5.5	6	14–19	17.7	99–119	112.0
6.0	49	8–20	17.9	80–122	110.3
6.5	80	8–20	15.6	71–122	103.8

7.5	37	2–18	10.1	37–114	83.3
8.0	54	2–16	8.1	38–113	75.9
8.5	23	0–11	3.7	33–93	56.5
9.0	11	0–5	N/A	24–57	n/A

Notes:
[a] Not applicable due to small sample.

Reliability

Reliability is defined as the extent to which a measure is free from random error, and is expressed as a reliability coefficient. However, reliability is a generic term, multiple types (and therefore many reliability coefficients) exist for each instrument. Each type of reliability addresses a different source (or sources) of random error. Ideally, all relevant types of reliability should be quantified.

For health measures the most important (but not the only) types of reliability are internal consistency and reproducibility (test–retest, inter-rater, and intrarater). Other types of reliability are beyond the scope of this chapter but are detailed in standard texts (Cronbach, 1949; Nunnally, 1978; Anastasi & Urbina, 1997). Internal consistency is the extent to which items within a scale are reliable measures of the same construct. This type of reliability only applies to multi-item measures like the SF-36 and Barthel Index and is determined using Cronbach's alpha coefficient (Cronbach, 1951). Reproducibility is the agreement between two or more ratings on the same person. Test–retest reliability is the agreement between two or more self-report ratings for the same patient. Intrarater reproducibility is the agreement between two or more ratings for the same patient made by the same observer. Inter-rater reproducibility is the agreement between two or more ratings for the same patient made by the different

Table 7.3. Product–moment correlations between the FIM, other measures of disability, and measures of handicap, psychological well-being, health status and age

	Barthel Index	EDSS[a]	LHS[b]	GHQ[c]	SF-36 PCS[d]	SF-36 MCS[e]	Age
FIM[f]	0.94	0.87	0.42	0.13	0.14	0.28	−0.05

Notes:
[a] EDSS = Kurtzke expanded disability status scale.
[b] LHS = London handicap scale.
[c] GHQ = general health questionnaire.
[d] SF-36 PCS = medical outcomes study 36-item short form health survey physical component summary score.
[e] SF-36 MCS = medical outcomes study 36-item short form health survey mental component summary score.
[f] FIM = functional independence measure.

observers. Reproducibility should be reported as an intra-class correlation coefficient for continuous data (Shrout & Fleiss, 1979), and Kappa coefficients for dichotomous data (Cohen, 1960).

Validity

The validity of a health measure is the extent to which it measures what it purports to measure (Nunnally, 1978). Determining the validity of a health measure is difficult for three reasons: validity cannot be proven it can only be supported, there is no consensus as to the minimum requirement of evidence to satisfy validity, and evidence supporting validity in one context does not guarantee validity for another.

Although any evidence that an instrument measures the construct it is purported to measure supports its validity, the strongest evidence is provided by examining its correlations with other measures collected at the same time (convergent and discriminant construct validity; Cronbach & Meehl, 1955). Validity is supported by the extent to which correlations conform with the direction, pattern, and magnitude of predictions. For example, Table 7.3 presents correlations between the FIM and a selection of other scales in 64 MS patients undergoing inpatient rehabilitation. If the FIM measures disability, we would predict: high correlations with other measures of physical disability (BI, EDSS); higher correlation with measures of disability than with measures of handicap (LHS), and psychological well-being (GHQ); low correlations with age. The data in Table 7.3 conform with these predictions and therefore provide strong evidence for the validity of the FIM as a measure of disability in MS patients. Studies of convergent and discriminant construct validity are limited if the validating instruments themselves have not been comprehensively validated. Consequently, it is important to have results from multiple studies.

Responsiveness

Responsiveness is the ability of an instrument to detect clinically significant change in the attribute measured (Guyatt et al., 1987). Responsiveness methodology is less well advanced than that for reliability and validity, and whilst several methods have been proposed for determining the responsiveness of health measures there is no clear consensus as to which method is optimal (Liang, 1995). Most methods examine scores at two points in time, usually before and after an intervention thought to alter the attribute being measured. Responsiveness is reflected by the magnitude of the standardised change score (effect size). Simply reporting raw change scores as indices of responsiveness is limited because these do not take into account the sample studied nor allow comparison between different instruments. Only reporting the statistical significance of change scores as an index of instrument responsiveness is also limited because this is heavily dependent upon the sample size. Moreover, statistical significance doesn't guarantee clinical significance (Cohen, 1994; Cortina & Dunlap, 1997). For these reasons it is recommended that responsiveness is reported in the form of an effect size (standardized change score). The formula for the most commonly reported effect size is: mean change score divided by the standard deviation of the baseline scores (Kazis et al., 1989). The larger the effect size, the greater the responsiveness of an instrument. To aid the clinical interpretation of effect size values it has been recommended that Cohen's arbitrary criteria are applied: 0.20 = small; 0.50 = medium; 0.80 = large (Cohen, 1988; Kazis et al., 1989). However, when comparing instruments, the strongest evidence for the superior responsiveness of an instrument comes from head-to-head comparisons of instruments.

Practical aspects of scale evaluation

Data quality, scaling assumptions, and internal consistency reliability can be examined from a single administration of a rating scale to a sample of people. Some aspects of validity, for example intercorrelations between scales and group differences validity, can also be examined. Convergent and discriminant validity can be examined from a single administration when other scales are administered at the same time.

Reproducibility (test–retest, inter-rater, intrarater) and responsiveness require an instrument to be administered on two or more occasions. The time interval between the two administrations for reproducibility estimation is important. Whilst some authors recommend around two weeks (Streiner & Norman, 1995), the most appropriate interval is study dependent. The aim is to achieve the optimum balance between raters (patient of clinicians) remembering their answers and therefore observed reliability being an overestimate, and true change occurring in the person being rated. Memory effect leads to overestimates of reliability and change results in underestimates of reliability. Nevertheless, more conservative estimates are best. Responsiveness studies require that an instrument is re-administered after change has occurred.

As many measurement properties can be evaluated from the single administration of a scale, psychometric studies can often be undertaken on the data arising from clinical trials. Whilst we do not encourage the retrospective evaluation of scales as the primary approach to determining the psychometric properties of an instrument, such data are important evidence of the value of a rating scale in a given clinical setting.

There is no consensus or even published guidelines for sample size calculations for psychometric studies. However, there are two rules of thumb. First, the sample studied should be representative of the population in whom the rating scale is going to be used. Secondly, the larger the sample the greater the confidence of the results. It is also important to consider clinical practicality. It may be impossible to study large samples of people with rare or uncommon diseases. Finally, some evidence is better than none.

Choosing a rating scale

Clinical trialists often have to choose one scale from among many potential candidates (Bowling, 1991, 1995; Wade, 1992; Wilkin et al., 1992; McDowell & Newell, 1996; Herndon, 1997). Unfortunately, no one scale exhibits all desirable qualities, different scales have different virtues, and instruments that are useful for one clinical trialist may not be useful for others. Therefore, scales must be selected for the particular purpose for which they are to be used and the scale user must be able to choose measures intelligently based on their needs.

For success in clinical trials, instruments must be clinically useful and scientifically sound. Clinical usefulness refers to the successful incorporation of an instrument into clinical practice and its appropriateness to the study sample. Scientific soundness refers to the demonstration of reliable, valid, and responsive measurement of the outcome of interest. Clinical usefulness does not guarantee scientific soundness, and vice versa. Below is a list of questions that we think should be addressed when selecting a rating scale.

Does the scale measure the appropriate health entity?

This is a fundamental question that must be addressed head on. Instruments selection should be based on a clear hypothesis of the impact of the intervention under study. Choosing scales simply because of their popularity, or because they were developed locally, is likely to result in the measurement of outcomes that are distal to the ideal. Under these circumstances the effectiveness of an intervention may be misrepresented.

Is the method of administration appropriate for the study?

The method of administration of an instrument should not be changed from that recommended by the instrument developers in order to suit the needs of a study. This is because altering the method of administration may affect the scientific properties (reliability and validity) of a measure. If an alternative method of administration is considered necessary, the validity of this method needs to be evaluated before the instrument is used. This can be achieved by correlating scores for patients obtained by the two methods, the higher the correlation the greater the validity of the alternative method of administration.

Is the rating scale acceptable to patients?

User acceptability is important in obtaining the cooperation of persons in the study. Patients in clinical trials are often ill or disabled and their tolerance for completing long and complex questionnaires may be limited. Seemingly irrelevant items arouse criticism. Busy clinicians with no ownership of a study have little personal gain from the

results. These factors influence the interest of patients and clinicians in participating in clinical trials, affect the reliability and validity of scores, and also the relationships between the investigators, clinicians and patients.

Does the spectrum of health measured by the scale match the level of health in the study sample?

The range of health addressed by a rating scale needs to match the distribution of scores in the sample otherwise there will be notable floor and ceiling effects (percentage of subjects scoring the minimum and maximum possible scores, respectively). Floor and ceiling effects represent subsamples of patients for whom actual changes in health will be underestimated (floor) or not recorded (ceiling) by a rating scale. The acceptability of a scale can be determined by examining score distributions for the sample of interest. Ideally, scores should span the entire scale range, means scores should be near the scale midpoint, and floor and ceiling effects should be small (<15%) (McHorney & Tarlov, 1995).

Does the rating scale generate reliable estimates?

When evaluating reliability data available for instruments, investigators should try and answer three questions:

Have the appropriate types of reliability been assessed?

Internal consistency can be examined in all multi-item measures. Test–retest reproducibility should be examined for self-report measures. Inter-rater and intrarater reproducibility should be examined for observer report measures. It is unusual to find instruments were the assessment of reliability is comprehensive. For multi-item measures the most useful index of reliability is the internal consistency because the major source of error is item sampling. A full explanation of this can be found in standard texts (Nunnally, 1978). Also, there is good evidence that estimates of internal consistency and reproducibility are similar (Ware et al., 1978, 1979) and that Cronbach's alpha tends to provide a conservative reliability estimate (Bravo & Potvin, 1991). Finally, high test–retest reliability with low internal consistency is much more likely than low internal consistency with high test–retest reliability.

Were the reliability studies conducted in appropriate samples?

All psychometric properties are dependent upon the samples from which they were determined. Therefore, results can only be generalised from one sample to another if the reliability in the two samples is expected to be similar. For example, demonstration of high reliability for a self-report health measure in persons with cervical myelopathy cannot be assumed to indicate high reliability in persons with dementia. However, evidence of reliability from multiple studies in different groups suggests reliability is a stable property for the instrument. There is no consensus as to the sizes of samples for reliability studies. However, it is important that the sample is representative of the larger sample in which the rating scale is to be used.

Has adequate reliability been demonstrated?

Widely recommended minimum requirements are 0 .80 (ideally 0.85 (Nunnally & Bernstein, 1994)) for group comparison studies, and 0.90 (ideally >0.95) for individual comparison studies (Nuyens et al., 1994; Lohr et al., 1996). The need for high reliability in individual comparison studies is clear when confidence intervals around individual scores are calculated using the standard error of measurement (SEM). This estimates the standard deviation of scores obtained if an instrument were administered repeatedly to the same individual using the following formula:

$\text{SEM} = \text{SD} \times \sqrt{(1 - \text{reliability})}$;
95% confidence intervals (+/− 1.96 SEM).

Table 7.4 illustrates the effect of decreasing reliability on the confidence intervals of Barthel Index scores and demonstrates why scores for individual patients should be interpreted with extreme caution.

Is the rating scale valid?

To determine whether an instrument is valid for a specific purpose, clinical trialists must assess the strength of empirical evidence available. Evidence for content validity

Table 7.4. Effect of different levels of reliability on the confidence intervals around individual patient scores for the Barthel Index

Reliability	95% confidence interval
0.95	+/−2.6
0.90	+/−3.7
0.80	+/−5.2
0.70	+/−6.3
0.60	+/−7.3
0.50	+/−8.2

Notes:
Barthel Index scores: $n = 149$; mean score = 11.5; SD = 5.9; sample range 0–20; floor effect = 2.5%; ceiling effect = 5.4%.

is weak validity evidence. Stronger evidence is provided by studies of group differences. Even stronger validity evidence is provided by studies of convergent and discriminant construct validity.

Is there evidence that the scale will detect change?

When evaluating responsiveness data, the most useful studies are head-to-head comparisons of instruments purported to measure the same health construct. These data are rare. The most likely scenario, if responsiveness has been examined, is that the statistical significance of the change scores is reported. These results can be misleading as *P* values are sample size dependent. Are the raw data available to compute effect sizes?

Developing scales

Developing clinical scales is a labour-intensive process requiring considerable expertise in health measurement (Spector, 1992). Therefore, clinical trialists are advised to carefully evaluate available measures before abandoning them. The psychometric properties of available measures can be determined more quickly. Here, we present an overview on instrument development.

Development of a measurement instrument in accordance with psychometric theory involves four stages: first, defining a conceptual model; secondly, generation of an item pool; thirdly, reduction the item pool to form an instrument; fourthly, testing the reliability, validity and responsiveness of the final instrument.

A conceptual model is the rationale for, and description of the concept(s) that the measure is intended to assess (Lohr et al., 1996). The importance of a conceptual basis for the measurement of latent variables cannot be overemphasized (DeVellis, 1991; Kopec et al., 1995). However, this is often absent or poorly defined for health measurement instruments (McDowell & Newell, 1996). For example, a clinical trialist may wish to develop a measure of disability for MS. The trialist must first define disability in MS and decide which aspects to measure. Only when this has been done can a comprehensive approach to item generation be undertaken.

There are four sources from which candidate items can be generated: semistructured interviews of patients with the disorder under study, consensus opinion of experts in the field, literature review, and examination of available measures. Patient interviews are very valuable as they help to identify areas that are important to them, a process that maximizes the validity of an instrument. From these four sources, items are devised aiming to address the appropriate range and depth of concept/s to be measured. These items are then pretested on a small sample to assess how easily they can be understood and completed. Appropriate alterations are made and this version is used in the preliminary field test.

The purpose of the preliminary field test phase is to reduce the number of items and to develop a scale. The instrument is administered to a large sample of patients and the results are analysed using standard psychometric techniques for item analysis (Nunnally & Bernstein, 1994; Streiner & Norman, 1995). The aim of item reduction is to select, on an empirical basis, the items that measure the construct of interest, that is items that discriminate between individuals, are stable over time, and measure the same underlying construct. The importance of selecting items on an empirical basis is that approaches to measurement on an intuitive basis often fail to produce the desired empirical results (Nunnally, 1970). After items have been reduced, they may need to be grouped into scales if it is anticipated that the instrument may measure more than one related but different construct. Items can be grouped in two ways: first, on a theoretical basis and, secondly on an empirical basis using item-level exploratory factor analysis. Item groupings, both hypothesized and empirically defined, are then tested using multitrait scaling techniques to define which method of grouping items produces the best empirical measurement instrument (Ware et al., 1997). When items have been reduced and scales formed, the final instrument must be tested on an independent sample for its clinical usefulness and scientific soundness (reliability, validity and responsiveness) using the techniques outlined above.

It is encouraging to see that traditional psychometric methods are being used increasingly in the neurosciences (Peto et al., 1995; Jenkinson et al., 1999; Williams et al., 1999; Hobart et al., 2001).

New development in psychometrics

The methods we have described above are termed traditional psychometric methods. These methods have been used successfully to develop reliable and valid patient-based health outcome measures (Stewart & Ware, 1992). Most of these measures are multi-item rating scales in which scores across several items or questions are summed to generate a total (raw) score that quantifies the health variable of interest (e.g. physical function). Nevertheless, the raw scores generated by these rating scales have important limitations that restrict the impact

of patient-based outcomes on clinical trials, epidemiological studies and routine clinical practice.

The first limitation is that raw scores are non-linear counts and not interval measures. This potentially biases the interpretation of scores and score changes, and may result in treatment effectiveness being underestimated (Wright & Linacre, 1989; Wright, 1997). A second limitation is that raw scores are scale dependent. Therefore, different scales purporting to measure the same health construct cannot be accurately equated, or their results combined for systematic reviews and meta-analyses (Bjorner & Ware, 1998). A third limitation is that the psychometric properties of scales are sample dependent and, therefore, not necessarily stable across different samples (McHorney et al., 1994). A fourth limitation is that rating scales tend to cover a limited spectrum of health. Samples in clinical studies often extent outside of the range of the scale resulting in floor and ceiling effects. These represent subsamples of patients for whom health changes will not be detected, or be underestimated by scales. A final limitation is that raw scores are not precise enough for individual patient clinical decision-making. Therefore, rating scales cannot be used in routine clinical practice (McHorney & Tarlov, 1995).

These limitations of summed rating scales were recognized years ago in education and psychology. Research led to the development of Rasch item analysis (Rasch, 1960) and Item Response Theory (IRT; Lord & Novick, 1968) models. These new psychometric methods convert raw scores into interval measures using a log odds-ratio transformation (Wright & Stone, 1979). Moreover, these methods claim to generate sample-free item calibrations and scale-free person measures, thereby enabling the accurate cocalibration of measures of the same health construct and the formation of calibrated item banks from which any subsets of items can be chosen to solve measurement problems (Wright, 1977). Calibrated item banks lay the foundation for rapid and efficient individual-patient measurement using computer algorithms (Wainer et al., 1990).

Since 1990 there has been considerable interest in applying Rasch analysis and IRT to health measurement. Initially, studies concentrated on using these methods to evaluate (Linacre et al., 1994; Tennant et al., 1996a, b), and refine (Prieto et al., 1998) existing rating scales. More recently, studies have successfully used Rasch and IRT to equate rating scales in oncology (Chang & Cella, 1997), elderly adults (McHorney & Cohen, 2000), and headache (Ware et al., 2000). Although many believe that Rasch item analysis and IRT have the potential to take the health outcomes field to a new plateau (Cella & Chang, 2000; Hambleton, 2000; Hays et al., 2000; McHorney & Cohen, 2000; Ware et al., 2000), these methods have been criticized (Divgi, 1986; Rust & Golombok, 1999) and are not as widely used as their apparent advantages would suggest they should be (Embretson & Hershberger, 1999). These facts have been attributed, in part, to a misunderstanding of the models and ill-considered applications (Linacre, 2000). Nevertheless, there have been surprisingly few empirical studies critically evaluating these methods in health measurement and comparing them with traditional psychometric approaches.

Conclusions

Latent variables can be measured rigorously using Likert scales and should be used as outcomes in the evaluation of therapeutic interventions in neurology. When assessing available instruments, clinical trialists must evaluate their clinical usefulness and scientific soundness with respect to a particular study. First, find instruments that can be incorporated into the study design, whose items look like they measure the required constructs for the study (don't be misled by instrument names), and are appropriate to the study sample. Next, examine the empirical evidence that these measures are reliable, valid and responsive in the study sample. Start with evidence for reliability as this is a prerequisite for (but not sufficient for) validity and responsiveness. Have the important types of reliability been determined in appropriate samples, and have minimum criteria for the type of study (group or individual comparisons) been satisfied? Next, examine the empirical evidence that the instrument measures what it purports to measure. What type of evidence supports the instrument's validity and how strong is this evidence? Finally, what evidence is there that the instrument has the ability to detect change over time?

The trialist is commonly left with no instrument fulfilling all the above criteria. Can further evaluative studies be undertaken on available instruments, or does the study design need to be reconsidered? If no instrument exists and no compromise is acceptable, a new instrument may need to be developed. Be sure to collaborate with a health measurement expert, but also be sure that they have one foot in clinical reality (Aaronson, 1988). Finally, new methods of data analysis have the potential to overcome the limitations of summed rating scales and improve the value of health measurement to clinical practice.

Principles of clinical neuro-epidemiology

Michael D. Hill and Thomas E. Feasby

Department of Clinical Neurosciences, University of Calgary, Alberta, Canada

Epidemiology is 'the study of the distribution and determinants of health-related states or events in specified populations, and the application of this study to the control of health problems' (Last, 1995). Historically, the science of epidemiology began with the study of outbreaks of infectious disease. It has since progressed in parallel with a shift, in the Western world, from infectious disease to chronic diseases as the major causes of morbidity and mortality. New branches have developed, such as clinical epidemiology, which again have spawned the concept of evidence-based medicine. The modern neurologist must now have both an understanding of the traditional concepts of epidemiology, such as incidence and prevalence of major diseases, and also a solid understanding of clinical research methods and how results of clinical trials apply to their patients. This chapter is designed, with brevity in mind, to provide an initial overview of these fundamentals.

Population-based research in neurological disease

Populations and sampling

There is no substitute for good natural history data. In some cases, society has legislated that all instances of a disease be reported. Both rare diseases, such as rabies or previously more common diseases such as poliomyelitis, are reportable in most jurisdictions in the western world. Legislated data collection results in population-based information. It is no coincidence that these examples are both infectious diseases. With the shift to chronic or degenerative diseases such as atherosclerosis, cancer, arthritis as the leading killing and disabling illnesses, we have not made the same commitments to collecting data as with infectious diseases. We rely upon extrapolation from much smaller samples drawn from the population.

If one could study every human being, it would be unnecessary to understand sampling. Even in very large studies, researchers can only study a tiny proportion of the population; pragmatism dictates it. The principle of sampling is to select from the population a truly representative group for study. A population is any group of persons described as generally or as specifically as appropriate. One may study the entire population of the Western hemisphere, the population of North American First Nations peoples, or the population born in a particular year or years, e.g. the 'baby boomers'. A sampling unit is the basic unit of sampling, e.g. individual, family, city, etc. This entire list of sampling units is called the sampling frame. The sample is derived from the sampling frame.

Samples may, or may not, be random. For example, in studying individual patients, a simple random sample is one in which each person in the population has an equal probability of being chosen for the sample. Sampling may be stratified according to some characteristic or done in a clustered fashion, e.g. by household. The choice of sampling methodology is governed by such things as cost, convenience, generalizability and has an important bearing on the interpretation of the results of the study.

Causation and causal inference

Determination of the causative factors in human disease is not a facile exercise. This is particularly true in the western world where diseases with long latency between exposure and disease onset have replaced shorter latency infectious diseases as the major causes of morbidity and mortality. Koch postulated that in determining the cause of disease, the following conditions should be met: (i) the agent must be found in every case, i.e. it was a necessary

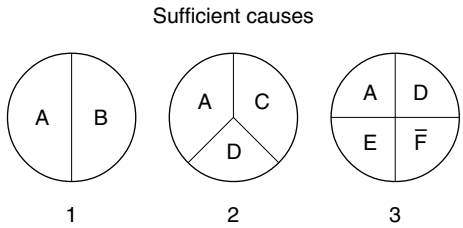

Fig. 8.1.

cause; (ii) the agent should occur in no other situation; and (iii) the agent must be isolated from a case and induce disease when transferred to a susceptible host. These were reasonable for the time but, in fact, do not apply even to most infectious diseases. For instance, the tubercle bacillus does not necessarily comply with postulates 2 or 3. It is a necessary but not sufficient cause. Disease causes are multifactorial.

Rothman described a modern deterministic model of disease causation, suggesting that sets of one or more factors act as sufficient causes (Rothman & Greenland, 1998). Each sufficient cause has an independent effect on disease causation, being responsible for a number of cases. Consider, for example, that there are six factors involved in the cause of a disease, and that these combine to form three sufficient causes (Fig. 8.1).

The effects of each component cause within each sufficient cause are mutually interdependent. For instance, in sufficient cause 2, A does not cause the disease unless C and D are present. If the sufficient cause is complete, the disease becomes inevitable, and the latent period begins. A component cause which appears in each sufficient cause, is known as a necessary cause. For instance, herpes simplex virus type 1 is a necessary but not sufficient cause for herpes simplex encephalitis. That is, many people carry the virus but some additional factor (s) is necessary to produce a sufficient cause. Because of the impossibility of determining the component causes in individuals, it is necessary to study samples of populations and use a probabilistic approach to determine causal relationships between exposure and disease. Factors shown to have a causal relationship with a disease are known as risk factors.

Several criteria have been proposed to strengthen the concept of causal inference, since the probabilistic approach lacks the finality of a true experiment, such as a clinical trial. Doll and Hill (1950) proposed six criteria based upon their work examining cigarette smoking and lung cancer. To conclude that an exposure is a causative factor in human illness, they suggested that the following be considered:

(i) the strength of the statistical association
(ii) the biological credibility
(iii) the consistency with other investigations
(iv) the temporal relationship between exposure and disease
(v) the dose–response relationship
(vi) the effect of removal of exposure

The two most important statistical ratio measures of association are the odds ratio (OR) and the relative risk (RR). These describe, in different ways, the difference in the risk of disease occurrence between those exposed and not exposed. Thus, the higher the RR or OR, the stronger the association. Because inferring causation for many of the determinants of health and disease is not simplistic, many so-called 'causes' of disease are really only associations. Based upon the above criteria, we assume with a leap of faith, that they are causative.

Study designs and interpretation

Epidemiologic studies can be descriptive, examining the distribution of disease or analytic, uncovering the determinants of disease. Descriptive epidemiology encompasses both individual level studies and population level research. Analytic epidemiology involves highly selected groups of subjects and exposures.

Descriptive: case reports, case series, cross-sectional studies and ecologic studies

The simplest observational studies are case reports and case series. These represent clinical observations and may be the first step toward an important understanding of neurological disease. Cross-sectional studies are designed usually to assess prevalence. They may examine the burden of disease, prevalence of risk factors, resource utilization, demographics, etc. They do not provide evidence for causation. The fallacy of reverse causality may occur when two factors A and B are identified in a cross-sectional survey and A is imputed to be the cause of the B. This may be a false deduction as B could just as easily be the cause of A, or both could be influenced by something else. Similarly, one must recognize that all prevalence studies are a reflection of disease duration as well as disease incidence. Nevertheless, these study designs are useful as hypothesis generating tools.

Ecological studies generally analyse groups, such as regions or worksites. Administrative and/or public health data such as mortality data are often used. Comparison of the incidence of multiple sclerosis and rate of seropositivity to HHV-6 across several cities would be an example of an ecological study. It would be erroneous to link a possible

exposure, e.g. HHV-6, with the disease (MS) on an individual basis in this kind of study since it is impossible to control for confounding. This error of logic is named the ecological fallacy. Similarly, temporal association between putative risk factors cannot be assessed by this study design.

Analytic: case-control and cohort studies and clinical trials

Case-control methodology was devised in response to a shift from acute to chronic diseases as major causes of morbidity and mortality in the western world. A case-control study is best used to study rare diseases or events. Subjects are classified according to disease status. The cases and non-cases (controls) are sampled separately and the proportions of subjects with a given exposure in each group are compared. From this type of analysis, an odds ratio (OR) can be derived as an expression of the magnitude of association between the disease and the exposure (risk factor).

The advantages of case control studies include low cost, rapid completion, suitability for studying rare outcomes, the possibility of examining multiple exposures and the quantification of the magnitude of association. Case-control studies are subject to selection bias. It is imperative that the controls be chosen, preferably randomly, from the same population as the cases. Similarly, the information collected and setting should be the same for both cases and controls. Research personnel should be blinded to case or control status and if possible, to the study hypothesis. It may be difficult to establish temporal relationships and it may not be possible to derive incidence rates unless the study is population based.

A recent case-control study assessed the risk of a rare outcome – hemorrhagic stroke – in association with a common exposure – phenylpropanolamine in commonly available cold remedies and appetite suppressants (Kernan et al., 2000). There was an increased odds of hemorrhagic stroke in women (OR = 16.6) but not in men.

Cohort studies are longitudinal studies of a defined group or population, stratified on the basis of exposure status. A well-known example of a prospective cohort study is the Framingham study. In this study, an inception cohort was defined from one geographic location (Framingham, MA) and subjects, divided into groups on the basis of exposures such as hypertension, were studied at baseline and sequentially over time. This type of study is expensive, lengthy and labour intensive; it is not easy to follow people prospectively over time. Undertaking representative sampling, minimizing loss to follow-up, standardizing follow-up and blinding outcome assessment are important measures to be taken in reducing potential bias. This type of study design is robust in that it can assess risk factors which were measured premorbidly, allowing the calculation of relative risk (RR).

Clinical trials

A clinical trial is an interventional cohort study. This is a prospective study in which the subjects are randomly assigned to the exposure (treatment) at the outset, with blinded follow-up for the measurement of outcome. This design is thought to be the ideal method of eliminating selection bias and unknown confounding factors. Successful randomization should result in equal distribution of any premorbid factors in each group or groups. Several design variations on the clinical trial include cross-over vs. parallel group design, factorial design and pseudo-randomization. Most clinical trials are analysed on an intention-to-treat basis. This implies that outcomes are assessed based upon the initial assignment of exposure group, regardless of whether patients dropped out or switched treatment regimens. Such studies are expensive and labour intensive. Additionally, it is not clear that results of randomized trials can be generalized to the usual situation in day-to-day medical practice, since the study subjects are not necessarily representative of the population. Nevertheless, because it is the epidemiological gold standard methodology, the randomized clinical trial has been adopted as the standard by which new pharmacotherapies and surgical interventions are tested.

Several important issues arise at the inception of any intervention trial. Perhaps, the most important is ethical. Is there sufficient uncertainty to withhold a treatment from one half of the cohort? The ethical underpinnings of RCTs have been recently readdressed in the literature (Weijer et al., 2000; Shapiro & Glass, 2000; Ellenberg & Temple, 2000a, b).

Neurology has become a specialty in which therapy plays an increasing role. New treatments for stroke, Guillain–Barré syndrome, multiple sclerosis, amyotrophic lateral sclerosis, and Alzheimer's disease have all been proven to have efficacy based upon randomized clinical trials (National Institute, 1995; Plasma Exchange, 1997; IFNB Multiple Sclerosis Study Group, 1995; Lacomblez et al., 1996; Rogers et al., 1998).The clinician needs to be able to understand the clinical trial and how it might apply to his/her patients and the neurology community must assess the effectiveness of a given therapy in the community once it has passed the test of a clinical trial. The magnitude of effect of tested agent or procedure in a clinical trial can be measured in several ways. Both ratio measures and difference measures can be used (Table 8.1).

Table 8.1.

		Outcome		
		+	−	
Treated	+	a	b	a + b
Placebo	−	c	d	c + d
		a + c	b + d	a + b + c + d

The relative risk (RR) is the risk of disease in the exposed (treated) group compared to the non-exposed (placebo or usual care) group.

$RR = [a/(a+b)]/[c/(c+d)]$

The risk difference (RD) is the incidence of the outcome in the exposed group less the incidence in the non-exposed group. This difference is also called the absolute risk reduction (ARR) and should be carefully distinguished from the relative risk reduction (RRR).

$ARR = a/(a+b) - c/(c+d)$

These are known as measures of efficacy. Where the exposure and outcome are causal, the ARR can be interpreted as the attributable risk – the risk attributable to the exposure.

$NNT = 1/ARR$

In understanding clinical trial results, the reciprocal of the absolute risk reduction (1/ARR) is used to derive the number need to treat (NNT) to prevent one occurrence of the outcome. For example, in the NASCET study (1991) of carotid endarterectomy to prevent stroke, the ARR in favour of surgery for symptomatic carotid stenosis with 70% or greater narrowing measured on angiography was 0.17 or 17%. This results in an NNT of 6 implying that, in order to prevent one ipsilateral stroke or death over 2 years of follow-up, six patients must be treated with endarterectomy compared to medical therapy. Alternatively, the number of patients who benefit per 1000 patients can be expressed at the ARR% × 10. Both methods of understanding the ARR are useful but limited by what they measure. They only provide an indication of the benefit or lack of it according to the outcome measure chosen by the study designers. For instance, an NNT of 9 for tPA treatment of acute ischemic stroke does not imply that the eight patients who did not achieve an excellent functional outcome did not benefit. Additionally, one must consider the time of follow-up. The NASCET study was instructive in showing that the event rate in the medical group waned considerably after 2 years. Extrapolating constant event rates from short term follow-up data may not be valid. In Table 8.2, we have listed some examples of major trials in clinical neurosciences and the NNT.

Guyatt et al. (1993, 1994) have provided criteria for reviewing and interpreting the results of clinical trials as part of a series on evidence-based medicine, published in the *JAMA*. The reader is encouraged to review the series.

The concept of effectiveness is beginning to gain credence in contemporary medicine. Despite solid evidence that the treatment of hypertension reduces the risk of stroke, MI and vascular death, it is common parlance (without tongue in cheek), that only half of hypertensives know they are hypertensive, half of those who know are treated and half of those who are treated actually comply with their prescribed medicine. Similarly, the rate of treatment of atrial fibrillation with anticoagulation is poor (Leckey et al., 2000). Two recent reports suggest that carotid endarterectomy for both asymptomatic and even symptomatic carotid stenosis may be vastly overused because community-based effectiveness does not measure up to the standard established in clinical trials (Chaturvedi et al., 2000; O'Neill et al., 2000). These are examples where the benefit established as efficacy of therapy in tightly controlled clinical trials has not been generalisable to the community as effectiveness of therapy. This distinction becomes particularly relevant where the risk–benefit ratio of any given therapy is close to one. Often, in 'real-life' the risks are higher and the benefit achieved lower than in clinical trials. If the demonstrated benefit is obliterated by the elevated risk observed in community practice, the treatment cannot be routinely justified. This may be the case for carotid endarterectomy for asymptomatic carotid stenosis in many jurisdictions in North America (Perry et al., 1997; Feasby, 2000).

Diagnostic and screening tests for neurologic diseases

Sensitivity, specificity, positive-predictive value (PPV) and negative-predictive value (NPV) are conditional probabilities and are best understood using a 2 × 2 table (Table 8.3).

The sensitivity of a test is the probability that the test is positive given that the patient has the disease $[a/(a+c)]$. Specificity is the probability that the test is negative, given that the patient does not have the disease $[d/(b+d)]$. The positive predictive value is the probability that the patient has the disease given that the test is positive $[a/(a+b)]$ and the negative predictive value is the probability that the patient does not have the disease given that the test is negative $[d/(c+d)]$.

Table 8.2.

Trial	Outcome measure	Absolute RR	NNT
Carotid endarterectomy for ≥70% symptomatic stenosis (NASCET Collaborators, 1991)	Ipsilateral stroke or death over 2 years	17%	6 – treat 6 pts and follow for 2 years to prevent 1 outcome
Carotid endarterectomy for ≥60% asymptomatic stenosis (Exec. Comm. ACAS, 1995)	Ipsilateral stroke or death over 5 years	5.9%	17 – treat 17 patients and follow for 5 years to prevent 1 outcome
Intravenous tPA for acute ischemic stroke (Nat. Inst., 1995)	Excellent functional outcome at 90 days	11%	9 – treat 9 patients and follow for 3 months to get 1 outcome
β-interferon for relapsing–remitting MS (IFNB MS Study Group, 1993)	Proportion of symptom-free subjects in the high-dose treatment group at 2 years	15%	7 – treat 7 patients for 2 years to prevent 1 outcome
Treatment of isolated systolic hypertension in the elderly (SHEP) (1991)	Incidence of total stroke over 5 years	3%	33 – treat 33 patients for 5 years to prevent 1 outcome

Table 8.3.

		Disease (truth)		
		+	−	
Test	+	a	b	a+b
	−	c	d	c+d
		a+c	b+d	a+b+c+d

Table 8.4.

		Disease (truth)		
		+	−	
Test	+	2	4	6
	−	1	93	94
		3	97	100

In clinical practice, the interpretation of diagnostic testing is most informed by the use of PPV and NPV. This is because one does not know whether the patient has the disease or not, while one does know the test result. Both sensitivity and specificity are functions of the test itself. However, PPV and NPV depend upon the patients and the population from which they arise and therefore will vary as the prevalence of disease within a population. Calculation of PPV and NPV when the characteristics of a test are known (sensitivity and specificity), is a function of Bayesian theory (Table 8.4).

In the foregoing example, the prevalence of the disease is only 3%. The result is that the PPV = 0.5 and NPV = 0.99. Therefore, when the prevalence of a disease is low, a positive test may not be helpful since there may be a significant probability that the test is a false positive. A negative test adds only minimally to the diagnostic process since the prior probability of the diagnosis was only 3%.

The usefulness of any test depends very much upon what its intended use is. One can deduce from the above explanations of sensitivity and specificity that increased sensitivity comes at the expense of decreased specificity and vice versa. For example, when selecting a test for the diagnosis of a disease, a test with high specificity, which results in the highest positive predictive value, will be most useful. Alternately, if you wish to exclude a disease then a test with high sensitivity is best. For tests used in screening, similar considerations apply.

Graphically, this relationship is shown in a receiver–operator characteristic (ROC) curve. A ROC curve provides a visual method to examine the sensitivity and specificity of a diagnostic or screening tool at every possible cut-off point (Murphy et al., 1987). It is created by plotting the sensitivity of a diagnostic or screening tool as a function of (1 − specificity). This reveals a function that, at each point in the distribution of the screening test, yields a sensitivity and specificity for identifying those with disease. For tests where no clear cut-off for identification exists, the point of maximal sensitivity and specificity can be found.

Burden of neurologic disease

Major neurologic diseases

Neurological illness routinely creates long-term disability; it is therefore important to understand the differences between incidence and prevalence. Incidence is the number of new cases of a disease in a specified time in a population. Prevalence is the number of existing cases of a disease in a population. When a disease has either a high mortality or high resolution rate, the prevalence and incidence will be approximately equal. For example the incidence of Bell's palsy is 15–40 cases per 100 000 population. The prevalence is the same because mortality from Bell's palsy is nil and there is a high rate of spontaneous resolution. For chronic illnesses, such as multiple sclerosis, which have low mortality and low spontaneous cure rates and therefore long durations, the prevalence will be higher than the incidence.

Stroke is numerically the most important neurological disease. The incidence and prevalence are significantly higher than any of the other major neurological diseases and neurological mortality is highest for stroke. Stroke may increasingly account for the rising incidence of epilepsy in the older population. Indeed, as the population ages, brain neoplasms and dementia will play an increasing role in population neurological morbidity and mortality.

In the developing world AIDS plays an increasingly devastating role. Much of the continent of Africa continues to be and will be for the foreseeable future, bludgeoned by the virus. Neurological manifestations of AIDS resulting both from the virus (e.g. progressive multifocal leukoencephalopathy, primary CNS lymphoma, HIV dementia) and from the treatment (e.g. myopathy, painful neuropathy) are very important components of the overall morbidity and mortality from the virus.

Stroke

Stroke is a major cause of both mortality and morbidity. It is the third leading cause of death in North America and Canada and a leading cause of acquired adult disability. US data suggests that there are seven to eight times more stroke survivors than stroke deaths. The age-adjusted incidence of stroke, determined from the Framingham study, is 603 per 100 000 men and 453 per 100 000 women. There is a clear association of increasing stroke incidence with increasing age. As with other diseases, there is substantial regional variability in stroke incidence.

Of interest in stroke epidemiology has been the dramatic decline in age-adjusted mortality rates from stroke. Parallel declines have been seen in other atherosclerotic diseases such as coronary heart diseases. However, the impending aging of the population in many countries will more than make up for the declining mortality and we will see increasing numbers of patients with stroke over the next several decades.

The cost and burden of stroke are enormous because of the sheer numbers of persons affected. Estimates of societal cost in the US approach tens of billions of dollars per annum (Taylor et al., 1996). This is therefore an exciting period, with the introduction of the first new and cost-effective therapy (tPA) for acute ischemic stroke, bringing the potential for reduced cost and suffering (Kwiatkowski et al., 1999; Fagan et al., 1998).

Brain cancer

Brain tumours are second after stroke as a cause of neurological death. There are wide geographical variations in incidence ranging from 1.0 to 14.3 per 100 000 population (Bahemuka, 1988). However, older studies are marred by incomplete ascertainment due to the lack of modern imaging techniques. Indeed, an ongoing issue in the epidemiology of brain tumours is lead-time bias. Studies that suggest longer survival after brain tumour therapy may be biased by earlier diagnosis due to increased use of CT and MRI scanning. A corollary to this concept is that more asymptomatic tumours are uncovered in life rather than as incidental findings at autopsy (Nakasu et al., 1987).

The age-adjusted incidence of brain neoplasms was 14.1 in Olmstead County, Minnesota (Annegers et al., 1981). Incidence of primary brain neoplasms clearly rises with age. Types of brain tumours vary by gender. For example, meningiomas are more common in females and glioma more common in males (Preston-Martin, 1989).

Despite several reports suggesting that the incidence of primary brain tumours is rising rapidly, it appears that, with the exception of primary CNS lymphoma, brain tumour incidence is stable. The dissemination and widespread use of CT and MR imaging has resulted in greater diagnostic accuracy and increased case recognition rates (Radhakrishnan et al., 1995).

Primary CNS lymphoma, accounting for only 1% of CNS neoplasms, has shown an increasing incidence (threefold) over the last several decades. Although the AIDS epidemic has dramatically increased the absolute number of cases, it appears that the trends to increasing numbers began before the AIDS epidemic accelerated. Increased case acquisition also does not explain the rising incidence (Eby et al., 1988).

Dementia

Dementia, like stroke, is an enlarging public health issue because of aging populations in many parts of the world. Dementia, of which Alzheimer's disease is the most common, occurs with steeply increasing incidence and prevalence with age. Data on the descriptive epidemiology of dementia is quite consistent across the world, where it has been gathered. However, the prevalence of the disease in older age groups is more variable because small sample sizes in the oldest old produce more variation in these age brackets (Fratiglioni et al., 1999).

While Alzheimer's disease is the most common form of dementia, differing case definitions of vascular dementia allow for variations in the proportion of cases attributable to each and in which age brackets (Hebert & Brayne, 1995). Recent work suggests that there is a very strong synergy between cerebrovascular disease and Alzheimer's disease (Snowdon et al., 1997). Because of difficulties in premorbid clinical diagnosis, it remains unclear how commonly other forms of dementia, e.g. diffuse Lewy body disease, the fronto-temporal dementias, progressive supranuclear palsy, etc., are found across the world.

Multiple sclerosis (MS)

Interest in the epidemiology of MS is piqued by the non-random distribution of the disease with increasing prevalence according to increasing latitude in both hemispheres (Kurtze, 1975, 1977; Hammond et al., 1988). In addition, smaller migration studies have suggested that migrants take on the prevalence of the disease in the indigenous population of the new country. These observations 'favour an environmentally-based latitude effect' upon MS prevalence (Ebers & Sadornick, 1998). Genetic influences have generally not been controlled for in these studies such that, despite enthusiasm for viral and other infectious causes of MS, genetic predisposition with a non-specific inciting environmental agent may be the most plausible ontogenic theory of MS.

The prevalence of MS varies from 5/100 000 to as high as 120/100 000 population. The incidence of the disease is much harder to estimate for several reasons. The biology of the disease suggests that it exists well before a clinically definite diagnosis can be reached, and this lag time may be quite variable among patients. Improving diagnostic strategies may improve this situation but they also cast doubt upon research done prior to routine magnetic resonance imaging. Data from Olmstead County, Minnesota suggest an annual incidence rate of 3.6 per 100 000 (Percy et al., 1971).

The burden of MS upon patients, families and society is tremendous. A majority of patients are unemployed either inside or outside of the home after 10 years. Depression and other psychiatric conditions occur in MS due to both the disease itself and its effects upon the psyche. Cost estimates including both direct and indirect medical care as well as lost wages suggest that MS is an expensive disease. Although there is excess mortality from MS, particularly the malignant, rapidly progressive forms (e.g. Marburg variant) and from suicide, the societal impact is due to chronic morbidity and reduced quality of life rather than increased mortality (Swingler & Compston, 1992).

Table 8.5.

Disease[a]	Estimated age-adjusted annual incidence per 100 000 population
Stroke	603 (men); 453 (women)
Dementia[b]	80–400 for the age-group 60–64 4980–13 570 for the age group >95
Epilepsy	24–53
Primary brain neoplasms	9.0
MS	3.6
Guillain–Barré syndrome	1–2

Notes:

[b] Not age adjusted.

Epilepsy

Epilepsy is a disease of the extremes of age in the developed world. While the overall incidence varies between 34 and 53/100 000/y, children (<20 y) and older adults (>60 y) have two to four times that incidence. In Africa and South America, this U-shaped curve is flatter and an increase in incidence in the elderly has not been observed (Rwiza et al., 1992; Lavados et al., 1992). The prevalence of epilepsy worldwide is much higher, ranging from 400–800 per 100 000 population (Hauser & Hesdorffer, 1990).

Epilepsy is slightly more common in males and its overall incidence in the western world has been stable. However, data from Rochester suggest that overall stability reflects significant declines in the pediatric age group and increases in incidence in the group over 60 y (Hauser et al., 1993) (Table 8.5).

In conclusion, a solid comprehension of basic clinical epidemiology is invaluable to the practicing clinician. Particularly as clinical neuroscience practice becomes more and more subject to the results of clinical trials, clinicians will need to know how to interpret the literature for both therapeutic and diagnostic modalities. The concepts

outlined here are only the tip of the iceberg and further exploration is suggested (Sackett et al., 1991).

Review of some of the major neurological diseases is helpful in placing both ourselves as treating physicians and our patients in context. From a public policy point of view, interventions to prevent stroke will have the most chance of reducing neurological morbidity and mortality. From the viewpoint of physicians and patients, knowledge of disease prevalence aids in the interpretation of diagnostic testing and awareness of risk factors aids preventative management. Understanding from where and how these data are derived can only further the practice of good clinical medicine.

Principles of therapeutics

Peter J. Goadsby

Institute of Neurology, The National Hospital for Neurology and Neurosurgery, Queen Square, London, UK

Traditional neurology has been dominated by a focus on diagnosis with accurate neuroanatomical localization of the lesion or pathophysiological definition of the underlying disease process. With some notable exceptions, such as changes in the pattern of infectious diseases in the Western world, neurological diseases have not altered much since Gowers (1888) set out the problem. The process of diagnosis, certainly for structurally based conditions, has been immeasurably served by brain imaging, first with X-ray computerized tomography and most recently with magnetic resonance imaging. Pathological study remains a cornerstone of accurate disease classification for some brain disorders, notably tumours, while the pathophysiological basis of many diseases has been elucidated by techniques including molecular biology, clinical neurophysiology and functional brain imaging. However, therapeutics in neurology can be barren, indeed neurology has often suffered the tag of being expert on diagnosis and wanting in treatment. While there can be no doubt that patients seek a label, or explanation, for their problems, treatments, indeed cures, for neurological maladies must be our aim.

Several areas of neurology have seen substantial advances in their therapeutic armamentarium in recent times and it seems appropriate to consider some of the underlying principles that drive neurological therapy and how new therapies may fit such a framework. First, some principles will be covered, after which some specific generic issues will be considered, clinical trial evaluation, dose selection, drug metabolism and interactions, and some issues of special populations.

Some principles

While everything in neurology, indeed medicine, can be individualized there are some underlying themes. The emphasis on these themes will vary with the condition being considered, and the needs of the patient. However, some part of these principles can be applied in many clinical conditions.

- Patients need an explanation of the condition from which they suffer and how their symptoms fit that diagnosis.
- Patients need to know the natural history of their condition so they can judge the likely benefit of treatments.
- Patients need to know the treatment options, both complementary if they exist, and orthodox.
- It should be made clear whether a treatment will address symptoms or the underlying disease process.
- Realistic goals need to be set for treatment: if the best that can be expected is a 50% improvement this needs to be stated clearly.
- Commonly expected or potentially serious side effects need to be stated and explained.

Naturally, these principles simply state what most neurologists do, coming as no surprise to the clinician. In the modern, ever more technologically driven and litigious environment in which we practice one might add some expectations of patients. Therapeutics should not be a battle, with tension between treatments and side effects, but a partnership. Most practitioners seek to do good and it is a shame that this is not the starting point in all clinical interactions. Notwithstanding the best intentions an adequate record of the management plan, including side effects explained and options offered needs to be recorded in the case notes for the many good reasons that such records are made.

Evaluating clinical trials

The cornerstone of modern neurotherapeutics is the controlled trial. The importance of proper, scientifically sound

clinical studies cannot be overemphasized. Many neurological disorders have such remarkable variability with time or between ictal events that uncontrolled studies are unacceptable. This does not imply that good clinical observation has no place in modern therapeutics; indeed many important developments come from the careful observer notingchange where it was not expected, but this approach generates hypotheses not textbook advice. Some conditions lend themselves to clinical study and some do not. For rare conditions the *N*-of-1 approach (Jones & Kenward, 1989) deserves more exploration, often overcoming the problem of recruitment.

Ideally therapeutic studies need a control group and must be randomized and double-blinded. Clinicians need to understand the many biases of single blinding, of the patient without the clinician, and generally reject such designs. If it is undesirable to offer treatments without evidence, it is even more unhelpful to conduct studies that cannot by their design yield useful information. The control group needs careful consideration, it should be contemporaneous, not historical, carefully matched for obvious variables: age, sex and disease, and consider other issues of matching, such as weight, that may effect the study outcome. Often a placebo control group is desirable but for some indications in which there are established treatments an active control group, in addition or instead of the placebo group, may be desirable. An active control group can help clinicians position a new treatment, whereas a placebo control can facilitate comparison with previous studies in a therapeutic area.

A special problem arises when, as in the case of multiple sclerosis, several treatments are licensed to modify the course of the disease but none is more than modestly effective and better treatments are clearly needed. Because there are licensed treatments available, it may no longer be ethically justified to perform large, double blind, placebo controlled, randomized clinical trials. In this context historical controls may be necessary; mathematical modelling of disease course utilizing data from the placebo arms of previous clinical trials and from epidemiological studies may provide a basis for comparison of the effects of new agents. The Sylvia Lawry Centre for Multiple Sclerosis Research in Munich set up by the Multiple Sclerosis Federation is an attempt to develop such an approach.

Study analysis and data presentation is an area that is often found lacking when new data are published. Study size is crucial; how was the study powered and to what endpoint? When new treatments are being evaluated against established therapies and equivalence is claimed, was the study powered adequately for equivalence? What clinical difference is being evaluated? Is a difference of 5% of any clinical relevance? What was the primary end-point and was it significant? How many hypotheses have been tested to obtain a positive result? In our clinical desire to have new treatments it is important that substandard studies do not end up driving clinical practice inappropriately.

Some principles in evaluating clinical trials

These include:

- Has the therapy been studied in randomized controlled double-blinded studies?
- Is the control group appropriate and suitably matched?
- Is the primary end-point clear and was it statistically significant?
- Was the study adequately powered?
- Are the reported differences and benefits clinically important?
- Were the adverse events clearly stated, and were there any serious adverse events that will be important to mention in clinical practice?

Dose selection

The pharmaceutical industry has often taken the view that simplicity is best and one dose should fit all patients. It is borne of the perception that anything too complex will not be used and dose titration is too much trouble. It is a nonsense to expect that a treatment studied in 70–80 kg patients would necessarily be of any use to those weighing 100 kg, or that tolerability will not be a problem in those weighing 40 kg. Weight is a simple but clear example of the need to consider dose carefully. Patients can often be engaged in such a process of dose selection understanding that one is trying to do what is best for the individual rather than applying a *herd-based* therapeutic approach.

If individualization, where possible, is one guiding principle, the other must be the often-quoted medicinal aphorism: start low and go slow. Patient responses may be idiosyncratic, indeed side effects may be unpredictable on the base of dose so that giving a low dose and making small increments will greatly aid compliance and alert the clinician to a problem when the drug load is low. Many drugs that are used in neurology have significant central nervous system side effects that can be tolerated if patients are gradually exposed. It is a shame to lose a useful treatment in the rush for a response. Again, it is important to make it clear to the patient why one is taking this approach so that their expectations for a response are suitably modified.

An obvious general exception to the slow and steady principle is the neurological emergency. In some situa-

tions, such as acute stroke or giant cell arteritis, dosing must reflect the significant morbidity, indeed mortality, of the condition being treated.

Pharmacokinetics: giving drugs safely and effectively

When prescribing a treatment, the clinician needs to consider how the substance might interact with the patient, in terms of metabolism and drug interactions. Such interactions vary from trivial alterations in drug metabolism to profound change, as may be seen with some of the older anticonvulsants.

Issues of drug metabolism have become more complex as our treatment options expand, and those of other specialties conspire to make administration much harder in some individuals. It is beyond the scope of this chapter to discuss every aspect of pharmacokinetics but as a checklist one might consider:

- absorption issues in oral medications vs. other routes of administration;
- bioavailability and the effect of feeding or interactions with the disease on absorption, such as impaired oral absorption in acute migraine;
- drug metabolism involving monoamine oxidase (MAO) or cytochrome P450 pathways that can cause potential interactions with other medications;
- drug delivery issues, such a protein binding or special brain issues, such as whether a medication is a substrate for the brain P-glycoprotein (PGP) pump (Wacher *et al.*, 1995), which can specifically promote efflux of medicines out of the brain, or the state of blood–brain barrier itself;
- drug half-life issues that may drive dosing considerations, and thus affect compliance;
- drug elimination issues such as those seen in hepatic impairment or renal failure.

The list is not exhaustive, but illustrates the challenges we face as we seek to employ new medications into daily practice. On-line and various electronic PDA solutions will help alert clinicians to potentially fatal interactions but will not replace the thoughtful, well-trained neurologist who plays the pivotal role in bringing innovative medicines to daily clinical practice.

Special populations

Some populations are so special that therapeutics can be a particular challenge, which deserves particular attention.

Females of child-bearing age and pregnancy

For very good reasons females of child-bearing age and pregnant women are generally excluded from clinical studies of new therapeutic agents. While it is easier to include females in the child-bearing age by adequate screening and discussion, pregnant women are a complex therapeutic proposition. Generally, females of child-bearing age should not be denied the potential benefits of treatments for their neurological conditions. Contraceptive issues can be discussed and the lack of experience of any treatment in pregnancy explained. Indeed clinical trials should seek actively to include patients in the demographic distribution of the target condition. Pregnancy is a more complex issue.

Given that most therapeutics studies will exclude pregnant females, there can be no data concerning the effects of a new agent on the pregnant female or the fetus. The possibility of teratogenicity or abortion must be mentioned even though it is effectively impossible to give any reliable estimates of the chance of an adverse event. Often the clinical condition will assist in making these decisions in that the disease itself may adversely affect the fetus; situations such as a prolonged seizure or acute migraine with vomiting and dehydration, weigh into the risk–benefit of treating pregnant females. Ideally treatments whose risks are minimal, or at least clearly understood, can be presented to the patient. It is attractive and often helpful to have both parents, when possible, hear the same information and certainly to document what is said.

It is worth remarking that effects of the pregnancy on a treatment should be considered. Metabolic, hormonal or simply blood volume changes should be considered when dosing the pregnant female. Having taken a decision to treat, that treatment must be adequate to prevent or control symptoms, as desired.

Younger patients and the elderly

Neurological disorders clearly affect children and adolescents, as well as the elderly. The general issues surround dosing and desirability to treat these groups. Dosing is an obvious issue with simple weight adjustments being a minimal consideration in the young, while in the elderly drug metabolism needs to be factored into dosing considerations. The route of elimination of a compound is important, particularly for renal excretion in the elderly, and if dose adjustment is recommended this needs action.

Some conditions, perhaps most notably stroke and degenerative diseases, affect the population more with time, and development programmes for new treatments

will reflect this reality. However, some conditions of younger patients also affect the elderly, and are no less disabling. Where the age cut-off for studies should be, and what constitutes elderly, is no simple decision. Many patients over 65 years, and particularly under the age of 75, are remarkably biologically agile, while many adolescents acquire both the physiology and responsibility of adulthood before their 18th birthday. Lack of exposure of a new therapy to an older or younger age must be weighed against the disability that is attendant the disease process. For the young, perhaps school attendance and performance, and for the elderly issues of quality of life need to be considered when planning treatment. For children careful involvement of the parents or care-givers is essential.

In conclusion, neurotherapeutics is likely to be the next great change to neurological practice. Increasingly neurologists will be required to treat what has been untreatable, to palliate where only suffering was previously on offer, and eventually to alter the course of neurological diseases as modifying and curative approaches become available. The challenges are substantial and the rewards considerable. Neurotherapeutics will drive subspecialization in neurology as patient expectations grow and the number of options becomes more complex. Careful attention to the principles will help the clinician bring the fruits of the post-human genome translational therapeutic revolution to the group of diseases that neurologists are charged with managing.

Windows on the working brain: functional imaging

John A. Detre[1,2] and Paul D. Acton[2]

[1] Department of Neurology and [2] Department of Radiology, University of Pennsylvania, PA, USA

Functional imaging encompasses methods used for visualizing a variety of aspects of cerebral physiology ranging from cerebral blood flow and metabolism to neurotransmitter binding and turnover. Functional imaging has numerous applications in basic and clinical neuroscience, many of which are now in routine clinical use. These techniques may be used to image physiological alterations in the brain that cannot be detected by structural assessment, or to elucidate metabolic changes which underlie structural lesions. The major modalities used for functional imaging of the brain include positron emission tomography (PET), single photon emission tomography (SPECT), and magnetic resonance imaging (MRI). PET and SPECT methods measure the distribution of exogenously administered radioactive tracers, while functional MRI (fMRI) studies primarily utilize endogenous contrast and as such are completely non-invasive. For this reason, over the past 5 years fMRI has begun to replace PET as the technique of choice for mapping regional brain function in response to sensorimotor and cognitive tasks, as well as for imaging alterations in cerebral blood flow and metabolism. However, because of the extreme sensitivity of radioactive tracer techniques, PET and SPECT remain the only means of mapping changes occurring at very low concentrations, such as receptor binding. This chapter will provide an overview of these approaches to physiological imaging of the brain. Applications to neurological diagnosis and management as well as to cognitive neuroscience will also be addressed.

Physiology of regional brain function

A number of cellular and metabolic processes in the brain can be monitored using functional imaging methods, and have relevance to basic and clinical neuroscience. Figure 10.1 illustrates these processes which include neurotransmitter binding and reuptake, glucose utilization (CMRGlu), oxygen metabolism ($CMRO_2$), and hemodynamic parameters of cerebral blood flow (CBF), cerebral blood volume (CBV), and mean transit time (MTT) and time to peak (TTP) for intravascular tracers. Depending on the specific application, some of these parameters may be more relevant than others. For example, studies in cerebrovascular disease have focused on hemodynamic parameters and their effects on oxidative metabolism, as well as on the apparent diffusion coefficient (ADC) in brain, a biophysical parameter available in MRI that reflects early cytotoxic injury. By contrast, functional imaging studies in epilepsy have primarily examined ictal hyperperfusion using CBF imaging and interictal hypometabolism using CMRGlu imaging, and in Parkinson's disease, where brain dysfunction is better understood at a neurochemical level, much of the functional imaging has involved receptor mapping of the dopaminergic system.

In cognitive and systems neuroscience, there has been great interest in using functional neuroimaging to map regional brain function in response to cognitive or sensorimotor tasks. In patients these approaches may also be used to map eloquent function as part of preoperative evaluation for neurosurgical procedures, and for studying reorganization of function following focal brain injury. Nearly all studies of task-specific activation using functional neuroimaging rely on the existence of a coupling between regional changes in brain metabolism and regional cerebral blood flow (CBF), herein referred to as activation-flow coupling (AFC). Changes in blood flow and metabolism occur with excitatory or inhibitory neurotransmission, both of which are energy consuming processes. Surprisingly little is known about the physiology underlying AFC, which was originally described in 1890 by Roy and Sherrington. Studies over the intervening century have yet

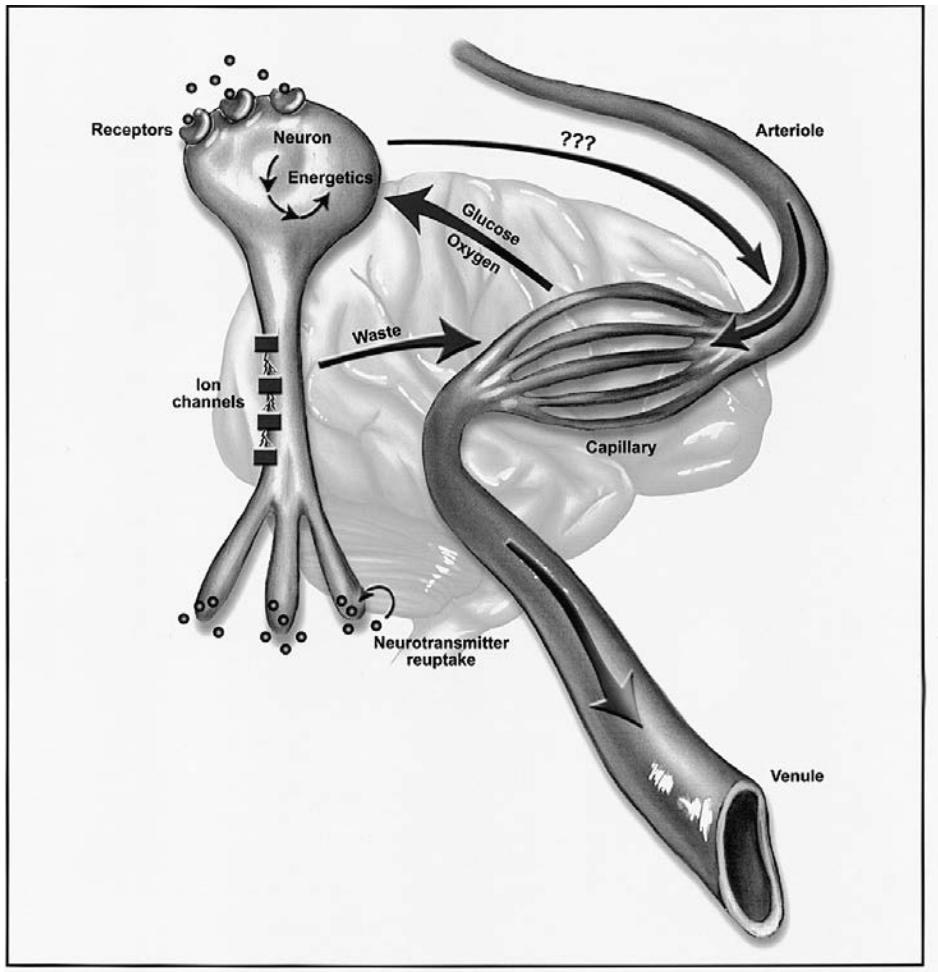

Fig. 10.1. Schematic diagram illustrating the physiological mechanisms which can be visualized by functional imaging. Brain function is represented by a neuron that receives synaptic input, conducts electrical signals by an energy dependent process, and has synaptic output with transmitter recycling. The adjacent microvasculature provides oxygen and glucose to support these functions through perfusion, which also affects local blood volume and blood oxygenation.

to fully characterize the mechanisms and mediators of AFC (Villringer & Dirnagl, 1995). The extent to which non-neuronal constituents of brain parenchyma contribute to the overall metabolic rate is also uncertain, and may be variable. Nonetheless, regional blood flow changes have typically colocalized with known functional specialization.

Functional imaging using radioactive tracers; PET and SPECT

The techniques of PET and SPECT enable the three-dimensional distribution of a radioactively labeled tracer to be measured in vivo. Radioisotopes used in PET imaging decay with the emission of positrons, which travel only a short distance in tissue before annihilating with an electron to form two colinear photons, each with 511 keV energy. In contrast, SPECT tracers emit just a single gamma ray, with energies dependent on the specific radioisotope used. The technology for detecting these gamma rays differs between the two systems, with PET generally having superior spatial resolution and system sensitivity, although SPECT is considerably less expensive, and much more widely available.

The spatial resolution of PET is limited by the range of positrons in tissue, and the slight acolinearity of the emitted gamma rays. Depending on the radioisotope, the absolute limit of resolution is approximately 1.5–2.5 mm, though generally this is not achieved in routine clinical practice. SPECT resolution is limited by the design of the

Table 10.1. Selected radiotracers for PET and SPECT imaging of the brain

Measurement	PET tracers	SPECT tracers
Cerebral blood flow	$H_2{}^{15}O$	[^{123}I]IMP, [^{99m}Tc]HMPAO, [^{99m}Tc]ECD
Cerebral blood volume	^{11}CO, $C^{15}O$	[^{99m}Tc]red blood cells
Oxygen metabolism	$^{15}O_2$	
Glucose metabolism	^{18}FDG	
Dopamine D_1 receptors	[^{11}C]SCH23390, [^{11}C]NNC756	[^{123}I]TISCH
Dopamine D_2 receptors	[^{11}C]raclopride, [^{11}C]NMSP	[^{123}I]IBZM, [^{123}I]IBF, [^{123}I]epidepride
Dopamine synthesis	[^{18}F]DOPA	
Dopamine transporters	[^{11}C]cocaine, [^{11}C]β-CIT, [^{11}C]FP-CIT, [^{11}C]CFT, [^{11}C]methylphenidate	[^{123}I]β-CIT, [^{123}I]FP-CIT, [^{123}I]IPT, [^{99m}Tc]TRODAT, [^{123}I]altropane
Serotonin 5-HT_{1A} receptors	[^{11}C]WAY100635, [^{18}F]MPPF	
Serotonin 5-HT_{2A} receptors	[^{11}C]MDL100907	[^{123}I]R-91150
Serotonin transporters	[^{11}C](+)McN5652	[^{123}I]β-CIT, [^{123}I]5-iodo-6-nitroquipazine, [^{123}I]IDAM, [^{123}I]ADAM
GABA receptors	[^{11}C]flumazenil	[^{123}I]iomazenil
NMDA receptors	[^{18}F]AFA	[^{123}I]MK801, [^{123}I]CNS1261
Nicotine receptors	[^{11}C]nicotine	[^{123}I]nicotine
Opioid receptors	[^{11}C]carfentanil, [^{11}C]diprenorphine	
Gene expression	[^{18}F]FIAU, [^{18}F]FGCV	[^{123}I]FIAU
Brain tumours (various types and modes of action)	^{18}FDG, [^{11}C]methionine, [^{11}C]thymidine	^{201}Tl, [^{123}I]MIBG, [^{111}In]octreotide

collimator, and the distance from the subject to the detector. Most clinical systems can attain a resolution of 6–7 mm, though better resolution is possible with more specialized collimators. The temporal resolution of both systems is poor, as it can take several minutes of scanning to acquire sufficient statistics to form an image. However, despite the poorer spatial and temporal resolution of PET and SPECT compared with other modalities, such as fMRI, their tremendous advantage is their exquisite sensitivity. PET and SPECT can measure picomolar (10^{-12} M) concentrations of tracer, many orders of magnitude less than can be detected with MRI. The quantity of radiotracer injected is tiny, and generally has no effect on the biological system under study.

Radiotracers for PET and SPECT

Many radioisotopes for PET imaging are found naturally in living organisms and are amenable to labeling biologically interesting molecules. These include carbon (^{11}C), nitrogen (^{13}N), oxygen (^{15}O), and fluorine (^{18}F). SPECT radioisotopes tend to be much larger, such as technetium (^{99m}Tc) and iodine (^{123}I), and are more difficult to incorporate into a radiotracer without disturbing the biochemical properties of the molecule. However, SPECT tracers generally have longer half-lives, and are therefore much more widely available than PET radioisotopes, which usually require an on-site cyclotron and production facility. Applications of these imaging technologies have gone hand-in-hand with developments in radiopharmaceutical chemistry. Both PET and SPECT are now capable of imaging biological systems with unprecedented accuracy and sensitivity, mainly due to the tremendous advances in the development of novel radiopharmaceuticals (Table 10.1).

Cerebral blood flow and metabolism

Originally, PET and SPECT were used to measure cerebral blood flow and metabolism. A number of tracers exist which can measure regional cerebral blood flow (rCBF), such as [^{123}I]IMP, [^{99m}Tc]HMPAO and [^{99m}Tc]ECD for SPECT, and $H_2{}^{15}O$ for PET. The SPECT tracers are examples of the 'trapping' mechanism for measuring cerebral function. For a molecule to enter the brain, it must be neutral

and lipophilic which enables it to pass by passive diffusion through the lipid bilayer in the blood–brain barrier (BBB). Once across the BBB, the molecule may become trapped if it interacts with an intracellular component that either reduces its lipophilicity or restricts further free diffusion of the tracer. Chemical instabilities in the ^{99m}Tc-complex in [^{99m}Tc]HMPAO result in the conversion to a less lipophilic species causing sustained retention in brain tissue. Hence, the concentration of tracers such as [^{99m}Tc]HMPAO in the brain are determined by the rate of tracer delivery by the blood supply, giving an indirect measure of rCBF at the time of injection of the tracer. Imaging of rCBF can be carried out at a later time, for example allowing rCBF during brief neurological events such as seizures to be determined without requiring immediate access to the scanner. Conversely, radioactive water, $H_2{}^{15}O$, used for PET measurements of rCBF is unchanged within the brain, freely diffusing across the BBB, and will concentrate in brain tissue at a rate proportional to rCBF. Unlike [^{99m}Tc]HMPAO, which only provides a single 'snapshot' of rCBF, the uptake of $H_2{}^{15}O$ changes over time as the demands for blood flow alter in the brain. This has led to its use as a sensitive and quantitative indicator of changes in rCBF in sensorimotor and cognitive tasks, though fMRI is now becoming more popular in this application.

Blood volume can be measured using a tracer that binds to red blood cells and remains within the vasculature of the brain. For PET, carbon monoxide can be labelled with either ^{11}C or ^{15}O and inhaled, where it will bind tightly to the hemoglobin in red blood cells. Alternatively, SPECT measurements of blood volume can be made using the subject's own red blood cells labelled with ^{99m}Tc. Both techniques give a quantitative measure of regional cerebral blood volume (rCBV). In a similar manner, equilibrium images of inhaled $^{15}O_2$ obtained in conjunction with these measures can yield the rate of cerebral oxygen metabolism ($CMRO_2$).

Another powerful indicator of cerebral function is the measurement of regional cerebral glucose metabolism. Glucose provides approximately 95–99% of the brain's energy requirement under normal conditions, and the rate at which glucose is utilized in different regions of the brain is an excellent indicator of local energy-requiring functions. Glucose is transported across the BBB where it is phosphorylated by the enzyme hexokinase to glucose-6–PO_4. The glucose analogue ^{18}F-labelled fluorodeoxyglucose (^{18}FDG) is a competitive substrate for this phosphorylation stage, where it, too, is converted to ^{18}FDG-6–PO_4. However, while glucose-6–PO_4 undergoes further metabolism, ^{18}FDG-6–PO_4 does not, and becomes trapped in brain tissue, as it cannot diffuse back across cell membranes. The metabolic trapping of ^{18}FDG can be used to derive the cerebral metabolic rate of glucose utilization (CMRGlu).

Measurements of cerebral blood flow and metabolism have been used widely to study a variety of disorders, ranging from cerebral infarct to drug addiction, and Alzheimer's disease (AD) to mood disorders. Large-scale changes in cerebral function can be detected with high sensitivity using blood flow tracers, and remains the gold standard in many diagnostic imaging applications, such as epilepsy (Spencer et al., 1995). However, structural and hemodynamic changes induced by many neurological and psychiatric disorders are generally small, and often only evident when the disease is into an advanced stage. In addition, the changes in cerebral activity measured using rCBF, rCBV, $CMRO_2$, CMRGlu, or any other index of cerebral blood flow or metabolism are highly non-specific. This has led to the further development of specialized radiotracers that enable PET and SPECT to image directly various neurotransmitter systems and the complex interactions between them.

Neuroligand binding studies

Neuroreceptors are proteins in the membrane of neurons, which are sensitive to neurotransmitters, chemicals that transmit signals from one nerve cell to another. Receptors play two key roles; they recognize only certain neurotransmitter(s), and they activate additional events based on that recognition. The interaction of the neurotransmitter with the specific receptor mimics the effects of nerve stimulation, and begins a sequence of events that either excite or inhibit further neuronal firing. The concentration of neurotransmitter within the synaptic cleft is controlled by other transmembrane transporter proteins, which reuptake the chemical back into the presynaptic nerve terminal.

To study receptor binding sites in vivo, several radiolabelled ligands have been developed which selectively bind to specific neuroreceptors or presynaptic reuptake sites (Table 10.1). The uptake and retention of a radioligand depends on a number of factors, such as its lipophilicity, the presence of non-specific binding, the affinity of the tracer for the receptor, and the concentration of available receptors. Most importantly, these radioligands are active competitors with other exogenous and endogenous chemicals for the binding site, a situation that has been used to great effect in many neurotransmitter studies. A compartmental kinetic model can describe neuroligand imaging. The free, unmetabolized tracer present in plasma crosses the BBB into cerebral tissue, where it can bind selectively

to the receptor under study. Simplifications of this kinetic model have been developed, most notably to eliminate the necessity of performing rapid arterial blood sampling (Lammertsma & Hume, 1996). Techniques also have been developed which use a continuous infusion of radiotracer to maintain a constant equilibrium state between specific binding and plasma activity (Laruelle et al., 1993).

Studies of neuroreceptor concentrations in disease initially focused on measuring differences between healthy control subjects and subjects with neurological and psychiatric disorders. In some cases the findings have been unequivocal, such as PET and SPECT measurements of dopaminergic neuronal degeneration in Parkinson's disease (PD) using radioligands which bind to the dopamine transporter (Brooks et al., 1990; Innis et al., 1993; Mozley et al., 2000). More recently, the availability of radioligands for imaging the serotonergic neurotransmitter system have given many insights into depression and other mood disorders (D'Haenen et al., 1992; Malison et al., 1998). However, many disorders, such as schizophrenia, have failed to exhibit the expected changes in receptor densities. This has led investigators away from studies of static receptor systems, in the belief that these disorders may be a result of neurotransmitter system dynamics, rather than simple alterations in receptor concentrations.

Drug challenge studies, using both exogenous and endogenous chemicals to stimulate the neurotransmission process, have yielded new information on several diseases. Many drugs occupy the same binding sites in the brain as the radioligand; reductions in specific binding of a tracer can be interpreted as an increase in the concentration of a competing drug. For example, the modes of action of antipsychotic drugs have been investigated in vivo by measuring the competition between the radioligand and the drug, which both bind to the same dopamine and serotonin receptors (Farde et al., 1992; Pilowsky et al., 1992).

While many interesting results have been obtained by introducing an exogenous drug that competes with the same binding sites as the radioligand, some of the most exciting recent developments have occurred using the endogenous neurotransmitter as the competing drug. If the levels of endogenous neurotransmitter can be manipulated, either chemically or using a cognitive or sensorimotor task, the degree of specific binding of the tracer will change to reflect the alterations in neurotransmitter. Other studies have used drugs to manipulate one neuroreceptor while studying the effects 'downstream' on another, revealing the modulatory effect neurotransmitters have on each other (Smith et al., 1997). Most recently the chemical manipulation of neurotransmitter behaviour was replaced by a cognitive task, where the release of endogenous dopamine as a result of playing a video game was measured using [^{11}C]raclopride and PET (Koepp et al., 1998). This potentially provides an opportunity to study cerebral activation at the neuronal level, where the involvement of each individual neurotransmitter system can be examined during a cognitive or sensorimotor task.

Other PET and SPECT studies

Recent developments in radiopharmaceutical chemistry have opened up entirely new applications for PET and SPECT imaging in the brain. For example, novel radiopharmaceuticals are being created which bind selectively to amyloid plaques in Alzheimer's disease, providing an early diagnostic tool for detecting amyloid deposition long before structural changes become apparent (Zhen et al., 1999). Imaging of gene expression is now possible, particularly in tumors, using reporter genes labelled by reporter probes (MacLaren et al., 1999). The ability to quantitatively and repeatedly measure the expression of particular genes in vivo will become a powerful tool in the study of genetic contributions to disease, and to monitor gene therapy.

Functional imaging using magnetic resonance

Magnetic resonance utilizes electromagnetic rather than ionizing radiation to probe structure and function. The vast majority of MRI utilizes the nuclear magnetic resonance signal of water protons that are present in high concentration in biological systems. Image contrast is derived from variations in the molecular environment of water in various structures and compartments. These contrast mechanisms are summarized in Table 10.2. FMRI simply refers to MRI scanning in which significant tissue contrast can be attributed to changes in blood flow and/or metabolism. For measurement of task activation, such changes are typically of the order of only a few per cent or less of the overall signal intensity. The primary contrast mechanisms used for detecting task activation with fMRI are blood oxygenation level dependent (BOLD) contrast and perfusion contrast obtained using arterial spin labelling (ASL). Because BOLD contrast is easier to obtain and generally provides higher signal-to-noise for task specific activation, it has been widely adopted as the method of choice for imaging regional brain activation using MRI. In contrast to PET methods for mapping task activation which have often relied on a multisubject design, BOLD fMRI provides sufficient sensitivity to reliably carry out studies in single subjects. To maximize temporal resolution and slice coverage

Table 10.2. Contrast mechanisms for functional MRI (fMRI)

MRI contrast	Imaging sequence	Physiological parameter
Dynamic susceptibility contrast (DCS)	T_2*-weighted during administration of MRI contrast agent, typically echoplanar or spiral.	Cerebral blood volume and mean transit time. CBF calculated through central volume principle
Arterial spin labeling	Preparatory radiofrequency labelling of arterial water. Any imaging sequence can be used, typically short TE echoplanar or spiral.	Cerebral perfusion in ml/g min or relative perfusion change
Blood oxygenation level dependent (BOLD)	T_2*-weighted, typically echoplanar or spiral.	Deoxyhemoglobin concentration (represents a complex interaction between CBF, CBV, and oxygen utilization)
Diffusion	T_2-weighted with and without diffusion sensitization gradients, typically echoplanar or spiral.	Apparent diffusion coefficient (ADC) reflects water mobility within voxel; ADC is reduced in cytotoxic injury and across myelinated fiber tracts

as well as to minimize image degradation by subject motion, most fMRI studies utilize ultrafast imaging methods such as echoplanar or spiral techniques in which each imaging slice is obtained in 100 ms or less using a single radiofrequency excitation (Vlaardingerbroek & den Boer, 1996).

For clinical applications, hemodynamic measurements can also be made by following the initial passage of an exogenously administered susceptibility contrast agent through the cerebral vasculature, termed dynamic susceptibility contrast (DSC) perfusion MRI. Since these agents remain intravascular, only mean transit time, time to peak, and blood volume can be precisely measured, while CBF must be estimated using the central volume principle (Sorensen et al., 1997). This approach was used to generate the first report of fMRI in humans during photic stimulation (Belliveau et al., 1991). However, since contrast administration is required for each measurement, its use for task activation studies in humans has waned.

The practical spatial resolution limits of fMRI are currently unknown. While MRI is capable of imaging structures in the micron range, signal-to-noise varies directly with voxel size and signal-averaging time for extremely small voxels would likely be prohibitive for most human applications. In addition, degradation by motion becomes a very significant problem with high-resolution imaging, particularly since even normal physiological motion such as that induced by arterial pulsatility can be of the order of millimeters. The spatial extent of AFC is also unknown, but current thinking is that flow effects are considerably less localized than metabolic effects. However, at least in some brain regions, the vascular supply is organized in a functionally significant manner. This has been demonstrated for rat whisker barrel cortex where the cortical region subserving each whisker appears to have a dedicated microvascular supply (Woolsey et al., 1996). Although these regions are less than 1 mm, it has been possible to visualize them using fMRI in the rat brain at high fields (Yang, Hyder & Shulman, 1996). It has also been possible to visualize similarly sized ocular dominance columns in calcarine cortex in cats (Kim et al., 1999) and in humans (Menon et al., 1997).

Blood oxygenation level dependent (BOLD) contrast

BOLD contrast reflects a complex interaction between blood flow, blood volume, and hemoglobin oxygenation (Ogawa et al., 1998). Functional contrast is obtained because the iron present in hemoglobin becomes paramagnetic only when it is deoxygenated, producing a local susceptibility increase manifested as a change in T2*, among other effects. This change in hemoglobin oxygenation is usually monitored using gradient echo echoplanar sequences which particularly emphasize T2* effects and allow multiple slices to be acquired at rapid intervals. With regional brain activation, a reduction in T2* is observed, reflecting a decrease in regional deoxyhemoglobin which has been attributed to increases in CBF which exceed increases in oxygen metabolism, though the universality and precise basis for this mismatch is uncertain.

A typical BOLD response consists of a 0.5–5% change in regional image intensity which develops over 3–8 s following task initiation. This peak latency of several seconds represents a major limiting factor in the temporal resolution of functional imaging methods that rely on AFC. There is growing evidence that prior to the increase in regional CBF,

there is a more localized decrease in hemoglobin oxygenation, presumably due to a more rapid increase in oxygen utilization than in blood flow (Malonek & Grinvald, 1996), however this subtle effect has been difficult to detect reliably. Sensitivity to T2* increases at higher magnetic field strengths, such that at 4.0 Tesla BOLD peak signal changes may approach 25% with sensorimotor tasks. This increased signal can be used to improve sensitivity or spatial resolution. Higher field strengths may also increase the sensitivity for detecting the initial decrease in BOLD signal. Task specific BOLD signal changes are not directly quantifiable in physiological units, but rather are expressed as a percentage signal change or as a statistical significance level based on a particular statistical model. Absolute or resting function cannot be easily assessed, and for clinical studies it may be difficult to know whether any observed abnormalities are due to baseline or task-specific effects.

Perfusion MRI

Classical perfusion can also be measured directly using endogenous contrast with ASL (Detre & Alsop, 1998). This class of techniques utilizes electromagnetically labelled arterial blood water as a diffusible tracer for blood flow measurements, in a manner analogous to that used for $^{15}0$ PET scanning. The 'electromagnetic' tracer has a decay rate of T1, which is sufficiently long to allow perfusion of the microvasculature and tissue to be detected. This form of image contrast can be sampled with any imaging sequence. ASL techniques are capable of quantifying cerebral blood flow in well-characterized physiological units of ml/100 g min, or may be used in a qualitative fashion similar to that used in BOLD fMRI. The development of multislice ASL (Alsop & Detre, 1998) has considerably enhanced its utility. The use of ASL methods for imaging task activation has been less widespread than BOLD methods because these techniques produce a lower signal change for activation and are somewhat more difficult to implement. However, potential advantages of ASL approaches include greater temporal stability due to absolute quantification of flow changes, direct comparison with PET rCBF studies, and the possibility of detecting activation in the presence of high static magnetic susceptibility.

Diffusion MRI

Diffusion weighted MRI (DWI) uses large magnetic field gradient pulses to spatially label tissue water, allowing its microscopic motion over tens of milliseconds to be measured (Le Bihan et al., 1986). The resulting apparent diffusion coefficient (ADC) reflects a weighted average of intracellular and extracellular water, and the shift from extracellular to intracellular water which occurs during early cytotoxic injury results in a large signal change using this contrast (Moseley et al., 1990). DWI and perfusion MRI are now in fairly routine use in hyperacute stroke evaluation (Baird & Warach, 1998; Neumann-Haefelin et al., 2000). Directional effects also occur in DWI due to anisotropy of microscopic diffusion of water in white matter tracts, an effect that has high sensitivity to changes in fibre tract myelination. By separately measuring diffusion effects using orthogonal gradients for diffusion sensitization, a diffusion tensor image can be generated which reflects fibre orientation (Pierpaoli et al., 1996) and may be used to examine connectivity between brain regions.

Mapping cognition with functional imaging

Perhaps the greatest promise for functional neuroimaging is to elucidate mechanisms of higher cognitive function. This pursuit has intensified with the advent of fMRI because it affords a sensitive and inexpensive means of detecting task-specific regional brain activation. Since hemodynamic changes occur on a drastically longer timescale and with considerably poorer spatial localization than neuronal firing, and since the mechanisms of coupling between neural activity and hemodynamic changes remain to be completely understood, cognitive mapping using functional imaging remains an indirect link to neural function. While considerable effort is now being given to determining the relationship between neural activity and hemodynamic effects as well as the spatial and temporal resolution limits of functional imaging, the strategies for making inferences about cognitive function based on imaging experiments are still being developed. At present, cognitive brain mapping experiments are most effective for determining the locations of task activation rather than their magnitude or relative contributions to overall task performance. Identification of the ventral 'what' and dorsal 'where' streams in visual function is an example of cognitive processing mechanisms that were elucidated at least partly through functional neuroimaging (Ungerleider & Haxby, 1994).

Paradigm design for cognitive brain mapping

Because PET studies of regional brain activation have poorer temporal resolution than fMRI, most PET activation studies have examined differences in regional brain

activation during blocks of repetitive stimuli of differing types. Subtraction of blocks of stimuli differing in a single cognitive process is then used to determine the localization of that process. For example, activation during reading of pseudofont words might be subtracted from reading true font words to determine brain region involved in written language processing. Based on this tradition, early fMRI studies also used blocked-trial designs with alternating epochs of task and control conditions, each consisting of multiple trials. This approach maximizes sensitivity, since large signal changes are sustained, and also minimizes the requirement of an accurate estimate of the hemodynamic response.

More recently, many investigators have explored techniques that allow fMRI responses to individual task stimuli to be segregated (Buckner et al., 1996). These approaches allow different classes of stimuli to be randomized, reducing habituation effects, and also facilitate retrospective analysis of fMRI data based on subject performance on individual trials (Brewer et al., 1988; Wagner et al., 1998). Thus, regional brain activation following only correctly or incorrectly performed trials can be compared across subjects or across control and patient groups, independent of overall performance on the task. However, the results of individual trial analysis may depend heavily on the assumed neural activity and AFC response.

A fundamentally different approach to functional brain imaging in clinical populations which circumvents the issue of task performance is to correlate specific neurocognitive deficits with alterations in resting brain function using quantitative functional imaging such as CBF measurements using ASL techniques (Alsop et al., 2000). Since only resting perfusion is measured, the interpretation of the imaging data is not confounded by task performance. This approach is also applicable to structural imaging data (Mummery et al., 2000).

Analysis of functional activation data

Task-specific functional activation is typically determined by statistical analyses of time series data with respect to the administered task. This can be accomplished using a simple correlation analysis, though multiple linear regression methods (Friston et al., 1994) including a variety of confounds now more common, and non-parametric approaches as well as task-independent approaches are being developed. Linearity between neural activity and AFC responses is often assumed in these analyses, though deviations from linearity clearly occur. For both resting and activation studies, time series data must be examined and corrected for motion effects. Task-correlated motion may be particularly difficult to distinguish from functional activation. A thresholded statistical map is ultimately superimposed upon high-resolution anatomical images or other representations of the brain. Thresholding for significance is complicated, and requires consideration of spatial and temporal autocorrelation in the data as well as false positive activation that may result from multiple comparisons, since three-dimensional images may contain thousands of pixels.

Comparison of functional localization across subjects presents yet additional challenges in the interpretation of clinical functional neuroimaging studies. Many such comparisons have been accomplished through the use of transformation into standard neuroanatomical spaces such as Talairach space (Talairach & Tournoux, 1988), though more complicated algorithms are available, including those which attempt to unfold cerebral gyri. These algorithms rely on characteristic signal intensities of gray matter, white matter, and cerebrospinal fluid that can be altered in the presence of lesions such as tumours, strokes, or focal atrophy. When lesions are large, they may distort the brain sufficiently to make automated or semiautomatic morphing into a standard space impossible.

Functional imaging in neurological diagnosis and management

Functional imaging techniques have been applied to nearly every category of central nervous system disorder, with variable results (Detre & Floyd, 2000). This section will focus on selected applications in which functional imaging has successfully contributed to neurological differential diagnosis or patient management.

Presurgical localization of function

Since fMRI provides sufficient sensitivity to map functional activation within a single subject, one of the earliest clinical applications of fMRI was the localization of motor cortices with respect to brain tumours requiring neurosurgical resection. In several studies, fMRI localization of finger tapping paradigms has been compared with cortical stimulation. Since cortical stimulation is essentially a 'lesion' study confined to the superficial cortex while BOLD fMRI measures endogenous function throughout the brain, these modalities may be expected to differ somewhat in functional localization. Nonetheless, an excellent correlation has been consistently found between regions of motor activation seen on BOLD-fMRI and intraoperative cortical stimulation (Yetkin et al., 1997).

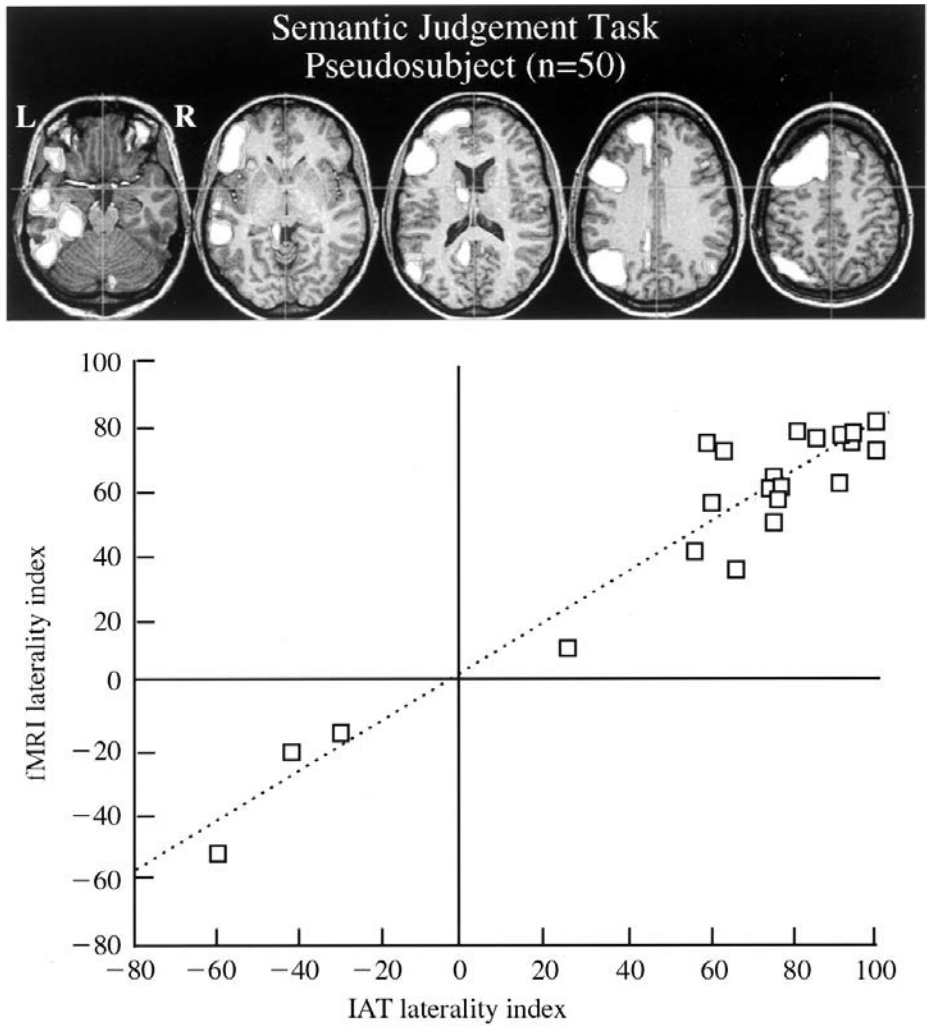

Fig. 10.2. FMRI lateralization of language and comparison with intracarotid amobarbital testing. These studies utilized a semantic judgement task with a tone sequence judgement task as a baseline. The top panel shows averaged fMRI task activation from 50 normal right-handed subjects, demonstrating left hemisphere lateralization of language-related activity. The scatter plot below shows the strong correlation ($r = 0.96$, $P < 0.0001$) between an IAT language laterality index and an analogous index based on fMRI in 22 epilepsy patients. (These data are presented courtesy of Dr Jeffrey Binder.)

FMRI has also been compared to intracarotid amobarbital testing (IAT) for presurgical lateralization of language and memory in several studies. While the IAT has been the gold standard for identifying lateralization of language and memory function preoperatively, it is invasive and carries significant risks. Further, fMRI offers the capability of spatially resolving functional activation within each hemisphere, potentially guiding tailored resections to spare eloquent cortex. Successful functional activation studies using motor and language tasks have been reported in partial complex epilepsy by several groups. Binder et al. (1996) reported a cross validation study comparing language dominance determined by both fMRI and IAT in 22 epilepsy patients. Examples of fMRI lateralization of language are illustrated in Fig. 10.2. A semantic decision task was used to activate a distributed network of brain regions involved in language specialization. Excellent agreement in language laterality was observed in this and other studies, though there has been some controversy concerning the optimum task for lateralizing language. A complex visual scene encoding task has been used to lateralize mesial temporal lobe memory dysfunction in patients with temporal lobe epilepsy, and showed a good correlation with memory lateralization by IAT in preliminary studies (Detre et al., 1998).

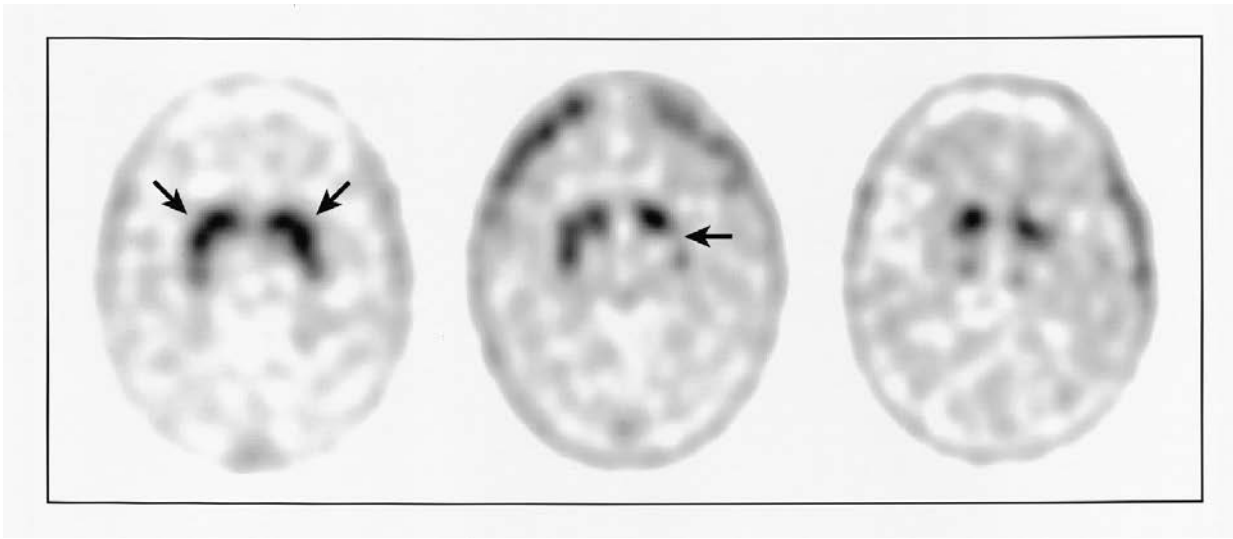

Fig. 10.3. SPECT images of [^{99m}Tc]TRODAT-1 binding to dopamine transporters in the striatum. The healthy subject (*left*) shows high uptake in the striatum (arrows), while patients with progressively more severe Parkinson's disease exhibit unilateral (arrow, *centre*) and bilateral (*right*) degeneration of dopaminergic neurons, and a reduction in tracer binding. (Images courtesy of Dr David Mozley, University of Pennsylvania.)

Functional imaging has also contributed to the localization of seizure foci. Interictal hypometabolism measured using FDG-PET is now widely accepted in clinical lateralization of temporal lobe epilepsy (Duncan, 1997). Ictal events can be localized using HMPAO-SPECT, as noted above, as well by fMRI with (Krakow et al., 1999) or without EEG triggering (Detre et al., 1995). Localized changes in tissue diffusion have also been observed in patients with focal status epilepticus (Lansberg et al., 1999).

Parkinsonian syndromes

PET and SPECT imaging of the dopaminergic system in the differential diagnosis of parkinsonian disorders may become the first routine clinical application of neuroligand imaging (Fig. 10.3). Studies of neuronal degeneration in the nigrostriatal pathway, using tracers that bind to dopamine transporters, have nearly 100% accuracy in diagnosing some forms of neurodegenerative disease (Brooks, 1997). The diagnosis at an early stage in the progression of PD, even before clinical symptoms have become apparent, is possible, although differentiating PD from other parkinsonian disorders, such as multiple system atrophy, progressive supranuclear palsy, or Huntington's disease, may require multiple imaging modalities or combinations of tracers.

Early diagnosis may become increasingly important once the genetic contribution to parkinsonian disorders is fully understood. PET and SPECT imaging are beginning to make important contributions to the understanding of the pathogenesis of PD, and may be able to elucidate the role of other neurotransmitter systems, such as NMDA and GABA, in the onset and progression of PD (Acton & Mozley, 2000). Longitudinal studies of patients undergoing treatment, whether by neuroprotective drugs or surgical intervention, will become increasingly important in the assessment of treatment efficacy, and also to determine the exact mode of action of each therapy.

Dementia

Post mortem studies have shown a high degree of misdiagnosis of dementia using clinical symptoms alone. This has led to a growing trend to use imaging techniques to provide a more accurate, unbiased diagnosis, and to assess treatment efficacy. PET and SPECT imaging in dementia generally measure reductions in cerebral blood flow or metabolism resulting from the disease, using tracers such as $H_2{}^{15}O$, [^{99m}Tc]HMPAO and ^{18}FDG (Frey et al., 1998). A pattern of hypoperfusion and hypometabolism in temporoparietal brain regions, with frontal changes occurring as the condition deteriorates, has been established in Alzheimer's disease (Fig. 10.4). Abnormalities on functional images may precede cognitive defects, raising the possibility of using PET and

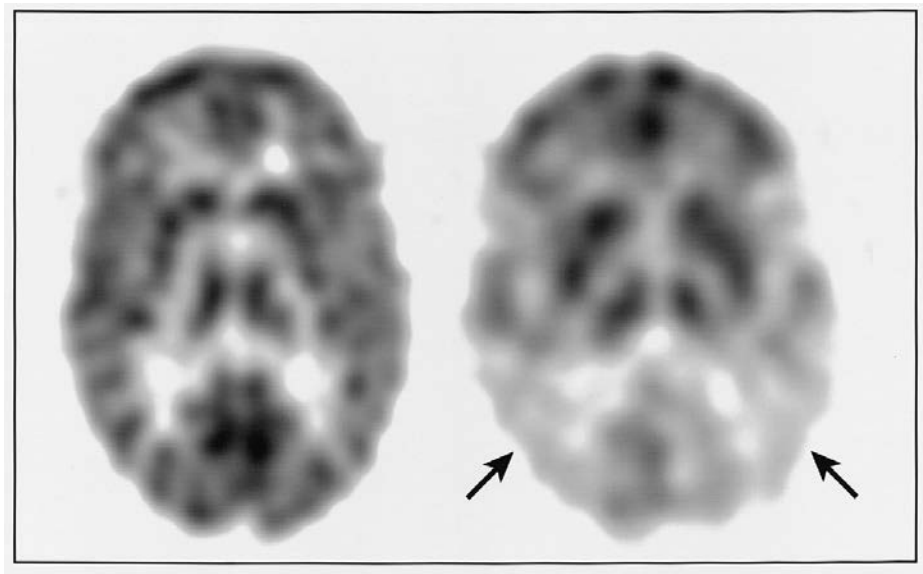

Fig. 10.4. Comparison of cerebral glucose metabolism, measured using ^{18}FDG and PET, in a normal healthy subject (*left*) and a patient with Alzheimer's disease (*right*). The pattern of hypometabolism reflects neuronal degeneration in the temporoparietal regions (arrows), which is consistently found in AD. (Images courtesy of Dr David Mozley, University of Pennsylvania.)

SPECT in the early, presymptomatic diagnosis of dementia (Rapoport, 1997). Some studies suggest that functional imaging with PET or SPECT is superior to structural imaging in the diagnosis of some dementias, particularly Alzheimer's disease.

Tumour imaging

Functional imaging plays an important role in brain tumour management due to the difficulty in differentiating post-therapy residual viable tumour tissue from local recurrence and necrosis using structural imaging. One of the most useful radiotracers for imaging tumours of almost any kind is ^{18}FDG, which takes advantage of the dramatic increase in glucose metabolism in tumour cells. PET imaging of the brain with ^{18}FDG is capable of the early detection of tumours, provides information on the staging and response to therapy, and is a good prognostic indicator. However, due to the high uptake of ^{18}FDG in normal brain tissue, the tumour-to-background ratios can be quite low. Alternatively, labelled amino acids, such as [^{11}C]methionine, or indicators of excessive DNA fabrication, such as [^{11}C]thymidine, provide high contrast images of many brain tumours, and can distinguish between viable tumour and radiation necrosis.

Radioactive thallium (^{201}Tl) has been used extensively for SPECT imaging of tumours. While the exact mechanism of thallium uptake by tumour cells is not clear, it provides very high contrast images of brain tumours. Thallium imaging provides good diagnosis and staging of malignant disease, clear delineation between viable tumour and cell necrosis, and is used to assess the response to chemotherapy and radiation treatment. Other SPECT tracers, such as MIBG, have been shown to be effective diagnostic tools for neuroblastomas and other neural crest tumours, and even can be administered in much larger radiation doses for radiotherapy. More recently, attention has focused on the overexpression of certain types of receptors by tumours. In particular, many tumours express somatostatin receptors, which has been used to great advantage in the development of radiolabelled somatostatin analogues, which bind selectively to these receptors and can be used to image many types of brain tumour.

Cerebrovascular disease

Functional imaging has been used extensively in cerebrovascular disease and acute stroke in an attempt to better characterize physiological changes accompanying brain ischemia, identify brain tissue at risk for infarction, and predict outcome. Studies of patients with stroke using ^{15}O PET measures of CBF, CBV, and oxygenation characterized the pathophysiology of cerebral ischemia, with initial autoregulation of CBF though vasodilatation, followed by hypoperfusion with increased oxygen extraction fraction (OEF) and finally decreased $CMRO_2$ and infarction (Heiss &

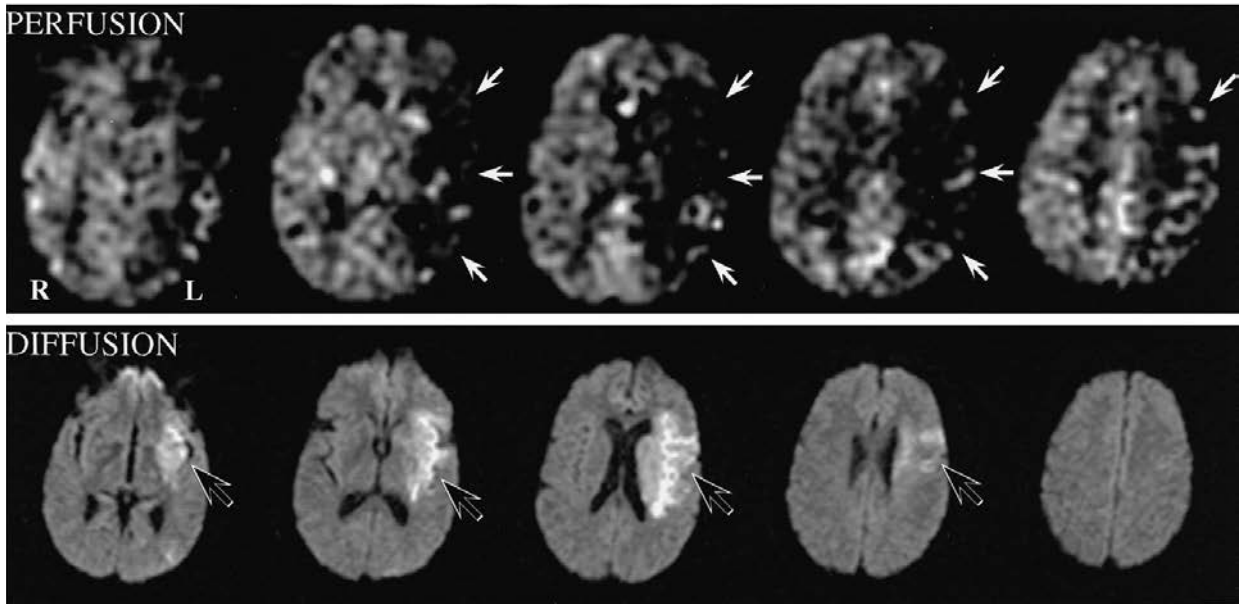

Fig. 10.5. Perfusion and diffusion MRI in a patient presenting with acute right hemiparesis and aphasia. Top panel: Perfusion MRI obtained using ASL demonstrates hypoperfusion throughout the left middle cerebral artery distribution (white arrows). Bottom panel: Diffusion MRI demonstrates a somewhat smaller region of cytotoxic injury (black arrows). Images are in radiological orientation (left is on the right).

Podreka, 1993). In chronic cerebrovascular disease, an increased OEF predicts an increased stroke risk (Grubb et al., 1998) and suggests a need for therapeutic intervention such as revascularization. Since PET scanning remains limited to only a few academic centres, over the past decade much interest has been focused on more widely available imaging modalities. A reduced CBF response to acetazolamide or carbon dioxide measured using computer-assisted tomographic (CAT) scanning with xenon or perfusion MRI has recently been used as an indication of hemodynamic compromise, and also indicates an increased stroke risk (Webster et al., 1995). While the relative contribution of primary hypoperfusion versus thromboembolism to stoke incidence remains controversial, it is hoped that these approaches can also be used to improve patient selection for interventions such as angioplasty or carotid endarterectomy.

The demonstration of effective thrombolytic therapy for hyperacute stroke has intensified the need for rapid assessment of regional brain physiology in stroke patients. This application of functional imaging would ideally be obtained in only a few minutes and would confirm the presence of ongoing ischemia, indicate the risk of hemorrhage following thrombolysis, and replace symptom duration as the determinant of reversible versus irreversible brain injury. There is also a rationale for using functional imaging to measure the effects of novel neuroprotective therapies in acute stroke, since clinical measures have thus far failed to detect any incremental benefits. MRI scanning with diffusion and perfusion contrast, along with magnetic resonance angiography, currently appears best suited for these purposes (Tong & Albers, 2000), though CT scanning with xenon perfusion and computed tomographic angiography also shows promise in this regard. An example of MRI scanning in a patient with acute stroke is illustrated in Fig. 10.5.

Recovery of function

Several groups have used functional neuroimaging to explore changes in functional brain organization in response to focal lesions such as stroke. Utilizing PET in humans after deep capsular infarcts, Weiller and Chollet (Chollet & Weiller, 1994) identified increased cerebral blood flow in bilateral premotor and supplementary motor areas, in unaffected primary motor cortex and along the rim of the cortical infarct, suggesting a hierarchical network of compensatory function. Some of this activation was ultimately attributed to mirror movements in the unaffected limb. FMRI studies in motor recovery have largely confirmed prior PET results with activation of a motor network in the unaffected hemisphere to a greater extent than found in

controls, increased degree of supplementary motor area activation, and perilesional activation. The location of ipsilateral motor cortex activation both in normals and following stroke appears to be ventrolateral to the region which is activated by contralateral movements (Cramer et al., 1999), suggesting that it may correspond to a separate motor homunculus. Although perilesional recovery of function has been confirmed by cortical and cellular electrophysiological methods in animals and using transcranial stimulation in humans, it remains difficult to conclusively prove that all of the perilesional effects observed with fMRI are functionally significant. Some apparent activation observed using blood flow as a surrogate marker for neural function might actually reflect vascular reorganization following ischemic brain injury.

In patients with stroke and aphasia, spontaneous redistribution of function to the right hemisphere has frequently been observed within days of the stroke. However, a prospective PET study of language activation in patients with acute left hemispheric stroke concluded that although right hemispheric activation clearly occurred, recovery of useful language only correlated with left hemispheric activation (Heiss et al., 1997). These results highlight the difficulties of interpreting regional activation in terms of being either necessary or sufficient for supporting a given cognitive or sensorimotor function.

Neuroimaging techniques have also been used to study the dynamic reorganization of function following amputation. In animal models, cortical sensory organization has been shown to occur within minutes. In human amputees, the somatotopic representation of the phantom limb may be activated by stimulation of other body regions such as the face. Since phantom limb effects probably occur independently of any alteration in cerebral vasculature, interpretation of fMRI findings in terms of neural reorganization is perhaps more convincing.

An emerging application of fMRI is in brain bionics. Implantable stimulators are now used in the management of a variety of neurological syndromes including Parkinson's disease, epilepsy, and chronic pain. It is possible to use fMRI to visualize the hemodynamic effects of neurostimulation (Rezai et al., 1999). FMRI can also be used to guide the placement of electrodes into brain regions under conscious control such as motor cortex. Such electrodes have been used to control computerized robotics in paralyzed patients (Kennedy & Bakay, 1998), and fMRI should also be of use in monitoring functional reorganization resulting from brain-electrode interactions.

In conclusion, functional imaging techniques provide numerous approaches to visualizing regional brain activity non-invasively, and are sensitive to a broad range of physiological and neurochemical processes. These techniques have numerous applications in basic and clinical neuroscience and should provide new insights into brain organization and function. Because the technology for functional imaging of the brain is now widely available, its impact on neurological diagnosis and management could be substantial.

Nuclear magnetic resonance (NMR) spectroscopy is an observational technique based on detection of signals from magnetic atomic nuclei such as ^{1}H, ^{31}P, ^{13}C, ^{15}N, and ^{17}O. It is most familiar to physicians and the public as magnetic resonance imaging (MRI), which uses the strong signal from water protons to make the most highly detailed pictures of living tissue available from any non-invasive method. In consequence, MRI, including its special forms magnetic resonance angiography, diffusion-weighted imaging, and magnetization transfer imaging – quickly became a major tool for medical diagnosis and research on living creatures. Its applications to neurological disease are described in several other chapters of this book.

Magnetic resonance spectroscopy (MRS) is the designation used in the biomedical world for measurement of NMR signals from non-water protons and other magnetic nuclei. The usage is not accurate, MRI is the MRS of water, but it is convenient. MRS signals detectable in living brain are thousands of times weaker than the water proton signal; hence observing them requires extra time and special procedures. The reward for the effort is an abundance of chemically specific information which can be acquired as often as necessary, since the measurement process is non-invasive. In the living human brain, ^{1}H signals can be obtained from *N*-acetyl aspartate, creatine, choline moieties, glutamate, glutamine, lactate, and several other small molecules. Phosphocreatine, adenosine triphosphate, and inorganic phosphate can be measured directly by their ^{31}P signals, and intracellular pH calculated from its effect on these signals. Information from the ^{31}P spectrum allows calculation of the rate of the creatine kinase reaction. The spectra of ^{13}C, ^{15}N, ^{17}O, and other magnetic nuclei contain many more small signals from a variety of molecules which will become detectable as technology advances.

This unprecedented measurement capability provides an opportunity for characterization of human neurological diseases along several axes of chemical variation throughout their natural histories. The data are obtained without hazard to the patient, are free from artefacts of tissue preparation, and can be compared in as much detail as necessary to identically acquired information from normal subjects. As MRS matures technically over the first decades of the twenty-first century, it can be expected to take a place among the principal technologies contributing to illumination of disease processes and evaluation of new treatments.

For these reasons, MRS had become well established as an important research technology in neurology and neuroscience by 2001, but not yet as a diagnostic resource necessary for much of neurological practice, as MRI had been for some years. That is likely to change. The wealth of MRS data accumulated on diseases of the human brain since the mid-1980s indicates several possible avenues to routine diagnostic application. As this literature is far too extensive to review here, we emphasize three aspects of MRS which we believe will flourish during the years following publication of this volume, producing novel data of interest to most neurologists. These are: spectroscopic imaging (SI), a way of mapping anatomical distribution of specific compounds in the brain; measurement of γ-aminobutryic acid (GABA) in the ^{1}H spectrum; and labeling of brain metabolite pools with ^{13}C.

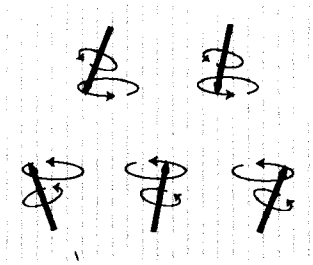
We first present a brief account of how NMR measurements are made, the signals available in the ^{1}H spectrum, localization methods, and some highlights of ^{1}H MRS findings in neurological disease.

The physical basis of NMR measurements

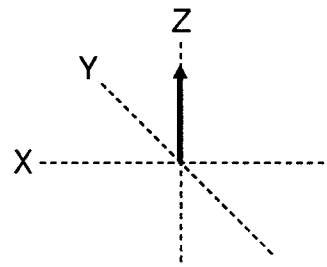
Figures 11.1 and 11.2 (see colour plate section) illustrate in cartoon form one common way of making basic NMR

1 Certain atomic nuclei are magnetic; ^{1}H, ^{31}P, ^{13}C, ^{15}N & ^{17}O are examples of biological interest. They behave like small compass needles which spin around their own long axis, even when bound to other atoms in molecular structures:

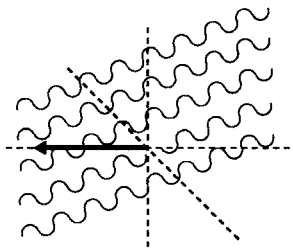
2 In the strong magnetic field of an NMR spectrometer, they line up along the flux lines in a Boltzmann distribution, a few more with the field than against it, and their spins cause them to precess around the flux lines:



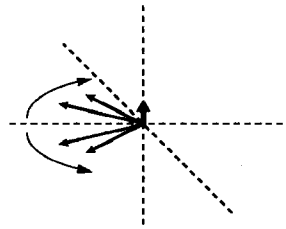
3 The net magnetization of such a spin population is a vector parallel to the flux lines, along the magnet's Z axis:



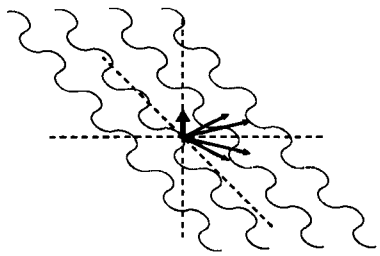
4 For measurements by the common spin echo method, an additional small magnetic field rotating near the precession frequency of the spins is applied briefly to tip the vector in the X–Y plane:



5 Slight differences in precession frequency due to magnetic field inhomogeneities cause spins to spread out in the X–Y plane (dephase), up spins one way, down spins the other (T2 relaxation), while some return to the Z axis (T1 relaxation):



6 Another kind of brief magnetic pulse flips spins still in the X–Y plane by 180 degrees:



7 Because spins still in the X–Y plane continue to precess in the same direction, their net magnetization refocuses as a vector along –X:

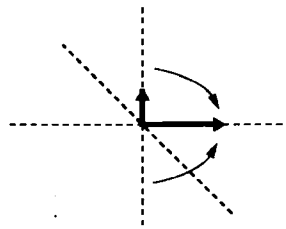


Fig. 11.1. NMR principles.

measurements, the spin echo technique, and the general procedure by which images are generated from NMR data. Many variations on these basic techniques exist, and new ones are constantly being developed.

Several aspects of NMR technology not evident in the cartoons are important for understanding both its power and its limitations:

MRS sensitivity is low

The Boltzmann distribution illustrated in panel 2 of Fig. 11.1 actually produces a difference between up and down spins not in the 2: 3 ratio shown, but only about 1 part in 10^6. The strength of NMR signals is proportional to the size of the difference, which is why they are weak. For this reason, MRS of the human brain cannot detect compounds below the millimolar range under most circumstances. Methods for temporarily increasing the polarization difference of spin populations are under development, but so far only for increasing the signal obtainable from inhalable gases used as MRI contrast agents.

MRS signals come from small, mobile chemical entities

Only molecules which tumble freely in solution or especially mobile parts of large fixed molecules yield signals large enough to detect in living tissue. Hence free glutamate and aspartate can be detected, but the same molecules are invisible when their movement is constrained by incorporation into proteins. Together with the inherent insensitivity mentioned above, this limitation precludes MRS measurement of many important brain substances, such as biogenic amines, acetylcholine, and most membrane structural elements.

MRS and MRI are sessile, motion-sensitive techniques

All measurements must be made in a large, heavy magnet which usually remains in a fixed location. Subjects must lie nearly motionless in the magnet bore while measurements are made, which can be an hour or more for MRS, due to the small size of the signals. These conditions circumscribe the range of physical activity that can be incorporated into study design essentially to small finger and toe movements.

MRS and MRI are safe

Because the Boltzmann difference between up and down spins is so small, only a small amount of energy is necessary to perturb the spin population for measurements. Neither that injected magnetic energy nor the static magnetic field used to align the spin population has any deleterious effect on living tissue. The major hazard to subjects is from movement of ferromagnetic objects within or near their bodies caused by the static field and is easily avoided by adherence to safety procedures.

Stronger magnetic fields give better measurements

The static magnetic field represented by vertical lines in panel 2 of Fig. 11.1 determines the strength of NMR signals and the degree to which signals from different chemical entities are resolved (separated) from each other. For most biomedical applications, the stronger the field, the higher the quality of the information that can be obtained. By 2001, the standard field for clinical MRI machines had reached 1.5 tesla, or about 30 000 times as strong as the terrestrial field which aligns a compass needle. Much stronger fields have been used for in vivo animal research for years with no indication that they damage tissue. Several dozen human research instruments with fields ranging from 2 to 8 tesla exist and have been shown to improve brain MRS signal quality. The outer limit of practical field strength is not yet known; it may be dictated more by instrument cost than by safety considerations.

The ^{1}H spectrum

Figure 11.3 is a ^{1}H spectrum acquired from a small volume of cat brain in a 2 tesla instrument. With special effort, spectra showing this degree of detail can be obtained from human brain at 1.5 tesla, but they are routine in the 2–7 tesla machines that were becoming available in research facilities by 2001. The figure therefore illustrates what can reasonably be expected from ^{1}H MRS over the decade or so following publication of this volume.

The spectroscopic signatures of several distinct molecules are evident in Fig. 11.3. The strongest determinant of signal intensity is the tissue concentration of the molecule that generates it, although the relaxation times T1 and T2 (see panel 5 of Fig. 11.1) of each signal also influence signal intensity and depend on conditions of signal acquisition. Apart from the water signal, which was selectively reduced by acquisition procedures, the strongest signal in the figure is from *N*-acetylaspartate (NAA). This amino acid of unknown function is present in neurons but not glia of normal mature brain at a concentration of 7–10 mmole/kg of tissue. The other labelled signals identify compounds that are consistently detectable in ^{1}H spectra of human

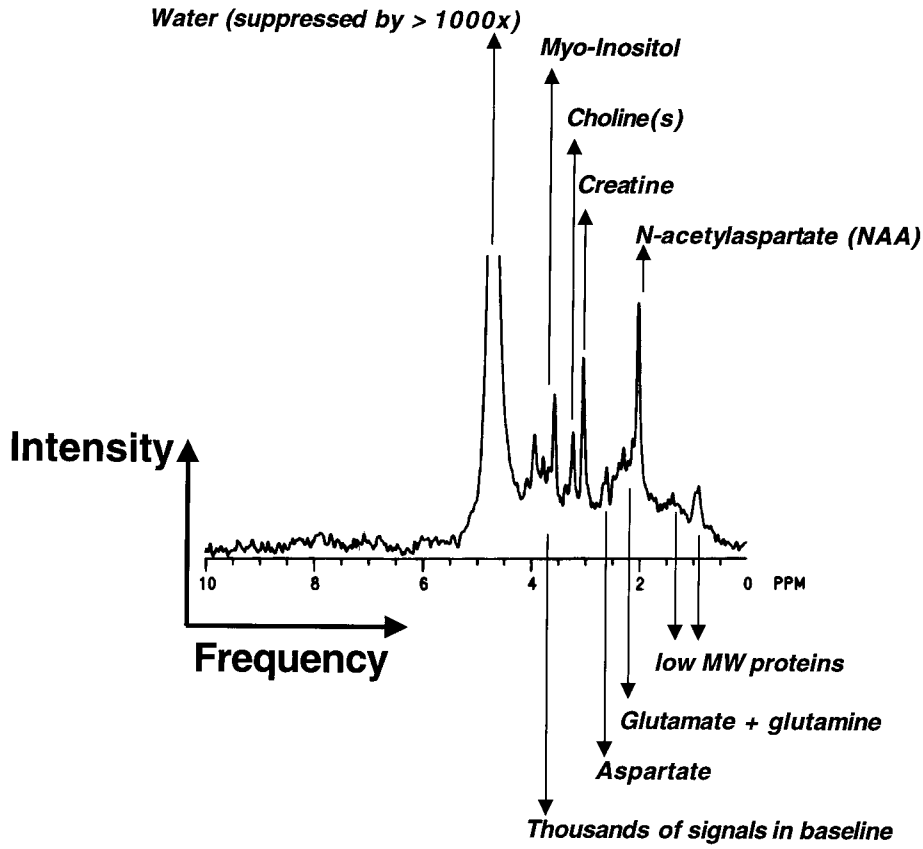

Fig. 11.3. Proton (^{1}H) spectrum of living cat brain obtained at 2 tesla. PPM: parts per million; standard units for expressing 'chemical shift', the displacement of resonant signals relative to that of a reference compound.

brain in standard 1.5 tesla clinical instruments equipped with MRS capability.

Spectral noise defines one ultimate limit on signal detection. This can be appreciated by comparing the NAA signal to the noise level that is most obvious in the leftmost portion of Fig. 11.3. Signals from a molecule with the same spectral properties but present at a concentration only 1/10th that of NAA would be barely discernible above noise, and signals only a little weaker would not be detectable at all. Metabolite detection threshold can be lowered by signal-to-noise ratio improvements achieved by time averaging or enlargement of the sampled volume. Averaging of repeated signal acquisitions tends to cancel the noise while accentuating signals that are the same every time. A bigger sampled volume increases the number of nuclei which contribute to the signal. Both procedures are quite useful in practice, but each brings its own new set of limitations: averaging degrades temporal resolution and increases the risk of movement artifact; larger volumes reduce anatomical resolution and may mix together signals that actually have different properties. The optimum balance among these factors must be matched specifically to each application.

Spectral crowding also complicates isolation of signals from individual molecular species. Many atomic nuclei transmit on very nearly the same frequency, and their signals overlap each other. The broad hump from about 0.5 to 5.5 ppm in Fig. 11.3 is the sum of thousands of small signals from a variety of molecules. Selective extraction of a single signal from many overlapping ones is sometimes possible by spectral editing procedures which exploit some property possessed only by the desired signal. The GABA detection scheme illustrated in Fig. 11.6 is an example of such a strategy, in that case based on selective magnetic perturbation of the C3 protons in a way that changes their influence on the C4 protons and distinguishes the signal of the latter from overlapping ones. Glutamate, lactate, and some other molecules can be detected selectively in similar fashion, but many more, including NAA, creatine, cholines, and myo-inositol among the large signal sources

in the ^{1}H spectrum, lack features of chemical structure which make editing of their signals possible. When signals of that kind change during brain activity or under the influence of disease, any combination of changes in the overlapping signals may be responsible; interpretation must therefore be guided by independent information about of how many overlapping signals are present and how the molecules generating them behave under the particular circumstances of the observation.

Signals from larger and less mobile molecules such as proteins, nucleic acid polymers and proteolipid aggregates are of special importance in this regard. Compounds with molecular weights greater than about 1000 daltons usually produce signals with very short T2 and very long T1. Because of short T2, their signals do not persist long enough to be measured accurately without a great deal of averaging of responses to repeated stimulations, and even when they are detectable, they are very broad, overlapping each other and the narrow signals from smaller, more mobile molecules. At the same time, their long T1s require long waiting times between successive stimulations. Both factors reduce the signal-to-noise ratios that can be achieved in a given time and thereby limit the ability of MRS to detect macromolecular signals selectively.

In one way, the low signal-to-noise ratio of macromolecular resonances is an advantage for measurement of the narrow signals in Fig. 11.3. If the intensity of myelin signals were proportional to myelin concentration, ^{1}H spectra from brain would be overwhelmed by them, and most of the observations described in this chapter would be extremely difficult or impossible. This does not happen because myelin protons have an extremely short T2 relaxation time.

But in another way, broad macromolecular signals complicate quantitative measurement of narrow ones, because they are a potentially variable baseline on which the latter are superimposed. Methods are under development for determining whether an apparent change in a narrow signal is actually due in whole, or in part, to changes in macromolecular signals underlying it.

Signal localization

Matching the spatial resolution of MRS to the anatomical heterogeneity of the brain well enough to permit reliable measurement of localized functional and disease effects on brain chemistry has absorbed the effort of many spectroscopists since human MRS research began. The problems are the same in principle as the ones encountered in the quest for ever greater anatomical resolution in MRI, which is below 1 mm; but because MRS signals are so much smaller than the water proton signal, resolution in the millimetre range is hard to achieve.

For most of its history, MRS was possible only on single volumes of brain. Recently, acquisition from multiple volumes simultaneously has become practical by techniques usually referred to as chemical shift imaging or spectroscopic imaging. The characteristics of the single volume approach make the advantages of the multiple volume approach clear.

Single volume MRS

Spectra can be acquired from single cubic or rectangular tissue volumes down to about 2 cubic centimetres, localized to a region of interest with the help of a guiding MRI. Appropriately equipped commercial MRI machines can acquire localized spectra from volumes of that size or larger in automated fashion, once the desired volume is selected.

Localized single volume MRS has distinct advantages and disadvantages. The principal advantage is that it provides a single spectrum from a tissue volume defined by MRI in a few minutes. The characteristics of the acquisition can be adjusted to permit a number of spectroscopic features to be accentuated. For example, it is usually possible to collect the spectroscopic information at relatively short echo time which provide the full array of detectable tissue signals without excessive loss associated with T2 relaxation. Alternatively, if less complex spectra are desired, the echo time may be lengthened to suppress signals with short T2s.

The principal disadvantages of localized single volume MRS are its inherent time inefficiency, poor conformance of acquisition volume to brain anatomy, and the difficulty of localizing signal to precisely the same volume in different subjects or in the same subject at different times. Acquisition of spectra from more than one brain location requires separate measurements, each taking several minutes. When several regions are to be compared, the limits of subject tolerance are quickly reached. Volumes of interest must be bounded by planes; practical methods for defining volumes with curved surfaces are not available. Therefore, fitting the acquisition volume to a region of interest is usually only approximate. Finally, the goal of detecting signal from a particular anatomical region in consistently reproducible fashion is an elusive one. Small variations in placement of the volume in different subjects or in the same subject from one examination to the next

can easily confound comparison of subjects and monitoring of changes over time in an individual.

Spectroscopic imaging (SI)

This method of localizing MRS signals works by acquiring spectra simultaneously from a grid of tissue regions within a brain volume. The techniques are similar to some of those used in conventional MRI. The entire volume of interest is excited by stimulating cues which induce the magnetic nuclei within it to broadcast their signals. Additional manipulations extract spatially localized information from the complicated signal by a series of measurements in which the cueing pulse sequence is altered slightly in a systematic manner. Analysis of how the total signal varies with alterations in the cueing process permits the signal contributions of each volume element in the grid to be determined.

SI has not yet come into routine use because of its technical complexity. However, it has been shown to be practical for research and diagnosis in several brain diseases, it is much more powerful than single volume methods in dealing with the heterogeneity of brain anatomy and pathology, and it offers significant gains in time efficiency. Accordingly, its clinical applications can be expected to increase rapidly.

MRS findings in neurological disease

Thousands of MRS studies covering all major categories of human brain disease were published in the first 15 years after the technique became available. More extensive consideration of this literature than can be given here is available in a recent book (Danielsen & Ross, 1999), where the reader can also find numerous examples of how an experienced research group has applied early MRS techniques to specific diagnostic problems in clinical neurology.

Most MRS studies of brain disease show some combination of three changes: loss of NAA signal, interpreted to signify loss of neurons; elevation of lactate, signifying lack of tissue oxygen or infiltration of high-lactate cells such as macrophages; and an elevated choline signal, thought to reflect acceleration of metabolic pathways involving components of biological membranes. As these changes appear to come about by different mechanisms in different diseases, they reflect general pathophysiological processes more often than disease-specific phenomena. In some instances, however, they have stimulated new thinking about particular diseases and shown promise for refinement of diagnosis and treatment evaluation. Space limits the examples we can offer to a few.

Stroke

Loss of NAA and elevation of lactate in acute stroke was predicted by decades of earlier work, and they were confirmed in human patients when ^{1}H MRS became available (Graham et al., 1992). However, persistence of lactate elevation for months after a stroke was not anticipated (Graham et al., 1993); the fact that it could be labelled with ^{13}C from infused glucose showed that it was metabolically active, not trapped in dead tissue (Rothman et al., 1991). Other MRS work suggested that persistently high lactate is in macrophages and other cells participating in the infarcted tissue's response to injury (Petroff et al., 1992).

An interesting body of data indicates that changes in ^{1}H spectra of hemispheres perfused by diseased carotids precedes clinical symptoms of cerebral ischemia (Klijn et al., 2000). If this finding is confirmed, MRS may one day help distinguish patients who need surgical intervention from those who can safely be treated by medical means.

Epilepsy

Decreased NAA in one or both temporal lobes compares well with lateralization of seizure foci and positron emission tomography in identifying the correct side for surgical treatment of intractable temporal lobe epilepsy (Cendes et al., 1997a). It may emerge as the single most useful laboratory technique for that purpose, due to its favourable combination of specificity with non-invasiveness.

Loss of NAA signal is apparently not always due to permanent loss of neurons. Normalization of temporal NAA during seizure-free periods in temporal lobe epileptics indicates that reversible neuronal dysfunction associated with the ictal state is a significant pathophysiological factor in this condition (Cendes et al., 1997b).

Multiple sclerosis

Decreased NAA is regularly observed in acute plaques, implying that more axonal damage occurs in such lesions than had been thought; as in the seizure-free temporal lobes mentioned above, NAA recovers partially in demyelinating lesions in a manner that correlates with clinical recovery, confirming the role of reversible axonal dysfunction in the disease (Matthews et al., 1991; Arnold et al., 1992; Davie et al., 1994). More recently, decreased NAA has been observed in white matter that is normal on MRI, and

in patients with chronic illness, this change correlates better with clinical disability than the MRI lesions (Fu et al., 1998).

Childhood ataxia with diffuse central nervous system hypomyelination (CACH)

This is a rare genetic disorder with variable clinical manifestations. A ^{1}H MRS study showed changes (low NAA, choline, and creatine in heterogeneous distribution) that were more consistent than the clinical data (Tedeschi et al., 1995). The result is an early example of what may become a prominent role for MRS in disease classification.

MRS observations have also been made repeatedly in Alzheimer's disease and other dementias, parkinsonism, motor neuron disease, HIV encephalopathy and metabolic disorders which affect the brain. New findings may bring it to the front line of diagnosis, treatment monitoring, or research in any of these areas as the technology matures.

Spectroscopic imaging of brain tumours

Intracranial neoplasia is a historically intractable clinical problem, which is much in need of new approaches. Accordingly, when magnetic resonance instrumentation capable of doing MRS on human brain became available in the mid-1980s, investigators almost immediately began using it to evaluate human intracranial neoplasms, and interest in the possibility that chemically specific data obtained non-invasively can facilitate brain tumour management has remained high ever since.

Single volume ^{31}P and, later, ^{1}H methods were the first available for this purpose, and in a short time they confirmed that a number of common biochemical characteristics of brain tumours could be detected in undisturbed lesions by MRS. However, these single volume measurements were subject to the same sampling problem that bedevils brain tumour biopsy data, the cellular heterogeneity of the lesions. MRI and X-ray computed tomography can document the vascular changes and edema associated with a particular brain tumour with a high degree of precision, but they cannot reliably identify the tumour's predominant cell type or detect anatomical variations in its chemistry.

One promising way to probe those areas is by positron and single photon emission tomography of radionuclide binding patterns specific for tumour type, once appropriate ligands are developed. Another is ^{1}H SI. Non-invasively obtained information about chemical variation within brain tumours has considerable potential for individual patient management and as a surrogate endpoint for evaluation of new treatments. Being free of hazard to the patient, the measurements can be repeated and correlated with MRI studies as often as necessary. With further technical development already under way, their anatomical resolution will be competitive with that of radionuclide methods.

The results of a ^{1}H SI study done on a patient with a tumour shortly afterward identified at surgery as a glioblastoma multiforme are shown in Fig. 11.4 (see colour plate section). The technique used long echo time (TE 272 ms) and multiple slices. Fig. 11.4(*a*) shows MRI scans of the three slices that were chosen for SI measurements. The white grids on the images in Fig. 11.4(*b*) show all the brain volume elements that generated an interpretable ^{1}H spectrum.

Figure 11.4(*c*) illustrates the characteristic chemical differences between the tumour (left spectrum and image) and adjacent normal tissue (right). In the tumour, choline-containing compounds (Cho) are greatly elevated, *N*-acetylaspartate (NAA) is undetectable, and a large lactate signal (Lac) is present. In the spectrum from normal tissue, these resonances appear as they would in a brain undisturbed by pathology. Of the prominent resonances, only the one from creatine (Cre) is the same in both spectra.

Figures 11.4(*d*) and 11.4(*e*) are the main point of this illustration. In the same way that the water proton signal was used to make the images in Fig. 11.4(*a*), the Cho and NAA signals were used to make (*d*) and (*e*). The metabolite images are much coarser, because the metabolite signals are so much weaker than that of water. Colour coding is commonly added to coarse images to emphasize variations, which are less obvious in grey-scale display of the same information. Elevated Cho in the tumour region and the void of NAA there are clearly evident in the images.

Single volume MRS cannot detect anatomical variations on the scale of Fig. 11.4(*d*) and 11.4(*e*). For chemical analysis of anatomically heterogeneous lesions in an anatomically heterogeneous organ, the future lies with SI.

Figure 11.5 (see colour plate section) shows ^{1}H SI results from another patient with a glioblastoma multiforme, also untreated at the time of study. The metabolite images demonstrate four distinct biochemical features of the lesion: Elevation of the choline signal in and near the tumour; relative diminution of the creatine and NAA signals; and elevation of lactate and lipid signals. The lactate signal appears in the same portion of the spectrum as signals generated by mobile lipid molecules and is therefore difficult to separate from them in the raw spectra, although spectral editing techniques mentioned elsewhere in this chapter can extract it cleanly when necessary.

Caveat spectator!

The metabolite images in Fig. 11.5 (see colour plate section) appear to be more finely resolved than the ones in Fig. 11.4 (see colour plate section). In fact, they were acquired in the same time with the same pulse sequences. Although the signal changes were actually somewhat larger in the Fig. 11.5 patient, most of the difference from Fig. 11.4 is due to postacquisition SI signal processing, for which no standards currently exist. Efforts to establish standards are under way. Meanwhile, SI interpretation for clinical purposes must be done with explicit awareness of how the data were processed.

The biochemical differences between tumours and normal brain illustrated in Figs. 11.4 and 11.5 (see colour plate section) are most pronounced in aggressive brain tumours, but they occur in various combinations in more slowly growing tumours of several histological types. By current biological interpretation, they reflect the reduced neuronal fraction of tumour cell mass (decreased NAA), anaerobic metabolism (elevated lactate), and acceleration of membrane metabolism (increased signals from cholines and small lipid molecules free to tumble in solution). To become useful in brain tumour management, the changes must be correlated quantitatively with tumour histology, treatment responsiveness, or both. These are active areas of current research.

Spectroscopic images are naturally registered with MRI scans and therefore offer an opportunity for chemical analysis of tumours and the tissue around them at the anatomical resolution of ^{1}H SI, currently about 0.2 cubic centimetres. As its anatomical and biochemical resolutions are improved yet further by intense technical development efforts under way in several countries, the rich store of chemically specific information from non-invasive SI can be expected to figure prominently in brain tumour research and therapy.

^{1}H MRS studies of GABA in the living human brain

GABA is the major inhibitory neurotransmitter in the cerebral cortex. It is synthesized from glutamate in specialized neurons, which release it from synaptic terminals that are intimately integrated into most cortical networks. Extensive studies in animals, isolated brain cells, and brain slices have shown that GABAergic function is altered in a variety of models of neurological and psychiatric disease (Roberts, 1986; Meldrum, 1989; Olsen & Avoli, 1997). Several antiepileptic and psychiatric drugs are targeted on GABAergic systems. Non-invasive measurements of GABA are therefore of interest to a wide range of neuroscientists, neurologists, and psychiatrists. Novel ^{1}H MRS techniques have made such measurements possible in recent years.

The most useful GABA resonance in the ^{1}H spectrum of living brain is overlapped by more intense resonances from glutathione and creatine (Behar & Boehm, 1994). Spectral editing techniques which permit separation of the GABA resonance from the others created a new opportunity for non-invasive study of GABA metabolism and GABAergic function in animals and humans (Rothman et al., 1984, 1993).

Figure 11.6 illustrates the current GABA editing technique. The remarkable signal-to-noise ratio of the GABA resonance in the difference spectrum allows measurement of rather small variations in GABA concentration caused by drugs and disease.

GABA studies in epileptics receiving vigabatrin

Impaired GABAergic function has been implicated in the etiology of epilepsy (Meldrum, 1989). Consistent with this proposal, ^{1}H MRS editing studies have found decreased brain GABA in adult (Petroff et al., 1996c, 2000) and pediatric (Novotny et al., 1999) epilepsy. Release of cytosolic GABA has been proposed as an important mechanisms for seizure suppression (Kocsis & Mattson, 1996; Richerson & Gaspary, 1997). The finding that low GABA concentration was strongly associated with poor seizure control in epileptics supports the idea that the relationship is causal rather than coincidental. An opportunity to test the idea by direct GABA measurements in the human brain was afforded by development of the ^{1}H MRS methods described above.

Vigabatrin is a drug which irreversibly inhibits the enzyme GABA transaminase (GABA-T), which catalyses breakdown of GABA in GABAergic neurons and in astrocytes, and thereby causes an elevation in GABA concentration. Animal studies indicate that vigabatrin reduces cortical excitability by this mechanism. Non-invasive measurement by ^{1}H MRS editing of GABA elevations caused by GABA-T inhibitors was first demonstrated in the rat brain (Behar & Boehm, 1994; Preece et al., 1994).

MRS editing studies of GABA have subsequently illuminated several aspects of vigabatrin action in the brains of epileptic patients. These include the following.

(i) The effectiveness of vigabatrin in controlling seizures depends upon elevating GABA concentration above the mean level found in non-epileptic subjects, and,

(ii) chronic dosing above 3 grams per day does not increase GABA concentration further (Petroff et al., 1996a; b, c).

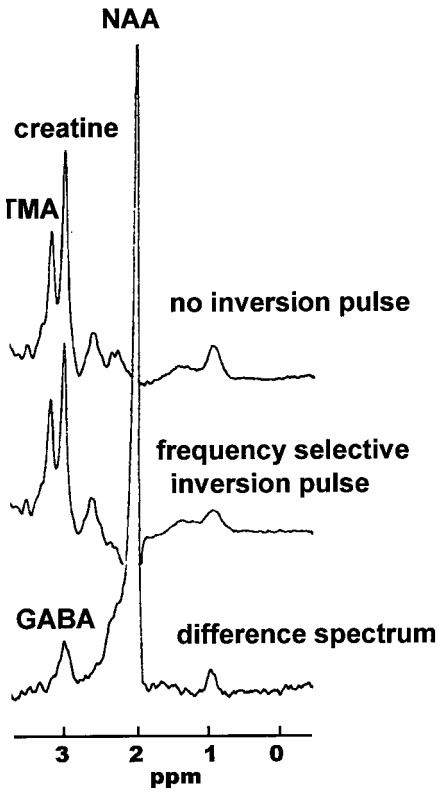

Fig. 11.6. GABA signal detection by spectral editing in human brain. The top spectrum is unmodified. During acquisition of the middle spectrum, the GABA C3 proton resonance near 1 ppm was selectively inverted by frequency-specific magnetic pulses. The C3 resonance itself is not visible due to a larger signal at the same chemical shift; the inversion pulse reduces the intensity of the larger signal in the middle spectrum compared to the top one. Magnetic interaction between the inverted C3 proton signal and the C4 proton resonance near 3 ppm alters the latter, transferring to it part of the effect of the inversion pulses at 1 ppm. When one spectrum is subtracted from the other, all of the metabolite signals drop out except the ones affected directly by the inversion pulses and the GABA C4 proton signal affected indirectly by them (difference spectrum). The GABA C4 proton signal is thereby isolated from larger coresonant signals, and its high signal-to-noise ratio allows accurate measurement of its intensity, which reflects GABA concentration. The residual water signal does not drop out because it is slightly affected by the inversion pulses and its high intensity magnifies the effect. TMA – tetramethylamines. (Unpublished data, similar to Rothman, 1993.)

(iii) GABA concentration reaches a maximum level within two hours of initial drug administration, and,
(iv) GABA concentration remains elevated over 48 hours after a single dose of vigabatrin (Petroff et al., 1999a, b).
(v) No down-regulation of GABA-A receptors occurs during chronic dosing with vigabatrin (Petroff & Rothman, 1998).

These data correspond well with other information about the clinical pharmacology of vigabatrin in epileptic patients. They imply strongly that the antiepileptic effect is due to elevation of brain GABA.

Data like these are available only from human brain MRS. They expose the human neuropharmacology of vigabatrin to a new standard of precise analysis, and they point the way to similar studies of other drugs which affect MRS-measurable resonances.

Some of these observations are of immediate practical significance. The finding that brain GABA concentration increases with vigabatrin dose up to, but not above, 3 grams per day suggests that, in general, better seizure control need not be sought above that dose. Figure 11.7 illustrates the phenomenon in quantitative form.

Such insights achieved by non-invasive observation of drug action directly in the brain can be expected to take clinical management of epilepsy to higher level of effectiveness, much as measurements of antiepileptic drug concentrations in the blood did by revealing individual differences in drug metabolism a generation ago. That earlier advance came about through better understanding of what happened to the drug outside the blood–brain barrier. Non-invasive MRS allows the analysis to be continued on the other side of that barrier, in the brain itself.

GABA studies of other antiepileptic drugs

MRS studies similar to the ones described above have found that several antiepileptic drugs with unknown mechanisms of action also cause rapid elevation of brain GABA concentration. These include gabapentin, topiramate, and lamotragine (Petroff et al., 1996b, c, 1999a, b, 2000; Hetherington et al., 1998; Kuzniecky et al., 1998). Their effects on GABA may be the mechanism of their antiepileptic action, as appears to be the case with vigabatrin. Data now available certainly motivate experiments to test that idea, but until a correlation between GABA elevation and seizure control is actually demonstrated, as was done for vigabatrin in the studies mentioned above, the idea is but an interesting possibility. Some antiepileptic drugs may elevate brain GABA and thereby prevent seizures. Others may elevate GABA but prevent seizures by a differ-

ent mechanism. Drugs which elevate GABA but do not prevent seizures may be found. The point here is that non-invasive MRS measurements of GABA in the human brain allow a more direct approach to such questions than is possible by any other means.

GABA studies of depression and other brain disorders

Reduced GABA concentration has been found in unipolar depression (Sanacora et al., 1999), alcohol withdrawal, and hepatic encephalopathy (Behar et al., 1999). Results from the depression study are shown in Fig. 11.8.

These disorders are associated with an alteration in inhibitory GABAergic function. The finding of low GABA associated with them is additional evidence that the brain metabolic GABA pool is closely related to GABAergic function.

Low cortical GABA in unipolar depression appears paradoxical since the condition is not associated with enhanced cortical excitability. A potential explanation is that the low GABA concentration is a compensation for the reduction in excitatory glutamatergic activity (Sanacora et al., 1999). Future studies using ^{13}C MRS to monitor the flow of ^{13}C through observable metabolic pools in the brain (see below) may be able to test this hypothesis.

Parsing the edited GABA resonance

Both GABA and the GABA derivative homocarnosine, a condensation product of GABA and histidine, contribute to this signal. Homocarnosine is a neuromodulator present in a specific subclass of GABAergic neurons in the primate brain. Short TE ^{1}H MRS with macromolecule suppression may be used to measure the homocarnosine histidine proton resonances in the downfield region of the short TE spectrum (Behar et al., 1994; Rothman et al., 1997). Combining the homocarnosine measurement and the total GABA editing measurements allows separate measurement of homocarnosine and GABA. By additional modification of editing selectivity the GABA derivative pyrrolidinone can also be measured in the edited spectrum (Hyder et al., 1999). Changes in concentrations of GABA, homocarnosine, and pyrrolidinone have been found to have different time courses in response to a first-time challenge with vigabatrin (Petroff et al., 1999a, b).

The homocarnosine resonance titrates with pH. Hence the cytosolic pH of the GABAergic neurons where it is principally localized can be measured in the ^{1}H spectrum (Rothman et al., 1997). Together with measurement by ^{31}P MRS of cytosolic pH in the large fraction of brain cells

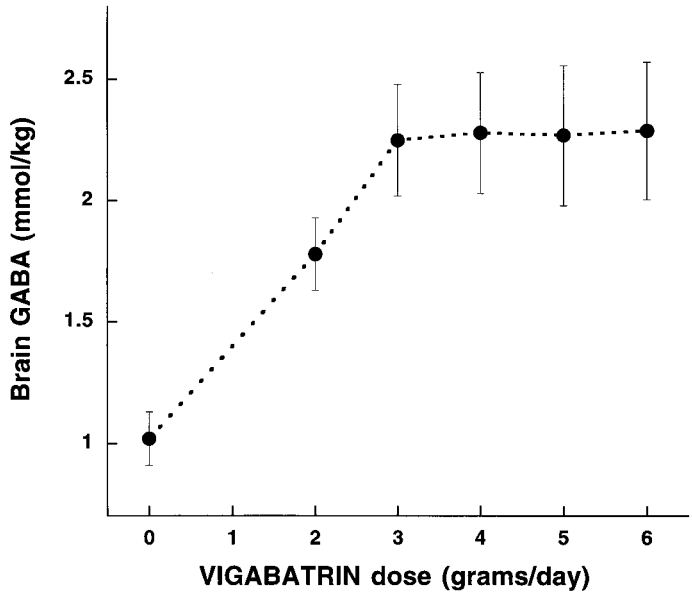

Fig. 11.7. Vigabatrin effect on occipital cortex GABA in a total of 26 patients with complex partial epilepsy. Doses above 3 grams/day caused no further GABA elevation, as the figure shows, and seizure control was not further improved either. Means ± standard deviation. (Redrawn with permission from Petroff et al., 1996a, 1999a.)

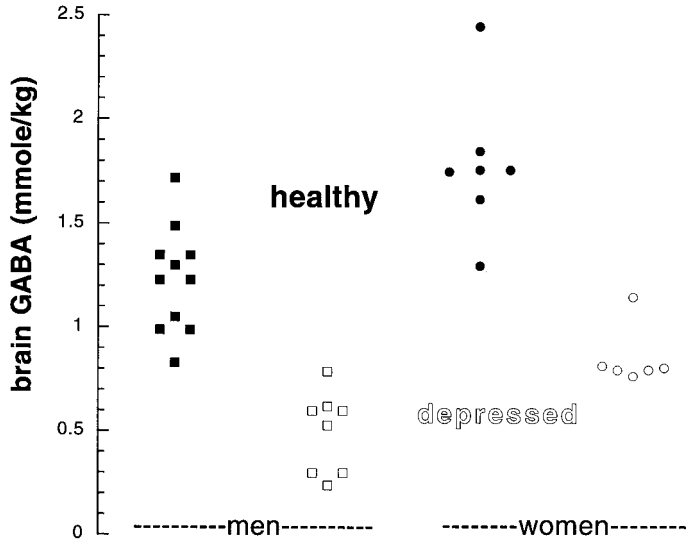

Fig. 11.8. Occipital cortex GABA in 18 normal (filled markers) and 14 medication-free depressed (open markers) men (squares) and women (circles). Analysis of covariance showed a highly significant 52% overall reduction of GABA in depressed patients. Significant age and sex interactions with GABA, but not diagnosis, were also present. (Redrawn with permission from Sanacora et al., 1999, Fig. 2. © American Medical Association.)

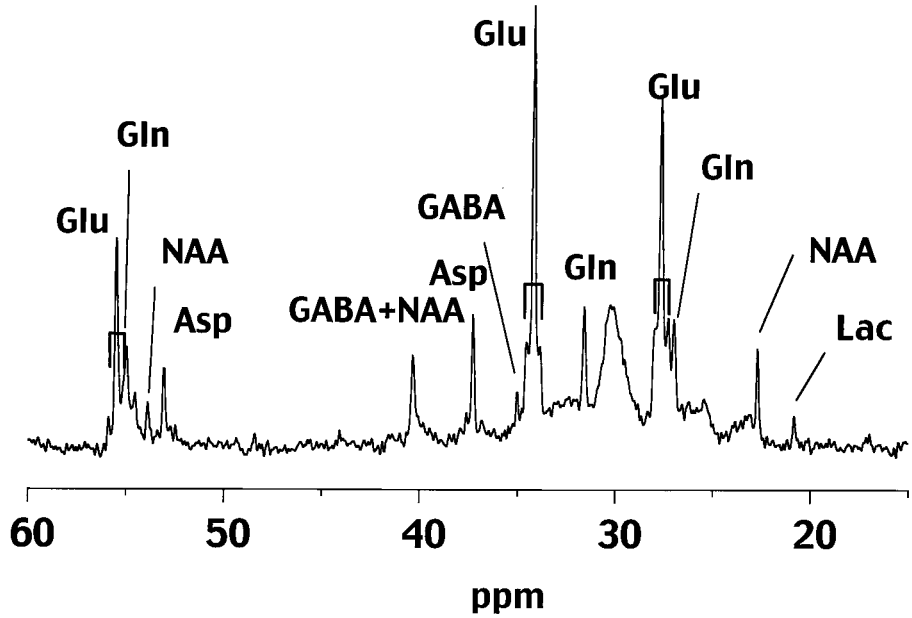

Fig. 11.9. ^{13}C spectrum from human occipital–parietal cortex acquired in a 4 tesla instrument after infusion of 1-^{13}C-glucose for 50 minutes. Only the resonances from NAA and the broad one at 30 ppm were present in the natural abundance spectrum prior to the infusion. The others reveal metabolic incorporation of ^{13}C into various positions of glutamate (Glu), glutamine (Gln), aspartate (Asp), and lactate (Lac), as well as GABA. Although the metabolite resonances are better resolved (separated) in ^{13}C than in ^{1}H spectra (see Figs 11.3 and 11.6), the long acquisition times required by the lower sensitivity of the ^{13}C nucleus make indirect detection of ^{13}C metabolites through the ^{1}H spectrum more useful for most metabolic studies, particularly if labelling time course is to be measured (see text and Fig. 11.10). (Reproduced with permission from Gruetter, 1998.)

which contain inorganic phosphate, this capability offers new opportunities for analysis of how pH is related to brain function and pathology (Prichard et al., 1998).

Metabolic rate studies by ^{13}C and ^{1}H-^{13}C MRS

The ^{13}C nucleus is a stable (non-radioactive) isotope of carbon which is 1.1% abundant in nature; the nearly 99% abundant ^{12}C nucleus is not magnetic. Thus, about 11 carbon atoms in every 1000 are potentially detectable directly by ^{13}C MRS. The isotopic fraction of ^{13}C in brain metabolic pools observable in vivo can be raised above 1.1% by infusion of ^{13}C enriched substrates, usually 1–^{13}C-glucose.

The presence of ^{13}C in brain metabolic pools can in some cases be measured with enhanced sensitivity by indirect detection of ^{13}C by ^{1}H MRS, which can report the presence of a ^{13}C atom covalently bonded to protons. Among the carbon atoms in important molecules that can be studied in this way are C1 of glucose, C3 of lactate, C4 of glutamate, and C2 of GABA. Measurements of ^{13}C flow through these positions yield estimates of glycolytic and oxidative fluxes which have been shown to agree with data from other techniques and to vary appropriately with changes in metabolic demand.

Building on methods developed in animal research, several groups have demonstrated the feasibility of using rates of ^{13}C incorporation into brain metabolic pools to measure metabolic flux, enzyme activity, and metabolic regulation in the living human brain (Rothman et al., 1992; Gruetter et al., 1994, 1998; Mason et al., 1995; Shen et al., 1999).

Figure 11.9 shows the ^{13}C-labelled resonances in a ^{13}C spectrum obtained from occipital/parietal region of the brain of a human subject after infusion of 1–^{13}C-glucose for 50 minutes. Only the NAA signals and the broad one at 30 ppm were present before the infusion.

As is evident from the figure, separation of resonances along the frequency axis is much greater in ^{13}C than in ^{1}H spectra. However, ^{13}C MRS is not the most effective way to do ^{13}C-labelling studies in vivo. The spectra take much longer to acquire, because ^{13}C gives a much weaker signal than ^{1}H, and they give information only about the fraction of a metabolite pool which contains ^{13}C. The combined ^{1}H/^{13}C method solves these problems.

Observation of the brain by ^{1}H techniques which reveal the presence of ^{13}C at certain positions of glutamate, glutamine, lactate, and other detectable metabolites (Rothman et al., 1992) opens a new era in the study of brain metabolism, both as it operates during normal brain function and as it is altered by disease.

Figure 11.10 shows the time course of ^{13}C labelling from 1–^{13}C-glucose of glutamate and glutamine in the human occipital region obtained with the $^{1}H/^{13}C$ method (Shen et al., 1999). The high sensitivity of ^{1}H MRS allowed a data point to be acquired every 5 minutes. Detection of the unlabelled portions of the metabolite pools allowed calculation of the time course of increase in their isotopic fractions (not shown). Data like these provide direct access to dynamic aspects of brain metabolism with time and space resolutions which surpass those available from any other non-invasive technology. Improvements in both kinds of resolution and detection of additional compounds are possible by use of higher magnetic fields and other technical advances which are known to be feasible. These facts ensure that MRS technology will figure prominently in metabolic research on the living human brain for years to come.

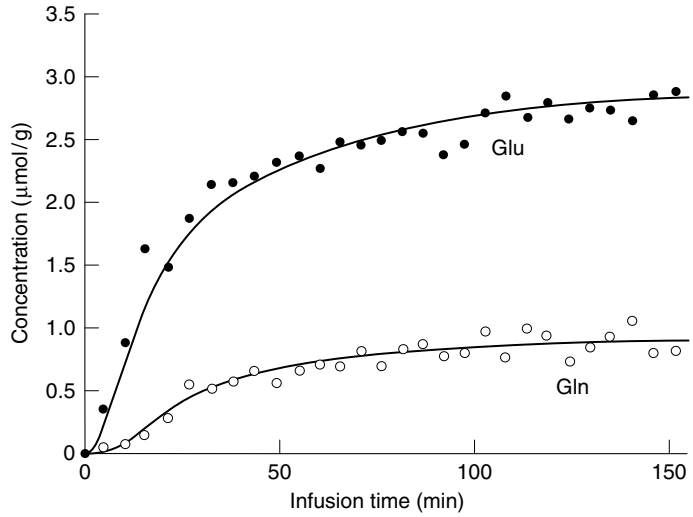

Fig. 11.10. Time course of incorporation of ^{13}C from infused 1-^{13}C-glucose into the C4 positions of glutamate (Glu) and glutamine (Gln) in human occipital cortex. Data were obtained by a combined $^{1}H/^{13}C$ method (see text) in a 2.1 tesla instrument. Curves were fitted by a model which allows rate calculations of glucose oxidation, the tricarboxylic acid cycle, and the glutamate/glutamine cycle. The future

Much of the achievement of brain MRS before 2001 was demonstration that it can observe, in the living organ, in an hour or less, phenomena that decades of invasive research had laboriously established to be true of brain function occurring normally and altered by disease. With confirmation of its capabilities now firmly in hand, MRS can be used with increasing confidence to acquire information about normal and pathological brain function that is beyond the reach of any other observational technology.

Books focused as this one is on mechanisms of neurological disease invite consideration of where precisely the boundary between normal and pathological brain function lies and how it may be defined. Most of the methods mentioned in this chapter can be used to improve that definition in novel ways.

An early example was demonstration of a lactate rise in human visual cortex during stimulation by flashing lights (Prichard et al., 1991; Sappey-Marinier et al., 1992). Previously, lactate elevations had been universally regarded as a sign of distress in brain tissue. This MRS-enabled finding provided new insight concerning how glycolytic and oxidative metabolism are integrated during normal brain activity, and it fuelled a controversy on the subject that can end nowhere but in improved understanding of how the brain works normally.

MRS methods have the potential to probe such matters much more deeply. The information gained is certain to anchor new data on brain disease mechanisms to a firm background of steadily improving insight into normal brain function.

Windows on the working brain: evoked potentials, magnetencephalography and depth recording

Hans-Joachim Freund[1] and Hans Joachen Heinze[2]

[1] University of Dusseldorf Neurology Clinic, Germany
[2] University of Magdeburg, Germany

A number of techniques have been developed for the study of human brain functions in normal and disordered states. Each of them monitors function from a selective point of view. Whereas functional imaging techniques are based on neurovascular coupling (functional magnetic resonance imaging (fMRI), positron emission tomography (PET), near-infrared spectroscopy (NIRS) and optical imaging), electrophysiological methods directly reflect neuronal activity. Electroencephalography (EEG) and magnetencephalography (MEG) provide information about global as well as regional activity under stationary conditions or for evoked or event related responses. Subdural or epicortical recordings for the identification of epileptogenic foci and microelectrode recordings for functional target identification during stereotactic neurosurgery complement the spectrum of the clinical application of neurophysiological tools.

Taken together, the neurovascular and neurophysiological methods provide largely complementary information that allows better insights in normal and disturbed brain function. The superimposition of MEG data on MR images combines the high spatial and temporal resolution of the respective methods. EEG recordings can now be conducted inside the MR scanner allowing the recognition of epileptogenic foci during EEG-defined seizure episodes.

Towards an integrative MEG and EEG study of cognitive brain functions

EEG and MEG measures arise from the same cortical source, namely from ordered intracellular currents in the pyramidal cells (Okada, 1982). Since the pyramidal cells in a circumscribed area show basically the same orientation orthogonal to the surface, the superimposed neural currents may result in macroscopically measurable electromagnetic fields. The electric and magnetic fields have orthogonal orientation and bear formally equivalent information; however, it may well be that stimulus-triggered event related potentials (ERPs) or magnetic fields (MFs) reveal different aspects of the underlying neural sources depending, for example on the nature of the task and the anatomy of the cortical region of interest. For several reasons, source estimation based on MFs is often superior to ERP based fits. First, opposite to electrical currents MF remain almost unchanged when passing through anatomical structures between the cortex and the sensor sets. Hence, the MFs are less susceptible to inadequate head models, both regarding anatomical shape and tissue conductivities (CSF space, scull, scalp). Secondly, the superficially observed MF originate from the primary neuronal currents (i.e. currents inside the dendrites) whereas volume currents do not contribute for physical reasons. In contrast, ERPs reflect both primary and volume currents. As a consequence, in comparison to the MEG, the electrical signal shows spatial blurring that necessarily increases uncertainties during source localization. Thirdly, the magnetic field distribution outside the head arises mainly from source currents that flow tangentially to the head surface (Williamsen & Kaufman, 1987); radially oriented source components do not significantly contribute to the observed MEG for physical reasons. This contrasts with the ERP component distribution that reflects both tangential and radial current sources. In anatomical terms, measurable magnetic activity arises almost exclusively from the sulcal part of the cortical grey matter. Accordingly, the extracranial magnetic fields are linked to a selective part of the cortical sources and not obscured by overlying fields generated by radial sources.

The role of attention in visual perception

Higher visual functions involve a number of potentially overlapping radial and tangential electromagnetic sources in the visual cortex. For instance, visual attention can modulate the signal flow in adjacent early visual areas and is a

good example to illustrate the MEG/EEG comparison. Convergent input to subsequently higher cortical processing levels (V1 to V4, IT, MT) entails progressively enlarging receptive fields with a coarser representation of visual input at higher cortical levels. An increasing portion of stimuli competes inside receptive fields and, therefore, necessitates effective disambiguation mechanisms. There is evidence from brain imaging, human electrophysiology and single-cell recording that a competition bias on different cortical levels provides a solution for this coarse coding problem (Reynolds et al., 1999; Luck & Hillyard, 1994). For instance, recording ERPs triggered by a search array that contains a target feature or feature conjunction gives rise to a negative voltage of approximately 200–300 ms over posterior scalp electrodes contralateral to the field where the target occurs. This N2pc component (negativity in the N2 time range posterior contralateral) appears to be a common correlate of attentional selection across different feature types in visual search and is thought to represent a manifestation of cortical processes related to the suppression of interfering visual input from distractor items (Luck et al., 1997). So far, efforts to characterize the neural origin of the N2pc using ERP source analysis have not been successful.

In a recent study, the neural origin of this component was investigated by using a combined EEG and MEG analysis (Hopf et al., 2000). MEG data were recorded using a 148 whole-head magnetometer, and EEG data were simultaneously acquired from 32 electrode sites. As an experimental task, subjects had to identify a predefined target stimulus in the left or right visual field (LVF or RVF) among a number of randomly distributed distractor items. To derive the N2pc component, ERP-/MF-responses triggered by the RVF targets were subtracted from responses triggered by LVF targets. By this subtraction the electric and magnetic activity specifically related to the focusing of attention was obtained. Figure 12.1 (see colour plate section) illustrates the ERP scalp distribution (*a*) and magnetic field distribution (*b*) for two subsequent time windows that cover the early (180–200 ms) and late (220–240 ms) portion of the N2pc component. Shown are the average data over four independent experimental sessions of one subject. As can be seen, ERP voltage distributions in the early and late time window (Fig. 12.1(*a*)) are roughly identical showing the previously known bilateral occipital topography (Luck & Hillyard, 1994). Contrastingly, a comparison of magnetic field distributions in the early and late time range (Fig. 12.1(*b*)) reveals qualitatively different patterns. Between 180 and 200 ms the magnetic field configuration suggests a generating source in the parietal cortex as indicated by a parietal flux transition zone between the maximum magnetic outflux- and influx regions (arrow). The field configuration between 220 and 240 ms, however, shows two major transition zones over left and right inferior temporal sensors implying the presence of two independent posterior–temporal sources. A distributed source analysis using the minimum norm least square method in combination with a realistic volume conductor model derived from structural MR data indicates the presence of two qualitatively different source configurations for this late magnetic attention effect (Fig. 12.2(*b*), see colour plate section). In contrast, source density estimates of the ERP data revealed a similar pattern for the early and late attention effect with a broadly distributed scalp topography over the posterior cortex (Fig. 12.2(*a*), see colour plate section).

The source estimates for MF and ERP data differ in two major respects. First, there is no indication in the ERP data for a separation into early (parietal) and late (temporal) sources, and, secondly, source configurations between 220 and 240 ms are qualitatively different for both data sets. The first difference may be related to spatial blurring of ERPs leading to a confluence of scalp topographies of a weak early and stronger late field components. The second difference may result from inverse dipole modelling of the ERP data as illustrated in Fig. 12.3 (see colour plate section). In this case, ERP source modelling erroneously links two independent field components (Fig. 12.3(*a*) and (*c*), see colour plate section) to a common underlying source (Fig. 12.3, green dipole, see colour plate section) probably due to suboptimal field projections (Fig. 12.3(*b*) and (*d*)) of the underlying sources (Fig. 12.3, black dipoles, see colour plate section). Note, the problem of suboptimal field projections is not inherently linked to ERP data and may in other experiments also be relevant for MEG data. Taken together, the present example clearly demonstrates that the validity of inverse source modelling considerably benefits from a comparison of complementary electrophysiological measures like ERP and MEG. This is because EEG and MEG provide different electromagnetic views onto the same underlying current source. A combination of both datasets necessarily draws a more complete picture and clearly diminishes the risk of source mislocalization during inverse modelling.

The study of memory functions

The study of memory functions in humans is another example of how MF analysis can improve our analysis of higher brain functions. MEG sensors can detect hippocampal postsynaptic activity (Tesche et al., 1988; Wu & Okada, 1998; Okada et al., 1997). They selectively measure the tangential source components of the closed field and, therefore, are able to measure hippocampal pyramidal cell

activity. MEG sensors are now being used to record non-invasively stimulus-evoked neural population responses in human hippocampal structures (Tesche et al., 1996; Nishitani et al., 1999; Tesche & Karhu, 1999). These studies describe ongoing oscillatory 4–12 Hz activity (Tesche & Karhu, 1999) and P300-like activity in oddball tasks (Nishitani et al., 1999) generated by hippocampal structures of healthy humans.

Combined ERP and MF analysis can differentiate electrophysiological indices of episodic memory in humans. Cognitive models of recognition converge on the notion that normal recognition has two qualitatively different bases. Recollection-based recognition or 'remembering' is accompanied by contextual information about the episode in which an item was encountered, whereas familiarity-based recognition, or 'knowing' is devoid of such information (Tulving, 1985). Remembering and knowing, in turn, can be considered as characterizing episodic and semantic memory, respectively. There is experimental evidence from behavioural studies that recollection and familiarity-based judgements cannot be reduced to a quantitative difference, but, instead, reflect two qualitatively different aspects of recognition memory (Knowlton & Squire, 1995). This distinction is supported by ERP findings which have revealed qualitatively distinct electrical brain patterns associated with recollection and familiarity. Recollecting recognized words causes an increase in ERP positivity between 500 and 700 ms after the onset of word presentation, a shift sometimes referred to as the late positive component or LPC effect (Rugg et al., 1998). On the other hand, familiarity-based recognition causes an earlier shift in ERP positivity between 300 and 500 ms, referred to as the N400 effect (Duzel, 1997; Paller et al., 1995). These two ERP effects have a different scalp topography suggesting that they are generated by different neuronal populations.

It remains unclear from ERP studies, however, where the corresponding neural populations are located. Lesion studies in animals and humans raise the possibility that both recognition effects should receive contributions from different structures within the temporal lobes (Murray & Mishkin, 1998; Vargha-Khadem et al., 1997b). We used combined EEG and MF recordings to localize the generators of the N400 and LPC effects of recognition in 11 healthy young subjects. EEG and MF were recorded simultaneously for correctly recognized old (repeated) words (hits) and new words (correct rejections) in 11 subjects. Current sources were computed separately for hits and correct rejections for each single subject taking into account their individual brain anatomy. Figure 12.4 (upper part, see colour plate section) shows the current source results obtained for a single subject for correct rejections and hits in the N400 and LPC time window. It can be seen that in the N400 time window, correct rejections induce stronger current flows than hits in the anterior temporal lobe. In contrast, hits induce stronger current flows in the posterior inferior temporal lobe than correct rejections. To further quantify whether this relationship was significant across subjects, the current source maps were transformed into Talairach space. Scatter plots (lower part, Fig. 12.4) illustrate the current flow of each individual subject in the anterior inferior temporal cortex and for the LPC time window the same is illustrated for the posterior inferior temporal cortex. It can be seen that, in the anterior inferior temporal cortex, all but two subjects show higher currents for correct rejections than for hits. In contrast, in the posterior inferior temporal cortex all but two subjects show higher current flow for hits than for correct rejections. These findings suggest that the N400 old/new effect reflects mainly decremental current strengths during repetition while the LPC old/new effect reflects mainly incremental current strengths during repetition and these two types of processes are spatially dissociated in the left human inferior temporal cortex. So far, this conclusion was not possible on the basis of ERPs alone.

The investigation of sequential cerebral processing stages

A major potential of the MEG is to identify subsequent processing stages of the neural activations during well-defined behavioural states. The neurovascular imaging methods cannot only specify the multiple areas contributing to the functional network but by means of event related fMRI (efMRI) also separate subsequent activations if they are separated by long enough time spans. But efMRI cannot resolve fast sequential processing and the dynamic interactions of these structures. The advantage of the combination of the reasonably good spatial and excellent temporal resolution of the MEG can be illustrated by a study on single word reading in developmental stutterers (Salmelin et al., 2000). Stuttering represents a temporal disorder of still unknown pathophysiology and is therefore of considerable interest for such an inquiry. The task in this study was that normal subjects and stutterers read 7–8 letter words presented for 300 ms. After a blank interval of 500 ms a question mark appeared 2000 ms later prompting the subject to read the word aloud. Mouth movement and speech onset were used for motor related analyses. Figure 12.5 shows the source areas in fluent subjects and stutterers whereas the time histories of the neural activations as revealed by event related changes in the spectral power of distinct frequency bands are shown in Fig. 12.6. Although

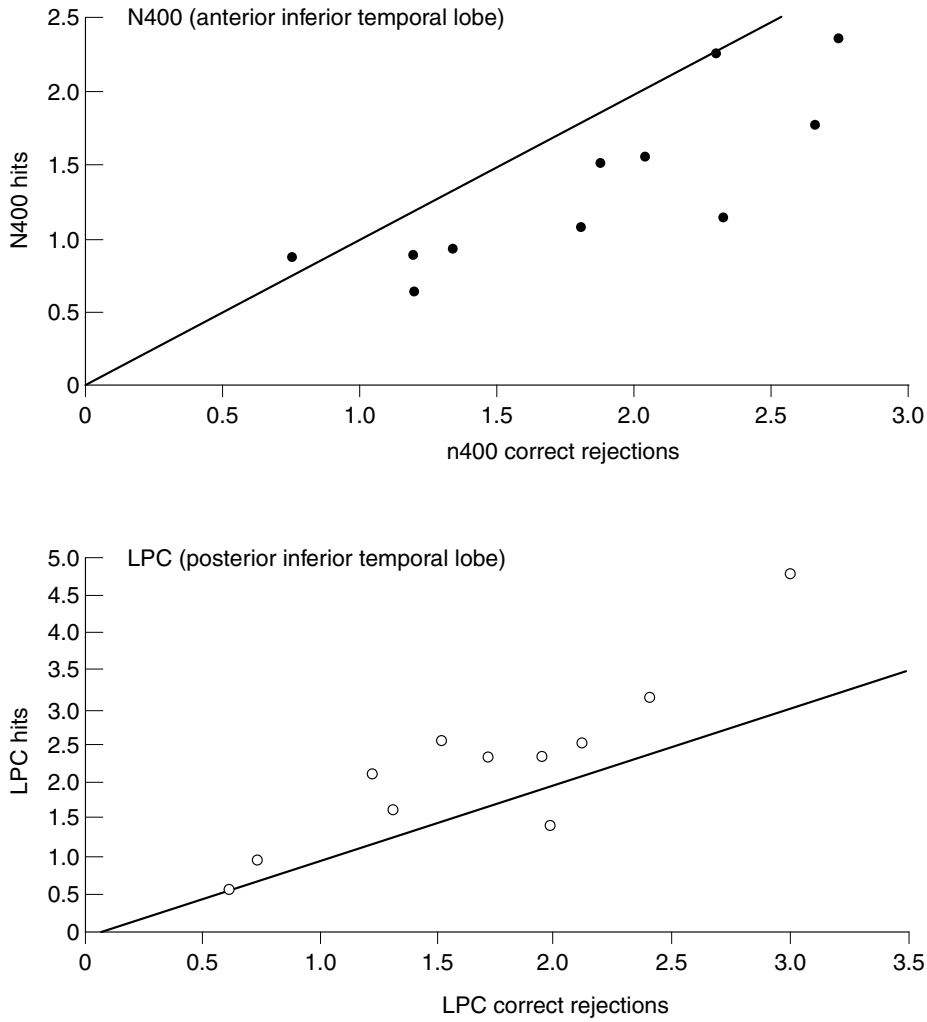

Fig. 12.4. *Lower part:* Scatter plots of the current source strengths for correctly rejected new words and hits measured in the N400 time window in the anterior inferior temporal lobe (upper diagram) and in the LPC time window in the posterior inferior temporal lobe (lower diagram). All but two subjects showed higher current flows for correctly rejected new words than hits in the anterior inferior temporal lobe in the N400 time window. In contrast, current flow was higher for hits in all but two subjects in the posterior inferior temporal lobe in the LPC time window.

the overt performance was essentially identical in the two groups, the stutterers were fluent in this task, cortical activation patterns showed clear differences for the evoked responses and the suppression of 20 Hz oscillation.

As shown in Fig. 12.6 cortical processing proceeded in the following stages:

(i) The overall temporal activation patterns showed occipital and parieto-occipital responses starting 100–150 ms after word onset (visual analysis, continuing until the appearance of the question mark) and in the left and right inferior occipito-temporal cortex (letterstring specific analysis).

(ii) Between 200 and 600 ms left more than right inferior frontal cortex responses probably reflect articulatory aspects of phonological processing, and in left middle superior temporal cortex semantic activation.

(iii) 200–800 ms following word onset, responses in the left and right posterior parietal cortices may reflect phonological aspects of linguistic processing or attentional factors of visual perception. In the third stage the left and right fronto-parietal cortices became involved and remained active throughout vocalization prompt and speech onset.

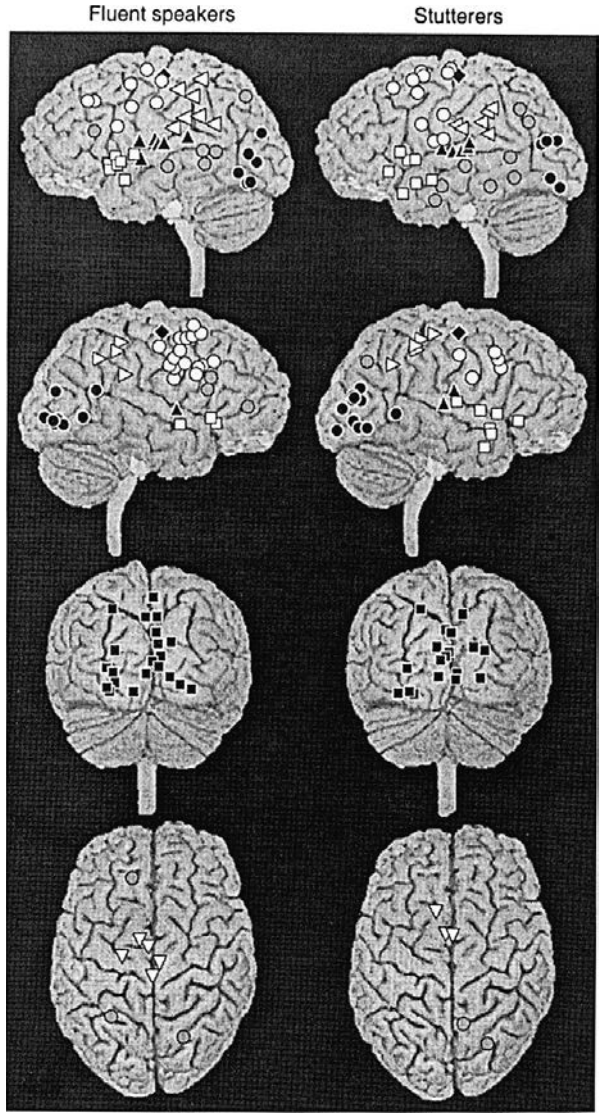

Fig. 12.5. Source areas in fluent subjects (left) and stutterers (right), when the MEG signals were averaged with respect to word onset. The different shapes and colours of the symbols (white and black circles, triangles, squares and arrows) depict the grouping of sources into distinct regions of interest. The grey circles denote sources which do not belong to any well-defined cluster. The black diamond indicates the location of the hand sensorimotor cortex. The size of the symbols equals the mean accuracy of localization (6 mm) (from Salmelin et al., 2000).

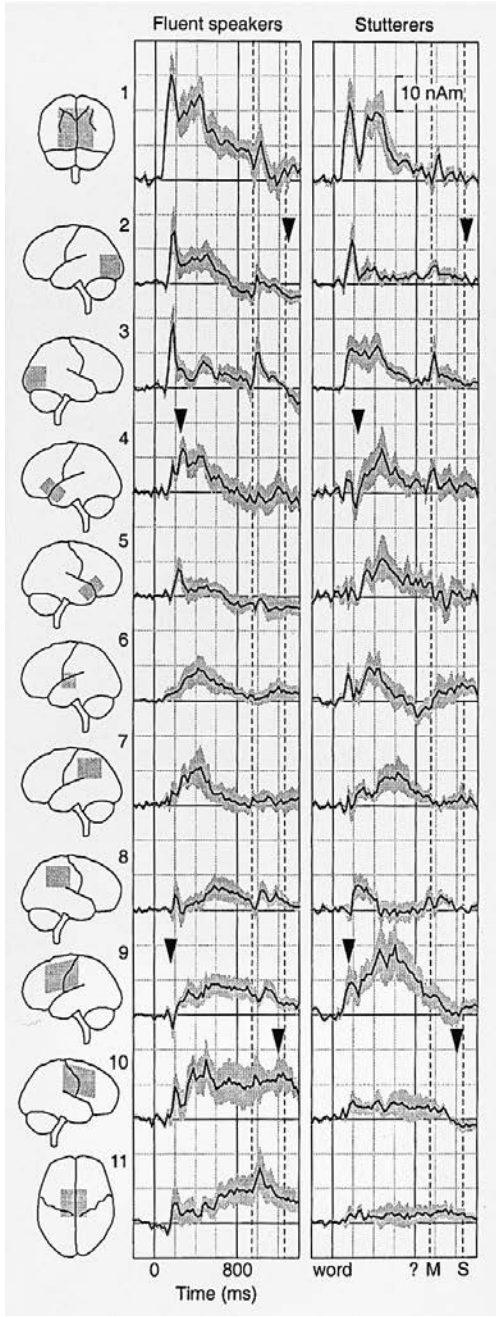

Fig. 12.6. Mean ± standard error of the mean (black curve and shading) source strengths as a function of time in fluent subjects (left) and stutterers (right). The word and question mark onsets are indicated with solid vertical lines and mouth movement (M) and speech (S) onsets with dashed lines. The black arrowheads denote the regions (ROI) and time windows of interest where the responses of stutterers and fluent speakers differed significantly from each other. The studied ROIs are illustrated on the schematic drawings of brains on the left. (From Salmelin et al., 2000.)

It follows that the normal subjects' activity proceeds from the left inferior frontal cortex (articulatory programming) to the lateral part of the left central sulcus and to the dorsolateral premotor cortex (motor preparation) within the first 400 ms after seeing the word. This sequence was reversed in the stutterers who showed an early left motor cortical activation followed by the inferior frontal signal. Stutterers thus appeared to initiate motor programmes before the preparation of the articulatory code. During speech production the right motor area was active in fluent subjects but was silent in stutterers. These findings disclose the nature of such a temporal disorder and demarcate the altered functional connectivity in the respective network, in this case between the left inferior frontal cortex and the right motor/premotor cortex, a circuitry supposed to be relevant for merging linguistic and affective prosody with articulation during fluent speech. This example is meant to illustrate the unique contribution of the MEG to our understanding of the pathophysiology of brain disorders that cannot be accomplished by any other method.

Parallel vs. sequential processing

The combination of relatively high spatial and superb temporal resolution opens new avenues for the study of brain physiology and pathophysiology. For somatosensation it was unclear how the processing of tactile and pain information proceeds in the postcentral primary somatosensory areas, each containing separate body representations for the different submodalities. The comparison of nociceptive as compared to tactile processing showed that the nociceptive sources in the postcentral gyrus were located 10 mm more medially than the early tactile responses arising from area 3b. Whereas tactile stimuli activate sequentially peaking sources in area 3b and 1, nociceptive stimuli activate area 1 indicating that this input does not share the complex hierarchical tactile processing chain (Ploner et al., 2000). MEG data further provided evidence for serial processing from SI to SII and from SI to posterior parietal cortex for tactile input. In contrast nociceptive afferents from the hand are projected to SI and SII in parallel (Ploner et al., 1999). Along these lines the channelling of information processing can be explored for other systems.

MEG in the evaluation of patients with epilepsy

Comparative recordings with MEG and invasive electrical recordings showed excellent agreement for the location of the interictal spike zones and of the spatial relationship of the irritative zone and the structural lesion (Baumgartner et al., 2000a). MEG is also helpful to guide the placement of subdural grid electrodes in patients with non-lesional neocortical epilepsies. For temporal lobe epilepsy (TLE) two types of MEG spike dipoles have been identified: an anterior vertical and an anterior horizontal dipole attributing spike activity to different temporal lobe compartments. This allows differentiation between patients with mesial and lateral temporal seizure onset (Baumgartner et al., 2000b). The disadvantage of the MEG, that it cannot be used for long-term recordings, may be counterbalanced by combined MEG/EEG recordings. The EEG can now even be recorded within the MRI scanner. This allows the use of functional MRI for the localization of EEG identified seizures in patients with focal or partial epilepsy.

The comparison between simultaneous MEG and invasive EEG recordings showed that epileptic foci in mesial temporal structures cannot be detected by MEG if they do not exceed an epileptogenic area of 6–8 cm^2. By contrast, lateral neocortical temporal lobe generators can better be detected. In a prospective study comparing several diagnostic methods (ictal and interictal scalp and intracranial EEG, MRI and MEG) in 58 patients with refractory partial epilepsy the main outcome measure was the efficacy of these methods to identify the resected epileptogenic zone (Simos et al., 2000). MEG (52%) was second only to ictal intracranial EEG in predicting the epileptogenic zone for the entire group of patients who had an excellent surgical outcome. For temporal lobe surgery this relation was MEG 57%, and ictal intracranial EEG 62%. For extratemporal resections ictal (81%) and interictal (75%) intracranial EEG were superior to MEG (44%) in predicting the surgery site in patients with excellent outcome. As compared with video-EEG, MEG was better than ictal (33%) or interictal (45%) scalp VEEG. In another series comprising 53 epilepsy surgery candidates MEG foci were identified in 47 patients in 46 of whom the lesions were resected (20 of the anterior temporal lobe and 26 of the extratemporal lobe cases) (Wheless et al., 1999). Results of this kind implicate that the MEG may obviate the need for invasive EEG in many cases. In cases selected for pediatric epilepsy surgery, the comparison with invasive intracranial EEG showed that both methods colocalized the epileptogenic focus (Minassian et al., 1999).

MEG for presurgical mapping

MEG can also be used for presurgical mapping in tumour cases in order to delineate eloquent areas (Ganslandt et al.,

1999). Comparative studies based on MEG/MRI comparisons indicate that both methods are suitable for mapping eloquent cortex in relation to tumour-invaded tissue. As a general result activations are almost exclusively seen outside the tumour invaded area (Wunderlich et al., 1998). Reliable mapping of the functionally active zone is particularly useful in the many cases with considerable displacement distorting the regional anatomy. Presurgical mapping is usually performed for the sensorimotor strip but also for the language areas. When comparing language lateralization by word-matching tasks or other language paradigms in the MEG the results are similar to those obtained to the Wada test (Simos et al., 2000).

The data on presurgical mapping are also of interest for the assessment of tumour induced plasticity following tumour resection. The rearrangement of the displaced activations can be monitored and the changes in functional maps related to functional recovery. Cortical plasticity may be associated with functional improvement but may also be maladaptive. An example for the latter case are the extensive changes in somatosensory cortical maps following amputation or somatosensory deafferentation. It has been shown (Flor et al., 1995) that the amount of cortical alteration and the magnitude of a phantom pain in amputees reveal a positive relationship ($r = 0.93$). But there was no correlation between non-painful phantom phenomena and the amount of cortical reorganization. This, and related data, indicate that phantom limb pain goes along with plastic changes in primary somatosensory cortex and its afferent stages.

Combination of electromagnetic and hemodynamic measures

The idea behind this approach is to relate the areas of functionally relevant brain activations, as identified by regional blood flow changes, to the time course of associated neural processes, as reflected by successive ERP or MF components. For a linear sequence of discrete cognitive events, for example, one would expect a corresponding sequence of electric or magnetic components mapped onto a distinct pattern of hemodynamic brain activations. However, our experiences suggest that these relationships are highly complex and usually do not allow for simple solutions. In this respect, an important question is whether and to what extent it is reasonable to assume that electromagnetic and hemodynamic parameters are related, given that ERP and MF components reflect postsynaptic activity and blood flow change might occur seconds after the electromagnetic events. Evidently, electrophysiological and hemodynamic indices of cortical activation do not necessarily match. For instance, cognitive ERP components in the later time range may reflect the integrated activity of multiple and broadly distributed sources and, therefore, are difficult to relate to few circumscribed hemodynamic sources as revealed by standard statistical mapping neuroimaging procedures. Therefore, some neural processes may be hidden in these results because the corresponding data just do not reach significance due to a poor signal-to-noise ratio or because of a too rigid significance thresholding. On the other hand, an activated area identified by hemodynamic measurements may generate electromagnetic signals that cannot be recorded at scalp locations because the fields cancel locally due to the cortical geometry. Together, the combined imaging approach does not aim for a complete integration of different physiological parameters; rather, the goal is to obtain complementary information about different aspects of the same neural process.

An important step towards a combined analysis of neural functions implies a physiologically, anatomically and mathematically profound approach to the so-called inverse problem. This term denotes the estimation of the intracranial sources of electromagnetic activity sampled at various scalp locations given the fact that a scalp recorded pattern of electromagnetic parameters does not have a unique intracranial solution. At present, most studies apply the so-called equivalent dipole model or the distributed cortical surface model. The dipole model simulates the neuroelectric activity as generated by a single point source with a certain location, an orientation and an amplitude, as can be assumed for a relatively small activated cortical region. The distributed source approach is suitable for the estimation of more widely spread activity sources. It assumes a multitude of dipoles distributed over the brain. For an improved solution, they may be constrained by restricting their location to the MR-based cortical surface and their orientation perpendicular to it; with the location and orientation of the dipoles fixed, only their strength needed to be solved. As a result, the solution resembles a distributed electrical solution of the cortical surface.

The source estimation provided by these different algorithms is only a first step in the combination of electromagnetic and hemodynamic parameters. Consider an experiment in which parallel recording of ERPs and fMRI in the same subject under the same experimental conditions has identified a number of electromagnetic sources and MR signal changes related to a particular performance. What kind of evidence substantiates the assumption that these different parameters reflect the same or different neural processes? There are different approaches to answer this question. One is called the ‘seeded forward

solution' (Heinze et al., 1994). This solution implies that the equivalent dipoles of electromagnetic activity are placed within the anatomical areas defined by MR signal change to test whether these dipoles could have generated the electrical patterns that were recorded from the scalp. If this is the case, the next step is to show that other possible locations of these dipoles provide a worse or at least not significantly better (in terms of goodness of fit) solution than the seeded dipole fit. Another approach is to test the covariation of MR and electrical signals when the task changes. The logic is that if both signals reflect the same cognitive event, one would expect a covariation over task manipulations. New developments in combined neuroimaging incorporate statistical approaches for estimating the most probable numbers, locations, orientations and strength of active cortical regions.

To illustrate such a comparative approach and the advantage of MEF measurements over EEG data a combined EEG, MEG and fMRI study assessing the neural indices of word fragment completion can be used. Seven subjects completed four-letter fragments to German words whose length varied between 7 and 9 letters and indicated the time point of completion with a right hand, index-finger button press. EEG and MF data were analysed response locked to the motor response that indicated completion. With both EEG and MF, response-locked waveforms deviated from zero starting at approximately 500 ms before the motor response. The current density solution of this 500 ms time window was derived using the MF data, and for comparison also using the EEG data alone. Both types of solutions were compared to the fMRI measurements (different subjects) obtained during the same task. In accord with the fMRI findings, the combined EEG and MF current density analyses revealed a left frontal and two bilateral temporal sources of activity (Fig. 12.7, see colour plate section). In contrast, current density performed with EEG data alone, misallocated the bilateral parietal sources to a single, widely distributed source located over the convexity of the parieto-central scalp. Both types of source analyses, however, correctly revealed activity in the left motor cortex starting from 20 ms prior to the motor response. These data provide fMRI supported evidence that source analysis based on EEG data alone can provide wrong solutions in the case of more complex, bilateral neural activity, and the MEG data can help to substantially improve the spatial resolution in these cases.

The study of cortical rhythms

EEG/MEG studies have provided evidence that the mixed frequency content of the human brain oscillations can be fractionated into several region specific intrinsic rhythms. The functional significance of these rhythms is still unclear, but there is increasing evidence that some of them respond to peripheral sensory or motor events. This can be shown by calculating the event related modulation in the spectral power of these cortical rhythms (Hari & Salmelin, 1997; Pfurtscheller & Aranibar, 1979).

Sources around the parieto-occipital sulcus generate the well known α-rhythm. They show dampening of the α-rhythm within 200 ms after the presentation of visual stimuli and also during visual imagery. The Rolandic Mu-rhythm consists of 10 and 20 Hz components with different source locations. The 10 Hz component is supposed to be somatosensory in origin, whereas the 20 Hz signal originates mainly from motor cortex (Hari & Salmelin, 1997) with clearly detectable somatotopy of the oscillatory sources. These components are suppressed by either somatosensory input or movement. The human auditory cortex shows spontaneous oscillations around 10 Hz (tau rhythm) that is transiently suppressed during auditory input (Lehtala et al., 1997). Oscillatory responses in the γ-band (25–50 Hz) also showed differences in relation to the perception of auditory stimuli.

The spatial analysis of these rhythms and their interdependence is of considerable significance for a better understanding of the pathophysiology of cortico-cortical and cortico-thalamic interaction, but also for cortico-muscular coupling. Llinas and coworkers (1999) have recently proposed that patients with neurogenic pain, Parkinson's disease or depression show increased low frequency theta rhythmicities associated with a pronounced increase in coherence between high and low frequency oscillations. This was supposed to indicate thalamo-cortical dysrhythmia as a common principle underlying the abnormal coherence in the theta range.

New approaches for the study of coherence

The understanding of the synchronization of neuronal firing within and across areas is pivotal for the understanding of brain function and dysfunction. Coherence between signals of sensors or electrodes covering different scalp areas is usually taken as a measure of functional coupling. This approach was hitherto limited by methodical constraints. A new method, dynamic imaging of coherent sources (DICS), has been introduced by Gross et al., (2001). Since MEG and EMG signals are non-stationary, this new tool has been implemented for the detection of phase synchronization in non-stationary noisy data (Tass et al., 1998). In contrast to classical coherence, this method

allows the separation of amplitude and phase information by means of the Hilbert transform. DICS allows different approaches to the study of coherence. One is to identify a cortical area showing the strongest coherence with a peripheral signal and to take this as a reference for calculating cortico-cortical coherences. Another strategy is to calculate coherences between all sensor pairs and then select the strongest coherence between non-adjacent sensors. Finally a *priori* information can be used to define a reference region based on knowledge of anatomical structures or pathways or results from other functional imaging studies.

The examination of cortico-muscular coherence during static isometric muscle contraction and simultaneous electromyographic and MEG recordings revealed significant coherence in the 15–33 Hz frequency range (Conway et al., 1995; Salenius et al., 1997). This corresponds to the 20–30 Hz coherence between local field potentials in primary motor cortex and rectified EMG from the contralateral hand and forearm muscles in monkey (Baker et al., 2000). The coupling of central oscillatory activity to peripheral muscle activity is apparent in the MEG signal averaged to the onset of motor unit potentials (Fig. 12.8(*a*)) and in the coherence (Fig. 12.8(*b*)) between rectified EMG signal and the neural activity of the contralateral primary motor cortex (Fig. 12.8(*c*)). The delays between the oscillatory motor cortical and EMG signals computed from their phase difference provide information about conduction times. Figure 12.9 shows the close agreement with the conduction times as determined by transcranial magnetic stimulation.

For the clinic this method opens new applications. One is the measurement of conduction times and conduction velocities in normal conditions and demyelinating disorders. Another possibility is the detection of abnormal synchronization. This is not only at issue for hypersynchronized states such as tremor, myoclonus or epilepsy but also for disclosing abnormal interareal coupling or changes due to afferent pathology. The latter has recently been demonstrated in cases with pseudo-chorea-athetosis, a condition characterized by continuous involuntary finger movements following partial or complete deafferentation. Whereas the coherence during isometric muscle contraction was normal, the involuntary finger movements during rest exhibited an abnormally strong 12 Hz coherence between motor cortex and EMG reflecting a disinhibition of rhythmic cortical output. This coherence was not seen during voluntary finger movements (Timmermann et al., 2001).

A major difference between MEG and fMRI lies in the detection of dynamic and static behavioural states. fMRI is well suited to detect dynamic changes of behaviour. When examining the relationship between the fMRI signal during a static finger flexion task and dynamic finger flexions no or inconsistent small fMRI responses were recorded during the static task (Thickbroom et al., 1999). In contrast, the MEG is well suited to continuously record cortico-muscular or cortico-cortical coherences during static muscle contractions or behavioural states (Gross et al., 2000).

Microelectrode recordings

Microelectrode recordings can specify pathophysiology at a finer grain than macropotentials. They can reveal changes characteristic for certain disorders such as altered neuronal discharge patterns and rates or abnormal synchronization as they occur in movement disorders. Although such recordings have been employed for the study of cortical functions, the major field for microelectrode studies in the human brain is functional target localization during stereotactic surgery for the treatment of Parkinson's disease (STN), tremor (thalamus) and dystonia (thalamus, GPi). One major issue is the determination of the borders of the target nuclei and of the somatotopy therein, thus improving the precision of electrode placement. Beside somatotopy the discharge behaviour, firing pattern and rate, are characteristic for different basal ganglia compartments along the trajectory to the target as illustrated in Fig. 12.10. The adequate interpretation of these discharge patterns rests on comparisons with data recorded from non-human primates because normal data cannot be obtained from human subjects.

Recordings in Parkinson's disease

Gold-standard for our understanding of the pathophysiology of Parkinson's disease is the comparison with its animal model, the MPTP monkey where recordings in the basal ganglia show typical changes in discharge rates and pattern. Intraoperative microelectrode recordings in Parkinsonian patients show similar abnormalities. Spontaneous discharge rates in the STN that normally lie around 40 Hz are increased in Parkinson's disease and decreased in Huntington's chorea (Fig. 12.11). The increased firing rates of the excitatory glutamatergic STN neurons elicit increased firing rates in the inhibitory GABAergic output neurons of the GPi resulting in strong inhibition of their thalamic or brainstem target neurons. This inhibition is thought to arrest the ongoing motor activity in the thalamo-cortical loops involved in the regulation of motor behaviour. In contrast, intraoperative micro-

The dashed vertical line at –15 ms in the inset marks the minimum in the signal and the dashed trace shows the part of the signal that is accounted for by the dipole. (*b*) Coherence as function of frequency between EMG and M1 (solid line) and between EMG and the MEG signal with the highest coherence (dotted line). (*c*) The dipole superimposed on the subject's brain. (From Gross et al., 2000.)

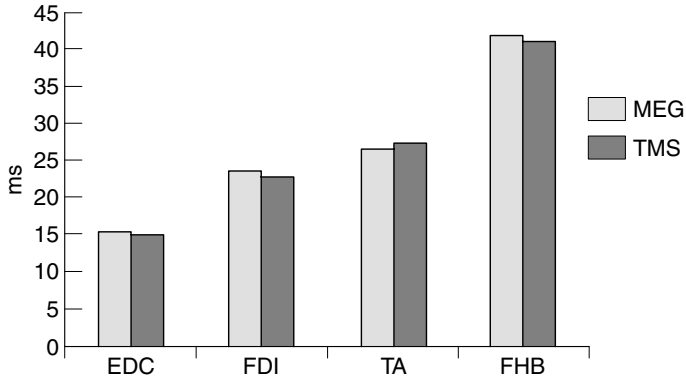

Fig. 12.9. Latencies calculated from cortico-muscular phase differences between MEG sources and EMG of the respective muscle (left column). The right column denotes the cortico-muscular conduction times determined by transcranial magnetic stimulation. (From Rothwell et al., 1991.)

electrode recordings from the GPi in dystonic patients revealed abnormally low spontaneous discharge rates of the pallidal neurons along with changes in the discharge characteristics from tonic to phasic discharge patterns (Lenz et al., 1999). The lower than normal firing rates in the GPi imply decreased inhibition of thalamic throughput to motor and premotor cortex.

The identification of the actual changes in firing rates and patterns along with the determination of increased synchronization between neurons, which is now possible with the use of multielectrodes, is of prime importance for disclosing the relevant aspects of the pathophysiology of the disease. They further provide the basis for a better understanding of the effects of deep brain stimulation (DBS) on these disordered neuronal states. DBS is assumed to act by desynchronizing and decreasing abnormal discharge rates thus counteracting the pathological discharge characteristics resulting from dopamine depletion.

What is presently unknown is the impact of DBS on neuronal discharge behaviour as it relates to the processing of motor but also limbic or complex loop information. Investigating the functional anatomy of these different basal ganglia loops in the monkey has shown that these segregated channels are funnelled through the basal ganglia via distinct microcircuitries. Accordingly, recordings in the human GPi or STN revealed that only a relatively small proportion of the neurons are motor related. Alterations in the discharge characteristics of the limbic and complex loop neurons will provide a more comprehensive picture of these complex relationships and hopefully allow a better understanding of the non-motor aspects of basal ganglia disorders.

Thalamic recordings

The thalamus is a major target for the treatment of tremor, but also for dystonia and pain (Hua et al., 2000). Thalamic recordings mainly in Vim show tremor related rhythmic burst activities possibly representing the neural drive for the motor network generating rhythmic motor output (Magnin et al., 2000). The thalamic oscillations are in part generated by the electrical properties of the neurons with the slow oscillatory tendency that is reinforced by the re-entry properties of the network connecting cortex and thalamus. Thalamic cells are barely activated by voluntary movements.

Recordings in the ventral caudal thalamus in dystonic patients showed large scale modifications of sensory maps with increased receptive fields of the somatosensory afferents showing extensive overlap and distortions of the somatotopic map (Hua et al., 2000). These changes are similar to those described in a monkey model where dystonia-like movements were induced by overuse of certain repetitive hand movements. Representations of the hand surface showed distinct remodelling in S1 with cutaneous receptive field extending across multiple digits and the whole hand, a somatotopic reorganization grossly different from the normal small distinct topographically ordered distribution (Byl et al., 1997). These alterations in thalamic somatotopic maps are particularly interesting with respect to receptive field enlargements in patients with amputations who show increases in the thalamic area from which stimulation evokes sensations in the stump area.

In conclusion, the microelectrode recordings are not only useful tools for improving the remaining inaccuracy of anatomical targeting but they provide new insights in the characteristic pathophysiological features. This information can solely be obtained by microphysiological exploration. For these reasons microphysiological recordings that are increasingly employed are relevant for new applications of DBS for the treatment of other disorders such as dystonia, bulimia and epilepsy.

Cortical recordings

Microelectrode recordings from the right and left superior, middle and inferior temporal gyri in conscious humans during open brain surgery for the treatment of epilepsy showed no significant differences between the right and left hemisphere with respect to neuronal responses to words and sentences (Creutzfeld et al., 1989a). All neurones in the superior temporal gyrus (STG) of both sides responded to various aspects of spoken language either by

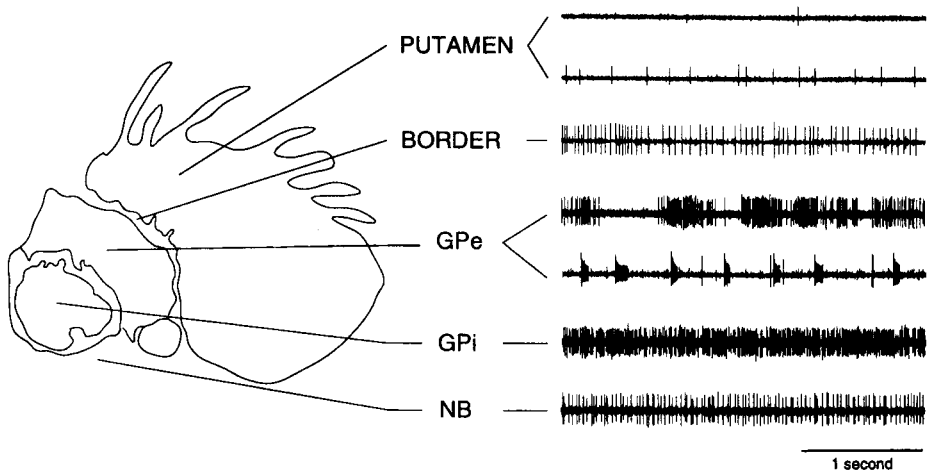

Fig. 12.10. Different patterns of neural activity encountered in the basal ganglia during a single penetration with the microelectrode. GPe: globus pallidus pars externa, GPi: globus pallidus pars interna, NB: nucleus basalis. (From Vitek et al., 1997.)

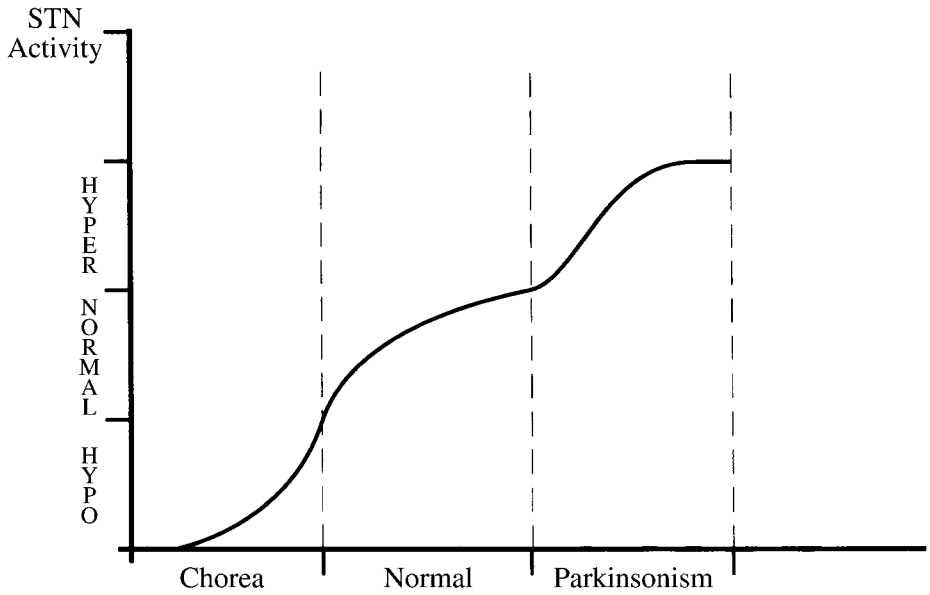

Fig. 12.11. Schematic explanation of how differences in the activity of the subthalamic nucleus (STN) modify the threshold for the appearance of chorea/ballism. In the parkinsonian state, STN activity is greatly augmented so that its lesion reduces basal ganglia output towards normal levels without necessarily reaching the threshold for dyskinesias. The normal state has a relatively wide range. Thus, a small focal lesion of the STN may not induce ballism. However, a large lesion will always be associated with ballism because it reduces the activity to well below the dyskinesia threshold. (From Guridi & Obeso, 1997.)

activation or inhibition without obvious changes in firing pattern or rate in response to non-linguistic acoustic input. Most neurones in the middle and inferior temporal gyri showed only minor modifications by listening to words or sentences.

Neuronal activity in response to the subject's own voice during overt naming or reading words or short sentences was also equally modified in the temporal lobes on both sides. Again, neurons in the STG responded clearly and in a characteristic manner (Creutzfeld et al., 1989b). These data demonstrate symmetrical language-related neuronal activity in both hemispheres of the adult brain. This opens

new perspectives for discussing concepts on asymmetries as known from clinical evidence and neuroimaging. The recordings are of particular interest with respect to the capacity of the minor hemisphere to take over language functions, as exemplified in children after left-sided hemispherectomies (Vargha-Khadem et al., 1997a).

In conclusion MEG and MEG/EEG combinations can identify event-related changes thus complementing fMRI and PET on a finer timescale. New developments overcame some previous limitations and now allow for reliable spatial localizations of multiple independent coherent sources. These maps can be compared with those established by fMRI and superimpose the fourth dimension of functional imaging, the high temporal resolution. For clinical neurology, MEG is a robust method for presurgical mapping, for the detection of epileptic foci and for the monitoring of postlesional plasticity. The examination of brain rhythms and coherences opens new inroads into the study of cortico-cortical and cortico-muscular coupling along with the determination of the respective conduction times. In contrast to the neurovascular methods they also provide information about this relationship in steady state conditions. Microelectrode recordings can assess regional pathophysiology in a unique way and help to understand how disturbed functions emerge and may be corrected.

[3] Harvard Medical School, Boston, MA, USA

Developmental malformations of the cerebral cortex represent a heterogeneous group of disorders that are individually rare, but that collectively account for a large number of cases of epilepsy, mental retardation and other cognitive disorders. Though many of the disorders discussed in this chapter have been known for decades, our view of them has been revolutionized in recent years. Two recent major advances facilitated our understanding of these disorders. First is the use of non-invasive brain imaging techniques, particularly MRI, in clinical neurological practice (Osborn et al., 1988). This has enabled accurate diagnosis of disorders of cortical development, which had only been diagnosed by post mortem examinations in the past. Improved imaging techniques have also led to the recognition of new clinical entities and the recognition of mendelian inheritance of many cortical malformations. Second are the advances in molecular genetics, which have allowed identification of genes responsible for inherited diseases using methods of positional cloning (Walsh, 1999). Identification of genes responsible for cortical malformations has led to molecular diagnosis in many cases. Furthermore, genes identified as responsible for human disorders have provided us with important clues to understand the mechanisms of normal brain development.

With these advances in our knowledge, the traditional classification scheme of cortical malformations, which is solely based on morphological abnormalities, has been reassessed. Several attempts have recently been made to classify the disorders of cortical development, reflecting new insights into their pathogenesis. A classification based on the time that the derangement is presumed to have occurred has been proposed (van der Knaap & Valk, 1988). Another classification system devised by Barkovich et al., (1996) is based on a combination of embryology, genetics, imaging and pathology. Because our understanding of these disorders is still incomplete, any classification is somewhat provisional. In this chapter, the disorders are categorized according mainly to the disturbed developmental process. As our knowledge about their pathogenesis evolves, the classification systems will inevitably be modified and refined.

Normal development of the cerebral cortex

The neurons of the cerebral cortex are formed in the ventricular zone, which consists of a specialized proliferative region along the wall of the lateral ventricles. The postmitotic neurons then leave the ventricular zone and migrate over considerable distances to reach the cortex. The first postmitotic neurons to leave the ventricular zone form a pioneer layer called the primordial plexiform layer (Marín-Padilla, 1971). This layer is later split into an outer marginal zone and a deeper subplate layer by later arriving neurons, which form the cortical plate. The cortical plate subsequently increases its thickness as it is populated by arriving neurons. Neurons are added to the cortical plate in an 'inside-out' fashion so that newly arriving neurons always migrate past older cortical plate neurons until they arrest immediately underneath the marginal zone. Consequently, the deeper cortical layers contain neurons born earlier in gestation, while more superficial cortical layers contain neurons born later in gestation (Fig. 13.1). In the marginal zone, Cajal–Retzius cells secrete a large extracellular protein, Reelin, which appears to act as a 'stop signal' for migrating neurons (Dulabon et al., 2000). The long-range migration of cortical neurons is guided by long, radially aligned glial cells, termed radial glial cells (Rakic, 1971, 1972). These cells extend from the ventricular zone to the pial surface, and serve as a 'scaffold' for the migrating neurons (see Fig. 13.1, in colour plate section).

Recently, it became clear that a large fraction of cortical neurons, particularly inhibitory interneurons, actually

originate outside of the cortex itself (Anderson et al., 1997; Tamamaki et al., 1997; Lavdas et al., 1999). These neurons are generated in the ganglionic eminence, which gives rise to the basal ganglia, and then migrate into the developing cortex moving tangentially. This mode of migration is called 'tangential' migration in contrast to the classic 'radial' migration (Walsh & Cepko, 1992). Tangentially migrating neurons do not appear to be guided by radial glial fibres in their course from the ganglionic eminence to the cortex.

In human cortex, postmitotic neurons start to migrate out of the ventricular zone into the primordial plexiform layer between the sixth and seventh fetal week (Marín-Padilla, 1983). Initial formation of the cortical plate occurs from the seventh to tenth fetal week (Sidman & Rakic, 1973; Marín-Padilla, 1983). Migration of neurons into the cortical plate appears to peak between the eleventh and fifteenth week of gestation (Sidman & Rakic, 1973). A majority of neurons have entered the cortical plate by around the twenty-fourth week of gestation (Marín-Padilla, 1990), although it is not clear when migration is finally completed. Distal processes of the radial glia disappear between the fifth and seventh month of gestation (Marín-Padilla, 1970), suggesting that little or no glia-guided migration occurs after this stage. With this general background we will briefly review the major developmental disorders in the rough sequence in which they disrupt patterning, proliferation, specification, and later stages of cortical neuronal development.

Disorders of pattern formation in the forebrain

Holoprosencephaly

The left and right cerebral hemispheres derive from the prosencephalon, which represents the rostral end of the neural tube. Holoprosencephaly (HPE) is a malformation characterized by failure of the normal cleavage of the prosencephalon to form two cerebral hemispheres. HPE shows a wide spectrum of severity, and clinically is categorized into three subgroups, namely, alobar, semilobar and lobar types. Alobar HPE refers to cases with complete or almost complete lack of cleavage. A single ventricle in the midline is seen in these cases. In semilobar HPE, there is often cleavage in the posterior aspect of the hemispheres, but the anterior portion lacks a separation. Lobar HPE shows formation of an interhemispheric fissure in both posterior and anterior aspects, and only a mild degree of incomplete separation is seen. The prevalence of HPE has been estimated to be 5–12/100 000 live births (Croen et al., 1996; Rasmussen et al., 1996; Olsen et al., 1997), but this may underestimate the true incidence, as milder cases are increasingly recognized. Also, in one large series, HPE was found in 0.4 % of embryos (Matsunaga & Shiota, 1977).

The clinical manifestations of HPE cover a wide spectrum, reflecting the wide range of structural abnormalities. Microcephaly is the rule. Dysfunction of the hypothalamic–pituitary axis, including diabetes inspidus and growth hormone deficiency, can be seen. Children with alobar HPE have profound developmental delay, but even these children can often acquire new skills and interact with the environment, albeit slowly and in limited fashion (Barr & Cohen, 1999). Associated facial anomalies also vary widely. Alobar HPE can be accompanied by cyclopia, ethmocephaly (ocular hypotelorism with proboscis, which is a rudimentary nose-like structure), cebocephaly (ocular hypotelorism and a blind-ended, single-nostril nose) or a median cleft lip. In contrast, semilobar HPE or lobar HPE are often accompanied by milder facial phenotypes, including ocular hypotelorism, hypertelorism, a unilateral or bilateral cleft lip, or a single midline incisor (Cohen, 1989).

The etiology of HPE is complex, and both genetic and environmental factors seem to play a role. Approximately 20–40% of children with HPE have chromosome anomalies, with trisomy 13 being most common, followed by trisomy 18 (Kinsman et al., 2000). HPE can also be seen in association with various genetic syndromes, such as the Smith–Lemli–Opitz syndrome. These observations, as well as autosomal dominant inheritance in some families, strongly suggested genetic causes of HPE. A recent extensive search for causative genes has implicated at least 12 different loci in 11 chromosomes (Roessler & Muenke, 1998). So far, four genes have been identified as causative genes for HPE. The first one to be identified was the *Sonic Hedgehog* (*SHH*) gene on chromosome 7q36, which is homologous to the *Drosophila melanogaster* segment polarity gene *hedgehog* (Roessler et al., 1996). *SHH* is highly expressed in the ventral neural tube, and considered a critical molecule in dorsoventral patterning of the neural tube. *SIX3* (Wallis et al., 1999) and *ZIC2* (Brown et al., 1998), localized on chromosomes 2p21 and 13q32, respectively, are transcription factors that are implicated in forebrain development. More recently, a homeobox gene on chromosome 18p11.3, named *TGIF*, has been found to be mutated in HPE (Gripp et al., 2000). Cellular mechanisms by which mutations in these genes cause HPE are being studied intensely. Environmental factors also seem to be crucial in some cases, and maternal gestational diabetes has been associated with increased risk of HPE in the offspring (Martínez-Frías et al., 1998).

Disorders of cell fate, proliferation and specification

Microcephaly

Overview

Microcephaly is a condition in which the size of the cranial vault, measured by the occipito-frontal head circumference (OFC), is significantly smaller than the standard for the person's age and sex. OFC of less than 2 standard deviations below the mean is often used as a definition, although some researchers use other cut-off points such as 3 standard deviations. The etiology of microcephaly is extremely diverse, posing challenges to clinicians dealing with this condition, but can be broadly divided into environmental and genetic causes. Common environmental causes include congenital infection, intrauterine exposure to teratogenic agents, and hypoxic–ischemic injury. The clinical history usually provides important diagnostic clues in these cases. On the other hand, even the genetic causes of microcephaly are quite diverse (Table 13.1; Mochida & Walsh, 2001). For example, hereditary metabolic disorders, which cause neuronal degeneration, usually cause the postnatal onset of microcephaly (acquired microcephaly) and are not discussed here.

Genetic causes of microcephaly associated with microcephaly at birth (congenital microcephaly) frequently reflect developmental malformations of the cerebral cortex. For example, microcephaly is frequently seen in association with chromosomal abnormalities or other well-defined genetic syndromes (e.g. Smith–Lemli–Opitz syndrome). These disorders are not reviewed here. An overview of 'syndromal' microcephaly has also been provided by Opitz and Holt (1990). In these cases, the characteristic patterns of involvement of other organ systems and/or the presence of specific dysmorphic features often help make the diagnosis. Other well-characterized CNS disorders such as neuronal migration disorders (e.g. lissencephaly) can be associated with microcephaly without other organ involvement, and these conditions are described below. Finally, there are an increasing number of syndromes and genetic loci in which the central nervous system is typically the only affected organ system and in which the brain is characteristically quite small but the normal pattern is relatively well preserved ('isolated microcephaly'). The prototype of this group of disorders is microcephaly vera, which is discussed next. Other forms of isolated microcephaly are also briefly mentioned in the section.

Table 13.1. Genetic forms of microcephaly

I.	Isolated microcephaly
	A. Autosomal recessive microcephaly
	(i) Microcephaly vera
	(ii) Microcephaly with simplified gyral pattern
	B. Autosomal dominant microcephaly
	C. X-linked microcephaly
II.	Microcephaly associated with major brain malformations
	A. Holoprosencephaly
	B. Schizencephaly
	C. Lissencephaly
	D. Others
III.	Chromosomal disorders
	A. Down's syndrome and other trisomies
	B. Chromosome deletions/duplications
	C. Others
IV.	Microcephaly associated with genetic syndromes
	A. Smith–Lemli–Opitz syndrome
	B. Rubinstein–Taybi syndrome
	C. Angelman syndrome
	D. Rett syndrome
	E. Cornelia de Lange syndrome
	F. Others
V.	Microcephaly associated with hereditary metabolic disorders

Notes:
This table briefly summarizes genetic conditions associated with microcephaly. Only major disorders are listed in the categories II through IV, and the existence of additional syndromes that are not included is indicated by 'others'. The vast assortment of degenerative metabolic disorders associated with postnatal onset of microcephaly are described in other chapters and are not listed here.

Microcephaly vera

Introduction

This term, meaning 'true' microcephaly, was coined by Giacomini in 1885 to denote a condition in which no gross pathological abnormality other than smallness of the brain was observed (Friede, 1989a). When this term is used in a broader sense, it may include a wide variety of isolated microcephaly. Here we use a narrower definition, implying a subgroup of isolated microcephaly with certain clinical features described below.

Clinical features

Microcephaly vera is characterized by microcephaly at birth, relatively normal early motor milestones and mental retardation of variable severity. Usually, there are few

dysmorphic features, except narrow, sloping forehead and relative prominence of ears. Seizures are relatively uncommon. On imaging studies, there are little or no gross abnormalities of the brain architecture, except its smallness. Other subtypes of isolated microcephaly are often associated with different clinical manifestations (see below).

Pathology

Grossly, the gyral pattern is relatively well preserved despite the often striking smallness of the brain. Histopathological study of the brain may reveal no microscopic abnormality in cortical laminar formation (McCreary et al., 1996). In some cases, depletion of neurons in cortical layers II and III (i.e. later-born neurons), as well as early depletion of cells in the germinative zone near the ventricles have been observed (Evrard et al., 1989). This led to a hypothesis that premature exhaustion of neuronal progenitors in the ventricular zone might be responsible for microcephaly vera (Evrard et al., 1989).

Genetics

Microcephaly vera is often inherited as an autosomal recessive trait, and has recently become a subject of active linkage analysis. Microcephaly is frequently seen in geographical areas with high consanguinity rates, such as the Middle East (Farag et al., 1993). Recently, five genetic loci for autosomal recessive microcephaly have been mapped. These loci, termed *MCPH 1*, *2*, *3*, *4* and *5*, map to chromosomes 8p22-pter (Jackson et al., 1998), 19q13.1–13.2 (Roberts et al., 1999), 9q34 (Moynihan et al., 2000), 15q (Jamieson et al., 1999) and 1q25–32 (Jamieson et al., 2000; Pattison et al., 2000), respectively. The clinical presentation of the patients in pedigrees that map to these five distinct loci is similar enough to suggest that there will be significant genetic heterogeneity in autosomal recessive microcephaly.

Some cases of isolated microcephaly, however, are distinguished on the basis of imaging studies and clinical phenotypes. For example, there are patients who show an abnormally simplified gyral pattern, namely too few and often shallow sulci (Barkovich et al., 1998), and some of these cases are consistent with an autosomal recessive mode of inheritance(Peiffer et al., 1999; Sztriha et al., 1999). This group of patients tend to show more severe neurological signs and symptoms, such as spasticity, severe developmental delay and seizures. An autosomal dominant form of microcephaly has also been described, and is perhaps relatively common; however, this form is often associated with normal intelligence and may not come to clinicians' attention very often (Ramírez et al., 1983).

The assessment of recurrence risk of microcephaly is often challenging because of the heterogeneous nature of this condition. Unless the mode of inheritance is evident from family history and examination, accurate assessment may be difficult. In one population-based study in British Columbia, Canada, the recurrence risk of mental retardation in the siblings of microcephalic individuals was estimated to be 5.9%, one-third of whom also had microcephaly (Herbst & Baird, 1982). Another study estimated the recurrence risk of microcephaly in siblings of microcephalic individuals to be 19% (Tolmie et al., 1987), more suggestive of an autosomal recessive trait. This large difference may reflect differences in the percentage of autosomal recessive forms of microcephaly in each population studied.

Biological basis

Since no genes responsible for this condition have been found yet, the exact pathogenesis remains unclear. Although a decreased number of neurons in the cerebral cortex is considered to be primarily responsible for the smallness of the brain in microcephaly vera, there are many potential ways in which the number of cortical neurons can be subnormal. For example, decreased proliferation of neuronal progenitors, decreased production of mature neurons by each neuronal progenitor, or excessive cell death of neuronal progenitors or of mature neurons may all lead to an eventual decrease in the number of neurons. One or more of these mechanisms may be involved in the pathogenesis of microcephaly vera, but these mechanisms will not be clear until genes are identified.

Schizencephaly

Introduction

The term 'schizencephaly', originally coined by Yakovlev and Wadsworth in 1946, refers to a full-thickness cleft of the cerebral mantle (Yakovlev & Wadsworth, 1946a, b). The cleft extends from the pial surface to the lateral ventricle, and the walls of the cleft are usually lined by abnormal polymicrogyric cortex. Schizencephaly can be divided into two subtypes, namely, closed-lip type and open-lip type. When two walls, or lips, are in apposition, it is called closed-lip schizencephaly. On the other hand, in open-lip schizencephaly, the two walls are separated by a cerebrospinal fluid space (Fig. 13.2). Although the word schizencephaly has gained wide acceptance, the term 'porencephaly' is often favoured by pathologists in describing the same anatomical abnormality.

Fig. 13.2. Open-lip schizencephaly. Axial MRI shows a large schizencephalic cleft, which is lined by polymicrogyric cortex (arrowheads). Absence of the septum pellucidum is also noted (arrow).

Clinical features

The clinical presentation of patients with schizencephaly varies depending upon the type and extent of malformation, as well as the location of the cleft. The closed-lip type often presents with hemiparesis or seizures. The open-lip type can present with motor delay or seizures, but hydrocephalus may be the first presentation (Packard et al., 1997). In open-lip schizencephaly, sometimes large amounts of cerebral mantle, spanning more than one lobe, may be absent, and affected patients generally have poor neurodevelopmental outcome compared to the closed-lip variety. Seizures are commonly seen, and the seizure types can be either focal or generalized. Some cases may present with infantile spasms. Seizures can be refractory, but there are no good early predictors of seizures that are difficult to control.

Pathology

The walls, or lips, of the cleft are usually lined with polymicrogyric cortex (see Fig. 13.2). The areas of abnormal cortex may extend outside the cleft. Where the walls are in apposition, they form a so-called pia-ependymal seam. When followed from outer surface into the cleft, cells of the pia show transition to ependymal cells of the ventricular surface via this 'seam'. There are often other associated developmental abnormalities, such as absence of the septum pellucidum or focal cortical dysplasia.

Genetics

Schizencephaly is usually sporadic, but there have been case reports of recurrence in siblings, suggesting a possible genetic origin in at least some cases (Hosley et al., 1992; Hilburger et al., 1993; Haverkamp et al., 1995). In 1996, heterozygous mutations in a homeobox gene, *EMX2*, were reported in three patients with severe cases of schizencephaly (Brunelli et al., 1996). Subsequent reports described additional patients with mutations, including a family with two affected siblings (Faiella et al., 1997; Granata et al., 1997). These mutations were *de novo*, namely not present in the parents. At this point, it is not clear what proportion of patients with schizencephaly has mutations in *EMX2*. It is possible that there are other genes that can cause schizencephaly.

Biological basis

The role of *EMX2* in brain development is yet to be fully elucidated, but recent reports suggest it has a role in determining area identity in the neocortex. *EMX2* is expressed highly in caudal and medial areas of developing mouse neocortex, and in *EMX2* knockout mice, areas of neocortex with caudal and medial identity are found to be contracted (Bishop et al., 2000; Mallamaci et al., 2000). These mice, as well as heterozygous mutant mice, do not have a phenotype that resembles human schizencephaly.

There is also a strong argument for the presence of non-genetic causes of schizencephaly. Hypoxic–ischemic insult early in fetal life has been considered to be a strong possibility. Schizencephalic clefts are usually lined by polymicrogyric cortex, and this may argue for a common pathogenesis of schizencephaly and polymicrogyria. Since there is evidence suggesting hypoxic–ischemic injury as a cause of polymicrogyria in some cases (see below), it is conceivable that some cases of schizencephaly may be a result of a similar insult. This notion of shared pathogenesis between schizencephaly and polymicrogyria may further be supported by the observation that areas of cortical dysplasia in schizencephalic brains often appear to be polymicrogyria (Barkovich & Kjos, 1992c).

Focal cortical dysplasia

Introduction

Focal cortical dysplasia (FCD) refers to a localized area of disorganized cortex, which interrupts a morphologically

normal cortex. This concept was originally proposed by Taylor et al., (1971). They reported ten patients who underwent lobectomy for epilepsy and were found to have similar histopathologic features. Microscopic examination of the resected specimens showed 'localized disruption of the normal cortical lamination by an excess of large aberrant neurones scattered randomly through all but the first layer'. In most cases, 'grotesque cells, probably glial in origin, were also present in the depths of the affected cortex and in the subjacent white matter'. These bizarre cells are called 'balloon cells', and their origin is not clear.

Clinical features

Common clinical manifestations include seizures, focal neurological signs, and when the abnormality is extensive, developmental delay. FCD is a well-known cause of intractable epilepsy, and it is reported to be found in 15–40% of cases of extratemporal lobe resection (Wolf et al., 1993; Frater et al., 2000). MRI is useful in detecting FCD. Characteristic findings include blurring of the grey–white junction, widening of gyri, thickening of the cortical ribbon and increased T_2-weighted signal in subcortical white matter underlying the abnormal cortex (Yagishita et al., 1997; Chan et al., 1998; Lee et al., 1998). Detection of FCD by MRI frequently requires the use of specialized techniques and data reformatting (Barkovich et al., 1995; Grant et al., 1997). The term 'focal transmantle dysplasia' has recently been coined to describe a subtype of FCD, in which the area of dysplasia spans the entire thickness of the cerebral mantle (Barkovich et al., 1997).

Pathology

Histological changes in FCD include cortical laminar disorganization, neuronal cytomegaly (enlargement of the neuronal cell body), increased neurons in the molecular layer (layer I), heterotopic neurons in the white matter and balloon cell change (Mischel et al., 1995; Frater et al., 2000). Often two or more of these findings are seen in combination within a single lesion. The histological changes may be mild and, for example, limited to disorganization of cortical architecture, or marked with all of the features described in the original report by Taylor et al. The latter is sometimes called 'Taylor-type' FCD, and balloon cells are often considered its hallmark. These cells are typically located in the deep cortical layers or in the white matter underneath the abnormal cortex. They have a large cell body with glassy, eosinophilic cytoplasm and pleomorphic, eccentric nuclei. Immunohistochemical stains reveal variable staining with neuronal markers, glial markers or both (Vinters et al., 1992; Vital et al., 1994). In some cases, tumours, such as ganglioglioma or dysembryoplastic neuroepithelial tumour, may be found to coexist with an area of FCD (Prayson et al., 1993; Frater et al., 2000).

Genetics

FCD is usually encountered as a sporadic, non-inherited condition. Although one pedigree has been reported with apparently familial FCD, this is quite unusual (Muntaner et al., 1997).

Biological basis

The pathogenesis of FCD is not yet clear. However, it has been suggested that cell fate determination and differentiation are deranged in this condition. Balloon cells are known to express markers for neuronal and/or glial lineage, which may suggest failure of appropriate cell fate determination. Recently, altered staining patterns of proteins in the Wnt/Notch signalling pathway, which is important in neuronal cell fate determination and differentiation, was also reported, further suggesting abnormality in commitment of progenitor cells (Cotter et al., 1999).

The histopathological features of FCD show similarity to cortical tubers seen in tuberous sclerosis. Within the tubers, normal laminar structure is lost, and enlarged, dysmorphic neurons as well as 'giant cells' (or 'balloon cells') with abundant eosinophilic cytoplasm are seen. These giant cells variably express neuronal and glial markers (Hirose et al., 1995). These similarities have led to a debate whether FCD represents a 'forme fruste' of tuberous sclerosis, though this has not been settled yet (Andermann et al., 1987).

Disorders of neuronal migration

Classical lissencephaly

Overview

The term 'lissencephaly' derives from the Greek words '*lissos*', meaning 'smooth', and '*enkephalos*', meaning 'brain'. As the name implies, lissencephaly refers to a brain with a lack or severe paucity of normal gyri, and as a result, it appears smooth on the surface (Fig. 13.3). Related terms include 'agyria' and 'pachygyria'. Agyria refers to a complete lack of gyri, whereas pachygyria refers to a broadening of gyri. As many patients with lissencephaly have mixed agyric and pachygyric areas, some people prefer 'agyria/pachygyria'. Several clinical entities are associated with this type of malformation, including Miller–Dieker syndrome, isolated lissencephaly and double cortex/X-

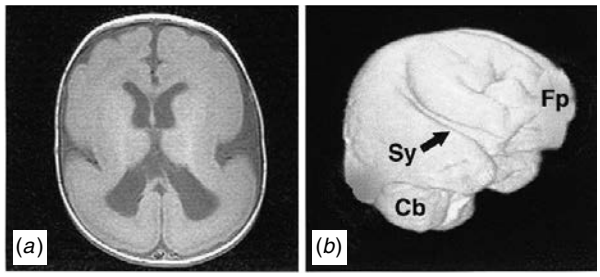

Fig. 13.3. Classical lissencephaly. Axial MRI image of classical lissencephaly (*a*) shows paucity of gyri and typical 'figure-eight' appearance. 3D-reconstruction of MRI images (*b*) illustrates lack of gyration, with posterior aspects of the brain being more severely affected, and a few rudimentary gyri remaining anteriorly. The sylvian fissure is exposed because of poor development of the operculum. Fp = frontal pole, Sy = sylvian fissure, Cb = cerebellum. (Courtesy of Dr P. Ellen Grant.)

linked lissencephaly syndrome. These disorders will be discussed below.

Miller–Dieker syndrome and isolated lissencephaly sequence

Introduction

The prototype of the disorders with classical lissencephaly is Miller–Dieker syndrome (MDS), which consists of classical lissencephaly and characteristic dysmorphic facial features. Even though the cases reported by Miller (1963) and Dieker et al., (1969) were familial, most cases of MDS are sporadic. Patients with classical lissencephaly, but without characteristic facial features of MDS, are classified as having isolated lissencephaly sequence (ILS) (Dobyns et al., 1984).

Clinical features

Essentially all children with classical lissencephaly have profound developmental delay. About half achieve essentially no developmental milestones, and the rest acquire some social and motor skills (Dobyns et al., 1993). The majority of the patients have seizures, which often start during the first 6 months of life (de Rijk-van Andel et al., 1990). Various seizure types are seen, but infantile spasms are common. Only a minority of patients are microcephalic at birth, but almost all fall within the microcephalic range during the first year of life due to a lack of normal brain growth (Dobyns et al., 1993). Patients with MDS have characteristic facial features, which include a prominent forehead, bitemporal narrowing, widely spaced eyes with upward slanting palpebral fissures, short nose with anteverted nares, thin vermilion border of the upper lip, and small chin (Jones et al., 1980; Dobyns et al., 1993). Some patients with MDS also have digital abnormalities (e.g. syndactyly), congenital heart disease and other visceral abnormalities (Jones et al., 1980; de Rijk-van Andel et al., 1990).

On imaging studies, the cerebral hemispheres have decreased convolutions. Often agyric areas coexist with pachygyric areas in a given patient. There is a lack of development of the frontal and parietal opercula, which leads to a characteristic 'figure-eight' shape of the brain on axial images. The lateral ventricles, particularly posterior aspects, are enlarged. Absence or hypoplasia of corpus callosum may be seen. Small midline calcifications in the region of the septum pellucidum may be present in patients with MDS (Dobyns et al., 1993).

Pathology

The cerebral cortex of classical lissencephaly is abnormally thick, and the ratio of grey to white matter is greatly increased. The cortex comprises four layers instead of the normal six layers (Crome, 1956). These four layers are (i) marginal layer, (ii) superficial cellular layer, (iii) sparsely cellular layer, and (iv) deep cellular layer. Whereas the cell-sparse subpial marginal layer corresponds to layer I of the normal cortex, the precise relationship of the three other lissencephalic layers to the five other normal cortical layers is not certain. In the brainstem, dysplastic inferior olivary nuclei with large heterotopias are characteristic (Kuchelmeister et al., 1993). On the other hand, the cerebellum in MDS is typically remarkably normal.

Genetics

Identification of patients with MDS and monosomy of chromosome 17p suggested that this locus might harbour a gene responsible for this condition (Dobyns et al., 1983). A decade later, the causative gene for MDS was found in this locus, and was named *LIS1* (Reiner et al., 1993). Subsequent analyses showed more than 90% of patients with MDS and approximately 40% of patients with ILS have deletions of the *LIS1* gene (Pilz et al., 1998). Point mutations of *LIS1* have also been identified among patients with ILS (Lo Nigro et al., 1997). As the deletions are generally larger in patients with MDS than those with ILS, it has been suggested that MDS may represent a contiguous gene syndrome, in which deletion of additional genes is responsible for the dysmorphic features of MDS (Dobyns et al., 1993).

Most of the mutations of *LIS1* that cause MDS and ILS seem to arise *de novo*. Therefore, if a deletion or a mutation of *LIS1* is found in a patient, the risk of recurrence in siblings is considered to be very low (Leventer et al., 2000). An

exception to this is when one of the parents harbours a balanced translocation involving the *LIS1* locus. In such a situation, the risk is considerably higher, with up to 33% of the offspring having an abnormal genotype (i.e. deletion or duplication of chromosome 17p) and/or phenotype (Pollin et al., 1999). Translocations involving chromosome 17p were later found in both families originally reported by Miller (1963) and Dieker et al., (1969), explaining recurrence in these families (Dobyns et al., 1984).

Biological basis

After identification as the causative gene for MDS, *LIS1* was found to encode a regulatory subunit of platelet activating factor acetylhydrolase, an enzyme which inactivates platelet activating factor (PAF) (Hattori et al., 1994). However, the role of PAF in neuronal migration has not been well established. It has been suggested that the LIS1 protein may regulate neuronal migration through pathways other than PAF. For example, LIS1 has been shown to associate with microtubules directly and to stabilize them (Sapir et al., 1997), and to interact with other protein components of the microtubule organizing center (Feng et al., 2000). As microtubules are important in cell motility, this function is probably pertinent to the control of neuronal migration.

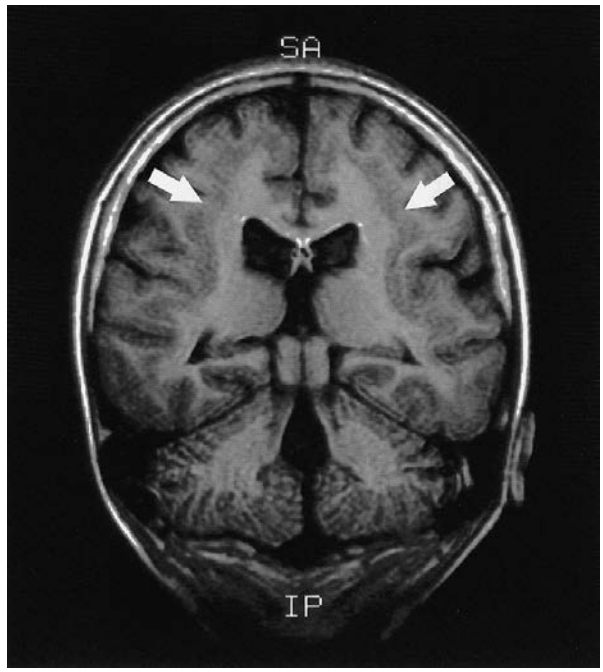

Fig. 13.4. Double cortex. Coronal MRI image shows a band of heterotopic grey matter (arrows) between the cortex and the lateral ventricles.

Double cortex/X-linked lissencephaly syndrome

Introduction

In this unusual condition, males and females are both clinically affected, but show very different disorders due to mutation in a common, X-linked gene. Males with mutation of the *doublecortin* (*DCX*) gene show classical lissencephaly that is generally similar to that seen in *LIS1* mutation. On the other hand, affected heterozygous females show a different malformation called 'double cortex' syndrome (DC; also known as 'subcortical band heterotopia' or 'laminar heterotopia'), where there is a band of heterotopic neurons in between the cortex and the lateral ventricles (Fig. 13.4). Even though DC has been known for many years from autopsy studies (Matell, 1893; Friede, 1989b), its recognition as an X-linked disorder, which causes lissencephaly in males, did not come until recently. In 1994, two families were reported, in which mothers with DC had sons with lissencephaly and daughters with DC (Pinard et al., 1994). This established the mode of inheritance, and also led to the recognition that there is a second genetic locus for classical lissencephaly.

Clinical features

The main clinical features of the affected females are epilepsy and mental retardation. Seizures often start during the first decade. Various seizure types have been documented, including generalized tonic–clonic, complex partial, myoclonic, atypical absence and atonic (Palmini et al., 1991; Barkovich et al., 1994; Gleeson et al., 2000a). Response to anticonvulsant therapy varies widely. Mental retardation is often mild to moderate. There is some suggestion that cognitive development may slow after the onset of seizures (Palmini et al., 1991). Imaging studies of the females usually show a symmetric, thick band of grey matter deep to the cortex (see Fig. 13.4; Barkovich et al., 1989). The overlying cortex often shows mild pachygyria (Barkovich et al., 1989; Palmini et al., 1991). On the other hand, the affected males show similar neurological manifestation as Miller–Dieker syndrome and isolated lissencephaly sequence, with profound developmental delay and epilepsy. Imaging findings of the males are also very similar to that of Miller–Dieker syndrome. However, the pattern of malformation is slightly different. In the X-linked lissencephaly (XLIS), anterior aspects of the brain tend to be more severely affected, in contrast to the lissencephaly due to *LIS1* mutations, where posterior aspects of the brain are almost always more severely affected (Pilz et al., 1998; Dobyns et al., 1999).

Pathology

Brains with DC show a symmetric band of grey matter between the cortex and the lateral ventricles. Microscopically, the overlying cortex shows a normal six-layered structure (Friede, 1989b). Heterotopic grey matter consists of coalescent clusters of unlaminated, well-differentiated neurons (Palmini et al., 1991). Males with XLIS show brain pathology similar to Miller–Dieker syndrome (Berg et al., 1998).

Genetics

Linkage analysis of familial cases and studies of a patient with lissencephaly and a translocation involving the X-chromosome localized the DC/XLIS locus in chromosome Xq22.3–q23 (des Portes et al., 1997; Ross et al., 1997). Subsequently, a novel gene in this region was cloned as the causative gene, and was named *doublecortin* (*DCX*) (des Portes et al., 1998; Gleeson et al., 1998). While most cases of DC or XLIS represent *de novo* mutations, families with multiple affected children can occur if the mother has subtle clinical signs or is a somatic mosaic for *DCX* mutation (Gleeson et al., 2000b). Mutation analysis of a large number of patients with DC revealed that there are patients who do not harbor a mutation in *DCX* gene (Gleeson et al., 2000a). This suggests that DC is a genetically heterogeneous disorder, and other genetic loci may be responsible for some cases of DC. Mutation analysis of patients with isolated lissencephaly sequence, who did not show deletion of *LIS1* locus detectable by fluorescence *in situ* hybridization, revealed mutations of *LIS1* gene in 40% of the cases and mutations of *DCX* gene in 20% (Pilz et al., 1998). Thus, these two genes are thought to be responsible for the majority of cases with isolated lissencephaly sequence.

Biological basis

Doublecortin is a protein that is specific to the developing nervous system, and that is widely expressed by migrating neurons (Francis et al., 1999; Gleeson et al., 1999). It has been shown to interact with microtubules, and to increase the stability of microtubules (Francis et al., 1999; Gleeson et al., 1999; Horesh et al., 1999), and the amino acid substitution mutations that cause DC/XLIS occur in the microtubule binding domain of the protein (Sapir et al., 2000; Taylor et al., 2000). It is interesting to note that two proteins that are associated with classical lissencephaly, LIS1 and Doublecortin, have been shown to interact with microtubules and possibly regulate them. This supports the hypothesis that regulation of microtubule dynamics is essential in neuronal migration, and that interruption of this process contributes to the pathogenesis of classical lissencephaly.

Lissencephaly with cerebellar hypoplasia

Lissencephaly with cerebellar hypoplasia is an autosomal recessive condition characterized by an abnormally thick and simplified gyral pattern of the cerebral cortex and hypoplasia of the cerebellum. Clinical features include hypotonia, severe developmental delay, seizures, and nystagmus (Hourihane et al., 1993; Al Shawan et al., 1996). Recently, mutations in the *RELN* gene were identified as a cause of this malformation (Hong et al., 2000). The protein product, Reelin, is a human homologue of a mouse protein, which was originally identified as the gene product that is mutated in the '*reeler*' mouse (D'Arcangelo et al., 1995). The anatomical abnormalities of the *reeler* mouse include disorganized lamination of the cerebral cortex, as well as severe hypoplasia of the cerebellum (de Rouvroit & Goffinet, 1998). Reelin is a protein secreted by Cajal–Retzius cells, which are early-born neurons that populate the embryonic marginal zone. Several molecules such as lipoprotein receptors (D'Arcangelo et al., 1999; Hiesberger et al., 1999; Trommsdorff et al., 1999), cadherin-related neuronal receptors (Senzaki et al., 1999) and $\alpha 3\beta 1$ integrin (Dulabon et al., 2000) have all been shown to act as potential receptors for Reelin. Although there is some evidence that Reelin functions in arresting migrating neurons at their proper cortical location (Dulabon et al., 2000), the precise molecular pathways through which Reelin regulates neuronal migration have not been completely elucidated.

Periventricular heterotopia

Introduction

Periventricular heterotopia (PH) is a malformation in which heterotopic nodules of grey matter are seen in the subependymal region (Fig. 13.5). Several familial cases of PH were recently reported, and this led to the recognition that this entity is genetic (DiMario et al., 1993; Kamuro & Tenokuchi, 1993; Huttenlocher et al., 1994). It was noted that typically only females were affected, and there was a high rate of miscarriages among affected females. These observations suggested that periventricular heterotopia was an X-linked disorder with prenatal lethality in affected males (Huttenlocher et al., 1994). It is now recognized that many of these cases reflect mutations of the X-linked gene, *FLN1*.

Clinical features

The most common presentation of PH in affected females is epilepsy. Common seizure types include generalized tonic–clonic and complex partial (Barkovich & Kjos, 1992a; Huttenlocher et al., 1994). Onset of the seizures is most

Fig. 13.5. Periventricular heterotopia. Axial MRI image shows nodular masses of grey matter (arrowheads) lining the wall of the lateral ventricles. Note that the nodules have the same signal characteristics as the normal grey matter.

commonly before the mid-20s, with an average of around 15 years (Ekşioğlu et al., 1996). Seizures may be infrequent and easily controlled, or intractable. Most individuals with PH have normal intelligence, and a minority have borderline mental retardation (Dobyns et al., 1996); 25% of affected patients may have no obvious neurological manifestations (Ekşioğlu et al., 1996). An increased incidence of patent ductus arteriosus and strokes at younger age has been reported (Fox et al., 1998).

MRI imaging characteristically shows nodular, subependymal masses, which are isointense with cortical grey matter in all imaging sequences (see Fig. 13.5; Barkovich & Kjos, 1992a). The heterotopic nodules are usually bilateral, though they may occur unilaterally. The overlying cortex is typically normal appearing. Enlargement of the cisterna magna, which may represent subtle cerebellar hypoplasia, is also common.

Pathology

The heterotopic grey matter lines the lateral ventricles as round nodules separated from each other by myelinated fibres. Microscopically, the nodules consist of highly differentiated neurons, which are haphazardly oriented (Ekşioğlu et al., 1996).

Genetics

PH may be familial or sporadic. Familial cases show X-linked dominant inheritance with presumed prenatal lethality in affected males. Most of the sporadic cases are also females, though sporadic male patients with a similar clinical presentation to females have been known (Huttenlocher et al., 1994; Dobyns et al., 1996).

Linkage analysis in familial cases identified the disease locus in chromosome Xq28 (Ekşioğlu et al., 1996). Subsequently, mutations in *FLN1* gene were identified as the cause of this disorder (Fox et al., 1998). Some of the sporadic cases have also been found to harbor mutations in *FLN1* (Fox et al., 1998).

Biological basis

The *FLN1* gene encodes Filamin 1, a large cytoplasmic actin-binding protein that is also known as actin binding protein 280 (ABP-280). It was originally identified as a high molecular weight protein isolated from macrophages that precipitated actin (Hartwig & Stossel, 1975). Subsequently, Filamin 1 was shown to be essential for migration in malignant melanoma cells (Cunningham et al., 1992) and macrophages (Stendahl et al., 1980) in vitro, but its role in neuronal migration was not suspected until it was identified as the causative gene in PH. *FLN1* gene is expressed by the cortical neurons during migration (Fox et al., 1998). It probably acts as a link between extracellular signals and the actin cytoskeleton, thereby controlling actin cross-linking, which is critical to the neuronal migration. Filamin 1 has been suggested to have roles in hemostasis and vascular remodelling, which may explain the high prevalence of strokes at young ages and patent ductus arteriosus in females, and the apparent prenatal lethality of affected males (Fox et al., 1998).

How the presence of heterotopic nodules leads to epilepsy is poorly understood. The heterotopic neurons were shown to form synapses, but the source of this innervation is unclear (Ekşioğlu et al., 1996). Knowledge of the functional connectivity of the heterotopic neurons will most likely help understand the pathogenesis of epilepsy in this disorder.

Disorders of the integrity of the pial surface

Cobblestone dysplasia

Introduction

Cobblestone dysplasia is characterized by disorganized cortical lamination and the proliferation of gliovascular

tissue, which contains ectopic neurons on the pial surface of the brain. This surface abnormality gives rise to a nodular appearance, therefore the term 'cobblestone dysplasia' is applied. It is also called 'type II lissencephaly' (in contrast to 'type I' or 'classical' lissencephaly) or 'cobblestone lissencephaly', because normal gyration is often absent and as a result, the brain appears smooth on its surface. However, cobblestone dysplasia often shows various abnormal gyral patterns, including agyria, pachygyria and polymicrogyria. Therefore, it is probably better to avoid applying the term lissencephaly in this condition, and the term cobblestone dysplasia has been developed to describe it more precisely.

Cobblestone dysplasia is seen in association with three human genetic disorders: Fukuyama-type congenital muscular dystrophy (FCMD), Walker–Warburg syndrome (WWS) and muscle–eye–brain disease (MEB). FCMD is primarily seen in Japan, and MEB is most commonly seen in Finland. WWS has been reported from various parts of the world.

Clinical features

Brain and muscle involvement is common to all three disorders, but the clinical features are more or less unique in each disorder. FCMD presents with early (before 8 or 9 months) hypotonia, generalized weakness (including facial muscles), mental retardation and occasional seizures, and the condition appears to be very slowly progressive (Fukuyama et al., 1981). WWS generally has a much more severe phenotype. Often, affected children present with severe hypotonia and lethargy during the neonatal period. Median survival for live-born infants in one study was 18 weeks, although some children survive beyond 5 years (Dobyns et al., 1989). Various forms of eye and retinal abnormalities are seen, including microphthalmia, coloboma, retinal dysplasia, retinal non-attachment/detachment (Pagon et al., 1983; Dobyns et al., 1989). Occipital encephalocele may be occasionally seen. The clinical features of MEB were reported by Santavuori et al., (1989). The patients often present during the neonatal period with hypotonia and weakness, and later develop spasticity and contracture to a various degrees. Mental retardation is severe. Eye abnormalities usually manifest as severe visual failure and myopia.

On imaging studies, cobblestone dysplasia usually appears as an agyric or pachygyric area. It should be noted, however, that even though the lesions may be described as agyria or pachygyria, these are entirely different from agyria and pachygyria seen in classical (type I) lissencephaly in histologic appearance. A thick outer layer of grey matter and a thinner, irregular inner layer may be distinguished (Barkovich, 1998). In FCMD, the frontal lobe typically shows polymicrogyria, and cobblestone dysplasia is limited to the temporo-occipital area (Barkovich, 1998; Aida, 1998). In WWS, abnormalities are more striking, coinciding with severe clinical manifestations. These include diffuse agyric or pachygyric cobblestone cortex, enlarged ventricles, hypoplasia of the pons and cerebellar vermis, and fusion of the superior and inferior colliculi (Barkovich, 1998; van der Knaap et al., 1997). Diffuse abnormality of the cerebral white matter signal is the rule in WWS, reflecting almost complete lack of myelination (van der Knaap et al., 1997; Barkovich, 1998). Imaging findings of MEB are similar to those of WWS, but usually less extensive, and the white matter abnormality is often patchy (van der Knaap et al., 1997; Valanne et al., 1994; Barkovich, 1998). Cerebellar polymicrogyria with or without small cysts may be seen in all three conditions.

Pathology

Pathological features of cobblestone dysplasia, that are common to all three disorders, include gliovascular proliferation near the surface and disorganized lamination with disoriented neurons (Takada et al., 1984; Williams et al., 1984; Dobyns et al., 1985; Haltia et al., 1997). The gliovascular tissue often obliterates the subarachnoid space, and may penetrate inward to separate the cortex into 'islands' of grey matter (Dobyns et al., 1985; Haltia et al., 1997). Although it is difficult to speculate about the pathogenesis of the cobblestone dysplasia from these findings, recent pathologic studies of fetal cases of FCMD (which presumably show the cobblestone dysplasia in evolution) have suggested that the basic defect may be abnormalities in the pial–glial barrier (the outermost surface of the brain composed of the pia, basement membrane and glial endfeet) (Takada et al., 1987; Nakano et al., 1996; Yamamoto et al., 1997). Overmigration of the neurons through 'breaches' in the pial–glial barrier into the subarachnoid space may be the fundamental pathogenetic mechanism for all three conditions. Muscle pathology in all three disorders is consistent with muscular dystrophy.

Genetics

FCMD, WWS and MEB are all inherited as autosomal recessive traits. FCMD was localized to chromosome 9q31 (Toda et al., 1993, 1994, 1996), and subsequently, the causative gene was cloned. This gene encodes futukin a novel secreted protein (Kobayashi et al., 1998). In 87% of the FCMD chromosomes, the mutation was the same insertion of retrotransposon sequence in the 3′ untranslated region, suggesting a Japanese founder mutation (Kobayashi et al., 1998). It has been suggested that this mutation only partly inhibits the function of the gene, whereas other reported mutations cause an even more

severe phenotype that can be prenatally lethal (Kondo-Iida et al., 1999). Thus, this single mutant allele is virtually solely responsible for the existence of FCMD. The biological function of fukutin in relation to the pial–glial barrier is not understood.

It has been debated whether these three conditions share the same genetic etiology, and this has been clarified recently. MEB has recently been shown to map to chromosome 1p32–p34 (Cormand et al., 1999), and hence is not allelic to FCMD. The locus for WWS has not been found, but a family with three siblings showing either FCMD or WWS phenotype has been reported (Toda et al., 1995). This might argue for genetic identity between these two disorders, though this still remains controversial.

Disorders of less certain pathogenetic mechanisms

Polymicrogyria

Introduction

Polymicrogyria refers to an area of the cortex with numerous small meandering gyri. It is heterogeneous both in clinical presentation and etiology. For example, as mentioned above, polymicrogyria can be seen in cobblestone dysplasia or schizencephaly. Traditionally, polymicrogyria has been regarded as a result of environmental insults, such as hypoxic–ischemic injury during fetal life or congenital infection, but recently genetic etiologies have been implicated in some cases.

Clinical features

The clinical presentation of polymicrogyria depends on the anatomical distribution and extent of the abnormality. Patients with bilateral, diffuse polymicrogyria often have severe developmental delay, seizures and hypotonia with subsequent development of spasticity (Barkovich & Kjos, 1992b). Patients with unilateral, focal polymicrogyria are more likely to present with less severe developmental delay, seizures and contralateral hemiplegia (Barkovich & Kjos, 1992b). On MRI imaging, polymicrogyric cortex appears as thickened cortex with shallow sulci, mimicking pachygyria. However, with high-resolution imaging, irregularity of the grey–white junction is usually apparent (Barkovich & Kuzniecky, 1996).

Pathology

Grossly, numerous small gyri are visible. However, because the molecular layers of the adjacent gyri often fuse, it may give an appearance of abnormally thick and broad gyri in low resolution MRI or even grossly (Friede, 1989b). There are two histological subtypes of polymicrogyria. One is called 'four-layered' type, and the other is called 'unlayered' type. Four-layered polymicrogyria consists of (i) molecular layer, (ii) outer cellular layer, (iii) cell-sparse layer, and (iv) inner cellular layer (Richman et al., 1974). Even though a four-layered lamination is also seen in classical lissencephaly, they are quite distinct entities. For example, the thickness of the cortex in polymicrogyria is much less than that of lissencephaly. In unlayered polymicrogyria, no cell-sparse layer is seen.

Genetics

Usually, polymicrogyria is encountered as a sporadic condition. However, genetic forms of polymicrogyria also appear to exist. For example, possible X-linked inheritance of a unique subtype of polymicrogyria called congenital bilateral perisylvian syndrome, in which polymicrogyria is seen in perisylvian region, has been documented in some cases (Guerreiro et al., 2000). Also, several reported patients with bilateral frontal or frontoparietal polymicrogyria were born to consanguineous parents, possibly suggesting autosomal recessive inheritance (Straussberg et al., 1996; Guerrini et al., 2000; Sztriha & Nork, 2000). Cases of polymicrogyria associated with chromosome 22q11 deletions have been reported as well (Cramer et al., 1996; Bingham et al., 1998).

Biological basis

There is convincing evidence that environmental insults such as hypoxic-ischemic injury to the developing cortex can lead to polymicrogyria. There are several cases with well-documented, dated prenatal insults leading to polymicrogyria. For example, a case of a child born with polymicrogyria after carbon monoxide poisoning of the mother during the 5th month of the pregnancy has been reported (Hallervorden, 1949). Richman et al., (1974) suggested that four-layered polymicrogyria resulted from post-mitotic laminar necrosis. They demonstrated by a detailed pathological analysis of a 27-week fetus with four-layered polymicrogyria that the cell-sparse layer corresponded to layer V of normal cortex, with normal topographical relationships retained in layers II, III, IV and VI. This finding was supported by a Golgi analysis of another case (Williams et al., 1976). On the other hand, animal models have produced four-layered polymicrogyria only when cortical injury was induced during the course of neuronal migration (Dvořák and Feit, 1977; Dvořák et al., 1978). Further studies are necessary to identify the relationship between the nature and the timing of injury and development of polymicrogyria.

Other types of intrauterine insults, in particular cytomegalovirus infection, have been associated with polymicrogyria. The pathogenetic mechanism of polymicrogyria in cases with cytomegalovirus infection is not clear.

Conclusions

With the combination of genetic and radiographic analysis, disorders of cerebral cortical development are increasingly coming into focus as a series of well-defined disorders. While their clinical features are often not distinctive, consisting of epilepsy and mental retardation, imaging studies are often distinctive, and give important keys to prognosis and recurrence risk. The near future promises clearer information and the broader application of DNA-based, as well as MRI-based, diagnosis.

The aging brain: morphology, imaging and function

Marilyn S. Albert[1] and Guy M. McKhann[2]

[1]Department of Psychiatry and Neurology, Harvard Medical School, Boston, MA, USA
[2]Department of Neurology, Johns Hopkins School of Medicine, Baltimore, MD, USA

Not too many years ago, the concept by both physicians and the general public was that your brain deteriorated as you got older. It was believed that, with aging, the brain shrank, there was significant drop out of nerve cells throughout the brain, and that once lost, those cells could not be replaced. In addition, at a subcellular level, data suggested that synaptic contacts markedly decreased. Moreover, it was thought that these changes began among individuals in young adulthood and progressed inexorably across the adult life span. As we will emphasize, among individuals who are optimally healthy these previously held concepts are wrong. The information that allows us to draw this conclusion is based on modern technologies for studying postmortem tissue, imaging the living brain, careful cognitive evaluations, and the innovative use of animal models.

Methodologic and technical issues

Focus on optimally healthy older individuals

One of the major changes to occur in the study of brain–behaviour relationships in aging is the focus on optimally healthy participants. This permits one to differentiate changes related to disease from those related to age. Among human subjects, this requires careful exclusion of subjects in the early stages of dementia. However, many medical diseases are common in older individuals (e.g. hypertension, respiratory or cardiac disease, vitamin deficiency), all of which may impair intellectual function. Ideally, if one wants to study healthy individuals, these disorders should be excluded as well. Subjects selected without evidence of clinical disease will differ greatly from a group of older persons that is chosen at random from a population, containing many individuals with serious medical illness. Some of these illnesses will include those with considerable impact on cognitive function, such as Alzheimer's disease (Odenheimer et al., 1994). Thus, optimally healthy individuals, although non-representative, can be of heuristic value, and may ultimately make it easier to identify interventions that can minimize age-related cognitive change.

Inter-individual differences and aging

In recent years, when researchers have focused their attention on animal models and human studies of aging, it has become clear that, even among optimally healthy subjects, there is considerable variability in both cognitive and physical abilities. Within a group of healthy older individuals, there are invariably individuals whose brain structure and function appears similar to that of persons many decades younger than themselves. Thus, the general statements about age-related changes in function apply to the changes for the average individual in the group, but cannot be said to apply to all individuals. For example, as shown in Fig. 14.1, the ability to recall information after reading a paragraph is better on average in younger subjects than in older ones; however, many older individuals perform just as well as their younger colleagues. The cause of this inter-individual difference is an area of intense interest, as it suggests that there may be ways of reducing change among a larger number of older persons.

Approaches to studying aging populations

In general, there are two approaches to the study of aging populations. The most commonly used, and certainly the easiest, is the cross-sectional approach. In this method, a group of younger people is compared to a group of older people at a particular point in time. The problem is that

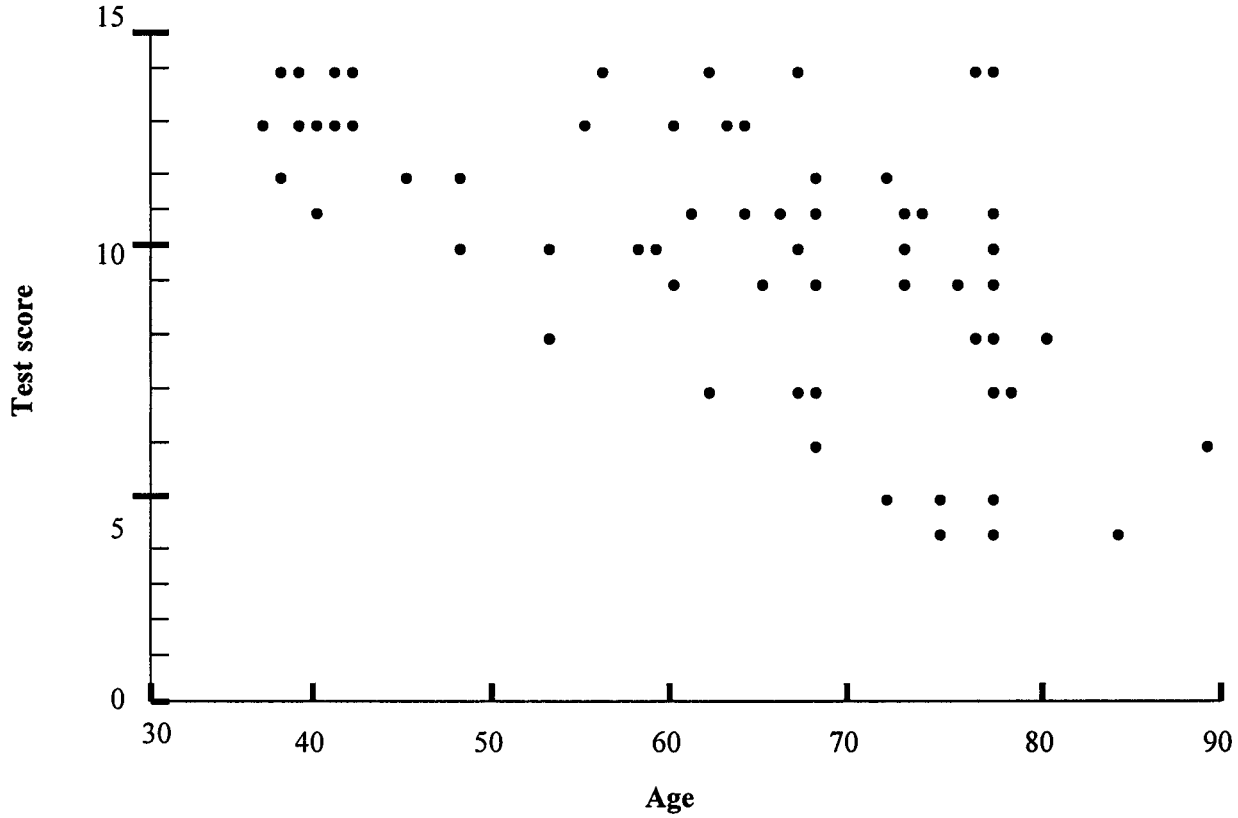

Fig. 14.1. Test scores by optimally healthy subjects 30–80 years of age on recall of a lengthy paragraph. Subjects were selected so that the level of education is not significantly different across the decades. Each dot represents the score of an individual subject.

humans born and raised at different time points have experienced different life events that can have long-term consequences on them. For example, individuals born in the 1920s to 1930s typically constitute the aging subjects in any current cross-sectional study of aging, and those born and raised in the 1970s to 1980s would constitute the sample of young adult subjects. During the 70+-year period from the 1920s, countless improvements in health care have taken place that have resulted in a dramatic change in the average human. For example, the improvements in prenatal care, postnatal care, nutrition and antibiotics have resulted in a population of young adults that not only are taller and heavier in body weight than their grandparents or great-grandparents but who also have bigger brains.

In addition, major worldwide events that have taken place at particular time points in history have had profound impacts on particular segments of a cohort. For example, large numbers of males were killed at relatively young ages by various wars. At the time of these wars, the screening process for determining who was potentially placed at greatest risk was not always socioeconomically or socioeducationally unbiased, suggesting that the remaining population of males, in particular, may have been biased by this selection process.

Longitudinal studies are designed to reduce these secular trends. While such studies must overcome the difficulties associated with the loss of subjects due to drop out, they nonetheless provide us with greater insights into the direct affects of age. Longitudinal studies have suggested that age-related declines occur slightly later in the life span than do cross-sectional ones. There is one area, as we will discuss, where longitudinal studies are essential, that is, the definition and establishment of predictive factors of change.

Postmortem examination of carefully screened subjects

Another change that has produced a dramatic revision of our concepts of brain aging derives from new techniques for the study of postmortem tissue. Postmortem examination of well-studied individuals represent the most long-standing method for establishing brain–behaviour relationships. The major technological advance pertains to

the development of non-biased stereological techniques, which permit investigators to accurately count neurons within a prescribed volume of tissue. It is this technological advance, combined with careful screening to assure that subjects with evidence of any relevant disease are excluded from examination, that has changed our concepts of the amount and nature of neuronal loss with advancing age, as described below.

Non-invasive imaging techniques

The advent of modern imaging techniques, beginning in about the mid-1970s, provided another major advance in the ability to study aging and structure–function relationships. For the first time it was possible to study the living brain. This was particularly advantageous for the study of aging, because it became possible to examine optimally healthy individuals and determine whether changes in the brain occurred in the absence of clinical disease and, if so, how this related to changes in cognition. These imaging techniques can loosely be divided into two basic types, structural scans and functional scans. The structural scans produce highly detailed images of the anatomical features of the brain. In fact, the images produced by the most advanced of these techniques look very similar in detail to that seen on postmortem examination of brain tissue. Examples of this type of structural scan include computerized tomography (CT) and magnetic resonance imaging (MRI). Functional scans, on the other hand, provide an indication of the activity of the brain, but do not tend to produce high anatomical detail. Examples of functional imaging scans include positron emission tomography (PET) and functional MRI (fMRI). When these functional methods are combined with structural scans, as is now commonly done, considerable localization of function is possible. Non-invasive imaging procedures have demonstrated that changes in the brain are, at least in part, responsible for age-related declines in cognition. However, a comprehensive explication of the reasons for these declines has not yet been provided by either the structural imaging procedures currently available, or by the initial functional methods that have been applied to this question, as will be discussed below.

Changes in brain structure and function with age

Neuronal studies

Neuronal number

Recent morphological data in humans (Haug, 1984; Leuba & Garey, 1989; Terry et al., 1987), indicate that, with advancing age, neuronal loss in the cortex is either not significant or not as extensive as reports prior to 1984 had suggested (Brody, 1955, 1970; Colon, 1972; Shefer, 1973; Henderson et al., 1980; Anderson et al., 1983). While large neurons appear to shrink, few are lost (Terry et al., 1987).

There are, in addition, comparable data in monkeys. Minimal neuronal cortical loss with age in monkeys has now been demonstrated in the striate cortex (Vincent et al., 1989), motor cortex (Tigges et al., 1992), frontal cortex (Peters et al., 1994), and the entorhinal cortex (Amaral, 1993). These general conclusions have been reached not only on the basis of a comparison of counts of neurons in young (5 to 6 years) and old (over 25 years of age) monkeys but also on the basis of an examination of the cortical tissue by electron microscopy (Peters et al., 1994). Beyond an accumulation of lipofuscin granules in the cell body of some neurons and some cellular debris in neuroglial cells, there is very little evidence of changes with age in the neurons of these cortical regions (Peters et al., 1991).

Given the intense interest in age-related changes in memory, it is important to emphasize that the weight of the evidence from postmortem studies supports the conclusion that the hippocampus also shows minimal structural change with advancing age. The postmortem data in humans and monkeys indicate that neuronal loss is surprisingly low in most subfields of the hippocampus. For example, the subiculum shows a significant age-related loss in humans, with a similar trend in monkeys, however, the CA1, CA2 and CA3 subfields of the hippocampus show no evidence of age-related neuronal loss (Amaral, 1993; Rosene, 1993; West et al., 1994; Gomez-Isla et al., 1996). Equivalent data have recently been reported in rodents, where it was shown that even in the subset of animals with declines on a memory task, there was no decrease in the number of neurons in the various hippocampal subfields (Rapp & Gallagher, 1996). (See Morrison & Hof, 1997, for a more detailed discussion of these issues.)

Neuronal loss and neurotransmitter changes

There is substantial neuronal loss in selected subcortical regions that is likely responsible for decreases in the production of neurotransmitters important for cognitive function, such as in the basal forebrain and the locus coeruleus (e.g. Chan-Palay & Asan, 1989; Rosene, 1993). For example, in humans and monkeys there is approximately a 50% neuronal loss with age in the basal forebrain and 35–40% loss in the locus coeruleus and dorsal raphe (Kemper, 1993). This compares with an approximate loss of 5% in the CA1 subfield of the hippocampus. The neuronal loss in these subcortical nuclei may be very important for memory function, as these brain regions influence the

production of several neurotransmitters important for memory (such as acetylcholine and serotonin). Though subcortical, these nuclei have extensive connections with the cortex, and thus are responsible for the level of many neurotransmitters within the cortex.

It should also be noted that there are alterations in at least one receptor type (i.e. NMDA receptors) within the hippocampus that play an important role in cognitive change, particularly in memory function (Gazzaley et al., 1996; Barnes et al., 1977).

Synaptic integrity

Even though there does not appear to be enough neuronal loss to account for age-related cognitive change, there could be changes in other aspects of neuronal function, specifically the number and/or function of synapses. Most of the studies that have explored this question with respect to aging pertain to learning and memory in rodents. Modern theories of memory mechanisms imply changing strengths of connections between neurons, based on activity-dependent synaptic plasticity in particular regions of the brain (Martin et al., 2000). It has been demonstrated that there are synaptic changes in the CA3 region of the hippocampus when one compares older rodents who are memory-impaired to younger rodents (Smith et al., 2000). Specifically, older rodents with spatial learning deficits display significant reductions in synaptophysin immunoreactivity in the CA3 region of the hippocampus, but not in other subfields. This region receives its input from layer II of the entorhinal cortex. Thus, it has been hypothesized that there are circuit-specific changes involving the entorhinal input to CA3 that influence the computational function of the hippocampus and are thereby related to age-related memory change (Smith et al., 2000). This hypothesis is consistent with electrophysiological alterations in aged rodents with learning deficits (Barnes et al., 1997; Tanila et al., 1977). Though comparable studies are not possible in humans, these results suggest that the variability seen in memory changes with advancing age among healthy individuals might be related to variations in synaptic integrity in specific brain circuits related to learning and memory.

Neuronal proliferation in the adult brain

One of the most strongly held dogmas of neurobiology was the concept that once nerve cells were formed they could only die. There was no such thing as endogenous neuronal replacement. There is increasing evidence that that concept is incorrect. The work of Altman over 30 years ago suggested that, in the rodent, neurogenesis could continue in selected regions of the brain into adulthood, particularly in the dentate region of the hippocampus, the olfactory system and cerebellum (Altman & Das, 1965). In recent years, this issue has been revisited in rodents and there is ample evidence, based on the DNA marker, bromodeoxyuridine, that neurogenesis occurs in the hippocampus and olfactory system. Similar findings have also been demonstrated in old world monkeys (Kornack & Rakic, 1999; Gould et al., 1999), and even in the human (Eriksson et al., 1998).

In the dentate gyrus of the macaque monkey, labelled cells are thought to proliferate in the border zone between the hilus and granular cell layer, and then to migrate and differentiate in the granule cell layer. The proliferation of new neurons decreases with age. In the rodent there appears to be a gradual increase in total numbers of neurons; in primates, such an accumulation is less certain. It has been suggested (Kornack & Rakic, 1999) that the number of neurons in the hippocampus is constant, but with a fixed replacement rate: neurogenesis balanced by the rate of apoptosis and cell removal. They even invoke the intriguing analogy of neurons being replaced 'like successive rows of shark teeth'.

The source of these new neurons may be pluripotential stem cells or neural progeniture cells. In the rodent it has been shown that physical activity stimulates this neurogenesis from stem cells (Kemperman et al., 2000). Investigators are exploring ways to cause these cells to produce new neurons. This is an active area of research in neuroregeneration.

White matter changes

In addition, age-related alterations in the white matter have recently been described in some detail (Peters et al., 1994; Peters, 1996; Neilson & Peters, 2000). At first glance, the data suggesting loss of white matter in the brain without a loss of grey matter can be difficult to understand. Conventional knowledge suggests that white matter consists of the axons of neurons and that if there is a loss of axons, there should be cell death and a loss of grey matter. However, the white matter of the brain is also composed of a number of glial elements, particularly oligodendrocytes. Evidence from the non-human primate suggests that the oligodendrocytes, that are responsible for forming the myelin sheath surrounding the axons, may be less efficient with age. For example, when the oligodendrocytes of old and young monkeys were compared (Peters, 1996) it was found that the myelin sheaths in the old monkeys were abnormal and appeared to be degenerating. However, when the number of axons in old and young monkeys was compared by the same investigators (Nielsen & Peters, 2000) relatively few degenerating axons were found in the

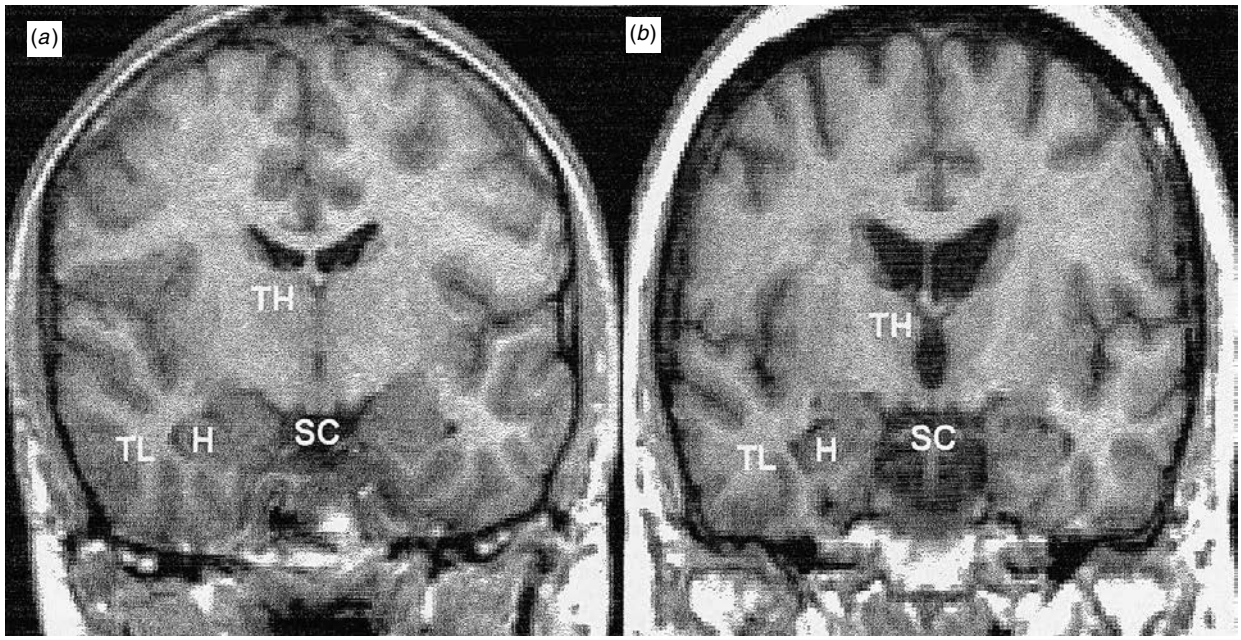

Fig. 14.2. An example of a structural MRI (*a*) in a healthy young and (*b*) healthy older individual. H = hippocampus, TH = thalamus, SC = suprasellar cistern

old monkeys. Taken together, these findings suggest changes in myelin, rather than axonal loss, are at least in part responsible for age-related changes in white matter observed with advancing age.

Imaging studies

Structural imaging

The first striking finding to emerge from computerized tomography (CT) studies of healthy adults across the age range was that there is clear evidence of decreases in the amount of brain tissue in older individuals compared with younger ones, i.e. atrophy. In general, CT studies have concluded that the average individual above 55 to 65 years of age demonstrates brain atrophy and increasing amounts of atrophy are seen as people get older. Thus, as people get older, the volume of CSF within the ventricles increases and the volume of brain tissue decreases (Roberts & Caird, 1976; Hughes & Gado, 1981; Barrow et al., 1976; Brinkman et al., 1981; de Leon et al., 1989; Gado et al., 1982, 1983; Huckman et al., 1975; Kaszniak et al., 1979; Stafford et al., 1988; Zatz et al., 1982).

CT studies conducted in the same individuals over time have demonstrated this phenomenon as well. Longitudinal evaluation over a 1-year period (Gado et al., 1983) and a 3-year period (e.g. de Leon et al., 1989) have demonstrated an approximate rate of atrophy of 2% per year among healthy older individuals over the age of 64. This rate of change is relatively low compared to the 9% rate of atrophy seen in the brains of patients with Alzheimer's disease (de Leon et al., 1989).

MRI studies of healthy adults across the age range have confirmed the findings described above for CT. That is, regardless of the sequence type, overall brain volume shows a decrease with age, while the amount of CSF increases, even if individuals are healthy (Christiansen et al., 1994; Coffey et al., 1992; Harris et al., 1994; Jernigan et al., 1990, 1991; Lim et al., 1992; Murphy et al., 1992; Matsumae et al., 1996; Pfefferbaum et al., 1994; Tanna et al., 1991).

Visual examination of an MRI image from a healthy young and older individual exemplifies some of the changes described above. Figure 14.2 shows an MRI image, taken at approximately the same anatomical level, in a healthy, young adult (see Fig. 14.2(*a*)) and a healthy, older adult (see Fig. 14.2(*b*)). As can be seen, the general shape and size of the bone around the brain is nearly equal in both subjects. However, the image on the right appears to have less tissue than the image on the left. The cavities within the brain that contain CSF are also larger in the older individual than in the young. The largest CSF spaces in the brain, the lateral and third ventricles, clearly appear

larger in the older person, but it is more difficult to determine visually whether the lower portion of the lateral ventricle (known as the 'inferior horn of the lateral ventricle') is enlarged. In addition, sulci on the cortical surface appear to be more spread apart in the older than in the younger subject. The space between the temporal lobes (i.e. the supracellar cistern, [SC]) also appears to be wider in the older person than the young.

However, the grey matter of the brain does not appear to be as changed as the CSF spaces. The ribbon of grey matter forming the outer surface of the cortex appears as thick in the older subject as it does in the young. The hippocampal formation (H) is of nearly equal size in the two subjects. The deep grey matter structures, such as the thalamus (TH), also appear to be of approximately equivalent size in the two individuals. Close inspection of the images suggests that the white matter of the brain may be changed in the older person. Overall, there appears to be less white matter in the older individual than in the young, however, this is difficult to assess convincingly with visual inspection.

Functional imaging

One of the most important innovations for the study of brain–behaviour relationships has been the development of functional imaging, using PET and fMRI. In PET scanning, a radioactive isotope is either injected or inhaled by the subject, and the scanning machine evaluates the differential decay of radioactivity in order to assess regional changes in blood flow in the brain. The blood flow is considered a surrogate for neuronal activity. Likewise, fMRI uses the magnetic qualities of water molecules to evaluate the differential distribution of oxygenated blood in the brain, and the ratio of oxygenated to deoxygenated blood is thought to be an indirect measure of neuronal activity.

To obtain information about how the brain performs cognitive tasks, these imaging techniques are combined with cognitive paradigms, which produce a range of brain activations. Through careful design of such paradigms, it becomes possible to obtain information about the brain regions that are involved in a specific cognitive activity. Perceptual and emotional experience can also be interrogated in a similar manner. When such functional imaging procedures are combined with structural imaging, one can obtain data with highly accurate anatomical detail.

Positron emission tomography

Most PET studies that have included older individuals have focused on the examination of memory changes with age. Due to the technological limitations of PET, these studies have generally focused on either the encoding or the retrieval phase of memory.

The most important general concept to emerge from such studies is that multiple brain regions are essential for encoding or retrieving new information. Moreover, some of the brain regions that appear to be integral to 'memory networks' have not been easy to evaluate by other imaging modalities. The most important in this regard is the frontal lobes, which are activated during both encoding and retrieval in normal young individuals (Kapur et al., 1994, 1996; Demb et al., 1995; Fletcher et al., 1995; Wagner et al., 1998a; Madden et al., 1999; Buckner et al., 1999).

The hippocampus, known to be essential for normal memory based primarily on lesion studies (Squire et al., 1988), is more difficult to activate than many other brain regions, for reasons that are not entirely clear. Nevertheless, many recent PET studies have shown that significant activations of the hippocampus may be demonstrated when an individual is attempting to learn or retrieve new information. The parahippocampal gyrus, a cortical region adjacent to the hippocampus, is also frequently activated in cognitive paradigms focused on explicit memory (Schacter & Wagner, 1999; Gabrielli et al., 1997; Brewer et al., 1998; Martin et al., 1997; Stern et al., 1996; Wagner et al., 1998a), as is the prefrontal cortex (e.g. Haxby et al., 1996; Wagner et al., 1998b).

The most consistent finding to emerge from PET studies of aging is that there are alterations in the activation of the frontal lobes during encoding and/or retrieval of new information, (e.g. Cabeza et al., 1997, 2000; Hazlett et al., 1998; Grady et al., 1999), although the specific nature of these age-related differences remains to be clarified. Some have found increased activity, while others have found decreases. However, the nature of the activation paradigms have differed considerably among these studies, no doubt contributing to the differential findings.

There has been even less agreement about age-related changes in the hippocampus. For example, a PET study in which young subjects demonstrated significant hippocampal and prefrontal activation during an encoding task failed to produce similar activations in the elderly (Grady et al., 1995). Conversely, a PET study that examined subjects during a recall task reported similar activations in the hippocampus and/or parahippocampal gyrus in both young and elderly subjects, but substantial differences between the age groups in other brain regions, particularly the frontal lobes (Schacter et al., 1996). Differences between the cognitive paradigms in the two studies, particularly in the degree to which the subjects learned the to-be-remembered material, are the most likely cause of these discrepancies.

Functional magnetic resonance imaging

Since fMRI does not involve exposure to radioactivity, and measurements are closer to real time, many investigators who previously employed PET are turning to fMRI. Though few such studies have been published, a number have been reported at meetings. They concur with the PET studies in finding altered prefrontal activity during encoding, mentioned above. Most of these fMRI studies have demonstrated decreased activation of the prefrontal lobe when older individuals are trying to learn new information (e.g. Sperling et al., 1999, Logan et al., 2002). It has been hypothesized that the differences in prefrontal activation between the young and the elderly subjects may reflect the fact that the two age groups use differing strategies to perform the task (e.g. Cabeza et al., 1997; Grady et al., 1999). This is consistent with numerous reports showing that elderly individuals are less likely to spontaneously use mnemonic strategies than the young, when trying to learn new information (for reviews see Craik, 1977; Arenberg & Robertson-Tchabo, 1977). An alternate possibility is that the same strategy is being applied in different ways by the two age groups.

Increased activation in the elderly compared with the young has also been demonstrated. For example, in tasks where the stimuli to-be-remembered are visual in nature, older individuals have shown greater activity than the young in the parietal cortex (one of the brain regions involved with spatial organization) (Bates et al., submitted; Sperling et al., 1999). This may also be a reflection of the differential deployment of cognitive strategies during the task, as mentioned above.

It should also be noted that some investigators have reported differences between the young and the elderly in hemodynamic response (D'Esposito et al., 1999; Ross et al., 1997; Taoka et al., 1998). While the nature of these changes is still controversial, ranging from the possibility of decreased hemodynamic response (and therefore signal change) in the elderly, to increased noise with no absolute reduction in the magnitude of signal change, it is clearly possible that these differences are, at least in part, responsible for some of the fMRI differences between healthy young and older individuals. It is, however, reasonable to hypothesize that, if such underlying hemodynamic changes exist, they might affect the ability to remember new information.

Domains of cognitive function

Although one could fractionate cognitive function into an almost unlimited number of components, most investigators in the field of neuropsychology view higher cortical function as composed of a relatively small number of major categories. For the purposes of this chapter, we will discuss changes in cognitive function with age within the following domains: (i) attention, (ii) memory, (iii) executive function, (iv) language, (v) visuospatial processing, and (vi) general intelligence.

Memory performance and aging

Workers in the field of memory have accepted the conclusion that memory is not a unitary phenomenon, and most models of memory function hypothesize that memory consists of a series of specific yet interactive stores (e.g. Waugh & Norman, 1965; Tulving, 1972). They include, at a minimum: sensory memory, primary memory, and secondary memory. In addition, a distinction has been made between information that is consciously learned (called explicit or declarative memory) and information that is acquired over time, unrelated to specific conscious effort of episodes (called implicit or procedural memory) (Reber & Squire, 1994).

Sensory memory

Sensory memory, also called registration, represents the earliest stage of information processing. It is modality specific (i.e. visual, auditory, tactile), highly unstable, and characterized by rapid decay.

Primary memory

The component of the memory system referred to as primary memory (or alternatively, immediate memory or short term memory) permits one to hold spans of auditory and/or visual information for relatively long periods of time by active rehearsal. The ability to concentrate on, rehearse, and recall a span of digits, words or visual features is perhaps the best example of this capacity. Any disruption to the rehearsal process results in the information being lost from immediate memory. Experiments by Petersen and Petersen (1959) have demonstrated that normal subjects forget a significant proportion of new information in less than 1 minute when distractions are present. The amount of information that immediate memory can store is limited to about five to seven items, as mentioned earlier. There is not complete consensus among neuropsychologists and memory researchers as to whether immediate memory should be considered a form of memory at all. Primary or immediate memory, as described here, may rely more on attentional skills. Thus, Spitz (1972), among others, has argued that digit span forward is actually a measure of attention rather than of memory.

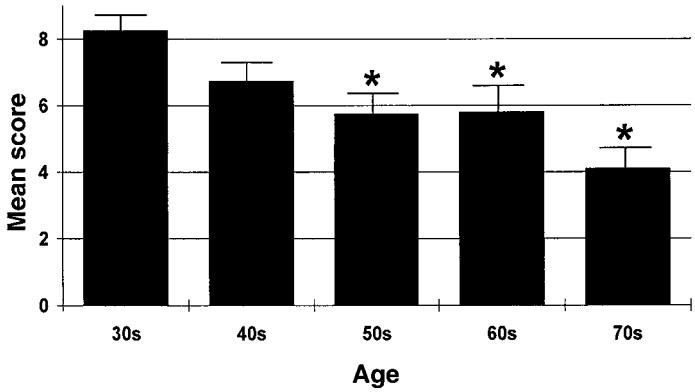

Fig. 14.3. Delayed recall performance of healthy subjects 30 to 80 years old. The subjects are asked to report what they remember of two lengthy paragraphs after a 15-minute delay.

Secondary memory

Secondary memory (also referred to as long-term memory) is involved when information must be retained over a long period of time. Thus, information from immediate memory must be assembled into multimodal units to be placed in storage. Storage of information by the memory system appears to take place differentially. As early as 1949, Hebb postulated that two processes were necessary for the brain to retain information. The first process, analogous to what we have termed primary memory, required the continual reverberation of a neural circuit. The second process, equivalent to secondary memory, required an actual structural change in the neural pattern of the central nervous system.

Sensory memory and age

There is considerable information to indicate that changes in explicit sensory memory are minimal with age. For example, the time necessary to identify a single letter does not change significantly between the late teens and early 70s. When seven-letter strings are used, the rate of letter identification increases with age by a factor of 1.3 (Cerella et al., 1982). These and other data indicate that there is a minimal decline in sensory memory with age (see Craik, 1977; for detailed review, see Poon, 1985).

Primary memory and age

Primary explicit memory also shows little decline with age. Most studies report no significant age differences in digit span forward (Drachman & Leavitt, 1972), no age differences in word span (Talland, 1967), and only moderate differences in letter span (Botwinick & Storandt, 1974). Older subjects show as much of a recency effect (i.e. retrieval of the last few items on a list in a word list learning task) as younger subjects (Raymond, 1971).

Secondary memory and age

However, there are substantial changes in explicit secondary memory, in contrast to the minimal age changes in sensory and primary memory (for a review, see Craik, 1977; Poon, 1985). The age at which changes in secondary memory occur depends upon the methods that are used to test the memory store. Difficult explicit memory tasks (e.g. delayed recall) demonstrate statistically significant differences by subjects in their 50s, in comparison to younger individuals (Albert et al., 1987a). Age decrements are greater on recall than recognition tasks. This is true whether words or pictures are used. Cueing during encoding or retrieval also alters the appearance of an age decline. Cueing at both encoding and retrieval produces the smallest age differences, whereas no cueing at either stage of the task maximizes age differences (Craik et al., 1987). However, even with cued recall and recognition, there are often declines. Rabinowitz (1986) reported a 33% age-related decrement in cued recall, and an 11% age-related decrement in recognition, when comparing young and old subjects (mean age 19 vs. 68).

Figure 14.3 shows the performance of subjects across the age range on delayed recall of two lengthy paragraphs. That is, each subject is read two lengthy paragraphs and, immediately after hearing each one, and then again after 20 min, the subject is asked to state what he/she can recall of the paragraphs.

A close examination of these data indicates that the older individuals are not more rapidly forgetting what they learned, but rather they are taking longer to learn the new information. For example, if one compares the difference between immediate and delayed recall over the lifespan, there are no statistically significant age differences (Petersen et al., 1992). Thus, if one allows older subjects to learn material well (i.e. to the point where few errors are made), they do not forget what they have learned more rapidly than the young (see Fig. 14.3). However, if older subjects are not given the ability to learn material to the same level of proficiency as younger individuals, after a delay, less information will be retained by the average older person.

However, there is considerable variability among older subjects on tasks of this sort. There are many healthy older subjects who have test scores that overlap those of subjects many years younger than themselves, e.g. about one-third of healthy 70-year-old humans have delayed recall scores that overlap those of 30-year-olds (equated for education).

Executive function

The complex set of abilities sometimes referred to as 'executive functions' include: concurrent manipulation of information (e.g. cognitive flexibility), concept formation and cue-directed behaviour. The wide variety of abilities that are sometimes included under the term 'executive function' is therefore striking.

Tests evaluating concept formation and set shifting uniformly show significant changes with age, primarily when subjects are in their late 60s or 70s. For example, the similarities subtest of the Wechsler Adult Intelligence Scale (WAIS), which asks subjects to identify how two objects (e.g. a table and a chair) are similar to each other, is the subtest on the Verbal scale of the WAIS that shows the greatest decline with age (Heaton et al., 1986). Education appears to be a modifier of this decline, in that subjects with lower amounts of education demonstrate declines at younger ages, however, all subjects in the oldest group (mean age 68 years), regardless of educational level, show significant declines in performance.

Series completion tests also show substantial age declines. These tests generally require the subject to examine a series of letters or numbers and determine the rule that governed the sequencing of the items in the series. Cross-sectional and longitudinal data demonstrate age-related declines on tasks of this sort (e.g. Lachman & Jelalian, 1984; Schaie, 1983).

Proverb interpretation tests, which require the subject to provide the general meaning of a proverb (e.g. 'barking dogs seldom bite'), also demonstrate age-related declines (Albert et al., 1990). This is true whether or not subjects are asked to provide the meaning of the proverb themselves or are given alternate choices among which to choose. Similarly, set shifting tasks, such as the visual–verbal test (in which subjects are asked to look at a series of cards and indicate how three of the four objects on each card are alike in one way, and then how three of the objects are alike in another way), also show substantial age-related declines. These changes appear to be related to the fact that older subjects have difficulty switching from one abstract answer to another (i.e. they tend to get the first item in the set correct but the second one wrong). Slowness in establishing mental set (i.e. getting the first item in the set wrong but the second one right) and failure to establish set (i.e. getting both items in the set wrong) did not increase differentially with age (Albert et al., 1990).

Visuospatial function

Visuospatial function is characterized by the ability to produce, and recognize figures and to form relationships among spatial locations. Specific visual functions include the ability to recognize familiar faces, the ability to copy or match objects or pictures, and the ability to translate spatial elements from one mode to another. Translation of mirror image spatial arrangements into self-oriented positions is an example of a task that requires intact and efficient visuospatial abilities.

Visuospatial ability therefore can be assessed by (i) constructional tasks, such as the assembly of blocks, sticks or puzzles; (ii) drawing tasks that involve copying; or (iii) matching tasks that require the subject to identify pictures with similar elements.

The most complex three-dimensional construction task in common use is the block design subtest of the WAIS. The subject is presented with a two-dimensional drawing in red and white of a target design, and a set of blocks (some sides of the blocks are all red, some are all white, and some are half red and half white). The subject is asked to arrange the blocks, which are, of course, three dimensional, so that they mimic the two-dimensional design. To receive credit, the subject must assemble the blocks correctly within a specified time limit. This task shows substantial declines with age (Doppelt & Wallace, 1955), perhaps because it is a timed task, and involves perception of three-dimensional space (see below) as well as a shifting and monitoring of behaviour.

Performance on figure drawing tasks is also affected by age. Older subjects are impaired, in comparison to the young, in depicting and perceiving three-dimensional drawings. Plude et al., (1986) asked a group of young and old adults (mean ages 21 and 67, respectively, and equated for static visual acuity) to draw a cube to command. The cubes were then rated by ten independent raters, with an interrater reliability of 0.98. The drawings of the young adults were rated as significantly better than those of the old. The older subjects were also less accurate than the young in judging the adequacy of drawings of cubes that were distorted to varying degrees. The elderly were less accurate than the young in discriminating between distorted and undistorted cubes. They were, however, equally able to copy a cube when landmarks were provided regarding the size of the lines. Comparable reports of the depiction and perception of two-dimensional drawings are not available.

Language

Linguistic ability is thought to encompass at least four domains: phonological, lexical, syntactic and semantic. It was previously assumed that linguistic ability is preserved into very old age, primarily because performance on the

vocabulary subtest of the WAIS, the best general estimate of verbal intelligence, is well maintained until individuals are in their 80s (Schaie, 1983). However, within the last decade, a number of studies have shown that some aspects of linguistic knowledge decline with age, although not until relatively late in the lifespan (i.e. >70).

Phonology

Phonologic knowledge refers to the use of the sounds of language and the rules for their combination. Phonologic capabilities are well preserved with age (Bayles & Kaszniak, 1987).

Lexicon

Psycholinguists distinguish between the lexical representation of a word, i.e. the name of an item, and its semantic representation, i.e. the meaning of a word (Clark & Clark, 1977). The lexicon of healthy older individuals appears to be intact, as are the semantic relationships of the lexicon.

Syntax

Syntactic knowledge refers to the ability to meaningfully combine words. A large number of studies have shown that age has little effect on syntax. Obler et al., (1985) found that syntactic forms that were difficult for older individuals were also difficult for younger ones.

Semantic knowledge

Older individuals appear to have difficulty with the semantic aspects of word retrieval. Several groups of investigators have reported that scores on a test of confrontation naming decrease with age (Borod et al., 1980; LaBarge et al., 1986; Albert et al., 1987b). However, declines in naming ability do not become statistically significant until subjects are in their 70s (Albert et al., 1987b). When subjects could not correctly name an item, the most common error they committed was semantic in nature, i.e. they produced semantically related associates, circumlocutions, and nominalizations. The nature of these semantic errors suggests that older individuals have a great deal of knowledge about the target word. For example, a semantically related associate ('dice' for 'dominoes') can only be produced if the subject apprehends the general category associated with the stimulus item.

Verbal fluency also assesses semantic ability. In a verbal fluency task a subject is asked to name as many examples of a category (e.g. animals or vegetables) as possible in specified period of time (e.g. 1 min) or as many words beginning with a particular letter (e.g. F) within a specified period of time. Several studies report a decline in verbal fluency with age (Obler et al., 1985; Albert et al., 1987b). These changes also occur relatively late in the life span (>70). Thus, semantic linguistic ability appears to change with advancing age, while other aspects of linguistic ability are relatively well preserved.

General intelligence

Although intelligence tests measure most of the abilities previously discussed, they do so in a complex way. Intelligence tests were designed to predict with a reasonable degree of certainty how a person would function in an academic environment, not to provide a complete assessment of cognitive function. Thus, intelligence tests do not assess all aspects of cognitive ability. For example, the Wechsler Adult Intelligence Scale does not include an evaluation of memory. In addition, IQ tests do not assess cognitive abilities in relative isolation from one another. Many of the tasks require a complex interaction of abilities and often depend upon speed for an adequate level of performance. Nevertheless, intelligence testing has been one of the most widely explored topics in the psychology of aging.

There is widespread agreement that there are changes in intelligence test performance with age. There has, however, been considerable debate about the point at which declines occur and the magnitude of the declines. The age at which declines are observed appears to depend upon the methodology employed. There is some consensus that relatively little decline in performance occurs prior to the time that people are in their 50s (Schaie & Labouvie-Vief, 1974). After this age, results differ depending upon whether cross-sectional or longitudinal testing designs were employed. The cross-sectional method shows declines of 1 SD or more beginning about age 60 (Doppelt & Wallace, 1955; Schaie, 1983), over the age of 70 scores drop sharply. The longitudinal method shows declines beginning in the late 60s. Both methods find substantial declines after individuals are in their mid-70s. Thus, the major difference between cross-sectional and longitudinal investigations is observed between subjects in their late 50s and early 60s. In this age range, the cross-sectional method shows greater age declines than the longitudinal method.

Summary

In summary, changes in cognitive function with age occur only in specific domains and in specific components of these domains, as indicated in Table 14.1.

Table 14.1. Cognitive changes with age

Domain	No change	Change	Age range
Memory			
sensory memory	*		
primary explicit memory	*		
secondary explicit memory		*	50s and over
Executive function		*	60s–70s
Visuospatial ability		*	60s and over
Language			
phonology	*		
lexicon	*		
syntax	*		
semantic knowledge		*	70s
General intelligence		*	60s–70s

Prediction of future cognitive status

Maintenance of cognitive function

As the aging population grows, there is increasing interest in maintaining cognitive function at its maximum. One of the major studies that sought to answer this question followed approximately 1000 participants who were 70 to 80 when the study began. These individuals had been selected because they fell within the top third of the population in terms of both physical and mental function (Berkman et al., 1993). Over time (i.e. 5–10 years), some of these individuals maintained their high level of cognitive performance and others declined. Thus, it was possible to determine what behaviours differentiated these two groups. Those who maintained cognitive function had higher levels of education, physical activity, lung function, and feelings of self-efficacy (Albert et al., 1995). It is hypothesized that each of these four variables directly influence the status of the brain and thereby, cumulatively, influence maintenance of cognition.

Prediction of decline in cognitive function

The concern of many older people, when they are unable to find their car keys or blank on attempting to recall a name, is that they have the first indication of a serious and progressive problem with memory. Thus, the ability to predict who has the expected cognitive changes with age, and who may go on to Alzheimer's disease or some other dementing process, it of utmost importance. Studies to answer this question have also employed a longitudinal approach, using data from baseline to predict subsequent outcomes. This baseline information has included cognitive performance, imaging and genetics (Albert et al., 2001a). Some of these studies compare those without significant memory complaints with those with mild memory complaints. Over time, some in each category may progress or 'convert' to the clinical symptoms of dementia. Predictions are based on comparing the baseline characteristics of the Converters with the non-Converters and with those who continue to have memory problems but do not have evidence of dementia. The cognitive measures that are predictive of conversion are tests of memory and executive function (Albert et al., 2001b). The imaging measures that are useful in this regard include volumetric measures of the entorhinal cortex, the anterior cingulate, and the hippocampus (Killiany et al., 2000), and perfusion measures of hippocampal-amygdaloid complex, the posterior cingulate and related structures (Johnson et al., 1998).

Another approach has been to compare individuals with a genetic risk for AD, based on their apolipoprotein E status (see Chapter 17), and to examine cognitive and imaging differences among them. These studies have not followed individuals to the point where a substantial number have converted to AD, however, they have demonstrated imaging differences, particularly using PET scanning, in posterior cingulate and superior parietal regions (Small et al., 1995; Reiman et al., 1996).

Based on these preliminary observations, it is likely that predictive paradigms for who will and who will not convert to dementia will be developed and validated. Such paradigms will be useful not only clinically, but in the design of intervention studies.

Neurodegenerative diseases

Stanley B. Prusiner

Institute for Neurodegenerative Diseases and Departments of Neurology and of Biochemistry and Biophysics, University of California, San Francisco, CA, USA

Twenty-five years ago, there was little understanding of the causes of neurodegeneration. In fact, the term degenerative disease was used as a wastebasket for illnesses of unknown etiology. But progress over the past quarter of a century in research focused on degenerative disorders of the central nervous system (CNS) has been impressive. It is now clear that neurodegenerative diseases are caused by the misprocessing of proteins. In each disease, one or more specific proteins have been identified that are misprocessed; this results in the accumulation of one or more particular proteins.

The proteins that accumulate in the CNS of patients with neurodegenerative diseases were initially identified by purifying these polypeptides from the brains of animals or humans with these diseases (Glenner & Wong, 1984; Masters et al., 1985; Prusiner et al., 1982). Subsequently, molecular genetics was used to identify the genes responsible for the familial forms of Alzheimer's and Parkinson's diseases as well as amyotrophic lateral sclerosis (ALS) and frontotemporal dementia (FTD). Similarly, molecular genetic investigations of Huntington's disease (HD) and the spinocerebellar ataxias have led to the identification of the genes responsible for the pathogenesis of these illnesses.

Of all the studies on neurodegenerative diseases, the discovery of prions has been most unexpected. The finding that a protein can act as an infectious pathogen and cause degeneration of the CNS was unprecedented (Prusiner, 1998b). The prion concept was so novel that achieving acceptance required a long and arduous battle (Prusiner, 1999). The prion concept not only explained how a disease can be both infectious and genetic, but it has also created new disease paradigms and revolutionized thinking in biology.

Although progress in the study of neurodegeneration has been impressive, there are still no curative treatments. Only for patients with Parkinson's disease is there a palliative drug with reasonable efficacy (Cotzias et al., 1967). L-dopa and related drugs do not stop the underlying degeneration, which often renders patients refractory to pharmacologic treatment in the later stages of Parkinson's disease (Marsden & Parkes, 1977). Stereotactic surgery has produced limited success in ameliorating the symptoms of Parkinson's disease when L-dopa becomes ineffective. Transplantation of cells secreting dopamine into the brains of patients with advanced Parkinson's disease is the subject of much research. It is noteworthy that many patients with Parkinson's disease develop dementia in the later stages of this disorder.

This chapter is not intended as an exhaustive review of neurodegenerative diseases and as such the bibliography is regrettably limited. Rather, it is an attempt to view the many common features of these degenerative illnesses from the perspective of the prion diseases (Prusiner, 1984). Progress in deciphering the etiologies of many neurodegenerative diseases has greatly strengthened the unifying concepts presented here. Based on the common features of these maladies, I suggest a new definition for the neurodegenerative diseases.

Aging and neurodegeneration

Age is the single most important risk factor for degenerative diseases of the CNS (Holman et al., 1996; Kawas & Katzman, 1999; Lilienfield, 1993). Many, but not all, cases of neurodegenerative diseases are sporadic in that no heritable, toxic, or infectious etiology can be discerned. These disorders are often characterized by a chronic, progressive deterioration of the CNS lasting from several months to more than a decade. Although the disease process is relentless, the immune system seems to remain quiescent.

Table 15.1. Epidemiology of neurodegenerative diseases[a]

Disease	Number of US patients	US prevalence per 100 000[b]
Prion diseases	400	0.1
Alzheimer's disease	4 000 000	1200
Parkinson's disease	1 000 000	300
FTD	40 000	14
Pick's disease	5000	2
PSP	15 000	5
ALS	20 000	7
Huntington's disease	30 000	10
Spinocerebellar ataxias	12 000	4

Notes:

[a] Abbreviations: FTD = frontotemporal dementia, PSP = progressive supranuclear palsy, ALS = amyotrophic lateral sclerosis.

[b] Population of United States is approximately 275 million in the year 2000.

Table 15.2. Sporadic, genetic and infectious etiologies of neurodegenerative diseases

	Etiologic frequency (%)		
Disease	Sporadic	Genetic	Infectious
Prion diseases	85	>10	<1
Alzheimer's disease	90	10	
Parkinson disease	95	<5	
FTD	90	10	
Pick's disease	95	<5	
PSP	95	<5	
ALS	90	10	
Huntington's disease		100	
Spinocerebellar ataxias		100	

Patients are afebrile and exhibit neither leukocytosis in blood nor pleocytosis in the cerebrospinal fluid (CSF).

While a complete compendium of neurodegenerative diseases is quite long, a brief list composed of the more common disorders and a few less common maladies, which have been particularly amenable to investigation, are discussed here (Table 15.1). Alzheimer's and Parkinson's diseases are the most common neurodegenerative diseases. Over four million people suffer from Alzheimer's disease (AD) in the United States and another million have Parkinson's disease (Kawas & Katzman, 1999; Lilienfield, 1993; Tanner & Goldman, 1996). Far less common are ALS, FTD, prion diseases, Huntington's disease and spinocerebellar ataxias. The vast majority of the first five neurodegenerative diseases are sporadic with 10% or less of cases being inherited (Table 15.2). In contrast, virtually all cases of Huntington's disease and the spinocerebellar ataxias are inherited disorders.

Because people are living longer, there is now considerable concern about the increasing numbers of individuals who are developing Alzheimer's and Parkinson's diseases. At age 60, the risk of developing AD is approximately 1 in 10 000 but by age 85 the risk is greater than 1 in 3 (Evans et al., 1989). Such statistics argue that, by the year 2025, more than 10 million people will suffer from AD in the United States and by the year 2050, the number of afflicted individuals will approach 20 million (Kawas & Katzman, 1999). Just as staggering as the number of people with AD is the cost of caring for these patients. It is estimated that AD currently costs the United States as much as $200 billion annually for the care of these people as well as in lost productivity of both the patients and caregivers.

Like Alzheimer's disease, age is the most important risk factor for Parkinson's disease. By age 85, nearly 50% of people exhibit at least one symptom or sign of Parkinsonism (Bennett et al., 1996).

Prions

Prions are infectious proteins. In mammals, prions reproduce by recruiting the normal, cellular isoform of the prion protein (PrP^{C}) and stimulating its conversion into the disease-causing isoform (PrP^{Sc}).

A major feature that distinguishes prions from viruses is the finding that both PrP isoforms are encoded by a chromosomal gene (Prusiner, 1998b). In humans, the PrP gene is designated *PRNP* and is located on the short arm of chromosome 20. Limited proteolysis of PrP^{Sc} produces a smaller, protease-resistant molecule of ~142 amino acids, designated PrP 27–30; under the same conditions, PrP^{C} is completely hydrolyzed (Fig. 15.1). In the presence of detergent, PrP 27–30 polymerizes into amyloid (McKinley et al., 1991). Prion amyloid formed by limited proteolysis and detergent extraction is indistinguishable from the filaments that aggregate to form PrP amyloid plaques in the CNS. Both the rods and the PrP amyloid filaments found in brain tissue exhibit similar ultrastructural morphology and green-gold birefringence after staining with Congo red dye.

PrP^{C} is rich in α-helix and has little β-sheet while PrP^{Sc} has less α-helix and a high β-sheet content. Comparisons

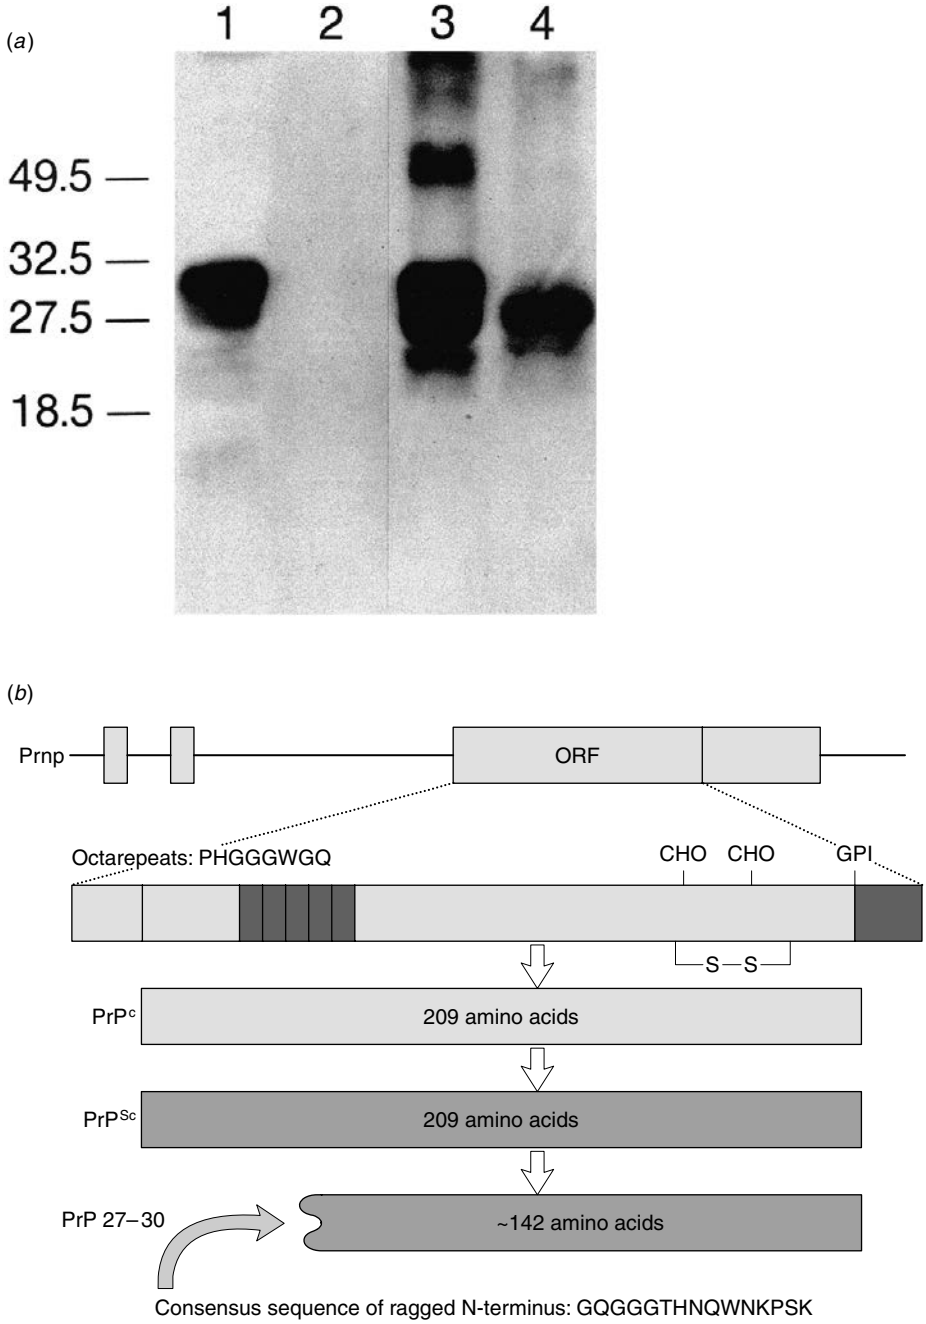

Fig. 15.1. Prion protein isoforms. (*a*) Western immunoblot of brain homogenates from uninfected (lanes 1 and 2) and prion-infected (lanes 3 and 4) Syrian hamsters (SHa). Samples in lanes 2 and 4 were digested with 50 μg/ml of proteinase K for 30 min at 37 °C. PrP^{C} in lanes 2 and 4 was completely hydrolyzed under these conditions whereas approximately 67 amino acids were digested from the NH_2-terminus of PrP^{Sc} to generate PrP 27–30. After polyacrylamide gel electrophoresis (PAGE) and electrotransfer, the blot was developed with anti-SHaPrP R073 polyclonal rabbit antiserum (Serban et al. 1990). Molecular size markers are in kilodaltons (kDa). (*b*) Bar diagram of SHaPrP gene which encodes a protein of 254 amino acids. After processing of the NH_2- and COOH- termini, both PrP^{C} and PrP^{Sc} consist of 209 residues. After limited proteolysis, the NH_2-terminus of PrP^{Sc} is truncated to form PrP 27–30 that is composed of approximately 142 amino acids, the N-terminal sequence of which was determined by Edman degradation.

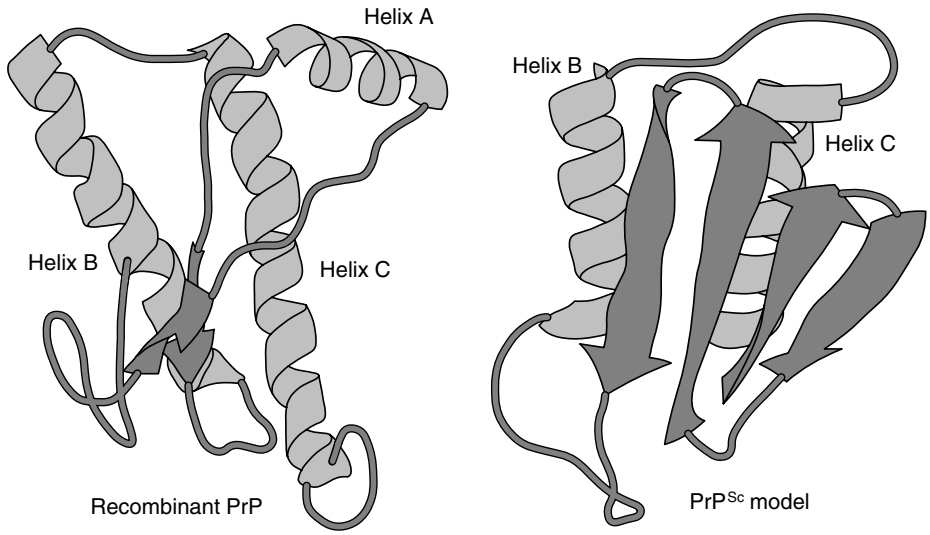

Fig. 15.2. Structures of prion protein isoforms. (*a*) NMR structure of Syrian hamster (SHa) recombinant (rec) PrP(90–231). Presumably, the structure of the α-helical form of recPrP(90–231) resembles that of PrP^{C}. recPrP(90–231) is viewed from the interface where PrP^{Sc} is thought to bind to PrP^{C}. α-helices A (residues 144–157), B (172–193), and C (200–227) residues 129–134 encompassing strand S1 and residues 159–165 in strand S2; the arrows span residues 129–131 and 161–163, as these show a closer resemblance to β-sheet. (*b*) Plausible model for the tertiary structure of human PrP^{Sc}. S1 β-strands are residues 108–113 and 116–122 in red; S2 β-strands are residues 128–135 and 138–144; α-helices B (residues 178–191) and C (residues 202–218). (Illustrations prepared by Fred E. Cohen.)

of secondary structures of PrP^{C} and PrP^{Sc} were performed on the proteins purified from Syrian hamster (SHa) brains (Pan et al., 1993). Based on these data, structural models for PrP^{C} and PrP^{Sc} were proposed (Huang et al., 1995). Subsequently, solution NMR structures of recombinant SHa and mouse PrPs produced in bacteria showed that it is likely that PrP^{C} has three α-helices and not four as predicted by molecular modelling (Fig. 15.2) (Liu et al., 1999; Riek et al., 1996). The computational model of PrP^{Sc} is supported by studies with recombinant antibody fragments, which have been used to map the surfaces of PrP^{C} and PrP^{Sc} (Peretz et al., 1997). This α- to-β transition in PrP structure is the fundamental event underlying prion diseases, which are disorders of protein conformation.

Much has been learned about the basic biology of prions using yeast in which two different proteins, unrelated to PrP, form prions (Sparrer et al., 2000; Wickner, 1994).

Four new concepts

Four new concepts have emerged from studies of prions. First, prions are the only known example of infectious pathogens that are devoid of nucleic acid. All other infectious agents possess genomes composed of either RNA or DNA that direct the synthesis of their progeny. Secondly, prion diseases may be manifest as infectious, genetic, and sporadic disorders. No other group of illnesses with a single etiology presents with such a wide spectrum of clinical manifestations. Thirdly, prion diseases result from the accumulation of PrP^{Sc}, the conformation of which differs substantially from that of its precursor PrP^{C}. Fourthly, PrP^{Sc} can exist in a variety of different conformations, each of which seems to indicate a specific disease phenotype. How a specific conformation of a PrP^{Sc} molecule is imparted to PrP^{C} during prion replication to produce nascent PrP^{Sc} with the same conformation is unknown. Additionally, it is unclear what factors determine where in the CNS a particular PrP^{Sc} molecule will be deposited, which results in neurologic dysfunction.

Common themes define neurodegeneration

With the recognition that a common feature of all well studied neurodegenerative diseases is the misprocessing of proteins, it is reasonable to propose a new definition of neurodegenerative disease based on this unifying etiologic characteristic. I suggest the following: 'neurodegenerative diseases are progressive nervous system disorders

of protein processing. Aberrant protein processing includes misfolding, altered post-translational modification, aberrant proteolytic cleavage, anomalous gene splicing, improper expression, and diminished clearance. The misprocessed proteins often accumulate because the cellular mechanisms for removing these proteins are ineffective. Neurodegenerative diseases typically present as sporadic and genetic maladies of delayed onset, but can also be infectious illnesses with prolonged incubation times. The particular protein that undergoes misprocessing determines the disease-specific phenotype, which results from the malfunction of distinct sets of neurons.'

In the past, degenerative diseases of the CNS have often been defined as idiopathic disorders accompanied by mental deterioration. Neuropathologically, they have been defined in terms of region-specific retrogressive changes in cells resulting in impaired function. Such pathologic changes have also been equated with the death of specific neuronal populations (Martin, 1999).

The broad spectrum of presenting clinical deficits in the prion diseases illustrates how ineffective a clinical classification scheme can be; these diseases can present with dementia, ataxia, insomnia, paraplegia, paresthesias and deviant behaviour (Will et al., 1999a). While none of the clinical presentations of prion diseases are diagnostic, patients who present with a rapidly progressive dementia accompanied by myoclonus often have Creutzfeldt–Jakob disease (CJD). The spectrum of neuropathologic changes in prion diseases ranges from none to widespread atrophy, from rare to frequent neuronal loss, from sparse to severe vacuolation or spongiform change, from mild to intense reactive astrocytic gliosis, and from none to abundant PrP amyloid plaques (DeArmond & Prusiner, 1997). None of these neuropathologic changes except the presence of PrP amyloid plaques is unequivocally diagnostic. Past attempts to classify and characterize other neurodegenerative diseases (Table 15.1) based on the clinical presentations or neuropathologic manifestations have been equally unsatisfying.

The discovery of amyloid in brain fractions enriched for prion infectivity was completely unexpected (Prusiner et al., 1983). The amyloid plaques in prion diseases and AD as well as large intracellular structures such as Lewy and Pick bodies were not considered to be of etiologic importance. Once anti-PrP 27–30 antibodies were raised, the amyloid plaques in prion diseases were found to stain readily (Bendheim et al., 1984; DeArmond et al., 1985).

It seems likely that the mechanisms, by which misprocessed proteins disrupt cellular functions such as signal transduction and gene transcription, are diverse. The secondary responses to misprocessed proteins may amplify the damage done by these macromolecules by activation of cytokine release, reactive gliosis, apoptosis, and oxidative injury (Cotman et al., 1999; Markesbery & Ehmann, 1999). In some neurodegenerative diseases, the misprocessed proteins might cause CNS dysfunction when they are monomers or oligomers while in other disorders, larger aggregates may prove to be the culprits (Chiti et al., 1999). In the case of PrP^{Sc}, the protein accumulates and fragments sometimes polymerize to form amyloid fibrils that are deposited in the extracellular space as plaques. With α-synuclein, tau and mutant huntingtin proteins, ubiquitinated deposits are found as Lewy bodies, Pick bodies and nuclear aggregates, respectively (Table 15.3). As discussed below, the aggregates may not cause cellular dysfunction but simply represent the attempt of cells to sequester these misprocessed proteins in a form that is less deleterious. Finding ubiquitinated deposits of α-synuclein, tau and mutant huntingtin argues that these proteins were destined for clearance but the process was incomplete. The covalent attachment of ubiquitin, which is a 76-residue polypeptide, to particular proteins targets them for degradation (Hershko & Ciechanover, 1998).

In sporadic cases, which account for more than 85% of all human prion disease (Table 15.2), the prion concept explains how wild-type (wt) PrP^{C} is progressively con-

Table 15.3. Protein deposition in neurodegenerative diseases

Disease	Protein	Aggregate
Prion diseases	PrP^{Sc}	PrP amyloid
Alzheimer's disease	Aβ tau	Aβ amyloid PHF in NFT[a]
Parkinson disease	α-synuclein	Lewy bodies
FTD	tau	straight filaments and PHF
Pick's disease	tau	Pick bodies
PSP	tau	straight filaments in NFT
ALS	neurofilament	neuronal aggregates
Huntington's disease	huntingtin	nuclear inclusions
Spinocerebellar ataxia 1	ataxin 1	nuclear inclusions
Spinocerebellar ataxia 2	ataxin 2	cytoplasmic inclusions
Machado–Joseph disease	ataxin 3	nuclear inclusions

[a] PHF, paired helical filaments; NFT, neurofibrillary tangles.

verted into PrP^{Sc}. Although the mechanism of prion replication is unclear, the stimulation of this process by PrP^{Sc} provides the driving force for the misfolding of PrP^{C} into PrP^{Sc}. No similar formulation exists to explain the progressive deterioration of the nervous system that follows the misprocessing of proteins in sporadic cases of AD, FTD, Parkinson's disease, and ALS. For example, factors driving the accumulation of the Aβ peptide in the CNS of people destined to develop sporadic AD are unknown except for the allelic variants of ApoE. Likewise, factors driving the accumulation of the α-synuclein to form Lewy bodies within the neurons of the substantia nigra of people destined to develop sporadic Parkinson's disease are unknown.

In the inherited neurodegenerative diseases, the same problem attends in the sense that these diseases are usually of late onset even though the mutations are present from conception. With few exceptions, the inherited neurodegenerative diseases are autosomal dominant disorders so the mutations are unlikely to produce disease through loss of function. Instead, such dominant mutations are likely to act as gain of dysfunction or as dominant negatives. Even though the mutant protein is expressed in the CNS early in life, no damage is detected clinically for decades in the inherited cases of AD, Parkinson's disease, FTD, ALS, and the prion diseases. Only in the triplet repeat diseases, such as HD, do children manifest neurologic disease when the repeat expansions become very large.

How the aging process features in these diseases is unclear. Is the misprocessing of a particular protein simply a stochastic process, which happens with a much higher probability when it is mutated? In such a model, prolonged periods of time are required for either the mutant or wt protein to be misprocessed into a disease-causing form. But perhaps, the milieu of the aging brain provides a more permissive environment for the misprocessing of proteins. The accumulation of proteins modified by oxidation has been suggested as a possible factor in virtually every degenerative disease (Markesbery & Ehmann, 1999). Clearance of misprocessed proteins may diminish with age and thus, may be responsible for their accumulation.

The neurodegenerative diseases elude detection by the immune and interferon defense systems: patients remain afebrile throughout the courses of their illness and show no leukocytosis in blood or pleocytosis in the CSF. Grossly, the brain can be atrophic with enlarged ventricles as in many cases of AD; alternatively, the basal ganglia may show selective atrophy as in HD. The degree of neuronal loss and the extent of reactive astrocytic gliosis can be quite variable for a particular disease. Although microglia often accumulate and cytokines are released late in the various neurodegenerative diseases, no inflammatory response characterized by accumulation of antigen–antibody complexes, lymphocytic infiltration or the perivascular accumulation of monocytes is generally seen.

Prion biology and diseases

Because prions and the mechanism of disease pathogenesis are without precedent, the classification of the prion diseases has been quite varied. For many years, the human prion diseases were classified as idiopathic degenerative disorders of the CNS based upon pathologic changes confined to the CNS. With the transmission of kuru and CJD to apes, investigators began to view these diseases as CNS infectious illnesses caused by 'slow viruses' (Gibbs et al., 1968).

The sporadic form of CJD is the most common prion disorder in humans and typically presents with dementia and myoclonus (Table 15.4). Sporadic CJD (sCJD) accounts for ~85% of all cases of human prion disease while inherited prion diseases account for 10–15% of all cases (Tables 15.2 and 15.4). Familial CJD (fCJD), Gerstmann–Sträussler–Scheinker disease (GSS), and fatal familial insomnia (FFI) are all dominantly inherited prion diseases caused by mutations in the PrP gene (Table 15.5) (Dlouhy et al., 1992; Gabizon et al., 1993; Hsiao et al., 1989a; Petersen et al., 1992; Poulter et al., 1992).

Even though the familial nature of a subset of CJD cases had been well described (Kirschbaum, 1968), the significance of this observation became more obscure with the transmission of CJD to animals (Gibbs et al., 1968). The conundrum that faced investigators reporting transmission of familial cases of CJD and GSS to apes and monkeys (Masters et al., 1981; Roos et al., 1973) is of considerable interest. They offered three hypotheses to explain fCJD and GSS. First the 'CJD virus' was transmitted to family members living in close proximity. Secondly, patients with fCJD or GSS carried a genetic predisposition to the ubiquitous CJD virus. Thirdly, the CJD virus was transmitted from parent to offspring either in utero or during birth as was later seen with HIV. All three of these explanations proved to be incorrect: the CJD virus does not exist and the familial prion diseases are caused by mutations in the PrP gene (Hsiao et al., 1989b).

The prion concept readily explains how a disease can be manifest as a heritable or sporadic disorder as well as an infectious illness. Moreover, the hallmark common to all of the prion diseases, whether sporadic, dominantly inherited, or acquired by infection, is that they involve the aberrant metabolism of the prion protein.

Table 15.4. The prion diseases

Disease	Host	Mechanism of pathogenesis
Kuru	Fore people	Infection through ritualistic cannibalism
iCJD*	Humans	Infection from prion-contaminated HGH, dura mater grafts, etc.
vCJD	Humans	Infection from bovine prions
fCJD	Humans	Germline mutations in PrP gene
GSS	Humans	Germline mutations in PrP gene
FFI	Humans	Germline mutation in PrP gene (D178N, M129)
sCJD	Humans	Somatic mutation or spontaneous conversion of PrP^{C} into PrP^{Sc}?
sFI	Humans	Somatic mutation or spontaneous conversion of PrP^{C} into PrP^{Sc}?
Scrapie	Sheep	Infection in genetically susceptible sheep
BSE	Cattle	Infection with prion-contaminated MBM
TME	Mink	Infection with prions from sheep or cattle
CWD	Mule deer, elk	Unknown
FSE	Cats	Infection with prion-contaminated beef
Exotic ungulate encephalopathy	Greater kudu, nyala, oryx	Infection with prion-contaminated MBM

Notes:
* Abbreviations: BSE, bovine spongiform encephalopathy; CJD, Creutzfeldt–Jakob disease; sCJD, sporadic CJD; fCJD, familial CJD; iCJD, iatrogenic CJD; vCJD, (new) variant CJD; CWD, chronic wasting disease; FFI, fatal familial insomnia; FSE, feline spongiform encephalopathy; sFI, sporadic fatal insomnia; GSS, Gerstmann–Sträussler–Scheinker disease; HGH, human growth hormone; MBM, meat and bone meal; TME, transmissible mink encephalopathy.

Table 15.5. Mutant genes in familial neurodegenerative diseases

Inherited disease	Gene	Mutation
Prion diseases	PrP	point mutations and octarepeat expansions
Alzheimer's disease	APP	point mutations
	PS1	point mutations
	PS2	point mutations
Parkinson's disease	α-synuclein	point mutations
	Parkin	point mutations
FTD	tau	point mutations deletions
Pick's disease	tau	point mutations
ALS	SOD1	point mutations
Huntington's disease	HD	polyglutamine expansions
Spinocerebellar ataxia 1	SCA1	polyglutamine expansions
Spinocerebellar ataxia 2	SCA2	polyglutamine expansions
Machado–Joseph disease	SCA3	polyglutamine expansions

In both the sporadic and inherited prion diseases, infectious prions are generated *de novo* within the host. In the sporadic prion diseases, wt PrP^{C} is converted into wt PrP^{Sc}, which is infectious. In the inherited prion diseases, mutant PrP^{C} is converted into mutant PrP^{Sc}, which in some cases appears to be able to stimulate the conversion of wt PrP^{C} into wt PrP^{Sc}. In these diseases, the process of prion formation begins endogenously. The accumulation of sufficient wt PrP^{Sc} to establish a slow infection and ultimately disease is a rare event and is presumably governed by both the frequency of PrP^{Sc} formation and the rate of PrP^{Sc} clearance. In contrast, the accumulation of sufficient mutant PrP^{Sc} to establish a slow infection and ultimately disease is a much more frequent event since all people carrying a PrP mutation will develop disease if they live long enough (Chapman et al., 1994; Spudich et al., 1995). Whether some pathologic PrP mutations act primarily by increasing the frequency of PrP^{Sc} formation and others by decreasing the rate of PrP^{Sc} clearance remains to be established.

Six diseases of animals are caused by prions (Table 15.4). Scrapie of sheep and goats is the prototypic prion disease. Mink encephalopathy, bovine spongiform encephalopathy (BSE), feline spongiform encephalopathy, and exotic ungulate encephalopathy are all thought to occur after the consumption of prion-infected foodstuffs.

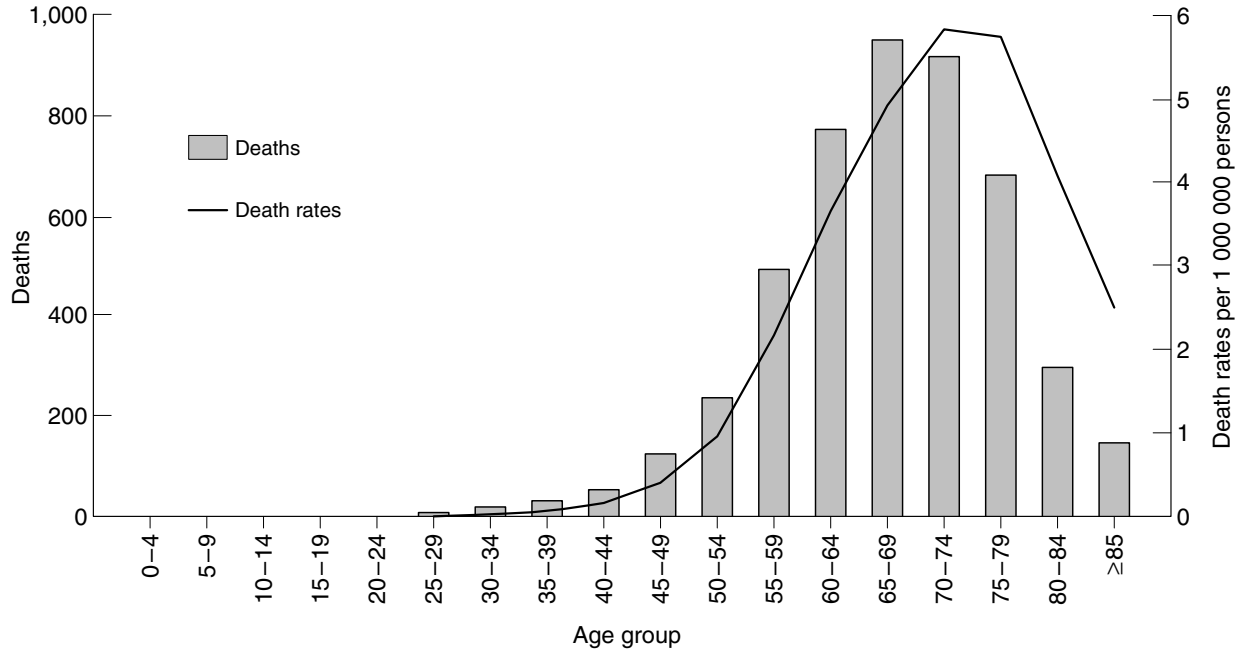

Fig. 15.3. Age-specific incidence of Creutzfeldt-Jakob disease in the United States. Total numbers of deaths for the period 1979 to 1998 are shown by the open bars and the death rates per million population are depicted by the solid line. (Graph prepared by Lawrence Schonberger.)

Epidemiology

Prions cause CJD in humans throughout the world. The incidence of sporadic CJD is approximately one case per million population (Masters et al., 1978), but is nearly five per million people between the ages of 60 to 74 (Fig. 15.3) (Holman et al., 1996). Patients as young as 17 years and as old as 83 have been recorded (Cathala & Baron, 1987; Masters et al., 1978). CJD is a relentlessly progressive malady that results in death usually within a year of onset. Each geographic cluster of prion disease was initially thought to be a manifestation of the communicability of the CJD virus (Kahana et al., 1974), but each was later shown to be due to a *PRNP* gene mutation, which results in a non-conservative substitution. Although infectious prion diseases account for less than 1% of all cases and infection does not seem to play an important role in the natural history of these illnesses, the transmissibility of prions is an important biologic feature. Attempts to identify common exposure to some etiologic agent have been unsuccessful for both the sporadic and familial cases (Cousens et al., 1990). Ingestion of scrapie-infected sheep or goat meat as a cause of CJD in humans has not been demonstrated by epidemiologic studies although speculation about this potential route of infection continues (Johnson & Gibbs, 1998). Studies with Syrian hamsters demonstrated that oral infection by prions can occur, but the process is quite inefficient compared to intracerebral inoculation (Prusiner et al., 1985).

Why the human prion diseases are so rare compared to the more common disorders of AD and Parkinson's disease is unknown. AD is about four times more common than Parkinson's disease and approximately 10 000 times more common than CJD (Table 15.1). Deciphering the mechanism of these remarkable differences in prevalence may help elucidate the factors underlying the etiologies and pathogenesis of these maladies.

Neuropathology

Frequently, the brains of patients with CJD show no recognizable abnormalities upon gross examination. In patients surviving several years, variable degrees of cerebral atrophy are likely to result in brain weights as low as 850 g.

The pathologic hallmarks of CJD at the light microscopic level are spongiform degeneration and astrogliosis (Fig. 15.4(*a*) and (*b*), see colour plate section) (DeArmond & Ironside, 1999). The lack of an inflammatory response in CJD and other prion diseases is an important pathologic feature of these degenerative disorders. Generally, the spongiform changes occur in the cerebral cortex,

putamen, caudate nucleus, thalamus, and molecular layer of the cerebellum. Spongiform degeneration is characterized by many 5–20 μm vacuoles in the neuropil between nerve cell bodies. Astrocytic gliosis is a constant but nonspecific feature of prion diseases (DeArmond & Prusiner, 1997). Widespread proliferation of fibrous astrocytes is found throughout the grey matter of brains infected with CJD prions. Astrocytic processes filled with glial filaments form extensive networks.

Amyloid plaques have been found in ~10% of CJD cases. Purified CJD prions from humans and animals exhibit the ultrastructural and histochemical characteristics of amyloid (Prusiner et al., 1983). In first passage to mice from some human Japanese CJD cases, amyloid plaques were found in the mouse brains (Tateishi et al., 1996). These plaques were stained with antisera raised against PrP.

The amyloid plaques of GSS are distinct from those seen in kuru, AD, or scrapie. GSS plaques consist of a central dense core of amyloid surrounded by smaller globules of amyloid (Fig. 15.4(*c*) and (*d*)). Ultrastructurally, they consist of a radiating fibrillar network of amyloid fibrils with scant or no neuritic degeneration. The plaques can be distributed throughout the brain but are most frequently found in the cerebellum. They are often located adjacent to blood vessels. Congophilic angiopathy has been noted in some cases of GSS. In addition to the multicentric plaques of GSS, unicentric kuru plaques may also be seen (Masters et al., 1981). In GSS caused by the F198S mutation, neurofibrillary tangles (NFT) composed of paired helical filaments (PHF) are frequently seen surrounding PrP amyloid plaques (Dlouhy et al., 1992; Gambetti et al., 1999).

In new variant CJD (vCJD), a characteristic feature is the presence of 'florid plaques'. These are composed of a central core of PrP amyloid surrounded by vacuoles in a pattern suggesting petals of a flower (Fig. 15.4(*e*) and (*f*)).

Species barrier

Studies on the role of the primary and tertiary structures of PrP in the transmission of prion disease have given new insights into the pathogenesis of these maladies. In general, transmission of prion disease from one species to another is inefficient, in that not all intracerebrally inoculated animals develop disease, and those that fall ill, do so only after long incubation times, which can approach the natural lifespan of the animal (Pattison, 1965). This 'species barrier' to transmission is correlated with the degree of homology between the amino acid sequence of PrP^{C} in the inoculated host and of PrP^{Sc} in the prion inoculum (Prusiner et al., 1990). Thus, the amino acid sequence of PrP encodes the species of the prion, and the prion derives its PrP^{Sc} sequence from the last mammal in which it was passaged (Scott et al., 1997). The importance of sequence homology between the host and donor PrP argues that PrP^{C} directly interacts with PrP^{Sc} in the prion conversion process; PrP^{Sc} seems to function as a template in determining the tertiary structure of nascent PrP^{Sc} molecules as they are formed from PrP^{C}.

Prion strains

The existence of prion strains raised the question of how heritable biological information can be enciphered in a molecule other than nucleic acid (Bruce & Dickinson, 1987; Dickinson et al., 1968; Ridley & Baker, 1996). Strains or varieties of prions have been defined by incubation times and the distribution of neuronal vacuolation (Dickinson et al., 1968). Subsequently, the patterns of PrP^{Sc} deposition were found to correlate with vacuolation profiles and these patterns were also used to characterize strains of prions (Bruce et al., 1989; DeArmond et al., 1987).

Mounting evidence supports the hypothesis that prion diversity is enciphered in the conformation of PrP^{Sc} (Prusiner, 1991); thus, prion strains seem to represent different conformers of PrP^{Sc} (Bessen & Marsh, 1994; Safar et al., 1998; Scott et al., 1997; Telling et al., 1996). Persuasive evidence that strain-specific information is enciphered in the tertiary and quaternary structure of PrP^{Sc} comes from transmission of two different inherited human prion diseases to mice expressing a chimeric human-mouse PrP transgene (Telling et al., 1996). In FFI, the protease-resistant fragment of PrP^{Sc} after deglycosylation has a molecular size of 19 kDa, whereas in fCJD with a substitution of a lysine (K) for glutamate (E) at residue 200 (E200K) and most sporadic prion diseases, it is 21 kDa (Table 15.6) (Parchi et al., 1996). This difference in molecular size was shown to be due to different sites of proteolytic cleavage at the NH_2-termini of the two human PrP^{Sc} molecules, reflecting different tertiary structures. These distinct conformations were not unexpected because the amino acid sequences of the PrPs differ.

Extracts from the brains of FFI patients transmitted disease into mice expressing a chimeric human-mouse PrP transgene about 200 days after inoculation and induced formation of the 19 kDa PrP^{Sc}, whereas fCJD(E200K) and sCJD extracts produced the 21 kDa PrP^{Sc} in mice expressing the same transgene (Telling et al., 1996). On second passage, transgenic (Tg) mice inoculated with FFI prions showed an incubation time of ~130 days and a 19 kDa PrP^{Sc}, whereas those inoculated with fCJD(E200K) prions exhibited an incubation time of ~170 days and a 21 kDa PrP^{Sc} (Prusiner, 1998b). The experimental data demonstrate that chimeric PrP^{Sc} can exist in two different conformations based on the sizes of the pro-

Table 15.6. Distinct prion strains generated in humans with inherited prion diseases and transmitted to transgenic mice[a]

Inoculum	Host Species	Host PrP Genotype	Incubation time [days ± SEM] (n/n_0)	PrP^{Sc}(kDa)
None	Human	FFI(D178N, M129)		19
FFI	Mouse	Tg(MHu2M)	206 ± 7(7/7)	19
FFI → Tg(MHu2M)	Mouse	Tg(MHu2M)	136 ± 1 (6/6)	19
None	Human	fCJD(E200K)		21
fCJD	Mouse	Tg(MHu2M)	170 ± 2 (10/10)	21
fCJD → Tg(MHu2M)	Mouse	Tg(MHu2M)	167 ± 3 (15/15)	21

Notes:

[a] Data from references (Prusiner, 1998a,b; Telling et al., 1996). Tg(MHu2M) mice express a chimeric human-mouse PrP gene. Clinicopathologic phenotype is determined by the conformation of PrP^{Sc} in accord with the results of the transmission of human prions from patients with FFI to Tg mice (Telling et al., 1996).

tease-resistant fragments; yet the amino acid sequence of PrP^{Sc} is invariant.

This analysis was extended when patients with sporadic fatal insomnia (sFI) were found. Although they did not carry a PrP gene mutation, the clinical and pathologic phenotype was indistinguishable from that of FFI patients. Furthermore, 19 kDa PrP^{Sc} was found in their brains and upon passage of these human prions to mice expressing a chimeric human-mouse PrP transgene, the 19 kDa PrP^{Sc} was also found (Mastrianni et al., 1999). These findings contend that the disease phenotype is dictated by the conformation of PrP^{Sc} and not by the amino acid sequence. The results also demand that PrP^{Sc} acts as a template for the conversion of PrP^{C} into nascent PrP^{Sc}.

Sporadic and genetic neurodegenerative diseases

Prion diseases

Initiation of sporadic disease may follow from a somatic mutation and thus, develop in a manner similar to that for germline mutations in inherited disease (Table 15.5). In this situation, the mutant PrP^{Sc} must be capable of recruiting wt PrP^{C}, a process known to be possible for some mutations (e.g. E200K, D178N) but less likely for others (e.g. P102L) (Telling et al., 1995). Alternatively, the activation barrier separating wt PrP^{C} from PrP^{Sc} could be crossed on rare occasions when viewed in the context of a large population (Fig. 15.3) (Cohen & Prusiner, 1998).

More than 20 different mutations in the human PrP gene resulting in non-conservative substitutions have been found to segregate with inherited human prion diseases, to date (Gambetti et al., 1999). Missense mutations and expansions in the octapeptide repeat region of the gene are responsible for familial forms of prion disease. Five different mutations of the PrP gene have been linked genetically to heritable prion disease (Dlouhy et al., 1992; Gabizon et al., 1993; Hsiao et al., 1989a; Petersen et al., 1992; Poulter et al., 1992).

Although phenotypes may vary dramatically within families, there is a tendency for certain phenotypes to associate with specific mutations (Gambetti et al., 1999). A clinical phenotype indistinguishable from typical CJD is usually seen with substitutions at codons 180, 183, 200, 208, 210, and 232. Substitutions at codons 117, 102, 105, 198, and 217 are associated with the clinicopathological variant of prion disease known as GSS disease. The normal human PrP sequence contains five repeats of an octapeptide sequence. Insertions of an additional 2 to 9 extra octapeptide repeats are associated with variable phenotypes ranging from a condition indistinguishable from CJD to a slowly progressive dementing illness of many years' duration. A mutation at codon 178, resulting in substitution of asparagine for aspartate, produces FFI if a methionine is encoded at the polymorphic 129 residue on the same allele (Goldfarb et al., 1992). Typical CJD is seen if a valine is encoded at position 129 of the mutant allele.

Particularly puzzling are the factors that determine the disease phenotype. As noted above, there is excellent evidence that the tertiary structure of PrP^{Sc} determines whether this disease-causing protein is deposited in subsets of thalamic neurons producing fatal insomnia or it is deposited more widely and resulting in a dementing illness labeled CJD. As more cases of inherited prion diseases have been studied, multiple exceptions have been recorded in which a mutation that produces GSS with ataxia also results in a dementing

illness and vice versa (Hsiao et al., 1990, Mastrianni et al., 1999). Within a single family carrying a PrP mutation, some patients develop peripheral neuropathologies while others do not. Elucidating all of the factors that govern the clinical and neuropathologic phenotypes will be challenging.

PrP gene polymorphisms and dominant negative inhibition

Polymorphisms influence the susceptibility to sporadic, inherited, and infectious forms of prion disease. The methionine/valine polymorphism at position 129 not only determines the clinical phenotype as noted above but it also modulates the age of onset of some inherited prion diseases (Gambetti et al., 1999; Palmer et al., 1991). The finding that homozygosity at codon 129 predisposes to sCJD supports a model of prion production that favours PrP interactions between homologous proteins, as appears to occur in Tg mice expressing SHaPrP inoculated with either hamster prions or mouse prions (Prusiner et al., 1990) as well as in Tg mice expressing a chimeric SHa/Mo PrP transgene inoculated with 'artificial' prions.

A lysine residue at 219 has been found in 12% in the Japanese population and this group seems to be resistant to prion disease (Shibuya et al., 1998). Substitution of the basic residue lysine at position 219 produced dominant negative inhibition of prion replication. In scrapie-infected neuroblastoma (ScN2a) cells and Tg mice, substitution of lysine at position 219 prevented PrP^{C} from being converted into PrP^{Sc} (Kaneko et al., 1997; Zulianello et al., 2000) (V. Perrier, K. Kaneko, S.J. DeArmond, F.E. Cohen and S.B. Prusiner, in preparation). Not only was PrP^{C}(219K) unable to support prion replication but it also prevented wt PrP^{C} from being converted into PrP^{Sc}. Dominant negative inhibition of prion replication has also been found in sheep with substitution of the basic residue arginine at position 171. The sheep with arginine are resistant to scrapie (Hunter et al., 1997; Westaway et al., 1994). Both the inability of PrP^{C}(171R) to support prion replication and exhibit dominant negative inhibition have been demonstrated in ScN2a cells and Tg mice.

Alzheimer's disease

In AD, Aβ amyloid plaques and NFT are found whether the disease is sporadic or inherited (Table 15.3). Like the familial prion diseases, the inheritance of familial AD is autosomal dominant. In contrast to the prion diseases in which only mutations in the PrP gene have been identified to cause familial prion disease, familial AD can be caused by a mutation in one of at least three different genes: amyloid precursor protein (APP), presenilin 1 (PS1), and presenilin 2(PS2) (Table 15.5) (St. George-Hyslop, 1999). Cleavage of APP at residue 671 by β-secretase and at either residue 711 or 713 by γ-secretase produces Aβ(1-40) or Aβ(1-42), respectively. Aβ(1-40) is soluble and its levels do not correlate with AD whereas Aβ(1-42) readily forms fibrils and is thought to cause CNS dysfunction prior to being deposited in plaques (De Strooper and Annaert, 2000; Selkoe, 1999; Wilson et al., 1999). The cleavage of APP by γ-secretase within the plasma membrane is a highly regulated, complex process (Brown et al., 2000; De Strooper & Annaert, 2000). Cleavage at residue 687 by α-secretase prevents Aβ peptide formation. Six different mutations of the APP gene have been implicated in familial AD. More than 30 mutations of the PS1 gene and two of the PS2 gene in familial AD have been found (St. George-Hyslop, 1999). PS1 and PS2 are thought to form complexes with at least one other protein, nicastrin, and these complexes have γ-secretase activity (Yu et al., 2000). Mutations in PS1 have been shown to increase the amount of Aβ(1-42) peptide.

NFT in AD are composed of PHF that are composed of hyperphosphorylated tau (Goedert et al., 1988; Lee et al., 1991; Wolozin et al., 1986). The tau protein binds to microtubules and facilitates assembly of these polymers but hyperphosphorylated tau isolated from AD brains does not bind to microtubules. Six different isoforms of tau are produced by alternative splicing of a single copy gene expressed in brain. Although mutations of the tau gene cause neurodegeneration as described below, they do not cause AD.

The age of onset of both the sporadic and familial AD is modulated by the allelic variants of apolipoprotein E (ApoE) (Saunders et al., 1993). Three alternative allelic products of ApoE, denoted ε2, ε3 and ε4, differ at amino acid residues 112 and 158. Many people with two ε4 alleles can expect to develop AD at least a decade before those with two copies of ε2, whereas those with ε3 exhibit an intermediate age of onset (Farrer et al., 1997). How ApoE modulates the onset of AD is unknown but one hypothesis suggests that ApoE features in the clearance of the Aβ(1-42) peptide. A less compelling hypothesis argues that ApoE modulates the formation of NFTs that are composed of PHF (Roses, 1994).

Frontotemporal dementia

Mutations in the tau gene are responsible for inherited cases of FTD and Pick's disease (Clark et al., 1998; Hutton et al., 1998; Spillantini et al., 1998b). Like AD, about 90% of FTD cases are sporadic and approximately 10% are familial (Table 15.2). In familial FTD, straight filaments composed of hyperphosphorylated mutant tau have been found (Table 15.3) (Hong et al., 1998). In patients from

some families with FTD, NFT composed of PHF have been found; the formation of PHF seems to depend upon the specific tau mutation and the expression of specific isoforms that are determined by alternative splicing (Table 15.5) (Buée et al., 2000). In sporadic FTD, aggregates of tau are rarely found.

Approximately 15% of FTD cases coming to autopsy were found to have Pick bodies (Brun, 1993), which are the neuropathologic hallmark of Pick's disease. Pick bodies are intracellular collections of ubiquitinated tau fibrils (Kertesz & Munoz, 1998). Like FTD, most cases of Pick's disease are sporadic.

In some familial cases of FTD caused by tau mutations, Parkinson's disease and disinhibition have been found (Wilhelmsen et al., 1994). Additional disorders thought to be caused by the aberrant processing of tau include progressive supranuclear palsy (PSP), progressive subcortical gliosis, and corticobasal degeneration (Buée et al., 2000; Conrad et al., 1997; Goedert et al., 1999; Kertesz & Munoz, 1998).

Parkinson's disease

In Parkinson's disease, the same theme of protein deposits in the CNS of patients with sporadic and familial forms of the disease has been discovered. Although most patients with Parkinson's disease have a sporadic form of the disease (Nussbaum & Polymeropoulos, 1997; Tanner et al., 1999), mutations have been discovered in the α-synuclein gene of patients with familial Parkinson's disease (Polymeropoulos et al., 1997). When antibodies were raised to α-synuclein, they were found to stain intracellular aggregates of protein in the malfunctioning neurons of the substantia nigra called Lewy bodies (Spillantini et al., 1997). Lewy bodies are present in both the sporadic and familial forms of Parkinson's disease. While the inheritance of Parkinson's disease caused by mutations in the α-synuclein gene is autosomal dominant, a childhood form of Parkinson's disease caused by mutations in the ubiquitin-protein ligase gene (*parkin*) is a recessive disorder (Table 15.5) (Shimura et al., 2000). The recessive inheritance Parkinson's disease caused by mutations in the *parkin* gene is currently the only familial neurodegenerative disease that is not dominantly inherited. Whether people carrying mutations in the *parkin* gene develop Parkinson's disease due to decreased ubiquitination of α-synuclein is unknown, but the ubiquitin pathway is known to participate in the degradation of α-synuclein. There is considerable interest in the possible role of oxidative metabolism in the etiology of Parkinson's disease and selective nitration of α-synuclein in Lewy bodies has been found (Giasson et al., 2000).

The onset of Parkinson's disease in people age 70 or older is associated with a high incidence of dementia (Hughes et al., 2000). At autopsy, the brains of these people often display the neuropathologic hallmarks of both AD and Parkinson's disease. Ubiquitin and α-synuclein immunostaining to identify cortical Lewy bodies has helped resolve the conundrum of how a patient could have insufficient numbers of plaques and NFTs for diagnosis of AD but still be demented. It is estimated that α-synuclein deposition as Lewy bodies in cortical neurons may by itself or in combination with AD changes be the second most common form of neurodegeneration, accounting for 20 to 30% of dementia cases over the age of 60 (Hansen et al., 1990; Hashimoto & Masliah, 1999). A small group of younger people with Parkinson's disease become demented due to diffuse Lewy body disease, in which Lewy bodies are found throughout the cerebral cortex (Spillantini et al., 1998a).

For nearly two decades, some investigators have argued that Parkinson's disease is acquired by the accumulation of toxic molecules in neurons of the substantia nigra (Tanner et al., 1999). The dramatic ability of the synthetic heroin derivative MPTP to produce the symptoms and signs of Parkinson's disease in humans and apes provided seductive evidence in favour of the toxin hypothesis (Langston et al., 2000) as did the possibility that a molecule in cycad plants causes an ALS-Parkinson's disease complex in the indigenous people of Guam (Spencer et al., 1990). Studies of the etiology of Parkinson's disease have also been complicated by Parkinsonism (or the symptoms of Parkinson's disease) that is seen in a variety of neurologic disorders, including post-encephalitis lethargica following the influenza pandemic of 1916–1926 and post-hypoxic encephalopathy.

ALS

While most cases of ALS are sporadic, familial cases have been identified (Table 15.2) (Bobowick & Brody, 1973; Hudson, 1981; Swash, 2000). Approximately 20% of all familial ALS cases has been shown to be due to mutations in the cytoplasmic superoxide dismutase (SOD1) (Table 15.5) (Rosen et al., 1993). Deposits of SOD1 have been found in the CNS of some patients with sporadic and familial forms of ALS (Cleveland & Liu, 2000). Of note, some mutant SOD1 molecules exhibit increased SOD activity compared to wt SOD while others display activities that are similar or decreased compared to wt SOD (Wong et al., 1995). In some cases of ALS, abnormal collections of neurofilaments have been seen in degenerating motor neurons but no familial cases of ALS have been shown to be due to mutations in any of the neurofilament genes (Cleveland & Liu, 2000). In a few cases of sporadic ALS and one family with ALS, deletions in the tail domain of the large neurofilament subunit (NF-H) have been reported.

Huntington's disease and spinocerebellar ataxias

HD and the spinocerebellar ataxias (SCA) provide important contrasts and similarities to the foregoing neurodegenerative diseases. In contrast to AD, FTD, Parkinson's disease, ALS, and the prion diseases, in which most of the cases are sporadic, both HD and the SCAs are exclusively genetic diseases (Table 15.2) (Reed & Neel, 1959) caused by expanded polyglutamine repeats (Table 15.5) (Lin et al., 1999; Martin, 1999; Paulson, 1999). But like the inherited forms of AD, FTD, Parkinson's disease, ALS, and the prion diseases, most cases of HD and the SCAs present with neurologic deficits in adulthood despite the mutant gene products being expressed in the CNS from early in life. Childhood forms of HD and the SCAs are known to be due to enlarged expansions of the triplet repeats that cause these diseases (Lin et al., 1999; The Huntington's Disease Collaborative Research Group, 1993; Zoghbi & Orr, 2000).

In both HD and SCA, the mutant gene products appear to be deposited in the CNS of patients. These misprocessed mutant proteins seem to accumulate in malfunctioning neurons and to be responsible for the neurologic deficits that these patients exhibit. In HD, SCA1, and Machado-Joseph disease (SCA3) as well as in some cases of SCA2, nuclear inclusions of the mutant proteins, which are ubiquitinated, have been found (Koyano et al., 1999; Lin et al., 1999).

Additional disorders caused by the misprocessing of proteins with expanded polyglutamine repeats include spinobulbar muscular atrophy (SBMA) also called Kennedy's syndrome, in which the androgen receptor carries the expanded repeat (LaSpada et al., 1991), as well as dentatorubropallidoluysian atrophy (DRPLA), and the spinocerebellar ataxias 6 and 7 (Martin, 1999; Paulson, 1999).

The neurodegenerative diseases described here represent only a small fraction of the total number of neurologic maladies given this label. Undoubtedly, many of these disorders will require reclassification as the molecular basis of each is elucidated.

Infectious prion diseases

Although infectious prion diseases constitute less than 1% of all cases, the circumstances surrounding these infectious illnesses are often dramatic (Table 15.4) (Will et al., 1999a). The ritualistic cannibalism involved the transmission of kuru among the Fore people of New Guinea, the industrial cannibalism responsible for 'mad cow disease' in Europe, and the growing group of patients with vCJD contracted from prion-tainted beef products are all examples of infectious prion diseases that almost defy imagination.

Kuru

Kuru has disappeared, but the impact of this illness on medical science remains immense. Kuru was the first human prion disease to be transmitted to experimental animals (Gajdusek et al., 1966). Based on the similarities of the neuropathologic lesions of scrapie and kuru (Hadlow, 1959), transmission studies to apes were performed and similar investigations followed with CJD (Gibbs et al., 1968; Klatzo et al., 1959). The transmissibility of kuru suggested that the disease resulted from ritualistic cannibalism among the Fore people living in the highlands of New Guinea (Alpers, 1968). Presumably, kuru began with a person who had developed a sporadic case of prion disease; at death, the brain was removed and distributed to relatives in order to immortalize the spirit of the deceased.

Iatrogenic prion disease

Accidental transmission of CJD to humans appears to have occurred with corneal transplantation (Duffy et al., 1974) and contaminated EEG electrode implantation (Bernouilli et al., 1977). Corneas removed from donors who unknowingly had CJD have been transplanted to apparently healthy recipients who developed CJD after prolonged incubation periods. The same improperly decontaminated EEG electrodes that caused CJD in two young patients with intractable epilepsy were found to cause CJD in a chimpanzee 18 months after their experimental implantation (Gibbs et al., 1994).

Surgical procedures may have resulted in accidental inoculation of patients with prions during their operations (Collins et al., 1999; Gajdusek, 1977; Will & Matthews, 1982), presumably because some instrument or apparatus in the operating theatre became contaminated when a CJD patient underwent surgery. Although the epidemiology of these studies is highly suggestive, no proof for such episodes exists.

Dura mater grafts

More than 70 cases of CJD after implantation of dura mater grafts have been recorded (Centers for Disease Control, 1997). All of the grafts were thought to have been acquired from a single manufacturer whose preparative procedures were inadequate to inactivate human prions. One case of CJD occurred after repair of an eardrum perforation with a pericardium graft (Tange et al., 1989).

Human growth hormone therapy

The possibility of transmission of CJD from contaminated human growth hormone (HGH) preparations derived from human pituitaries has been raised by the occurrence of fatal cerebellar disorders with dementia in more than 100 patients ranging in age from 10 to 41 years (Fradkin et al., 1991; Will et al., 1999a). These patients received injections of HGH every 2 to 4 days for 4 to 12 years (PHS, 1997). Assuming these patients developed CJD from injections of prion-contaminated HGH preparations, the possible incubation periods range from 4 to 30 years. Even though several investigations argue for the efficacy of inactivating prions in HGH fractions prepared from human pituitaries using 6 M urea, it seems doubtful that such protocols will be used for purifying HGH because recombinant HGH is available. Four cases of CJD have occurred in women receiving human pituitary gonadotropin (Cochius et al., 1990).

New variant Creutzfeldt–Jakob disease

The restricted geographical occurrence and chronology of vCJD have raised the possibility that BSE prions have been transmitted to humans. Over 80 vCJD cases have been recorded, but the incidence has been too low to be useful in establishing the origin of vCJD (Balter, 2000; Will et al., 1999b). No set of dietary habits distinguishes vCJD patients from apparently healthy people. Moreover, there is no explanation for the predilection of vCJD for teenagers and young adults. It is noteworthy that epidemiological studies over the past three decades have failed to find evidence for transmission of sheep prions to humans (Cousens et al., 1990). Attempts to predict the future number of cases of vCJD, assuming exposure to bovine prions prior to the offal ban, have been questioned because so few cases of vCJD have occurred (Ghani et al., 2000). Are we at the beginning of a human prion disease epidemic in Great Britain like those seen for BSE and kuru, or will the number of vCJD (vCJD) cases remain small as seen with iatrogenic CJD (iCJD) caused by cadaveric HGH?

Although the mechanism of infection of vCJD has not been yet established, mounting evidence argues for transmission of bovine prions to humans. This conclusion is based on multiple lines of inquiry including: (i) the spatial-temporal clustering of vCJD (Will et al., 1996; Zeidler et al., 1997), (ii) the successful transmission of BSE to macaques with induction of PrP plaques similar to those seen in vCJD (Lasmézas et al., 1996), (iii) the similarity of the glycoform pattern of brain but not tonsil PrP^{Sc} in vCJD to that in cattle, mice, domestic cats, and macaques infected with BSE prions (Hill et al., 1997, 1999), and (iv) transmission studies in non-Tg mice suggesting that vCJD and BSE represent the same prion strain (Bruce et al., 1997). The prolonged incubation periods and inefficient transmission of prions that is seen after inoculation of foreign prions into non-Tg mice can readily confuse the interpretation of the findings (Lasmézas et al., 1997; Prusiner, 1998a).

The most compelling evidence that vCJD is caused by BSE prions has come from experiments using mice expressing the bovine (Bo) PrP transgene (Scott et al., 1999). The incubation times, neuropathologic profiles, and patterns of PrP^{Sc} deposition in Tg mice expressing the BoPrP gene are indistinguishable whether the inocula originated from the brains of cattle with BSE or humans with vCJD (Scott et al., 1999). Neither CJD nor fCJD(E200K) prions have transmitted disease to the Tg(BoPrP) mice. In contrast to CJD and CJD(E200K) prions, which transmit disease efficiently to mice expressing a chimeric human-mouse PrP transgene, vCJD prions do not. Interestingly, none of the Tg mice expressing the chimeric human-mouse PrP developed disease after more than 600 days when inoculated with BSE prions from cattle.

Since the Tg(BoPrP) mice are also excellent hosts for transmission of natural sheep scrapie, this raises the possibility that sheep carry several strains of prions, including the BSE strain (M. Scott and S.B. Prusiner, in preparation). But the BSE strain might replicate more slowly in sheep than many scrapie strains and thus, is present at low levels. If the scrapie strains were more heat labile than the BSE strain, then the rendering process used in the late 1970s and most of the next decade might have selected for the BSE strain. This BSE strain might have then been reselected multiple times as cattle were infected by ingesting prion-contaminated meat and bone meal (MBM). In this situation, the infected cattle were slaughtered and their offal rendered into more MBM, which was subsequently fed to more cattle.

The foregoing scenario suggests that the BSE strain may be widely distributed in sheep and these prions composed of sheep PrP^{Sc} are non-pathogenic for humans. Once the BSE prions are passaged through cattle, they acquire bovine PrP^{Sc} and become pathogenic for humans.

Diagnostic tests

The attempts to develop diagnostic tests for prion diseases are instructive with respect to the other neurodegenerative diseases. The need for accurate, sensitive diagnostic tests for neurodegenerative diseases, preferably blood- or urine-based, is extreme. Advances in imaging the CNS may also aid in the early diagnosis of neurodegeneration. When effective treatments for neurodegenerative diseases are

eventually developed as discussed later, early accurate detection of the disease will be critical in order to institute therapies before CNS function is substantially compromised. The difficulty in distinguishing between early AD and depression in older people would benefit from a diagnostic test since both disorders are so common.

With the exception of brain biopsy, there are no specific tests for CJD. If the constellation of pathologic changes frequently found in CJD is seen in a brain biopsy, then the diagnosis is reasonably secure (Fig. 15.4(*a*) and (*b*)). The rapid and reliable diagnosis of CJD postmortem can be accomplished by using antisera to PrP. Numerous Western blotting studies have consistently demonstrated PrP immunoreactive proteins that are proteinase K-resistant in the brains of patients with CJD. It is noteworthy that PrP^{Sc} is not uniformly distributed throughout the CNS so that the apparent absence of PrP^{Sc} in a limited sample, such as a biopsy, does not rule out prion disease (Serban et al., 1990; Taraboulos et al., 1992).

A highly sensitive and quantitative immunoassay was developed based upon epitopes that are exposed in PrP^{C} but buried in PrP^{Sc} (Fig. 15.5(*a*)). Unlike all other immunoassays for PrP^{Sc}, this conformation-dependent immunoassay (CDI) does not require limited proteolysis to hydrolyze PrP^{C} prior to measuring the protease-resistant core of PrP^{Sc} (PrP 27–30) (Safar et al., 1998). Using the CDI, a new form of PrP^{Sc} has been identified, which is protease-sensitive and is denoted $sPrP^{Sc}$. The levels of $sPrP^{Sc}$ are proportional to the length of the incubation time (Fig. 15.5(*b*)) and are often much higher than those of protease-resistant PrP^{Sc}. Why levels of $sPrP^{Sc}$ should be directly proportional to the length of the incubation time is unclear. Whether measurement of $sPrP^{Sc}$ will become the basis of diagnostic tests for prion diseases remains to be established.

If the patient has a family history suggestive of inherited CJD, sequencing the PrP gene may facilitate the diagnosis. Sometimes, the PrP sequence is helpful in even seemingly non-familial cases. Obviously, DNA sequencing is a crucial diagnostic tool in all of the inherited neurodegenerative diseases. In the sporadic form of AD, ApoE allelic typing is a necessary adjunct to any clinical study. Moreover, sporadic neurodegenerative diseases require that both alleles encoding the etiologic, misprocessed protein possess the wt sequence.

In the prion diseases, AD, FTD, and Parkinson's disease, the CT or MRI may be normal or show cortical atrophy. In the prion diseases, the MRI scan may show a subtle increase in intensity in the basal ganglia with T2 or diffusion-weighted imaging, but this finding is neither sensitive nor specific enough to make a diagnosis. In AD, widespread atrophy with enlarged ventricles is often seen, especially late in the disease, but this finding is not diagnostic. Many cognitively intact elderly people have similar radiographic findings (Gertz et al., 1988; Kitagaki et al., 1998). In FTD, atrophy is confined to the frontal and temporal lobes while in HD, profound atrophy of the basal ganglia is commonly seen. In all of the neurodegenerative diseases, the CSF is nearly always normal but may show a minimal protein elevation (Cathala & Baron, 1987). Although the protein 14-3-3 is elevated in the CSF of many CJD patients, similar elevations of 14-3-3 are found in patients with herpes simplex virus encephalitis, multi-infarct dementia, and stroke (Johnson & Gibbs, 1998; Zerr et al., 1998). In Alzheimer's disease, 14-3-3 is generally not elevated. In the serum of some patients with CJD, the S-100 protein is elevated, but like 14-3-3, this elevation is not specific (Zerr et al., 1998). Attempts to use Aβ(1–40) levels in blood and urine have been unrewarding (Ghiso et al., 1997) but use of fluorescence correlation spectroscopy with CSF may provide a reliable diagnostic test for AD (Pitschke et al., 1998).

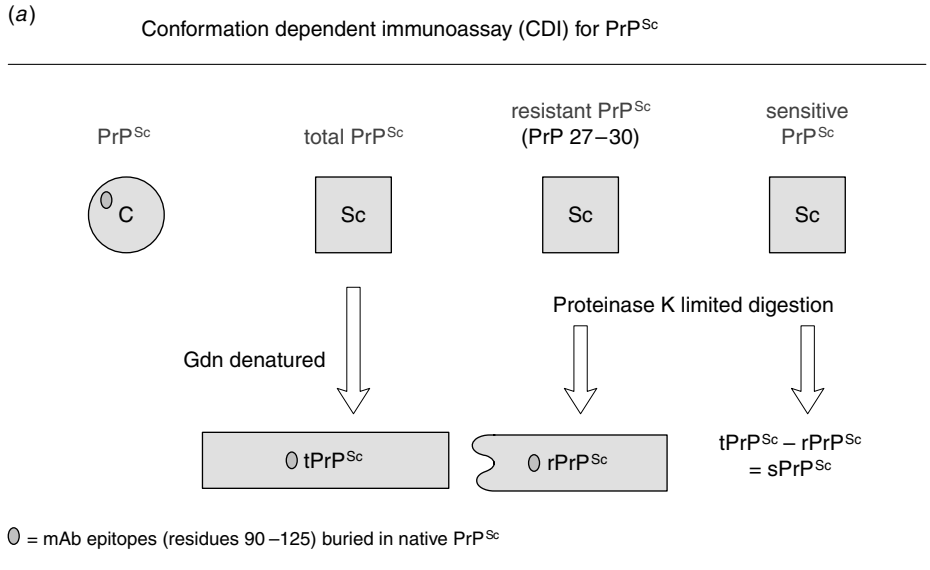
In contrast to AD, FTD, and Parkinson's disease, the electroencephalogram (EEG) is often useful in the diagnosis of CJD. During the early phase of CJD, the EEG is usually normal or shows only scattered theta activity. In most advanced cases, repetitive, high voltage, triphasic, and polyphasic sharp discharges are seen but, in many cases, their presence is transient. The presence of these stereotyped periodic bursts of $<$200 ms duration, occurring every 1 to 2 sec, makes the diagnosis of CJD very likely (Cathala & Baron, 1987; Johnson & Gibbs, 1998; Kirschbaum, 1968; Nevin et al., 1960). These discharges are frequently but not always symmetrical; there may be a one-sided predominance in amplitude. As CJD progresses, normal background rhythms become fragmentary and slower.

The possibility of Hashimoto's thyroiditis should always be considered in the differential diagnosis of CJD (Seipelt et al., 1999) since this autoimmune disease is treatable and CJD is not. That the clinical and neuropathologic findings can be so similar in Hashimoto's thyroiditis and CJD is striking; moreover, it raises the possibility that protein misprocessing may underlie both degenerative and autoimmune diseases.

Transgenic models of neurodegeneration

Prion diseases

The development of Tg mouse models that reproduce virtually every aspect of naturally occurring prion disease has created a firm foundation upon which to decipher



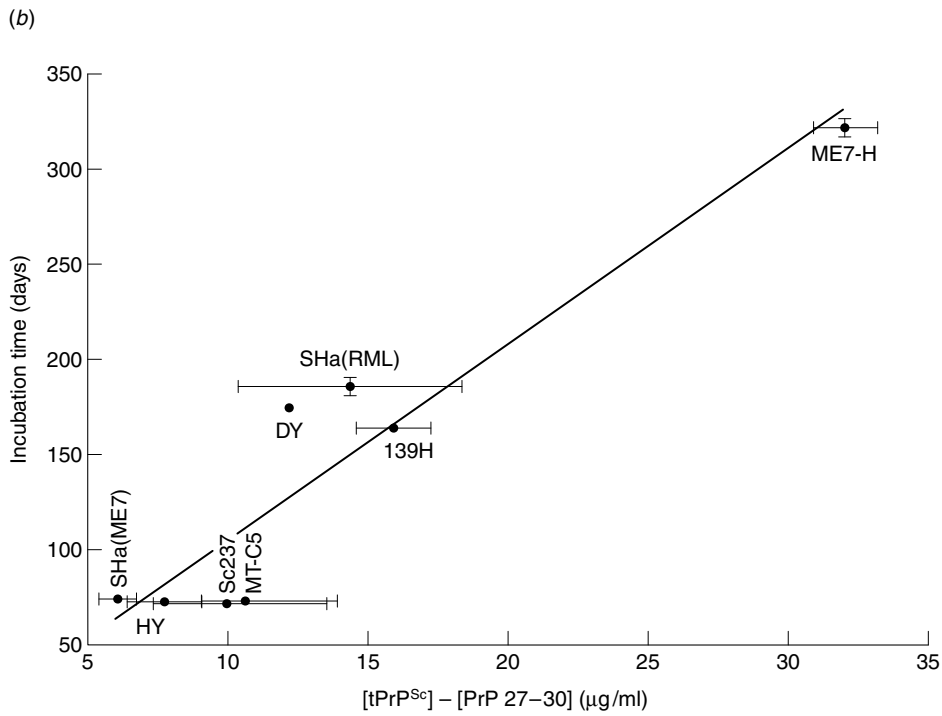


Fig. 15.5. Conformation-dependent immunoassay and prion strains. (*a*) The conformation dependent immunoassay (CDI) permits measurement of PrP^{Sc} without limited digestion by protease to eliminate PrP^{C}; instead, antibodies to epitopes that are exposed in PrP^{C} but buried in PrP^{Sc} are used to distinguish between the two isoforms. Using the CDI, it became possible to detect two different forms of PrP^{Sc}: one which is resistant to limited digestion by protease and the other which is readily digested. Using one fraction of a sample, total (t) PrP^{Sc} is measured while another aliquot is digested prior to determining the protease-resistant (r) PrP^{Sc} level. $rPrP^{Sc}$ is equivalent to PrP 27–30. By subtracting $rPrP^{Sc}$ from the $tPrP^{Sc}$, the amount of protease-sensitive (s) PrP^{Sc} can be determined. (*b*) When the levels of $sPrP^{Sc}$ in brain for eight different prion strains were plotted as a function of the incubation times in Syrian hamsters, a straight line was obtained with an r value of 0.94. (Data from Safar et al., 1998.)

the molecular pathogenesis of prion disease. Tg mice expressing mutant PrP develop CNS degeneration spontaneously and transmit disease to inoculated recipients (Hsiao et al., 1994). Tg mice expressing wt PrP from foreign hosts have been rendered susceptible to foreign prions with abrogation of species barriers (Prusiner et al., 1990), which manifest as a prolongation of the incubation time upon first passage in a foreign host (Pattison, 1965). As the level PrP transgene expression was increased, the incubation time decreased (Prusiner et al., 1990). The species barrier was reproduced in Tg mice expressing a mouse PrP molecule of 106 amino acids with two large deletions accounting for almost 50% of the residues. In these mice, a transmission barrier was observed after inoculation with prions from wt mice, but was abolished once miniprions composed of PrP^{Sc} with 106 residues were used as the inoculum (Supattapone et al., 1999a).

Tg mice expressing the P102L mutation causing GSS the mice developed signs of CNS dysfunction from 50 to 200 days of age (Hsiao et al., 1994). Although little protease-resistant PrP was found, widespread deposition of PrP amyloid and reactive astrocytic gliosis were observed. Extracts from the brains of these ill mice transmitted disease to Tg196 mice expressing the same mutant transgene at a low level that infrequently produces spontaneous disease. The Tg196 mice developed neurologic signs about 240 days after receiving the brain extract and the disease could be serially transmitted. A synthetic peptide of 55 residues carrying the P102L mutation produced disease in Tg196 mice about 360 days after inoculation and the illness could be serially transmitted (Kaneko et al., 2000). Only the mutant peptide in a β-sheet conformation induced by exposure to acetonitrile produced neurologic disease.

Some lines of PrP-deficient ($Prnp^{0/0}$) mice developed ataxia at about 18 months of age (Sakaguchi et al., 1996), while other lines did not (Büeler et al., 1992). Subsequent studies showed that those developing ataxia and Purkinje cell degeneration overexpress an adjacent gene designated Prnd, which encodes the protein doppel (Dpl) (Moore et al., 1999). PrP and Dpl represent an ancient gene duplication with considerable sequence divergence but structural conservation. In mice developing cerebellar degeneration, high levels of an intergenic mRNA were found where the two untranslated exons of the PrP gene were spliced to the Dpl exon containing the open reading frame (ORF) or protein coding region. High levels of Dpl protein expression were found to be toxic for Purkinje cells, but overexpression of PrP rescued the ataxic phenotype (Nishida et al., 1999).

Alzheimer's disease

Tg mice expressing mutant APP have been found to develop amyloid plaques filled with the Aβ peptide (Games et al., 1995; Hsiao et al., 1996). In some cases, these mice show behavioural abnormalities while in others, such changes have not been reported. The development of Aβ plaques was accelerated when extracts from the brains of patients with AD were injected into Tg mice expressing mutant APP (Kane et al., 2000). In earlier studies, AD brain fractions enriched for tau induced deposits of Aβ in the brains of rats (Shin et al., 1993). In uninjected bigenic mice, development of Aβ plaques was hastened by expression of mutant APP and PS1 transgenes (Borchelt et al., 1997). In other bigenic mice expressing human mutant APP and human ApoEε4 but not ε3, cognitive deficits were identified at 6 months of age even though no Aβ plaques could be found (Raber et al., 2000). These findings argue that the neuronal dysfunction in Alzheimer's disease may not be due to the Aβ plaques, but to events occurring prior to the sequestration of Aβ and other molecules into the plaques (Mucke et al., 2000). Such a scenario would be in accord with the findings for prion diseases in which PrP amyloid plaques are not obligatory for disease pathogenesis. In fruit flies, disruption of the APP-like gene or presenilin causes nervous system dysfunction, and overexpression of wt presenilin in flies causes cell death. In worms, suppression of nicastrin expression induces a phenotype similar to that seen with disruption of the presenilin-like genes (Yu et al., 2000).

Nicastrin and the presenilins are thought to form complexes that have γ-secretase activity, which may function in regulated intramembrane proteolysis (Rip) to produce the Aβ peptide from APP (De Strooper et al., 1999). Several other examples in intramembrane proteases acting in diverse metabolic processes have been discovered (Brown et al., 2000; De Strooper & Annaert, 2000).

Frontotemporal dementia

Expression of human tau with the P301L mutation in Tg mice produced neurofibrillary tangles and Pick bodies in neurons throughout the CNS (Lewis et al., 2000). By 10 months of age, ~90% of these Tg mice developed progressive neurologic dysfunction resulting in death within a month.

Parkinson's disease

The expression of either wt or mutant human α-synuclein in fruit flies produced adult onset loss of dopaminergic

neurons and locomotor dysfunction (Feany & Bender, 2000). Additionally, filamentous, intraneuronal inclusions of α-synuclein were found. In Tg mice expressing mutant and wt human α-synuclein, intraneuronal inclusions of human α-synuclein were found in the neocortex and hippocampus as well as substantia nigra where a significant loss of dopaminergic neurons was observed (Masliah et al., 2000; van der Putten et al., 2000).

ALS

In Tg mice expressing mutant SOD1, vacuolation, neuronal death, and reactive gliosis in the spinal cord have been found as well as cytoplasmic inclusions of SOD1 in motor neurons (Cleveland & Liu, 2000). Tg mice overexpressing the human large neurofilament subunit (NF-H) produced altered function in large myelinated motor neurons (Kriz et al., 2000). Of particular interest are bigenic mice in which wt NF-H and mutant SOD1(G37R) have been expressed. The overexpression of NF-H extended the lifespan of mice expressing mutant SOD1 by ~6 months (Couillard-Després et al., 1998). The results of these experiments suggest that much of the neurofilament protein was trapped in the cell bodies and thus, was prevented from being transported into the axons where altered neurofilaments would cause dysfunction. Less striking is the increase in survival by ~40 days in Tg mice expressing mutant SOD1(G37R) due to disruption of the neurofilament genes (Williamson et al., 1998).

Huntington's disease

Tg mice expressing the mutant huntingtin protein with 48 or 89 repeating Gln residues develop neurologic dysfunction and striated degeneration (Reddy et al., 1998). In attempts to reproduce all aspects of HD, a large number of Tg mice has been produced using different vectors and varying numbers of CAG repeats (Shelbourne et al., 1999). Notably, YAC clones of the huntingtin gene with 46 or 72 repeating Gln residues have been used to produce selective striatal degeneration (Hodgson et al., 1999). Using the tetracycline inducible transgene system, regulated expression of exon 1 of the huntingtin gene with 94 polyglutamine residues has been used to produce an HD model with reversible neurodegeneration (Yamamoto et al., 2000). Using exon 1 with 92 and 111 repeating Gln residues, gene targeting has been used to produce knockin mice that show accumulation of mutant huntingtin in the nuclei of spiny neurons of the striatum (Wheeler et al., 2000). In Drosophila, expression of the huntingtin protein carrying a polyglutamine repeat of 75 amino acids produced striking neuronal degeneration (Jackson et al., 1998).

Using cultured neurons from the striatum and hippocampus of the rat, expression of a fragment of the huntingtin protein with 68 repeating Gln residues produced nuclear inclusions of the mutant protein and apoptosis (Saudou et al., 1998). When the nuclear inclusions were diminished by inhibiting ubiquitination, apoptosis increased, arguing that aggregation of the mutant protein helps protect cells. Although some investigators argue that aggregation is an essential feature of the polyglutamine repeat diseases (Perutz, 1996), these results and those discussed below for Tg mice expressing mutant ataxin 1 argue that the misfolding of monomers or oligomers of proteins with Gln expansions is responsible for disease and that nuclear inclusions, which are often seen in humans and Tg models, may reflect sequestration of potentially pathogenic proteins.

Spinocerebellar ataxias

Expanded GIn repeats in ataxin 1 causing SCA1 have been expressed in Tg mice and shown to cause ataxia and Purkinje cell degeneration. Mutation of the nuclear localization signal in ataxin 1 with 82 repeating Gln residues prevented disease in Tg mice (Klement et al., 1998; Lin et al., 1999). In contrast, deletion of 122 amino acids comprising the self-aggregation domain in ataxin 1 with 77 repeating Gln residues did cause disease when expressed in Tg mice. These results argue that nuclear localization is required for disease pathogenesis but aggregation is not. In Tg mice, expression of ataxin 2 with an expanded glutamine repeat of 58 residues resulted in impaired motor skills and cytoplasmic but not nuclear aggregates of the protein in Purkinje cells (Huynh et al., 2000). Tg mice expressing ataxin 3 with an expanded glutamine repeat of 79 residues failed to develop neurologic dysfunction as well as degeneration of cerebellar dentate neurons and the basal ganglia that is seen in Machado–Joseph disease (MJD), also known as SCA3 (Ikeda et al., 1996). When the 79 Gln residues were expressed with adjacent 42 amino acids that are found immediately at the C-terminal of the repeat, they developed ataxia by four weeks of age and showed widespread degeneration of the cerebellum by eight weeks. In *Drosophila*, expression of the ataxin 3 carrying a polyglutamine repeat of 78 amino acids resulted in degeneration of the eye (Warrick et al., 1999).

The ability to reproduce virtually every aspect of the human prion diseases in Tg mice has proved to be a useful goal for studies of other neurodegenerative diseases. The progress in modelling other neurodegenerative disorders

in Tg mice, flies, and worms is impressive. When the CNS dysfunction accompanied by region-specific neuropathology mimicking the human disease is produced in organisms expressing mutant transgenes, it is reasonable to assume that significant progress in understanding the disease process is being made.

Oligomers vs. large aggregates

In a cell culture model of HD and Tg mice expressing mutant ataxin 1, formation of nuclear aggregates was separated from cell death as described above. The issue of whether large aggregates of misprocessed proteins or misfolded monomers (or oligomers) cause CNS degeneration has been addressed in several studies of prion diseases in humans as well as in Tg mice. In humans, the frequency of PrP amyloid plaques varies from 100% in GSS and vCJD to ~70% (Will et al., 1996) in kuru (Klatzo et al., 1959) and ~10% in CJD, arguing that these plaques are a non-obligatory feature of the disease (DeArmond & Prusiner, 1997). In Tg mice expressing both mouse and SHa PrP, those animals inoculated with hamster prions produced hamster prions and developed amyloid plaques composed of SHaPrP (Prusiner et al., 1990). In contrast, those Tg mice inoculated with mouse prions did not develop plaques even though they produced mouse prions and died of scrapie.

While intracellular collections of misprocessed proteins, such as Lewy bodies, nuclear inclusions and Pick bodies, may represent a mechanism whereby cells sequester proteins that cannot be readily degraded, PrP and Aβ amyloid plaques may play a similar role in the extracellular space of the CNS (Table 15.4).

Prevention and therapeutics

There is no known effective therapy for treating or preventing CJD or any of the other neurodegenerative diseases. Only in Parkinson's disease does an effective treatment exist that ameliorates the symptoms (Cotzias et al., 1967; Marsden & Parkes, 1977) but it does not halt the underlying degeneration. Because the prion diseases progress more rapidly than the other neurodegenerative disorders, fatalities from these maladies are more readily measured. There are no well-documented cases of patients with CJD showing recovery either spontaneously or after therapy, with one possible exception (Manuelidis et al., 1976), for which there is no confirmatory example. In the highlands of New Guinea, individuals who were thought to have recovered from kuru were eventually shown to have hysterical illnesses.

The difficulty of developing effective drugs for the prevention and treatment of the neurodegenerative diseases should not be underestimated. New principles of pharmacotherapeutics will undoubtedly emerge from development of drugs for treating neurodegeneration. The history of successful therapeutics for preventing or reversing protein misprocessing is extremely limited. As more is learned about the molecular pathogenesis of the neurodegenerative diseases, more opportunities for drug targets will emerge (Orr & Zoghbi, 2000). Directing these new drugs to specific regions of the CNS will also be challenging.

Preventing misprocessing

Structure-based drug design focused on dominant negative inhibition of prion formation has produced several lead compounds (Perrier et al., 2000). Prion replication depends on protein–protein interactions and a subset of these interactions gives rise to dominant negative phenotypes produced by single residue substitutions (Kaneko et al., 1997; Zulianello et al., 2000). The task of exchanging polypeptide scaffolds for small heterocyclic structures without loss of biological activity remains difficult. Whether this approach, designed to prevent the misfolding and aberrant processing of proteins, will provide general methods for developing novel therapeutics for Alzheimer's and Parkinson's diseases, as well as ALS and other neurodegenerative diseases, remains to be established.

The γ-secretase, which catalyses the hydrolytic cleavage of APP in the production of the Aβ peptide, continues to be a focus with respect to possible therapeutics for AD (Selkoe, 1999). Inhibitors of γ-secretase have been identified and are being evaluated for their efficacy in slowing the ravages of AD. Recent studies suggest that anti-inflammatory and cholesterol-reducing drugs can significantly reduce the risk of AD (Jick et al., 2000).

Enhanced clearance

Several compounds have been demonstrated to eliminate prions from prion-infected cultured cells. A class of compounds known as 'dendrimers' seems particularly efficacious in this regard (Supattapone et al., 1999b). Numerous drugs have been demonstrated to delay the onset of disease in animals inoculated with prions if the drugs are given around the time of the inoculation (Priola et al., 2000). The most common scenario in which one would want to treat humans is either patients showing signs of

disease or presymptomatic patients carrying mutations predisposing them to develop prion disease. No treatment has shown any efficacy in animal models of these two scenarios.

A novel approach to treating AD has been developed using Tg mice overexpressing a mutant APP gene. Immunization of these Tg mice with the Aβ peptide resulted in a profound decrease in the Aβ amyloid in the CNS, presumably by accelerating the clearance of Aβ peptides (Schenk et al., 1999). Whether this approach will prove fruitful in patients suffering from AD or applicable to other neurodegenerative disorders is unknown.

Replacement therapy

Because the neurodegeneration in Parkinson's disease is confined largely to the substantia nigra, especially early in the disease process, replacement therapy has proved to be useful; however, many patients eventually become refractory to L-dopa therapy (Marsden & Parkes, 1977).

Similar approaches to AD have been disappointing in large part because the disease process is so widespread. The widespread neuropathology in ALS, FTD, and prion diseases also makes replacement therapy an approach that is unlikely to be successful.

Speculation on the spectrum of degenerative diseases

Besides the neurodegenerative diseases that were discussed previously, it is tempting to speculate that protein misprocessing features in other common diseases of the CNS, such as schizophrenia, bipolar disorders, and autism. Most cases of schizophrenia, bipolar disorders, and autism are sporadic but a substantial minority appear to be familial. The lack of consistent neuropathologic changes in the brains of people with these diseases has impeded studies and complicated phenotypic analysis. Not unlike these diseases are alcoholism and other forms of addiction in which most cases are sporadic but a minority are familial. In one group of patients with inherited FTD, alcoholism and Parkinson's disease are prominent features; these people carry a mutation in the tau gene (Wilhelmsen et al., 1994).

Whether diseases, such as multiple sclerosis (MS), that are frequently classified as neurodegenerative diseases, are caused by protein misprocessing is unknown (Seboun et al., 1997). In MS, the immune system features prominently in the pathogenesis of the disease and thus, it is often argued that MS should be classified as a T-cell mediated autoimmune disorder. In some MS cases, antibody-mediated demyelination has been found (Genain et al., 1999) and in other cases, degeneration of oligodendrocytes has been observed with little or no evidence for immune-mediated damage (Lucchinetti et al., 2000).

Whether the misprocessing of proteins features in neurodegeneration that is independent of the inflammatory process in MS or it initiates an aberrant immune response is unknown. Like the neurodegenerative diseases discussed above, most cases of MS are sporadic while a minority are familial. The inheritance of MS is polygenic but to date, no single mutant gene causing MS has been identified (Haines et al., 1998). Molecular mimicry has been suggested as the mechanism that initiates the immune-mediated demyelination of the CNS in MS, in which an antigenic site on the protein of an infectious pathogen, such as a virus, provokes an immune response directed at an epitope of a myelin protein (Fujinami and Oldstone, 1985; Wucherpfenning and Strominger, 1995). The participation of an infectious pathogen in MS remains an attractive hypothesis that could explain the geographically isolated clusters as well as how the risk for MS is acquired during childhood.

Systemic diseases such as juvenile type I and adult onset type II diabetes mellitus are likely to be caused by protein misprocessing. Juvenile diabetes seems to be an autoimmune disease; despite control of the insulin deficiency, progressive degeneration of peripheral nerves, the retinas, and kidneys often proceeds (Taylor, 1995). In the β-islet cells of patients with type II diabetes, the protein amylin frequently accumulates as amyloid fibrils. Like the juvenile form of diabetes, control of the insulin deficiency does not prevent the development of polyneuropathy, retinopathy, and renal disease in adult onset diabetes. When reflecting on MS, perhaps illnesses like ulcerative colitis, Crohn's disease, rheumatoid arthritis and lupus ought to be considered as possible disorders of protein misprocessing in which misfolded proteins might evoke an autoimmune response. Like the neurodegenerative disorders (Table 15.2), a minority of cases of these autoimmune diseases are familial while the majority are sporadic.

The systemic amyloidoses share important features with the neurodegenerative diseases. In primary amyloidosis, immunoglobulin light chains form amyloid deposits that can cause cardiomyopathy, renal failure and polyneuropathy (Benson, 1995). In response to chronic inflammatory diseases, the serum amyloid A protein is cleaved to form the amyloid A protein, which is deposited as fibrils in the kidney, liver, and spleen. The most common systemic hereditary amyloidosis is caused by the deposition of mutant transthyretin. More than 40

mutations of transthyretin gene have been found to result in proteins causing familial amyloidotic polyneuropathy.

While speculation about the possible role of protein misprocessing in many diseases presents a series of attractive and, in some instances, provocative hypotheses, other mechanisms that compromise cell function need to be entertained. For example, apoptosis can be initiated by a variety of pathways, in which protein misprocessing is likely to play little or no role.

The future

As the lifespan of humans continues to increase through the efforts of modern medical science, an increasing burden of degenerative diseases is emerging. Developing effective means of preventing these disorders and treating them when they do occur are paramount to the personal, political, and economic future of our planet. The problems caused by AD and Parkinson's disease are already so large that if these maladies continue to increase in accord with the changing demographics of the world population, they will bankrupt both the developed and underdeveloped nations over the next 50 years. It is remarkable to think that by the year 2025, more than 65% of people over the age of 65 will be living in countries that are now designated as the developing nations (United Nations, 1999). Unless effective treatments and methods of prevention are developed, this immense group of people will be subject to the same risk for AD, Parkinson's disease, and other neurodegenerative disorders as people who are currently living in the most affluent of nations.

In summary, the discovery of prions and many other findings now permit a molecular definition and classification of the neurodegenerative diseases. Alzheimer's and Parkinson's diseases as well as ALS, FTD and the prion diseases are all disorders of protein processing as are Huntington's disease and the spinocerebellar ataxias. Until recently, clinical signs and neuropathologic lesions were the primary means of describing these disorders. While these characteristics remain useful in diagnosis, the etiologies can now be attributed to the misprocessing of particular proteins. In each of the neurodegenerative disorders, the particular protein that undergoes misprocessing determines the disease-specific phenotype, which results from the malfunction of distinct sets of neurons.

The remarkable progress in elucidating the etiologies of the major neurodegenerative diseases over the past two decades argues that the time has come to intensify the search for drug targets and develop compounds that interrupt the disease processes. In some of the neurodegenerative diseases, it may be most efficacious to design drugs that specifically block the misprocessing of a particular protein while in other cases, drugs that enhance the clearance of an aberrant protein or fragment may prove to be more useful. Regardless of the therapeutic approach, the need for accurate, early detection of neurodegeneration will be extremely important so that drugs can be given before significant damage to the CNS has occurred.

The task of developing useful diagnostic tests and effective therapeutics for neurodegenerative diseases should not be underestimated. Past experience with cardiovascular disease and cancer should be a forewarning of the difficult paths that lie ahead. Nevertheless, the remarkable progress in deciphering the etiologies of the neurodegenerative diseases and the urgency to prevent these age-dependent disorders should provide vigorous encouragement.

Acknowledgements

This work was supported by grants from the National Institutes of Health (NS14069, AG02132 and AG10770) and the American Health Assistance Foundation as well as a gift from the G. Harold and Leila Y. Mathers Foundation. I thank Drs Fred Cohen, Stephen DeArmond, Kirk Wilhemsen, Robert Edwards, Warren Olanow, Steve Finkbiener, and Steve Hauser for their important criticisms and valuable suggestions.

Aging and dementia: principles, evaluation and diagnosis

Sudha Seshadri[1] and David A. Drachman[2]

[1] Framingham Heart Study, Department of Neurology, Boston University School of Medicine, Framingham, MA, USA
[2] Department of Neurology, University of Massachusetts Medical School, Worcester, MA, USA

'Aging', or 'senescence' usually refers to the involutional changes that occur after an individual has reached full structural and functional maturity (Masoro, 1995). While it is clearly related to the passage of time, there is considerable variability among individuals in when the declines in function occur, the extent of the changes and the selective involvement of specific structures. The onset of impairment due to senescent changes, as well as the overall longevity of individuals, may vary by 50% or more. Senescent changes may involve the heart, joints, skin, brain or other organs in different individuals; and both the organ(s) involved and the degree of decline may be related to genetic and/or experiential factors. Adults between the ages of 65 and 85 years are classified as the 'young-old'; those over age 85 as the 'oldest-old' (Suzman et al., 1992). As the elderly are the fastest growing segment of the population, there is much interest in the causes of senescence, and potential medical means of preventing or delaying their effects, many of which constitute the 'degenerative diseases' of the elderly.

Because of the variability in senescent decline, the concept of 'normal' aging has been controversial, and the term has been used in at least three different ways:

- The optimal level of function seen in individuals of a given age;
- The level of function seen in individuals of a given age in the absence of disease; and
- The mean level of function of all individuals of a given age.

Each of these concepts of 'normal aging', used in the appropriate context, is of value in recognizing and defining the usual expectation, specific disorders, and maximum potential of individuals with advancing age (Rowe & Kahn, 1987). The genetic endowment, the accidents of chance, and the wear and tear of lifetime experience assure that no one definition is necessarily the correct one. Regardless, all three definitions endorse the fact that some decline in function occurs over time; and the relationship between gradual decrements in performance with age, and more rapid and significant impairment of function with disease, is a key issue in understanding the neurologic basis of dementia.

In this chapter we will review:

- anatomic, physiologic and pharmacologic changes that occur in the aging brain;
- cognitive changes with advancing age;
- the molecular basis for age-related changes (ARCs) that cause senescent decline;
- the relationship between aging and dementia;
- clinical manifestations of dementia; and
- a brief classification of dementing disorders.

Anatomical and physiological changes with aging

Gross changes in the aging brain

Autopsy studies have shown that brain weight declines increasingly after age 50, at a rate of about 2% per decade (Miller et al., 1980); by the age of 80 the brain weight is typically decreased by about 10% compared with young adults. CT and MRI studies on aging populations show a linear decrease in brain volume with increasing age (Murphy et al., 1992), and a proportionally more marked increase in ventricular and sulcal volume with age. There is more shrinkage of grey matter than white matter (Pfefferbaum et al., 1994), but gyral atrophy affects predominantly the association and limbic cortices, sparing the primary sensory and motor cortices. On MRI scans, atrophy is seen most prominently in the frontal lobes, less so in the temporal lobes and least in the parieto-occipital

lobes; frontal atrophy is more marked in males and parietal atrophy in females (Murphy et al., 1996). In the temporal lobes, medial temporal and hippocampal atrophy predominates, particularly on the left side. The rate of hippocampal atrophy over time correlates with the risk of developing dementia (Jack et al., 1998).

Age-related myelin loss in the brain involves predominantly the small myelinated fibers (Tang et al., 1997). On MRI imaging, white-matter hyperintensities increase exponentially in aging subjects, with only 4.4% of a large, community-dwelling elderly population being entirely free of these changes (Longstreth et al., 1996). The pathological basis and clinical significance of these MRI changes are uncertain; some are ischemic in nature, while periventricular 'caps' may be due to subependymal gliosis (Fazekas et al., 1993).

Microscopic pathology of the aging brain

Changes in the aging brain include neuronal loss, synaptic loss, gliosis and often the accumulation of neuritic plaques and neurofibrillary tangles. Neurons are primarily postmitotic cells and although some may be replaced by neural stem cells (Roy et al., 2000), the vast majority are believed to be irreplaceable. Different neuronal systems have differential vulnerability to aging; the neuronal systems most vulnerable to aging are located in the basal forebrain nuclei, hippocampus, entorhinal cortex, neocortex and brainstem monoaminergic systems. Neuronal loss appears to be regional and lamina specific rather than global, however, and modern stereologic counting techniques show less severe neuronal loss than was previously thought (Coleman & Flood, 1987). The regional pattern of neuronal loss appears to differ in normal aging and Alzheimer's disease: the number of neurons in the entorhinal cortex (layer II), hippocampal CA1 region and the locus ceruleus is not reduced in normal aging, while these regions lose up to 70% of their neurons in Alzheimer's disease (West et al., 1994; Gomez-Isla et al., 1996; Mouton et al., 1994). Similarly, losses of dendrites and synapses are not inevitable correlates of aging. Certain cortical areas show a decline in synaptic density (Lippa et al., 1992; Masliah et al., 1993) while in others there may even be an increase in the synaptic density with aging. While the increase in local synaptic density with aging may be an effort to compensate for regional neuronal loss (Arendt et al., 1995), it may reflect a decrease in neuropil volume. Loss of synapses correlates better with the severity of cognitive impairment in an aging brain than other changes, such as the accumulation of senile plaques and neurofibrillary tangles (NFTs), described below (Terry et al., 1991). Age-related changes also include granulovacuolar degeneration (1–5 μ intracytoplasmic, neuronal vacuoles with a 1 μ central, basophilic granule) and the appearance of Hirano bodies (eosinophilic, spindle-shaped, intracytoplasmic inclusions), both occurring predominantly in the hippocampus.

With aging, glial proliferation occurs (Hansen et al., 1987), and both neuritic plaques and neurofibrillary tangles are often found, sometimes in large numbers (Fukumoto et al., 1996; Wisniewski et al., 1979). Amyloid is the core constituent of the plaques, where it is surrounded by dystrophic neurites and glial proliferation. Amyloid may also be deposited in and around the walls of aging cerebral arterioles (amyloid angiopathy) or as diffuse plaques without a surrounding glial response. Neurofibrillary tangles (NFT) are intraneuronal silver-staining bodies, seen as paired helical filaments ultrastructurally, and consisting of hyperphosphorylated tau – a microtubule-associated protein, which may also be deposited as intracellular or as extracellular neuropil threads. While amyloid plaques and NFTs increase in frequency and number with normal aging, they are also considered the hallmark of Alzheimer's disease in demented patients (Ball & Murdoch, 1997), using semiquantitative counts of plaques or NFTs as well as their distribution (Khachaturian, 1985; Braak et al., 1993) to distinguish normal from disease. The quantitative histologic distinction between age-related and disease-related findings is still uncertain, especially in the oldest-old, however.

Age-related changes in neurophysiology

In older subjects, resting cerebral blood flow decreases frontally on MR angiography, PET and to a lesser degree SPECT studies (Buijs et al., 1998; Martin et al., 1991); while decreased parietal metabolism may be seen as a marker of early Alzheimer's dementia (Reiman et al., 1996). On EEG, 'healthy aging' by itself causes few EEG changes, such as diminished alpha reactivity and an increase in beta activity (Roubicek, 1977; Koyama et al., 1997). Other changes often seen with aging, such as a decrease in mean alpha frequency and focal temporal slowing, may be correlated with declines in performance on memory and cognitive tests (Drachman & Hughes, 1971).

Age-related changes in neurotransmitter function

Decline in neurotransmitter function is an important factor in the cerebral impairment of aging and dementia (Drachman, 1977; Strong, 1998). In Alzheimer's disease, loss of cholinergic projections from the nucleus basalis of Meynert to the hippocampus and cortex correlate with the

loss of memory (Bierer et al., 1995), and the visual hallucinations seen in Lewy body dementia are associated with decreased neocortical cholinergic activity (Perry et al., 1999). It is less certain that acetylcholine levels decline significantly in disease-free aging (Muller et al., 1991; Sarter & Bruno, 1998). A decline in nigral dopamine levels is also well documented in normal aging (Martin et al., 1989), and decreased serotonergic and peptidergic function have been invoked to explain mild age-related memory loss (Buccafusco & Terry, 2000). Response to neurotransmitters may be altered as well; even in the healthy, aging neurons become more susceptible than younger neurons to excessive extracellular glutamate or dopamine levels, and are more likely to suffer excitotoxic cell death (Beal, 1992).

Cognitive changes with aging

Some cognitive changes are nearly universal in the elderly, including a decline in memory storage (i.e. the ability to learn new information), and a decline in the speed of mental processing. Schofield found that 31% of healthy older adults reported memory complaints, such as difficulty remembering names and misplacing of commonly used objects such as keys (Schofield et al., 1997a). Conscious recall (declarative memory) is more often impaired than is motor memory for previously learned skills, such as playing the piano (procedural memory) (Fuld, 1980; Drachman, 1986). Recall of context-specific information (episodic memory) is more affected than the recall of general information (semantic memory); and retrieval is more impaired than recognition. Immediate memory span (what can be recalled after a single hearing) and long-term memory for events in the remote past are preserved. In patients who become demented, this pattern of memory impairment is exaggerated.

Cognitive tasks involving speed of processing begin to show impairment in the fourth decade, and as processing speed continues to slow (Salthouse, 1996), this affects many tests of cognitive function. Actual performance on global intelligence tests, such as the Wechsler Adult Intelligence Scale (WAIS), declines with age, although IQ scores are age corrected, thus numerically masking this decline. To achieve an IQ of 100 at age 75, for example, one need be correct on only half as many items as at age 21 (Wechsler, 1981). The greatest age-related decline in scores is noted in the timed 'performance' subtests (picture completion, digit symbol substitution, block design), with smaller, declines on the untimed 'verbal' subtests (vocabulary, digit span). The time required to perceive a stimulus increases, as measured by tests involving 'backward masking', i.e. the delivery of a second stimulus so close to the first, that the initial stimulus is not perceived (Kline & Szafran, 1975). The central processing time increases, as shown by a disproportionate increase in choice reaction time (Fozard et al., 1994), and documented by increased latency in the central component of event-related P300 evoked responses (Polich, 1996). Visuospatial construction ability decreases with age, but this does not typically affect daily function. 'Crystallized intelligence', accumulated knowledge as measured, e.g. in tests of vocabulary, tends to be retained, while 'fluid intelligence', the ability to manipulate new information to solve problems, declines with aging (Horn & Cattell, 1967). Cognitive decline with aging is more likely to be seen in elderly subjects with systemic disorders such as hypertension and diabetes mellitus, although the mechanism of causality is uncertain (Skoog, 1997; Skoog et al., 1996). The norms of cognitive function in the oldest-old, those above age 85, are inadequately defined, with only a few studies, such as the Mayo Clinic's Older Americans Normative Study, extended to include subjects in this age range (Ivnik et al., 1997; Lucas et al., 1998).

Other neurological changes with aging

A decrease in special senses is common. Visual acuity declines due to presbyopia and cataract formation (Kini et al., 1978); altered blue perception due to yellowing of the lens; decreased pupillary size and reactivity; and diminished upward gaze. Hearing, especially for high frequencies, decreases (presbyacusis) (Critchley, 1931; Kaye et al., 1994). Olfactory perception (Doty, 1991) and odour identification decrease (Larsson et al., 1999). Motor system changes include diminished muscle bulk and power (a consequence of decreased activity and atrophy of fast-twitch type II fibres) (Aniansson et al., 1986), mild increase in muscle tone (Kaye et al., 1994), slowing of movement (Waite et al., 1996) and an increased frequency of both essential and extrapyramidal tremors (Skre, 1972). Changes in gait include impairment of postural reflexes, a decrease in stride length, gait velocity and arm swing, and gait changes due to orthopedic problems (Murray et al., 1969; Larish et al., 1988) such as osteoarthritis and changes in the spine. The ankle jerks are often hypoactive (Prakash & Stern, 1973). The perception of vibratory and proprioceptive sensation is diminished in the lower limbs.

Molecular mechanisms for age-related changes (ARCs)

Senescence is the consequence of specific biological mechanisms that cause the progressive accumulation of

'age-related changes' (ARCs). Many of these ARCs originate at a molecular or cellular level; they result in clinically evident disorders when sufficient attrition in neural numbers or function occurs so that brain systems can no longer work effectively. ARCs result from both intrinsic events: those due to the inherent attrition of critical survival elements, and those designed to dispose of imperfect components, and from random, extrinsic adverse events. Genetic differences among individuals modify both the timing and the rate of progression of intrinsic events, and the susceptibility to, and effect of, extrinsic events. The precise point at which accumulating ARCs increase the vulnerability to neurodegenerative disorders, or may reach a threshold and become manifest as clinical 'disease', is as yet unclear.

Intrinsic ARCs

The nature of intrinsic ARCs is clearly exemplified by the finite survival of cells and their limited ability to divide in tissue culture, first demonstrated by Hayflick and Moorhead in the early 1960s (Hayflick & Moorhead, 1961). Until that time, it was widely believed that cells grown in culture were immortal. Rigorous studies by Hayflick and his colleagues showed that cells in culture could undergo only a limited number of divisions, then underwent growth arrest at the G_1-S boundary, became dormant and eventually died (Hayflick & Moorhead, 1961; Hayflick, 1965, 1980). Human fetal fibroblasts have the capacity to divide about 50 times, while adult cells can divide only about 20–30 times, the number of replications decreasing with advancing age. The capacity to divide resides in the cellular nucleus, rather than the cytoplasm. When nuclei taken from young cells were transplanted into the cell bodies of older cells, the number of subsequent divisions was increased, based on the age of the young donors; while nuclei from old cells transplanted into young cells bodies reduced the number of divisions and survival to that of the donors.

The nature of the mechanism enabling cells to 'keep count' of the number of divisions they have undergone is largely explained by *telomeric shortening*. The telomere, or chromosome tail, consists of hundreds of TTAGGG repeat sequences, found on each end of every chromosome. Each time a cell divides, its chromosomes lose part of their telomeric tails; when the tails become too short the cell can no longer divide. Most human cells undergo telomeric shortening with advancing age; although this does not apply to adult neurons which are postmitotic, it affects both glial cells and stem cells (Ostenfeld et al., 2000). The enzyme telomerase is present in normal cells but inactive; when activated, it allows cells to regenerate their telomeres. In germinal cells, cancer cells and 'immortalized cells' telomerase is active, and reactivation of telomerase may increase cell longevity (Greider 1990, 1998; Zhu et al., 2000).

Early concepts regarding the molecular mechanisms contributing to ARCs were the 'somatic mutation theory', proposed by the atomic physicist, Leo Szilard, and the 'error catastrophe theory' of Leslie Orgel. Szilard hypothesized that aging might be due to the accumulation of random mutations in DNA (Szilard, 1959); while Orgel suggested that errors occurring in key functional proteins, such as enzymes, might initiate a cascade of cumulative, increasingly destructive biochemical errors, resulting in senescence and death (Orgel, 1963). Neither of these theories has found direct experimental support, however (Norwood et al., 1990); chemically abnormal proteins are found only occasionally in cell cultures and rarely in vivo.

A novel process, thought to be restricted to aging cells and first described in neurons, is the incorrect conversion of genomic information from normal DNA into nonsense RNA transcripts with subsequent translation into mutant, non-functional proteins. This process has been called 'molecular misreading' and causes some errors unrelated to DNA damage (van Leeuwen et al., 2000).

Accumulation of catabolized structural protein products in increased amounts is found in normal aging and several dementias. The cerebral amyloid precursor protein (APP) normally undergoes enzymatic degradation to form β-amyloid 1–40 and 1–42 (Glenner & Wong, 1984) which accumulates in senile plaques with advancing age. In Alzheimer's disease the exaggerated deposition of β-amyloid 1–42 (Sisodia et al., 1990) results in the hallmark increase in cerebral plaque formation and may cause dementia (Jarrett et al., 1993). Tau, a microtubule associated protein (MAP) normally abundant in the axon stabilizes polymerized microtubules and plays a role in axonal transport. Excessive hyperphosphorylated tau is found in neurofibrillary tangles (Lee et al., 1991), which are found in aging, and are increased in Alzheimer's disease, frontotemporal dementia and other dementing disorders. Other protein products that accumulate in the brain and are associated with age-related degenerations include: α-synuclein (Parkinson's disease and Lewy body dementia) (Spillantini et al., 1998) and ubiquitin (Lewy bodies).

While genetic mutations producing chemical changes in key proteins are probably not an important aging mechanism, conformational changes in proteins may be (Danner & Holbrook, 1990; Johnson et al., 1996; Taubes, 1996; Gafni, 1997). These are post-translational structural changes due to initial misfolding of proteins, or alteration of their normal functional shapes due to cross-linking, covalent

bonding, phosphorylation, glycation or other changes (Gafni, 1997; Levine et al., 1996; Richardson & Holbrook, 1996). It is known, for example, that 0.1% of the body's proteins undergo dextrorotation each year, forming right-handed conformations that are non-functional. The chaperone systems, such as the heat-shock proteins (HSPs) of the HSP 70 group, normally both aid in the initial folding of proteins, and in the recognition and refolding, or removal, of conformationally abnormal proteins. The functional capacity of the chaperone systems declines with age, however, related in part to the energy requirements of the process, and the decline in available energy (see below).

Damage to DNA, proteins and membrane lipids may be a result of oxidative stress (Beal, 1995; Venarucci et al., 1999). As a byproduct of oxidative metabolism and normal energy production, oxygen alone or in combined forms (hydroxyl or peroxide radicals) may be produced with an extra unpaired electron. These volatile radicals rapidly oxidize adjacent molecules by donating their extra electrons. Mitochondrial DNA is particularly vulnerable to oxidative stress since it is close to the site of oxidative energy production via phosphorylation; and mitochondrial DNA lacks the repair capability of nuclear DNA. This initiates a cascade of destructive events: impaired mitochondrial function causes decreased energy production, with its consequences: calcium influx into cells, excitotoxic cellular damage, failure of chaperone repair mechanisms, and eventual cellular death (Harman, 1992; Nagley et al., 1992; Julius et al., 1994; Fletcher & Fletcher, 1994; Mattson, 1994). It is not clear whether oxygen free radicals play a major role in senescence, or whether they have an important etiological role in causing parkinsonism, Alzheimer's disease, amyotrophic lateral sclerosis or other degenerative neurologic disorders of aging (Beal, 1995; Mattson, 1994; Harman, 1996; Knight, 1995; Chiueh et al., 1994; Floyd, 1991; Wolozin et al., 1996).

In an experimental model, the brains of aged gerbils contained twice the amount of oxidized protein as those of young gerbils, and the levels of two enzymes helpful in disposing of oxidized products (neutral protease and glutamine synthetase) were reduced with age (Carney et al., 1991). Older gerbils made more errors than younger adult gerbils in running radial mazes, but this difference was abolished if *N*-tert-butyl-α-phenylnitrone (PBN), a powerful 'spin-trapping' agent that removes free radicals, was administered to both groups of animals (Carney et al., 1991). Accumulation of metals such as aluminium and ferrous iron may facilitate oxidative damage while Vitamins C and E, both antioxidants, are postulated to retard age-related changes. In the Honolulu–Asia aging study of 3385 men aged 71–93 years, use of vitamin C or E supplements was associated with better performance on tests of cognitive function (Masaki et al., 2000).

Caloric restriction (CR), limiting food intake of animals by 50–70%, consistently prolongs the lifespan of many experimental species by up to 40% and postpones most age-related pathology, possibly by reducing oxidative stress (Masoro, 2000; Eckles-Smith et al., 2000). A recent study with an experimental yeast model demonstrated a potential mechanism of this antiaging effect (Lin et al., 2000; Campisi, 2000). Caloric restriction in yeast prolonged survival, but only if genetic pathways for production of Sir2 protein were intact. Sir2p is a 'silencing protein' which maintains compactness of chromosomes by preventing recombination during cell cycling, and requires an energy-providing compound (NAD), which is decreased as a result of oxygen free radicals.

Thus, the cellular basis of aging appears to involve free oxygen radicals, chromosomal integrity, protein conformational accuracy and telomeric adequacy, in addition to as yet unknown changes that occur over time.

Apoptosis is an intrinsically (i.e. genetically) coded and regulated process that results in cell death by means of a predetermined degenerative pathway, in contrast to necrosis. Apoptotic cell death is characterized by a lack of inflammatory changes, the appearance of bullae in the apoptotic cells, and eventually segmentation of the nuclear DNA into small pieces to produce a 'laddered' appearance on electrophoretic gels. During normal cellular function there is an array of opposing factors that can promote or prevent cell survival or division. When the balance tilts sufficiently to invoke the cell death sequence, the apoptotic program begins. Ordinarily, oncogene proteins (e.g. Bcl-2, p35) promote survival and division, and antioncogene proteins (e.g. Rb, p53,) oppose cell division; cell cyclins vary in their roles (Monti et al., 1992). A vast array of opposing factors regulates the survival, growth and division of cells (Steller, 1995; Bump et al., 1995; Rubin et al., 1994). As cells age, these balanced regulatory controls are weakened, and the cells are more readily tipped towards excessive growth (malignancy) or death by apoptotic pathways. The final executioner for most neural apoptotic mechanisms appears to be caspase (Braun et al., 1999); caspase inhibitors may prevent neural degeneration in some age-related disorders such as Huntington's disease (Kim et al., 1999).

Lack of growth factors and generation of proinflammatory cytokines may also play a role in degeneration. Neural growth factors generate 'survival signals' for the neuron; for insulin-like growth factor this 'survival signal' is known to be phosphatidylinositol 3' kinase (PI3 kinase).

Cytokines, such as TNF-α and interleukin-1β, can induce cell-death because TNF receptor activation causes 'silencing of survival signals' (SOSS) (Venters et al., 2000), which may be an important mechanism of neuronal loss in ischemic brain injury and other conditions. Similarly, the interaction of nerve growth factor (NGF) with tyrosine kinase A (*trkA)*, a receptor for this growth factor, promotes survival, differentiation and growth of basal forebrain cholinergic neurons in mouse models; BDNF (brain derived neurotrophic factor) promotes survival and neuronal function in the substantia nigra (Hefti, 1986; Hyman et al., 1991).

Regulation of vascular function by vascular endothelial growth factor (VEGF) and nitric oxide may affect neuronal aging (Kalaria et al., 1998; Rivard et al., 1999; McCann, 1997). Recent reports suggest that dementia may be dramatically reduced in patients treated with HMGCoA reductase inhibitors (statins) for hyperlipidemia, probably independent of the lipid-lowering effects of these drugs, and due to their improvement of microvascular function by increasing endothelial nitric oxide synthetase (eNOS) and reducing endothelin-1, thereby increasing endothelial dilatation and cerebral blood flow (Jick et al., 2000; Wolozin et al., 2000).

The rate of brain aging is affected by the condition of the organ systems that nourish the brain. Systemic disorders can accelerate brain aging through a variety of mechanisms, some of these putative pathways including glycation or cross-linking of proteins (Masoro, 1991), lack of estrogen (Yaffe et al., 1998) and/or dihydroepiandrosterone (DHEA) (Huppert et al., 2000; Moffat et al., 2000), immune failure, or an exaggerated inflammatory response (Maes et al., 1999). Estrogen may improve cerebral circulation, allow brain cells to form and maintain synaptic connections, reduce amyloid deposition and increase brain levels of acetylcholine (McEwen, 1999).

The relationship between aging and dementia

Aging, with the progressive accumulation of ARCs, is the most important risk factor for the development of dementia (Drachman, 1994; Bierer et al., 1995). The annual incidence of dementia rises exponentially with age from less than 1% at age 60 to more than 12% above age 85 (Jorm et al., 1987); the prevalence at 85 is 30-fold greater than at 65. The adverse effects of any brain insult, such as a subarachnoid hemorrhage or a brain tumour, are also greater in older adults (Lanzino et al., 1996; Recht et al., 1989). Women are more likely to develop dementia than men, in part because they live longer. For a 65-year-old woman, the remaining lifetime risk for dementia is approximately 17%, nearly twice the risk of a man the same age (9%); higher than her risk for breast cancer, and equivalent to her lifetime risk of sustaining a hip fracture (Seshadri et al., 1997). Elderly subjects demonstrate a spectrum of cognitive decline, ranging from the normal changes in memory, response speed and channel capacity described earlier, through 'mild cognitive impairment' (MCI) of uncertain clinical significance, to progressive clinical dementia. The extent to which these degrees of impairment represent a spectrum of change, or a series of distinctive disorders, is as yet not entirely clear.

Mild cognitive impairment

Several terms have been used to describe mild decline in cognition in the elderly. In 1962, Kral termed stable minor memory impairment with preserved insight 'benign, senescent forgetfulness' (Kral, 1962). In 1986, Crook and colleagues (Crook et al., 1986) defined age-associated memory impairment (AAMI) as subjective memory loss in the elderly with performance more than 1 S.D. below mean values for young adults on formal memory tests. Aging-associated cognitive decline (AACD) was defined using age-adjusted norms, rather than normal values for young adults, and involved cognitive domains besides memory (Levy, 1994); it is used as a functional category in the DSM-IV classification.

Some investigators take the position that all cognitive decline with age is a consequence of disease, either systemic or involving the brain, and that the standard of 'normal' is optimal cognitive function. Neuropathological changes and measurable neuropsychological declines invariably occur to some extent with aging; yet in some individuals, these changes may represent the beginning of a progressive dementia (Elias et al., 2000). The early stage of cognitive impairment, with impaired memory or cognitive functioning for age, but preserved ability to function in daily life, has been called mild cognitive impairment (MCI) (Zaudig, 1992; Petersen et al., 1999), a diagnosis restricted to older adults when no systemic, psychiatric or neurological disease explaining the memory impairment can be identified. MCI, defined in this way, may represent a preclinical stage of Alzheimer's disease, and a predisposition to clinical dementia following unrelated neurological insults, such as a stroke. A 10–15% annual rate of progression to clinical dementia has been documented in some studies (Petersen et al., 1997). At autopsy the brains in subjects with MCI appear to have significantly more Alzheimer-type changes than those of cognitively intact age-matched subjects (Haroutunian et al., 1999; Price &

Morris, 1999). There is considerable interest in the development of drugs for this group that would delay dementia; but it is not clear what proportion of subjects with MCI would eventually develop dementia, or how to distinguish those who will show progressive deterioration. Accepting MCI as a clearly identifiable diagnostic entity has legal, ethical and financial implications and currently is of use primarily in a research setting.

Dementia

Dementia is defined as a clinical syndrome characterized by the acquired loss of cognitive abilities severe enough to interfere with work or usual social activities, including family obligations. The definition of dementia requires a decline from a prior level of cognitive function and persistence of the condition, the duration being defined in months and years rather than days or weeks. Usually, though not always, the condition is progressive. It requires a diffuse disturbance affecting multiple domains of intellectual function. The DSM-IV criteria require involvement of short-term and long-term memory and at least one of the following spheres of mental activity: language, praxis, executive function (abstract thought, judgment and problem solving) and cortical perception (gnosis) (American Psychiatric Association, 1994). Finally, the diagnosis presupposes an alert patient, without clouding of consciousness (thus excluding the acute confusional states or delirium).

Epidemiology of dementia

Estimates of the prevalence of dementia vary greatly depending on the criteria used to define dementia and the life expectancy of the population. In developed countries, fewer than 1% of the population aged 65 or younger are demented; the prevalence increases exponentially, doubling approximately every 5 years (Molsa et al., 1982; Rocca et al., 1986). Over the age of 85, between 25% and 50% of all subjects are at least mildly demented (Evans et al., 1989), and 20% are completely incapacitated (Wernicke et al., 1994). The incidence of dementia probably increases indefinitely with age; but because of shorter survival in patients over age 90 the prevalence tends to level off at about 45–50% (Ebly et al., 1994; Drachman, 1994). In population-based studies more than 50% of all dementia is due to Alzheimer's disease; a further 15% to vascular dementia; and another 15% to a combination of the two ('mixed dementia') (Schoenberg et al., 1987). Other causes of progressive degenerative dementia of the aged are listed in Table 16.1.

Genetic basis of aging and dementia

Most late-onset dementia is sporadic, with a few identified polymorphisms that modify the risk of dementia, most notably the Apolipoprotein E $\varepsilon 4$ allele (Pericak-Vance et al., 1991; Seshadri et al., 1995). The APOE $\varepsilon 4$ allele increases the risk of late-onset Alzheimer's disease two- or threefold when present, and halves the risk if absent. Some dementias have an autosomal dominant inheritance, including Huntington's disease; early-onset AD with mutations on chromosome 14 (S182/ PS1) (Sherrington et al., 1995), chromosome 21 (trisomy and APP mutations) (St George-Hyslop et al., 1987), or chromosome 1 (STM2/ PS2) (Rogaev et al., 1995); and frontotemporal dementia with chromosome 17 mutations (tau) (Hutton et al., 1998).

Survival to old-age is not entirely a chance event; the gene pool in very-old subjects differs from that in young adults, (e.g. there is a lower incidence of the APOE $\varepsilon 4$ allele) (Yashin et al., 1999; Sobel et al., 1995). Among the oldest-old survivors there may be different etiologies of dementia, and pathological series suggest that 'dementia of unknown etiology' increases to nearly 50% in nonagenarians (Crystal et al., 2000), although clinical Alzheimer's disease remains a major cause of dementia.

Environmental risk factors for dementia

Head injury and minimal education are reported to increase the risk of dementia (Stern et al., 1994; Schofield et al., 1997b). The effect of education may be due to socioeconomic disadvantages, a cohort effect (Cobb et al., 1995), an artefact of culturally biased testing, or to an actual beneficial effect of education on brain development. A cerebrovascular accident increases the risk of dementia fivefold in the first year following stroke and doubles the control risk thereafter (Tatemichi et al., 1990). Risk factors for vascular disease have been recognized as risk factors for dementia: e.g., hypertension and diabetes (Breteler et al., 1998; Swan et al., 1998). Physical activity may improve cognitive function and reduce the risk of dementia (Kramer et al., 1999).

Approach to the diagnosis and differential diagnosis of dementia

Screening for dementia and scales used in the assessment of dementia

Simple cognitive screening tests are useful to evaluate cognitive function and establish a performance baseline in

Table 16.1. Disorders that may produce adult-onset dementia

1. Static dementia due to a known cause of brain injury
a. Traumatic brain injury
b. Post anoxic syndrome
c. Single stroke
d. Post infectious sequelae (after recovery from meningitis, encephalitis, ADEM)
e. Dementia pugilistica

2. Symptomatic dementias (some potentially reversible)
a. Endocrine disturbances: hypothyroidism, hyperthyroidism, hyperparathyroidism, Cushing's syndrome, insulinoma
b. Nutritional deficiencies: Wernicke–Korsakoff syndrome, Vitamin B12 or folate deficiency
c. Malignancy (primary or secondary brain tumour, para-neoplastic syndromes, radiation dementia)
d. Chronic subdural hematoma
e. Normal pressure hydrocephalus
f. Multiple sclerosis, adult-onset leukoencephalopathies
g. Systemic lupus erythematosis, cerebral vasculitides
h. AIDS-associated dementias
i. Creutzfeldt–Jakob disease, fatal familial insomnia and other prion diseases
k. Other CNS infections (tuberculous and fungal meningitis, neurosyphilis, neurocysticercosis)
l. Alcoholic dementia, drug or toxin-induced dementias
m. Metabolic encephalopathy: hepatic failure, renal insufficiency, dialysis dementia, hypoxia
n. Inherited metabolic causes of dementia: Wilson's disease, cerebrotendinous xanthomatosis, Kuf's disease, mitochondrial disorders: MELAS, MERRF, lysosomal storage disorders, adult polyglucosan body disease

3. Vascular dementia

4. Alzheimer's disease

5. Non- Alzheimer degenerative dementias with extrapyramidal features
a. Dementia with Lewy bodies
b. Progressive supranuclear palsy
c. Huntington's disease
d. Multisystem atrophy

6. Non-Alzheimer degenerative dementias with focal lobar involvement
a. Frontotemporal dementias (including Pick's disease)
b. Corticobasal ganglionic degeneration

Source: Modified from Rossor (1992).

those over 75. Such screening tests include the Folstein Mini-Mental Status Examination (MMSE) (Folstein et al., 1975), the self-administered Cognitive Assessment Screening Test (CAST) (Drachman & Swearer, 1996; Drachman et al., 1996), and Clock-drawing. More extensive psychometric tests are useful in research settings, or when screening tests signal the need for more detailed clinical evaluation.

Standardized cognitive and functional batteries are used to measure the severity of cognitive impairment (e.g. the Blessed Dementia Rating Scale (Blessed et al., 1968) and Mattis Dementia Rating Scale (DRS) (Mattis, 1988)), and assess both cognitive function and the patient's ability to perform adequately in activities of daily living. The Clinical Dementia Rating Scale (CDR) (Berg, 1988) is a functional rating scale that derives scores from a clinical interview with the patient and caregiver regarding performance in six functional domains (memory, orientation, judgement, home and hobbies, community affairs and personal care). The Index of Activities of Daily Living (IADL) (Lawton & Brody, 1969) and the Physical Self-Maintenance Scale (PSMS) (Lawton & Brady, 1969; Lawton et al., 1982) are used to document impairment in daily activities. These scales document both the diagnosis of dementia and progression of deterioration. There are also well-validated scales to address behavioural changes in dementia, such as the Neuropsychiatric Inventory (NPI) (Cummings et al., 1994), the BEHAVE-AD (Reisberg et al., 1987) and the caregiver obstreperous behaviour rating assessment (COBRA) (Swearer & Drachman, 1996), and to assess depression in

the setting of dementia (Cornell Scale for depression in dementia (Alexopoulos et al., 1988); Hamilton Depression Rating Scale (HAM-D) (Hamilton, 1967)). The Hachinski Ischemic Score (HIS) (Hachinski et al., 1975), is used to evaluate the probability of vascular dementia.

Clinical evaluation of a patient with suspected dementia

Individuals may be evaluated for dementia because of self-expressed concerns, referral by a family member or by a physician. The history, obtained from a reliable family member, should include the duration of symptoms, the nature of initial complaints, the rate and pattern of deterioration, and specific areas of cognitive and behavioural impairment including memory, orientation, judgement and problem solving, affect and behaviour. The subject's financial, work, driving, shopping, homemaking and recreational abilities and interests should be documented, as well as the ability to handle personal ADLs (dressing, grooming, bathing, toileting and feeding) compared to prior performance. The instrumental ADLs (cooking, laundry, using a telephone, etc.) are typically impaired before basic ADLs.

Entirely normal performance on office screening tests makes significant dementia less likely; but at times, despite even a detailed clinical and neuropsychological evaluation, the diagnosis may remain uncertain. In these subjects, repeat testing after 6 months or a year can often clarify the diagnosis.

Differential diagnosis of dementia

Once the presence of dementia has been established, the specific underlying dementing disorder is based on the clinical picture: the subject's age, family history, initial symptoms, rate and pattern of progression, findings on systemic and neurological examination, cognitive deficits and behavioural patterns, laboratory evaluation and imaging studies.

The various etiologies of dementia are listed in Table 16.1. Evaluating patients and distinguishing among these numerous causes is facilitated by using a stepwise approach (Drachman et al., 1994). Static dementias, those due to a single event such as a head injury or encephalitis, without progressive deterioration, can be distinguished by the history from progressive dementias. Progressive dementias may be divided into symptomatic dementias, due to an identifiable, and often reversible, cause; and the degenerative dementias. Table 16.2 lists a battery of investigations that permit the identification of most symptomatic dementias. A detailed discussion of the differential diagnosis of dementia is found in Chapter *xxx*.

Table 16.2. Investigations in patients with dementia

Laboratory:	CBC and differential BUN/Creatinine Electrolytes (sodium, potassium, calcium) Liver function tests Thyroid function tests Serum B12
Imaging:	MRI scan
When indicated:	EEG (CJD, metabolic encephalopathy, recurrent CPS) CSF examination Screening for malignancy Carotid and cardiac evaluation HIV serology; serological tests for syphilis, Lyme disease Urine for drug studies, heavy metals Brain biopsy

The degenerative dementias are divided into three groups: (i) Alzheimer's disease and its variants; (ii) the extrapyramidal dementias such as Lewy body dementia; and (iii) focal cortical dementias. Consensus clinical criteria have been published for several etiologies of progressive dementia. Widely accepted clinical criteria exist for the diagnosis of Alzheimer's dementia (McKhann et al., 1984); and more recently criteria have been proposed for dementia with Lewy bodies (McKeith et al., 1996), progressive supranuclear palsy (Litvan et al., 1996), frontotemporal dementia (Neary et al., 1998), and corticobasal ganglionic degeneration (Grimes et al., 1999). Definite diagnosis of dementia type is often possible only by using clinicopathological correlation of clinical and postmortem findings. Some subjects with clinical dementia do not fit pathological diagnostic criteria for any of the classical degenerative dementias, and a number of new disease entities have been proposed, including: argyrophilic grain disease (Braak & Braak, 1998); dementia lacking distinctive histology (Knopman et al., 1990); and hippocampal sclerosis (Dickson et al., 1994; Corey-Bloom et al., 1997). The clinical categorization of some patients with degenerative dementia may be difficult, because of an atypical presentation or unusual overlap of symptoms.

The entity of vascular dementia (VaD) has remained difficult to define. In the first half of the twentieth century, 'cerebral arteriosclerosis' was considered the commonest cause of dementia in the elderly (Mayer-Gross et al., 1960). In 1970, Tomlinson and colleagues showed that, in patients

with 'senile dementia' the most frequently found pathologic changes were those of Alzheimer's disease (Tomlinson et al., 1970). Hachinski coined the term 'multi-infarct dementia', and defined criteria for this entity (Hachinski et al., 1974); it was generally accepted that brain tissue loss due to cerebral infarction was the cause of VaD. More recently, the criteria for the diagnosis of VaD have been debated (Drachman, 1993; Roman et al., 1993); and it has become evident that vascular compromise may play a major role in much dementia of the elderly, including Alzheimer's disease (Jick et al., 2000).

In conclusion, chronological aging, with its associated senescent age-related changes (ARCs) is the single most important risk factor for the development of sporadic dementias. The cumulative effect of a number of known and as yet unknown ARCs produce molecular, cellular, anatomical, physiological and pharmacological changes that render the aging brain vulnerable to neuronal and functional loss, and to degenerative disorders that produce more rapidly progressive cognitive impairment. Although mild declines in cognitive function are inevitable with aging, the factors that transform the vulnerable, aging brain into one with a progressive dementing disorder are not as yet well understood. Genetic, environmental, vascular and experiential factors undoubtedly interact with the normal ARCs to lead to progressive degenerative dementias. Prevention and treatment of Alzheimer's disease, vascular dementia, fronto-temporal dementia, Lewy body dementia and others will depend both on elucidating the specific mechanisms of each of these diseases, and on developing strategies to forestall the ARCs that make the aging brain so vulnerable to these disorders.

Alzheimer's disease

Raymond J. Kelleher III[1,2] and John H. Growdon[1]

[1] Memory Disorders Unit, Neurology Service, Massachusetts General Hospital, and Department of Neurology, Harvard Medical School, Boston, MA, USA
[2] Center for Learning and Memory, Department of Brain and Cognitive Sciences, Massachusetts Institute of Technology, Cambridge, MA, USA

Alzheimer's disease (AD) is an age-related, neurodegenerative disorder that represents the most common cause of dementia and is one of the leading causes of medical morbidity and mortality in the developed world. The implications of increasing longevity and shifting population demographics have led to the recognition of AD as a public health problem of major proportions. The percentage of the US population over age 65 will more than double over the next 30 to 40 years. According to these projections, as many as 10 million persons will be afflicted with dementia, the majority of whom will suffer from AD, with associated annual health care costs of over $100 billion (Cummings, 1995). On a personal level, the insidious but relentless decline in the affected individual's cognitive and functional abilities imposes a particularly heavy burden on patient, caregivers and family members alike. These considerations have greatly increased public awareness of AD during the past 20 years, and have stimulated the increasingly rapid pace of scientific progress directed toward the development of effective, disease-modifying treatments.

Historical perspective

In 1907, Alois Alzheimer published the initial report of the clinical and pathologic features of the disease that was soon named after him by Emil Kraepelin (Alzheimer, 1907; Kraepelin, 1910; Maurer et al., 1997). This report summarized a lecture he had given the prior year on the case of 'Auguste D', a 51-year-old woman admitted in 1901 to the Hospital for the Mentally Ill and Epileptics in Frankfurt, Germany. Alzheimer described a syndrome of 'rapidly increasing memory impairments', aphasia, disorientation, paranoia, and auditory hallucinations. His detailed histopathological analysis upon her death in 1906, which was aided by the new staining techniques introduced by his colleague Franz Nissl, revealed 'numerous small miliary foci . . . caused by the deposition of a peculiar substance in the cortex'. These 'foci' or neuritic plaques, as they came to be called, were accompanied by extensive loss of cortical neurons and striking neurofibrillary changes: 'In the center of an otherwise normal cell there stand out one or several fibrils due to their characteristic thickness and peculiar impregnability.' Alzheimer provided a more thorough description of this original case, along with an account of a second case ('Johann F'.) from his Munich clinic, in a subsequent publication that included numerous illustrations of the characteristic neuritic plaques and neurofibrillary tangles (Alzheimer, 1911).

Alzheimer's description of the key pathologic features, along with contemporaneous reports of similar findings by Fischer (1907), Bonfiglio (1908) and Perusini (1909), promoted the acceptance of 'Alzheimer's disease' as a distinct and important disease entity. Despite the relatively young age of Alzheimer's original two patients, it gradually became apparent that the clinical and pathologic features of presenile and senile cases were essentially indistinguishable. For example, Perusini stated in 1909: 'The pathological process recalls the main features of senile dementia; however, the alterations in the cases described are more far-reaching, although some of them represent presenile diseases.' (cf. Maurer et al., 1997). In the eighth edition of his influential textbook *Psychiatrie*, published in 1910, Kraepelin was the first to attribute the definitive description of the disease to Alzheimer, who was then his colleague in Munich: 'The clinical interpretation of this Alzheimer's disease [*Alzheimersche Krankheit*] is still unclear. Although the anatomical findings suggest that we are dealing with a particularly serious form of senile dementia, the fact is that this disease sometimes starts as early as in the late forties.' The following year, Alzheimer himself accordingly entered the postmortem diagnosis of Johann F. in the Munich clinic records as '*Alzheimersche Krankheit*' (Graeber et al., 1997). From this modest initial

description of two case reports, AD has come to be recognized as the most important cause of intellectual deterioration in adult life, and the underlying neuropathological abnormalities described by Alzheimer represent the most common disease process leading to progressive cerebral atrophy, neuronal death and dementia.

Epidemiology and risk factors

Age is the single greatest risk factor for AD. Estimates of the prevalence of dementia among individuals older than age 65 in population-based studies from the US, Europe, and Asia have ranged from approximately 2% to 10% (Rocca et al., 1986; Schoenberg et al., 1987; Evans et al., 1989; Zhang et al., 1990), with the variability probably attributable to differences in study design and diagnostic criteria. AD is uncommon before the age of 60 years, but increases exponentially thereafter, with incidence and prevalence estimates doubling every 5 years after age 65 (Ott et al., 1995; Jorm et al., 1987; Ritchie et al., 1992; Hebert et al., 1995). The proportion of individuals affected by dementia thus increases from 1% in the age group 65–69 years to greater than 40% among nonagenarians, with AD accounting for the majority of cases regardless of age, sex or ethnic group. Incidence estimates increase from 0.6% among those 65–69 years old to 8.4% among persons over age 85. Inasmuch as prevalence estimates remain well short of 100%, even among the oldest old, dementia is not an inevitable consequence of the aging process, at least not within the current limits of human lifespan.

The next most significant risk factor for AD is a positive family history of the disease. Familial aggregation of AD has been recognized for many years; 20–40% of AD patients have an affected first-degree relative, and increases in the cumulative incidence of dementia among first-degree relatives of AD patients ranging from two- to sixfold have been reported in various studies (Heston et al., 1981; Heyman et al., 1983; Breitner & Folstein, 1984; Nee et al., 1987; Breitner et al., 1988; Farrer et al., 1989; Mayeux et al., 1991; Silverman et al., 1994). In a small number of families, perhaps 150–200 worldwide, there is a clear, autosomal-dominant mode of disease transmission, with early onset between 30 and 60 years of age. In the majority of these early-onset familial AD pedigrees, the disease is caused by point mutations in one of three chromosomal loci: the amyloid precursor protein (APP) gene on chromosome 21; the presenilin-1 (PS1) gene on chromosome 14; and the presenilin-2 (PS2) gene on chromosome 1 (see below). In contrast to these early-onset pedigrees, 90% of AD cases exhibit onset after age 65 and occur in a sporadic fashion without any clear familial pattern of transmission.

More than 25 genetic risk factors have been associated with late-onset AD, including polymorphisms in the genes encoding apolipoprotein E (ApoE), α2-microglobulin, cystatin C, LDL receptor-related protein (LRP), and interleukin-1 (for review see Price et al., 1998; St.George-Hyslop, 1999). Of these, the best-characterized susceptibility locus for sporadic AD is the gene on chromosome 19 encoding ApoE, a lipid transport protein (for review see Roses, 1996). The *APOE* gene was initially identified as a susceptibility locus for late-onset familial AD by positional cloning strategies, but was subsequently shown to represent a major risk factor for sporadic AD as well (Corder et al., 1993; Poirier et al., 1993; Rebeck et al., 1993; Saunders et al., 1993; Strittmatter et al., 1993). Polymorphisms in the *APOE* gene define three distinct alleles, designated ε2, ε3, and ε4, which influence the relative risk and age of onset for the development of AD. Inheritance of the ε4 allele confers an increased risk and earlier age of onset for both familial and sporadic AD, while the ε2 allele appears to be protective in both respects.

Additional minor risk factors for AD identified in some but not all studies include prior head trauma (Heyman et al., 1984; Mortimer et al., 1985) and low educational level (Katzman, 1993; Stern et al., 1994; Ott et al., 1995). The roles of these potential risk factors have been disputed due to their confounding effects on cognitive performance. There is some evidence for a higher prevalence of AD among women, independent of longer life expectancy (Kay, 1986; Katzman et al., 1989). Various environmental exposures have been proposed as predisposing factors for AD, particularly aluminium and other heavy metals (Basun et al., 1991; Perl & Good, 1987), but the weight of evidence has fallen against a causative role for such exposures. Retrospective analyses have identified several factors that may exert a protective effect against the development of AD, most notably the use of non-steroidal anti-inflammatory drugs (NSAIDS) (Breitner, 1996), estrogen replacement therapy (Paganini-Hill & Henderson, 1996), the use of HMG-CoA reductase inhibitors (Jick et al., 2000; Wolozin et al., 2000) and wine consumption (Orgogozo et al., 1997).

Clinical features and course

AD is characterized clinically by prominent impairments in cognition, often accompanied by neuropsychiatric behavioural disturbances, in the face of an otherwise bland elementary neurologic examination. Clinical criteria for the diagnosis of AD (DSM-IV, ICD-10, and NINCDS–ADRDA) all share common features: onset between ages 40

and 90; progressive dementia, as defined by prominent memory loss plus impairment in at least one other cognitive domain (such as language or praxis) sufficiently severe to impair social and/or occupational function; no disturbance of consciousness; and absence of other brain and systemic diseases that can cause dementia (McKhann et al., 1984). The NINCDS–ADRDA criteria further subdivide the diagnosis into definite (autopsy-proven), probable (meets all clinical criteria) and possible (some atypical features). The accuracy of these criteria relative to the neuropathological diagnosis of AD has been validated in clinicopathologic studies (Joachim et al., 1988; Tierney et al., 1988). Staging schemes for AD generally incorporate ratings of the severity of impairments in both cognitive and functional abilities; the systems in widest use are the Global Deterioration Scale (GDS) and the Clinical Dementia Rating scale (CDR) (Reisberg et al., 1988; Hughes et al., 1982). The CDR, for example, defines the severity of dementia as questionable (CDR 0.5), mild (CDR 1.0), moderate (CDR 2.0) or severe (CDR 3.0) based upon the scores in subcategories for memory, orientation, judgment, problem solving, community affairs, home and hobbies, and personal care.

AD typically begins with the gradual onset of forgetfulness (amnesia). Impairment of explicit memory for recent events is the most prominent early deficit. The observation that patients have difficulty learning or retaining new information reflects the early involvement of medial temporal lobe structures, including the entorhinal cortex and hippocampal formation, in the disease process. Forgetfulness for recent events or conversations, misplacement of objects, and repetitive questions are gradually noticed by family members or friends, even though patients themselves may be unaware of the problem (anosognosia). Word-finding difficulty (anomia) is the next most common manifestation. This feature generally emerges after the onset of amnesia, and reflects dysfunction of the temporal and frontal neocortices. An important practical index of the significance of reported cognitive disturbances is the extent to which they interfere with everyday functional abilities in the home or workplace. Difficulty with organizational tasks that were previously easily accomplished, such as management of the household finances or occupational duties, may become evident during the early stages of the illness and prompt neurologic evaluation. A change in personality is common: some patients become anxious or irritable, while others become quiet, withdrawn, and lose interest in their surroundings. These behavioural changes may resemble depression, but most often stem from apathy related to frontal lobe dysfunction. In spite of these limitations, social graces and other automatic behaviours are generally well preserved in the early stages of AD.

As the disease progresses, the impairments in memory and language become more profound, and the patient is no longer able to work. Visuospatial difficulties and trouble with dressing or the use of utensils (apraxia) become evident to varying degrees. The patient may become lost when out of the house, and assistance with the activities of daily living becomes necessary. Eventually, daily supervision may be required to prevent wandering or protect the patient from harm. Neuropsychiatric manifestations become more frequent and may include disinhibition, agitation, disruption of the sleep–wake cycle, hallucinations and frank delusions. These features probably arise as a primary consequence of the neurodegenerative process, and are thus 'organic' in nature. In the latter stages of the disease, speech disintegrates and functional abilities are progressively lost. Ultimately the patient is left in a mute, rigid, bedridden state requiring complete care; death usually results from a superimposed infection or medical illness. The average duration of AD is approximately 8 years from onset to death (Barclay et al., 1985), with a range of 1 to 25 years. There is considerable variation in the rate of progression; the clinical course is often marked by long periods of apparent stability, while in other cases patients can experience a rapid, relentless decline.

The elementary neurologic examination is generally unremarkable in the early stages of AD. The presence of primitive reflexes, such as snout, palmomental, grasping or suck responses, is frequently noted as the disease progresses to involve the frontal lobes. Olfactory deficits have been reported in a small number of patients (Serby et al., 1985). Focal neurologic signs are not observed unless the disease has been complicated by a discrete parenchymal lesion, such as a stroke, tumour or hemorrhage. Late in the course, patients may develop parkinsonian extrapyramidal signs of bradykinesia and rigidity, but rarely tremor. Some exhibit myoclonus, and a small fraction develop generalized seizures. The presence of prominent parkinsonism early in the course of dementia should prompt consideration of the alternative diagnosis of diffuse Lewy body disease (DLBD), while prominent early myoclonus should suggest the possibility of metabolic encephalopathy or Creutzfeld–Jakob disease.

Neuropathologic features

The gross appearance of the brain in AD is marked by diffuse cerebral atrophy, gyral atrophy with thinning of the cortical grey matter ribbon and secondary ventricular

enlargement. These features are not specific for AD, however, since considerable age-associated atrophy can be seen in the absence of dementia or AD pathology. The cerebral atrophy in AD reflects the underlying neuronal degeneration and is most prominent in the temporal lobes, hippocampi and association areas of the frontal and parietal lobes. Primary motor and sensory cortices are relatively spared, as are subcortical structures, with the notable exception of the amygdala, basal forebrain nuclei and locus ceruleus.

The microscopic hallmarks of AD are the presence of numerous extracellular neuritic or senile amyloid plaques (SPs), intraneuronal neurofibrillary tangles (NFTs), neuropil threads and cerebral vascular amyloid deposits. These changes are accompanied by selective neuronal and synaptic loss in the cerebral cortex and certain subcortical regions. Microscopically, neuronal loss is evident in the subiculum and CA1 fields of the hippocampus, the neocortex of the frontal and temporal lobes, the cholinergic nucleus basalis of Meynert, septal nuclei, amygdala, noradrenergic locus ceruleus, serotonergic dorsal raphé nucleus, and dorsal tegmental nucleus. In some regions, such as the entorhinal cortex and superior temporal sulcus, 50% of the neurons are lost (Gomez-Isla et al., 1996). Synaptic loss, revealed by electron microscopy and immunostaining with markers for synaptic terminals, has been described in many of these regions, particularly in the hippocampus and neocortex (Masliah et al., 1989; Hamos et al., 1989; Scheff et al., 1990). Although the SPs and NFTs are the most readily detected pathologic features, neuronal loss and decreased synaptic contacts are the proximate causes of the clinical manifestations of dementia in AD.

The mature SP has a dense central core of amyloid surrounded by dystrophic neuronal processes ('neurites') interspersed with the processes of activated microglia and reactive astrocytes, indicating an inflammatory response and neuronal injury associated with the amyloid deposition (Fig. 17.1(*a*) and (*b*)). Ultrastructurally, the plaque core consists of ordered arrays of amyloid fibrils, and the binding of Congo red dye to the core indicates that these fibrils possess a β-pleated sheet structure (this feature is the basis of the descriptive term amyloid, as in the case of other diseases characterized by extracellular, Congo red-positive deposits). In the brains of normal elderly individuals, diffuse deposits of amyloid lacking neuritic features are a common finding. These diffuse, non-neuritic plaques stain weakly with Congo red and ultrastructurally exhibit little fibrillary character. The principal molecular constituents of both neuritic and non-neuritic plaques are 40 to 42 amino acid β-amyloid (Aβ) peptides derived from proteolytic processing of the large amyloid precursor protein, a finding which led to the identification of mutations in APP as the first known genetic cause of AD (see *Etiology*, below). Biochemical analyses have revealed that the diffuse plaques are primarily composed of the slightly longer and more hydrophobic 42-amino acid form of Aβ, whereas neuritic plaques contain both Aβ42 and the more soluble, abundant Aβ40 peptide (Iwatsubo et al., 1994). Amyloid

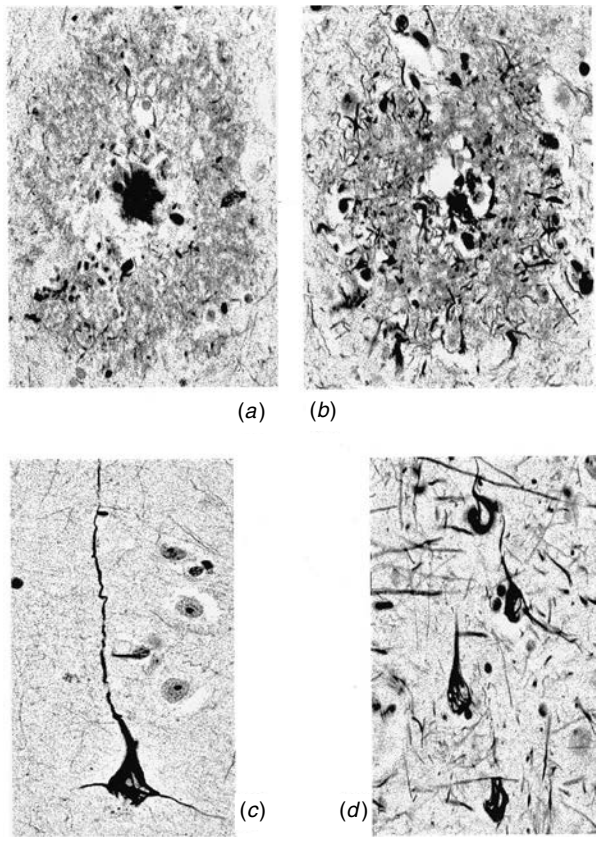

Fig. 17.1. Microphotographs of neuritic plaques (*a*), (*b*) and neurofibrillary tangles (*c*), (*d*) in the brain of a 65-year-old woman with end-stage Alzheimer's disease. (*a*) Neuritic plaque involving the amygdala. The discrete, centrally located amyloid core is surrounded by a clear halo, with argyrophilic dystrophic neurites scattered at the periphery of the plaque (Bielschowsky stain, original maginification 500×). (*b*) Neuritic plaque involving the neocortex (third layer of Brodmann area 9). The centrally located amyloid core is fragmented and dystrophic neurites are abundant (Bielschowsky, 500×). (*c*) Argyrophilic neurofibrillary tangles involving the uncus. Note the presence of three apparently normal neurons alongside the tangle (Bielschowsky, 500×). (*d*) Four argyrophilic neurofibrillary tangles involving the third cortical layer of the superior parietal lobule (Brodmann area 40; Bielschowsky, 500×). (Photomicrographs courtesy of Dr Jean-Paul Vonsattel, Massachusetts General Hospital.)

deposition in the form of diffuse plaques can thus clearly precede the onset of the clinical manifestations of AD, particularly in the case of Down's syndrome (Rumble et al., 1989), suggesting that diffuse plaques may represent a substrate for the formation of neuritic plaques. The deposition of Aβ42 may therefore be an initiating event that in some circumstances leads to the further deposition of Aβ40 and neuritic plaque formation. Aβ oligomers also form within neurons, and may contribute directly to cell dysfunction and death (Walsh et al., 2000).

NFTs are composed primarily of hyperphosphorylated, ubiquitinated forms of the microtubule-associated axonal protein tau (Fig. 17.1(*c*) and (*d*)). These cytoplasmic deposits also have an ultrastructural fibrillary appearance, consisting of dense bundles of long, twisted filaments. Such paired helical filaments are also found in the dystrophic neurites of neuritic plaques. Like amyloid deposits, NFTs are not specific to AD, as they can occur in much smaller numbers with normal aging. Moreover, NFTs with slight variations in ultrastructural and biochemical features characterize a number of neurodegenerative diseases, including Pick's disease, progressive supranuclear palsy, and corticobasal degeneration. This observation has prompted the conceptualization of these diseases as 'tauopathies', postulating a central role for NFTs in their pathogenesis (Goedert, 1998; Lee & Trojanowski, 1999).

SPs and NFTs exhibit distinct topographic distributions within the AD brain (Arnold et al., 1991). NFTs initially and preferentially affect the structures of the medial temporal lobe, including the amygdala, hippocampal formation, and parahippocampal regions, whereas amyloid plaques are more uniformly distributed throughout the neocortex of the frontal, temporal and parietal lobes. In late-stage AD, NFTs are plentiful in temporal, parietal and frontal neocortices. Given this hierarchical distribution, NFTs are a better pathological correlate of the pattern of neuronal loss and the severity of dementia than are amyloid plaques, and a pathological staging system has been proposed based on NFTs alone (Braak & Braak, 1991; NIA/Reagan criteria, 1997). In contrast to the NFT criteria, CERAD criteria for the neuropathological diagnosis for AD depend on an assessment of the frequency of amyloid plaques in three specific neocortical regions, the superior temporal gyrus, the prefrontal cortex, and the inferior parietal lobule, with an emphasis placed on the presence of neuritic plaques. In conjunction with the clinical findings, the 'plaque scores' for these areas define AD as possible, probable, or definite. The correspondence between the NIA/Reagan and CERAD criteria is high (Newell et al., 1999).

Multiple neurochemical abnormalities have been identified in the AD brain, reflecting the depletion of specific neuronal subpopulations (Francis et al., 1985; Mann & Yates, 1986; Bowen et al., 1994). Decreases in indices of the neurotransmitter acetylcholine in hippocampus and neocortex reflect atrophy and loss of cholinergic neurons in the ventral forebrain (Whitehouse, 1998). Similarly, neuronal loss in the noradrenergic locus ceruleus and the serotonergic dorsal raphé nuclei correlates with deficiencies in the corresponding neurotransmitters, and the depletion of excitatory pyramidal neurons in association neocortex contributes to a reduction in cortical glutamate levels. The deficiencies in multiple neurotransmitter systems suggest that pharmacologic therapies based on transmitter replacement will be of limited benefit, and that effective treatment will require prevention of the underlying neuronal loss.

Etiology

Molecular genetics and the amyloid hypothesis

Genetic studies based on large, multigenerational families with early-onset AD have identified causative mutations in three genes that can cause autosomal-dominant AD: the genes encoding APP, PS1 and PS2 (for review see Selkoe, 1996; Wasco & Tanzi, 1997; St. George Hyslop, 2000). The observation that pathogenic mutation in all three of these genes increases the production of β-amyloid underlies the amyloid hypothesis of AD, which postulates that amyloid deposition in the brain initiates a cascade of events that eventually leads to neuronal dysfunction and death. Additional chromosomal loci responsible for familial AD also apparently exist, since FAD pedigrees without mutations in these genes have been reported.

The *APP* gene encodes a type I integral membrane glycoprotein whose normal function remains unclear. Proteolytic processing of APP around its C-terminal transmembrane domain gives rise to a complex array of secreted and membrane-associated fragments (Fig. 17.2). APP cleavage by α-secretase splits the β-amyloid region and generates a long, soluble N-terminal fragment that possesses neurotrophic properties. Aβ peptides, which have neurotoxic properties (Yankner et al., 1989), are produced by the sequential action of two other proteases: β-secretase, which cleaves the juxtamembranous extracellular region of APP to yield the N-terminal end of Aβ, and γ-secretase, which cleaves the transmembrane portion of APP at two distinct positions to yield secreted Aβ peptides of either 40 or 42 amino acids (for review, see Vassar & Citron, 2000).

Although the cleavage of APP within the Aβ region by α-secretase predominates, Aβ peptides are produced at low

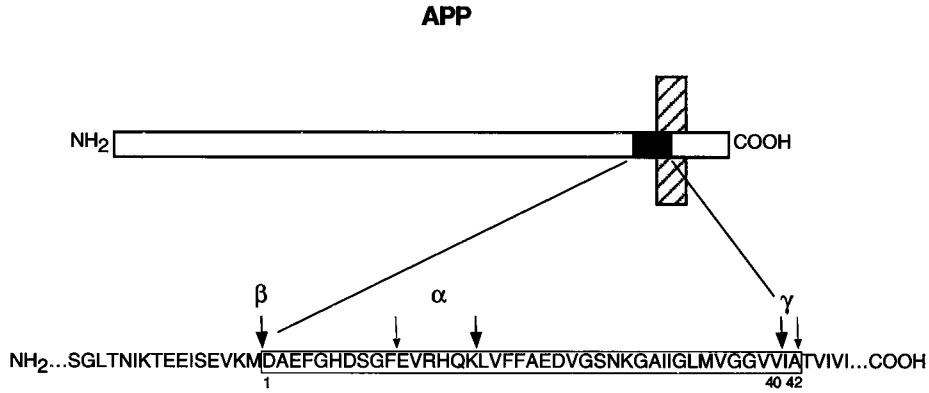

Fig. 17.2. Schematic diagram of proteolytic processing of the amyloid precursor protein (APP). The hatched box represents the plasma membrane, and the solid area of APP represents the β-amyloid region, whose amino-acid sequence is expanded below. The cleavage sites of the α-, β- and γ-secretases are indicated by the corresponding arrows. The boxed area of the β-amyloid region corresponds to the 40–42 residue Aβ peptides produced by the sequential action of β- and γ-secretase. Note that α-secretase cleaves within the β-amyloid region, thereby precluding the generation of Aβ species. The alternative intramembranous cleavage sites for γ-secretase produce either Aβ40 or Aβ42.

levels during normal cellular metabolism, and increased Aβ production (or an increased ratio of the levels of Aβ42 to Aβ40) has been consistently associated with the genetic lesions in familial AD (for summary, see Selkoe, 1997, 1999). All known FAD-linked mutations in APP occur at or near the sites of β- and γ-secretase cleavage that release the Aβ fragment, increasing the generation of Aβ42, and elevation of the Aβ42: Aβ40 ratio can be detected presymptomatically in carriers of an FAD mutation. Similarly, patients with Down's syndrome show increased levels of Aβ production, and the invariant association of the classic neuropathology of AD with adult cases of Down's syndrome is likely explained by the presence of an additional copy of the APP gene.

In addition to overproduction of Aβ, it is possible that alterations in degradation or clearance mechanisms may contribute to amyloid deposition in AD. Endogenous pathways for the degradation of Aβ and its clearance from brain tissue, which may antagonize cerebral amyloid deposition, have been identified. Several metalloendopeptidases have been implicated in the proteolytic degradation of Aβ, including insulin-degrading enzyme (IDE) (Vekrellis et al., 2000; Qiu et al., 1998) and neprilysin (NEP) (Iwata et al., 2000). NEP, which was shown to degrade Aβ42 in vivo, is a zinc–metalloprotease that inactivates several biologically active brain peptides, including enkaphalins, tachykinins, bradykinin and endothelins. Interaction of Aβ with ApoE and α-macroglobulin may provide another major clearance route. Both of these molecules are internalized by low-density lipoprotein receptor related protein, which is hypothesized to regulate the complex metabolic cascades that balance Aβ synthesis and clearance (Hyman et al., 1984).

Reproduction of the genetic alterations associated with familial AD in animal models has provided important experimental support for the 'amyloid hypothesis.' Overexpression of APP-bearing FAD-linked mutations in transgenic mice is sufficient to cause persistently elevated levels of soluble Aβ and an age-dependent accumulation of amyloid plaques in the cerebral cortex that closely resemble those in the brains of AD patients (Games et al., 1995; Hsiao et al., 1996). In contrast, mice in which both copies of the *APP* gene have been inactivated (*APP* 'knockout' mice) exhibit only slight phenotypic abnormalities, and do not develop AD-like neuropathological changes (Zheng et al., 1995). Consistent with the autosomal-dominant inheritance pattern of FAD, the results from mouse model systems suggest that APP mutations do not result in a loss of protein function, but rather promote the abnormal accumulation of cerebral amyloid through a gain-of-function mechanism.

While APP mutations have been found in fewer than 2–3% of reported AD pedigrees, mutations in the *PS1* gene on chromosome 14 account for the majority of early-onset, familial AD. The *PS1* gene was initially identified by positional cloning based on genetic linkage to a region of the long arm of chromosome 14 (Sherrington et al., 1995), and more than 50 pathogenic mutations in the *PS1* coding region have subsequently been identified (Wasco & Tanzi, 1997; Fraser et al., 2000). Mutations in the highly related *PS2* gene on chromosome 1, which was originally identified on the basis of homology with *PS1*, have been linked

to familial AD in a small number of pedigrees (Rogaev et al., 1995; Levy-Lahad et al., 1995a, b). (An annotated compendium of the mutations in APP, PS1 and PS2 linked to FAD is available at http: //www.alzforum.org.)

The presenilins are integral membrane proteins that are involved in the proteolytic processing of both APP and Notch (for review see Selkoe, 1998; Haass & De Strooper, 1999). Studies in cell culture and transgenic mice have demonstrated that pathogenic mutations in PS1 and PS2 enhance Aβ production (particularly the production of the more amyloidogenic species, Aβ42). Conversely, Aβ levels are considerably reduced in cultured neurons derived from *PS1* knockout mice, with the reduction primarily attributable to decreased γ-secretase activity (De Strooper et al., 1998). As in the case of APP, mutations in the presenilins thus appear to contribute to the pathogenesis of AD through a gain-of-function mechanism. Analysis of *PS1* knockout mice and studies of PS1-deficient cultured cells have further shown that PS1 regulates the activity of the Notch transmembrane receptor protein, a key regulator of cellular differentiation during development (Shen et al., 1997; De Strooper et al., 1999; Song et al., 1999; Handler et al., 2000).

Presenilin mutations produce effects on APP processing in the brains of affected individuals that are consistent with their apparent role in γ-secretase cleavage: levels of Aβ are elevated in patients bearing PS1 or PS2 mutations, even at presymptomatic stages; the density of plaques containing Aβ42 is increased in the brains of such patients; expression of mutant presenilin genes in cultured cells causes increased Aβ (Aβ42) production; overexpression of mutant PS1 in transgenic mice results in increased brain levels of Aβ42, and causes accelerated formation of amyloid plaques in the presence of a mutant APP transgene. On the basis of these observations and additional structure-function studies, it has been proposed that presenilins may themselves possess γ-secretase activity (Wolfe et al., 1999). At the very least, PS1 is a component of a multiprotein complex necessary for γ-secretase activity (Yu et al., 2000).

Beyond amyloid: tau pathology and neurodegeneration

The amyloid hypothesis may paint an incomplete picture of the pathogenesis of AD, as major unanswered questions remain concerning the connection between Aβ deposition and the other neuropathological features of AD. With respect to neuronal loss, it has been proposed that Aβ may exert a direct neurotoxic effect, or that it may injure neurons indirectly through the activation of an inflammatory response mediated by microglia and astrocytes (Yankner, 1996). The inflammatory response is associated with the formation of dystrophic neuronal processes in the neuritic plaques, and may contribute to derangement of neuronal metabolism, alterations in the cytoskeleton and the formation of neurofibrillary tangles. One limitation of the amyloid hypothesis, however, has been the failure to observe neurofibrillary changes as a result of experimental manipulations that increase Aβ production or deposition in any of the systems studied. In addition, significant neuronal loss has not been observed in the transgenic mouse models of AD, despite massive amyloid deposition in older animals (Irizarry et al., 1997). These considerations lead to the interpretation that amyloid accumulation, while likely a critical step in the pathogenesis of AD, is not sufficient to produce the full neuropathological picture of AD (Fig. 17.3).

The significance of neurofibrillary changes in the mechanistic process leading to neuronal loss has been emphasized by the discovery that mutations in the tau protein are sufficient to cause neurodegeneration and dementia in the absence of Aβ deposition. A variety of mutations occurring in and around the microtubule-binding repeats of the tau protein have been identified in autosomal-dominant pedigrees with frontotemporal dementia and parkinsonism linked to chromosome 17 (FTDP-17; for review see Goedert, 1998; Lee & Trojanowski, 1999). The neuropathology of some FTDP-17 cases resembles that of Pick's disease, with prominent circumscribed atrophy and neuronal loss in the frontal and temporal lobes, accompanied by intraneuronal filamentous deposits of hyperphosphorylated tau. Additional subcortical changes and intraglial tau deposits are sometimes seen, but significant amyloid pathology is absent. These findings provided strong evidence linking tau dysfunction and deposition to the pathogenesis of the large group of neurodegenerative diseases ('tauopathies') characterized by neurofibrillary lesions independent of Aβ accumulation. Exonic tau mutations associated with FTDP-17 have been shown to decrease the binding of tau to microtubules, impairing its ability to promote microtubule assembly (Hong et al., 1998). Hyperphosphorylation of tau also inhibits its binding to microtubules, though the relationship between hyperphosphorylation and tau deposition is unclear (Goedert, 1998). These observations suggest that biochemical alterations in tau structure and function may contribute to neuronal dysfunction through destabilization of the neuronal cytoskeleton and disruption of axonal transport. In addition, an increase in cytoplasmic levels of tau that is not bound to microtubules may promote its aggregation, possibly conferring an additional 'toxic' gain of function. In support of this notion, overproduction of wild-type tau or tau bearing an FTDP-17-linked mutation (P301L) in the brains of transgenic mice resulted in an age-

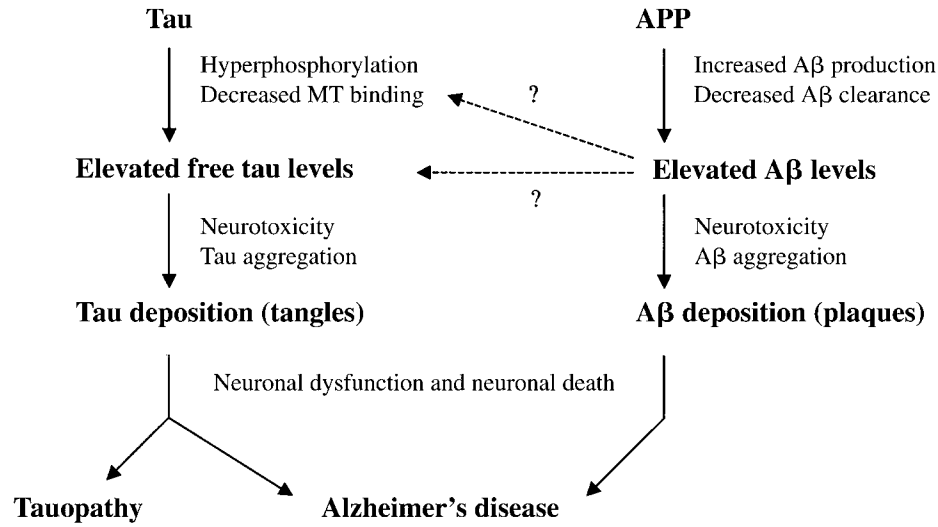

Fig. 17.3. A model for the pathogenesis of Alzheimer's disease (AD). The central roles of tau and the amyloid precursor protein (APP) in the molecular and cellular events leading to neurodegeneration are highlighted. Tau hyperphosphorylation and decreased microtubule binding may promote tau aggregation by elevating the levels of free unbound tau, possibly resulting in neurotoxicity as a result of cytoskeletal dysfunction. Elevated levels of β-amyloid (Aβ) peptides, particularly the more amyloidogenic species Aβ42, may result from either increased β- and/or γ-secretase cleavage of APP or decreased Aβ degradation and clearance. Increased soluble Aβ and Aβ aggregation, either intracellularly or in the form of amyloid plaques, are thought to promote neurotoxicity and neurodegeneration. Tau pathology and neuronal death in the absence of Aβ pathology characterize the 'tauopathies', whereas the neuronal death in AD is associated with the presence of both NFTs and amyloid deposition. Although the connections between tau and amyloid pathology (indicated by dashed lines) in AD remain unclear, a sustained increase in the levels of Aβ may be the initiating event that activates multiple cellular pathways leading to neuronal dysfunction and death, including tau aggregation and NFT formation.

and dose-dependent accumulation of filamentous deposits containing phosphorylated tau (Ishihara et al., 1999; Lewis et al., 2000). In two recent reports, overexpression of a mutant human APP transgene or intracerebral injection of $A\beta_{42}$ fibrils enhanced the formation of tau deposits in the brains of mutant tau transgenic mice (Lewis et al., 2001; Götz et al., 2001), providing experimental evidence that Aβ can influence the development of tau neurofibrillary pathology (see Fig. 17.3).

Despite advances in understanding the molecular basis of AD, the events that ultimately precipitate neuronal death remain uncertain. Programmed cell death, or apoptosis, is a potential mechanism for the neuronal loss in a variety of neurodegenerative diseases (Rinkenberger & Korsmeyer, 1997; Nijhawan et al., 2000). Apoptosis is a cellular suicide pathway, largely operative during embryogenesis and in the immune system, that induces characteristic molecular and cellular alterations leading rapidly and irreversibly to cell death, such as activation of specific death proteases, endonucleolytic degradation of DNA and dissolution of cellular membranes. It has not been convincingly shown, however, that the neuronal loss in AD and other neurodegenerative diseases occurs via an apoptotic mechanism. In addition, studies in a variety of cell culture systems have produced conflicting results on the effects of the presenilins on sensitivity to apoptosis, suggesting both pro- and anti-apoptotic functions. Lack of PS1 function in the embryonic brain of *PS1* knockout mice, however, does not lead to increased neuronal cell death (Handler et al., 2000). Other avenues of investigation into the mechanisms of neuronal death in neurodegenerative disease have implicated free radical injury and mitochondrial dysfunction, which can produce neuronal death through both apoptosis and necrosis (Beal, 2000). Such pathways may represent primary causes of neurodegeneration, or alternatively, they may be activated as downstream events subsequent to some other initiating event, such as amyloid deposition.

Diagnostic evaluation

There are more than 50 medical, psychiatric, and neurological diseases considered in the differential diagnosis of dementia (Mayeux et al., 1993). Alzheimer's disease is by far the most common cause of dementia; DSM-IV and ICD-10 criteria follow closely on the NINDS-ADRDA guidelines first published in 1984 (McKhann et al., 1984).

Because of these common international standards, diagnostic procedures for AD are remarkably uniform throughout the world. In a survey of 26 centres specialized for AD care in the U.S., Europe, and Japan, six items out of a menu of 17 were specified as essential steps in the diagnosis of AD (Growdon, 2001). These procedures were: history of illness, physical examination, laboratory blood tests, a mental status test, psychometric testing, and a CT or MR brain scan. There was a high (>50%) frequency of use and importance ascribed to results obtained from these six measures, regardless of the geographic region. All other procedures, including many proposed as biomarkers of AD, were much less frequently used. Thus, there is worldwide consensus regarding the core features of the diagnostic evaluation for AD-type dementia.

The history is always obtained from an informant who knows the patient well, e.g. spouse or adult child. While interviewing the family members, it is always necessary to conduct the diagnostic assessment with the differential diagnosis of dementia in mind, so that history can be obtained to support or exclude diagnostic possibilities. The physical examination, including a compulsory neurological evaluation and a psychiatric examination as indicated, seeks to identify signs that might point to causes of dementia that might be confused with AD, such as Huntington's disease or Parkinson's disease. Laboratory blood tests are conducted to exclude underlying medical or metabolic derangements that can produce dementia. For example, it is necessary to exclude liver or kidney failure, or thyroid abnormality as a contributing cause of dementia. Mental status testing is recommended to document the presence of dementia and to estimate its severity. The three most common tests employed: the Information, Memory and Concentration subscale of the Blessed Dementia Score (Blessed et al., 1968), the Mini-Mental State Examination (Folstein et al., 1975), and the Alzheimer's Disease Assessment Scale (Rosen et al., 1984), are comparable rating scales. These tests require five to ten minutes to administer, and have a high intertest correlation (Solomon et al., 1999).

Psychometric tests explore aspects of cognition that are affected in AD in greater detail than mental status testing. Results of psychometric tests give confidence to the diagnosis of dementia by showing that AD patients have impairments in multiple cognitive domains. Cognitive tests range from such standard neuropsychiatric measures as the Wechsler Adult Intelligence Scale and the Wechsler Memory Scale to sets of tests that have been developed specifically for AD patients, such as the CERAD set of tests (Welsh et al., 1992) and the set of tests administered in the Massachusetts Alzheimer's Disease Research Center (Locascio et al., 1995). These latter specialized tests assess memory, language capacity, visual-spatial function, abstract reasoning, and frontal lobe function. Regardless of the set of cognitive tests, the findings are similar: in AD, there is an early and pronounced deficit in explicit memory, as tested by delayed recall. In addition, there are variable impairments in the other cognitive domains that decline over time. The decline in explicit memory is rapid and curvilinear; the decline in other functions, such as verbal fluency and naming objects, tends to be more linear and steady (Fig. 17.4). The results of cognitive tests provide an index of brain function and reflect the underlying pathology in AD. The pathologic bases of impaired delayed recall are atrophy of cholinergic ventral forebrain neurons (Whitehouse, 1998) and deafferentation of the hippocampus (Hyman et al., 1984), both of which occur early in the course of AD. Worsening language and visual-spatial abilities likely reflect progressive loss of neocortical neurons and their connections.

Neuroimaging is the sixth standard procedure. Standard CT or MRI scans are performed to search for brain lesions that could account for dementia or contribute to it; examples include hydrocephalus, stroke, and brain tumour. Conventional interpretations of these morphologic brain images do not add to the positive diagnosis of AD, but serve to exclude these and other conditions that can masquerade as AD. To extract more diagnostic information from the images, quantitative methods are being developed to measure brain regions vulnerable to AD pathology, such as the medial temporal lobe. There is ample experimental data now that atrophy of the medial temporal lobe, and hippocampal structures in particular, is greater in AD than in age-matched non-demented control subjects (de Leon et al., 1993; Jack et al., 1997). With sophisticated MR quantification, even greater precision is possible: in one study (Killiany et al., 2000), baseline MRI measures of atrophy in the entorhinal cortex, superior temporal sulcus and anterior cingulate were characteristic of AD, and identified with 95% sensitivity and 90% specificity non-demented individuals with mild memory difficulty who converted to Alzheimer's disease after three years. These findings are internally consistent with what is known about the pathophysiology of memory loss in AD: the deficit in explicit memory is usually the first sign of AD dementia (Locascio et al., 1995); explicit memory depends heavily upon the entorhinal–hippocampal–medial temporal lobe region (Corkin et al., 1997); and there is massive loss of neurons in the entorhinal cortex in AD (Gomez-Isla et al., 1996).

As dementia worsens, deficits in cognitive domains other than memory emerge or worsen, even if they had been normal at initial examination. The neuropathological substrate for further cognitive decline is decreased

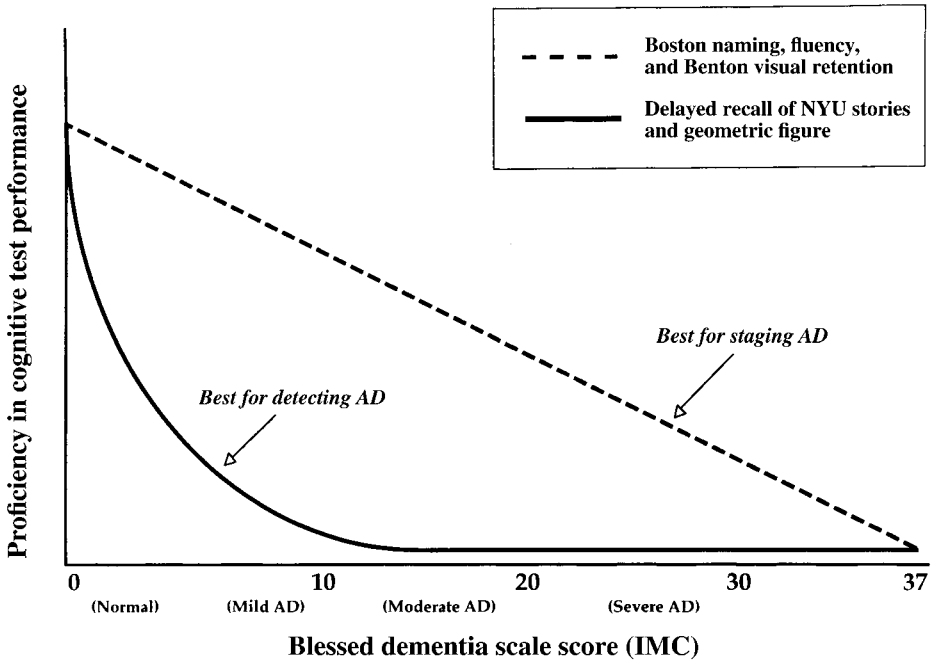

Fig. 17.4. Relation between specific cognitive test scores and a continuous index of dementia severity in AD patients: the information, memory and concentration (IMC) score of the Blessed Dementia Scale. Performance on tests of explicit memory, such as delayed recall of stories and geometric figures, falls precipitously early in the course of AD, and is therefore helpful in detecting the presence of dementia. Since performance on other measures, such as language tests, declines in a steady linear fashion over time, the Boston Naming and verbal fluency tasks are best for staging the severity of dementia and tracking its course. (Reproduced by permission from Locascio et al. 1995).

number of cortical synaptic contacts and neuronal loss (Gomez-Isla et al., 1997). Based upon serial MRI examinations, total brain volume in AD was found to decrease by about 2–3% per year compared to less than 1% per year in normal control subjects (Fox et al., 1999). Physiological brain imaging with positron emission tomography (PET) or single photon computed tomography (SPECT) brain scans has made it possible to detect neuronal dysfunction in life, even when the brain structure is normal on conventional CT or MR scan. Bilateral posterior parietal/temporal hypometabolism and hypoperfusion are characteristic of AD and found in 80–85% of cases (Kennedy, 1998). This pattern of deficit matches the distribution of pathological lesions in AD, which affects the multimodal association neocortices in temporal and parietal lobes out of proportion to the somatosensory and occipital regions (Arnold et al., 1991).

In centres that specialize in the diagnosis and care of patients with dementia and Alzheimer's disease, these six diagnostic procedures lead to a clinical diagnosis of AD that is confirmed pathologically in about 90% of cases. Diagnostic accuracy may be lower in practices outside of specialized academic centres, and regardless of site, these conventional diagnostic procedures are labour-intensive, time-consuming, and expensive. Thus, there is a need for a biomarker or set of biomarkers that would quickly and accurately diagnose AD and circumvent the current practice of expensive and time-consuming testing. The search for biomarkers builds upon advances in understanding the biology of AD, and ranges from uncovering genetic risk factors to documenting the pathology of AD and describing the resultant molecular and biochemical changes that result from the AD process. These advances have sparked the hope of detecting some of these characteristic changes, especially those noted in brain tissue, during life (NIA/Reagan workshop 1998).

Although there are scores of biological correlates of Alzheimer's disease, no biological marker has yet gained full acceptance in practice as the sole test needed to diagnose AD. Several biomarkers, however, show promise, usually as a confirmatory aid in the conventional diagnostic assessment of a patient with dementia. Detecting a mutation in the *APP*, *PS1* or *PS2* gene carries high specificity for the diagnosis of AD, but such screening cannot be recommended as a routine measure because of extremely low sensitivity (infrequent number of affected individuals) in the total AD population. Thus, searching for a mutation should generally be limited to instances of familial AD

cases under the age of 50 years. Detecting the $\varepsilon 4$ allele of *APOE* can add a small increment of confidence to the AD diagnosis when used in conjunction with conventional diagnostic workup, but by itself has low diagnostic sensitivity and specificity.

Given the central position of cerebral amyloid deposition as the potential toxic event initiating a cascade of neurodegeneration, many molecular biomarkers centre on amyloid fragments in blood and CSF. Characteristic findings are increased levels of Aβ42 in plasma of patients with familial AD due to mutations in the *APP, PS1* and *PS2* genes (Scheuner et al., 1996); increased Aβ42 levels in some non-familial cases (Mayeux et al., 1999); and reduced APP isoform ratio in platelets of AD patients compared to control subjects (Baskin et al., 2000). CSF levels of Aβ42 are reduced in AD whereas CSF levels of the hyperphosphorylated tau protein are increased (Motter et al., 1995; Hulstaert et al., 1999). These tests have not achieved widespread diagnostic use either because they lack sufficient diagnostic sensitivity and specificity, or because they are available only in an experimental setting. Neuroimaging procedures appear most promising in the diagnosis of AD, especially quantitative measures of medial temporal lobe structures and whole brain volume. Because conventional brain scans are part of the standard diagnostic evaluation, quantitative measures can be readily adapted to the image data that are collected. In contrast to MRI, the use of PET scans will likely be limited to confirmatory or experimental studies performed in academic centres because of limited availability and expense.

Therapy

Currently available therapies for AD are symptomatic in nature, and ameliorate the cognitive or neuropsychiatric impairments without altering the course of the disease. Drugs that inhibit acetylcholinesterase are the current mainstays of treatment for the cognitive abnormalities of AD. Their use is based on the cholinergic hypothesis of memory dysfunction, which links pathological, biochemical and pharmacological evidence for a deficit in cholinergic neurotransmission with impaired memory (Bartus et al., 1982). The initial drug of this class, tacrine (Cognex®), improved memory in some patients but is now rarely prescribed due to its associated hepatotoxicity and the availability of safe alternative agents. Aricept® (donepezil), the cholinesterase inhibitor presently in widest use, produces modest improvement in memory performance when given as a single daily dose of 5 or 10 mg (Rogers & Friedhoff, 1996; Greenberg et al., 2000). Rivastigmine (Exelon®) is available in twice-daily dosing and has similar efficacy to donepezil (Corey-Bloom et al., 1998).

Apathy, depression, agitation, delusions and hallucinations are common neuropsychiatric alterations in AD. The selective serotonin reuptake inhibitors (SSRIs) are the drugs of choice to treat depression in the context of AD due to their favourable side effect profile, and particularly the absence of significant anticholinergic effects. Low doses of sedative or anxiolytic drugs may be used to treat agitation, but should be monitored closely to avoid possible side effects such as increased confusion or even a paradoxical increase in agitation. Paranoia, hallucinations and agitation generally respond to antipsychotic therapy, and the newer atypical neuroleptics (e.g. risperidone, olanzepine) are preferred because of their low risk of causing extrapyramidal side effects.

Agents that simply replace, or bypass, a neurotransmitter deficit will produce at most only short-term symptomatic benefit. The next generation of therapies for AD will attempt to correct the underlying pathogenic processes that lead to dementia. The first step in this effort was to administer high doses (2000 I.U./day) of the anti-oxidant vitamin E, which reportedly slowed the rate of deterioration in AD patients (Sano et al., 1997). Attempts to develop more effective disease-modifying therapies for AD have focused on antiamyloidogenic approaches that either block Aβ production or reduce its deposition in brain. The clinical implementation of such strategies will thus represent a formal test of the amyloid hypothesis of AD. Promising lines of development include small molecules that inhibit β- and γ-secretase, which should decrease Aβ production (Vassar & Citron, 2000). Another proposed approach is immunization against Aβ peptide, which is postulated to increase immune-mediated clearance of soluble Aβ (Schenk et al., 1999). Such strategies to decrease brain levels of soluble Aβ may also promote the dissolution of insoluble Aβ deposits by shifting the equilibrium in favour of solubility.

Future approaches to AD therapy may exploit other aspects of our understanding of the pathogenesis of AD. For example, stimulation of endogenous pathways for the degradation and clearance of Aβ may offer an alternative approach to antiamyloidogenic therapy. Inhibition of tau aggregation and NFT formation, possibly through modulation of tau phosphorylation, may help to promote neuronal survival in AD and other tauopathies. Strategies that block the pathways leading to neuronal death, whether apoptotic or otherwise, may provide benefit in neurodegenerative disorders of diverse etiologies. Finally, therapies relying on implantation of neural stem cells (Erickson et al., 1996) or stimulation of endogenous adult neurogenesis

(Björklund & Lindvall, 2000) may help to combat neuronal loss and restore or preserve cognitive function in AD.

History

The concept of the clinical syndrome of 'dementia with Lewy bodies' arose within the context of correlations with the pathological descriptions of Lewy body inclusions. These inclusions were first described by F. H. Lewy in 1912 in the dorsal motor nucleus of the vagus and substantia innominata (Lewy, 1912), and Lewy bodies in the substantia nigra were postulated to be specific for Parkinson's disease by Tretiakoff in 1919 (Tretiakoff, 1919). Cortical Lewy bodies were initially described in association with postencephalitic parkinsonism (Lipkin, 1959), in elderly with incidental nigral Lewy bodies (Forno, 1969), in severe dementia (Okazaki et al., 1961), and in institutionalized psychiatric patients (Woodward, 1962). From a clinicopathologic study of 20 cases in 1980, K. Kosaka proposed that the neuroanatomical spectrum of Lewy bodies ranged from isolated substantia nigra inclusions to widespread cortical inclusions; he coined the term 'diffuse Lewy body disease' to describe a clinical syndrome of parkinsonism, dementia, and/or psychosis associated pathologically with Lewy bodies in cortical and limbic regions in addition to subcortical nuclei (Kosaka et al., 1980). In more recent nomenclature, the clinicopathological syndrome has been termed 'Dementia with Lewy bodies' (DLB).

Epidemiology

DLB has been recognized as the second most common form of degenerative dementia, after Alzheimer's disease, occurring in 15–36% of pathological series of dementia (Hansen et al., 1990; Holmes et al., 1999; Perry et al., 1990), with an estimated prevalence of 10–25% in hospital and community elderly with dementia (Ballard et al., 1995; Shergill et al., 1994). Furthermore, cortical Lewy bodies are found in more than 25% of AD cases (Bergeron & Pollanen, 1989; Ditter & Mirra, 1987; Forno & Langston, 1993). In a review of autopsy-confirmed cases of DLB and AD, the frequency of males was greater in DLB (M:F 1.7 in DLB vs. 0.53 in AD), the average age of onset was similar (70 years old in DLB, 71 years old in AD), with a trend toward more rapidly progressive illness in DLB (duration 6.25 of years in DLB vs. 7.3 of years in AD) (McKeith & O'Brien, 1999).

Clinical features

The clinical features of DLB have been incorporated into consensus criteria for the clinical diagnosis of DLB (Table 18.1) (McKeith et al., 1996). The criteria list dementia in association with fluctuating mental status, visual hallucinations, and parkinsonism as required or core features of DLB; supportive features are repeated falls, syncope, transient loss of consciousness, sensitivity to extrapyramidal side effects of neuroleptics, delusions and other hallucinations. Additional proposed supportive features include depression and REM sleep behavioural disorder (McKeith et al., 1999). Several studies have addressed the accuracy of the clinical criteria for DLB. The specificity (proportion of non-DLB cases correctly identified) of the clinical criteria for probable DLB compared to neuropathological diagnosis ranges from 0.84–1.00 in prospective and retrospective studies (Holmes et al., 1999; Litvan et al., 1998; Luis et al., 1999; McKeith et al., 2000a; Mega et al., 1996; Verghese et al., 1999). The sensitivity of the clinical criteria for probable DLB has been more variable, as high as 0.83–0.89 in prospective studies (McKeith et al., 2000a; McShane et al., 1998), and ranging from 0.40–0.65 in retrospective studies (Litvan et al., 1998; Luis et al., 1999; Mega et al., 1996; Verghese et al., 1999).

Dementia (slowly progressive global cognitive impairment) is a mandatory feature of DLB, and is the presenting

Table 18.1. Clinical and pathological features in dementia with Lewy bodies

Clinical features	Pathological features
1. Central feature: Progressive dementia	1. Essential for diagnosis: Lewy bodies
2. Probable (2/3)[a] or possible (1/3) if:	2. Associated but not essential
– fluctuating cognition and alertness	Lewy-related neurites
– recurrent visual hallucinations	Amyloid plaques (all types)
– spontaneous parkinsonism	Neurofibrillary tangles
3. Supportive features: repeated falls, syncopes, neuroleptic hypersensitivity, delusions, hallucinations in other modalities, REM – sleep, behaviour disorder, depression	Neuronal loss / synapse loss
	Spongiform change (temporal)
	Neurotransmitter abnormalities

Notes:
[a] Two of the three features are required for a diagnosis of probable DLB, one for possible DLB.
Source: From McKeith et al. (1996).

feature in about 82% (range 40–100%) (McKeith & O'Brien, 1999). Psychometric features of the cognitive dysfunction in DLB such as amnesia, dyscalculia, and aphasia, overlap those of AD, not surprising given the frequently coexisting pathology. However, several studies suggest that, compared to AD patients of comparable global severity of dementia, patients with DLB perform less poorly on tests of verbal memory, and worse in tests of attention, visuospatial and visuoconstructive function, and fluency (Galasko et al., 1996; Gnanalingham et al., 1997; Hansen et al., 1990; Mori et al., 2000; Shimomura et al., 1998; Walker et al., 1997). Early in the illness, memory deficits may be minimal, or consist of selective deficits of memory retrieval, with recall significantly improved by prompting. This may be distinct from the deficits in memory acquisition and consolidation characteristic of AD (Ballard et al., 1999a; Walker et al., 1997). Frontal lobe dysfunction and visuospatial impairment may be more prominent early on in DLB. Language dysfunction of dysnomia progressing to dysphasia tends to parallel the clinical course of AD, although speech block has been described early in the illness. The rate of cognitive decline is faster in DLB compared to AD (Ballard et al., 1996; Olichney et al., 1998), and DLB has been associated with shorter survival, 7.7 ± 3.0 years after onset of cognitive symptoms versus 9.3 ± 3.5 years in AD (Olichney et al., 1998), although in a prospective study, no differences were found between age of onset, age of death, or survival between AD and DLB (Walker et al., 2000a, b).

A particular feature of the mental status in DLB is fluctuations, including periods of confusion, inattention, somnolence, or worsening cognitive impairment alternating with more lucid periods. These periods of variation may last from minutes to days (McKeith et al., 1996), and are unrelated to exogenous factors such as anxiety or unfamiliar surroundings; they are distinct from 'sundowning' episodes of evening confusion common in Alzheimer's disease. The prevalence of fluctuation in cognition in autopsy-proven DLB has ranged from 40–86% (Hohl et al., 2000; McKeith et al., 1992b; Verghese et al., 1999), and can be noted early in the course of the illness (McKeith & O'Brien, 1999). Episodes of syncope or transient loss of consciousness may be more extreme forms of the fluctuations. In the elderly, these symptoms must be differentiated from delirium from infection or toxic–metabolic encephalopathy, transient ischemic attacks, focal seizures, orthostasis, and cardiac disease.

Spontaneous, complex visual hallucinations occur in 40–75% of DLB patients, typically early in the illness and unrelated to medications (Galasko et al., 1996; Klatka et al., 1996; McKeith & O'Brien, 1999; Mega et al., 1996; Weiner et al., 1996). Delusional misidentification is also common early in DLB (Ballard et al., 1999b). Auditory hallucinations are less common, noted in an average of 19% of patients at presentation or during the entire course of illness (McKeith & O'Brien, 1999).

Parkinsonism is common as an early or initial feature of DLB, occurring at presentation in 43% (range 10–78%), and during the entire course in 77% (range 50–100%) (McKeith & O'Brien, 1999). The parkinsonism is usually symmetric, consisting of parkinsonian gait with reduced arm swing and *en bloc* turning, bradykinesia, rigidity, and hypomimia. Parkinsonian resting tremor is less common. Parkinsonism may contribute to falls, which occur in 28% of DLB patients at presentation, and 37% of DLB patients during the entire course of illness (McKeith & O'Brien, 1999). Patients with DLB also are sensitive to the extrapyramidal side effects of neuroleptic medications, including

severe rigidity and obtundation at low doses of neuroleptics that persist after drug withdrawal. Neuroleptic sensitivity is noted in an average of 61% of DLB patients relative to 15% of AD patients (McKeith & O'Brien, 1999).

Depressive features are nearly twice as common in DLB relative to AD, noted in an average of 29% of DLB patients at presentation, and 38% during the course of illness (McKeith & O'Brien, 1999).

Atypical Lewy body syndromes include primary autonomic failure, associated with Lewy bodies in the sympathetic neurons of the spinal cord, and Lewy body dysphagia, associated with Lewy bodies in the dorsal vagal nuclei.

The differential diagnosis of DLB involves other parkinsonian and/or dementia syndromes in addition to Parkinson's disease and Alzheimer's disease, such as multiple system atrophy, progressive supranuclear palsy, cortical basal degeneration, Pick's disease and frontal lobe dementias, Creutzfeld–Jakob disease, normal pressure hydrocephalus, multi-infarct dementia and Binswanger's disease, and Hallervorden–Spatz disease.

Imaging and laboratory investigations

There has been considerable interest in the use of CT and MRI imaging studies to differentiate the dementias. A CT measure of minimum temporal lobe width was significantly reduced in dementia (10.4–10.9 mm) relative to depression (13.7 mm), but could not distinguish DLB from AD or vascular dementia (VD) (O'Brien et al., 2000). MRI imaging in DLB is non-specific. While both AD and DLB brain show generalized atrophy relative to non-demented brains (Hashimoto et al., 1998), medial temporal atrophy tends to be intermediate between non-demented cases and AD (Barber et al., 1999b; Harvey et al., 1999; Hashimoto et al., 1998). White matter hyperintensities on MRI, which occur with increased aging, are more extensive in dementia than controls, although they do not differentiate AD from DLB (Barber et al., 1999a).

Metabolic studies of DLB using SPECT and PET suggest a more global pattern of hypermetabolism compared to the typical temporal–parietal hypometabolism of AD. This may be reflected in reduced frontal (Defebvre et al., 1999) or occipital perfusion (Donnemiller et al., 1997; Ishii et al., 1999) by SPECT in DLB relative to AD, and reduced occipital glucose metabolism by PET in DLB relative to AD (Higuchi et al., 2000; Ishii et al., 1998). Dopamine transporter function as assessed by CIT SPECT may also be more impaired in DLB than AD (Donnemiller et al., 1997). PET measures of occipital glucose utilization in particular could differentiate DLB from AD with relatively high sensitivity (86–92%) and specificity (91–92%) in a small clinical studies (Higuchi et al., 2000; Ishii et al., 1998). Nonetheless, conventional SPECT scan is limited in its diagnostic utility in distinguishing AD from DLB given the heterogeneity of perfusion patterns, semiquantitive nature, and low sensitivity and specificity (Pasquier et al., 1997; Talbot et al., 1998).

Electrophysiologic studies with EEG in DLB show slowing with loss of alpha activity as the dominant rhythm and temporal slow wave transients. EEG slowing is common in DLB, characterized by loss of alpha activity as the dominant rhythm, and may be correlated to MMSE (Barber et al., 2000; Briel et al., 1999). Temporal lobe slow wave transients have also been described, correlated to reported episodes of loss of consciousness in DLB (Briel et al., 1999). Fluctuating cognition may correlate with fluctuation in mean EEG frequency over 1.5 minutes by EEG brain mapping (Walker et al., 2000a, b). While slowing of alpha rhythm and temporal slow wave transients are common in DLB, they are not specific, and may be seen in AD (Briel et al., 1999).

The usefulness of CSF biochemical markers in DLB is unclear, as most studies have looked at small clinical samples. Some studies show elevated CSF tau in DLB similar to AD (Arai et al., 1997; Higuchi et al., 2000), while others demonstrate normal CSF tau and low Aß42 (Kanemaru et al., 2000).

Genetics

Genetic factors in the etiology of DLB are suggested by pedigrees of familial DLB (Hardy et al., 1998; Ohara et al., 1999) or PD in which members have developed dementia. Furthermore, some studies find an increased risk of dementia in first-degree relatives of PD patients (Van Duijn et al., 1991), and of PD in first-degree relatives of AD patients (Amaducci et al., 1986; Hofman et al., 1989), although other studies have disputed these findings (Mickel et al., 1997). Genetic studies in DLB have assessed genetic risk factors and causative genes that are important in PD and AD.

AD related polymorphisms that have been evaluated in DLB include apolipoprotein E (*APOE*), butyrylcholinesterase, α1-antichymotrypsin (*AACT*), presenilin-1 (*PS1*), and α2-macroglobulin (*A2M*). The *APOE* ϵ4 allele is a risk factor for late-onset sporadic and familial AD (Rebeck et al., 1993; Saunders et al., 1993). The *APOE* ϵ4 allele is over-represented in DLB cases to a lesser degree than in AD (Benjamin et al., 1994a; Lamb et al., 1998; Morris et al.,

1996). Under-representation of the *APOE* ϵ2 allele, which may be protective for AD (Benjamin et al., 1994b; Corder et al., 1994; West et al., 1994), has not been found in DLB (Lamb et al., 1998; Morris et al., 1996).

The butyrylcholinesterase K allele is not over-represented in DLB; however, an increased number of homozygotes for the K allele was found in a small number of DLB cases (Singleton et al., 1998). No association with DLB was found with the *PS1* allele 1 intronic polymorphism (Singleton et al., 1997), the *AACT* A allele (Lamb et al., 1998), the *A2M*Val1000Ile polymorphism, or the *A2M* pentanucleotide deletion, although a trend toward increased homozygotes for the pentanucleotide deletion polymorphism was noted in DLB and AD (Singleton et al., 1999).

PD related genes evaluated in DLB include α-synuclein and the cytochrome P450 CYP2D6 (*CYP2D6*). α-Synuclein mutations have been identified in five pedigrees of autosomal dominant familial Parkinson's disease, but have not been found in sporadic PD or DLB (Higuchi et al., 1998). While allele 4 of the *CYP2D6* gene has been associated with PD, it is not associated with AD or DLB (Atkinson et al., 1999). Finally, a pentanucleotide repeat polymorphism in the promoter region of nitrogen oxide synthase 2A gene (*NOS2A*) has been linked to DLB but not AD in a single report (Xu et al., 2000).

Clinical management

Management of DLB targets motor, cognitive and behavioural symptoms. General principles of dementia management should be employed, including regular assessment of functional capabilities, family education, social service support, environmental modification, optimization of medications, and aggressive recognition and treatment of delirium. In addition, specific medication therapy may be required for treatment of motor, cognitive and behavioral symptoms. Trials of L-dopa or dopaminergic agonists may ameliorate motor symptoms of parkinsonism; however, patients with DLB are less likely to respond than PD patients, and are more sensitive to side effects of hallucinations, delusions, and agitation.

Similar to patients with AD, cholinergic agents can improve memory and behaviour in DLB. A double-blind, placebo- controlled study of the cholinesterase inhibitor rivastigmine (Exelon) 3–12 mg/d in DLB demonstrated greater improvement relative to placebo in the Neuropsychiatric Inventory (McKeith et al., 2000b).

Behavioural symptoms may require drug therapy if they are unresponsive to environmental modification and are disturbing to the patient and caregiver. Agitation may respond to non-neuroleptic medications such as anxiolytics (benzodiazepines, buspar), antidepressants (trazadone) or anticonvulsants (gabapentin, valproate). Hallucinations and delusions may require carefully monitored treatment with atypical neuroleptics. High potency neuroleptics such as haloperidol should be avoided, as patients with DLB are particularly susceptible to severe extrapyramidal side effects (McKeith et al., 1992a). Low doses of atypical neuroleptics such as risperidone, olanzepine, seroquel, and clozaril are preferable; however, even these may potentiate extrapyramidal symptoms in DLB.

Table 18.2

Pathological features in DLB

1. Essential for diagnosis: Lewy bodies in cortical areas
2. Associated but not essential:
Lewy-related neurites
Amyloid plaques (all types)
Neurofibrillary tangles
Neuronal loss/synapse loss
Spongiform change (temporal)
Neurotransmitter abnormalities

Pathological features in DLB

The hallmark and the essential pathological requirement for the diagnosis of DLB is the presence of Lewy bodies. Other pathological features are frequently associated with the Lewy bodies (Table 18.2).

Lewy bodies

Lewy bodies (LB) are eosinophilic intracytoplasmic inclusions with hematoxilin and eosin stain, that can be recognized with more sensitivity with ubiquitin immunostaining (Kuzuhara et al., 1988; Lennox et al., 1989b) and with great specificity with α-synuclein antibodies (Irizarry et al., 1998; Spillantini et al., 1997). The presence of this presynaptic protein seems to be so specific for the LB that α-synuclein intraneuronal immunoreactivity is considered now parallel to Lewy-related pathology. However, more than 20 different antigens have been detected in the LB (Gómez-Tortosa et al., 1998; Pollanen et al., 1993). The appearance of the LB varies slightly depending on their location in brainstem or in cortical regions (Fig. 18.1). Classic LB, as seen in brainstem, are compact,

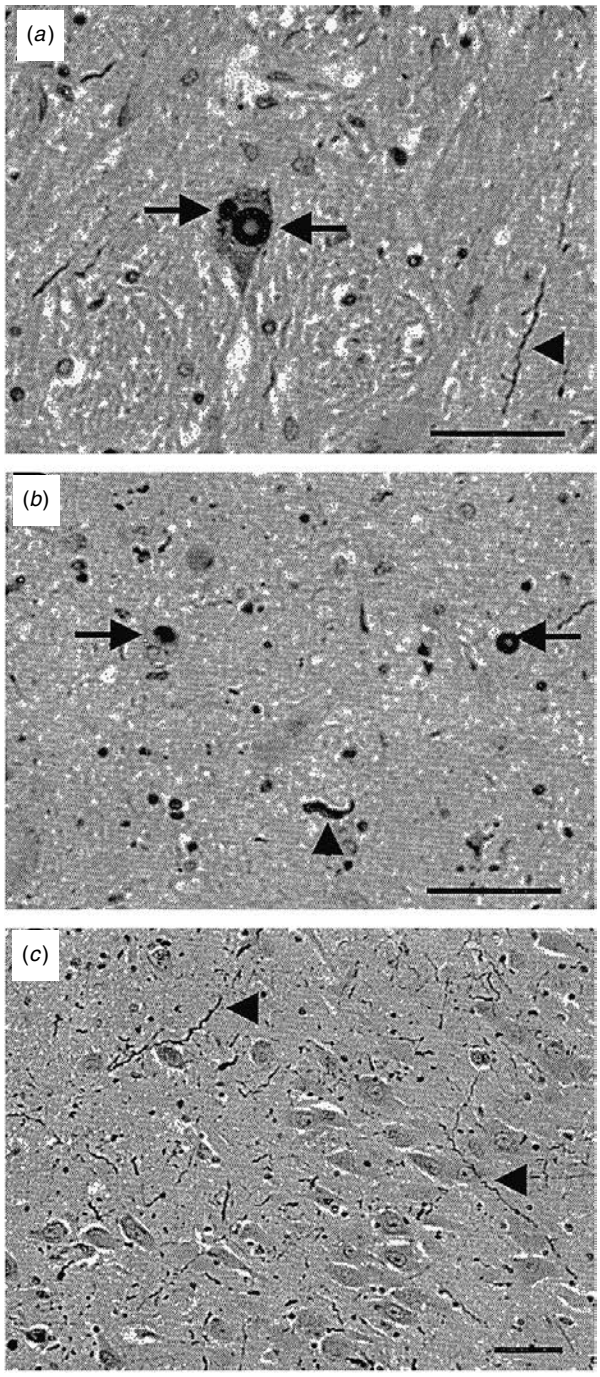

Fig. 18.1. Lewy bodies (arrows) and Lewy neurites (arrowheads) in substantia nigra (*a*), entorhinal cortex (*b*), and hippocampal CA2/3 subfields (*c*) in DLB by α-synuclein immunostaining (hematoxylin and eosin counterstain.) Scale bars = 50 μm.

with a well defined halo. When double immunostained for α-synuclein and ubiquitin, the first shows a tendency to be distributed in an outer rim, while ubiquitin is present more towards the core. In substantia nigra, α-synuclein immunoreactivity also shows a wide spectrum of intracytoplasmic inclusions with variable ubiquitin costaining that may represent progressive stages of aggregation and LB formation (Gómez-Tortosa et al., 2000). Cortical LB are less well defined, lack the halo (Lowe, 1994), and the pattern of double immunostaining is more homogenous.

The distribution of the LB in cases with DLB shows a very consistent hierarchical vulnerability to LB formation across brain regions. Substantia nigra and other brainstem nuclei are affected with the highest density of LB, followed by paralimbic regions (basal forebrain nuclei, entorhinal, cingulate and insular cortices) and neocortical regions having the lowest density (Gómez-Tortosa et al., 1999; Rezaie et al., 1996) (Fig. 18.2, see colour plate section). Depending on the more or less widespread distribution of the LB, the spectrum of Lewy body disorders is classified into three types (McKeith et al., 1996). LB restricted to brainstem and basal forebrain nuclei define the brainstem type which is basically the pathology of idiopathic PD. In the transitional type, LB are found in limbic and paralimbic regions, but not in neocortex. When LB are also present in neocortex, it is the neocortical type. The density of LB in substantia nigra does not necessarily correlate with the density of LB in paralimbic and neocortical areas (Gómez-Tortosa et al., 1999) which suggests that DLB does not simply reflect severe or long-lasting PD. In cortical regions, LB frequently occur in the deep cortical layers V and VI as if only certain subpopulations of neurons are vulnerable to develop the inclusions.

Lewy neurites

Lewy neurites in the CA2–3 regions of the hippocampus are a pathological feature frequently associated with the presence of LB (Dickson et al., 1991). They show the same immunohistochemical profile as the LB, in terms of containing α-synuclein, ubiquitin and neurofilaments (Dickson et al., 1994; Irizarry et al., 1998). Lewy neurites are found in about two-thirds to three-quarters of the cases with Lewy bodies and their presence is very specific for Lewy body diseases, because they do not appear in other neurodegenerative diseases with nigral degeneration but without LB (Kim et al., 1995). Thus, CA2–3 neuritic degeneration seems a manifestation of the same process that leads to LB formation. Double immunostaining against α-synuclein and either SMI-32 (non-phosphorylated neurofilament present in

dendrites) or SMI-312 (axonal phosphorylated neurofilament) suggests that Lewy neurites are mostly axonal fibres. Because the cell bodies in the hippocampus generally lack α-synuclein inclusions, these neurites are likely to derive from axonal afferents to CA2–3. The absence of tyrosine hydroxylase immunoreactivity suggests that CA2–3 neuritic processes do not derive from brainstem dopaminergic afferents to the hippocampus (Dickson et al., 1994). Thus, the origin of these neurites may be entorhinal cortex or septal nuclei, regions projecting to the CA2–3 fields of the hippocampus and usually affected by α -synuclein inclusions. Recent studies show that hippocampal pathology in PD and DLB is more extensive than recognized with α -synuclein immunostaining, as revealed by abnormal neurites immunostained with antibodies against β- and γ-synucleins in the dentate gyrus and mossy fibres that synapse on hilar neurons (Galvin et al., 1999).

In DLB, scattered neurites are also found in other regions, especially in the nigra, basal forebrain nuclei, amygdala, entorhinal and cingulate cortices (Braak et al., 1999; Gómez-Tortosa et al., 2000; Pellise et al., 1996).

Alzheimer changes

Concomitant Alzheimer changes, that is amyloid plaques and neurofibrillary tangles (NFT), are very common in DLB, but the frequency of this association varies depending on the criteria used to define neuropathological AD. About 30% of cases fulfilling neuropathological criteria for definitive or probable AD have some cortical LB and constitute what is called the Lewy body variant of AD. Thirty-two to 89% (depending on the criteria used) of the DLB cases have concomitant Alzheimer-type changes (Hansen, 1996). In general, the Alzheimer changes found in DLB are characterized by the predominance of senile plaques, mostly of diffuse type rather than neuritic, with more Aβ 42 than Aβ 40, and fewer NFT, especially in the neocortex (Hansen, 1996; Hansen et al., 1993; Heyman et al., 1999; Mann et al., 1998; Samuel et al., 1997b). A simplified but useful schema would be to consider AD with LB or the Lewy body variant of AD those cases having enough neocortical tangles to meet a Braak stage V or VI, while cases with only entorhinal and paralimbic tangles (Braak I to IV) would be considered as DLB (Gearing et al., 1999; Hansen, 1996).

In DLB, Alzheimer and LB pathology seem to be independent of each other, both in terms of distribution and quantity. The distribution of LBs does not coincide with that of neurofibrillary tangles, which are most abundant in the hippocampus and layers III and V of association cortex. There is no correlation between LB density and the degree of neurofibrillary tangle involvement or the amount of cortical senile plaques, which suggests an independence in the formation or in the dynamic turnover of these pathological structures (Gómez-Isla et al., 1999).

Neuronal loss

Neuronal loss in DLB is significant in brainstem and nucleus basalis of Meynert associated with Lewy-pathology (Lippa et al., 1999), but it seems that cortical neuronal loss is just modest, which is consistent with the lack of gross atrophy of DLB brains (Hashimoto et al., 1998; Lippa et al., 1998). Several studies have examined neuronal loss in different cortical regions. In the temporal cortex, DLB brains showed a 10 to 20% (non-significant) neuronal loss in comparison with controls, while DLB cases with concomitant AD changes had pronounced neuronal loss (around 40 to 50%), comparable to that of pure AD cases (Gómez-Isla et al., 1999; Lippa et al., 1994; Wakabayashi et al., 1995). The study of specific neuronal subpopulations characterized by the expression of neurofilaments (pyramidal neurons) and several calcium binding proteins (gabaergic interneurons) in the superior temporal sulcus cortex, also shows no differences in neuronal densities between DLB cases and controls (Gómez-Tortosa et al., 2001).

In entorhinal cortex, neuronal loss has been examined in specific layers and it is not significant in comparison with controls unless Alzheimer changes are present. Lippa et al. (1997) did not find neuronal loss in layer II, origin of the perforant pathway and a group of neurons affected very early by neuronal loss in AD (Gómez-Isla et al., 1996b). Nor is there neuronal loss in pure DLB cases in layers V/VI, where the LB are mainly found, compared to controls. The number of LB does not correlate with neuronal loss, suggesting that they are not directly implicated in widespread neuronal death in pure DLB. Other studies have not found neuronal or synapse loss in frontal cortex (Hansen et al., 1998; Lippa et al., 1994; Samuel et al., 1997a) or hippocampus (Ince et al., 1991; Lippa et al., 1994) of DLB compared with control brains. Thus, in contrast with AD, widespread cortical neuronal loss is not a major feature in the pathology of DLB. However, there is still the possibility of a selective or restricted neuronal loss, not yet recognized.

Other neuropathological features in DLB

Circumscribed spongiform change occurs in some DLB cases in layers II–III of the perirhinal cortex and in the

accessory basal amygdaloid nucleus (Iseki et al., 1997). This pathological feature is usually associated with a more aggressive disease with rapid onset of symptoms and a rapid course with a total duration of illness of less than three years (Hansen et al., 1989).

Finally, because of the involvement of basal forebrain and brainstem nuclei there are widespread neurotransmitter deficits in cortical regions. Monoamines and, especially, acetylcholine are severely depleted in the cortex of DLB brains in comparison with controls and AD (Langlais et al., 1993; Samuel et al., 1997a; Tiraboshi et al., 2000). Marked losses in midfrontal choline acetyltransferase (ChAT) activity occurs in DLB independently of coexistent AD changes (Tiraboshi et al., 2000). Reduced cortical ChAT correlates with neuronal loss and LB densities in the nucleus basalis of Meynert (Lippa et al., 1999).

Clinico-pathological correlations

It is not clear yet to what extent each of the above neuropathological features contributes to the clinical phenotype in DLB. It is also not known whether cortical LB are directly responsible for neuronal injury and, therefore, for the clinical syndrome; or whether the α-synuclein deposits within the Lewy neurites interfere with normal neurotransmission. Pathological changes coexisting with the Lewy pathology, such as Alzheimer-type changes, may also contribute to the clinical phenotype.

Lewy-related pathology

The contribution of the LB to the clinical phenotype has been studied with different approaches. The first has been to examine whether PD cases with dementia consistently have cortical LB that may account for the cognitive decline. What seems clear from clinicopathologic studies of PD patients is that there is not a clear threshold for cortical LB density that distinguishes between demented and nondemented PD. Among the 30 to 40% of idiopathic PD patients who develop dementia not all have cortical LB. In one study, cortical LB were considered to be the likely cause of dementia in only 10% of the demented cases (Hughes et al., 1993). AD changes seem to be the major determinant of the cognitive decline in PD patients (de Vos et al., 1995; Hughes et al., 1993).

The second is to correlate LB densities with the severity of the disease as assessed by a cognitive or functional score close to the time of death. The results with this approach are not uniform. Some studies have found a significant correlation between dementia severity and cortical LB counts (Lennox et al., 1989a; Mattila et al., 1998; Samuel et al., 1997a; Samuel et al., 1996), while others have failed to find any correlation (Churchyard & Lees, 1997; Gómez-Isla et al., 1999; Perry et al., 1990, 1996). There are several differences among these studies in terms of the clinical data used to represent severity of the disease, the degree of concomitant AD in the DLB cases, and the methodology used to quantitate LB, that may account for the different results. In several studies finding a significant correlation between cortical LB and severity of the disease, the significance seems to rely mainly upon the most severely demented cases having the highest LB densities (Lennox et al., 1989a; Mattila et al., 1998). Thus, there is the possibility that LB may be just a marker or be in parallel with a more widespread pathology underlying the disease and not necessarily be the cause of the cognitive decline.

The third approach is to correlate the density of LB in certain brain regions with specific clinical phenotypes. A plausible hypothesis would be that the presence in DLB cases of motor symptoms (such as parkinsonism or recurrent falls) would be associated with higher LB densities in substantia nigra and that the presence of psychiatric symptoms, such as delusions or hallucinations, would be related with a higher density of LB in paralimbic or neocortical regions, in comparison with cases who did not present these symptoms. However, no significant differences have been found in LB densities in substantia nigra, paralimbic regions and neocortex comparing patients with or without specific symptoms (Gómez-Tortosa et al., 1999). It is surprising that DLB patients with or without clinical parkinsonism had similar LB densities in nigra. There was a slight tendency for cases with hallucinations and delusions to have a higher density of LB in paralimbic regions versus those without these symptoms, but the differences were not statistically significant. One group has found an association between the presence of cortical Lewy body pathology and persistent hallucinations (McShane et al., 1995, 1996) but other studies have failed to demonstrate any correlation (Perry et al., 1990). Therefore, the distribution and number of cortical LB do not seem to be clearly associated with the clinical symptoms. In most clinico-pathological studies the density of cortical LB also does not correlate with the duration of the disease (Gómez-Isla et al., 1999; Gómez-Tortosa et al., 1999; Mattila et al., 1998).

The contribution of the Lewy neurites to the cognitive impairment is not understood yet, but they may well play a prominent role. Churchyard & Lees (1997) found a positive correlation between the density of hippocampal CA2–3 neurites and cognitive impairment (MMSE) in Parkinson's disease patients, even when in this same study

there was no correlation with the density of LB. The CA2–3 regions of the hippocampus receive major inputs from the dentate gyrus, entorhinal cortex, septal nuclei, amygdala and hypothalamus, and then project to the CA1 field, which in turn projects to the subiculum. These connections are crucial for memory and cognition, suggesting that the neuritic inclusions may disrupt hippocampal function by interfering with inputs to the CA1 field and contribute to the cognitive deficits in DLB. Furthermore, more extensive hippocampal neuritic abnormalities can be revealed with β- and γ-synuclein immunostaining in the dentate gyrus and mossy fibres that synapse on hilar neurons (Galvin et al., 1999). These abnormal processes are likely to impair synaptic transmission in the perforant pathway, which is a critical network for memory and cognition, known to be severely affected in AD. Therefore, the same hippocampal circuitry may be involved in Alzheimer and DLB diseases. As widespread α-synuclein-positive neuritic processes are revealed in DLB brains, there is a growing impression that abnormal neurites, not only in hippocampus but also in other cortical regions, may impair neuronal connectivity and play a significant role in the progression of the cognitive deficits in DLB.

Neuronal loss/Alzheimer changes

Alzheimer-type pathology likely has an additive or synergistic effect in producing the clinical phenotype of DLB, but cannot be the sole cause. First, there is a well documented number of DLB cases that represent pure LB pathology (Armstrong et al., 1997; Perry et al., 1996). Secondly, Alzheimer changes do not correlate with the severity of cognitive impairment in DLB (Gómez-Isla et al., 1999; Samuel et al., 1996). This is not surprising considering that there are few neurofibrillary tangles, which are most strongly correlated with neuronal loss and cognitive impairment in AD (Gómez-Isla et al., 1996a, 1997), and that amyloid plaques are mostly of the diffuse type, which are not associated with cognitive impairment and are present in cognitively preserved elderly (Crystal et al., 1993; Dickson et al., 1992). Furthermore, DLB cases are equally demented as AD cases with many fewer neurofibrillary tangles and senile plaques, which suggests that other pathological features besides the Alzheimer changes are contributing to the clinical phenotype. On the other hand, DLB cases are less demented than cases with the Lewy body variant of AD for equal LB densities and ChAT loss, which suggests that when present, AD changes have an additive effect in the clinical phenotype (Samuel et al., 1997a).

Neurochemical deficits

There is severe ACh depletion in DLB cases all through cortical regions (temporal, parietal, midfrontal, septal). This ACh depletion correlates with dementia severity, and its role in the cognitive phenotype is supported by the good response some DLB cases have to treatment with cholinesterase inhibitors. The most robust neurobiological correlate of the dementia so far identified appears to be extensive cholinergic deficits in the neocortex (Perry et al., 1997).

Finally, impairment of the mesocortical and mesoneocortical dopaminergic projections may be also implicated in cognitive dysfunction. The lesion of these connections in animals produces behavioural changes and it has been suggested that in humans such lesions may be responsible for the cognitive manifestations in PD, and for some neuropsychiatric disorders such as schizophrenia or Tourette's syndrome.

Underlying biochemical abnormalities reflected in Lewy bodies: the role of alpha-synuclein

An abundant component of Lewy bodies in dementia with Lewy bodies and related disorders is the presynaptic protein, α-synuclein (Irizarry et al., 1998; Spillantini et al., 1997). α-Synuclein is a highly conserved 140 amino acid phosphoprotein of unknown function that was originally isolated from *Torpedo californica* (Maroteaux et al., 1988). The name synuclein was coined on the basis of both synaptic and nuclear localization in *Torpedo*, however, nuclear localization has not been consistently observed in subsequent studies (George et al., 1995; Iwai et al., 1995; Jakes et al., 1994; Maroteaux et al., 1988). Although the normal function of α-synuclein is unknown, studies of song-learning in the zebra-finch have implicated a role for the protein in neuronal plasticity. In juvenile birds just learning their song, α-synuclein is especially abundant in the glutamatergic presynaptic terminals of the key regulatory projection essential for song memorization (George et al., 1995).

The structure of α-synuclein may provide clues to its possible function. The amino-terminal region contains 7 degenerate 11 amino acid imperfect repeat sequences predicted to form 5 amphipathic alpha helices. α-Synuclein is predicted to have a random coil conformation in solution (Weinreb et al., 1996), however, when studied in the presence of synthetic membranes, lipid binding is accompanied by an increase in alpha helicity (Davidson et al., 1998),

suggesting that, in an isolated system, α-synuclein may be membrane associated.

Studies into the genetic basis of familial Parkinson's disease have led to the identification of two missense mutations in the gene encoding α-synuclein (Ala53Thr and Ala30Pro) in some families with early onset familial Parkinson's disease (Krüger et al., 1998; Polymeropoulos et al., 1997). It is unclear how the mutations effect the normal function of α-synuclein but it has been hypothesized that the normal localization of the protein is disrupted, causing α-synuclein to accumulate in the cell bodies of degenerating neurons as a component of Lewy bodies.

Research aimed at understanding the role of α-synuclein in normal and parkinsonian cell function have led to the identification of several potential interacting species. α-Synuclein was found to bind synthetic vesicles containing acidic phospholipids in vitro (Davidson et al., 1998), and investigators have reported interactions of α-synuclein with the structural protein tubulin (Alim et al., 2002), tau (Jensen et al., 1999), microtubule-associated protein 1B (MAP-1B) (Jensen et al., 2000), and with a previously unknown protein called 'synphilin-1' (Engelender et al., 1999). Subsequently, MAP-1B (Jensen et al., 2000) and synphilin-1(Wakabayashi et al., 2000) have been identified as components of Lewy bodies suggesting that interactions of α-synuclein with these proteins may be a critical component of Lewy body formation.

Studies into the effects of the Parkinson's disease associated mutations have revealed that the Ala30Pro mutation abolishes the binding of α-synuclein to brain vesicles in vitro (Jensen et al., 1998) suggesting that this may lead to the accumulation of the protein and, as a result, its assembly into Lewy bodies. By contrast, neither the Ala30Pro nor Ala53Thr mutation was found to have an effect on the association of α-synuclein with cellular membranes (McLean et al., 2000). Further examination of the normal function of α-synuclein and the effect of the mutations on subcellular localization will provide insight into the mechanisms that lead to the accumulation of the protein in certain neurodegenerative disorders.

α-Synuclein protein has a demonstrated propensity to aggregate in vitro (Conway et al., 1998; Giasson et al., 1999) with the Ala53Thr mutant seemingly forming fibrils faster than both wild-type and Ala30Pro α-synuclein (Conway et al., 1998). Subsequent studies have suggested that both Parkinson's disease associated mutations (Ala53Thr and Ala30Pro) accelerate the rate of α-synuclein aggregation (Nahri et al., 1999). More recently, it has been suggested that a nonfibrillar oligomer species precedes the formation of fibrils of α-synuclein and that acceleration of oligomerization, rather than acceleration of fibrillization, is a shared property of both mutant proteins (Conway et al., 2000a). Interestingly, the fibrils generated in vitro from both wild-type and mutant α-synuclein have been found to possess features that are characteristic of amyloid fibrils (Conway et al., 2000b; Serpell et al., 2000).

A common mechanism whereby manipulations of the C-terminus lead to aggregation and inclusion body formation is suggested by recent studies where C-terminally truncated forms of α-synuclein more readily formed fibrils in vitro (Crowther et al., 1998). Furthermore, although Lewy bodies contain predominantly full-length α-synuclein, Baba et al. (1998) reported the presence of truncated α-synuclein in purified Lewy bodies which suggests that a truncation event occurs. In addition, α-synuclein aggregation in vitro was recently demonstrated to be a nucleation-dependent event (Wood et al., 1999) which raises the possibility that a C-terminally modified form of the protein acts as a seed for fibril formation. SH-SY5Y cells overexpressing C-terminally truncated α-synuclein, particularly the 1–120 residue protein, have been shown to be more susceptible to oxidative stress following exposure to hydrogen peroxide or to the dopaminergic neurotoxin MPP+ (Kanda et al., 2000).

Chemical manipulations have also been determined to promote α-synuclein aggregation in vitro. Coincubation of recombinant α-synuclein with cytochrome *c*/hydrogen peroxide or hemin/hydrogen peroxide induced α-synuclein aggregation that could be blocked by anti-oxidant agents such as *N*-acetyl-L-cysteine (Hashimoto et al., 1999a). Likewise, human α-synuclein was found to aggregate in the presence of ferric ion and this was inhibited by the iron chelator, deferoxamine (Hashimoto et al., 1999b). Consistent with the in vitro study by Hashimoto et al. (1999b), Osterova-Golts and colleagues demonstrated aggregation of α-synuclein in neuroblastoma cells in culture following exposure to iron or iron plus either hydrogen peroxide or dopamine, which generate free radicals (Osterova-Golts et al., 2000). Moreover, they observed that the Ala53Thr α-synuclein mutation had an increased tendency to aggregate, consistent with observations in vitro (Conway et al., 1998, 2000a; Giasson et al., 1999).

It is unclear at this time if the aggregation of α-synuclein into Lewy bodies is neurotoxic, which would suggest that Lewy bodies are analogous to amyloid plaques in Alzheimer's disease, which have been proposed to be toxic. Alternatively, Lewy bodies could be a result of neuronal damage, but are in themselves, not toxic. Finally, it has been proposed that Lewy bodies may be an inert end point in a process that, early on, produces a neurotoxic species, and that Lewy body formation may actually protect against

cell death by sequestering the toxic species (Conway et al., 2000a).

It has yet to be determined what role, if any, α-synuclein plays in neurotoxicity however, several studies have examined the effect of α-synuclein overexpression on cell death. Overexpression of human mutant α-synuclein (Ala53Thr) selectively induced apoptotic programmed cell death of primary dopamine neurons as well as mesencephalon-derived N27 cells (Zhou et al., 2000), with the mutant protein also potentiating the neurotoxicity of 6-hydroxydopamine (6–OHDA). Likewise, human dopaminergic neuroblastoma SH-SY5Y cells overexpressing Ala 53 Thr α-synuclein were significantly more vulnerable to oxidative stress following exposure to hydrogen peroxide or to the dopaminergic neurotoxin MPP^+ (Kanda et al., 2000). Similarly, aggregates of NAC and α-synuclein proteins induced apoptotic cell death in SH-SY5Y cells (El-Agnaf et al., 1998) and preaggregated NAC was toxic to rat primary mesencephalic neurons and to a PC12 cell line differentiated with nerve growth factor (Forloni et al., 2000).

Transgenic models

Animal models aimed at addressing the fundamental aspects of α-synucleinopathy have yielded some clues as to the normal function of α-synuclein and the effect of overexpression of the Parkinson's disease associated mutations. Mice lacking α-synuclein (α-syn$^{-/-}$) do not display any gross pathological abnormalities and possess a normal complement of dopaminergic cell bodies, fibres and synapses (Abeliovich et al., 2000). However, the α-syn$^{-/-}$ mice exhibit altered stimulus-dependent dopamine release, which suggest that α-synuclein is an activity-dependent negative regulator of dopamine neurotransmission. Neuronal expression of human α-synuclein and the Ala30Pro mutant in mice results in a progressive, abnormal accumulation of α-synuclein in neuronal cell bodies and neurites in several regions of the brain (Kahle et al., 2000; Masliah et al., 2000). Behavioural deficits are observed only in mice expressing the highest levels of wild-type α-synuclein (Masliah et al., 2000) and correspond to increased amounts of α-synuclein immunoreactive neuronal inclusions. Such an observation suggests that a critical threshold of α-synuclein accumulation is required before dopaminergic and behavioural deficits become apparent.

Analogous phenotypes have also been observed in a *Drosophila* model of Parkinson's disease where expression of wild-type and mutant forms of α-synuclein in *Drosophila melanogaster* produce adult-onset loss of dopaminergic neurons, filamentous intraneuronal inclusions containing α-synuclein, and locomotor dysfunction (Feany & Bender, 2000). These recent mouse and drosophila models of Parkinson's disease support a central role for the process of α-synuclein aggregation in the pathogenesis of α-synucleinopathies.

In conclusion, Lewy body dementia has emerged as a major clinical and pathological entity contributing to dementia. Although substantial data have been presented regarding the clinical and pathological features of this illness, and the identity of some of the proteins involved in the neuronal inclusions has been uncovered, major questions remain unanswered. The vast majority of instances of Lewy body dementia show at least some pathological overlap with Alzheimer's disease-related changes. This concordance far exceeds that which might be expected by chance alone; it suggests strongly that the disease processes are interrelated. This impression is reinforced by the observation that certain cases of early onset autosomal-dominant familial Alzheimer's disease show, in addition to marked Alzheimer changes, Lewy bodies in the cortex (Lantos et al., 1994; Lippa et al., 1995). It is uncertain whether this represents a common genetic predisposition to neurodegenerative diseases, common environmental influences that predispose to both diseases, or a more fundamental intertwining of these pathophysiological processes.

Although most cases of Lewy body dementia overlap with Alzheimer-type pathology, some cases exist where the Lewy bodies in widespread cortical regions are the sole neuropathological alterations. Clinically, these cases are essentially indistinguishable from those that overlap with Alzheimer's disease. Nonetheless, there is minimal or no neuronal loss, and the absolute number of Lewy bodies seems small in comparison to the devastating nature of the severe dementia syndrome. Thus, a major unanswered question remains 'what effect does the presence of Lewy bodies have on the cortex to impair neural systems so profoundly?'

Perhaps better understanding of the protein constituents that precipitate in Lewy body formation would be revealing. α-Synuclein appears to be the major protein constituent, and the presence of the mutations in α-synuclein that lead to autosomal dominantly inherited Parkinson's disease encourages the belief that α-synuclein dysfunction lies at the heart of the illness. Unfortunately, the neuronal functional role of α-synuclein remains unknown. α-Synuclein knockout mice have only a subtle phenotype and minimal electrophysiological dysfunction, suggesting that the impact of α-synuclein alterations in Lewy body diseases is not a simple loss of function (Abeliovich et al., 2000).

It has been suggested that protein misfolding, and thereby potential gain of function, lies at the heart of synuclein aggregation into Lewy bodies and, perhaps more generally, is a cause of synaptic dysfunction in Lewy body dementias. This is an appealing idea from the perspective of other neurodegenerative diseases in that similar mechanisms have been evoked in prion diseases, triplet repeat disorders, and Alzheimer's disease. Nonetheless, direct experimental evidence to support this idea remains elusive.

Thus, while the clinical, neuropathological, genetic, and even biochemical characterization of dementia with Lewy bodies is well underway, definitive understanding of the pathophysiology and therapy await answers to some of these remaining questions. The recent development of a transgenic mouse model of dopaminergic loss and inclusion body formation after overexpression of α-synuclein (Masliah et al., 2000) and the Drosophila model also based on genetic manipulation of α-synuclein (Feany & Bender, 2000), provide important tools for future studies.

Frontotemporal dementia

Bruce L. Miller,[1] Howard J. Rosen[1] and Michael D. Greicius[2]

[1] Department of Neurology, UCSF School of Medicine, San Francisco, CA, USA
[2] Department of Psychiatry and Behavioral Sciences, Stanford, CA, USA

Historically, classification schemas for degenerative dementias were framed around the clinical and pathological phenomenology of the illness. With improved understanding of the molecular basis for many degenerative conditions, traditional taxonomies are being replaced by molecule-based schemas. Nowhere has this transition been more evident than with frontotemporal dementia (FTD) where, until recently, FTD (or Pick's disease) was used to define a group of patients with selective degeneration of frontotemporal cortex in whom Alzheimer's disease (AD) pathology was absent. With the discovery of tau exon mutations (Poorkaj et al., 1998; Spillantini & Goedert, 1998; Clark et al., 1998) and intron mutations (Hutton et al., 1998) in familial cases with selective frontotemporal degeneration, a clinical/pathological syndrome suddenly had a well-defined molecular and genetic basis. This work clarified the importance of tau protein in the pathogenesis of both sporadic and familial FTD and many hoped that this would lead to a molecule-based diagnostic schema for FTD. However, not all cases with tau pathology have selective frontotemporal anatomic involvement and there are many patients with selective frontotemporal degeneration in whom tau pathology is absent (Kertesz et al., 2000). This has left the field somewhat in limbo with many patients falling in between clinical, pathological or molecule-based diagnostic criteria. Thus, although new insights about abnormalities in tau metabolism are an important piece of the FTD story, it is clear that other factors contribute to producing the clinical syndrome that is recognizable as FTD.

Despite still unresolved issues related to nomenclature, FTD represents an important disorder with distinctive epidemiology, genetics, neuropathology, clinical features and treatment. Importantly, it is possible to diagnose most FTD patients during life (Lopez et al., 1999) and to differentiate them from patients with AD. Because FTD has a distinctive pattern or brain degeneration, it offers many clues to the function of the frontal and anterior cortical regions.

Terminology and epidemiology

In recent years FTD has been recognized as a common cause for degenerative dementia. However, in many clinical settings FTD is rarely, if ever, diagnosed. One problem limiting its recognition is that many patients present with psychiatric symptoms (Gustafson, 1993; Lesser et al., 1989) and do not develop a dementia until much later in the course of their illness. Persistent variability in the diagnostic accuracy and diagnostic suspicion from site to site has compounded the confusion related to the epidemiological features of FTD. Indeed, defining the disease has proven difficult from its very beginnings. The term Pick's disease was coined not by Pick, but by two of his students, Onari and Spatz (Berrios, 1996). Although for many decades Pick's disease has been considered as a frontal lobe degeneration associated with neuronal inclusions, Arnold Pick had more interest in focal temporal than focal frontal atrophy. Similarly, the Pick body that carries Pick's name was first described by Alzheimer, and Pick never focused upon the microscopic features of FTD (Berrios, 1996). For many years after Pick's original discoveries, investigators took a restrictive view of the frontotemporal dementias, limiting the diagnosis to cases that demonstrated the classic neuropathological findings of Pick's disease, frontal atrophy with Pick bodies and Pick cells (silver-staining neuronal inclusions). Basing a diagnosis of a degenerative disorder upon the presence or absence of a sometimes-elusive silver-staining inclusion has always been problematic. Many FTD patients have inclusions that do not stain with silver, while other FTD cases lack any cellular inclusions (Nasreddine et al., 1999).

Beginning in the 1980s, investigators began to take a more inclusive view of FTD. Brun and Gustafson from Lund, Sweden and Neary and Snowden from Manchester, England, began considering all cases of non-AD, presenile dementia with frontal lobe atrophy under the category of frontal dementia (Brun, 1987; Neary et al., 1987). Although most investigators continued to separate patients with classical Pick bodies from those without these inclusions, some suggested an even more unified approach classifying all such cases under the category of Pick-Complex disorder (Kertesz et al., 1999). The term FTD was coined in 1994 by the Lund–Manchester groups in an attempt to establish reliable diagnostic criteria for a clinically heterogeneous group of disorders that still shared many pathological features (Brun et al., 1994). Recent advances in molecular genetics have supported the validity of this more inclusive perspective. In 1998 these criteria were modified further and the new diagnostic criteria for FTD divided frontotemporal dementias into three subgroups; primary progressive aphasia, semantic dementia and frontotemporal dementia.

The most frequently cited prevalence figures for FTD come from Europe. Based on clinical, pathologic, and imaging studies, these groups estimate that 12–16% of presenile dementias suffer from frontal lobe atrophy without AD pathology (Neary et al., 1988; Brun, 1987). Fewer than 20% of these cases show the classic pathologic findings of Pick's disease. FTD's true prevalence remains unknown but the disease is relatively common. If AD has a prevalence of four million (Evans et al., 1989) and is somewhere between 10 to 20 times more common than FTD, this would still leave FTD with a prevalence of somewhere between 200 000 and 400 000 cases.

Genetics

Roughly 40% of FTD cases are familial with up to 80% of these familial cases inherited in an autosomal dominant pattern (Gustafson, 1987; Chow et al., 1999). Wilhelmsen and colleagues made a major stride toward defining the genetic basis for this condition in 1994 with linkage of a familial FTD syndrome to chromosome 17 (Wilhelmsen et al., 1994). In 1998 came the discovery of at least ten new exonic or intronic mutations in at least 20 different families with FTD (Poorkaj et al., 1998; Spillantini & Goedert, 1998; Clark et al., 1998; Hutton et al., 1998). These families were extraordinarily diverse both in their clinical and pathological features, despite the fact that they carried nearly identical genetic mutations. In some families clinical features were dominated by frontal lobe degeneration (Lynch et al., 1994), while in others the presentation was shaped by loss of function in the amygdala and anterior temporal lobe (Bird et al., 1999). More recently, cases suggestive of corticobasal ganglionic degeneration (Bugiani et al., 1999) or progressive supranuclear palsy (Reed et al., 1998) have been noted, broadening the phenotype of familial-FTD. Remarkably in one family, a tau mutation led to frontotemporal degeneration in a father with a clinical presentation of corticobasal ganglionic degeneration in the son (Bugiani et al., 1999). Based upon clinical features alone, it is difficult to differentiate a sporadic from a genetic case of FTD.

The neuropathological cases with familial FTD linked to tau mutations show neuronal inclusions that stain positively for tau suggesting abnormal cellular processing of tau (Reed et al., 1998). In some families tau-staining neuronal inclusions alone are prominent, while in others, glial inclusions are also present. Even though neuronal inclusions are evident in most of the families, classical silver-staining Pick bodies are uncommon (Nasreddine et al., 1999). Neurofibrillary tangles are present in some cases, but absent in most. The majority of cases of FTD linked to chromosome 17 have demonstrated a mutation in tau (Heutink, 2000), although four kindreds with linkage to chromosome 17 have yet to yield specific mutations in the tau gene. Recently, Lee and colleagues found that in one of these families an absence of brain tau was a characteristic feature: so-called 'no tau tauopathy'. (Zhukareva et al., 2001). In total, these cases suggest that overexpression or underexpression of tau, or expression of mutated tau represent a major risk factor for FTD. Some even suggested that FTD should be considered a tauopathy.

However, the initial excitement for tau has been tempered. Not all familial cases of FTD are caused by tau gene mutations. At least three families have been identified which do not show linkage to the tau region of chromosome 17 (Gasser et al., 1996) and almost no sporadic cases have demonstrated tau mutations (Rizzu et al., 1999). Estimates of familial FTD cases with a known mutation in tau range from less than 10% up to 40% (Houlden et al., 1999; Rizzu et al., 1999). Similarly, other chromosomal locations have been found in familial FTD including chromosome three (Brown et al., 1995). Additionally, the mixture of FTD and amyotrophic lateral sclerosis has been linked to chromosomes 9 (Hosler et al., 2000) and 15 (K.C. Wilhelmsen et al., personal communication).

Pathology and pathogenesis

The more inclusive view of FTD includes patients with classical Pick's disease as well as those with the other non-

AD dementias with frontal or temporal lobe atrophy. The unifying feature across all these cases is the presence of focal atrophy in the frontal lobes, the temporal lobes, or both. The gross pattern of atrophy in FTD can have a unilateral predominance or it can be symmetrical and bilateral. In the temporal lobes the more anterior regions typically show greater pathology than the posterior regions. The amygdala, for example, shows more involvement than does the hippocampus (Brun, 1999), and the posterior parietal and temporal-occipital regions are relatively preserved. Subcortical structures such as the substantia nigra, putamen, and globus pallidus may show marked involvement by microscopy. Those cases with a motor neuron component also show pathological changes in the anterior horn cells.

The microscopic changes in the affected regions include neuronal loss, synaptic loss, gliosis, and spongiosis often most prominent in the first three cortical layers (Brun, 1993). Some cases of FTD demonstrate swollen neurons with inclusion bodies. Only a minority of the cases with cellular inclusions will exhibit the classic silver staining that is typical of a Pick body. However, in many cases 'Pick-like' inclusions in both neurons and glia that are not silver staining are identified (Nasreddine et al., 1999). Recent work has shown that the silver-staining is due to deposition of three repeat tau rather than the four repeat isoform found in the other inclusions (Delacourte, 1999). Tau immunoreactivity is the most common finding in familial and sporadic FTD. Furthermore, the presence of tau-positive inclusions in progressive supranuclear palsy (PSP) and corticobasal ganglionic degeneration (CBD) has even prompted some to view PSP, CBD, and FTD as clinical variants of a 'tauopathy' (van Slegtenhorst et al., 2000).

Tau is a microtubule-associated protein that binds, stabilizes and promotes the assembly of microtubules (Hong et al., 1998). Depending on how the tau gene is transcribed, the microtubule-binding region of the protein can have either 3 or 4 tandem repeats of a 31–32 amino acid sequence yielding 3Rtau or 4Rtau (Spillantini & Goedert, 2000). Mutations in the tau gene can cause either altered binding properties of tau or changes in the ratio of 3R to 4Rtau. With exon mutations, altered binding properties cause a relative loss of function by destabilizing microtubules and disrupting axonal transport (Hong et al., 1998). Alternatively, altered binding properties may result in a toxic gain of function by providing an excess of free, cytoplasmic tau available to form insoluble protein aggregates. A number of tau gene mutations increase the amount of 4Rtau presumably resulting in a toxic gain of function caused by insoluble protein aggregates (Hong et al., 1998). Tau aggregates typically contain the 4R isoform, although the aggregates found in Pick bodies contain the 3R isoform (Delacourte, 1999). The significance of different filament morphologies within tau aggregates (paired helical filaments, straight filaments) and their differential prevalence in AD vs. FTD remains to be elucidated (Spillantini & Goedert, 2000). Transgenic mice with tau abnormalities have recently been developed and offer promise for better understanding the pathogenesis of FTD.

Mice expressing the P301L human mutations and mice overexpressing human tau develop behavioural and motor changes, remarkably similar to those seen in the human forms of this condition (Lewis et al., 2000; Ishihara et al., 1999). These changes develop within 6 months allowing researchers the opportunity of studying interventions related to abnormal tau processing that might accelerate or slow this process. However, there are many cases of FTD where abnormal tau is not visualized in the brain and tau does not unify all of FTD. Munoz (2000) has emphasized that there are tau-negative and ubiquitin positive inclusions in many of the cases of FTD associated with motor neuron disease and none of the families with both prominent FTD and motor neuron disease have shown tau mutations.

A few studies on the neurochemistry of FTD suggest a specific neurochemical profile. In particular, there are severe losses of brain serotonin, of both pre- and post-synaptic receptors (Sparks et al., 1991). In contrast, FTD is one of the few conditions where cholinergic cell concentration in the nucleus basalis of Meynert is normal (Sparks, et al., 1991). The changes with dopamine are more variable. These neuropathological findings suggest that the AD treatments based upon a cholinergic deficit are unlikely to work with FTD. The clinical symptoms of irritability, depression, compulsions and hyperorality may be explained by the loss of brain serotonin seen with FTD (Miller et al., 1995).

Diagnosis

The mean age of onset for FTD is the sixth decade, although formal diagnosis is often delayed for many years due to the insidious course and early predominance of behavioural symptoms. The clinical presentation of FTD can vary depending on where the disorder begins in the brain. The illness starts in the anterior frontal or temporal lobes (Miller et al., 1993; Hodges et al., 1992; Neary et al., 1987). Lifespan following a diagnosis of FTD can vary considerably with an 8–9 years on average (Rossor, 1999).

A consensus group delineated three main cognitive subtypes of FTD (Neary et al., 1998). The first, referred to as

FTD, is characterized mainly by behavioural changes and develops in the patient with degeneration in the frontal lobes bilaterally or unilaterally in the right frontal lobe. Patients with this subtype will demonstrate loss of normal social interactions and may become withdrawn or disinihibited. Other features include lack of insight or empathy for others, blunted affect, decreased grooming, hyperorality, perseverative behaviours and social inappropriateness (Rosen et al., 2000).

The second subtype is referred to as progressive nonfluent aphasia. These patients display expressive language dysfunction with effortful speech, word-finding difficulty, grammatical errors and relatively preserved comprehension. Behaviour and social conduct are often remarkably spared until late in the illness in patients with progressive non-fluent aphasia. Complicating this diagnosis is that some patients with selective left parietal degeneration present with non-fluent aphasia and many of these individuals suffer from AD, not FTD (Galton et al., 2000).

The last subtype outlined by the consensus group is semantic dementia (Snowden et al., 1989). Here, the bulk of the pathology occurs in the left anterior temporal lobe, but most cases also show involvement of the right anterior temporal lobe. These patients progressively lose their semantic knowledge of the world (facts, words, objects, etc.). The content of speech eventually deteriorates with loss of language specificity. Hawks become 'birds', then 'animals' and then 'things' (Graham et al., 1999). Naming and comprehension are impaired due to loss of word knowledge. Many of the semantic dementia cases have right as well as left temporal degeneration. This group shows loss of insight, disinhibition, disregard of interpersonal space, and antisocial behaviour (Miller et al., 1993). Those with the right temporal variant exhibit loss of empathy, irritability, fixed and rigid thinking, poor grooming, and decreased facial expression (Edwards-Lee et al., 1997). These clinical distinctions are most apparent earlier in the course and many ultimately progress to more global impairment in frontal and temporal lobe functions.

The current terminology for FTD is complex, even for the experienced neurologist. In particular, it excessively relies upon language based clinical syndromes such as semantic dementia. However, most FTD patients can be reliably diagnosed during life (McKhann et al., 2001). In one study, hyperorality, loss of personal conduct, disabling compulsions, progressive loss of speech and sparing of drawing separated 30 FTD patients from 30 with AD (Miller et al., 1997). In a recent study of autopsy-proven FTD cases we found that loss of social conduct, relative absence of amnesia and hyperorality separated the vast majority of FTD patients from those with AD.

In addition to the various cortical symptoms, some FTD patients will develop Parkinsonian features or symptoms of motor neuron disease. The Parkinsonian features overlap with progressive supranuclear palsy with falls, axial rigidity and ophthalmoplegia more common than tremor. Knopman and colleagues (Knopman et al., 1990; Munoz, 2000) suggest that nearly 80% of FTD patients demonstrate midbrain degeneration. In our cohort, nearly 15% of FTD patients developed symptoms of motor neuron disease during life.

Given the pronounced variation in initial presentation and the common early prominence of behavioural symptoms, misdiagnosis is a common problem for patients and their families. Clinical criteria alone can be useful in distinguishing FTD from AD. Increasingly, however, neuroimaging is being relied upon to increase both the sensitivity and specificity of the diagnosis. The addition of SPECT to clinical criteria has been shown to improve diagnostic accuracy to as high as 90% (Read et al., 1995). FTD patients tend to show bifrontal and bitemporal hypoperfusion vs. the typical temporal parietal defects seen in AD (Miller et al., 1991). Specific patterns of tissue loss which relate to the clinical presentation can often be appreciated with MRI scanning as well (see Fig. 19.1, in colour plate section). Additionally, FTD patients show global atrophy of the corpus callosum (Kaufer et al., 1997), while AD patients show selective atrophy of the third and fourth segments of the callosum. Structural MRI has also shown promise as a test to help distinguish FTD from AD and other dementias (Miller & Gearhart, 1999).

Treatment

There are few diseases in all of medicine that cause greater difficulties for a family than does FTD. Poor judgement in the work place, financial arena or home environment can lead to loss of income, financial devastation or legal difficulties. Because loss of insight is such a prominent feature of FTD it is often difficult to reason with the FTD patient. When family members are probed, they often describe puzzling social withdrawal and loss of concern in the patient that profoundly disrupts the family unit. This, in turn, can diminish the empathy for these patients that they truly deserve. Because apathy intervenes in nearly all cases, the later stages of FTD can be easier to manage than the initial stages (Levy et al., 1996).

Treatment of FTD is limited to the behavioural disorders and there are no known preventive therapies or therapies that improve cognition. No placebo-controlled studies of FTD have been performed, although open-label studies

suggest that selective serotonin reuptake inhibitors may be beneficial in management of the disinhibition, depressive symptoms, carbohydrate craving, and/or compulsions frequently encountered in FTD (Swartz et al., 1997). Support for such an approach can be found in molecular studies showing low serotonin receptor binding in FTD (Sparks et al., 1991). Some behavioural symptoms may require more aggressive pharmacotherapy, including the use of antipsychotics, in which case, as with AD, the newer, atypical agents are favoured in order to minimize Parkinsonian side effects. Anticholinesterase medications do not appear to improve cognitive status and can worsen irritability (Perry, 2001).

Consciousness and its disorders

Antonio R. Damasio

Department of Neurology, University of Iowa College of Medicine, Iowa City, IA, USA

Background and working definition of consciousness

It is generally acknowledged that understanding the neurobiological mechanisms responsible for consciousness is one of the most difficult tasks in the agenda of neuroscience. At first glance, however, the notion of consciousness appears uncontroversial, and it has even been claimed that since everyone is conscious and the notion of consciousness obvious, there is hardly any need to define the phenomenon. Clinicians, neurologists and others tend to believe that determining whether consciousness is present or not is a simple matter. The view presented in this chapter, however, is less optimistic. Although experts and non-experts can come to an agreement on what constitutes the essence of consciousness, the full scope of the phenomena described under that term requires careful consideration and a provisional definition that can guide clinical evaluations and research. Both fundamental scientists and neurologists need a working concept of consciousness, and nothing prevents us from possibly modifying that concept in the future according to new evidence. Moreover, given the particular nature of consciousness, there are no standard neuropsychological tools to assess its impairments, and there may never be. Also, because the study of those phenomena is of recent vintage, we do not have yet available diagnostic imaging procedures for the evaluation of such impairments. For these reasons, the assessment of patients with impairments of consciousness relies primarily on systematic and comprehensive clinical observations, complemented by a good history and by fine structural neuroimaging and electrophysiologic studies.

Whether one consults a good dictionary, a neurology textbook, or a psychology textbook, the current definitions of consciousness one is likely to encounter are fairly similar: the definitions state that consciousness is the ability to be aware of self and surroundings. These are hardly ideal definitions, considering that consciousness is being defined in terms of awareness and that awareness and consciousness are usually regarded as synonyms. In spite of their awkwardness, however, these definitions capture something that we can agree on: 'consciousness is the ability to know of our own existence and of the existence of objects and events, inside and outside our organism'. Our proposed working definition of consciousness is in line with this idea and states that consciousness is 'a momentary creation of mental knowledge which describes a relation between the organism, on the one hand, and an object or event, on the other'; the definition also indicates that 'the presence of consciousness, as a mental phenomenon, is accompanied by certain observable behaviours'. To be conscious, at a given moment, is to have a sense of our own organism in the act of knowing an object (or event). Consciousness is not just about the object being known; it is always about the owner of the organism in the process of knowing. Individuals whom we describe as conscious are generating, continuously, 'moments of consciousness' which conjoin organism and object. They are generating in a seamless manner multiple and consecutive periods of mental knowledge along with the external behaviours that accompany such knowledge. (For more on the cognitive and neuroscientific background for this definition see Damasio, 1998, 2000. For other views on the phenomena of consciousness from philosophical, cognitive and neurobiological perspectives see Baars, 1988; Crick, 1994; Dennett, 1991; Edelman, 1989; Metzinger, 1995, 2000; Searle, 1992.)

A practical consequence of this definition is that consciousness must be considered from two standpoints: the external (or behavioural), and the internal (cognitive or mental). Taking the external standpoint, the human organism can be said to be conscious when it exhibits sustained

attention towards objects and events in its environment and when it gives evidence of sustained purposeful behaviour relative to those objects and events. The temporal scale for the qualification of 'sustained' is in the order of minutes, not seconds (a practical yardstick is 10 minutes). From the internal standpoint, a human organism can be said to be conscious if its mental state represents objects and events in relation to itself, in other words, if the representation of objects and events is accompanied by a sense that the organism is in the act of perceiving, that the perception is owned by the organism and established in its perspective.

The fundamental components of consciousness: mind and self

From the internal standpoint, we regard consciousness as a combination of two related processes. The first is the process of generating inside the human organism the mental patterns we call images, relative to an object or event. (By object we mean entities as diverse as a person, a place, a melody, state of localized pain, or a state of feeling; by image we mean a mental pattern in any of the sensory modalities, e.g. a sound image, a tactile image, the image of a state of pain or well being that is conveyed by visceral senses; images convey the physical characteristics of an object or the reaction of like or dislike one may have for an object or the plans one may formulate for it, or the relationships of the object to other objects.) The images that constitute the fabric of the mind are integrated spatially and temporally, across sensory modalities. For example, when we watch a person talking, we generate visual images of the person and also auditory images of her speech, yet those two streams of images are synchronized and spatially coherent, as we can verify by noting that the lip movements are in sync with the speech sounds, and the sound waves come from the appropriate region in space.

This first process of consciousness, then, consists of generating neural patterns in neural circuits and turning those neural patterns into the mental patterns we call images. When we commonly use the term consciousness, however, and certainly when we talk about consciousness according to the working definition provided earlier, we are referring to more than this first process of 'mind', to more than the process of generating spatially and temporally integrated mental images. We are also referring to a second process, that of engendering a sense of 'self in the act of knowing', a process that is parallel to, and combined with that of, engendering mental patterns for an object. This process allows the images of an object and of the complex matrix of relations, reactions, and plans related to it, to be sensed as the unmistakable mental property of an automatic owner who becomes an observer, a knower and a potential actor. This process allows us to know that we own our minds, and that the contents in our minds are shaped in a particular perspective, that of the individual inside of whom the mind is formed. This second process of consciousness allows us to construct not just the mental patterns of objects and events, the temporally and spatially unified images of persons, places, melodies, and of their relationships, but also the mental patterns which convey, automatically and naturally, the sense of a self in the act of knowing. The process of mind and the process of self are so intimately related that the latter is nested within the former. In effect, the second process is that of generating the appearance of an owner and observer for the mind, within that same mind (Damasio, 2000).

Kinds of consciousness

Consciousness can be separated into simple and complex kinds, and the evidence from neurological patients makes the separation transparent. The simplest kind, which we call core consciousness, provides the organism with a sense of self about one moment, now, and about one place, here. The scope of core consciousness is the here and now. Core consciousness does not illuminate the future, and the only past it vaguely lets us glimpse is that which occurred in the instant just before. The complex kind of consciousness, which we call extended consciousness and of which there are many levels, provides the organism with an elaborate sense of self, and places that self in individual historical time, in a perspective of both the lived past and the anticipated future. Core consciousness is a simple, biological phenomenon; it has one single level of organization; it is stable across the lifetime of the organism; and it is not dependent on conventional memory, working memory, reasoning, or language. Extended consciousness is a complex biological phenomenon; it has several levels of organization; and it evolves across the lifetime of the organism.

Extended consciousness is built on the foundation of core consciousness. Neurological impairments reveal that impairment of extended consciousness allows core consciousness to remain intact. This is exemplified by patients with profound disturbances of autobiographical memory caused by global amnesia. By contrast, impairments of core consciousness entail the collapse of extended consciousness, as happens in akinetic mutisms, absence seizures and epileptic automatisms, persistent vegetative state, coma, deep sleep (dreamless), and deep anesthesia. When core consciousness fails, in keeping with its foundational nature, extended consciousness fails as well.

To the two kinds of consciousness, correspond two kinds of self. The sense of self which emerges in core consciousness is the core self, a transient entity, ceaselessly recreated for each and every object with which the brain interacts. Our traditional notion of self, however, is linked to the idea of personhood and identity, and corresponds to a non-transient collection of unique facts and ways of being which characterize a person, the autobiographical self. The autobiographical self depends on systematized memories of situations in which core consciousness was involved in the knowing of the most invariant characteristics of an organism's biography (Damasio, 2000).

Other components of consciousness

In addition to separating the processes of mind and self within the larger process of consciousness, and in addition to distinguishing kinds of consciousness related to their complexity, it is important to tease apart subcomponents that contribute to consciousness but are not the same as consciousness. This componential analysis is vital both for research and for clinical assessment, and is usually neglected to the peril of proper research and diagnosis. For example, it is possible to separate consciousness in general from functions such as wakefulness, low-level attention, working memory, high-level (focused) attention, conventional memory, language, and reasoning.

Core consciousness is not the same as wakefulness or low-level attention, although it requires both to operate normally. Patients with absence seizures or automatisms or akinetic mutism are technically awake but not conscious. On the other hand, patients who lose wakefulness can no longer be conscious, the only exception to this rule being dream sleep.

Core consciousness is also not the same as holding an image over time, a process known as working memory (see Baddeley, 1992; Smith et al., 1996). The sense of self and of knowing is so brief and so abundantly produced, that there is no need to hold it over time in order for it to be effective. However, working memory is vital for the process of extended consciousness.

Core consciousness does not depend on making a stable memory of an image or recalling it, i.e. it does not depend on the processes of conventional learning and memory. Core consciousness is not based on language either. No less importantly, core consciousness is not the same as manipulating an image intelligently in processes such as planning, problem solving, and creativity. Patients with profound defects of reasoning and planning may exhibit normal core consciousness although the higher levels of extended consciousness may be compromised. In brief, wakefulness, image making, attention, working memory, conventional memory, language, intelligence, can be separated by appropriate analysis and investigated separately in spite of the fact that they operate in concert to permit consciousness or assist with functions that require consciousness, such as reasoning.

The relation between emotion and core consciousness, on the other hand, is quite different. Emotion and core consciousness are associated. Patients whose core consciousness is impaired do not reveal emotion by facial expression, body expression, or vocalization. The entire range of emotion, from background emotions to secondary emotions, is usually missing in these patients. By contrast, patients with preserved core consciousness but impaired extended consciousness have normal background and primary emotions. This association suggests that some of the neural devices on which both emotion and core consciousness depend are located within the same region.

Consciousness as a central resource

Disturbances of core consciousness affect the whole of mental activity and the full range of sensory modalities. Patients with disturbed core consciousness, from those with coma and persistent vegetative state to those with epileptic automatisms, akinetic mutisms, and absence seizures, have no island of preserved consciousness and the impairment covers mental images originating from all sensory modalities. Core consciousness serves the entire compass of mental images, i.e. of thoughts that can be made conscious. It is a central resource.

By contrast, the impairment of image making within one sensory modality, for example, visual or auditory, compromises only the conscious appreciation of one aspect of an object, e.g. the visual or the auditory, but does not even compromise consciousness of the same object through a different sensory channel, e.g. olfactory or tactile. Naturally, because consciousness operates on images, an impairment of all image-making capability abolishes consciousness altogether. The sensory processing for a sensory modality may be lost in its entirety as in cortical blindness, or one aspect of the modality may be lost, as in achromatopsia, or a substantial part of a process may be disrupted, as in prosopagnosia (Damasio et al., 1990). Those patients have a disturbance of the processing of the object to be known, but they have normal core consciousness for all the images formed in other sensory modalities, and they even have normal core consciousness for the specific stimuli that they fail to process normally. Patients who cannot recognize a previously familiar

face have normal core consciousness for the stimulus that confronts them, and are fully aware that they do not recognize a face that others expect them to. Those patients have normal core consciousness, and a normal extended consciousness outside of the island of defective knowledge. Their circumscribed defect underscores the fact that core consciousness and its resulting sense of self is a central resource.

The fact that core consciousness is separable from other cognitive processes does not mean that consciousness does not have an influence on them. On the contrary, core consciousness assists with the focusing and enhancement of attention and working memory; favours the establishment of memories; is indispensable for the normal operations of language; enlarges the scope of intelligent manipulations of images, e.g. planning, problem solving and creativity.

The clinical evaluation of consciousness

One of the notable areas of recent progress in neurology and neuroscience came from the development of standardized neuropsychological testing instruments which allow both clinicians and researchers to measure a large range of cognitive performances, from those related to reasoning, attention, and perceptual abilities, to those related to learning and memory, language, and personality. As noted, however, no comparable tests are available or are likely to become available to assess most impairments of consciousness. More often than not, consciousness is either normal (in which case a large range of other neuropsychological functions can be evaluated and found intact or disturbed), or so impaired that assessment of any neuropsychological functions is only possible indirectly by means of careful clinical observations.

Because the study of human consciousness requires both internal and external views, the investigation of consciousness is partially indirect. Behavioural acts are expressions of the mental process, but they are not the same thing as the mental process that precedes or accompanies them. The same is true of any kind of encephalogram, electrical or magnetic, and of functional imaging scans. All of these methods of analysis capture only correlates of the mental process.; they are not the same as the mental process. The fact that mental processes are only accessible to the organism who owns them, however, does not preclude their characterization through appropriate cognitive approaches, and the connection between the result of those characterizations and the correlates obtained through external approaches.

Table 20.1. The key areas of behavioural observation in the assessment of consciousness

State of wakefulness
Presence of background emotions
Presence of basic and sustained attention
Presence of purposeful behaviour

As noted, although consciousness occurs in the interior of an organism it is associated with a number of external manifestations. Those manifestations do not translate the internal process in the same direct way that a spoken sentence translates a thought, but there they are available to observation as correlates and signs of the presence of consciousness. Based on what we know about private human minds and on what we know and can observe of human behaviour, it is possible to establish a three-way correspondence among: (*a*) certain external manifestations, e.g. wakefulness, background emotions, attention, specific behaviours; (*b*) the corresponding internal manifestations of the human being having those behaviours as reported by that human being; and (*c*) the internal manifestations that we, as observers, can verify in ourselves when we are in circumstances equivalent to those of the observed individual. This three-way correspondence permits us to make reasonable inferences about human internal mental states based on external behaviours.

In brief, the contemporary approach to studying the biological basis of the private human mind involves two steps. The first step consists of observing and measuring the actions of an experimental subject; or collecting and measuring the reports of internal experience offered by a subject or both. The second step consists of relating the collected evidence to the measured manifestation of one of the neurobiological phenomena we are beginning to understand, at the level of molecules, neurons, neural circuits, or systems of circuits.

The evaluation of the state of consciousness in a neurological or psychiatric patient should concentrate on analysing their wakefulness, background emotions, attention, and purposeful behaviour. Let us consider these varied processes individually (Table 20.1).

Wakefulness

Wakefulness is easy to establish on the basis of a few objective signs. The eyes of the subject should be open; the muscular tone should be compatible with movements against gravity; and the electroencephalogram should reveal the

characteristic awake EEG pattern. Normal consciousness requires wakefulness, but the presence of wakefulness does not guarantee normal consciousness. As noted below, patients with impaired consciousness in conditions such as persistent vegetative state, epileptic automatisms, and akinetic mutisms, are technically awake. Wakefulness is disrupted in coma, general anesthesia, and during episodes of fainting.

Background emotion

The term emotion usually conjures up the primary emotions, e.g. fear, anger, sadness, happiness, disgust, or the secondary emotions, e.g. embarrassment, guilt, pride, but the field of emotion also includes background emotions, those that occur in continual form when the organism is not engaged in either primary or secondary emotions. Background emotions are experienced in configurations of body movement, in the face, the trunk and the limbs, and suggest to the observer states such as fatigue or energy; discouragement or enthusiasm; malaise or well-being; anxiety or relaxation. The continuity of background emotions is an important fact to consider in our observation of normal human behaviour. When we observe someone with intact consciousness, well before any words are spoken, we find ourselves presuming the subject's state of mind. Correct or not, the presumptions are largely based on the emotional signals available in the subject's behaviour. Importantly, normal consciousness is accompanied by background emotions, and the absence of background emotions usually betrays impairments of consciousness.

Attention

Besides exhibiting wakefulness and background emotions, conscious subjects also exhibit attention. They orient themselves toward objects and concentrate on them as needed. Eyes, head, neck, torso, and arms move about in a coordinated pattern which establishes an unequivocal relationship between subject and certain stimuli in their surround. The mere presence of attention toward an external object usually signifies the presence of consciousness, but there are exceptions. Patients in states of so-called akinetic mutism, whose consciousness is impaired, can pay transient attention to a salient object or event, for example, a phone ringing, a tray with food, an observer calling their name. Attention only guarantees the presence of consciousness when it can be sustained, over a substantial period of time, focused on the objects or events that must be considered for behaviour to be appropriate in a given context. This period of time is measured in many minutes and hours rather than seconds. As noted, a sample of 10 minutes is usually sufficient. Another important qualification is needed. Lack of attention toward an external object may indicate that attention is being directed toward an internally represented mental object and does not necessarily indicate impaired consciousness. This is the basis for absentmindedness. Sustained failure of attention as happens in drowsiness, confusional states, or stupor, is associated with the dissolution of consciousness. Attention is entirely disrupted in coma, general anesthesia, and episodes of fainting.

Conscious subjects are attentive to certain objects and concentrate on them, something that matches our own introspection when we think about our own mental events in comparable situations. Attention and consciousness are thus related, the former being necessary for the latter, but neither attention nor consciousness are monoliths. They occur in levels and grades, and they influence each other as they become more complex. Low-level attention is needed to engage the processes that generate core consciousness, but the process of core consciousness drives higher-level attention toward a focus.

Purposeful behaviour

The presence of adequate and purposeful behaviour is easy to establish in patients who can converse with the observer. When there are impairments of communication, however, the observation requires more detail. Conscious subjects behave purposefully toward the stimuli on which they concentrate, which means that their behaviour is part of an immediately recognizable plan that could only have been formulated by an organism cognizant of its immediate past, present, and anticipated future conditions. The sustained purposefulness and adequateness of behaviour requires the presence of consciousness even if consciousness does not guarantee purposeful and adequate behaviour. By sustained, we mean, once again, minutes to hours. A sample of 10 minutes, complete with evidence from the patient's history may be sufficient.

Sustained and adequate behaviour is accompanied by a flow of emotional states as part of their unfolding. The background emotions discussed above continuously underscore the subject's actions. Telltale signals include the overall body posture and the range of motion of the limbs relative to the trunk; the spatial profile of limb movements, which can be smooth or jerky; the speed of motions; the congruence of movements occurring in different body tiers such as face, hands, and legs; and last, and perhaps most important, the animation of the face. Even when the observed subject speaks, emotional aspects of the communication are separate from the content of the words and

sentences spoken. Moreover, specific emotions often succeed stimuli or actions that seemingly motivate them in the subject, as judged from the perspective of the observer. In effect, normal human behaviour exhibits a continuity of emotions induced by a continuity of thoughts.

The impairment of consciousness is not compatible with the maintenance of purposeful behaviour.

Confusing terms

On occasion, terms such as alertness and arousal are incorrectly used as synonyms of wakefulness, attention, and even of consciousness. The term alertness should be used to signify that the subject is both awake and disposed to perceive and act. The proper meaning of alert is somewhere between 'awake' and 'attentive'. The term arousal denotes the presence of signs of autonomic nervous system activation such as changes in skin colour (rubor or pallor), behaviour of skin hair (piloerection), diameter of the pupils, sweating, sexual erection and so on, which correspond to the lay term of excitement. Subjects can be awake, alert, and fully conscious without being aroused, in this sense, and subjects can be aroused, in this sense, during sleep and even coma, obviously when they are not awake, attentive or conscious.

Disorders of consciousness

A clinical classification of the disorders of consciousness

Consciousness is disrupted in a number of neurologic conditions and the profile of impairment varies with the neural systems that are rendered dysfunctional. For practical purposes, we classify the disorders of consciousness according to those profiles. In the largest group of these disorders both core consciousness and extended consciousness are impaired. The impairment or intactness of the other components of consciousness that we discussed earlier permit a further subclassification. In another group of disorders extended consciousness is impaired but not core consciousness.

An overview of the classification we have adopted is as follows.

Disruption of consciousness accompanied by disruption of wakefulness

The examples are coma, the transient loss of consciousness caused by head injury or fainting, and general (deep) anesthesia. The cases of coma caused by structural lesions reveal that the primary site of dysfunction is in structures of the upper brain stem, hypothalamus, and thalamus (Plum & Posner, 1980), although dysfunction in brainstem entails dysfunction elsewhere in the brain, namely in the cerebral cortex. In a recent study of 50 patients with brainstem stroke, we found that all 12 patients whose coma was caused by a structural lesion, had lesions in the upper brainstem tegmentum, involving either pons or midbrain or both (Parvizi et al., 2000). It is now apparent that, at least in some forms of general anesthesia, for example, propofol anesthesia, the anesthetics act in these same regions (Fiset et al., 1999).

In situations of coma caused by metabolic imbalance, drug overdose, and circulatory collapse, brain dysfunction is far more pervasive and compromises both cortical and subcortical territories (Plum & Posner, 1980).

Disruption of consciousness with preserved wakefulness but defective minimal attention/behaviour

Absence seizures and persistent vegetative state are the prime examples. Absence seizures are related to dysfunction in regions such as the thalamus and the anterior cingulate cortex and have a distinctive electroencephalographic pattern.

Persistent vegetative state can be distinguished from coma in that vegetative patients have cycles of sleep and wakefulness as shown by the opening and closing of their eyes and, sometimes, also by their EEG patterns. Vegetative states are typically caused by dysfunction in the same set of structures of the upper brainstem, hypothalamus, and thalamus that are compromised in coma, and often vegetative states become a stage in the recovery of comatose patients. But vegetative states can also be caused by extensive cortical damage affecting both hemispheres as, for example, in carbon monoxide poisoning (see Plum & Posner, 1980).

Disruption of consciousness with preserved wakefulness and preserved minimal attention/behaviour

The prime examples are akinetic mutisms and epileptic automatisms. Akinetic mutisms are caused by dysfunction in the cingulate cortex, in the basal forebrain, in the thalamus, and in the medial, parietal cortex surrounding the posterior cingulate cortex (see section below and Damasio, 2000, Chapter 8).

Selective disruption of extended consciousness with preserved core consciousness

The prime examples occur with disorders of autobiographical memory, as seen in permanent and transient global amnesia (see below and Damasio, 2000).

Further assessment of patients with impairments of consciousness

The several varieties of impaired consciousness, coma, persistent vegetative state, deep anesthesia, afford little opportunity for behavioural analyses because nearly all behavioural manifestations of consciousness are abolished, and all or nearly all the internal manifestations are presumed abolished as well. The notion that consciousness is suspended, in such situations, is an intuition based on solid reflections on our own condition and on equally solid observations of the behaviour of others. The notion is also supported by the rare but valuable reports of persons who return to consciousness after being in coma, and by reports of being placed under anesthesia and returning to consciousness. Patients can recall the loss of consciousness on the way to coma, much as we can recall the induction of general anesthesia, and both patients and non-patients can recall the return to knowingness. However, nothing at all is recalled of the intervening period, which can span weeks or months in the case of coma or vegetative state. It is reasonable to assume, given all the evidence, that little or nothing was going on in the mind in such circumstances.

Three groups of patients, however, afford some opportunity for behavioural analyses. One group is made up of patients with a complicated phenomenon known as epileptic automatism. The other group brings together patients who, as a result of a variety of neurologic diseases, develop a condition known by the blanket term akinetic mutism. In both groups, core consciousness and extended consciousness are profoundly affected, and yet not all of the manifestations of consciousness are abolished, thus allowing for the analysis of a residual performance. A third group is made up of patients with global amnesia in whom extended consciousness is compromised but core consciousness is intact.

Epileptic automatisms

Epileptic automatisms can appear as part of seizures or immediately following seizures (Penfield & Jasper, 1954; Penry et al., 1975). The most revealing, in relation to the phenomena of consciousness are associated with absence seizures, although automatisms are also seen in association with so-called temporal-lobe seizures. Absence seizures are one of the main varieties of epilepsy, in which consciousness is momentarily suspended along with emotion, attention, and purposeful behaviour. The disturbance is accompanied by a characteristic pattern in the EEG. Absence seizures are of great value to the student of consciousness, and the typical variety of absence seizure is one of the most pure examples of loss of consciousness, the term absence being shorthand for 'absence of consciousness'. The absence automatism that follows an especially long absence seizure is perhaps the purest example of all.

Patients so affected interrupt their behaviours abruptly (e.g. stop in the middle of a sentence) and freeze whatever movement was being performed, and stare blankly, the eyes focused on nothing, the face devoid of any expression, a meaningless mask. The patients remain awake, the eyes remain open and the muscular tone is preserved. The patients do not fall, or have convulsions, or drop whatever they are holding. This state of suspended animation may last for as little as 3 seconds, and for as long as tens of seconds. The longer it lasts, the more likely it is that absence proper will be followed by absence automatism, which can take a few seconds or many. As the automatism starts, the events are not unlike the unfreezing of film images when you release a freeze-frame control. As the patients unfreeze they look about, vacantly, their faces remaining a blank, with no recognizable emotional expression. They may smack their lips, fumble with clothes, get up and move without colliding with objects, and execute correctly a number of isolated actions that will never form a coherent pattern. One of several scenarios might unfold. In the most likely scenario, the patient might stop and stand somewhere in the hallway, appearing confused; or he might sit on a bench, if there were one. But the patient might possibly enter another room or continue walking. In the most extreme variety of such episodes, in what is known as an 'epileptic fugue', the patient might even get out of the building and walk about in a street. To a good observer he would have looked strange and confused, but he might get by without any harm coming to him. Along the trajectory of any of these scenarios, most frequently within seconds, more rarely within a few minutes, when the automatism episodes come to an end, the patients look bewildered. Consciousness returns as suddenly as it disappeared. The patients have no recollection whatsoever of the intervening time. They do not know what their organisms were doing during the episode. They remember what went on before the seizure and can retrieve those contents from memory, an indication that their learning mechanisms were intact prior to the seizure. They immediately learn what goes on after the seizure ends, a sign that the seizure did not produce a permanent impairment of learning. But the events that occur during the period of seizure are not committed to memory (or are not retrievable if they have been).

When the patients are interrupted at any point during the episode, they look bewildered or indifferent. They do

Table 20.2. The main sites of structural brain damage associated with impaired consciousness

The mesial parietal cortices (especially in precuneus)
The *right* somatosensory cortex complex (insula, SII, and SI)

not know who they or the observers are, spontaneously or upon specific questioning. The contents that make up a conscious mind are missing, and accordingly there are neither verbal reports nor intelligent actions. The patients remain awake and attentive enough to process the object that comes next into their perception, but that may be all that is going on in their minds. There is no evidence of plan, of forethought, of sense of individual wishing, wanting, considering, believing. There is no sense of self.

During such states, the presence of an object promotes the next action and that action may be adequate within the microcontext of the moment, e.g. opening a door. But that action, and other actions, will not be adequate in the broader context of circumstances in which the patient is operating. As one watches actions unfold, one realizes that they are devoid of ultimate purpose and are inappropriate for an individual in that situation (Table 20.2).

Akinetic mutisms

Another important source of information regarding impaired consciousness comes from the study of patients with akinetic mutism, a term suggestive of what goes on externally, but fails to account for the inside view. From all the available evidence, consciousness is severely diminished or even suspended altogether.

Akinetic mutism is often produced by bilateral cerebrovascular lesions in the mesial regions of the frontal lobe. The cingulate cortex, along with nearby regions is almost invariable damaged. Patients become suddenly motionless and speechless, and remain so for weeks or months. They lie in bed with eyes open but with a blank facial expression. When they catch an object in motion, they may track it for a few instants, eyes and head moving along for a moment, but the non-focused staring is rapidly resumed. The term neutral conveys the equanimity of these patients' facial expressions, but their bodies are no more animated than their faces. They may make a normal movement with arm and hand, but in general their limbs are in repose. Body and face never express any emotion, background, primary, or secondary, in response to the many stimuli that would normally evoke such emotions.

When asked about their situation, the patients are invariably silent, although, after much insistence they may say their names. They have nothing to say about the events leading to their admission, their past or present. They do not react to the presence of relatives or friends. As they emerge from this state and gradually begin to answer some questions, the patients have no recall of any particular experience during their long period of silence; they do not report having fear or anxiety or wishing to communicate. Unlike the patients with locked-in syndrome, akinetic mutes seem not to have had any sense of self and surroundings, any sense of knowing, for most of their akinetic mute period.

In some patients with advanced stages of Alzheimer's disease consciousness is also impaired, and in a manner similar to the one just described for akinetic mutism. Early in the disease, memory loss dominates the clinical presentation and consciousness is intact, but as the ravages of Alzheimer's deepen, one often finds a progressive degradation of consciousness. Unfortunately, textbooks and lay descriptions of Alzheimer's emphasize the loss of memory and the early preservation of consciousness and often fail to mention this important aspect of the disease. The decline first affects extended consciousness by narrowing its scope progressively to the point at which virtually all semblance of autobiographical self disappears. Eventually, it is the turn of core consciousness to be diminished to a degree in which even the simple sense of self is no longer present. Wakefulness is maintained and patients respond to people and objects in elementary fashion, but in a matter of a few seconds, the continuity of the patient's attention is disrupted, and the lack of overall purpose becomes evident. It is interesting to note that several brain regions whose integrity is necessary for normal consciousness are severely damaged in Alzheimer's disease. This is true of nuclei in the brainstem tegmentum, as has been shown recently by Parvizi et al. (2000), who demonstrated a selective involvement in some brainstem nuclei by both neurofibrillary tangles and amyloid plaques. This is also true of the posterior cingulate cortex and surrounding mesial parietal regions (Van Hoesen & Damasio, 1987).

Global amnesia

Loss of core consciousness entails the compromise of extended consciousness, but the converse is not true. Patients in whom extended consciousness is compromised retain core consciousness. The most notable exam-

ples of isolated impairments of extended consciousness occur acutely in transient global amnesia (TGA). Beginning acutely and lasting for a period of a few hours, an otherwise normal individual is suddenly deprived of the access to records that have been recently added to the autobiographical memory. The objects and events processed in the instants, minutes and hours before the onset of TGA, are no longer available to the mind. On occasion, nothing that has happened in the days prior to the beginning of TGA is available at all (Damasio, et al., 1983).

Because our memory constantly includes records of the events that we anticipate, it follows that patients struck by TGA do not have available any record of the intended plans for the minutes, hours, or days that lie ahead. Patients with TGA are thus deprived of both personal historical provenance and personal future, but retain core consciousness for the events and objects in the here and now. When patients fail to recognize a particular situation, there is core consciousness for the fact that some aspect of knowledge is no longer present. In spite of adequate consciousness for the current objects and actions the situation fails to make sense to the patient because, without an updated autobiography, the here and now is not meaningful. The predicament of TGA patients reveals the significant limitations of core consciousness. Without a way of explaining where current objects come from along with the motive for the current actions, the here-and-now is an indecipherable puzzle. This is the reason why TGA patients constantly repeat the same anxious questions: Where am I? What am I doing here? How did I come here? What am I supposed to be doing? The patients tend not to ask who they are because they often retain a basic sense of their persons, although even that sense is almost always impoverished. In conclusion, while patients with epileptic automatisms are good examples of the suspension of core consciousness and of everything that depends on it (core self, autobiographical self, extended consciousness), patients with TGA are a good example of suspended extended consciousness and autobiographical self, with the preservation of core consciousness and core self.

The loss of extended consciousness is seen in other conditions. One is the stable global amnesia caused by bilateral temporal lobe damage in patients with herpes simplex encephalitis (Tranel et al., 2000). Another condition is posttraumatic amnesia, one of the frequent consequences of acute head injuries. In such cases, the drama of TGA is frequently played in a matter of minutes. While the amnesia lasts, the patient is confined to core consciousness. Finally, extended consciousness is also impaired in Alzheimer's disease. When the loss of memory for past events is marked enough to compromise autobiographical records, the autobiographical self is gradually reduced and extended consciousness collapses. Only later in the progression of the disease does core consciousness collapse as well.

Ancillary tests

It has long been known that there is an electroencephalographic pattern characteristic of the awake state. Moreover the electroencephalogram can identify patterns characteristic of different types of seizure, of coma, and of persistent vegetative state. The electroencephalogram is thus an important complement to clinical observation in the assessment of consciousness (see Chapter 00).

By far the most important ancillary information for a clinician who is evaluating a patient with impaired consciousness comes from structural imaging, namely from magnetic resonance (MR). Leaving aside the situations of coma due to drug overdose and metabolic imbalance, most significant impairments of consciousness are associated with structural damage in a number of critical territories: (i) the brainstem tegmentum, especially at pontine and midbrain levels; (ii) the diencephalon, i.e. the hypothalamus and thalamus; (iii) the cingulate cortex, in its entirety, and the mesial parietal territories which surround the posterior section of this region, namely in the precuneus; (iv) the right hemisphere complex of somatosensory cortices formed by the insula, and the secondary (SII) and primary somatosensory cortices (SI).

The results of functional imaging tests are somewhat less helpful in clinical management, although they can provide important information especially for research. Cerebral blood flow is generally depressed in the most severe disorders of consciousness, namely, coma and persistent vegetative state, even when the cause is structural and confined to the brainstem (Laureys et al., 1999a, b), although on occasion islands of nearly intact blood flow may be seen (Plum et al., 1998). Notably, conditions such as locked-in syndrome do not reveal significant depressions of cerebral blood flow. Of interest, patients in persistent vegetative state who were studied with functional imaging, revealed activation of inferotemporal areas that are normally engaged by processing faces, when faces were flashed in their retinas (Meno et al., 1998). This result supports the notion that preserving the neural basis for image processing by no means guarantees that the processed images become conscious.

Reflection on the neuropathological correlates of the most frequent impairments of consciousness reveals one important fact. Most of the sites of brain damage associated with a significant disruption of consciousness share

one important trait: they are located near the brain's midline, and the left and right sides of these structures are like mirror-images of each other across the midline. At the level of the brainstem and diencephalon, the damaged sites are close to the system of canals and ventricles that defines the midline of the central nervous system. At cortical level, they are located in the mesial surface. These structures are evolutionarily old, they are present in numerous non-human species, and they mature early in individual human development.

The neurobiological basis of consciousness

We defined consciousness in terms of two participants, the organism and the object, and in terms of the relationships those participants hold. In this perspective, consciousness becomes the problem of constructing knowledge about two facts: the fact that the organism is involved in relating to some object, and that the object in the relation is causing a change in the organism. In its normal and optimal operation, consciousness is the process of achieving a particular mental pattern which brings together, in about the same instant, the pattern for the object, the pattern for the organism, and the pattern for the relationship between the two. The emergence of each of these patterns and their conjoining depends on the contributions of individual brain sites working in close cooperation. Elucidating the neurobiology of consciousness consists of identifying those individual contributions, namely discovering how the brain can construct neural patterns that map each of the two participants and the relationships they hold, and how the brain can conjoin the patterns.

Consciousness begins to occur when the brain generates an imaged, non-verbal account of how the organism's representation is affected by the organism's processing of an object, and when this process enhances the image of the causative object, thus placing it saliently in a spatial and temporal context. There are two component mechanisms: the generation of an imaged non-verbal account of the organism–object relationship; and the enhancement of the images of the object.

The imaged account is based on second-order neural patterns generated from structures capable of receiving signals from maps which represent both the organism and the object. The imaged account describes the relationship between the reactive changes in the internal milieu, the viscera, the musculoskeletal frame, and the object that causes those changes. The assembly of the second-order neural pattern describing the object–organism relationship subsequently modulates the neural patterns which describe the object and leads to the enhancement of the image of the object. The feeling of self knowing an object, emerges from the contents of the imaged account, and from the enhancement of the object.

The neural pattern which underlies core consciousness for an object, the sense of self in the act of knowing a particular thing, is a large-scale neural pattern involving activity in two interrelated sets of structures: the set whose cross-regional activity generates an integrated view of the organism (the proto-self) and second-order maps; and the set whose cross-regional activity generates the representation of the object. The latter set has a dual role: it is both the initiator of the changes in the former set and the recipient of its modulating influences.

The neuroanatomical structures required to accomplish these component mechanisms encompass, respectively, (i) the structures needed to map the structure and state of the organism; (ii) those needed to process the object; and (iii) those needed to generate the imaged account of the relationship and produce its consequences. Let us consider each of these anatomical requirements.

Much is known about how the organism is represented in the brain, although the idea that such representations could be linked to the notion of self has received little attention. The brain represents, within itself, varied aspects of the structure and current state of the organism in a large number of neural maps from the level of the brainstem and hypothalamus to that of the somatosensory cortices (insula, SII, SI). The state of the internal milieu, the viscera, the vestibular apparatus, and the musculoskeletal system are thus continuously represented (Damasio, 2000; Parvizi & Damasio, 2001).

There have been considerable efforts to understand the neural basis of object representation. Extensive studies of perception, learning and memory, and language, have given us a workable idea of how the brain processes an object, in sensory and motor terms, and an idea of how knowledge about an object can be stored in memory, categorized in conceptual or linguistic terms, and retrieved in recall or recognition modes. In the relationship process we have proposed for consciousness, the object is exhibited as neural patterns in the sensory cortices appropriate for its nature. For example, in the case of the visual aspects of an object, the appropriate neural patterns are constructed in a variety of regions of the early visual cortices, while memory records pertaining to the past perception of such objects are held in highest-order association cortices located in temporal, parietal, and frontal regions. These cortices are interconnected with the early visual cortices (Damasio & Damasio, 1994). In brief, early sensory cortices, and higher-order cortices are involved (*a*) in signalling the objects and

the events which come to be known because of core consciousness; (*b*) in holding records pertaining to their experience; and (*c*) in manipulating those records in reasoning and creative thinking. Thus, the early sensory structures are also involved in the process of making consciousness, but in a different manner from the structures involved in representing the organism. The participation of early sensory structures; includes: (*a*) initiating the process of generating consciousness by influencing the organism-representing structures (*b*) signalling to second-order structures, and (*c*) being the recipients of the modulatory influences consequent to the second-order neural patterns. It is because of the latter influence that the enhancement of the neural patterns which support the object does occur, and that varied components of the object being known in consciousness can become integrated.

The neuroanatomy underlying the imaged account of the relationship depends on several structures, the most important of which are the cingulate cortices and the medial parietal cortices which surround their posterior sector. Finally, the subsequent image enhancement is achieved via modulation from basal forebrain/brainstem acetylcholine and monoamine nuclei, as well as thalamocortical modulation.

In brief, core consciousness depends most critically on the activity of a restricted number of phylogenetically old brain structures, beginning in the brainstem and ending with the somatosensory and cingulate cortices. The interaction among the structures in this set: (*a*) supports the creation of an integrated map of the organism state (the proto-self); (*b*) engenders the second-order neural pattern which describes the relationship between the integrated organism representation (proto-self) and the object representation; and (*c*) modulates the activity of object-processing regions which are not part of the set.

The specificity with which these neural structures are enumerated should not be taken to mean that any one of them alone can be the basis for consciousness. None of the functions outlined above is executed at the level of a single structure, but emerges, rather, as a result of cross-regional integrations of neural activity.

There is a remarkable overlap of biological functions within the structures which support the integrated mapping of the organism state (the proto-self) and the second-order mappings. For example, the brainstem nuclei and the cingulate cortices are involved in most of the following functions: (*a*) regulating homeostasis and signalling body structure and state, including the processing of signals related to pain, pleasure, and drives; (*b*) participating in the processes of emotion and feeling; (*c*) participating in processes of attention; (*d*) participating in the processes of wakefulness and sleep; (*e*) participating in the learning process.

The meaning of these functional overlaps may be gleaned by focusing on the brainstem, where distinct 'families' of nuclei are closely contiguous, and in spite of their anatomical distinctiveness, the varied families of nuclei are highly interrelated by anatomical connections. It would be functionally convenient to have structures governing attention and emotion in the vicinity of each other. Moreover, it makes good functional sense that such structures should be in the vicinity of those which regulate and signal body states since the causes and consequences of emotion and attention are related to the fundamental process of managing life within the organism, and it is not possible to manage life and maintain homeostatic balance without data on the current state of the organism's body-proper. Finally, if we regard consciousness as another contributor to the regulation of homeostasis, it also makes functional sense to place the critical neural machinery of consciousness within and in the vicinity of the neural machinery involved in basic homeostasis, that is, the machinery of emotion, attention and regulation of body state.

This perspective does not deny that some brainstem structures are involved in wakefulness and attention, and that they modulate the activity of cerebral cortex via the intralaminar thalamic nuclei, via the non-thalamic cortical projections of monamines, and via the thalamic projections of acetylcholine nuclei. The point is that nearby brainstem structures, and perhaps even some of the very same structures, have other activities, namely, managing body states and representing current body states. Those activities are not incidental to the brainstem's well established activation role: they may be the reason why such an activation role has been maintained evolutionarily and why it is primarily operated from the brainstem.

The roles that have been traditionally assigned to the brainstem's 'ascending reticular activating system', and to its extension in the thalamus, as presented in the classical work of Moruzzi and Magoun (1949), Penfield and Jasper (1954), and in the modern work of Llinas and Paré (1991), Llinas and Ribary (1993), Hobson (1994), Steriade (1988, 1993a, b, 1995), Munk et al. (1996), and Singer (1998) is compatible with this interpretation. The activity of the 'ascending reticular activating system' contributes to creating the selective, integrated and unified contents of the conscious mind, although such a contribution is not sufficient to explain consciousness comprehensively.

Although even the simplest form of consciousness requires ensemble activity that involves varied regions of the brain, consciousness depends most critically on regions that are evolutionarily older rather than recent,

and are located in the depth of the brain rather than on its surface. These basic mechanisms are anchored on ancient neural structures, intimately interwoven with homeostasis, rather than on the modern structures of the neocortex, those on which fine movement, perception, language and high-reason are based.

Mechanisms of memory and amnestic syndromes

John D.E. Gabrieli and Silvia A. Bunge

Department of Psychology, Stanford University, Palo Alto, CA, USA

Memory comprises the recording, retention and retrieval of knowledge. All that we know, except for what is genetically predetermined, is acquired through experience. Such knowledge includes the events we remember, the facts we know, and the skills we master. Memory is not a unitary faculty, but rather an ensemble of multiple forms of learning that differ in their uses, their operating characteristics, and the neural networks that mediate their processing (Gabrieli, 1998). A memory system may be defined as a particular neural network that mediates a specific form of mnemonic processing. Neurological and psychiatric diseases result in characteristic mnemonic deficits that reflect which memory systems are injured by a particular disease.

Levels of analysis: cells and systems

Learning and memory reflect experience-induced plasticity in the brain. An experience leaves a memory trace composed of an enduring alteration in the cellular organization of the brain called an engram. Experience-induced plasticity can be examined at many levels of analysis, including molecular events at the cellular and synaptic level, reorganization of local neuronal circuits, and large-scale alterations in the functional neural architecture of memory systems.

Cellular mechanisms of memory

Little is known about neural plasticity in the human brain, but findings from in vitro and invertebrate models offer suggestions about the cellular bases of human memory. Studies of the marine snail *Aplysia* have revealed links between learning and alterations in neurotransmitter release. *Aplysia* have a gill withdrawal reflex that is triggered when the gill is touched by a rod. Repeated stimulation leads to habituation such that the gills are no longer withdrawn in response to the rod. Short-term habituation has been linked to decreased presynaptic transmitter release. Repeated stimulation with a highly noxious stimulus, such as an electric shock, can lead to sensitization, an intensification of the withdrawal response. Short-term sensitization involves increased neurotransmitter release from a facilitating interneuron (Kandel & Schwartz, 1982). Modulation of neurotransmitter release may underlie short-term changes in functional connectivity between neurons.

Long-term memory processes, in contrast, require messenger RNA and protein synthesis (Davis & Squire, 1984) to establish structural changes in synaptic connectivity as a record of experience. Long-term habituation may involve pruning of presynaptic terminals, whereas long-term sensitization may involve proliferation of presynaptic terminals (Bailey & Chen, 1983; Fig. 21.1). The best-studied candidate for a cellular basis of mammalian learning is long-term potentiation (LTP), usually examined in in vitro slice preparations from mammalian brains (Fig. 21.2). A neuron becomes potentiated (i.e. exhibits enhanced response to a given input) when bombarded with brief but rapid series of stimulations. LTP develops rapidly and can last for long periods, and is specific to the activated synapses. LTP has associative properties because it is driven by cooperativity, the simultaneous stimulation of different synapses. LTP has been studied most extensively in hippocampal synapses, in which NMDA glutamate receptors are essential for the establishment, but not the maintenance, of LTP. LTP has also been induced in the amygdala, cerebellum, and cerebral cortex, but differences in LTP properties across brain regions suggest that they are mediated by multiple cellular mechanisms. Mechanisms for long-term depression of synaptic efficacy have also been found in the hippocampus (Malenka, 1994) and cerebral cortex.

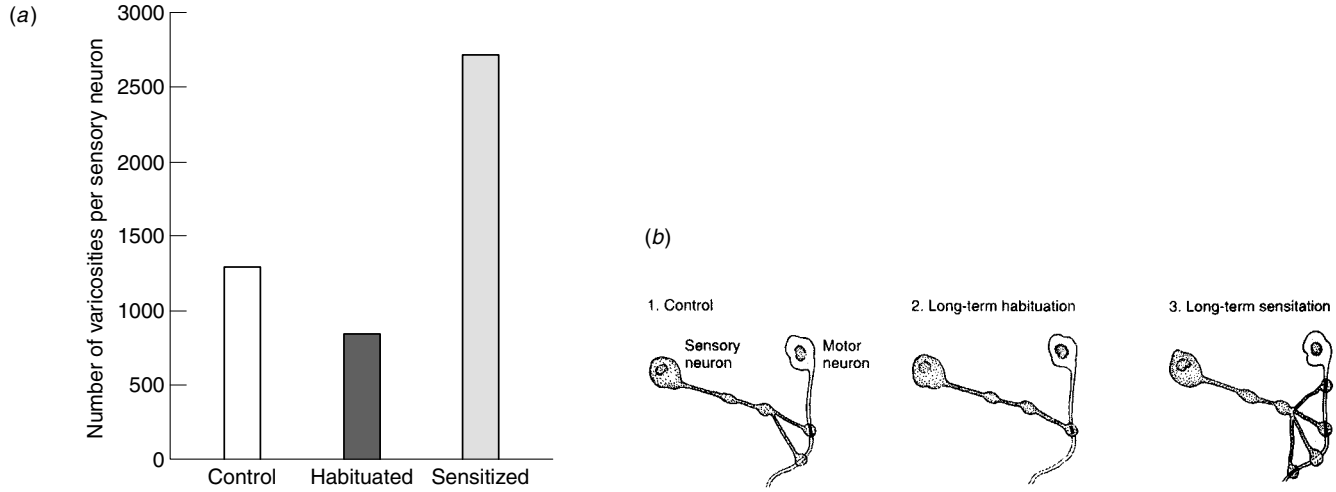

Fig. 21.1. Long-term habituation and sensitization in *Aplysia* involve structural changes in the presynaptic terminals of sensory neurons. (*a*) Number of presynaptic terminals in habituated and sensitized animals relative to control animals. (*b*) Long-term habituation leads to a loss of synapses, whereas long-term sensitization leads to an increase in synapses. (Adapted from Kandel et al., 1991.)

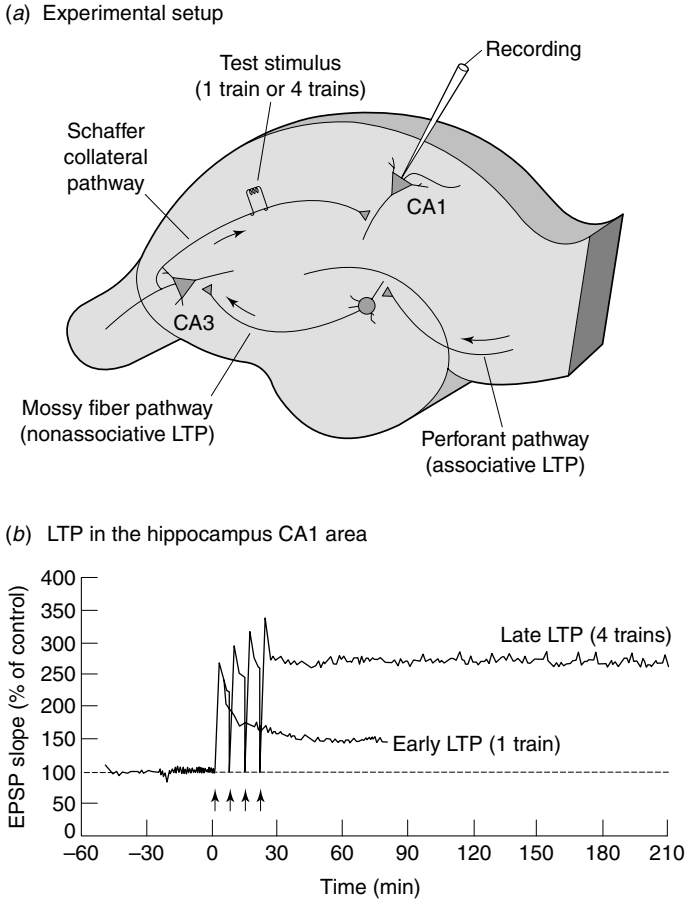

Large-scale memory systems

In humans, the functional neural architecture of memory is best understood in terms of mnemonic functions associated with particular anatomic structures. Studies of patients with brain lesions have provided the foundations of our knowledge about the biological organization of human memory. Lesions have produced dramatic and often unexpected mnemonic deficits that provide clues about the brain regions that are necessary for particular memory processes. The behaviour of memory-impaired patients with brain lesions, however, does not definitively point to the process subserved by the injured tissue. Rather, the behaviour reflects what uninjured brain regions can accomplish after the lesion. Further, naturally occurring lesions often impair multiple brain systems, either by direct insult to a large brain area or through disconnection of interactive brain regions. It is, therefore, difficult to associate particular brain structures with specific memory processes.

Fig. 21.2. LTP in the hippocampus. (*a*) Experimental setup for studying LTP in the CA1 region of the hippocampus. The Schaffer collateral pathway is stimulated electrically and the response of the population of pyramidal neurons is recorded. (*b*) Early and late LTP in a cell in the CA1 region of the hippocampus. Shown is a plot of the slope (rate of rise) of the excitatory postsynaptic potentials in the cell as a function of time. A test stimulus was given every 60 s to the Schaffer collaterals. To elicit early LTP, a single train of stimuli is given for 1 s at 100 Hz. To elicit the late phase of LTP, four trains are given separated by 10 min. The resulting early LTP lasts 2–3 hours, whereas the late LTP lasts 24 or more hours. (Adapted from Kandel et al., 2000.)

Functional neuroimaging studies using positron emission tomography (PET) or functional magnetic resonance imaging (fMRI) now permit the visualization of memory processes in the healthy brain. Functional neuroimaging studies allow for the design of psychological experiments targeted at specific memory processes. They are limited, however, by several factors. PET and fMRI derive their signals not from direct measures of neural activity, but rather from local changes in blood flow or metabolism related to neural activity. These indirect measures of neural activity limit the temporal and spatial fidelity of activations. Additionally, there is a great deal of psychological interpretation involved in understanding the meaning of an activation, i.e. in specifying the mental process signified by an activation. The combination of lesion and neuroimaging studies may overcome the limitations of each source of evidence and provide powerful, mutual constraints on ideas about memory systems.

Types of memory

Distinctions between different kinds of memory are useful from both clinical and neuroscience perspectives. A fundamental distinction is that of declarative versus nondeclarative forms of memory (Cohen & Squire, 1980). Declarative memory refers to the everyday sense of memory, and is responsible for the learning and remembrance of new events, facts and materials. It encompasses both episodic memories (remembrance of personal experiences that occurred at a particular time and place) and semantic memories (knowledge of generic information, such as the meaning of a word) (Tulving, 1983). It is the form of memory that people use to recollect facts and events consciously and intentionally, and is therefore also referred to as explicit memory (Graf & Schacter, 1985). In the clinic or experimental laboratory, declarative memory is usually tested directly by asking a person to recall or recognize information that was presented recently.

Non-declarative memory refers to the many forms of memory that do not depend on the psychological processes or brain regions essential for declarative memory. Non-declarative memories are not retrieved intentionally or explicitly, but rather incidentally or implicitly through behaviour. These forms of memory are established during an experience, and guide future behaviour in a way that is unrelated to any conscious awareness of that experience. Non-declarative forms of memory are tested implicitly or indirectly by measuring the influence of a specific prior experience upon subsequent performance, but without making any direct reference to that prior experience. Such experience-induced alterations in behaviour must reflect the consequence of memories established during the initial experience. Three main classes of non-declarative memory (skill learning, conditioning, and repetition priming) are discussed below.

Temporal properties distinguish one form of memory from another. Immediate memory refers to the recall of information without delay, either immediately after presentation or after uninterrupted rehearsal. Immediate memory is characterized by sharply limited capacities for how much and how long information can be remembered. For example, people can remember no more than about seven random digits, and only as long as they rehearse those digits. Immediate memory often has perception-like characteristics. For example, errors in immediate memory for words are more likely to reflect word sounds than word meanings (e.g. a person might recall 'pound' when they actually heard 'sound').

Working memory is a multi-component psychological system that mediates the temporary processing and storage of internal representations that guide and control action. Information can be held in working memory beyond the span of immediate memory, but only insofar as is useful for solving a problem at hand. Working memory is conceptualized to include immediate memory capacities and the executive or control processes that guide the goal-driven selection of relevant information to be held in immediate memory stores (Baddeley, 1986).

Long-term memory refers to large and permanent stores of episodic and semantic memories. Long-term memories are not, however, passively stored records of experience. Rather, they are constantly used to interpret new experiences. Our knowledge of words and concepts, for example, is used to interpret the meaning of sentences that we hear or see, and past experiences that resemble a current event are used to interpret that event. Long-term memory is often organized by meaning (semantics) or gist rather than by the perceptual characteristics of an experience. For example, people remember the content or gist of a sentence they have read far better than the specific order of words or the font in which the sentence was seen. Similarly, people remember a set of related words (e.g. birds) better than a set of unrelated words.

The rapid application of prior knowledge to interpret the meaning of a novel experience is a powerful mechanism for comprehension, but it can also generate inaccurate memories. Ongoing use of a long-term memory can alter the original memory (retroactive interference); indeed it is thought that forgetting is due much more to subsequent interference (multiple, related experiences are inadvertently blended) than to simple disuse of a memory.

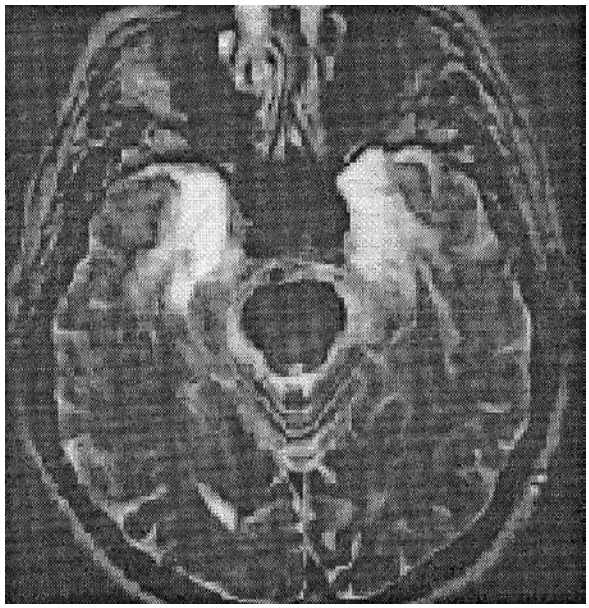

Fig. 21.3. T_2-weighted MRI image showing an axial slice through the temporal lobes of patient E.P. Damage to the bilateral medial temporal lobe extends caudally from the temporal pole and includes the hippocampal region, the entorhinal cortex, the perirhinal cortex, the parahippocampal cortex and the amygdaloid complex. The lesion also extends laterally to include the anterior portion of the fusiform gyrus. (Adapted from Teng & Squire, 1999.)

Remembering the gist of an experience is an efficient way to learn without recording minor details, but it is also prone to errors. For example, one can falsely remember that the name of a particular bird was included in a list of birds when it was not actually presented, simply because one has considered the gist of the set to be about birds.

Long-term memory involves three successive temporal phases. Encoding refers to processes that originally register an experience, including attentional, perceptual, and semantic processes. Storage (or consolidation) refers to the enduring maintenance of that memory. Retrieval refers to recovery of the memory at a later time. Accurate retrieval of a memory requires all three phases to be executed successfully. Long-term memories include those established many years or decades ago, sometimes referred to as remote memories.

The relation between short-term and long-term memory is susceptible to misunderstanding, in part due to various meanings of the term short-term memory. Sometimes short-term memory is used to refer to attention. An individual who cannot repeat back even a single digit or word is better described as having a deficit in attention than a deficit in any sort of memory. A second use of short-term memory is to refer to a memory mechanism that supports remembrance of a memory after a delay of seconds or minutes without rehearsal. There is, however, no evidence of any anatomical system that has a temporal span intermediate to those of immediate and long-term memory. Rather, there is constant and rapid loss of long-term memory for most events and facts. Therefore, memory for an episode after a brief delay of seconds or minutes will be superior to memory for that episode after a longer delay, just as memory for most episodes that occurred last week is superior to episodes that occurred last year. These differences, however, all reflect the temporal dynamics of long-term memory, and not the existence of a memory store that is intermediate between immediate and long-term memory. It is common to refer to an inability to acquire new long-term memories as a deficit in short-term memory. In this case, failure to learn new information is being contrasted with the preservation of remote memories, but the deficit is really one of failing to establish new long-term memories.

Amnesia and the declarative memory system

Amnesia is a selective disorder of declarative memory. It is defined by a behavioural syndrome rather than by etiology or lesion location. A pure amnesia refers to a relatively circumscribed disorder of declarative memory that cannot be accounted for by non-mnemonic deficits such as attention, perception, language, or motivation, because those abilities are all intact. In amnesia, immediate memory and cognitive abilities are intact. Anterograde amnesia refers to the inability to acquire new declarative memories. Retrograde amnesia refers to the loss of memories acquired prior to the onset of amnesia. Retrograde amnesia is described as flat when it extends back uniformly through an individual's life. More often however, retrograde amnesia is temporally graded, being most severe for, or limited to, a period of time immediately preceding the onset of the amnesia, and less severe or absent for more remote periods. Depending on the size and location of lesions, amnesias can vary considerably in extent and severity of anterograde and retrograde memory loss. Typically, the severity of the anterograde amnesia and the temporal extent of the retrograde amnesia are correlated, such that patients with a complete inability to form new memories have retrograde amnesia extending for long periods, up to decades (Rempel-Clower et al., 1996).

Amnesia results from injury to medial temporal lobe (Scoville & Milner, 1957; Fig. 21.3), diencephalic (von

Cramon et al., 1985; Dusoir et al., 1990), or basal forebrain (Damasio et al., 1985) regions. Bilateral lesions in any of these regions lead to global amnesia, a pervasive declarative memory failure that encompasses both verbal and non-verbal information. Patients with severe global amnesia fail all tests of declarative memory in all modalities, regardless of the difficulty of the test. They do not remember the most famous of public events or the most salient of personal events, such as the deaths of loved ones. Because the patient retains all other mental abilities, severe amnesia can appear to be a relatively minor problem. It is, however, remarkably debilitating because patients cannot take care of themselves, hold jobs, or develop human relations. When asked their age, the current year, or their home address, such patients respond with answers that are many years out of date. They cannot remember goals or intentions for more than a few moments, unless explicitly reminded with instructions. Milder cases of amnesia allow for some learning of especially salient or often repeated information, but even these patients have great trouble at home or at work. Unilateral left- or right-sided lesions typically result in material-specific memory dysfunctions for verbal or non-verbal information, respectively (Milner, 1974). This asymmetry can be more complex, however, in patients with longstanding unilateral injury when there is opportunity for reorganization, as can occur in epilepsy.

The medial temporal lobe region (Fig. 21.4) is comprised of a number of interconnected but anatomically distinct structures: the amygdala, the hippocampal formation, which includes cornu ammonis (CA) fields, dentate gyrus, subiculum, and fornix, the entorhinal cortex; the perirhinal cortex; and the parahippocampal cortex. Research with animals and humans indicates that each of these structures makes a unique contribution to declarative memory, and that they act in complex concert to establish new memories. It is now thought that the amygdala is not critical for most aspects of declarative memory. Rather, this region plays a specific role in the emotional modulation of memories, as reviewed below.

Higher-level olfactory, frontal, parietal, and temporal cortices provide widespread, convergent inputs to the medial temporal lobe region (Fig. 21.5). Two-thirds of these inputs traverse the perirhinal and parahippocampal cortices that surround the hippocampal formation. These regions send major input to the entorhinal cortex, which, in turn, provides major input to the hippocampal formation. The fornix is a major fibre bundle that connects the hippocampal formation to the septum and other subcortical structures.

Damage to medial temporal lobe structures is the most common etiology for pure amnesia or declarative memory disorders that are part of a more widespread dementia. This region is highly susceptible to a variety of insults, including epilepsy, anoxia, and herpes simplex encephalitis. Postmortem and in vivo imaging studies indicate that the entorhinal cortex and hippocampus are the first structures typically affected by Alzheimer's disease, in which a declarative memory disorder is the most common and severe initial behavioural deficit (Hyman et al., 1984; de Leon et al., 1993).

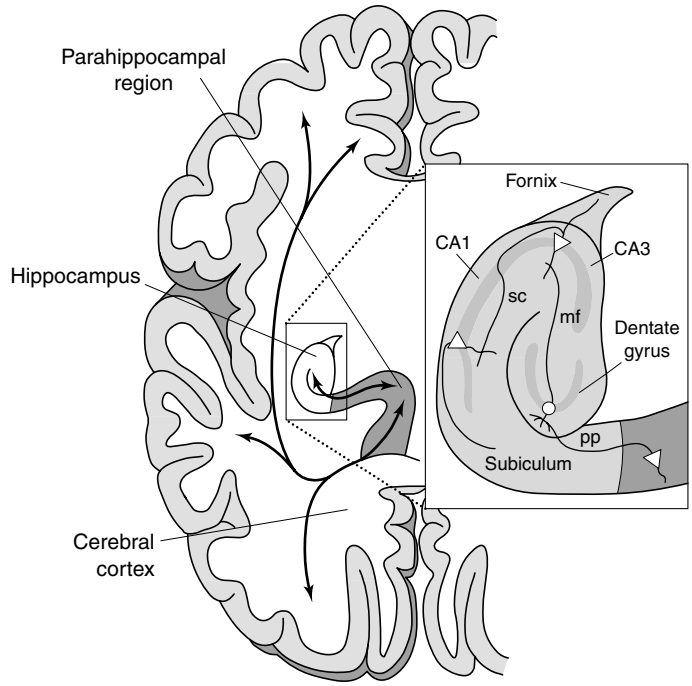

Fig. 21.4. Major pathways of the hippocampus. Left: A horizontal section through the human brain showing major pathways by which the hippocampus is connected with cortical areas. Inset: Diagram of major intra-hippocampal connections. (Adapted from Eichenbaum & Cohen, 2001.)

For many years, it was thought that the hippocampus *per se* was the critical structure among these for declarative memory. Focal damage restricted to the CA1 component of the hippocampus is indeed sufficient to yield a clinically substantial declarative memory deficit (Zola-Morgan et al., 1986). Animal research has shown, however, that perirhinal or other lesions can have at least as great a consequence on memory performance as hippocampal lesions (Murray & Mishkin, 1986; Zola-Morgan et al., 1989). In humans, more widespread damage to entorhinal, perirhinal, and parahippocampal cortices results in an increasingly devastating memory deficit (Rempel-Clower et al., 1996; Corkin et

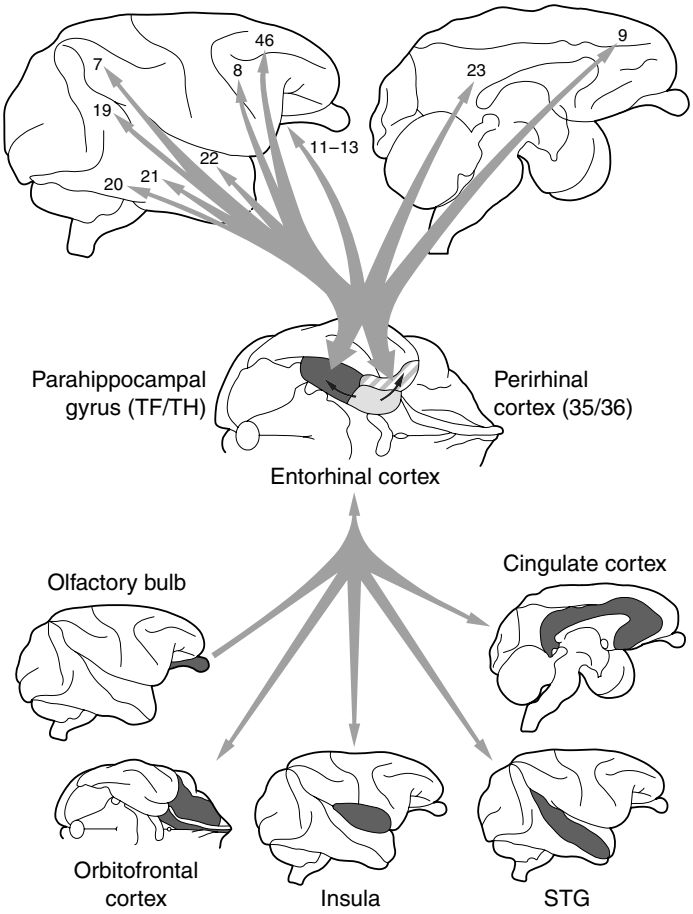

Fig. 21.5. Major cortical areas that compose the afferent sources and efferent targets of information to and from the parahippocampal region in monkeys. (Adapted from Eichenbaum & Cohen, 2001.)

al., 1997). In addition, damage to the fornix can produce global amnesia (Gaffan & Gaffan, 1991). The specific mnemonic roles of particular medial temporal lobe structures have not yet been well characterized in humans, because it is rare for an injury to damage one of these structures without injuring neighbouring structures.

Diencephalic regions linked to declarative memory include the dorsomedial and anterior nuclei of the thalamus, the mammillary bodies, the mammillothalamic fibre tract connecting the medial hippocampal complex to the anterior thalamic nuclei, and the ventroamygdalofugal fibre tract connecting the amygdala to the dorsomedial nuclei (Victor et al., 1971; Fig. 21.6). Damage to these regions is sufficient to produce severe memory impairments even when medial–temporal regions remain anatomically intact (Press et al., 1989). The precise roles of these structures are not well specified, in part because damage tends to co-occur in multiple structures. For example, the mammillary bodies and dorsomedial nuclei are both greatly affected in alcoholic Korsakoff's amnesia, the most common etiology of diencephalic amnesia. Acute thalamic lesions producing amnesia often injure both the dorsomedial nucleus of the thalamus and the surrounding mammillothalamic and ventroamygdalofugal tracts. The preponderance of evidence favours a critical role in declarative memory for the dorsomedial nucleus, perhaps in combination with the surrounding fibres of the mammillothalamic tract (von Cramon et al., 1985). The consequence of a lesion limited to the mammillary bodies is less certain. Lesions there sometimes appear to account for declarative memory deficits in patients (Dusoir et al., 1990), but do not yield the long-lasting memory impairments seen in monkeys after medial-temporal or dorsomedial thalamic lesions (Zola-Morgan & Squire, 1985). Declarative memory failure after diencephalic lesions appears quite similar to that seen after medial–temporal lesions, although additional non-mnemonic deficits may result from diencephalic lesions.

The basal forebrain is composed of midline structures including the septal nuclei, diagonal band of Broca, and substantia innominata. These regions provide the largest input of acetylcholine, the neurotransmitter most directly implicated as critical for declarative memory, to the hippocampus and many neocortical areas. The basal forebrain also supplies other neurotransmitters to the cerebral cortex that contribute to the modulation of memory, including dopamine, norepinephrine, and serotonin. An extensive lesion to the basal forebrain yields a severe declarative memory impairment (Damasio et al., 1985). Partial damage to this and adjacent ventromedial frontal cortex often occurs after ruptures of anterior communicating artery aneurysms, which often lead to mild but persistent anterograde amnesia.

Amygdala and the emotional modulation of memory

Lesion and functional neuroimaging findings have illuminated the importance of the amygdala in emotional aspects of human (Phelps & Anderson, 1997). Medial temporal lobe lesions are rarely restricted to the amygdala, but valuable information can be gained from a rare congenital dermatological disorder, Urbach–Weithe syndrome. This disorder leads to mineralization of the amygdala that spares the hippocampal formation (Fig. 21.7). It is also possible to study patients who have undergone amygdala resection for treatment of pharmacologically intractable

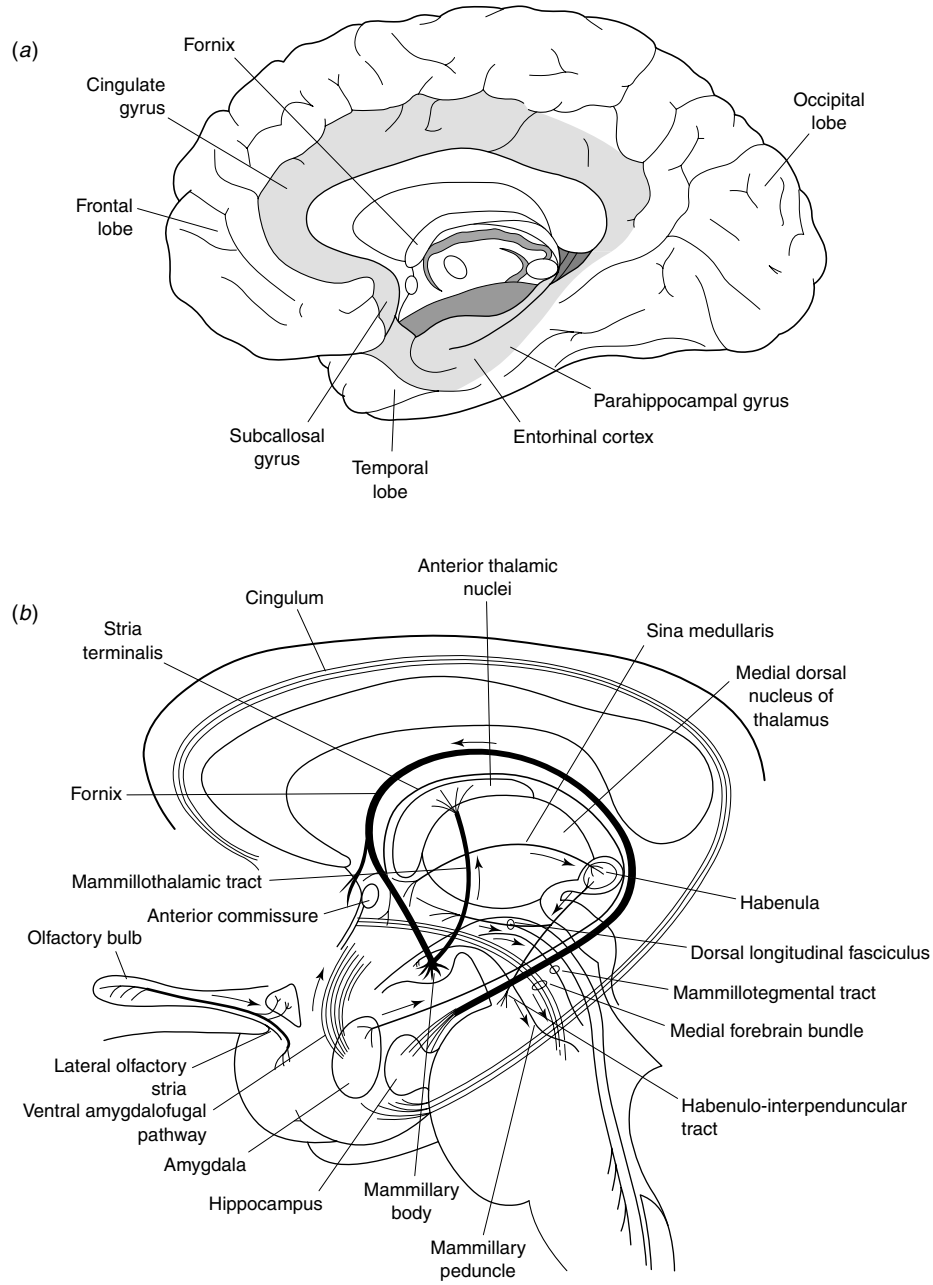

Fig. 21.6. The limbic system, consisting of the limbic lobe and deep-lying structures. (*a*) Medial view of the brain showing the limbic lobe (stippled area). (*b*) Interconnections of the deep-lying limbic structures. The predominant direction of flow of neural activity in each tract is indicated by an arrow, but the designated tracts are typically bidirectional. (Adapted from Kandel et al., 1991.)

epilepsy, but the resection usually involves additional medial–temporal structures.

There is convergent evidence of a specific role for the amygdala in emotional declarative memory. Healthy people show superior memory for emotionally disturbing relative to emotionally neutral stimuli. An Urbach–Weithe patient showed normal memory for neutral slides, but failed to show the normal additional memory for the emotionally salient slides (Cahill et al., 1995). In a PET study, amygdala activation correlated with individual differences in subsequent recall for emotional, but not for neutral, film clips (Cahill et al., 1996). In an event-related fMRI study, amygdala activation correlated with how emotionally intense people rated individually presented scenes (Canli et al., 2000). For scenes rated most emotionally intense, the magnitude of amygdala activation predicted later recognition memory. Most studies have examined participation of the amygdala in memory for negative events, but amygdala activation also predicts memory for positive emotional events (Hamann et al., 1999). Patients with amygdala lesions, however, typically report normal emotional evaluation of situations or stimuli, so the amygdala does not appear critical for generating emotions. Rather, the amygdala enables emotional arousal to strengthen memory encoding.

The amygdala participates not only in explicit memory for aversive stimuli, but also in implicit memory for aversive stimuli (reviewed later). Patients with amygdala lesions exhibit emotion-selective deficits in the identification of fearful or angry facial expressions (Adolphs et al., 1994) or prosody (Scott et al., 1997). Amygdala activations occur in PET and fMRI studies during the perception of fearful facial expressions or scenes (Morris et al., 1996). Thus, the amygdala appears to have a widespread role in processing negatively salient stimuli. This subcortical structure, however, is composed of multiple nuclei with distinct connectivity, and is adjacent to another brain region important for emotion, the substantia innominata. Thus, it is unclear whether some of these emotional and memory processes are mediated by the same or different specific pathways in that region. It is clear, however, that injury restricted to this region affects emotional memory without resulting in a global amnesia.

Neocortical basis of declarative memory

Declarative memory likely depends on interactions between the domain-independent regions described above, where injury results in broad memory failure, and domain-specific neocortical regions. Long-term episodic and semantic memories are thought to be stored in the neocortex, with different regions representing different types of knowledge. Thus, knowledge about the visual appearance of a tool may be stored near visual cortex, separate from knowledge about its use, which may be stored in areas such as premotor cortex (Martin et al., 1995). There is evidence that semantic memories for the names of people, tools, and animals are represented in distinct, adjacent left temporal lobe regions (Damasio et al., 1996). Damage to a cortical area can result in both the loss of previously acquired memories stored in that area and an inability to acquire new memories involving that kind of knowledge. A patient with a specific anomia for names of people, for example, would be unable to learn a new person's name but able to learn new names for animals or tools.

Personal knowledge also appears to be organized topographically in the neocortex. Some patients with mild anterograde amnesia exhibit a remarkable loss of personal memories concerning major life events or family members (Kapur et al., 1992). These patients typically have sustained damage to lateral temporal cortex, most often in the right hemisphere, which may store long-term autobiographical memory representations. They do not exhibit the temporally graded retrograde amnesia characteristic of patients with medial temporal lobe lesions.

Memory for an event or fact is conceptualized as being widely distributed in the neocortex, with specific perceptual, conceptual, and emotional features of an event represented in specialized cortical regions. It is hypothesized

that medial temporal lobe structures bind or relate the multiple features that define memory for an event across physically disparate neocortical regions.

Over time, the features somehow become consolidated in the neocortex and no longer require the medial temporal lobe for binding. It is thought that temporally limited retrograde amnesia reflects the sparing of remote, well-consolidated memories and the disruption of ongoing consolidation for more recent memories.

Immediate memory

Immediate memory, such as the recall of a series of digits that one has just heard or spatial locations that one has just seen, depends on cortical areas specialized for both modality (visual or auditory) and material (verbal or non-verbal). Patients with lesions of the left inferior parietal cortex may be able to repeat only two digits or words immediately after hearing them, in contrast to the normal span of seven items (Warrington et al., 1971). More posterior and inferior lesions at the occipital-temporal boundary can result in reduced visual–verbal immediate memory spans (Kinsbourne & Warrington, 1962). Reduced immediate memory for spatial locations and other visual–spatial displays can result from right occipital–parietal lesions (Warrington & James, 1967). Immediate memory, therefore, does not depend upon a common set of brain structures. Rather, there are distinct cortical regions, specialized both by modality and material, that briefly store information just heard or seen.

The consequences of a greatly reduced immediate memory span are remarkably few. Patients with very limited auditory–verbal immediate memory have trouble comprehending grammatically complex sentences and learning new foreign words, two situations in which a person may have to review carefully the sounds just heard because their meanings were not instantly grasped. Such patients, however, have normal or near-normal long-term memory for auditory–verbal information. This finding counters the expectation that information must pass through short-term memory in order to reach long-term memory. Instead, information from the environment enters immediate-memory and long-term memory stores in parallel rather than serially.

Working memory and strategic declarative memory

The frontal lobes appear to play a critical role in working memory (maintaining and manipulating information in a goal-directed manner for a brief period) and in strategic declarative memory. Frontal regions are thought to select goal-relevant information from immediate and long-term memory stores in posterior cortices (Fig. 21.8). Evidence that working memory depends critically on frontal cortices comes from many sources, including human and animal lesion studies (Goldman-Rakic, 1987; Owen et al., 1996), single-cell recording studies (Funahashi et al., 1989), and neuroimaging studies (e.g. Cohen et al., 1994; Jonides et al., 1993). Functional neuroimaging studies indicate that executive processes (working memory resources beyond immediate spans) in humans may be especially linked to dorsolateral prefrontal cortex (e.g. D'Esposito et al., 1995; Petrides et al., 1993). Patients with frontal-lobe lesions are impaired on tasks that demand substantial working memory resources, such as reasoning (Milner, 1963; Shallice, 1982). These patients do not, however, exhibit the pervasive or severe declarative memory deficit seen in amnesia.

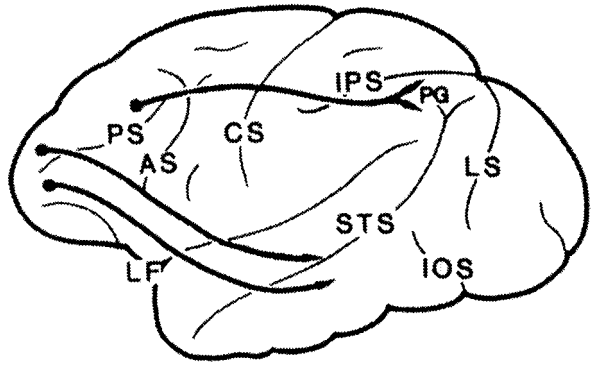

Fig. 21.8. Schematic of long-range projections between prefrontal and posterior association areas in the monkey. (Adapted from Pandya & Yeterian, 1985.)

Patients with dorsolateral prefrontal lesions are impaired on declarative memory tasks that have great strategic demands, i.e. memory tasks that demand substantial planning, organization, evaluation, or manipulation of information for accurate performance. Some declarative memory tasks have relatively minimal strategic demands. Recognition tests, in which studied items are re-presented along with novel distracter items, typically require little strategy, as responses can be guided relatively easily and quickly on the basis of stimulus familiarity. Free recall tests, on the other hand, require people to devise their own strategy for recollecting prior experiences without experimenter-supplied assistance.

Lesions to dorsolateral and anterior prefrontal regions lead to specific impairments on tests of source memory

(Janowsky et al., 1989), list discrimination (Butters et al., 1994); frequency of occurrence (Angeles-Jurado et al., 1997; Smith & Milner, 1988); recency (Milner et al., 1991), temporal ordering (Shimamura et al., 1990), and free recall (Wheeler et al., 1995). What is common across these tasks is that a person has to make a difficult memory judgment that requires the active planning and organization of a retrieval strategy. These strategic memory deficits occur even when performance on corresponding recognition tests is normal. Specific impairments in strategic declarative memory may be contrasted with those seen in amnesia. In most cases, amnesic patients perform poorly on both strategic and nonstrategic memory tests. The strategic memory deficit in amnesic patients, however, is the consequence of their global declarative memory deficit.

The working memory and reasoning deficits that result from frontal lesions may be related to the specific failure in strategic memory performance. Difficult memory tasks require that reasoning capacities be brought to bear on, or work with, memory retrieval. Thus, the strategic memory failure may be the consequence of diminished reasoning and working memory resources being applied to otherwise intact declarative memory processes.

Selective deficits of strategic declarative memory have been found also in degenerative or developmental diseases of the basal ganglia, such as Parkinson's disease (PD), Huntington's disease (HD), and Gilles de la Tourette's syndrome (Gabrieli, 1996). Striatal diseases also impair reasoning (Lees & Smith, 1983) and working memory (Gabrieli et al., 1996b), and these deficits are correlated with the strategic memory deficits.

Thus, strategic declarative memory appears to depend on the integrity of corticostriatal circuits (Alexander et al., 1986) that mediate working memory and reasoning. Furthermore, animal (Brozoski et al., 1979; Sawaguchi & Goldman-Rakic, 1991) and human (Luciana et al., 1992; Müller et al., 1998) drug studies indicate that the neurotransmitter dopamine plays a critical role in working memory. PD patients have severely reduced dopamine functioning, and dopamine treatment can enhance their working memory performance (Cooper et al., 1992).

Non-declarative memory systems

Despite their global anterograde amnesia, even the most severely amnesic patients have demonstrated entirely normal learning on a number of skill learning, repetition priming and conditioning tasks. These findings provide compelling evidence for the independence of multiple memory systems in the human brain. Preservation of these forms of memory in amnesia demonstrates that they do not depend upon the medial temporal lobe or other structures essential for declarative memory. Some of the neural systems underlying non-declarative memory have been identified in neuropyschological and neuroimaging studies. Non-declarative forms of memory do not depend on any common brain regions in the way that all forms of declarative memory depend on medial temporal lobe or diencephalic regions. Rather, each kind of non-declarative memory appears to involve experience-induced plasticity in the neural systems engaged by a particular task (e.g. motor areas for motor tasks, perceptual areas for perceptual tasks).

Skill learning

Skill learning (sometimes referred to as procedural memory) is expressed as the enhancement of accuracy or speed in performing a task across multiple training sessions. Amnesic patients have shown entirely normal and long-lasting skill learning on motor tasks (e.g. mirror tracing and rotary pursuit) (Milner, 1962; Corkin, 1968; Gabrieli et al., 1993), perceptual tasks (e.g. reading mirror-reversed text) (Cohen & Squire, 1980), and cognitive tasks (e.g. probabilistic classification) (Knowlton et al., 1994). Amnesic patients learn how to perform these tasks skillfully without knowing that they have had prior practice. Patients with basal ganglia diseases, especially HD, have shown impaired skill learning on many of these motor (Gabrieli et al., 1997b; Heindel et al., 1989), perceptual (Martone et al., 1984), and cognitive (Knowlton et al., 1996a, b) tasks. Thus, the basal ganglia appear to play an essential and widespread role in human skill learning that extends to cognitive skills.

Functional neuroimaging studies have revealed a dynamic plasticity of brain activations associated with skill learning. Learning a new skill is associated with expansion and reduction of initial activations and shifts in brain areas activated during initial, unskilled performance vs. later, skilled performance. For example, some motor skill learning tasks involve an expansion of activation in primary motor cortex and the basal ganglia (Grafton et al., 1992; Karni et al., 1995; Doyon et al., 1996; Hazeltine et al., 1997). For the perceptual skill of mirror reading, activation has been shown to increase in left inferior occipito-temporal cortex and decrease in bilateral parietal cortex as people improved their reading skill (Poldrack et al., 1998). These shifts in activity may represent a shift from reliance upon visuospatial decoding of mirror-reversed words in unskilled performance to more direct reading in skilled performance. These alterations in activation must reflect

alterations in neural connectivity that mediate skilled performance.

Conditioning

The neural circuitry underlying classical and other forms of conditioning has been studied extensively in animals. There appears to be a remarkable conservation of memory mechanisms for conditioning across mammalian species, which provides an opportunity to integrate invasive animal and noninvasive human research about memory systems.

The memory system underlying classical delay eyeblink conditioning has been delineated with great precision in the rabbit, and may be the most precisely understood mammalian memory system (Thompson, 1990; Fig. 21.9). In the typical delay paradigm, a 250–500 ms tone (conditioned stimulus or CS) is repeatedly followed by an air-puff (unconditioned stimulus or US) delivered to the eye that elicits a blink reflex, the unconditioned response (UR). The tone and air-puff coterminate. With repeated CS–US pairings, subjects learn to associate the tone with the air-puff, and initiate an eyeblink (conditioned response or CR) to the CS before the onset of the US. The convergence of CS and US projections in eyeblink conditioning occurs in the cerebellum ipsilateral to the eye receiving the air-puff. Lesions of the cerebellar dentate–interpositus nuclei prevent acquisition or abolish retention of the conditioned association, but lesions of the hippocampus do not affect delay conditioning (Schmaltz & Theios, 1972). In humans, delay eyeblink conditioning is intact in amnesic patients with bilateral medial–temporal (Gabrieli et al., 1995b) or bilateral thalamic lesions (Daum & Ackermann, 1994), but abolished in patients with cerebellar lesions (Daum et al., 1993).

More complex forms of conditioning, however, are impaired after medial–temporal lobe lesions in humans and rabbits. In animals, medial–temporal lesions impair trace eyeblink conditioning, which differs from delay conditioning in that there is a short time period, a second or less, between the offset of the CS and the onset of the US (Solomon et al., 1986). Amnesic patients with medial–temporal lesions who are unimpaired on delay conditioning show impaired trace conditioning with CS–US trace intervals as short as 500 ms (McGlinchey-Berroth et al., 1997). In animals, medial–temporal lesions also impair discrimination reversal, in which the two CS stimuli are switched in terms of their association with the US (Berger & Orr, 1983). Amnesic patients with medial–temporal lesions also have impaired conditioning for discrimination reversal (Daum et al., 1989). These findings suggest that the same medial–temporal lobe structures that are essential for declarative memory also mediate processes required for more complex forms of conditioning in humans and other mammals.

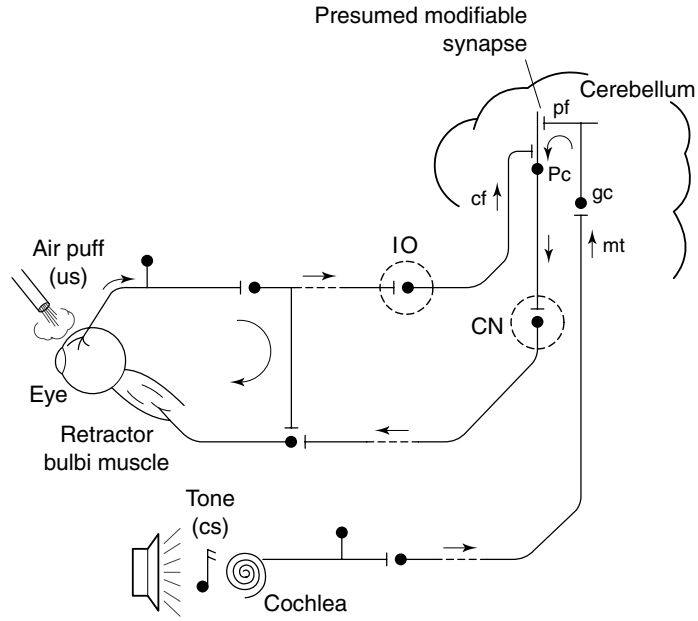

Fig. 21.9. Proposed minimal circuitry for eyeblink conditioning in the rabbit. An airpuff to the eye (us) is signalled to cerebellar Purkinje cells (PC) via the climbing fibres (cf), which originate in the inferior olive (IO). The tone (CS) is also signalled to the Purkinje cells through mossy fibres (mf), the cerebellar granule cells (gc), and the parallel fibres (pf). Modification at the putative plastic synapse (pf to Purkinje cell) would depend on properly timed activity in cf and pf. The Purkinje cells project to the cerebellar dentate–interpositus nuclei and then onto the motor neurons mediating the eyeblink response. (Adapted from Squire, 1987.)

The critical role of the amygdala in fear conditioning to aversive stimuli such as electric shocks has been well established in rats (Hitchcock & Davis, 1986). Amygdala damage also impairs fear conditioning in humans. In two studies, participants were exposed to pairings of initially neutral conditioned visual stimuli (CS) preceding aversive unconditioned auditory stimuli (US), white-noise or boat-horn bursts, which elicited an unconditioned response measured as a change in skin conductance response. Over multiple trials, normal participants showed fear conditioning, as evidenced by conditioned skin conductance responses to the CS. An Urbach–Weithe patient (Bechara et al., 1995) and patients with amygdala resections (LaBar et al., 1995) showed little or no fear conditioning. The fear-conditioning deficit was dissociated from declarative

memory because the patients had excellent declarative memory for the experimental experience, including the stimuli. In contrast, amnesic patients without amygdala damage demonstrated intact fear conditioning but impaired declarative memory for the experimental experience (Bechara et al., 1995).

Repetition priming

Repetition priming refers to facilitated processing of a stimulus, such as a word or picture, due to prior exposure to that or a related stimulus. In a typical experiment, participants process a set of stimuli in a study phase. In a subsequent test phase, participants perform a task with 'old' stimuli identical or related to the study-phase stimuli, and with 'new' stimuli that are unrelated to the study-phase and provide a baseline measure of performance. The difference in performance with old and new stimuli, the consequence of memories established during study, constitutes the measure of repetition priming (hereafter referred to as priming). For example, seeing the word STORK or a picture of a stork in a study phase makes people in a test phase more likely to identify that word or picture correctly when it is presented very briefly (e.g. less than one-twentieth of a second) or in a partial, fragmented form. People are also faster to read that word aloud and to name that picture aloud, and more likely to say 'STORK' when asked to complete three letters (STO _ _) with the first word that comes to mind, or to add letters so as to make a fragment (S _ _ R _) into a real word, or to say the first word that goes with BABY, or to provide examples of birds. Some of these examples of priming are primarily perceptual in nature and are linked to stimulus form (e.g. identifying a rapidly presented word); others are primarily conceptual in nature and are linked to stimulus meaning (e.g. listing examples of birds) (Roediger & McDermott, 1993).

Amnesic patients exhibit normal priming on many perceptual and conceptual tasks, despite little or no declarative memory for the stimuli they are identifying or producing with measurable benefits from prior processing (Warrington & Weiskrantz, 1970; Graf et al., 1984, 1985; Shimamura & Squire, 1984; Cermak et al., 1985; Cave & Squire 1992; Vaidya et al., 1995; Verfaellie et al., 1996). Amnesic patients can also show normal priming for novel materials (Gabrieli et al., 1990) and novel associations between materials (Moscovitch et al., 1986; Musen & Squire, 1993; Gabrieli et al., 1997a). Therefore, priming does not depend on medial–temporal lobe or other structures important for declarative memory. HD patients show intact priming (Heindel et al., 1989), so priming is also not dependent upon basal ganglia structures critical for skill learning.

Several lines of evidence indicate that priming is mediated by neocortical areas, with perceptual priming being mediated by modality-specific cortical areas and conceptual priming by amodal language areas. One source of evidence is the performance of AD patients, who exhibit severely reduced conceptual priming (Monti et al., 1996) but intact perceptual priming on visual tasks (Fleischman et al., 1995; Keane et al., 1991, 1995a). This pattern of impaired conceptual and intact perceptual priming may be interpreted in terms of the characteristic neocortical neuropathology in AD. In vivo metabolic imaging studies (e.g. (Frackowiak et al., 1981)) and postmortem studies of late-stage AD patients (Brun & Englund, 1981) find substantial damage to association neocortices in the frontal, parietal, and temporal lobes but relatively little compromise of primary visual, somatosensory, auditory, and motor cortices, the basal ganglia, or the cerebellum. The sparing of modality-specific cortices and the compromise of association cortices may account, respectively, for intact perceptual and impaired conceptual priming observed in AD. More direct evidence that modality-specific neocortex mediates modality-specific perceptual priming comes from patients with right occipital lesions. These patients have exhibited an absence of priming on visual tasks despite intact declarative memory and intact conceptual priming (Fleischman et al., 1995; Gabrieli et al., 1995a, b; Keane et al., 1995a).

Neuroimaging studies also indicate that separate cortical areas mediate perceptual and conceptual priming. Priming on visual tasks is associated with reduced activity in bilateral occipito-temporal regions (Squire et al., 1992; Schacter et al., 1996). Priming on conceptual tasks is associated with reduced activity in left frontal neocortex in healthy subjects (Raichle et al., 1994; Demb et al., 1995; Blaxton et al., 1996; Gabrieli et al., 1996a) and amnesic patients (Gabrieli et al., 1998).

Thus, lesion and imaging studies provide convergent evidence that different forms of priming reflect process-specific plasticity in separate neocortical regions. Visual priming is associated with changes in occipital cortex, whereas conceptual priming is associated with changes in language-related areas in left frontal cortex. Repetition priming in a given domain appears to reflect experience-induced changes in the same neural networks that subserved initial processing in that domain (Gabrieli et al., 1996a; Raichle et al., 1994). These changes facilitate or bias the subsequent reprocessing of the stimuli. The enhanced efficiency of reprocessing may diminish computational demands and thus lead to reduced activations relative to baseline conditions.

In conclusion, the global amnesia resulting from bilateral medial, diencepahlic, or basal forebrain lesions constitutes

the most striking and debilitating memory disorder. Clinical and experimental studies have shown, however, that the brain is composed of multiple memory systems that include the cerebral cortex, amygdala, basal ganglia, and cerebellum. Indeed, all brain regions appear to be involved in one sort or another of memory. Further, it is likely that many effective forms of human learning involve collaborative interactions among multiple memory systems. Memory systems may be seen as highly specialized instruments of memory that normally act in seamless concert to allow lessons from the past to guide actions in the future.

[2] Department of Neurology, School of Medicine and Department of Cognitive Science, Krieger Mind/Brain Institute, The Johns Hopkins University, MD, USA

In 1915, the British neurologist Henry Head commented on recent developments in clinical aphasiology and concluded that: 'It is generally conceded that the views on aphasia and analogous disturbances of speech found in the textbooks of today are of little help in understanding an actual case of disease' (Head, 1915). This may still be true to a certain extent, although perhaps for different reasons from those that Head had in mind. Most textbooks typically describe classical aphasia syndromes that are based on chronic, stable patients; thus by definition different from the patient with acute symptoms that the neurologist typically encounters. It has been estimated that only 20–30% of all patients with aphasia will fit neatly into one of the classical aphasia syndromes (Albert et al., 1991). Nonetheless, the clinical use of the classical syndrome classification as a basis for diagnosis has continued more or less unchanged.

The convenience of this approach in clinical settings notwithstanding, increasing dissatisfaction with the classical taxonomy of aphasia has been expressed by researchers in the field of aphasia, in particular psycholinguistics and cognitive psychologists (Schwartz, 1984). The principal concern is that the classical model does not necessarily generate any meaningful generalizations about the nature of brain-language relationships. Some have argued that the classical aphasia syndromes do not meet standard criteria for a syndrome, in that none of the syndromes can be characterized in terms of invariant features that are shared by all patients given a certain classification and are absent in patients with a different classification (Caramazza, 1984). Classical taxonomy can thus best be characterized as polytypic, implying that any given feature or impairment, for example phonological paraphasias, can be part of more than one syndrome (Schwartz, 1984).

Despite the controversy over classical aphasia taxonomy in research settings and the limited number of aphasic patients it accounts for, the clinical utility of classic aphasia syndromes has rarely been questioned. It appears to have been assumed that the syndromes are associated with a certain degree of anatomical predictability, which may allow the clinician to infer lesion location, etiology, and prognosis (Albert et al., 1991). Recent studies have questioned the validity of these assumptions, however. In particular, the expectation that aphasia syndromes have localizing value does not appear to have stood the test of time (Willmes & Poeck, 1993; Basso et al., 1985; Vignolo et al., 1986). The evidence that classic aphasia syndromes carry prognostic implications is also not compelling. The Boston Diagnostic Aphasia Examination (BDAE) diagnostic classifications are somewhat predictive of outcome for syndromes characterized by mild impairment, such as anomic and conduction aphasia, and for those characterized by severe syndromes, such as global aphasia. This is consistent with the findings from several studies showing that one of the best prognostic indicators for recovery from aphasia is initial degree of severity (Pedersen et al., 1995). Syndromes that are characterized by a greater range in severity, such as Broca's and Wernicke's aphasia, are not predictive of outcomes (Kertesz & McCabe, 1977).

Thus, classic subtyping of aphasia does not appear to offer any particular benefits for either research or clinical purposes. In the absence of a better system for characterizing clinical aphasia subtypes, it is nonetheless likely to persist. One commonly used alternative to the classic aphasia taxonomy is to dichotomize patients on the basis of speech fluency. Fluency can be rated on the basis of conversational speech. The BDAE criteria for fluency are based on the 'longest occasional uninterrupted string of words' that the patient is able to produce. The speech of non-fluent patients may range from complete mutism to slow, halting, and effortful production of individual

words. Mutism is a rare finding in aphasia and most often occurs as a transient initial sign. Non-fluent speech is often associated with articulatory problems or dysarthria, but some non-fluent aphasics have normal articulation. A subset of non-fluent patients have a tendency to omit grammatical words from their speech, resulting in telegraphic or agrammatic speech output. The speech of patients with fluent aphasia resembles normal speech in terms of rate of word production and phrase length. Non-fluent aphasia may be somewhat more common in younger patients, whereas fluent aphasia tends to predominate in patients 70 years or older (Ferro & Madureira, 1997). Speech fluency provides an approximate guide to lesion location in that non-fluent aphasia is most commonly associated with lesions that include anterior regions of the perisylvian language areas, whereas fluent aphasia is frequently associated with posterior lesions. This classification by itself does not necessarily carry much prognostic implication, although patients who remain non-fluent at 1 month after stroke are not likely to show substantial future improvement in fluency (Knopman et al., 1983).

Overall, there is no single language symptom that can adequately capture the nature of observed language disorders or provide adequate anatomic specificity to allow for an anatomic classification of aphasic disorders. Nor at this point, does any one language symptom provide a clear theoretical framework to account for what a particular brain region 'subserves' (e.g. there is no brain region that specifically performs a function like 'comprehension'). Thus, clinicians have been faced with performing a systematic evaluation of aphasia by characterizing a group of standard language components (e.g. speech, comprehension, naming, and repetition), assessing the pattern of impaired performance on these components, and inferring anatomic localization resulting in these deficits from these patterns.

Signs and symptoms of aphasia

Most cases of aphasia are secondary to stroke, and the abrupt onset of change in language-related functions may be the most reliable indicator that the symptoms stem from an aphasia. Very few aphasic symptoms are by themselves unique or diagnostic of aphasia. Dysnomia, paraphasias, and dysgraphias may occur in neurologically intact individuals. Therefore, it may be difficult to diagnose cases of aphasia due to causes other than stroke, such as primary progressive aphasia, during the early stages of the disease.

Dysnomia

Of the variety of symptoms associated with aphasia, none is more ubiquitous than dysnomia. A disorder of word finding or retrieval is present in all types of aphasia. In most cases, word finding difficulties are readily apparent in the patient's attempts at spontaneous speech. In milder cases, formal testing with confrontation naming may be required to document the dysnomia. Whereas non-fluent patients struggle to find individual words, the fluent patient often will substitute non-specific grammatical function words for content words. Poor recovery of naming has been associated with lesions involving either the posterior superior temporal lobe or the insula/putamen (Knopman et al., 1984). Unlike patients with Alzheimer's disease, whose naming failure may be principally on the basis of an impairment at the level of semantics, the dysnomia of patients with aphasia typically is on the basis of an impairment at the level of phonological activation. In some patients, the dysnomia may be restricted to certain semantic categories, such as colours, fruits and vegetables or tools (Warrington & Shallice, 1984; Hart et al., 1985). Although cases of category-specific naming deficits are relatively rare, detailed study of these cases may eventually provide critical information about the organization of the normal lexicon and its neural substrates (Caramazza & Shelton, 1998). Dysnomia in the absence of significant impairment in other aspects of speech and language does not appear to carry any specific localizing value.

Paraphasias

These refer to unintended substitutions at the level of individual sounds or words and are common in all types of aphasia. The principal subtypes of verbal substitutions are phonemic, semantic, and neologistic. Phonemic paraphasias refer to substitutions of one *sound* (or phoneme) for another, such as saying 'tork' instead of 'fork'. Phonemic paraphasias are common to most subtypes of aphasia, but are particularly abundant in aphasia secondary to incomplete lesions of the posterior language areas, such as conduction aphasia. Semantic paraphasias, or substitution of another word for an intended one, generally occur with significant involvement of the posterior superior temporal lobe (Wernicke's area). Neologisms are substitutions that are so far removed from the intended word that the target can no longer be recognized as an English word. Neologistic substitutions are most often seen with severe aphasias involving lesions of Wernicke's area and posterior extensions. Although both the frequency and type of paraphasic errors are relevant,

phonemic paraphasias are typically associated with milder forms of aphasia, while neologisms are associated with more severe forms.

Perseverations

Verbal perseverations, the unintended repetition of a preceding response, are common during the early stages of any acute aphasia syndrome, but occur in non-aphasic brain injured patients as well. Subtypes of verbal perseveration have been described (continuous, recurrent, stuck-in-set), but it is not clear whether these carry any prognostic information. The lesion correlates of perseverations are varied, but a recent study reported an association between head of caudate lesions and perseveration in patients with acute aphasia (Kreisler et al., 2000).

Echolalia

This refers to unsolicited, compulsive repetition (echoing) of verbal stimuli. Patients with echolalia do not echo everything they hear, but only utterances directed towards them. It is typically associated with poor comprehension. Despite this, aphasic patients with echolalia often demonstrate a completion-response (Stengel et al., 1947). If given a simple, but incomplete sentence, the patient will frequently complete the sentence spontaneously. Because of the implied intact repetition, echolalia does not usually occur with perisylvian lesions but is most common in so-called transcortical aphasias (Kornyey, 1975). Echolalia is also frequent in certain non-aphasic conditions, such as degenerative disorders and autism (Rapin & Dunn, 1997).

Stereotypical utterances

The speech of patients with severe non-fluent or global aphasia may sometimes be limited to one or two utterances, repeated in succession. These utterances may be real words or meaningless nonsense syllables. Repetitive stereotypical utterances, first described by Hughlings-Jackson (1880), represent a symptom that typically occurs only in patients with global aphasia (Brunner et al., 1982). The speech of Broca's initial patient Leborgne, who was only capable of uttering the word *Tan*, is one of the first known cases of stereotypical utterances. Curiously, it also suggests that Broca's first patient may, in fact, have had a global rather than what we today think of as Broca's aphasia (Selnes & Hillis, 2000). Stereotypical utterances, which may be one of the few pathognomonic signs of aphasia, invariably carry a poor prognosis.

Aprosody

Prosody, sometimes referred to as melodic line, refers to features such as stress, rhythm and intonational contours that convey both linguistic and non-linguistic information. Impairments of speech prosody are seen most often with non-fluent aphasia. In rare cases, the prosodic and articulatory changes are so prominent that the impression is given that the patient is speaking with a foreign accent. This condition was first described by the Norwegian neurologist Monrad-Krohn (1947), who reported the case of a woman with a war-related shrapnel injury to her left frontal lobe. When she recovered her speech, the rhythm and sentence melody were altered, and she was thought to be speaking with a German accent (Ryalls & Reinvang, 1985). Although an infrequent manifestation of aphasia, the foreign accent syndrome may occur during the recovery from severe non-fluency to a more fluent output. Foreign accent syndrome in the absence of aphasia has also been reported (Takayama et al., 1993). The role of the right hemisphere in prosody still remains controversial (Ryalls, 1986).

Palilalia

This is an acquired speech impairment characterized by recurrent repetition of a word or part of a word. With each recurrence, the rate tends to increase and the loudness decreases until the palilalia fades away. This symptom is relatively rare in aphasias with primarily cortical involvement, but can occur with subcortical involvement. Thus, palilalia with thalamic infarctions has been reported (Abe et al. 1993) and it frequently occurs in patients with Parkinson's disease.

Bedside language examination

At a minimum, the bedside language examination should include the basic elements listed in Table 22.1. Information about the quality of speech fluency and the ability to comprehend conversational speech can be obtained from the clinical interview. For patients with non-fluent aphasia, the use of automatic sequences, such as asking the patient to count from 1–10, reciting the letters of the alphabet, days of the week, and months of the year, can be helpful in eliciting enough speech to allow assessment of articulation and fluency. The critical elements in assessing spontaneous speech include: articulation, fluency, melodic line (prosody), grammatical form (syntax), paraphasic errors, and word-finding. In patients with no verbal output,

Table 22.1. Elements of the bedside language exam

comprehension

assessment of writing can help differentiate between aphasia versus aphonia. Auditory comprehension for individual words can be tested by asking the patient to point to body parts, everyday objects, or items in the room. Single word comprehension may be the best index of initial aphasia severity, and thus carries potential prognostic implications (Selnes et al., 1984). Sentence comprehension can be assessed by asking the patient to perform single or multistep commands. The ability to comprehend more complex syntactical relationships can be probed by the use of so-called syntactically reversible sentences. For example, in response to a sentence such as 'the lion was killed by the tiger, ' some patients have difficulty answering the question: 'which animal died?' Regardless of the severity of the aphasia, most patients will be able to demonstrate comprehension of commands that involve the body axis, such as: 'look up, look down, stand up, lean forward.' (Albert et al., 1991).

Naming can be assessed by asking the patient to name objects, body parts, or colors. For more detailed assessment, quantitative tests such as the Boston Naming Test are recommended (Kaplan et al., 1983). Repetition can be screened with sentences such as 'no ifs ands or buts'. Patients who are able to repeat this sentence generally have intact repetition. If the patient does not repeat this sentence correctly, however, additional testing of repetition with single words and simpler sentences should be performed. Writing can be assessed by asking the patient to write a sentence spontaneously. Patients unable to write a sentence should be asked to attempt to copy single words or sentences. In patients with severe motor deficits or apraxic agraphia, testing oral spelling can be useful. Reading aloud of single words, sentences, and paragraphs should be assessed. Most patients with problems in reading comprehension also have problems when reading aloud, but the converse is not true. A selective deficit of reading words that do not conform to standard sound-to-print rules, such as 'lieutenant, beautiful, steak', is sometimes observed.

Traditional anatomy of aphasia

For decades, our understanding of the anatomy of the left hemisphere language system was constrained by a bias in patient investigation: only patients with 'classic' symptoms of aphasia were investigated. Patients with left hemisphere lesions but no aphasia were rarely subjected to systematic study. Consequently, this resulted in a somewhat biased and restricted view. Advances in neuroimaging technologies over the past several decades have resulted in several modifications of the Wernicke–Lichtheim standard model of the left hemisphere language system. Although contemporary textbooks still feature the standard model of Wernicke's and Broca's areas interconnected by the arcuate fasciculus, evidence from several different lines of inquiry is now accumulating that this model is an oversimplification. There have been three major trends. First, it is now appreciated that lesions restricted to the traditional language areas of Broca and Wernicke are neither necessary nor sufficient to produce the classical syndromes. Secondly, it is now commonly accepted that multiple left hemisphere regions other than Broca's and Wernicke's areas appear to participate in language functions. Thirdly, there is significant variability in the lesion correlates of the so-called traditional syndromes (Basso et al., 1985; Vignolo et al., 1986).

Broca's area (Brodmann's area 44/45)

The first major revision to standard teaching about the role of Broca's area in language came with the studies of J.P. Mohr, who showed that a lesion restricted to Broca's area does not produce the clinical syndrome of Broca's aphasia (Mohr et al., 1999). According to Mohr, the lesion responsible for the clinical picture of Broca's aphasia is a large infarct in the sylvian area, which includes the operculum, the insula, and surrounding deep white matter. Others have shown that although the anterior insula is consistently involved, Broca's area proper need not be part of the lesion (Knopman et al., 1983; Blunk et al., 1981). Thus, a lesion of Broca's area is neither sufficient nor necessary for producing the syndrome of persistent non-fluent aphasia

of Broca. More detailed analysis suggests that despite considerable variability, components of the syndrome of Broca's aphasia, such as impaired articulation, delayed initiation of speech, and aprosody can be related to regional involvement of the frontal operculum (Alexander et al., 1992). Although there have been some contemporary studies of the anatomy of this area, more detailed studies of the cytoarchitecture, individual variability, and connectivity of this area are just beginning to emerge (Amunts et al., 1999; Petrides & Pandya, 1988).

Wernicke's area

The anatomical boundaries of the part of the posterior superior temporal lobe that constitutes Wernicke's region have never been specified, because there are no specific cytoarchitectonic or other criteria for supporting such a definition (Bogen & Bogen, 1976). A lesion of the posterior superior temporal lobe is almost always associated with fluent, paraphasic speech and poor comprehension. It has also been demonstrated that the degree of destruction of the posterior superior temporal lobe is correlated with outcome. Partial lesions are associated with favorable outcomes, whereas lesions that include more than 50% of the region are associated with poor outcomes (Selnes et al., 1984). If the lesion is limited to the posterior superior temporal lobe, prognosis for improvement to anomic aphasia is good, but if the lesion includes anterior extensions, prognosis for recovery is poor (Naeser et al., 1987).

Planum temporale

The planum temporale is a triangular structure located on the superior plane of the temporal lobe within the sylvian fissure. The normal anatomy of this region is quite variable, but cytoarchitectonically it consists of auditory association cortex. It has attracted considerable research attention after the discovery by Geschwind and Levitsky (1968) that this particular region of the brain tends to be larger on the left. Although the distribution of the anatomical asymmetry (left larger in 64% of brains) did not exactly fit with estimates of left hemisphere dominance, the assumption was made that the asymmetry somehow reflected the important role of the posterior superior temporal lobe in language. However, a specific role of this area in language, if any, has not yet been demonstrated (Binder et al., 1996).

Insula

The role of the insula in speech and language has been controversial since the time of Pierre Marie. The anterior insula is almost always implicated in patients with persistent non-fluent aphasia. A recent study reported that patients with so-called apraxia of speech all had lesions that involved the anterior insula, while none of the patients without apraxia of speech had a lesion that included this area (Dronkers, 1996). There is also evidence to suggest that some of the connections from the posterior superior temporal lobe to anterior speech areas actually pass through the extreme capsule (Petrides & Pandya, 1988). Lesions of the insula therefore frequently produce impaired repetition (Damasio & Damasio, 1980).

Angular/supramarginal gyri

The angular and supramarginal gyri are part of the inferior parietal lobe, and are strategically located for polymodal association of vision, touch and hearing. These areas may play an important role during language development, because basic linguistic functions, such as object naming, depend on establishing an association between auditory and other sensory modalities. Although there is some evidence that lesions restricted to the angular gyrus may produce an agraphia, the role of the angular gyrus in reading is less clear. Although traditionally implicated in the syndrome of alexia with agraphia, the lesions responsible for this syndrome typically include other structures as well (Sakurai et al., 2000). The so-called Gerstmann syndrome has also been shown to be associated with larger lesions that include the angular gyrus but not restricted to this area (Benton, 1992). With disconnection of visual input to the angular gyrus, alexia without agraphia occurs. Comprehension of written words is impaired, but writing is generally intact. Spelling, and comprehension of spelled words, is generally intact.

Arcuate fasciculus

The long white matter tract known as the arcuate fasciculus has traditionally been conceptualized as the direct pathway between the posterior and anterior language areas. Lesions of the arcuate fasciculus have been thought to be responsible for the repetition deficit observed in patients with conduction aphasia. The presumptive role of the arcuate fasciculus in repetition disorders has been surprisingly resistant to more recent findings suggesting that a lesion of the arcuate fasciculus is neither necessary nor sufficient for the production of the syndrome of conduction aphasia (Selnes et al, 1985; Damasio & Damasio, 1980; Brown, 1975; Shuren et al., 1995; Anderson et al., 1999). Recent anatomical studies also suggest that it is only the

most posterior areas of the superior temporal lobe that project to anterior speech areas via the arcuate fasciculus. The anterior two thirds of the posterior superior temporal lobe appear to be connected through white matter tracts that pass through the extreme capsule (Petrides & Pandya, 1988). Thus, there is neither compelling behavioural nor anatomical evidence for a specific role of the arcuate fasciculus in repetition.

Basal temporal language area

Functional localization of language-relevant cortex by using electrical stimulation has become routine in patients who are candidates for epilepsy surgery (Lesser et al., 1986, 1987; Schaffler et al., 1993). This methodology has revealed evidence of interference with language functions in areas outside the classical language areas. Electrical stimulation of the dominant basal temporal area has been shown to produce problems in both comprehension and production in some patients (Luders et al., 1986, 1991). Surgical resection of this area does not produce any lasting language deficits in most patients, but some patients have persistent dysnomia (Krauss et al., 1996). Thus far, the specific role this region subsumes in language functions is unclear.

Supplementary motor area

The anterior part of area 6 on the medial surface of the cerebral hemisphere, the supplementary motor area, has been implicated in speech functions since the work of Penfield and Roberts (1959), but its specific functions are still poorly understood. Stimulation of the supplementary motor area most commonly results in speech arrest (Fried et al., 1991). Surgical lesions of the dominant supplementary motor area may produce moderate to severe initial deficits, but significant lasting speech changes are uncommon (Rostomily et al., 1991).

The basic Wernicke–Geschwind model of the anatomy of language has thus undergone considerable evolution over the past several decades. The following quote from Mesulam is representative of this more contemporary view: 'There are no "centres" dedicated to comprehension, articulation, or grammar but a distributed network in which nodal foci of relative specialization work in concert.' (Mesulam, 1990). The extent to which this updated model will prevail remains to be seen, but as noted by Damasio: 'The time for modernizing the classic view is now, and the past decade has brought forth a number of new findings likely to make the modernization stick.' (Damasio, 1997).

Integrated cognitive neuroscience approach to the neural basis of language

Rapid developments in cognitive neuroscience in the past two decades have allowed us to develop a cognitive neuroscience model that describes how the brain encodes language operations and explains aphasic behaviour. The advantages of these types of models are that they (*a*) can account for the observed aphasic language disorders, (*b*) provide more theoretically and clinically relevant language components that correlate with specific brain regions, and (*c*) take advantage of the multitude of activation studies conducted in control subjects to understand how the normal brain performs language functions. This point raises the important issue that an integrated account of language and aphasia is required to reconcile the findings of activation and lesion studies in describing how the brain performs language operations.

The basic language operations assessed above in the classical approach are still correlated with their associated anatomic regions including this within their framework. The cognitive neuroscience approach supplements the classical approach by assessing the networks of brain regions associated with the linguistic components of semantic, orthographic, and phonological lexicons and syntax. These components are most useful for developing both theoretical and practical explanations for normal and aphasic language function. It is believed that these networks consist of various combinations of circumscribed brain regions subserving processing or access to representation of language units (e.g. words, letters, sounds, among others), some of which may be encoded in spatially distributed representations (Hinton, 1981).

Although the tests for assessing each of these components and their access can be similar to those outlined above, the results are interpreted and framed in terms of linguistic and cognitive components. The following outlines a framework for an integrated cognitive neuroscience approach to language representation in the brain and its application to explaining aphasic behaviour. As further studies are completed, clarification and expansion of the framework will provide a more detailed account of the networks involved.

Semantic lexicon (stores in the brain encoding the linguistic meaning of words)

This component is usually assessed by how a patient performs on comprehension questions (e.g. 'Do birds have wings?'), comprehension of single words, confrontation naming, and the output of spontaneous speech (e.g. error

patterns, word-finding difficulties). The pattern of performance across these types of tasks indicates deficits in the lexical semantic system, for example, if the patient has empty speech with word-finding difficulties and impaired comprehension.

Studies of clinical patients and activation studies have both demonstrated behavioural and anatomical aspects of the organization of the semantic lexicon and possible associated processing regions (see Hart et al., 2001). Evidence from focal brain lesions and from degenerative brain conditions has shown that aspects of the lexical semantic system may be organized by semantic category (see Caramazza & Shelton, 1998), because categories can be differentially affected by these neural injuries. Nielsen (1946) was the first to describe a double dissociation between the ability to name living things and non-living things (with opposite patterns of preservation or impairment across different patients). Since then, there have been many individual and group reports of such dissociations for a variety of categories including living things, animals, plants, food, fruits and vegetables, body parts, countries, emotional facial expressions, small manipulable objects, shapes, colours, letters, numbers, action names, verbs, case marking prepositions and tense, girls' and boys' names, family and friends, famous people, proper names, cities, rivers, countries, mountains (Semenza & Zettin 1988, 1989; Goodglass et al., 1966, 1986; Funnell & Sheridan, 1992; Hillis & Caramazza, 1991; Farah et al., 1991, 1996; Silveri et al., 1991; Damasio et al., 1990; Farah & Wallace, 1992; Farah, 1989; Temple, 1986; Warrington & Shallice, 1984; Rapcsak et al., 1989, 1993; McCarthy & Warrington, 1988; Hart et al., 1985; Berndt, 1988; Humphreys & Riddoch, 1987; Damasio, 1990; Silveri & Gainotti, 1988; Warrington & McCarthy, 1983, 1987; Hart & Gordon, 1992; Sartori et al., 1993; Robinson et al., 1996; Gainotti et al., 1995; Mauri et al., 1994; Tippett et al., 1996; Sartori & Job, 1988; Sacchett & Humphreys, 1992; Damasio et al., 1996; Cappa et al., 1998; Garrard et al., 1998; Ferreira et al., 1997; see Grossman et al., 1998 for similar issues in degenerative conditions). In addition, functional imaging studies of the picture naming task have suggested that aspects of this categorical organization may be localized to specific brain regions (e.g. animals selectively activated the left medial occipital lobe and tools selectively activated the left middle temporal gyrus and the left premotor region (Martin et al., 1996) or animals were associated with activation of the left 3rd (inferior) and fourth temporal gyri, whereas naming of tools was associated with activation of the left middle and inferior temporal gyri (Damasio et al., 1996). These distinctions have not yet been fully reconciled (see Spitzer et al., 1995; Moore & Price, 1999a).

In addition, there are distinct brain regions associated with aspects of semantic processing, including the left dorsal lateral prefrontal cortex (DLPFC) with selection between multiple semantic stimuli (Thompson-Schill et al., 1997; Posner et al., 1988; Demb et al., 1995; Kapur et al., 1994; Demonet et al., 1992; Ricci et al., 1999), left inferior parietal-posterior superior temporal region (Hart & Gordon, 1990; Vandenberghe et al., 1996) and the left fusiform gyri (Hart et al., 1998; Nobre et al., 1994; Abdullaev & Posner, 1988) with categorization, synonymity and property judgment as well as other semantic processing, and bilateral inferior (ventral) temporo-occipital regions.

As investigative techniques provide greater resolution, and further regions involved in the lexical semantic network are identified with their associated function, the anatomic substrates of the lexical semantic system will be further defined, resulting in descriptions of pure and mixed deficits associated with lexical semantics. In addition, further specification of lexical semantic components will aid in describing the selective language impairments seen in semantic aphasia and semantic dementia (Hodges et al., 1992).

Orthographic lexicons (stores in the brain encoding written version of words)

The most efficacious method of assessing these components is by having the patient write, read, and perform a lexical decision task (e.g. deciding if a letter string is a word or a non-word, 'trest' vs. 'treat'). These tasks readily assess the integrity of the orthographic lexical elements as well as access to them.

Localization of the input and output orthographic lexicons has been a controversial issue in functional imaging studies. Whereas some investigators suspect that the word representations or stores themselves are encoded in a spatially distributed fashion (Hart et al., 2000), others have suggested a more focal circumscribed localization (Petersen et al., 1988). These focal localizations isolated with functional imaging studies, however, have not always been substantiated by similar localizations in numerous lesion studies. Until more definitive studies are performed, at a minimum these activation studies identify regions associated with access to orthographic lexicons. These regions include the superior and middle temporal gyri and inferior parietal lobule (Hart et al., 2000; Moore & Price, 1999b; Simos et al., 2000) for the input lexicon; middle part of the left superior and middle temporal gyri for the input and posterior part of the left middle temporal gyrus for the output orthographic lexicon (Howard et al., 1992); the lateral occipital extrastriate area for the input orthographic

lexicon (Petersen et al., 1988); and the left frontal lobe for orthographic to phonological transformation (Fiez et al., 1999).

Extensive lesion studies of patients with alexia have delineated several plausible pathways involved in the three proposed routes to reading (direct access to an orthographic lexicon, orthographic-to-phonologic conversion, and direct access to semantics) and provide converging evidence that the above localizations may be important in accessing the input orthographic lexicon (see Coslett, 2000; Coltheart et al., 1980; Patterson et al., 1985). There is less evidence for anatomic localization of an independent output orthographic lexicon, although aspects of that lexicon have been behaviourally described (Hillis et al., 1999).

Phonological lexicons (stores encoding the sounds of words)

Speech discrimination tasks, repetition, and analysis of spontaneous speech are useful indices of the integrity of the phonological lexicons and their access. Phonemic paraphasic errors have been considered a hallmark feature of damage to the brain's internal storage system for the sounds of words for speech production, but it is also clear that inability to discriminate speech sounds can reflect impairment of an input phonological lexicon. This was demonstrated in the description of patient J.S., whose pure word deafness clinically was shown to stem from a disruption involving the input phonological lexical system (Caramazza et al., 1983).

It is clear that different neural mechanisms support input and output phonology, as well as different routes into these proposed lexical systems (e.g. access to input phonology from reading differs from access from speech perception) (Bub & Kertesz, 1982). As in the orthographic lexicons, it is not yet clear that anatomic localization defines the lexicons themselves or access to them. The localization of regions associated with access to input phonology from speech has been dissociated by focal, circumscribed temporary, reversible lesions produced by cortical electrical interference in left lateral superior temporal gyrus during speech discrimination tasks (Boatman et al. 1995, 1997). These regions bordered the primary auditory cortex, but were distinctly dissociated from it.

The network supporting the output phonologic lexicon has been shown through functional imaging studies to extend from the mouth representation in the primary motor cortex, the supplementary motor area, the inferior lateral premotor cortex (Broca's area), the anterior insula, and the cerebellum (Fox et al., 2000). In addition, the left posterior superior temporal gyrus has been shown to participate in phonemic aspects of speech production, as well as its previously described role in speech perception (Hickok et al., 2000). Distinguishing between the specific cognitive components that each region encodes, if they do function independently, is left to future studies.

Syntax (system of grammar)

Syntactical structures can be examined in both production and comprehension. Typical assessment of syntactic production extends from evaluating spontaneous speech for grammatical complexity (Kaplan et al., 1983), repetition of syntactically complex sentences or sentences with numerous function words (e.g. no ifs, ands, or buts), and reading of concrete and abstract words. Syntactic comprehension is routinely assessed at a basic level in a picture-sentence matching task using semantically reversible passive sentences ('Point to the correct picture describing this sentence, "The car was hit by the truck."')

Anatomical localization of syntactic processes have been variable (see Caplan, 1999). For example, in two patients aphasic syntactic and morphological aspects of grammar were localized to the left frontal lobe and the postcentral perisylvian cortex, respectively (Nadeau, 1988). In an activation study of syntactic processing, however, there was selective involvement of a deep component of Broca's area, a right inferior frontal region, and the left caudate nucleus and insula were activated (Moro et al., 2001). Alternatively, by studying sentences of increasing syntactic complexity, increased blood flow was found in Broca's area during syntactic judgment tasks (Caplan et al., 2000). Part of the variability in localizing syntactic processing may be attributable to different stimuli, testing paradigms, and investigative techniques, although some investigators have suggested that the variability is due to the lack of focal, circumscribed localization to syntactic processes.

Overall, the cognitive neuroscience approach is evolving as both functional imaging studies of normal and aphasic subjects are conducted. The success of this model will likely depend on several factors, not the least of which is to formally reconcile the disparities between activation and lesion studies to best determine the cognitive operation an anatomic region subserves. Another major factor will be the ability to combine experimental paradigms with the evolving investigative techniques to explore, in both spatial and temporal domains, the networks involved in the processing of these various linguistic components. As these techniques evolve, the cognitive neuroscience framework will also need to incorporate in the model the neural mechanisms (for example, electrophysiological

coherence, neurotransmitter mediation) that subserves the cognitive operations involved in language. And finally, it will be essential to integrate in this model not only the connections between the linguistic components within language (e.g. the interface between orthography and phonology, and others) but also with other cognitive components outside the language system proper but necessary to its successful operation. For example, while not included directly in the above neural circuits, it has become increasing clear through a variety of functional imaging studies (D'Esposito et al., 1999) that the dorsal lateral prefrontal cortex (DLPFC) is involved in aspects of working memory. As this region and its connections to other linguistic components are explored, it will be useful to integrate working memory and its substrates into the network model of language proposed here.

Aphasia in degenerative conditions

It is well recognized that changes in speech and language may occur during the later stages of most forms of dementing illness. If symptoms of aphasia occur as the presenting symptoms, alternate etiologies should be considered. In 1982, Mesulam described six patients with a history of slowly progressive speech and language symptoms in the absence of any signs of dementia (Mesulam, 1982). Although previous cases of slowly progressive aphasia had been described (Poeck & Luzatti, 1988), Mesulam's publication resulted in widespread recognition of the entity now commonly referred to as primary progressive aphasia (Mesulam, 1982). The epidemiology and risk factors for primary progressive aphasia are not known, in part because the disease is rare. In 1997, Westbury and Bub reviewed the findings from 112 cases published since 1982 (Westbury & Bub, 1997). Most patients with this condition will eventually develop a more generalized dementia syndrome. In rare cases, the patient may remain cognitively intact (except for language) for a number of years, but in most instances, some degree of cognitive impairment can be detected on standardized neuropsychological testing after 2–3 years of progression. Therefore, it has been suggested that a period of 2 years of language-related decline in a patient otherwise free of symptoms of dementia is sufficient for making the diagnosis (Weintraub et al., 1990). The average age of onset of symptoms in progressive aphasia is approximately 59 years, somewhat earlier than for typical Alzheimer's disease. Most patients present with a non-fluent aphasia, making it relatively easy to differentiate from early Alzheimer's disease (Caselli, 1995). The most common initial symptom is word-finding difficulty, but some patients also report early problems with comprehension of spoken language. Phonemic paraphasias and speech hesitancy may also occur relatively early. In rare cases, the patient may present with an otherwise isolated dysarthria (Selnes et al., 1996; Broussolle et al., 1996; Cohen et al., 1993). The degree of agraphia often mirrors the degree of speech impairment. Reading and repetition tend to be relatively preserved, during later stages of the disease. With progression of the disease, all language modalities become impaired, and vocalization may be reduced to single word utterances or complete muteness. MRI findings are not very specific, but often demonstrate bilateral atrophy in the perisylvian regions. Of the cases of primary progressive aphasia with autopsy information, some have shown changes consistent with Alzheimer's disease (Benson & Zaias, 1991), but the most common findings involve gliosis and neuronal loss of superficial cortical layers.

Other degenerative conditions that are sometimes accompanied by prominent speech and language changes include Pick's disease (Holland et al., 1985) and corticobasal degeneration (Sakurai et al., 1996). Detailed neuropsychological testing can be helpful for early differentiation of these syndromes from primary progressive aphasia.

Aphasia recovery and treatment

Recovery from aphasia has traditionally been thought to depend on a complex interaction of lesion size and location with patient characteristics such as age, gender and handedness. Nevertheless, large scale prospective studies of aphasia recovery have not confirmed a significant predictive relationship between demographic variables and degree of recovery. Although methods for assessing initial severity have varied across studies, there is considerable agreement that the most important factor predicting recovery from aphasia after stroke is initial degree of severity of language symptoms (Pedersen et al., 1995). Few systematic studies have compared recovery from aphasia after etiologies other than stroke, but some have found that post-traumatic aphasia has a better prognosis than aphasia due to cerebral infarction (Kertesz & McCabe, 1977).

Although it is well known that small lesions cause milder and shorter lasting impairments, only a handful of studies have examined the effect of lesion volume on aphasia recovery. Selnes and colleagues found that single word comprehension at 6 months after stroke was significantly related to lesion volume (Selnes et al., 1984). One subsequent study has also confirmed the importance of overall

lesion volume for degree of recovery (Goldenberg & Spatt, 1994). Furthermore, Naeser and her colleagues demonstrated that region-specific volume is also of importance, in that the degree of destruction within Wernicke's area itself was significantly related to levels of auditory comprehension. Patients with less than 50% destruction of Wernicke's area had good recovery of auditory comprehension at 6 months, whereas patients with destruction of more than half of Wernicke's region had limited recovery even at one year after onset. As with lesions of Broca's area, extension of the lesion beyond Wernicke's area was also associated with poor outcomes (Naeser et al., 1987).

The time course of recovery after aphasia may also depend on the initial level of severity. Patients with mild initial symptoms of aphasia often recover within a few weeks after the onset. With symptoms of moderate initial level, spontaneous recovery may last several months before a stable level of functioning is achieved (Pedersen et al., 1995). Patients with severe Global or Wernicke's aphasia may show some spontaneous recovery during the first 18 months after stroke, but the majority of the improvement takes place during the first 6 months (Nicholas et al., 1993).

There have been a number of studies attempting to quantify the degree of improvement, over and beyond spontaneous recovery, offered by speech therapy. In a recent meta-analysis of the findings from 21 studies, treatment by a speech-language pathologist was found to result in better outcomes (Robey, 1994). Treatment initiated during the acute stages of recovery was found to be significantly more effective than treatment initiated at later stages. In addition to behavioural treatments, pharmacotherapy for the treatment of symptoms of aphasia has also begun to be explored. Some studies have suggested a benefit of catecholaminergic drugs when used as an adjunct to behavioural therapy. At this time, further studies with appropriate controls are needed to assess which patients might potentially benefit from pharmacotherapy (Small, 1994).

Neglect

Kenneth M. Heilman

Department of Neurology, University of Florida College of Medicine, Gainesville, FL, USA

A patient with the neglect syndrome fails to report, respond or orient to, novel or meaningful stimuli presented to the side opposite a brain lesion (Heilman, 1979). If this failure can be attributed to either sensory or motor defects, the patient is not considered to have neglect.

The two basic mechanisms that are thought to be responsible for the failure to report, respond, or orient are defects in the systems that mediate sensory attention or motor intention. Whereas attentional defects may be associated with unawareness, intentional disorders may cause a failure to respond despite stimulus awareness. Attention and intention defects may occur in two domains: spatial and personal. Patients with neglect can also have spatial memory defects. This defect can be for new information or old memories (representational defects). This chapter describes tests that may be used to assess patients and behaviourally define these disorders. This chapter also discusses the pathophysiology underlying these disorders and their treatment.

Behavioural testing for the components of neglect

Tests for inattention and extinction

The attentional aspects of the neglect syndrome are detected by observing abnormal responses to sensory stimuli. Stimuli should be given in at least three modalities, somatesthetic, visual, and auditory, but other stimuli, such as gustatory and olfactory, may be used. Examiners often request immediate responses, however, delaying the response and using distractor techniques may help amplify the symptoms.

When testing with somatesthetic stimuli, one may control the intensity of a tactile stimulus by using Von Frei's hairs. However, fingers or cotton applicators are more convenient. Other cutaneous stimuli, such as pins, may be used. For bedside auditory testing, we use sounds made by either rubbing the fingers together or snapping them. When possible, perimetric and tangent screen studies should be used for testing visual fields. However, for bedside testing the confrontational method may be used; the examiner's finger movement can be used as the stimulus. A modified Poppelreuter diagram or written sentences may also be used.

These somatesthetic, auditory and visual stimuli should be presented to the abnormal (contralateral) side and to the normal side of the body in random order. If the patient responds normally to unilateral stimulation, simultaneous bilateral stimulation may be used. Unilateral stimuli should be randomly interspersed with simultaneous bilateral stimuli. Bender (1952) noted that normal subjects may show extinction to simultaneous stimulation when the stimuli are delivered to two different (asymmetric) parts of the body (simultaneous bilateral heterologous stimulation). For example, if the right side of the face and the left hand are stimulated simultaneously, normal subjects sometimes report only the stimulus on the face. Normal subjects do not extinguish symmetric stimuli (simultaneous bilateral homologous stimulation). Simultaneous bilateral heterologous stimulation can sometimes be used to test for milder defects in patients with extinction. For example, when the right side of the face and the left hand are stimulated, patients with left-sided neglect might not report the stimulus on the left hand, but when the left side of the face and right hand are stimulated, they might report both stimuli.

The most frequent response by patients is verbal (i.e. right, left or both). In addition, the patient may be instructed (verbally or non-verbally by gesture) to move the extremity or extremities the examiner has touched.

Patients may be considered to have hemi-inattention when they fail to orient, report, or respond to contralateral stimuli and when it can be demonstrated that the lesion does not interrupt afferent projectors and does not destroy primary sensory cortex or sensory thalamic nuclei. However, unless the site of the lesion is known, it may be difficult to distinguish between hemianesthesia or hemianopsia and severe somatesthetic and visual hemiattention. Occasionally, visual inattention may be distinguished from hemianopsia by changing the hemispace of presentation. Kooistra and Hellman (1989) reported a patient who could not detect single stimuli presented in the left visual field when the eyes were directed straight ahead, but could detect stimuli in the same retinotopic position when the eyes were directed toward right hemispace so that the left visual half-field was in the right hemispace.

Patients with hemianesthesia from unilateral cortical lesions probably suffer from inattention rather than from deafferentation. Elementary somatic sensation such as touch can be subserved by the thalamus. Lesions of the ventral posterolateral and ventral posteromedial thalamic nuclei result in hemianesthesia, but lesions in somatosensory cortex should not. Some patients with cortical lesions who appear to have tactile anesthesia can detect contralesional stimuli when cold water is injected into the contralesional ear. This increases orientation toward the side of the cold ear via vestibular mechanisms, suggesting that the hemianesthesia in fact results from sensory neglect (Vallar et al., 1995). One can also use psychophysiological procedures, such as early evoked potentials and skin conductance responses, to discriminate between inattention and deafferentation.

Although hemianesthesia and hemianopsia are fairly common manifestations of central nervous system lesions, unilateral hearing loss is almost always due to a disturbance in the peripheral hearing mechanisms or in the auditory nerve. Because the auditory pathways that ascend from the brainstem to the cortex are bilateral, each ear projects to both hemispheres. Thus, a unilateral central nervous system lesion will not produce unilateral hearing loss. Consequently, patients without peripheral hearing loss who fail to orient to, or report, unilateral auditory stimulation usually have hemi-inattention. Furthermore, because sound presented on one side of the body projects to both ears, patients with unilateral hearing loss caused by a peripheral lesion usually respond to unilateral auditory stimulation unless the stimulus is extremely close to the ear. Therefore, patients who neglect unilateral auditory stimuli most often have unilateral inattention.

Patients with unilateral neglect are most inattentive to stimuli contralateral to the lesion, but they are often also inattentive to ipsilateral stimuli, although ipsilateral inattention is not so severe.

Tests for personal neglect

Whereas the failure to detect tactile stimuli described in the preceding section may be a sign of personal neglect, patients with flagrant personal inattention may deny that their own limbs belong to them. This deficit is also called asomatognosia. The examiner can demonstrate personal neglect by asking patients to show a limb or by showing them their own limb and asking them to whom the limb belongs. Patients with personal neglect may also fail to groom or dress half of their body. Although anosognosia of a left hemiplegia and allesthesia (misplacing contralesional stimuli to the ipsilesional part of the body) are often associated with personal neglect, these three signs are often dissociable.

Coslett (1998) showed right hemisphere damaged patients diagrams of the palmar or dorsal aspect of the right or left hand and asked them to tell if the picture showed a right or left hand. To perform this task, one has to image one's own right or left hand in either the prone or supine position. Coslett's patients were impaired when shown diagrams of the left hand but not the right hand, suggesting a defect in the left side of a personal representation.

Tests for spatial neglect

Patients fail to act on contralesional stimuli presented in space. They may fail to act on stimuli presented to the left of their body (viewer centred hemispatial neglect), or they may fail to act on the left side of the environment or they may fail to act on the left side of the stimulus (allocentric spatial neglect). The three most frequently used methods for testing spatial neglect are the line bisection, the cancellation tasks and drawing. In the cancellation test, small lines are randomly drawn on a sheet of paper and the patient is asked to cross out all the lines. This can be made more difficult by using a task in which patients must either discriminate or focus their attention (Rapcsak et al., 1989). In the line bisection task an 8- to 10-inch line is presented to the patient, who is asked to bisect the line (find the middle of the line). This task can be made more difficult by using longer lines (Butter et al., 1988a) or by placing lines to the left of the midsagittal plane (Heilman & Valenstein, 1979).

When using very short lines patients with contralesional neglect may place their bisection mark on the side of the line that is contralateral to their hemispheric lesion. This

has been termed the cross-over effect (Halligan & Marshall, 1991).

Lastly, one can test for spatial neglect by having a subject copy drawings. Because neglect is often associated with right hemisphere lesions, patients may have constructional apraxia. Therefore, simple drawings (flower, clock) should be used.

Although spatial neglect is most often described in the horizontal plane (left spatial neglect), vertical neglect (Rapcsak et al., 1988) and radial neglect (Shelton et al., 1990) have also been reported. Vertical neglect and radial neglect can be assessed by orienting the line to be bisected in a radial or vertical direction.

Bisiach and Luzzatti (1978) asked patients to describe a familiar scene. Patients with left-sided neglect failed to recall the left side of the scene. Unfortunately, there is no simple bedside test for examining spatial representations. However, one can ask patients to describe the layout of their house, describe the sites on a famous street in their hometown going in a specific direction, or name the cities in the state in which they live. Failure to describe more items on one side than the other may suggest spatial representational neglect. Asking a patient to spell words from memory may also elicit spatial representational neglect but is an insensitive test. Finally, one could ask a patient who can copy drawings to make the same drawings from memory.

There are patients with hemispheric dysfunction who will bisect long lines toward contralesional rather than ipsilesional hemispace (Kwon & Heilman, 1991; Na et al., 1998a). This is called ipsilateral neglect.

Tests for motor-intention deficits: akinesia and motor neglect

Akinesia is the inability to initiate a movement that cannot be attributed to a defect in the motor unit or corticospinal neurons. Milder forms of akinesia may be expressed as a delay in initiating a movement (hypokinesia) or decreased amplitude of movement (hypometria). Akinesia may affect one or more body parts (legs, limbs, eyes, head) and may be spatial or directional. It may be seen only with spontaneously evoked activities (endo-evoked akinesia) or only in response to stimuli (exo-evoked akinesia) or may be mixed. When akinesia is mixed, involves a limb, and is not spatially or directionally specific, it may be difficult to dissociate from a motor defect caused by corticospinal tract damage, and one may have to rely on imaging studies or caloric stimulation.

When examining a patient for akinesia, one must make multiple observations, including watching spontaneous activity to see if the patient moves their eyes, head, and limbs in all directions. After an acute insult to the right hemisphere, it is not unusual for the head and eyes to be deviated to the right and not to move toward the left either spontaneously or in response to stimuli and instructions. However, even in the absence of this florid manifestation, contralesional directional akinesia may be detected using a modification of the crossed response task (Watson et al., 1978). The examiner holds one hand in the patient's right visual half-field and the other in the left visual half-field. In the first series of trials, the index finger of the examiner's right or left hand is moved and the patient is instructed to look at the moving finger. A patient who fails to look at the contralesional stimulus may have hemianopsia, visual inattention, or directional akinesia. These can be dissociated by instructing the patient to look to the side opposite that stimulated, so that when the examiner's right index finger is moved, the patient looks toward the left hand and vice versa. Failure to look at the contralesional hand indicates directional akinesia, and failure to look at the ipsilesional finger suggests inattention or hemianopsia (Butter et al., 1998b). In less severe cases of directional akinesia, patients may move in a contralesional direction by making multiple hypometric saccades (Heilman et al., 1980).

A condition similar to eye deviation may be detected in the arm by asking blindfolded patients with neglect to point to their midsagittal plane (Heilman et al., 1983a). Patients may point toward the ipsilateral hemispace. To detect directional akinesia of the limbs, a blindfolded patient may be placed before a table that has pennies randomly distributed over the top and be asked to pick up all the pennies. Patients with directional akinesia may fail to explore left hemispace. Patients may also have a directional hypokinesia of the limbs, so that movements toward the left are initiated more slowly than movements toward the right (Heilman et al., 1985). Patients may demonstrate hemispatial akinesia of the limbs such that when the limb is in contralateral hemispace it does not move or it moves less than when it is in ipsilateral hemispace (Meador et al., 1986).

Testing for anosognosia

Explicit verbal denial or unawareness of illness is termed anosognosia. Patients with neglect often deny a left hemiplegia, and they may also be unaware of a left hemianopsia. Verbally acknowledging a problem but failing to be concerned is called anosodiaphoria. Anosognosia and anosodiaphoria are best tested by asking patients why they came to the hospital. If they fail to describe their problems,

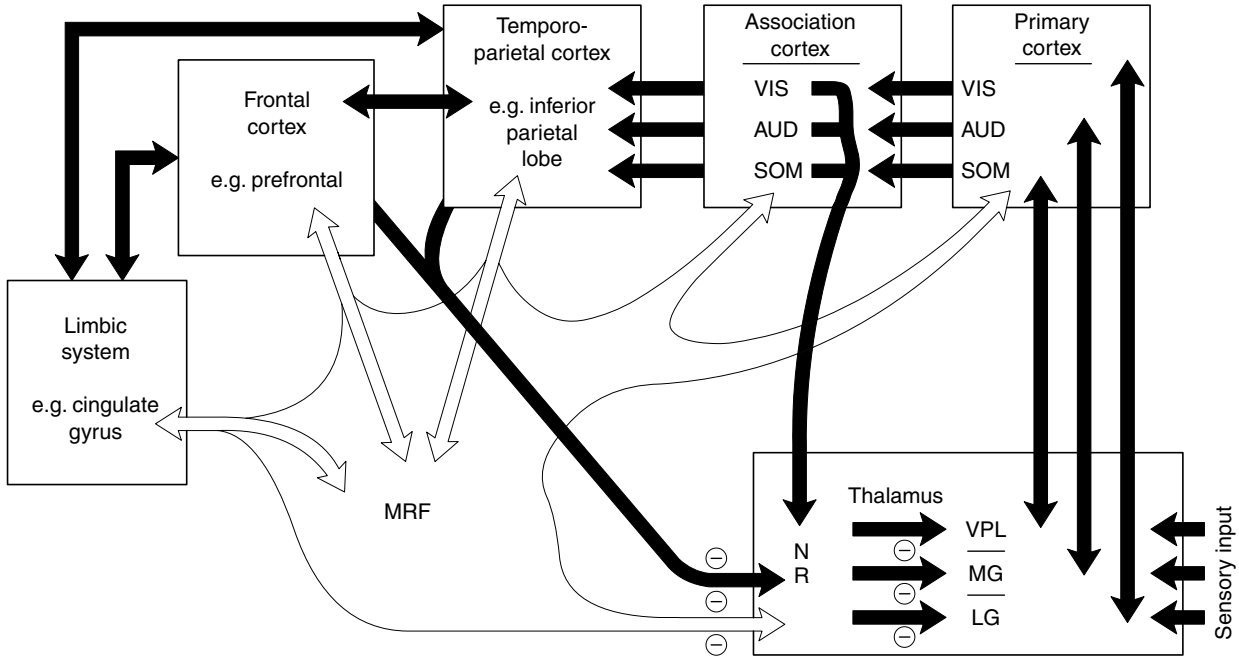

Fig. 23.1. Schematic representation of systems important in attention and arousal (see text for details). NR = nucleus reticularis thalami; MRF = mesencephalic reticular formation; VPL = ventralis posterolateris; MG = medial geniculate; LG = lateral geniculate; VIS = visual; AUD = auditory; SOM = somatosensory.

more specific questions may be asked. If patients have hemispatial inattention, the hemiparetic limbs should be brought into ipsilesional hemispace and the patients should be asked to move the limb and then asked again if they are impaired.

Testing for allesthesia and allokinesia

When stimulated on the side contralateral to a lesion, patients with allesthesia misplace the location of the stimulus to the normal side. Patients with allokinesia respond with the wrong limb or move in the wrong direction. Allesthesia and allokinesia should be distinguished from right–left confusion. Patients with right–left confusion do not make systematic directional errors, whereas patients with allesthesia misattribute left side stimuli to the right, but not vice versa.

Pathophysiology of the components of neglect

Pathophysiology of inattention

Unilateral inattention can be induced in humans by lesions in a variety of loci. Contralateral inattention may be induced by lesions in the temporal–parietal–occipital junction or inferior parietal lobe (Critchley, 1966; Heilman et al., 1983b). In humans, inferior parietal lobe lesions are probably most commonly associated with inattention, but lesions of the dorsolateral frontal lobe may also be associated with inattention (Damasio et al., 1980; Heilman & Valenstein, 1972). In humans and monkeys, lesions in the cingulate gyrus (Heilman & Valenstein, 1972; Watson et al., 1973) and subcortical lesions in such areas as the thalamus and mesencephalic reticular formation (Watson & Heilman, 1979; Watson et al., 1974) may also induce inattention.

Cerebral infarction is the most common cause of cortical lesions associated with neglect. Intracerebral hemorrhage is the cause of most subcortical lesions associated with inattention; however, other disease processes, including tumours, may induce inattention.

Inattention is probably caused by dysfunction in a cortical–limbic–reticular formation network (Heilman & Valenstein, 1972; Watson et al., 1974, 1981) (Fig. 23.1). A discussion of possible mechanisms requires some consideration of the phenomena of arousal, a physiologic state that prepares the organism for sensory and motor processing.

Stimulation of the mesencephalic reticular formation is associated with arousal and also with desynchronization of

the electroencephalogram, a physiologic measure of arousal (Moruzzi & Magoun, 1949). Unilateral stimulation induces greater desynchronization of the electroencephalogram in the ipsilateral than in the contralateral hemisphere (Moruzzi & Magoun, 1949). Bilateral mesencephalic reticular formation lesions result in coma. Unilateral lesions result in contralateral inattention, which is probably due to unilateral hemispheric hypoarousal (Reeves & Hagamen, 1971; Watson et al., 1974). The mesencephalic reticular activating system probably projects to the cortex in a diffuse polysynaptic fashion (Schiebel & Schiebel, 1967). This projection may occur through the thalamus (Steriade & Glenn, 1982) or basal forebrain.

There is another way in which the mesencephalic reticular activating system can affect cortical processing of sensory stimuli. Sensory information that reaches the cortex is relayed through specific thalamic nuclei. The nucleus reticularis thalami, a thin reticular nucleus enveloping the thalamus, projects to the thalamic relay nuclei and appears to inhibit thalamic relay to the cortex (Schiebel & Schiebel, 1966). The mesencephalic reticular formation projects to the nucleus reticularis. Rapid stimulation of the mesencephalic reticular formation (or behavioural arousal) inhibits the nucleus reticularis and is thereby associated with enhanced thalamic sensory transmission to the cerebral cortex (Singer, 1977). Unilateral lesions of the mesencephalic reticular formation may induce neglect because in the absence of mesencephalic reticular formation-mediated arousal, the cortex is not prepared for processing sensory stimuli and the thalamic sensory relay nuclei are being inhibited by the nucleus reticularis thalami.

Modality-specific association areas may detect stimulus novelty (Sokolov, 1963). When a stimulus is neither novel nor significant, corticofugal projections to the nucleus reticularis thalami may allow habituation to occur by selectively influencing thalamic relay. When a stimulus is novel or significant, the corticofugal projections may inhibit the nucleus reticularis thalami and allow the thalamus to relay additional sensory input.

Unimodal association areas converge on polymodal association areas (see Fig. 23.1) in the prefrontal cortex and in the posterior superior portion of the temporal lobe and inferior parietal lobe (Pandya & Kuypers, 1969). Polymodal convergence areas may subserve cross-modal associations and polymodal sensory synthesis. Polymodal sensory synthesis may also be important in the detection of stimulus novelty (modelling) and significance. In contrast to the unimodal association cortex that projects to specific parts of the nucleus reticularis thalami and thereby gates sensory input in one modality, these multimodal convergence areas may have a more general inhibitory action on the nucleus reticularis thalami and provide further arousal after cortical analysis. These convergence areas also may project directly to the mesencephalic reticular formation, which may either induce a general state of arousal because of diffuse multisynaptic connections to the cortex or increase thalamic transmission through connections with the nucleus reticularis thalami, or both. Evidence that polymodal areas of the cortex, such as the prefrontal and inferior parietal lobe, are important in arousal comes from neurophysiological studies showing that stimulation of these cortical sites induces a generalized arousal response (Segundo et al., 1955). When similar sites are ablated, there is electroencephalographic evidence of ipsilateral hypoarousal (Watson et al., 1977).

Although the sensory association cortex may mediate determination of stimulus novelty, stimulus significance is determined in part by the needs of the organism (motivational state). Limbic system input into the brain regions important for determining stimulus significance may provide information about biologic needs. The frontal lobes may provide input about needs related to goals that are neither dependent directly on the stimulus nor motivated by an immediate biologic need, because the frontal lobes have a critical role in goal-mediated behaviour and in developing sets.

The inferior parietal lobe has prominent limbic (cingulate) and frontal connections (Baleydier & Mauguiere, 1980; Pandya & Kuypers, 1969; Vogt et al., 1979) that may provide an anatomic substrate through which motivational states (for example, biologic needs, sets, and long-term goals) may influence stimulus processing (Heilman, 1979; Heilman & Valenstein, 1972; Watson et al., 1981).

Investigators have been able to study the physiologic function of specific areas of the nervous system by recording from single neurons in awake animals. In this experimental situation, the firing characteristics of individual neurons can be measured in relation to specific sensory stimulation or motor behaviour. Investigators have thus defined the properties of neurons in the inferior parietal lobule (area 7) of the monkey (Lynch, 1980; Mountcastle et al., 1975). Unlike the activity of single cells in primary sensory cortex, the activity of many neurons in the inferior parietal lobule correlates best with stimuli or responses of importance to the animal, and similar stimuli or responses that are unimportant are associated with either no change or a lesser change in neuronal activity. These cells appear to be critical in directing attention.

The attentional model we have discussed is summarized in Fig. 23.1. Unilateral inattention follows lesions of the unilateral mesencephalic reticular activation system

because loss of inhibition of the ipsilateral nucleus reticularis by the mesencephalic reticular activating system decreases thalamic transmission of sensory input to the cortex or because the mesencephalic reticular formation does not prepare the cortex for sensory processing, or both. Unilateral lesions of the primary or association cortices cause contralateral unimodal sensory loss or inability to synthesize contralateral unimodal sensory input. Corticothalamic collaterals from the association cortex to the nucleus reticularis may serve unimodal habituation and attention. Unilateral lesions of multimodal sensory convergence areas that project into mesencephalic reticular activating system and nucleus reticularis induce contralateral inattention because the subject cannot be aroused to, or process, multimodal contralateral stimuli. A lesion of the inferior parietal lobule, because of its reciprocal connections with polymodal areas and the limbic system, may impair the subject's ability to determine the significance of a stimulus.

Pathophysiology of extinction

Although patients may initially have hemi-inattention, most improve. Whereas at first they fail to detect stimuli presented to the side opposite the lesion, they eventually become able to report these stimuli. When given bilateral simultaneous stimulation, however, they often fail to report the stimulus presented to the side contralateral to the lesion (Anton, 1899; Bender, 1952; Loeb, 1885; Poppelreuter, 1917).

Extinction can be seen in normal subjects as well as in patients with central nervous system lesions (Benton & Levin, 1972; Kimura, 1967). The lesions causing extinction are often in the same areas as lesions that cause inattention. However, certain forms of extinction may also occur after lesions of the corpus callosum (Milner et al., 1968; Sparks & Geschwind, 1968), and left-sided extinction has even been reported after left hemisphere lesions (Schwartz et al., 1979).

The mechanisms underlying extinction in normal subjects and in patients with callosal lesions, sensory defects, or hemispheric lesions may differ and, in general, are poorly understood. Several investigators have suggested that extinction and perhaps obscuration in normal subjects and patients with sensory loss result from suppression or reciprocal inhibition. In the case of cerebral damage, the normal hemisphere inhibits the damaged hemisphere more than the damaged hemisphere inhibits the normal hemisphere. Consequently, stimuli contralateral to the damaged hemisphere are not perceived when the normal side is stimulated. The physiologic mechanisms that induce this reciprocal inhibition are unknown. However, as discussed earlier, the thalamic reticular nucleus can selectively inhibit various thalamic sensory nuclei. Each association cortex may not only project to the ipsilateral thalamic reticular nucleus but also influence the contralateral thalamic reticular nucleus. Unlike the ipsilateral connections, which are inhibitory, the contralateral projections may be facilitatory. Therefore, even under normal conditions, a stimulus on one side should induce an increase of threshold for stimuli on the other side. With a lesion of association cortex there should be less ipsilateral inhibition of nucleus reticularis thalami, which in turn should inhibit the thalamic sensory nuclei, thus making the thalamus less sensitive to contralateral stimuli. If the opposite side were simultaneously stimulated, activated attentional cells should further increase contralateral nucleus reticularis thalami activity, further inhibiting the thalamic sensory nuclei and thereby inducing extinction. The pathway by which one association cortex may influence the contralateral nucleus reticularis thalami is unknown.

Birch et al. (1967) proposed and provided support for the hypothesis that the damaged hemisphere processes information more slowly than does the intact hemisphere. Because of this inertia, the damaged side is more subject to interference from the normal side. When stimuli must be processed by a lateralized system, callosal lesions may induce extinction because the information cannot reach the processor or is delayed.

Another explanation for extinction, the limited attention theory, proposes that under normal circumstances bilateral simultaneous stimuli are processed simultaneously, each hemisphere processing the contralateral stimulus. However, a damaged hemisphere may be unable to attend to contralateral stimuli, making the organism inattentive to those stimuli. As the organism recovers, it can attend to contralateral stimuli. This improvement may be mediated by the normal (ipsilateral) hemisphere. The normal hemisphere, however, may have a limited attentional capacity. Therefore, with bilateral simultaneous stimulation the normal hemisphere's attentional mechanism, occupied with the contralateral stimulus, may be unable to attend to the ipsilateral stimulus (Heilman, 1979).

These theories may not be mutually exclusive. Because extinction can be caused by lesions in a variety of anatomically and functionally different areas, the reciprocal inhibition, limited attention, and interference theories may each be correct, but for different lesions.

Pathophysiology of akinesia and motor neglect

Attention and intention (preparation to make a movement) are closely linked, and lesions in many of the areas

that induce inattention and extinction may also induce akinesia. For example, unilateral sensory neglect (inattention) has been reported to follow unilateral dorsolateral frontal lesions in monkeys (Bianchi, 1895; Kennard & Ectors, 1938; Welch & Stuteville, 1958) and humans (Heilman & Valenstein, 1972). In most testing paradigms the animal is required to respond to a stimulus contralateral to the lesion either by orienting to the stimulus or by moving the limbs on the side of the stimulus. These animals with frontal lobe lesions were not weak, so it was assumed that they had sensory neglect when they failed to make the appropriate response. Although this neglect was usually assumed to result from inattention to the sensory stimuli, we suggested that it could equally well be caused by unilateral akinesia (Watson et al., 1978). Therefore, we trained monkeys to use the left hand to respond to a tactile stimulus on the right leg and the right hand to respond to a tactile stimulus on the left. After a unilateral frontal arcuate lesion, the monkeys appeared to have contralateral neglect, but when stimulated on their neglected side, they responded normally with the limb on the side of the lesion. When stimulated on the side ipsilateral to the lesion, however, they often failed to respond (with the limb on the neglected side) or responded by moving the limb ipsilateral to the lesion. These results cannot be explained by sensory or perceptual hypotheses and are thought to reflect a defect in intention to make a correct response.

In considering the possible role of the dorsolateral frontal lobes in attention and intention related to multimodal sensory and limbic inputs, it is important to examine their connections. The dorsolateral frontal lobe has reciprocal connections with unimodal and polymodal posterior sensory association cortex (Chavis & Pandya, 1976) and is an area of sensory convergence (Bignall & Imbert, 1969). The dorsolateral frontal lobe has reciprocal connections with medial (non-specific) thalamic nuclei. Projections to the mesencephalic reticular formation (Kuypers & Lawrence, 1967) and non-reciprocal projections to caudate also exist. Also, the dorsolateral frontal lobe receives input from the limbic system, primarily from the anterior cingulate gyrus (Baleydier & Mauguiere, 1980).

Its connections with neocortical sensory association and sensory convergence areas may provide the frontal lobe with information about external stimuli that may call the organism to action. The limbic connections (anterior cingulate gyrus) may provide the frontal lobe with motivational information. Connections with the mesencephalic reticular formation may be important in arousal.

Because the dorsolateral frontal lobe has sensory association cortex, limbic and reticular formation connections, it seems to be ideal for mediating a response to a stimulus to which the subject is attending. Physiologic studies support this hypothesis (Goldberg & Bushnell, 1981).

Motor neglect or akinesia may also accompany lesions of the non-specific intralaminar thalamic nuclei (Watson et al., 1978), which project to both the frontal lobe and the neostriatum. Akinesia may result from basal ganglia and ventral thalamic lesions (ventralis lateralis and ventralis anterior) (Velasco & Velasco, 1979). The basal ganglia project to the ventral thalamus, and this motor portion of the thalamus is also gated by nucleus reticularis thalami. The nucleus reticularis thalami may be inhibited by the mesencephalic reticular formation during an arousal or orienting response and be inhibited by the frontal lobes during a motor set.

Akinetic mute states are often induced by bilateral lesions of the frontal lobes, cingulate gyri, and medial thalamus. These lesions are usually caused by vascular disease (Segarra & Angelo, 1970). A cingulate gyrus lesion may be induced by an infarct in the distribution of the anterior cerebral artery, secondary to thrombosis, embolism, or aneurysm-induced spasm. Akinetic mutism of thalamic origin is most often the result of occlusion of the posterior thalamic–subthalamic paramedian arteries (Segarra & Angelo, 1970).

Degenerative diseases that affect the basal ganglia, limbic system and frontal lobes may also induce akinesia. These include Parkinson's disease, progressive supranuclear palsy, striatonigral degeneration, olivopontocerebellar degeneration and related diseases. Late in the course of several degenerative dementias, including Pick's disease and Alzheimer's disease, akinesia may be a prominent sign.

Lesions that disrupt the connections of the frontal lobes, limbic system, basal ganglia and thalamus may also be associated with akinesia. Hydrocephalus, tumours (such as butterfly gliomas), lacunae and Binswanger's disease are common causes of such lesions.

Pathophysiology of spatial neglect

Lesions associated with contralesional hemispatial neglect are similar to those associated with inattention and extinction. Although hemianopsia may enhance the symptoms of hemispatial neglect, hemianopsia alone cannot account for the deficit because some patients with hemispatial neglect do not have hemianopsia (McFie et al., 1950) and some patients with hemianopsia do not have spatial neglect.

The abnormal performance of patients in contralesional hemispace suggests that brain mechanisms related to the opposite hemispace have been disturbed. It also suggests that each hemisphere is responsible not only for receiving stimuli from the contralateral visual field and for controlling

the contralateral limbs but also for attention and intention in and toward contralateral hemispace, independent of which visual field the stimulus enters or which hand is used (Bowers & Heilman, 1980; Heilman, 1979). The postulate that each hemisphere attends to and intends in and toward contralateral hemispace has been supported by studies of normal subjects (Bowers et al., 1981).

Hemispace can be defined according to the visual half-field (eye position), head position, or trunk position. With the eyes and head facing directly ahead, the hemispaces defined by the eyes, head, and body are congruent. But if the eyes are directed to the far right, for example, the left visual field falls in the right hemispace, as defined by the head and body midline. Similarly, if the head and eyes are turned far to the right, the left head and eye hemispaces can both be in the right hemispace of the body. There is evidence that head and body hemispaces are important in determining the symptoms of hemispatial neglect (Bowers & Heilman, 1980; Heilman & Valenstein, 1979). For example, when patients with left hemispatial neglect are asked to bisect a line, their performance is poorer in left body hemispace than in right hemispace even when a strategy is used to ensure that the line is seen in the normal right hemifield (Heilman & Valenstein, 1979). Similarly, independent of visual field and body hemispace, lines are more poorly bisected in left head hemispace than in right head hemispace (Coslett et al., 1985).

Several neuropsychological mechanisms could account for the hemispatial defect associated with neglect. Patients with hemispatial neglect may have a hemispatial sensory-attentional deficit. Although the line is seen in the normal visual field, it is not attended and thus is not fully processed; the percept is therefore not consolidated and the stimulus does not affect the patient's behaviour. Alternatively, the percept can be weakened and appear of less magnitude. The attentional defect may also be associated with a hemispatial memory defect (Heilman et al., 1974).

Patients with neglect may have an attentional bias such that their attention is drawn to the side of space ipsilateral to their lesion (Kinsbourne, 1970) and they are unable to draw their attention away from the ipsilateral part of space. Partial support for the attentional bias hypothesis comes from the observation that, in a cancellation task, erasing lines is associated with better performance than cancelling lines. When lines are erased, they no longer draw attention (Mark et al., 1988).

Hemispatial neglect may be associated with a directional and hemispatial akinesia of the eyes and the arm. The former together with inattention would prevent patients from fully exploring the left side of space, and the latter would prevent patients with neglect from acting with their arms in the left side of space. As previously discussed, patients with neglect may have a directional akinesia of their eyes that is independent of their inattention (Butter et al., 1988b). In regard to the arm, Coslett et al. (1990) prevented patients from looking directly at their hand when performing a line bisection task; instead, a video camera projected the hand and the line to a video monitor. Using this technique, the hemispace where the action took place could be dissociated from the hemispace where visual feedback took place. Some patients did better when the monitor was in ipsilateral hemispace than in contralateral hemispace. Others were not affected by the position of the monitors but did better when the action took place in ipsilateral hemispace than they did when the action took place in contralateral hemispace. Coslett et al. (1990) suggested that patients with intentional neglect had more involvement of the frontal lobes than those with attentional spatial neglect who had involvement of the parietal lobes.

That spatial neglect can be associated with a motor-intentional bias or a sensory attentional bias is also supported by the work of Bisiach et al. (1990). They used a loop of string stretched around two pulleys. An arrow was attached to the top segment of string. Subjects with neglect and control subjects were asked to place the arrow midway between the two pulleys. In the congruent condition, the subject held the arrow on the upper string and in the non-congruent condition, the subject moved the arrow by lateral displacement of the lower string, which moved the arrow in the opposite direction. If neglect was caused by a directional hypokinesia, the error in the congruent and noncongruent conditions should be in opposite directions but if it was caused by an attentional bias it will remain in the same direction. Six of 13 subjects showed a significant reduction of neglect in the noncongruent condition, suggesting that they had a significant motor-intentional bias and these patients had predominately frontal lesions. The other subject showed an attentional bias. Na and coworkers (1998b) also attempted to dissociate attentional and intentional aspects of neglect by having subjects view their performance of a line bisection task on a video monitor on which the task was displayed either normally (direct condition) or right-left reversed (indirect condition). Subjects could not view the work space directly, but only on the monitor. This technique allows the investigator to investigate the relative contribution of attentional and intentional biases in the same subject. Using this apparatus Na et al. (1998a, b) found that most patients with spatial neglect have both intentional and attentional biases, but in patients with frontal lesions the intentional bias dominated, whereas in patients with temporal–parietal lesions

the attentional bias predominated. The finding of mixed attentional and intentional bias is consistent with the idea that the networks subserving attention and intention influence one another. Anatomically, the parietal and frontal lobes are involved in both networks.

Pathophysiology of ipsilateral neglect

Butter et al. (1988a, b), studied the eye movements of a patient with left-sided neglect from a right dorsolateral frontal lesion by asking the patient to move his eyes in the direction opposite a lateralized stimulus. When presented with a left-sided stimulus, instead of looking rightward the patient first looked leftward. This has been termed a visual grasp. The patient with ipsilateral neglect reported by Kwon and Heilman (1991) also had a visual grasp from a frontal lesion. Kim et al. (1999) studied a series of patients with ipsilateral neglect and demonstrated that most had frontal lesions. Patients with frontal lesions have manual grasp, sucking, and rooting reflexes. They also may have mitgehen and facilitory paratonia, all approach behaviours. Denny-Brown and Chambers (1958) proposed that the parietal lobes mediate approach behaviours and the frontal lobes mediate avoidance behaviours. Therefore, injury to the frontal lobes disinhibits the parietal lobes and induces aberrant approach. Kwon and Heilman suggested that the left-sided visual grasp and ipsilateral neglect may both be manifestations of inappropriate approach behaviours. Robertson et al. (1994) replicated Kwon and Heilman's observations, but suggested that ipsilateral neglect was related to a learned compensatory strategy. Some of the patients with ipsilateral neglect, however, reported by Kim et al. (1999), demonstrated this phenomenon almost immediately after their stroke suggesting that ipsilateral neglect could not be attributed entirely to a compensatory strategy. Na et al. (1998a) also demonstrated that ipsilateral neglect, like contralateral neglect, can be induced by both a contralesional attentional bias and a contralesional intentional bias.

Pathophysiology of representational defects

Denny-Brown and Banker (1954) described a patient who could not describe from memory the details of the side of a room opposite her cerebral lesion. Bisiach and Luzzatti (1978) asked two patients with right hemisphere damage to describe from memory a familiar scene in Milan from two different perspectives, one facing the cathedral and the other facing away. In both orientations, left-sided details were omitted. On the basis of these findings, the investigators postulated that the mental representation of the environment is structured topographically and is mapped across the brain so that it is split between the two hemispheres (like the projection of a real scene). With hemispheric damage there is a representational disorder for the contralateral half of this image. Brain (1941) proposed that the parietal lobes contain personal (body) and spatial schemata (representations). The two patients of Bisiach and Luzzatti (1978) and the one described by Meador and colleagues (1987) with hemispatial representational disorder all had right temporo-parietal damage.

There are at least three explanations for the failure of Bisiach and Luzzatti's patients to envision one half of the mental image: (i) the representation may have been destroyed, as suggested by Bisiach and Luzzatti; (ii) the representation may have been intact but could not be activated, so an image could not be formed; and (iii) the image was formed, but it could not be fully explored or attended to (e.g. hemispatial inattention to an internal representation). If a representation is destroyed, attentional manipulation should not affect retrieval, but if patients with neglect have an activational or attentional deficit, attentional manipulation may affect retrieval. Meador et al. (1986) not only replicated Bisiach and Luzzatti's observations but also provided evidence that behavioural manipulations could affect performance. When normal subjects are asked to recall an object in space, they move their eyes to the position the object occupied in space (Kahneman, 1973). Moving one's eyes to a specific spatial location may aid recall. Having patients move their eyes toward neglected hemispace may aid recall because the eye movement induces hemispheric activation or helps direct attention. Meador et al. (1986) asked a patient with left hemispatial neglect and defective left hemispatial recall to move his eyes to either right or left hemispace while recalling a scene. The patient's recall of details on the left side was better when he was looking towards the left than towards the right. This finding provides evidence that hemispatial representational deficit may be induced by an activation or an exploratory-attentional deficit.

Pathophysiology of denial of hemiplegia (anosognosia)

Denial or unawareness of hemiplegia is most often seen with right hemisphere lesions. The lesion usually includes both the frontal and parietal regions. There have been many explanations of this dramatic behavioural aberration. Weinstein and Kahn (1955) studied the premorbid personalities of patients with anosognosia and found that, before their strokes, they used denial mechanisms more frequently than did controls. However, Weinstein and Kahn's study cannot explain why denial of hemiplegia is

more frequently associated with right hemisphere dysfunction (Gilmore et al., 1992). Denial of hemiplegia is often associated with neglect, and perhaps patients do not recognize that they are hemiplegic because they have personal neglect. However, Bisiach et al. (1986) demonstrated that personal neglect was not always associated with denial of hemiplegia. The disconnection hypothesis has also been used to explain denial of hemiplegia, postulating that the damaged right hemisphere is disconnected from other areas of the brain, including speech–language areas (Geschwind, 1965). It is well established that the left hemisphere speech areas in the absence of input often confabulate a response (Gazzaniga, 1970). Neither the disconnection hypothesis nor the neglect hypothesis can explain why patients still deny hemiplegia when the paretic hand is brought into right hemispace or into the right visual field, where it gains direct access to the left hemisphere (Adair et al., 1995).

Many theories of anosognosia are related to defective feedback. Even though these feedback theories may help explain failure to recognize a hemianopsia, they cannot explain denial of hemiplegia when the arm is brought into a normal visual field and gains access to the normal hemisphere. We propose a 'feed-forward' or 'intentional' theory of denial of hemiplegia, in which the previously discussed intentional system may be responsible not only for activating the motor systems but also for feeding information about motor expectations to comparator systems. When a patient without anosognosia attempts to move a paretic limb, the comparator notes a mismatch between expectations and performance. However, when the intentional system is impaired (independently or along with the motor systems), not only is there inability to activate the motor neurons but also expectations are not fed to the comparator. When the patient fails to move there is no mismatch and, therefore, no awareness of a deficit. Perhaps this is why patients who have denial of left hemiplegia, when asked why they are not moving their arm, call it 'lazy' (Weinstein & Kahn, 1955). As discussed, intentional defects such as akinesia are more commonly associated with right then left hemisphere lesions. If denial of hemiplegia is related to intentional defects, it is not surprising that denial of hemiplegia is also more common with right hemisphere lesions.

Hemispheric asymmetries and the neglect syndrome

Many early investigators noted that inattention is more often associated with right than with left hemisphere lesions (Brain, 1941; Critchley, 1966; McFie et al., 1950). To account for hemispheric asymmetry of attention in humans, it has been postulated that temporo-parietal regions of the human brain have attentional or comparator neurons, but that the neuronal networks in the right hemisphere are more likely to have bilateral receptive fields than those in the left hemisphere. Thus, the networks in the left hemisphere would be activated predominantly by novel or significant stimuli on the right, but the networks in the right hemisphere would be activated by novel or significant stimuli on either or both sides (Heilman & Van Den Abell, 1980). If this were the case, right hemisphere lesions would cause inattention more often than left hemisphere lesions. When the left hemisphere is damaged, the right can attend to ipsilateral stimuli, but the left hemisphere cannot attend to ipsilateral stimuli after right-sided damage. Support for this hypothesis has been provided by electrophysiologic (Heilman & Van Den Abell, 1980) and imaging (Prohovnik et al., 1981; Rosen et al., 1981) studies. Extinction has also been shown to be more frequent with right than left hemisphere dysfunction (Meador et al., 1988) and may also be related to the hemispheric asymmetries in attentional capacity.

Some patients with right hemisphere lesions are also inattentive to right-sided stimuli (Albert, 1973). Although damage to attentional or comparator networks in the right hemisphere may induce an ipsilateral defect, the cortical lesions may also induce an arousal defect. Using a galvanic skin response and electroencephalographic power spectrum recording, it has been shown that right hemisphere lesions reduce arousal to stimuli presented to the hand ipsilateral to the lesion (Heilman et al., 1978) as well as to the opposite hand.

Patients with right hemisphere lesions also have contralateral limb akinesia more often than do patients with left hemisphere lesions (Coslett & Heilman, 1989). Hypokinesia, however, is not always limited to the contralateral extremities. Howe and Boller (1975) found that patients with right hemisphere lesions had slower reaction times than did patients with left hemisphere lesions. In their patients, the right hemisphere lesions associated with this slowing were not larger than those on the left. Although the right parietal lobe lesions appeared to induce the most profound slowing, these investigators did not mention whether the patients with ipsilateral slowing had unilateral neglect. In monkeys, no hemispheric asymmetries in production of the neglect syndrome have been noted. However, monkeys with lesions inducing neglect had slower ipsilateral reaction times than did monkeys with equal-sized lesions that did not induce neglect (Valenstein et al., 1987).

Lansing and colleagues (1959) have shown that warning stimuli may prepare an organism for action and thereby reduce reaction times. Pribram and McGuinness (1975) used the term activation to define the physiologic readiness to respond to environmental stimuli. Because patients with right hemisphere lesions have reduced behavioural evidence of activation (Howe & Boller, 1975), it has been postulated that in humans the right hemisphere dominates in mediating the activation process (Heilman & Van Den Abell, 1979). That is, the left hemisphere prepares the right extremities for action, and the right prepares both. Therefore, with left-sided lesions, left-sided limb akinesia is minimal, but with right-sided lesions there is severe left limb akinesia. In addition, because the right hemisphere is more involved than the left hemisphere in activating the right extremities, there is more ipsilateral hypokinesia with right hemisphere lesions, than with left hemisphere lesions.

That the right hemisphere dominates mediation of activation or intention (physiologic readiness to respond) has been demonstrated in normal subjects. They show more activation (measured behaviourally by the reaction time) with warning stimuli delivered to the right hemisphere than to the left hemisphere. That is, warning stimuli projected to the right hemisphere reduced reaction times of the right hand more than stimuli projected to the left hemisphere reduced left-hand reaction times; warning stimuli projected to the right hemisphere reduced reaction times of the right hand even more than did warning stimuli projected to the left hemisphere. These results support the hypothesis that the right hemisphere dominates activation or intention (Heilman & Van Den Abell, 1979).

Physical therapists and occupational therapists have noted that it is more difficult to rehabilitate patients with right hemisphere damage than those with left hemisphere damage. Right hemisphere-damaged patients have a greater mortality (related to pulmonary emboli and pneumonia) immediately after stroke. Both the difficulties in rehabilitation and the greater mortality after stroke may be related to the akinesia induced by right hemisphere lesions.

Lesions in the right hemisphere more often induce hemispatial neglect than do those in the left hemisphere. The neglect induced by right hemisphere lesions is also more severe (Albert, 1973; Costa et al., 1969; Gainotti et al., 1972). Verbal stimuli might activate the left hemisphere and thereby further enhance attentional–intentional hemispatial asymmetry (Heilman & Watson, 1978). However, when paradigms that do not use verbal stimuli or verbal instructions are tested, right hemisphere lesions induce more severe hemispatial neglect than do those on the left (Albert, 1973). The mechanism of this asymmetry may be similar to mechanisms already discussed. The left hemisphere may be able to attend and intend only in and toward the right hemispatial field. Therefore, with left hemisphere lesions the right hemisphere will attend and intend in and toward ipsilateral (right) hemispace. However, with right hemisphere lesions, the left hemisphere attends and intends in and toward the right hemispace and the left hemispace is neglected.

Recovery of function and treatment

Recovery

Hier et al. (1983) demonstrated that neglect spontaneously improves in many patients. The mechanism underlying recovery is not completely understood. One hypothesis is that the undamaged hemisphere is involved in recovery.

Crowne et al. (1981) showed that neglect resulting from frontal ablations was worse when the corpus callosum was simultaneously transected than when the callosum was intact, and Watson et al. (1984) demonstrated that monkeys that had a frontal arcuate gyrus ablation several months after a corpus callosum section had worse neglect than did animals with an intact callosum. Although callosal section worsened the severity of neglect, it did not influence the rate of recovery, suggesting that recovery is an intrahemispheric process.

Hughlings Jackson (Taylor, 1932) postulated that certain functions could be mediated at several levels of the nervous system. Lesions of higher areas (e.g. cortex) would release phylogenetically more primitive areas that might take over the function of the lesioned cortical areas. The superior colliculus receives not only optic but also somatesthetic projections (Sprague & Meikle, 1965). Sprague and Meikle thought that the colliculus is more than a reflex centre controlling eye movements: it is a sensory integrative centre. Tectoreticular fibres project to the mesencephalic reticular formation, and ipsilateral fibres are more abundant than contralateral fibres (Truex & Carpenter, 1964). Stimulation of the colliculus (like stimulation of the arcuate gyrus of the frontal lobe) induces an arousal response (Jefferson, 1958). Unilateral lesions of the superior colliculus induce a multimodal unilateral neglect syndrome, and combined cortical–collicular lesions induce a more profound disturbance, regardless of the order of removal (Sprague & Meikle, 1965). On the basis of these observations, we suspect that much of the recovery seen after cortical lesions may be mediated by the colliculus.

Subcortical lesions of ascending dopamine projections in rats induce permanent neglect (Marshall, 1982). The severity

and persistence of neglect induced by 6-hydroxydopamine injections into the ventral tegmental area of rats correlate with the amount of striatal dopamine depletion: those with more than 95% loss of striatal dopamine have a permanent deficit. The extent of recovery of these animals is also directly related to the quantity of neostriatal dopamine present when the animal is killed. Non-recovered rats show pronounced contralateral turning after injections of apomorphine, a dopamine receptor stimulant. Recovered rats given methyl-*p*-tyrosine, a catecholamine synthesis inhibitor, or spiroperidol, a dopamine receptor blocking agent, had their deficits reappear. These results suggest that restoration of dopaminergic activity in dopamine-depleted rats is sufficient to reinstate orientation (Marshall, 1979). Further investigation of these findings indicates that proliferation of dopamine receptors may contribute to pharmacologic supersensitivity and recovery of function (Neve et al., 1982). Implanting dopaminergic neurons from the ventral tegmental area of fetal rats adjacent to the striatum ipsilateral to the lesion induces recovery in rats with unilateral neglect resulting from a 6-hydroxydopamine lesion in the ascending dopamine tracts (Dunnett et al., 1981). This recovery is related to growth of dopamine-containing neurons into the partially denervated striatum.

Incorporation of ^{14}C-labelled 2-deoxy-D-glucose (2-DG) permits a measure of metabolic activity. In rats with 6-hydroxydopamine lesions of the ventral tegmental area that had shown no recovery from neglect, the uptake of labelled 2-DG into the neostriatum, nucleus accumbens septi, olfactory tubercle, and central amygdaloid nucleus was significantly less on the denervated side than on the normal side. Rats that recovered by 6 weeks showed equivalent 2-DG uptake in the neostriatum and central amygdaloid nucleus on the two sides. Recovery is therefore associated with normalization of neostriatal metabolic activity (Kozlowski & Marshall, 1981).

Similar results have been obtained for monkeys recovering from frontal arcuate gyrus-induced neglect (Deuel et al., 1979). Animals with neglect showed depression of ^{14}C-labelled 2-DG in ipsilateral subcortical structures, including the thalamus and basal ganglia. Recovery from neglect occurred concomitantly with reappearance of symmetric metabolic activity.

Treatment

Since neglect and related disorders are behavioural manifestations of underlying cerebral disease, evaluation and treatment of the underlying disease are of primary importance.

There are several behavioural and pharmacologic interventions that can be done to manage and treat some of the symptoms of the neglect syndrome. After he had a large right hemisphere stroke, President Wilson's wife would place him in a room so his left side was against the wall. This placement insured that he would be able to interact with visiting dignitaries. To optimize interactions, we also suggested that patients be positioned such that their 'good' side faces the area where interpersonal actions are most likely to take place. However, Kunkel et al. (1999) treated patients who had a hemiparesis and did not use their weak arm by binding their non-paretic arm and forcing them to use this hemiparetic arm. They found that this procedure induced recovery. It is possible that some of their patients' motor deficit was related to limb akinesia associated with motor neglect, rather than to weakness associated with corticospinal damage. In the last decade, studies have demonstrated that experience can change neuronal networks. It is possible, therefore, that stimulation of the contralesional side may induce functional reorganization and thereby reduce the severity of neglect. Some evidence for this postulate come from treating patients with hemispatial neglect by making them wear special glasses. Patients with neglect often fail to move their eyes to the contralesional (e.g. left) side and miss stimuli on that side because they fail to explore. Both lenses on these glasses are opaque on one side. The opaque half of the lens is ipsilateral to the hemispheric lesion. Thus for patients to see anything they must learn to move their eyes to contralesional hemispace (Arai et al., 1997). In contrast to these stimulation paradigms, studies of rats suggest that acute sensory depravation, such being kept in absolute darkness, may induce recovery from neglect (Corwin & Vargo, 1993). Unlike people, however, rats are nocturnal, and studies in humans have to be performed to help learn if stimulation is beneficial or harmful in the recovery from neglect.

Although we do not know if patients with neglect should be stimulated or sensorily deprived, we do know that we should not allow them to perform activities that may cause injuries to themselves or others. So long as a patient has the neglect syndrome, s/he should not be allowed to drive, or to work with anything that if neglected could cause injury to her himself or to others.

Many patients with neglect have anosognosia which makes rehabilitation difficult. For example, after a right hemisphere stroke Justice Douglas repeatedly checked himself out of hospitals being unaware that he was terribly disabled. In most patients, however, anosognosia is transient. In addition, because patients with neglect remain inattentive to their left side and in general are poorly motivated, training is laborious and in many cases unrewarding. Diller and Weinberg (1977) were able to train patients with neglect to look to their neglected side before they

acted; however, it was not clear that these top-down attentional–exploratory treatments generalized to other situations.

In contrast to this top-down treatment Butter et al. (1990) used a bottom-up attentional treatment. Structures such as the superior colliculus may play an important role in recovery from neglect. Dynamic stimuli readily summon attention in normal subjects and are potent activators of the visual colliculi. Butter et al. used dynamic stimuli and demonstrated that, when these stimuli were presented on the contralesional (left) side, the severity of neglect was reduced. Neglect patients with hemianopsia also improved, providing evidence that these dynamic stimuli influence the colliculi. Robertson and North (1993) demonstrated that having patients move their contralesional hand in contralesional hemispace can reduce the severity of hemispatial neglect and these investigators have used a hand movement strategy to manage neglect.

Asymmetrically activating the vestibular system in normal subjects may induce a spatial bias similar to that observed in neglect (Shuren et al., 1998). Rubens (1985) induced asymmetrical vestibular activation in patients with left-sided neglect by injecting cold water into the left ear and noting that unilateral spatial neglect abated. Valler et al. (1995) reported that vestibular stimulation could help sensory inattention, and Rode et al. (1992) found that vestibular stimulation even helped motor neglect. Inducing optokinetic nystagmus, by having patients look at series of stimuli moving in a contralesional direction (Pizzamigialo et al., 1990), and using vibration to stimulate muscle afferents from the neck (Karnath et al., 1995) also reduce neglect. Unfortunately, all these procedures produce only temporary relief, but it is unknown if repeated trials may confer a lasting benefit.

Coslett et al. (1990) demonstrated that patients with the attentional form of hemispatial neglect improved when visual feedback was presented to the ipsilesional side. Rossi et al. (1990) used 15-diopter Fresnel prisms to shift images from the neglected side toward the normal side. After using the prisms for four weeks, the treated group performed better than the control group in tasks such as line bisection or cancellation. However, activities of daily living did not improve. Rossetti et al. (1998) had subjects with neglect adapt to prisms by having them repeatedly point straight ahead while wearing the prisms. After this treatment, on tests of neglect, these treated patients showed a reduction of their ipsilesional bias. Although the effects of this treatment lasted for two hours after the prisms had been removed, it is uncertain how long this effect lasts. It is also unknown if this treatment generalizes to instrumental activities of daily living.

Neglect associated with cortical lesions may be reduced by destroying the ipsilateral colliculus or the intercollicular commisure (Sprague & Meikle, 1965). These findings suggest that the normal colliculus may inhibit the damaged colliculus. Because each colliculus gets greater input from the retina of the contralateral eye than it does from the ipsilateral eye, Posner and Rafal (1987) suggest that patching the ipsilesional eye may reduce neglect because it would deprive the superior colliculus ipsilateral to the intact hemisphere of retinal input and this reduced input may reduce collicular activation. Although some have found this ipsilesional patching procedure useful in reducing the signs of neglect (Butter & Kirsh, 1992) others have found that ipsilateral patching can make neglect more severe (Barrett et al., 1999). Therefore, when patching to treat neglect each eye should be tested before deciding which eye should be patched.

In regard to pharmacological treatment, we discussed the role of dopamine in neglect and recovery. Neglect in rats with unilateral frontal (Corwin et al., 1986) and parietal lesions (Burcham et al., 1997) were treated with apomorphine, a dopamine agonist. Dopamine agonist therapy significantly reduced neglect in these animals. Spiroperidol, a dopamine receptor blocking agent, blocked the therapeutic effect of apomorphine. Fleet et al. (1987) treated two neglect patients with bromocriptine, a dopamine agonist. Both showed dramatic improvements. Subsequently, other investigators have also shown that dopamine agonist therapy may be helpful in the treatment of neglect (Hurford et al., 1998; Geminiani et al., 1998). In addition Geminiani et al. found that dopaminergic agonist treatment helped both the sensory attentional and motor intentional forms of spatial neglect. In contrast, Barrett et al. (1999) and Grujic et al. (1998) found that in some patients dopamine agonist therapy increased rather than decreased the severity of neglect. Barrett et al.'s patient had striatal injury and it was suggested that the paradoxical effect seen in their patient may be related to involvement of the basal ganglia. In patients with striatal injury, dopamine agonists may be unable to activate the striatum on the injured side but instead activate the striatum on the uninjured side and thereby increase the ipsilesional orientation bias. Thus, if a patient has striatal injury, one should probably not use dopamine agonists. In addition, all patients should be repeatedly tested for neglect while these medications are being given. If there is an improvement over baseline, treatment should probably be periodically withdrawn so that one can be certain that the improvement was induced by treatment rather than spontaneous recovery.

Brain death

James L. Bernat

Dartmouth Medical School, Hanover, NH, USA

'Brain death' is the colloquial term for the determination of human death by showing the irreversible cessation of the clinical functions of the brain. It is an unfortunate term because it erroneously implies that there are two types of death: ordinary death and brain death. It also misleadingly implies that only the brain and not the human being is dead. In fact, the term properly refers to a method by which physicians may determine the unitary phenomenon of human death in the relatively rare situation in which ventilation (and hence circulation) are mechanically supported. Because the term 'brain death' is ingrained in common usage, it is essential that we understand and use it correctly. There is evidence that the term and concept of brain death are widely misunderstood by the public and by physicians (Youngner et al., 1989).

Several other terms have been used synonymously or in related contexts. The term 'cerebral death' should be abandoned because it adds nothing and promotes confusion. Some have used it to refer generally to brain death and others specifically to the higher brain formulation of death (discussed below) in which some scholars advocate the unaccepted idea that loss of functions of the cerebrum alone should be sufficient grounds for death. Translations of the term 'brain death' into other languages add to the confusion because it is *morte cerébrale* in French, *muerte cerebrale* in Spanish, and *morte cerebrale* in Italian.

Within the concept of brain death, scholars have argued about how much and what part of the brain must cease to function for a patient to be dead, and have coined the terms 'whole brain death', 'brainstem death', and 'neocortical death' discussed later (Bernat, 1992). These terms may be useful as theories of brain death but should not be used synonymously with the overall concept. The term 'irreversible coma', cited in the title of the Harvard Ad Hoc Committee Report (Ad Hoc Committee 1968), also adds confusion by suggesting that the brain dead patient is simply in a coma; it should be omitted in this context. The clearest statement a physician can make about a patient declared brain dead is 'the patient was declared dead using brain death tests'. This statement clarifies that death is a unitary phenomenon and brain death tests are merely one way to determine death.

History

The concept that the human being is dead when the brain is destroyed or irreversibly ceases functioning is not new but has become prominent in the past 50 years as the development of the mechanical ventilator has permitted such cases to be commonplace. In the ancient Hebrew tradition, the absence of *ruach* or breath was regarded as the primary sign of death, not the absence of heartbeat. Maimonides, the distinguished twelfth-century physician, philosopher, and rabbi, stated that the decapitated human was immediately dead and that the twitches of the limb muscles often present transiently following decapitation were not signs of life because they lacked central direction (Pernick, 1988). Throughout the eighteenth and nineteenth centuries, much fear was expressed over the incorrect medical diagnosis of death and premature burial. Several of the stories of Edgar Allen Poe are noteworthy in that regard.

In the late 1950s, French neurologists first described patients with what later would be called brain death. Several patients had suffered profound and diffuse brain injuries such that they had lost all clinical brain functions. The newly invented mechanical ventilator permitted their ventilation to be supported (which otherwise would have ceased) and hence their heartbeat and circulation could be maintained, at least temporarily. The neurological examination of these patients revealed a complete absence of all

clinical brain functions. Their coma was so profound that the neurologists coined the term *coma dépassé* to emphasize that they were in a state beyond coma (Mollaret & Goulon, 1959).

Throughout the next decade, several case reports of similar patients were published. In 1968, a committee of Harvard Medical School faculty published a seminal report that for the first time asserted that these patients were dead and provided tests to demonstrate it (Ad Hoc Committee 1968). They used the term 'brain death' which greatly influenced its subsequent popularity. They did not offer a rigorous philosophical defense of why such patients were dead but instead offered pragmatic reasons for the change, especially the growing need for organ donors and the futility of continued treatment (Giacomini, 1967).

Since 1980, the concept of brain death has been endorsed by American (President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioural Research, 1981), Canadian (Law Reform Commission of Canada, 1979), and British (Conference of Medical Royal Colleges and their Faculties in the United Kingdom, 1976) commissions charged with studying death, as well as numerous others from around the world. Brain death has become codified into law throughout the western and developed world. Medical societies from around the world have formulated and validated batteries of tests to determine brain death and all are remarkably similar (Quality Standards Subcommittee of the American Academy of Neurology, 1995; Canadian Neurocritical Care Group, 1999; Haupt & Rudolf, 1999). The public has accepted brain death as a standard of human death, and has widely supported the current program of multiorgan procurement for transplantation from brain dead donors.

The relatively little controversy that remains is centreed in universities where some scholars continue to argue that brain death is not truly human death but rather is a misunderstanding of the biology of death (Shewmon, 1998a, b), an inconsistent formulation of death (Halevy & Brody, 1993), a legal fiction to permit organ procurement (Taylor, 1997), or an anachronism to permit unilateral termination of life support (Truog, 1997). There is also opposition from some religious authorities who maintain that brain death is not compatible with their religious teachings (discussed below). However, at a recent meeting convened by the National Academy of Sciences Institute of Medicine to study the philosophical, medical, legal, and public policy issues of brain death, there was no support for changing current public laws permitting brain death determination based on the whole-brain criterion (Burt, 1999).

Biophilosophical basis

The concept of brain death became accepted by physicians and codified into law before it was conceptually grounded in rigorous philosophical analysis. Beginning in 1978 with the writings of Julius Korein (1978) and continuing with the papers of my colleagues, Bernard Gert and Charles Culver, and me (Bernat et al., 1981, 1982), brain death was provided a biophilosophical foundation as the most accurate biological representation of human death in our contemporary technological age. While it is beyond the scope of this chapter to provide the complete biophilosophical discussion, interested readers can consult my recently published comprehensive analysis (Bernat, 1998; Bernat, in press) that I briefly review here.

An analysis of death must begin by accepting certain preconditions and assumptions about death. First, death is primarily a biological concept so any definition of it must be compatible with biological reality. Secondly, a concept of death of the human should be consistent with death of other higher animal species. Thirdly, the concept of death should be applied to organisms and not components of organisms. Fourthly, all organisms must be either alive or dead; none can be in neither or in both states. Fifthly, death is an event, not a process, because the transition from alive to dead is necessarily instantaneous, but the timing of the event may not be able to be measured precisely and then only in retrospect. Finally, death is irreversible so no one can return from the dead.

The analysis of death must proceed in three sequential steps. First, one must conduct the philosophical task of defining death by making explicit our consensual concept of death. Secondly, one must conduct the medical and philosophical task of identifying a criterion of death to provide a general, measurable standard showing that the definition has been satisfied. Finally, physicians should construct and validate a set of tests to show that the criterion has been satisfied.

My colleagues and I believe that death is best defined as the irreversible cessation of the critical functions of the organism as a whole. Thus, death refers to the dissolution of the unity of the organism after which all that remains is a group of individual and independent subsystems that may continue functioning because of physiological support. The best criterion of death is the permanent cessation of the clinical functions of the brain because it is these functions that are responsible for the critical functioning of the organism as a whole. The clinical functions encompass those of the entire brain, thus this position has been dubbed 'whole brain death'. The tests for death are divided into two groups. In the most common situation in

which there is no mechanical ventilation provided or planned, the prolonged absence of respiration and circulation serves as a valid test of death because it quickly and inevitably produces destruction of the brain. In the rare situation of mechanically maintained ventilation (and hence preserved circulation) the batteries of brain death tests discussed below must be employed.

Some scholars reject outright the concept of brain death. Using philosophical analysis, Alan Shewmon holds that the brain does not provide sufficient integrating functions of the organism as a whole (Shewmon, 1999). Baruch Brody and Robert Truog believe that there is a mismatch between the definition and the criterion of death (Brody, 1999; Truog, 1997). Robert Taylor (1997) holds that brain death is a legal fiction and that the only true death is circulatory failure. Linda Emanuel (1995) holds that there can be no unitary criterion of death because death is an ineluctable process (Emanuel, 1995). I have addressed these criticisms elsewhere (Bernat, 1998).

Other scholars accept brain death on a conceptual basis but disagree on the criterion of death, that is, on precisely how much brain must be destroyed for death to occur. Robert Veatch (1993) advocates for the 'higher brain formulation' which requires only that the neocortex be destroyed ('neocortical death'), a concept that would declare dead patients in persistent vegetative states or with anencephaly (Veatch, 1993). Christopher Pallis holds the concept of 'brainstem death' in which the capacity for consciousness and respiration in the brain stem are the essentials of life (Pallis, 1997). Interestingly, there are only very minor differences in practice between this concept and the 'whole brain death' concept that prevails throughout the majority of the world outside the United Kingdom. I have analysed and critiqued these positions elsewhere (Bernat, 1992). Suffice it to say that despite over a quarter century of these scholars arguing to abandon or change 'whole brain death', its acceptance remains strong in the developed world and is becoming even more widespread in the developing world.

Pathophysiology

The primary pathologic events producing brain death in adults are traumatic brain injury, intracranial hemorrhage, cerebral infarction, brain tumours, and hypoxic–ischemic encephalopathy suffered during cardiopulmonary arrest. In cardiopulmonary arrest, there is evidence that ischemia is a more important cause of neuronal death than hypoxia (Simon, 1999; Miyamoto & Auer, 2000). In children, the most common primary pathologic events are traumatic brain injury, bacterial meningitis, asphyxia, and drowning (Staworn et al., 1994).

The widespread neuropathologic consequences of these primary illnesses and injuries are responsible for the global neuronal destruction that ensues. Following the direct cellular injury from the primary event, a series of widespread destructive changes are initiated including hypoxia, cerebral acidosis, endothelial swelling, intracranial hypertension, cessation of intracranial blood flow, and transtentorial herniation (Black, 1978). In most cases, as a result of diffuse cerebral edema, intracranial pressure rises until it exceeds mean arterial blood pressure. Intracranial pressure may transiently exceed even systolic blood pressure. In either event, intracranial hypertension produces a cessation of intracranial blood flow. This intracranial circulatory arrest produces global neuronal necrosis at sites distant to the primary pathology. The well-known syndromes of transtentorial herniation inevitably occur, permitting relatively easy clinical confirmation of the irreversibility of the global neuronal destruction by showing signs confirming the complete loss of brain stem clinical functions (Plum & Posner, 1980). Later, intracranial pressure falls and there is reperfusion of the necrotic tissue (Schroder, 1983).

Neuropathologic examination reveals widespread neuronal necrosis that is proportional to the time of continued perfusion following the event of brain death. It takes at least 12 hours for the first neuropathologic signs to be present (Black, 1978). In the early studies of Earl Walker and colleagues, the pathologic *sine qua non* was the 'respirator brain', a state of global liquifactive necrosis of all intracranial contents (Walker et al., 1975). The 'respirator brain' findings are the result of a completely infarcted brain in which liquefactive necrosis has been permitted to evolve by continued warm perfusion. If systemic circulation ceases earlier, these changes do not occur.

Clinical studies of patients admitted with diffuse brain injury who progressed to brain death have been reported in two series of patients admitted with Glascow Coma Scale scores of 3. The mean progression to brain death was 18 hours in one study (Matuschak, 1993) and 22 hours in another (Cabrer et al., 1992). Prior to brain death, the patients were markedly unstable with profound hypotension, spontaneous cardiac arrest, hypokalemia, temperature dysregulation, diabetes insipidus and coagulopathy (Matuschak, 1993).

The physiologic changes resulting from brain death in patients undergoing organ procurement have been summarized by Power and Van Heerden (1995). The two principal mechanisms are diffuse vascular regulation injury and diffuse metabolic cellular injury. The first phase of the

diffuse vascular regulation injury is a massive sympathetic outflow ('autonomic storm') resulting from the Cushing reflex. Organs can be damaged from direct neural stimulation or by catecholamine effect. In the secondary phase, there is a marked drop in sympathetic outflow producing inotropic and chronotropic cardiac effects leading to cardiac failure. In other organs, the loss of sympathetic tone produces generalized vasodilatation and impaired autoregulation (Power & Van Heerden, 1995). Some investigators believe that the sympathetic withdrawal is more important than the autonomic storm in the production of organ damage (Herijigers & Flaming, 1998).

Hemodynamic changes during incipient brain death include cardiac arrhythmia, hypertension, tachycardia, increased contractility and cardiac output, elevations in pulmonary and systemic vascular pressure, and elevation in pulmonary capillary 'wedge' pressure (Powner & Darby, 1999). After the event of brain death, hemodynamic changes include profound hypotension, vasodilatation and decreased cardiac contractility (Powner & Darby, 1999). Some hemodynamic responses may persist after brain death, including transient elevations in blood pressure and heart rate observed during organ procurement (Wetzel et al., 1985), but cold pressor tests usually detect no changes (Goldstein et al., 1993). In a recent series of brain dead organ donors treated to maintain hemodynamic stability, whereas 78% were hemodynamically stable on admission, only 30% remained stable by the time of procurement (Lagiewska et al., 1996).

Pituitary and hypothalamic function have been studied extensively in brain dead patients. Anterior pituitary releasing tests show severe hypothalamic failure whereas posterior pituitary secretion measurements suggest only partial hypothalamic failure of antidiuretic hormone secretion (Arita et al., 1993). It long has been observed that most brain dead patients develop diabetes insipidus, but some do not (Outwater & Rockoff, 1984; Fiser et al., 1987). These finding suggest that there may be a separate circulation for antidiuretic hormone secretion or that only a tiny residual function is sufficient to prevent diabetes insipidus.

Animal experimental models of brain death have been created to study its pathophysiology and its effects on other organs. Experimental models in the baboon and other species have been devised using an epidural balloon catheter that can be inflated to gradually or suddenly raise intracranial pressure (Novitsky et al., 1989; Shivalkar et al., 1993; Chen et al., 1996). The cardiac, pulmonary, renal and endocrine abnormalities have been summarized and analysed, and used as a basis to plan supportive therapy for brain dead organ donors prior to procurement to maximize success (Power & Van Heerden, 1995). For example, there is evidence that judicious administration of vasopressin and epinephrine (Yoshioka et al., 1986) and thyroid hormone (Randell & Hockerstedt, 1992) improves brain dead donor prolonged physiologic maintenance.

'Prolonged somatic survival'

In the early writings on brain death, it was asserted that, irrespective of treatment, no patients correctly declared brain dead could maintain heartbeat or circulation longer than two weeks because of refractory hypotension and cardiac failure (President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioural Research, 1981). Beginning in the early 1980s, reports began being published of cases of 'prolonged somatic survival': patients whose heartbeat and circulation were supported for months following a diagnosis of brain death as the result of aggressive medical treatment (Parisi et al., 1982). Many of the cases were reported as technologic *tours de force*, documenting the immense ICU effort made to physiologically maintain the patients using advanced ventilation techniques, vasopressors, hormones, temperature control, antibiotics, anticoagulants, and other advanced-technology intensive care therapies (Catanzarite et al., 1997).

Alan Shewmon recently reported a remarkable series of such cases he has termed 'chronic brain death' (Shewmon, 1998a, b). He described 56 cases of brain dead patients with circulatory persistence for greater than one week that were culled from his experience, that of colleagues, and a review of over 12 000 published articles describing cases or series of brain dead patients. Half the group retained circulatory function at 2 months following brain death declaration. He concluded that the medical instability of the brain dead patient is temporary and, if aggressively supported, some patients can enter a period of relative quiescence in which their circulation can be maintained for prolonged periods.

The Shewmon series is a mix of well-documented cases in which the patients clearly were brain dead and less well-documented cases in which the patients were presumed to be brain dead. Although all of them apparently received the clinical diagnosis of brain death, the documentation for many of them remains questionable or absent. Although Shewmon correctly points out that they are no less well documented than many other cases encountered in clinical neurology, there is a well-known but unfortunately great variation in the practice of brain death determination on adults and children (Earnest et al., 1986; Mejia & Pollack, 1995), and as a result, there are undoubtedly

false-positive diagnostic errors. The standard for making a serious claim such as Shewmon has made, that the presence of these cases invalidates the concept of brain death, requires documentation that the patients were clearly and convincingly brain dead. This standard is higher than that achieved in the presentation of many of his cases (Wijdicks & Bernat, 1999). In any event, the persistence of circulation in even those unequivocally documented cases remains a relatively rare occurrence.

Epidemiology

There are relatively little data on the incidence and prevalence of brain death. A large study from the United Kingdom found that approximately 10% of all patients dying in hospital ICUs were declared brain dead (Gore et al., 1992). A similar study in Spain found that 14% of patients dying in ICUs were brain dead (Navarro, 1996). In two reported large series of children in the United States, brain death accounted for 0.9% of pediatric ICU admissions (Staworn et al., 1994) and 37% of all pediatric ICU deaths (Mejia & Pollack, 1995).

Diagnosis

The determination of brain death has been a critical question since 1968 when the Harvard committee published the first battery of tests (Ad Hoc Committee, 1968). Throughout the next 15 years, several other medical centres and organizations proposed similar test batteries, which were reviewed in 1984 by Julius Korein (1984). The current definitive tests are those proposed by the President's Commission medical consultants in 1981 (Medical Consultants to the President's Commission, 1981) and by the American Academy of Neurology in 1995 (Quality Standards Subcommittee of the American Academy of Neurology, 1995), generated by the evidence-based review by Eelco Wijdicks (1995).

The diagnosis of brain death should be considered in the ventilated patient with profound, irreversible brain damage, apnea, unresponsiveness, and cranial nerve areflexia. A diagnosis of brain death requires that: (i) a structural lesion is present that can account for the clinical findings; (ii) no evidence of clinical brain functions can be found on repeated neurological examinations, by demonstrating utter unresponsiveness, apnea in the presence of hypercapnia and cranial nerve areflexia; and (iii) all potentially reversible metabolic and toxic factors have been excluded. If these conditions cannot be met, the diagnosis of brain death should be withheld until a confirmatory laboratory test can prove the irreversible absence of all clinical brain functions by showing an absence of intracranial circulation. The diagnosis should be made by an experienced physician, usually a neurologist, neurosurgeon, or intensivist. A diagnostic algorithm for the less experienced physician has been published (Kaufman & Lynn, 1986).

The first condition requires the presence of a structural lesion sufficient to account for the clinical findings. This condition usually is easy to fulfil in cases of massive head trauma, intracranial hemorrhage, stroke, and meningitis complicated by intracranial hypertension. Diffuse hypoxic–ischemic neuronal injury during cardiopulmonary arrest or asphyxia may be less obvious, and therefore, generally requires a longer period of observation.

Unresponsiveness

The coma of the brain dead patient is the deepest coma possible. Patients lie absolutely motionless when the ventilator is stopped. They make no response to any sensory stimuli including bright lights, loud noises, and noxious stimuli. They do not posture or make any other response to stimulation. Deep tendon reflexes usually are absent but may be retained. Because tendon reflexes are integrated at a spinal level, their presence or absence is not necessarily indicative of brain functioning.

A group of spontaneous movements rarely have been observed in brain dead patients. In the best-described movement, called the 'Lazarus' sign, the patient may slowly elevate both arms and adduct them across the chest (Ropper, 1984). Because this movement has been seen most often during apnea testing in the brain-destroyed patient with an intact spinal cord, it has been hypothesized to result from ischemia to cervical spinal cord motor neurons (Turmel et al., 1991). A series of other odd movements occasionally may be encountered, including automatic stepping (Hanna & Frank, 1995), decerebrate-like posturing (Marti-Fabregas et al., 2000), and finger jerks (Saposnik et al., 2000).

Apnea

Testing for apnea must be done while maximally stimulating the brainstem respiratory centres through hypercapnia while protecting against hypoxia. Although there are accepted standards for conducting apnea tests, they are often not followed in practice (Earnest et al., 1986; Mejia & Pollack, 1995). The impulse to breathe is generated in medullary respiratory centres stimulated by chemoreceptors sensitive to rises in pCO_2 (Bruce & Cherniak, 1987).

Intubated, brain-damaged patients in ICUs often are maintained with low pCO_2, however, so merely disconnecting them from the ventilator for a few minutes to see if they breathe is an inadequate test for apnea. To prove true apnea, the pCO_2 must be permitted to rise to a level high enough to maximally stimulate the medullary breathing centres. The optimal target pCO_2 is unknown, but most authorities state it is 60 torr (Schafer & Caronna, 1978; Ropper et al., 1981; Marks & Zisfein, 1990). In patients with chronic CO_2 retention from chronic obstructive lung disease, the target pCO_2 is higher (Prechter et al., 1990) and such patients often breathe primarily by their hypoxemic drive.

The technique of apneic oxygenation assures the preservation of the O_2 level while allowing the pCO_2 to climb to high levels (Ivanov & Nunn, 1969; Marks & Zisfein, 1990). The pCO_2 is permitted to normalize to the 40 torr range by adjusting the ventilator rate and volume. The inspired air is made 100% O_2 and the pO_2 is permitted to rise. In the absence of pulmonary edema or other pulmonary disorders blocking gas exchange, the PO_2 usually rises to the 350–400 torr range. At this point, the ventilator is stopped and 100% O_2 is permitted to passively exchange by introducing a catheter down the endotracheal tube and infusing the O_2 at 8 l/minute, or using blow-by. Because the pCO_2 climbs at a mean rate of 3–4 torr/minute of apnea, depending on the rate of CO_2 production (Schafer & Caronna, 1978; Ropper et al., 1981), the duration of apnea necessary to permit the pCO_2 to climb to 60 torr may be calculated. For true apnea to be present, there should be no respiratory effort, sighing, or hiccuping. The major complications of the apnea test are hypotension, acidosis, and hypoxemia, but usually it can be conducted safely (Belsh et al., 1986; Ebata et al., 1991; Jeret & Benjamin, 1994). An alternative apnea test shortening the duration of disconnection from the ventilator may be conducted by increasing the pCO_2 in the inspired air (Lang, 1995).

Cranial nerve areflexia

The brain dead patient must have unreactivity of all cranial nerve reflexes including those of the pupil to light, the cornea to touch, the vestibulo-ocular, gag, and cough reflexes. Pupils in brain dead patients usually are midposition and irregular in shape, reflecting simultaneous denervation of sympathetic and parasympathetic supply. They should be tested with a bright point light source. Pupillary reactivity may be absent from pre-existing disorders such as diabetes. Pupillary reflexes are usually unaffected by atropine given intravenously during resuscitation (Goetting & Conteras, 1991). Pupillary light reflexes similarly are unaffected by neuromuscular blockade in therapeutic dosages such as that given during general anesthesia (Gray et al., 1997).

The vestibulo-ocular reflex should be tested with the technique of maximal cold caloric stimulation. After inspecting the external auditory canals to exclude canal impaction with wax and punctured tympanic membrane, the canals are irrigated sequentially with 50 ml ice water with the head elevated 30 degrees and an assistant holding the eyelids open (Hicks & Torda, 1979). There should be neither reflex eye movement, grimace, limb movement, nor any response from the patient. Patients who have previously received large doses of vestibulotoxic drugs, such as aminoglycoside antibiotics, may have permanently lost vestibulo-ocular reflexes.

Corneal reflexes should be tested with a cotton-tipped applicator and should be completely absent. The gag and cough reflexes can be tested by observing the nurses cannulating the endotracheal tube with deep tracheal suctioning of the patient. There should be no coughing or 'bucking' movements of the chest.

Death declaration

The presence of unresponsiveness, apnea, and cranial nerve areflexia shows the absence of clinical brain functions. To prove that the absence is irreversible, a structural lesion accounting for the findings should be identifiable by CT scan, and potentially reversible metabolic and toxic factors must be excluded. In the case of asphyxia or hypoxic–ischemic encephalopathy from cardiopulmonary arrest, the test battery should be repeated after an interval of time and show the same results. The interval between tests varies as a function of the age of the patient and whether a laboratory confirmatory test has been done. In the latter circumstance, an interval of 4 hours is sufficient. As noted below, in children it is desirable to wait at least 24 hours between tests.

It is essential to exclude potentially reversible metabolic and toxic factors such as depressant drug toxicity, neuromuscular blockade, and severe hypothermia ($T<32.2$ °C). For example, barbiturate intoxication and profound hypothermia can mimic the clinical features of brain death yet be completely reversible. Neuromuscular blockade can produce nearly all the signs, except for the pupillary reflex absence. If there is a question of reversibility, it is best to treat the patient, allow time to elapse, and order toxicologic studies. Confirmatory tests are essential for a diagnosis of brain death in the presence of significant toxic and metabolic effects.

The patient ordinarily is declared dead upon completion of the second set of tests. This practice is consistent with

declaring death using cardiopulmonary tests. If the patient is an organ donor, following the second apnea test, the ventilator is reattached and the newly declared dead patient is taken to the organ procurement suite with respiratory support and intact circulation. If the patient is not an organ donor, the patient is not reattached to the ventilator following the second apnea test.

If the above tests are performed and interpreted correctly, there is no differential diagnosis; the patient is dead. Avoidance of the pitfalls noted above is critical to eliminate false-positive determinations (Posner, 1978).

Infants and children

The application of brain death tests to infants and children remains controversial, because of the greater tendency for young people to recover from illnesses and injuries. The Task Force for the determination of Brain Death in Children published guidelines in 1987 that have been generally though not universally accepted (Task Force for the Determination of Brain Death in Children, 1987). The guidelines prohibit brain death determination on premature infants or on infants under the age of one week. Infants between age one week and two months require two examinations separated by a 48-hour interval and a confirmatory test. Infants aged two to 12 months require two examinations separated by a 24-hour interval and a confirmatory test. Children over the age of 12 months are treated as adults. The experience of declaring brain death in children and infants reported from pediatric ICUs is similar to that in adults (Staworn et al., 1994; Parker et al., 1995). The specific considerations of neonatal brain death declaration have been reported (Kohrman, 1993; Ashwal, 1997).

Confirmatory tests

Brain death is a clinical diagnosis but the determination may be validated by several laboratory procedures called confirmatory tests. Confirmatory tests are useful in several situations. First, in some cases the clinical tests cannot be performed. Many patients with massive head trauma also have suffered facial trauma to the extent that it is impossible to assess pupillary reflexes, corneal reflexes and vestibulo-ocular reflexes. In many patients with severe pulmonary disease it is unsafe to perform an apnea test because of simultaneously producing severe hypoxemia. Secondly, the tests may be necessary to conform to regulations for the determination of brain death imposed by some authorities. This situation is true in some hospitals, several countries, and when declaring brain death on infants in the United States. Thirdly, the tests are useful in expediting organ donation by reducing the mandated interval between examinations. Finally, they may be useful in potentially medicolegal situations in which it may be desirable to have objective test data to supplement the physician's examination.

Laboratory tests to confirm brain death are of two types: those showing an absence of electrical activity from the brain, and those showing a cessation of intracranial blood flow. In general, the blood flow tests are more useful but the decision of which to order should be based upon their availability and on the experience and confidence of the clinician in their interpretation. Wijdicks has provided an evidence-based critique of the available studies as of 1995 (Wijdicks, 1995).

Electrical potentials

If electrical tests are chosen, it is desirable to choose both EEG and evoked potentials. The EEG assesses cerebral electrical activity and the brainstem auditory and somatosensory-evoked potentials assess brainstem electrical activity. While electrical activity also may be suppressed by metabolic and toxic disorders, the evoked potentials are less likely to be affected. Technical standards for the performance and interpretation of the EEG in brain death have been published by the American EEG Society (American Electroencephalographic Society, 1994). The EEG should show 'electrocerebral silence' with no recordable potentials greater than 2 μV at a gain of 2 μV/mm, using appropriate filters, and allowing at least a 30-minute recording. All experienced electroencephalographers are aware of the troublesome artefacts that occur at such a high gain (Hughes, 1978). The sensitivity of this study is limited. Grigg and colleagues found that 20% of brain dead patients continued to have rudimentary but measurable EEG activity for a week (Grigg et al., 1987). The specificity of EEG is also limited because electrocerebral silence has been reported in non-brain-dead patients after a variety of drug intoxications (Powner, 1976) and in the severest forms of persistent vegetative state (Brierley et al., 1971; Boutros & Henry, 1982).

Several studies have shown the absence of brainstem auditory-evoked potentials in brain death (Starr 1976; Goldie et al., 1981; Garcia-Larrea et al., 1987; Firsching, 1989; Machado et al., 1991; Hantson et al., 1997; Ruiz-Lopez et al., 1999). For example, Goldie and colleagues showed that all potentials except the cochlear microphonic potential (a peripheral potential) were absent in brain death. All potentials were easily recordable in patients in a persistent vegetative state (Goldie et al., 1981). The small series of published cases permits no clear esti-

mate of the positive and negative predictive value of these tests. Because they are not susceptible to metabolic and toxic suppression, they are useful in declaring brain death in patients with depressant drug intoxication (Hantson et al., 1997).

Short-latency somatosensory evoked responses in brain dead patients have been found to be absent beyond Erb's point in several studies (Anziska & Cracco, 1980; Goldie et al., 1981; Belsh & Chokroverty, 1987; Stohr et al., 1987; Chancellor et al., 1988; Wagner, 1996; Hantson et al., 1997; Ruiz-Lopez et al., 1999; Sonoo et al., 1999). For example, Wagner found that the median nerve-stimulated P14 evoked potential recorded at Fz-Pgz was absent in 100% of 108 brain dead patients but preserved in 100% of the 108 comatose but living patients. Chiappa has reviewed and critiqued the evoked potential studies up to 1997 (Chiappa, 1997).

Blood flow

The demonstration of cessation of intracranial blood flow is a sufficient confirmatory test for brain death because it proves there can be no surviving clinical functions of the brain. At some point in nearly all brain dead patients, intracranial pressure rises to exceed mean arterial blood pressure, at which time there can be no intracranial blood flow. Historically, contrast angiography was the first test used to demonstrate absent intracranial flow of the contrast medium as the internal carotid and vertebral arteries penetrate the dura (Bradac & Simon, 1974). Contrast angiography to confirm brain death is rarely performed in the United States now because it is cumbersome and other technologies can confirm brain death as accurately and more easily.

Intravenous radionuclide angiography is used widely for this purpose. Several studies have employed serum albumin-tagged technetium 99m injected intravenously with static and dynamic images of the brain recorded by a portable gamma camera. In brain death there is no observable intracranial blood flow, but blood is seen to flow into the face and scalp through the patent external carotid arterial system (Korein et al., 1977; Goodman et al., 1985; Flowers & Patel, 1997). There is an excellent correlation with conventional contrast angiography (Korein et al., 1977). One limitation is that slight flow through the posterior circulation may be difficult to detect.

More recently, single photon emission computed tomography (SPECT) scintigraphy using technetium-99m hexamethylpropyleneamineoxime (HMPAO) has been studied in several reports (Reid et al., 1989; Wilson et al., 1993; Yoshikai et al., 1997). The isotope is injected intravenously and a portable gamma camera records images. The images must be recorded immediately after the isotope is injected. The 'hollow skull' sign is seen in brain death revealing the absence of intracranial blood flow (Yoshikai et al., 1997).

Transcranial Doppler (TCD) ultrasound has been studied widely. Skull insonation and recording of the pulses of the intracranial arteries provides a highly specific recording of arterial blood flow in the brain. Several abnormal patterns have been described in brain death, depending upon the ratio of systemic blood pressure to intracranial pressure (Ropper et al., 1987; Powers et al., 1989; Petty et al., 1990; Ducrocq et al., 1998; Razumovsky et al., 1999). When intracranial pressure exceeds systolic blood pressure, no systolic pulses can be recorded. In the more usual circumstance, in which intracranial pressure exceeds mean arterial blood pressure but is lower than systolic blood pressure, the pattern of 'reverberating flow' is seen. It is called reverberating (or oscillating) because there is a forward progression of blood flow during systole but an equal reversal of blood flow to the original starting point during diastole. Multiple vessel insonations must be recorded to confirm the cessation of intracranial blood flow and the results are operator dependent. The American Academy of Neurology Therapeutics and Technology Assessment Subcommittee has published a statement supporting the use of TCD ultrasound in this circumstance (American Academy of Neurology Therapeutics and Technology Assessment Subcommittee, 1990). The reported sensitivity is 91.3% and the specificity is 100% (Petty et al., 1990).

Other techniques used to assess intracranial blood flow in brain death include xenon-enhanced CT scanning (Darby et al., 1987; Ashwal et al., 1989) and diffusion-weighted magnetic resonance imaging (Lovblad & Bassetti, 2000). The former requires specially equipped CT units not generally available. The latter has been reported in only a single case but is worthy of further study because of the wide availability and ease of this technology.

Ethical issues

The introduction of the concept of brain death has raised a series of challenging ethical issues that result from the unique circumstance of our technologic capacity to physiologically maintain certain bodily systems despite death of the human organism. Like many contemporary ethical issues, the question can be framed 'should we perform an intervention simply because we have the technologic capacity to do it'. I have considered these issues in further depth elsewhere (Bernat, 2002) and briefly review them here.

Brain death during pregnancy

Several reports have been published over the past two decades of pregnant women rendered brain dead by head trauma or intracranial hemorrhage in whom the decision to continue physiologic support was made, permitting the Ceasarian delivery of healthy infants (Dillon et al., 1982; Field et al., 1988; Bernstein et al., 1989; Nuutinen et al., 1989; Antonini et al., 1992; Catanzarite et al., 1997). Success in these cases required heroic efforts in the ICU to treat and compensate for myriad metabolic disturbances including respiratory failure, cardiac failure, hypothermia, diabetes insipidus, disseminated intravascular coagulation, infection, and hypopituitarism, as well as management of the pregnancy and nutritional support. Aside from the technical issues, the essential question is whether the good of salvaging a human life justifies subjecting the dead patient to the indignity of prolonged physiologic support, the family to the enormous emotional distress of suspending closure of a loved one's life, and society to the expense of such treatment (Kantor & Hoskins, 1993).

The first question is who should make such a decision. It is most reasonable that in the setting of a stable conjugal relationship in which the father intends to raise the child, the father should decide. In other situations in which grandparents or other family members may be raising the child, the decision should be made jointly among those with the greatest interest in the welfare of the dead mother and the fetus. Hospital ethics committees can assist families and physicians in the decision making in such difficult cases (Spike, 1999).

The ethical duty to try to rescue the fetus in this circumstance has been the subject of several analyses (Loewy 1987; Field et al., 1988; Kantor & Hoskins, 1993; Spike, 1999). In obstetrical practice, there is an ethical duty to insure the welfare of both the pregnant woman and the fetus (Mattingly, 1992). When the two goals come into conflict, ordinarily the welfare of the fetus is sacrificed for the welfare of the mother. But when there is no hope to save the mother, the primary goal is to rescue the fetus. Loewy has argued that the ethical duty to rescue the fetus in these cases increases with increasing fetal maturity because of the growing probability of therapeutic success and the diminishing harms to the mother resulting from the reduction of time for physiologic maintenance (Loewy, 1987).

Religious acceptance and rejection

Organized religions have not remained silent on the brain death issue. In the early writing on brain death, Frank Veith and colleagues asserted that brain death was consistent with the teachings of Roman Catholicism, Protestantism, and Judaism (Veith et al., 1977). This assertion remains mostly true. For the religious groups comprising Protestantism, including the most fundamentalist sects, this acceptance is universal (Campbell, 1999). For Roman Catholics, the acceptance is also strong. In an August 2000 address, Pope John Paul II asserted that the Roman Catholic Church formally regarded brain death as human death. Further, three Vatican Pontifical Councils and Academies assigned to study this topic over the past two decades have opined that brain death is consistent with Catholic teachings (White et al., 1992; Pontifical Council for Pastoral Assistance, 1994; Pontifical Academy of Life, Vatican City, Msgr. Elio Sgreccia, personal communication). In the United States, the National Catholic Bioethics Center (formerly known as the Pope John Center) has published opinions strongly supportive of the concept of brain death (Furton, 1999). Brain death determination and multiorgan procurement for transplantation are permitted at Roman Catholic hospitals throughout the world.

In Judaism, the acceptance of brain death is less uniform and it remains a point of heated rabbinic debate (Rosner, 1999). In general, Reform Judaism and most of Conservative Judaism accept the concept of brain death. But many Orthodox rabbis reject the concept insisting that ancient Jewish law dictates that the human being is not dead until breathing and circulation stop irreversibly, as required by the Talmud (Bleich, 1979; Soloveichik, 1979). But other Orthodox rabbis hold that brain death is consistent with ancient Jewish law because it is the functional equivalent of decapitation (Tendler, 1978; Rosner & Tendler, 1989). As a practical matter, brain death determination is accepted by a large majority of Jews in the United States and only the strictest Orthodox sects, such as Chasidim, reject it.

Islam has embraced the concept of brain death by a ruling of the Council of Islamic Jurisprudence Academy, and now permits multiorgan procurement for transplantation. In Saudi Arabia, for example, the Ullamah Council has authorized physicians to permit brain death determination (Yaqub & Al-Deeb, 1996). The recommended brain death tests are identical to those used elsewhere in the world (Abomelha & Al Kawi, 1992). The Sixth International Conference of Islamic Jurists addressed the various issues of determining brain death and facilitating organ procurement (Albar, 1991).

The acceptance by other religions in the world is varied. Hinduism, as expressed by the official practice in India, permits brain death (Jain & Maheshawari, 1995). In Japan, a cultural battle has been raging during the last quarter-

century over the acceptance of brain death advocated by western influences pitted against traditional Shinto, Confucian, and Buddhist religious and cultural practices (Kimura, 1991; Lock, 1995). The western influences appear to be winning because in 1997, Japanese law for the first time explicitly permitted brain death determination and organ transplantation (Akabayashi, 1997).

Research and teaching on brain-dead subjects

Brain-dead patients have been used as subjects for research and teaching purposes. As research subjects, brain-dead patients are ideal for experiments requiring normal organ system physiology in those organ subsystems remaining intact, particularly for dangerous experiments that could not be performed safely on living subjects. The ethical question is whether it is justified to continue physiologic support of dead subjects, with its attendant harms to the patient and family, solely for the purpose of experimentation (Martyn, 1986). Some have argued that it is acceptable because the dead may not have interests (Nelkin & Andrews, 1998).

Thoughtful investigators have proposed guidelines for using the brain dead as research subjects. Coller and associates stated that the research team should not participate in the brain death determination, the research protocol should be approved by the institutional review board, and the research protocol should not bar the possibility of organ procurement (Coller et al., 1988). La Puma added several conditions. The dignity of the human body should be preserved. The experiment should be brief. The consent of an authorized proxy decision maker should be obtained. The importance of the experiment should be great. And any resultant clinical charges should be borne by the investigators (La Puma, 1988).

Similarly, newly dead patients, including brain dead patients, have been used as subjects on whom physicians in-training may practice endotracheal intubation and other resuscitation techniques (Iserson & Culver, 1986). A few scholars have argued that the benefit to society of training young physicians in lifesaving procedures that cannot be learned effectively by any other means eliminates the duty to obtain consent from the patient's next-of-kin for this activity (Orlowski et al., 1988). Others have insisted that consent is necessary and should be requested, despite the awkwardness of such a request (Burns et al., 1994).

Organ procurement

The principal utility of brain death determination is to permit multiorgan procurement for transplantation. Except for the relatively new and not widespread practice of 'non-heart-beating organ donation' (Youngner & Arnold, 1993), and the evolving practice of 'partial donation' of liver and lungs from living donors (Singer et al., 1989), the brain-dead patient comprises the only acceptable donor for unpaired vital organs. There are ethical duties and legal requirements (in the United States) for physicians to identify potential organ donors from among brain-dead patients, and to ask families if they are willing to consent for their dead loved one to be an organ donor, the so-called 'required request' laws (Tolle et al., 1987; Darby et al., 1989). The ethical duty to encourage organ procurement stems from the lives potentially saved of the organ recipients.

Currently, and for the foreseeable future, the number of dying patients in need of vital organ transplants far outpaces the number of organ donors (Evans et al., 1992). Several strategies have been implemented to increase donation. The required request laws have not had the hoped-for effect of increasing organ donation rates (Caplan & Welvang, 1989). Organ procurement rates have been shown to increase with more expeditious brain death determination using confirmatory tests (Jenkins et al., 1998), and when the request for organ donation is made by trained organ procurement personnel (Gortmaker et al., 1998). Traumatic brain-injured patients deemed unsalvageable in emergency rooms should be admitted and declared brain dead to permit organ procurement, rather than be extubated (Riad & Nicholls, 1995). The criteria for the identification and management of the ideal multiorgan donor have been reviewed (Darby et al., 1989; Soifer & Gelb, 1989).

When brain-dead patients had completed organ donor cards, their families should be strongly encouraged to consent to donation to permit the autonomy of the patient to be respected, even after death. There must be a strict separation of the process of brain death determination and the request for organ donation. No member of the organ donor team should participate in the death determination. There is evidence that 'uncoupling the brain death determination from the organ procurement process in the family's mind improves the donation consent rate' (Hauptman & O'Connor, 1997). Families should understand that the benefit of organ donation is not restricted to the organ recipients. There is evidence that family members granting consent for donation experience transcendent meaning that renders the otherwise meaningless tragedy of illness or injury into a profound personal good (Douglass & Daly, 1995).

Legal issues

Laws in the United States, Canada, Mexico, Australia, and in nearly all European and in many South American, Asian, and African countries permit physicians to declare brain death as a test of death. Nearly all use the 'whole-brain' criterion, except for the United Kingdom that uses a brainstem criterion. As noted previously, the brainstem tests are essentially identical to the whole-brain tests, except the brain stem tests cannot use confirmatory tests showing EEG electrocerebral silence (Pallis, 1983) or intracranial blood flow studies showing an absence of intracranial circulation (Kosteljanetz et al., 1988) because these findings are not necessary for 'brainstem' death declaration.

In the United States, since Kansas enacted the first brain death statute in 1970, all states have enacted similar statutes or have issued administrative regulations permitting brain death declaration (Beresford, 1999). Most states employ the Uniform Determination of Death Act, sponsored in 1981 by the President's Commission, that provides:

> An individual who has sustained either (i) irreversible cessation of circulatory and respiratory functions, or (ii) irreversible cessation of all functions of the entire brain, including the brain stem, is dead. A determination of death must be made in accordance with accepted medical standards (President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioural Research, 1981).

There are similar statutes or regulations in other countries permitting brain death declaration.

In the United States, the question of accommodating religious disagreement with brain death has been drafted into law in two states: New Jersey and New York. New Jersey amended its death statute (New Jersey Declaration of Death Act, 1991) whereas New York issued administrative regulations through the State Department of Health (NY Comp Codes, Rules and Regs, 1992). The New Jersey statute prohibits physicians from using brain death tests when they 'violate the personal religious beliefs of the individual' (Olick, 1991) whereas the New York regulations require physicians to 'mandate notification of an individual's next of kin' and allow for a 'reasonable accommodation to an individual's religious or moral objections to the use of neurologic criteria to diagnose death' (Beresford, 1999). An important future public policy question for our society is the amount of latitude our public laws should permit in the determination of death (Veatch, 1999).

A clinical problem, encountered more commonly than a religious objection, is the family that for emotional reasons, cannot bear to see the ventilator discontinued on their loved one, despite the determination of brain death. Although there are legal precedents in the United States authorizing physicians to discontinue ventilators is such cases over the objection of the family (*In re Bowman* 1980; *Matter of Haymer* 1983), compassionate physicians try to help the family accept the inevitable futility of further treatment attempts (Cranford, 1999). Many physicians will continue the ventilator temporarily pending acceptance of the family, but the length and extent of such futile treatment to accommodate family wishes remains debatable (Hardwig, 1991; Miedema, 1991).

Disorders of mood

Dean F. MacKinnon and J. Raymond DePaulo

Department of Psychiatry, Johns Hopkins University School of Medicine, Baltimore, MD, USA

Depression refers in the medical setting to clinically significant but transient emotional states which are called adjustment disorders and also to a clinical syndrome called major depression which occurs in unipolar depressive disorder and bipolar disorders. Confusion of adjustment disorders with depressive syndromes plagues both medical care and reasoning about mechanisms. Once identified, mood disorders (unipolar and bipolar disorders) are treated quite successfully with any of several medications and/or psychotherapy. The pathophysiology of mood disorders remains obscure, but clues are emerging as to the neuroanatomic components, molecular systems and genes involved in the vulnerability to mood disorder. The cumulative effect of these developments on a number of scientific fronts will be to unravel the complex knot of etiologic factors, leading to the refinement of current empirical treatment and the development of rational treatment. When we can identify the mechanisms of mood disorder, we will also gain an improved perspective from which to understand the role of environmental factors in the development of depressive and manic disorders.

In the official diagnostic nomenclature of American psychiatry a transition from the term 'affective disorders' to 'mood disorders' was made in 1987, though the diagnostic criteria for major depression and mania did not change appreciably. We use the term mood to denote a persistent emotional state, and affect or affective to refer to a constellation of phenomena generally associated with and including mood. We will use the term depression, hereafter, only to denote the syndrome of depressive illness.

Epidemiology

Mood disorders are among the most common illnesses in the community and in the medical clinic. Depression, in a variety of community samples worldwide, affects as many as one in six individuals in the course of a lifetime (Doris et al., 1999). Mania occurs in 1–2% of the population. Ten to twenty per cent of patients screened in a primary care clinic have a major depressive disorder (Zung et al., 1993); depression was found in over one-quarter of patients in a neurology practice (Carson et al., 2000). Mania is less often a presenting problem for non-psychiatric physicians, but can occur as an iatrogenic complication from the use of antidepressants (Benazzi, 1997), corticosteroids (Sharfstein et al., 1982), or psychostimulants (Masand et al., 1995). Moreover, a number of medical conditions are associated with the syndromes of mania and depression, as will be described below.

Mood disorders are extremely painful for families as well as patients, and are costly to society. Suicide is the cause of death in at least 5% of individuals with a mood disorder, as found in community samples (Inskip et al., 1998), and the rate of suicide among patients requiring hospitalization is three- to fourfold greater than that. Psychological autopsy studies reveal consistently that at least two-thirds of completed suicides had strong evidence for a mood disorder prior to death, even though many were never diagnosed or treated for it (Barraclough et al., 1974). Depression carries high direct costs from absenteeism and occupational disability (Druss et al., 2000; Greenberg et al., 1993) and medical expenditure (Simon et al., 1995), as well as high indirect costs via other highly destructive behaviours like those related to substance abuse.

Clinical facts

Central features

The depressive syndrome consists of a persistent and pervasive disturbance of affective state. The mood itself,

however, is described as sad or depressed in only 50% of patients with major depression. The mood may be constantly dysphoric, or cycling through different dysphoric states, ranging from despair to apathy, anxiety, numbness, or irritability. The mood in the manic syndrome may be pleasantly euphoric, though often the accompanying excitement gives way to anxiety or irritability. A depressive or manic syndrome, as opposed to a normal lowering or elevation of mood, is concomitant with changes in self-attitude, vitality and neurovegetative functioning. The change in self-attitude manifests itself in depression with pathological guilt, self-loathing, feelings of worthlessness and failure. In mania, patients express expansive confidence and grandiosity, and with mixed or irritable manic states, there is often a combative self-righteousness. Vitality, or the physical sense of energy, capability, and stamina tend to be diminished in the depressed patient and elevated in the manic. Neurovegetative appetites for sex, sleep, food and stimulation are almost universally disturbed in some way in patients with mood disorder.

Mood disorder generally causes functional impairment, but impairment is neither necessary nor sufficient to differentiate mood disorder from normal emotional variation. Perturbations of energy and cognition tend to interfere with the conduct of work. Depressed patients tend to take longer to perform tasks, or think their way through problems. Manic patients can be so restless or distracted that they fail to complete tasks properly. However, the degree to which impairment is noticeable depends heavily on contextual factors, such as the difficulty of the work being performed, the stability of the patient's basic temperament (e.g. stoic vs. neurotic), and the depth of social resources on which the patient may draw. From similar reasoning, it is easy to see that many patients can exhibit severe functional decompensation in the absence of ongoing symptoms of mood disorder, if their discouragement leads to markedly altered behaviour.

Depressive and manic syndromes can be suspected based on chronic behavioural changes. However, behavioural changes alone do not make the diagnosis. The clinician must elicit the symptoms as described above to make the diagnosis. Depression, for example, should be suspected in patients exhibiting suicidal or self-mutilatory behaviour and in patients who withdraw socially and uncharacteristically fail to follow through with family and occupational obligations. Mania should be suspected when patients spend lavishly, engage in uncharacteristic sexual promiscuity, or exhibit other disinhibited behaviour. Because these behaviours may all arise under a variety of circumstances, it is important not only to elicit a history of any accompanying symptoms but also to know how the patient behaves at other times. In many cases, the diagnosis cannot be made without information from the patient's family about changes from prior behaviour.

A patient's resistance to or ignorance of the concept of mood disorder often obstructs diagnosis and treatment. Patients often do not recognize mood disorder as the primary source of their suffering. Mood disorder from the patient's perspective can be so insidious and pervasive that patients see their symptoms (however exaggerated compared to the normal range of human response) as an understandable reaction to adverse life events or to their own insufficient (or inflated) value as persons. Patients with depression may come to feel they deserve their despair; the belief that others would be better off without them all too often leads to suicide attempts. Manic patients, on the other hand, can evince an impenetrable arrogance, which thwarts efforts at management.

Classification

Patients with episodes of mania or hypomania are designated bipolar (synonymous with manic depressive illness) regardless of whether they have had documented depressive episodes. Patients with depressive episodes but no mania are called unipolar in the scholarly literature, and are given the diagnosis major depressive disorder in the official nomenclature of the American Psychiatric Association, the *Diagnostic and Statistical Manual (DSM)* (American Psychiatric Association, 1994). In many cases it is not easy to differentiate mild bipolar from unipolar depressive disorders, as patients and their families may not have recognized the milder manifestations of hypomania.

While most patients with bipolar or unipolar disorders have an episodic course, with substantial periods of remission, variations in the course of illness are accounted for in the classification scheme. Dysthymia refers to a mild-to-moderate depressive disorder, lasting years. Patients with four or more episodes of mania or depression per year are described as having 'rapid cycling'. Such patients can experience an episode once per season or can even cycle on a daily basis. Patients with the distinctive symptoms of mania and depression simultaneously are in what are called 'mixed states', first described by Kraepelin at the turn of the twentieth century (Kraepelin, 1921). Patients in mixed states often experience low and very irritable moods, but are physically and mentally hyperactive to the point of restlessness and distraction. Patients in these states are prone to violent and self-injurious rages.

The official operational definitions used in DSM diagnostic categories and based on clinical criteria sets ensure reliability, but not a valid nosology of mood disorders.

There is strong evidence for the validity of four or five of the subtypes listed in the manual. There may be meaningful biological distinctions between melancholic depression (blunted affect, insomnia, loss of appetite) and atypical depression (reactive mood, hypersomnia, hyperphagia) (Asnis et al., 1995) and between mood disorders with and without psychotic symptoms (Coryell, 1996). Other means of subtyping patients based on family history, comorbidity, and symptom severity remain a focus of research. Panic disorder, an anxiety disorder characterized by paroxysmal acute, severe anxiety, a feeling of impending death, derealization, and physical symptoms such as palpitations, shortness of breath, chest tightness and dizziness, occurs in 20% or more of individuals with bipolar and unipolar depressive disorders. Panic disorder comorbidity with bipolar disorder clusters in a subset of families containing multiple bipolar relatives and may be a marker of genetic heterogeneity in bipolar disorder (MacKinnon et al., 1998).

Somatic diseases and mood disorder

Patients with an unrecognized mood disorder often present with non-psychiatric complaints. Suspicion of an underlying mood disorder should be raised when patients present with uncontrollable pain, fatigue, requests for sleeping pills, and when there is uncharacteristic or unusually severe non-compliance with treatment or failure to rehabilitate after a medical illness. In the elderly, depression may manifest as an abrupt cognitive decline, though the diagnosis should be made only after delirium and dementia have been ruled out.

Depression is one of the most common comorbidities of medical illness (Coulehan et al., 1990). The interrelationship of depression and medical disorders underscores the significance of the task of identifying and treating depression. Depression is a major risk factor for the development of and morbidity from cardiovascular disease (Musselman et al., 1998). Mood disorders complicate the treatment and course of many neurological disorders, including seizure disorders (Wiegartz et al., 1999), cerebrovascular disease (Morris et al., 1993), Parkinson's Disease (Cummings & Masterman, 1999; Starkstein et al., 1990), Huntington's Disease (Peyser & Folstein, 1990), and multiple sclerosis (Patten & Metz, 1997). Mood disorders occur commonly with cancer (Spiegel, 1996) and AIDS, which produces both depressive and manic syndromes (Treisman et al., 1998). In some medical disorders with obscure pathology, like fibromyalgia (Ackenheil, 1998) and chronic fatigue syndrome (Lane et al., 1991) depression commonly coexists with the somatic symptoms and exacerbates the pain and fatigue.

In medically comorbid depression, however, the task of differentiating discouragement, which is also a common complication of illness, from depression is critical. The undertreatment of depression or overmedication of discouragement can have severe medical consequences in medically ill patients (Cassem, 1995). Medical illness often raises the risk for suicide in either case (Harris & Barraclough, 1994). Medically ill patients with depression have higher mortality rates (Covinsky et al., 1999; Herrmann et al., 1998). On the other hand, caution in prescribing is dictated by the significant risks of adverse side effects from medications (e.g. cardiac conduction delays with tricyclic antidepressants, delirium with any psychotropic medications), or unforeseen pharmacologic interactions (e.g. fluoxetine's inhibition of a cytochrome P-450 enzyme, lithium toxicity from concomitant use with thiazide diuretics or ibuprofen).

Therapeutic issues

Prior to the development of effective biological treatment for mood disorders, treatment focused on the containment of dangerous behaviour: suicide in melancholics, and violent agitation in manics, through institutionalization, sedation, and 'rest' (Goodwin & Jamison, 1990). In the middle third of the twentieth century, patients with milder forms of mood disorder often pursued psychoanalytically informed psychotherapy which, because it took place over a longer period than the expected natural duration of an episode of illness, was seen as probably effective in many cases. In the latter half of the twentieth century, an increasing array of effective pharmacologic and other biological treatments have supplanted the psychoanalytic and supplemented the pragmatic approach with empiric remedies and prophylaxis. The empiric means used to treat and forestall illness promise to inform our understanding of mechanisms of illness.

The first issue often confronting the physician treating depression is that patients can at the same time have major depression and be discouraged about having depression. Discouragement is an understandable emotional response to a state in which a mental disorder has caused one's enjoyment of life to be lost, one's bodily functions (sleep, appetite, libido) to be awry, and one's energy and cognitive fluency to be sapped. Biological treatments for depression all take weeks to months to have a full therapeutic effect, but patients tend to begin to feel better quickly when they are provided with hope for recovery. The amelioration of discouragement accounts for the rapid partial response seen both in placebo and treatment groups in many studies of antidepressant efficacy; however, after a week

the continued progress towards recovery tends to occur only in the treatment groups.

All biological treatments in use for the treatment of mood disorders were discovered either serendipitously or from analogy with treatments discovered serendipitously. The older antidepressant classes, tricyclics (TCA) and monoamine oxidase inhibitors (MAOI) were observed incidentally to relieve depression in patients treated for psychosis and tuberculosis, respectively (Pletscher, 1991; Potter et al., 1991). Lithium, though it was known to be a component of mineral waters and even soft drinks early in the twentieth century, was found to be an effective antimanic agent only after its sedative properties were observed, incidentally, in guinea pigs being studied for the toxic effects of uric acid. Electroconvulsive therapy (ECT) arose from the observation (false, as it turns out) that epileptics are somehow protected from depression. Carbamazepine was observed, again incidentally, to improve mood symptoms in patients treated for epilepsy, and was applied to the treatment of bipolar disorder based on speculation about shared pathophysiologic mechanisms (Post et al., 1982).

Investigation of putative mechanisms of action of these treatments has led to newer generations of treatment either in use or under investigation for use against mood disorders. Serotonin selective reuptake inhibitors (SSRI) arose from insights derived from research on the binding properties of TCAs that showed, for example, high affinity of TCAs for serotonin receptors (Paul et al., 1981). Valproic acid was applied to mania because of its overlapping specificity with benzodiazepines for GABA receptors (Emrich et al., 1980). While the mechanism of action of ECT remains obscure, the concept of ECT has led to investigation into transcranial magnetic stimulation (TCMS) as a means to deliver a highly focused magnetic field across the skull without inducing the significant cognitive side effects often seen with ECT (George et al., 1995b).

Efficacy of many antidepressant and antimanic treatments has been established; however, efficacy of treatment with the aim of preventing relapse has been established only for the use of lithium in bipolar disorder. Antidepressant agents, when given in an adequate dose over 6 to 8 weeks tend to bring recovery in two-thirds to three-quarters of patients, across different antidepressant types (Nelson, 1999). ECT is more effective still in treating acute depression and mania (Mukherjee et al., 1994). Efficacy in alleviating mania has been established for lithium, several anticonvulsants, and an atypical neuroleptic (olanzapine). Long-term efficacy of antidepressant maintenance for recurrent depression is not well established, as effective dosages of medications tend not to be maintained in the long run (Mueller et al., 1999). In bipolar disorder long-term efficacy is established for lithium (Davis et al., 1999), while the evidence is less strong or nonexistent for other agents currently in wide use (Bowden et al., 2000). Aside from medication, the advice offered by Kraepelin remains salient today:

> That a very even tenor of life in *protected circumstances*, especially also with *avoidance of alcohol*, may have a certain prophylactic effect with individuals who are liable to attacks, may be regarded as probable considering the frequently indubitable influence of external injuries [Kraepelin, p. 202, emphasis his].

Patients with mood disorder are well advised to avoid alcohol and drugs and to sleep, work and exercise regularly.

Pathophysiology and etiology

Development of rational treatments to enhance the specificity of action in order to target patient subgroups, minimize side effects, and possibly accelerate treatment response, hinges on the elucidation of pathophysiologic mechanisms. Explorations of the biology of human emotional distress, pharmacologic mechanisms of action of antidepressant and antimanic agents, and variation in brain structure and function have opened windows to these mechanisms. Pathophysiologic investigation informs and is informed by the discovery of genetic markers linked to mood disorder vulnerability.

Depression and the stress response

Many patients and their physicians accept at face value the intuition that stress causes depression. A biochemical correlate of this intuition is the hypothesis that depression arises from an abnormality in the stress response mechanism, i.e. the hypothalamic–pituitary–adrenal (HPA) axis. There is some support for a relationship of HPA axis dysfunction and mood disorder, however the nature of the relationship remains uncertain. Depressive and manic syndromes occur with considerable frequency in Cushing's syndrome and with the use of corticosteroids. Patients with depression sometimes abnormally manifest nonsuppression of morning cortisol levels after an evening dose of dexamethasone (Carroll et al., 1968), however, without sufficient predictive power to aid in diagnosis (Arana et al., 1985). Consistent evidence of elevated cortisol levels in depressed patients has been difficult to establish (Posener et al., 2000; Steckler et al., 1999). Nevertheless, evidence continues to accumulate regarding the association of stress and HPA axis perturbations with

altered emotional state. Corticotropin releasing factor (CRF) and its receptors have been implicated in the modulation of the stress response; mice bred to be lacking a CRF receptor show abnormally low anxiety in response to stress (Timpl et al., 1998), and human subjects with depression, panic disorder, or alcoholism all show a blunted corticotropin (ACTH) response to CRF (Holsboer et al., 1987). However, it is less clear that HPA axis dysfunction can be seen as a cause, rather than a cofactor or a result of mood disorder. Abnormal regulation of cortisol is seen with a variety of conditions that produce chronic stress, including non-depressed individuals who had experienced significant childhood trauma (Heim et al., 2000). Implication of chronic elevated stress and glucocorticoid levels as a cause of atrophy of hippocampal neurons (Magarinos et al., 1997; Sapolsky, 1996), which would predict diminished hippocampal volume in depressed patients, has found only mixed empirical support (Brown et al., 1999; Vakili et al., 2000).

Monoaminergic hypotheses

The noradrenergic hypothesis, derived in part from the emergence of depressive symptomatology in hypertensive patients taking reserpine, explains the mechanism of action of TCA medications and continues to gain empirical support (Lambert et al., 2000), but serotonergic dysfunction has been implicated more consistently as a possible pathophysiologic factor in depression. One line of empirical support for the serotonergic hypothesis is evidence of diminished serotonin function in the brains of depressed suicidal patients. The levels of serotonin metabolites have been found persistently to be decreased in the cerebrospinal fluid of patients with depression and suicidal intent (Traskman et al., 1981) and evidence for diminished functioning in the brain can be inferred from an increase in the number of serotonin receptors in the brains of suicide victims (Arango et al., 1990). The degree of serotonin deficiency correlates with the violence of the suicidal intention (Mann & Malone, 1997). Diminished levels of serotonin metabolites also have been discovered in the cerebrospinal fluid of violent and impulsive subjects in general (Stanley et al., 2000), so altered serotonin function is not necessarily specific to depression. The serotonin hypothesis is supported by the observation that correction of an apparent deficiency in serotonin neurotransmission correlates with alleviation of depressive symptoms. When depressed patients treated to at least partial remission with SSRI agents, which selectively block serotonin reuptake, are depleted of tryptophan, an amino acid precursor for serotonin, symptoms of depression return (Delgado et al., 1990); however, recurrence of depressive symptoms under tryptophan depletion is not observed in patients in full remission (Moore et al., 2000). Continued elucidation of the mechanisms of regulation of serotonin activity at the synapse may lead to improvement in the focus of pharmacotherapy (Blier & de Montigny, 1994).

Mood instability and the mechanisms of action of lithium

Lithium exerts a variety of effects on neurons. One or some combination of these effects might be the key to the therapeutic mechanism of action of lithium, thus to the pathophysiologic mechanisms of mood disorder (Manji et al., 2000b). A general hypothesis is that lithium's modulating effects on signal transduction and thus gene expression may be salient for understanding affective psychopathology (Lachman & Papolos, 1995; Manji et al., 1995). Chronic lithium administration interferes with receptor-G protein coupling (Wang & Friedman, 1999), reduces levels of inositol triphosphate precursors (Huang et al., 2000), and inhibits phosphorylation of cyclic AMP (Wang et al., 1999) in rat brains. There is not, as yet, evidence of dysfunction in any of these pathways to explain why lithium's modulating effect is required in bipolar patients. There is evidence, however, to suggest that chronic administration of lithium and valproate may protect neurons by stimulating expression of a cytoprotective protein bcl-2 (Manji et al., 2000a). Whether mood instability is the result of a primary pathological process in structures related to affective modulation, or the effect on brain of manic hyperarousal is focal neurotoxicity, demonstration of the salutary effect of chronic lithium on brain corresponds nicely with the long-term efficacy of lithium in bipolar disorder.

Anatomy of mania and depression

A key challenge for neuroanatomic hypotheses of mood disorder is to explain both the state of illness and the episodic course of affective disorder. Epilepsies notwithstanding, the complete resolution of symptoms between mood disorder episodes appears inconsistent with an illness model involving a static brain lesion. Studies of depressive illness following stroke suggest that lesion location, the time since the stroke, and the extent of functional impairment independently predict depressive illness. Functional neuroimaging of actively depressed and remitted patients and of healthy subjects under emotional activation paradigms point to the limbic–cortical systems as important structures in the genesis and resolution of depressive states. Integration of structural and functional anatomy

with hormonal, neurotransmitter and gene transcription hypotheses remains to be done.

Postmortem brain studies of patients with mood disorder, including suicide victims, have revealed no consistent histopathological differences in the brains of affected individuals, or gross evidence for pathology related to mood disorder (Goodwin & Jamison, 1990). Association of post-stroke lesions and depressive symptomatology became feasible with the advent of clinical neuroimaging. Depression in the immediate poststroke period has been associated with left anterior stroke location (Astrom et al., 1993; Robinson & Szetela, 1981). These depressions were comparable phenomenologically to idiopathic major depressions. They also responded similarly to treatment with a tricyclic antidepressant (Lipsey et al., 1984). Depression following months or years behind a stroke tends to correlate more with the degree of residual functional impairment than with specific location of injury; however there is some association of delayed post-stroke depressive states and right occipital location (Robinson, 2000; Shimoda & Robinson, 1999).

Expanding on these lesion studies, volumetric and functional analysis of depressed patients without brain injury tends to implicate frontal and limbic structures in affective pathophysiology. One illustrative volumetric analysis revealed diminished frontal lobe volume relative to controls (Coffey et al., 1993); however, no particular portion of the frontal lobe was consistently affected, and other studies investigating structural changes with mood disorder have been inconsistent (Steffens & Krishnan, 1998). PET scanning of patients with depression has confirmed diminished metabolic activity in the left prefrontal cortex (Martinot et al., 1990), which correlates specifically with degree of mood disturbance and psychomotor retardation (Bench et al., 1993). Emotional activation paradigms involving the elicitation of sad emotions typically implicate frontal cortex as well as limbic structures, however laterality varies across studies (Beauregard et al., 1998; George et al., 1995a). Evidence for limbic–frontal reciprocity has emerged from PET studies of both depressed patients before and after successful pharmacologic treatment and healthy subjects induced to experience sad emotions, suggesting that mood regulation is a function of the relationship of cortical and limbic structures rather than the function of a single structure (Mayberg et al., 1999). Thus, a left frontal lobe diminished structurally and functionally by ischemic injury or other pathogenic processes may contribute to core symptoms of low mood and psychomotor disturbance, but may not be a necessary factor in pathophysiology.

Structures associated with the limbic system have a role to play in mood regulation, and probably do so as well in the pathophysiology of affective disorders. The amygdala, in particular, has been established through animal studies to be a centre for integration of the fear response (LeDoux, 2000) and has been found in one report to be activated (on the left side) with induction of sad mood in normal humans (Schneider et al., 1997). A contribution of the amygdala to affective psychopathology might explain mania seen in patients with temporal lobe epilepsy (Lyketsos et al., 1993) and could provide some anatomic support for the kindling model in idiopathic affective disorders (Post et al., 1982). The amygdala has extensive connections with prefrontal cortex (PFC), in particular with the subgenual prefrontal cortex, a structure implicated in the neuroanatomy of depression that also has connections with the lateral hypothalamus, nucleus accumbens, locus ceruleus, substantia nigra, and other deep brain and brainstem nuclei (Drevets, 1999). Functional and structural lesions in the subgenual PFC have been associated with mood disorder; patients with depression show diminished size and local cerebral blood flow in this region (Drevets et al., 1997); histopathological analysis finds a diminution principally in glia cells (Ongur et al., 1998). Lesions in this area do not duplicate a classic depressive syndrome; however, the amotivational syndrome arising from subgenual PFC certainly resembles a core feature of depressive states.

Linkages of brain dysfunction to depressive and manic psychopathology in the context of dementia and delirious states are not easily interpreted. Delirious states can present with depressive affect, withdrawal, and nihilistic or even suicidal statements; alternatively, delirious patients may appear as agitated, combative, or with manic features (e.g. denial of impairment from an obvious illness). Such symptomatology emerges routinely in the hospital setting in the context of delirium, whether due to systemic illness or intoxication. While the pathophysiology of manic or depressive-like symptoms in these contexts may in time prove informative to the understanding of idiopathic mood disorder, one must be alert to dissimilarities (not highlighted in many reports) between these known pathologic states and bipolar or depressive disorders. For example, late onset mood disorders have been associated with diffuse periventricular white matter ischemia, but also are independently correlated with generalized cognitive deficits (Steffens & Krishnan, 1998). Diffuse white matter hyperintensities have often been reported in bipolar disorder (Altshuler et al., 1995; Dupont et al., 1990) and in vascular and demyelinating disorders without affective syndromes. However, they have not been observed in first-episode manic patients (Strakowski et al., 1993), suggesting that diffuse white matter lesions are

likely a contributing but not a primary causative factor in some cases of bipolar disorder.

Genetic risk

Familial risk for mood disorders is well established from family, twin, and adoption studies. Specific genetic risk factors for bipolar and unipolar disorders have not yet been discovered; however, it is possible from the evidence available to predict a complex genetic contribution to etiology. Genetic analysis promises to play a critical role in validating pathophysiologic mechanisms suggested by research in neuroanatomy and neuroendocrinology, and in suggesting further research into molecular mechanisms of illness.

Elevated familial risk for mood disorder is well established from family, twin and adoption studies (Bertelsen et al., 1977; MacKinnon et al., 1997; Mendlewicz & Rainer, 1977). Siblings of patients with bipolar disorder have about a fivefold elevated risk for bipolar disorder, and siblings of patients with unipolar disorder have about a twofold elevated risk (Tsuang & Faraone, 1990). Family study evidence also supports the conclusion that mood disorders do not elevate familial risk for schizophrenia, and vice versa (Gershon et al., 1982), so that these disorders may be seen as separate phenotypes, with probable separate pathophysiology. Analyses of patterns of inheritance of mood disorders have not consistently supported a dominant vs. recessive vs. X-linked mode of inheritance. Numerous explorations of the genome in families ascertained for bipolar disorder linkage study (genomic studies of unipolar disorder are, as of this writing, few in number) have yielded inconsistent support for linkage at a variety of genetic loci (Berrettini, 2000). While any one of these loci may or may not contain a gene coding for a protein involved in a mechanism salient to mood disorder, the fact that no one genetic locus is found to be linked to bipolar disorder in even a large minority of families suggests that bipolar disorder (and most likely unipolar disorder as well) is complex genetically as it is clinically.

The pattern of findings and non-findings in studies of genetic risk factors for mood disorder is consistent with a model in which vulnerability to mood disorder derives from the interaction of several proteins, neither of which is necessary or sufficient to produce symptoms individually. In other words, individual No. 1 may have an elevated risk for developing a first episode of mania or depression because of inheriting genetic variants A, B, and C, while individual No. 2 may have a similar risk because of C, D, and E, while No. 3's risk derives from F, G, and H. It can be seen that risk factors like C may be present in most, but not all individuals, while other risk factors may overlap not at all across individuals. Each genetic factor may elevate the risk by a factor of 2 or less, making detection even more difficult since a large proportion of individuals with a possible genetic risk factor will show no evidence of the phenotype. Multigenic etiology also may account for intrafamilial heterogeneity, a phenomenon that would severely limit the power to detect genetic risk using the methodologies available.

Progress in understanding the pathophysiology and etiology of mood disorders, therefore, is likely to hinge on cross-fertilization of scientific exploration across disciplines. This occurs already, in the form of candidate gene approaches in which known genetic loci coding for proteins involved in the function of neurotransmitter systems are tested for the association of polymorphisms (preferably with functional significance) with the phenotype under investigation. As the genome becomes completely mapped, and functions are assigned to the tens of thousands of genes as yet undiscovered as of this writing, it will be possible to evaluate using genetic analysis additional hypotheses to account for signal transduction defects, focal cytotoxicity in brain regions subserving affective modulation, impaired neuroendocrine regulation, and so on.

Conclusions and predictions

One of the most challenging and labour-intensive puzzles to be resolved in coming years is to differentiate mood disorders into clinically and pathophysiologically meaningful phenotypic subtypes. One can begin with the insight that unipolar depression responds differently than bipolar depression to antidepressants, sometimes. Increasingly, it will be possible to test hypotheses of clinical heterogeneity genetically, by linkage studies that show a common genetic variation in the affected individuals in some families, but not in others. Association of particular disease-related alleles with disease across families may yield additional pathophysiological insight, as molecular variations are related to physiologic dysfunction. While a presentation of current knowledge underscores the enormity of the gaps in our understanding of mood disorders, over the past generation the evidence has strengthened that mood disorders involve specific sorts of dysfunction in the brain and neuroendocrine systems. The means may now exist to begin to untangle the complexity of mental illness.

The intersecting study of neuroendocrine dysfunction, neuroanatomical pathology, cellular signal transduction and the genome will merge in time to provide the basis for

a full description of the biological vulnerability to mood disorder. As soon as a single gene can be definitively linked to mood disorder, it will be possible to begin to dissect the genetic and biochemical complexities, and to investigate the brain functions underlying mood disorders. Once the biological mechanisms are understood, the environmental risk factors for depression will stand in stark relief, and may be approached with full knowledge of the potentials and limitations of interpersonal, behavioural, or social intervention in alleviating or preventing mood disorder. In time, cross-disciplinary correlations of genomic markers and specific biochemical or neuroanatomic markers of vulnerability traits and disease states will aid in the development of comprehensive theories of mood and mood disorder and the development of rational therapeutics.

Schizophrenia

Paul J. Harrison

University Departments of Psychiatry and Clinical Neurology (Neuropathology), Oxford, UK

Although not the commonest psychiatric disorder, schizophrenia is at the heart of psychiatry. It is also the disorder which has caused most controversy in terms of its nature, its treatment, even its very existence. One particular debate has concerned its organic basis and, indirectly, the extent to which it is a disorder of brain or of mind. As such, schizophrenia, like epilepsy, has exemplified both the bridge and the gulf between neurology and psychiatry. When Kraepelin described the syndrome at the end of the nineteenth century, he persuaded his young colleague Alzheimer to investigate its neuropathology. However, no substantive progress was made and by the middle of the twentieth century the pendulum had swung almost entirely to psychological and sociological views of schizophrenia. The pendulum has swung back over the past 25 years, with convincing evidence of differences in the structure and function of the brain of patients with schizophrenia finally emerging.

Clinical features and epidemiology

Schizophrenia remains a clinical diagnosis, based upon the presence of certain types of delusions and hallucinations (sometimes grouped together as 'first rank symptoms') and thought disorder (Andreasen, 1995). These 'positive' symptoms are often complemented by the 'negative' symptoms of avolition, alogia and affective flattening. The criteria of the *Diagnostic and Statistical Manual of Mental Disorders* (4th edition) (DSM-IV; American Psychiatric Association, 1994) are used for most research studies (Table 26.1); the World Health Organization ICD-10 criteria are similar but require only a 1-month duration. Depending on the balance of symptoms, different subsyndromes are classically recognized: paranoid, hebephrenic (disorganized), catatonic, undifferentiated and simple subtypes. A final clinical domain, neglected until recently, is that there are neuropsychological deficits, with impaired performance across a wide range of memory and language tasks apparent in first episode patients (Bilder et al., 2000) as well as in most long-standing cases (Palmer et al., 1997). Interest in this aspect of schizophrenia has increased with recognition that the cognitive impairments may be a major contributor to poor outcome (Green, 1996).

Schizophrenia can begin at any time from early childhood onwards, with a peak age of onset in the third decade, occurring a few years earlier in men than women. The course and outcome are remarkably variable and unpredictable, but the prognosis is better than sometimes believed. Only a minority have a chronic, deteriorating course, though many others have recurrent or enduring functional deficits, including persistent negative symptoms and the cognitive deficits mentioned. There is a significant excess mortality from suicide and natural causes (Brown, 1997).

The diagnosis of schizophrenia is reliable, but as with any other syndromal diagnosis there are problems establishing its validity, deciding where its boundaries should be drawn, and debate as to whether it is a categorical or dimensional construct. In clinical practice, there are three main differential diagnostic issues. The first is to exclude a neurological or medical disorder producing a schizophrenia-like syndrome; there are many examples, including temporal lobe epilepsy, metachromatic leukodystrophy, Wilson's disease, Huntington's chorea, thyroid disease, and cerebral vasculitis (Lishman, 1998). The second is to identify a drug-induced psychosis; NMDA glutamate receptor antagonists such as phencyclidine (PCP) produce the most schizophrenia-like picture, although psychosis is also associated with amphetamine, cocaine, hallucinogen, and alcohol abuse. In one large study, an organic cause was identifiable in ~6% of people presenting with schizophrenia (Johnstone et al., 1987). Having excluded an organic

Table 26.1. Abbreviated DSM-IV diagnostic criteria for schizophrenia

A. Characteristic symptoms. Two or more of the following, each present for a significant part of a 1-month period:
1) Delusions
2) Hallucinations
3) Disorganized speech (e.g. derailment)
4) Disorganized or catatonic behaviour
5) Negative symptoms (i.e. affective flattening, alogia, avolition)

NB: Only one symptom needed if delusions are bizarre, or if the hallucinations consist of a voice keeping up a running commentary on the person's actions or thoughts, or two or more voices conversing with each other.

B. Functioning. Significant decline in one or more functional areas (work, relationships, self-care)

C. Duration. Continuous signs of disturbance for at least 6 months. (This may include prodromal or residual phases.)

D. Exclusion criteria.
1) Mood disorders or schizoaffective disorder
2) The disturbance is not due to the direct physiological effects of a substance
3) The disturbance is not due to a general medical condition
4) Autism or other pervasive developmental disorder

disorder, schizophrenia must be distinguished from other psychiatric disorders, especially bipolar disorder (manic depression), delusional disorder, schizoaffective disorder and certain personality disorders.

The lifetime risk of schizophrenia is about 0.8%, and is broadly similar across all cultures and countries (Cannon & Jones, 1996). There is an increased risk amongst relatives (e.g. 10% in the child of a schizophrenic parent, and about 40% in a monozygotic cotwin). Twin (Cardno & Gottesman, 2000) and adoption (Ingraham & Kety, 2000) studies show that the familial clustering is largely (if not entirely) due to shared genes not shared environment. Heritability is estimated at 60–90%, with most evidence implicating multiple genes and non-Mendelian inheritance. Several suggestive but small-effect loci have been identified, notably on chromosomes 1p, 5q, 6p, 8p, 13q and 18p (Owen et al., 2000); there is also an association with microdeletions of 22q11 (Bassett & Chow, 1999). Epigenetic factors may also be important (Petronis et al., 1999). There are few established environmental risk factors (McDonald & Murray, 2000), although prenatal events, especially birth complications, confer a small excess risk (Geddes et al., 1999).

Neuropathology

Structural imaging

Key findings

There have now been a large number of CT and MRI studies of the brain in schizophrenia. The cardinal findings are summarised in Table 26.2 (see also Hopkins & Lewis, 2000). There is enlargement of the cerebral ventricles, accompanied by a loss of cortical volume (Ward et al., 1996; Lawrie & Abukmeil, 1998; Wright et al., 2000). Greater reductions occur in temporal lobe, especially medial structures (hippocampus, parahippocampal gyrus and amygdala; Nelson et al., 1998). Cerebral asymmetries may be reduced (Petty, 1999). Subcortical structures have not been well characterized, though there is good evidence for basal ganglia enlargement, especially of the globus pallidus; unlike all the other volume changes, this is due to antipsychotic medication (Harrison, 1999b;

Table 26.2. Macroscopic brain changes in schizophrenia

Established by systematic reviews[1]
- Enlargement of lateral and third ventricles (+25–40%)
- Smaller brain volume (−3%)
- Smaller cortical volume (−4%)
- Smaller cortical grey matter volume (−6%)
- Relatively smaller medial temporal lobe volume (−5%)
- Relatively smaller thalamic volume (−4%)
- Larger basal ganglia (esp. globus pallidus)[2]

Other replicated (though still controversial) findings
- Greater cortical involvement of heteromodal association areas (esp. superior temporal gyrus)
- Decrease (or loss) of cerebral asymmetries

Notes:
[1] Summarized from Ward et al., 1996; Lawrie & Abukmeil, 1998; Nelson et al., 1998; Wright et al., 2000.
[2] Due to antipsychotic medication.

Wright et al., 2000). There is some evidence for smaller thalamic size.

Characteristics of the findings

Monozygotic twins discordant for schizophrenia have provided valuable information. In virtually all pairs, the affected twin has the larger ventricles and smaller cortical and hippocampal size (Suddath et al., 1990). The discordant monozygotic twin study design allows two conclusions to be drawn. First, that structural abnormalities are a consistent finding in schizophrenia, their identification being aided by controlling for other genetic and environmental influences on neuroanatomy. Secondly, that the alterations are associated with expression of the schizophrenia phenotype rather than merely with the underlying shared genotype. Family studies support this interpretation, in that schizophrenics have bigger ventricles and smaller brains than their unaffected relatives. However, relatives who are obligate carriers (i.e. unaffected by schizophrenia but who seem to be transmitting the gene(s)) have larger ventricles than other relatives; moreover, both groups of relatives have larger ventricles and smaller brain structures than control subjects from families without schizophrenia (Harrison, 1999d). These data indicate that a proportion of the structural pathology of schizophrenia may be a marker of genetic liability to the disorder.

Ventricle–brain ratio (VBR) in schizophrenia follows a unimodal distribution, indicating that ventricular enlargement is not restricted to a subgroup but is present to a degree in all cases (Daniel et al., 1991). Conversely, it is important to emphasize that despite the mean group differences there is a significant overlap between subjects with schizophrenia and controls for every structural parameter. Furthermore, none of the established changes are known to be diagnostically specific. Hence the importance of the imaging data is in demonstrating the existence and location of brain pathology in schizophrenia, rather than for clinical purposes.

The structural abnormalities are present in first episode cases, excluding the possibility that they are a consequence of the illness or its treatment. Furthermore, cross-sectional studies show no correlation with duration of illness, suggesting that the alterations are largely static after onset. However, as longitudinal data emerge, the picture is becoming more complicated. First, there is increasing evidence that medial temporal lobe volumes selectively decrease in size during the prodrome and first episode of psychosis. Secondly, some longitudinal studies, spanning up to 10 years, find continuing divergence from controls (DeLisi, 1997) Overall the timing, progression and possible heterogeneity of brain changes in schizophrenia remain controversial, and are important as they bears upon the hypothesised nature of the disease process (see below).

There are few established correlations between brain structure and the symptoms or course of schizophrenia. For example, the expectation that enlarged ventricles might be a correlate of poor outcome has not been consistently demonstrated.

Microscopic and molecular neuropathology

Spurred on by the in vivo imaging evidence that there is a pathology of schizophrenia to be found, contemporary histological studies have addressed two main areas. First, to clarify the frequency and nature of neurodegenerative abnormalities in schizophrenia. Secondly, to investigate the cellular organization (cytoarchitecture) of the cerebral cortex and limbic system.

Gliosis

The issue of gliosis (reactive astrocytosis) has been extensively investigated since a report that gliosis was common in schizophrenia, especially in the diencephalon around the third ventricle (Stevens, 1982) . As gliosis is a sign of past inflammation, this implicated etiopathogenic scenarios for schizophrenia involving infective, ischemic, autoimmune, or neurodegenerative processes. However, over a dozen subsequent investigations have not found gliosis, and the consensus is now that gliosis is not a feature of schizophrenia (Roberts & Harrison, 2000). The issue has considerable implications. The gliotic response is said not to begin until the end of the second trimester in utero, and hence an absence of gliosis is taken as *prima facie* evidence of a disease process occurring before this time. Unfortunately, both the absence of gliosis, and its interpretation, are less clear than often assumed. Firstly, detecting gliosis is surprisingly difficult, and it can be argued that the data do not wholly rule out its occurrence. Secondly, despite the widely cited time point at which the glial response is said to begin, the matter has not been well investigated and it is prudent not to use this to time the pathology of schizophrenia with spurious accuracy. Furthermore, it is a moot point whether the subtle kinds of morphometric disturbance described in schizophrenia, whenever and however they occurred, would be sufficient to trigger detectable gliosis.

Alzheimer's disease in schizophrenia

It is sometimes claimed that Alzheimer's disease is commoner than expected in schizophrenia (perhaps on the assumption that it explains the high prevalence of cognitive impairment in elderly patients). However, a meta-

analysis shows that this is false (Baldessarini et al., 1997), a conclusion which even applies in elderly schizophrenics with severe dementia, who show no evidence of any other neurodegenerative disorder either (Arnold et al., 1998). As such, the cognitive impairment of schizophrenia is unexplained. It may be a more severe manifestation of whatever substrate underlies schizophrenia, or it may be that the brain in schizophrenia is more vulnerable to cognitive impairment in response to a normal age-related amount of neurodegeneration.

Neural cytoarchitecture in schizophrenia

If neurodegenerative abnormalities are uncommon in, or epiphenomenal to, schizophrenia, it begs the question as to what *is* the pathology and how the macroscopic findings are explained microscopically. The answer has been sought in the cytoarchitecture of the cerebral cortex, with measurements of parameters such as the size, location, distribution and packing density of neurons and their synaptic connections (Table 26.3).

Three cytoarchitectural alterations have generated particular interest: abnormal neuronal organization (dysplasia) in the entorhinal cortex, disarray of hippocampal neurons, and an altered distribution of neurons in the subcortical white matter. These findings are important because they support the hypothesis of an early neurodevelopmental anomaly underlying schizophrenia. However, none have been unequivocally and independently replicated, and for each there is at least one non-replication (for references see Harrison, 1999a).

A less well-known yet seemingly more robust cytoarchitectural feature of schizophrenia is that many neurons are smaller (i.e. have a reduced cell body area or volume). This has been shown in three studies of pyramidal neurons in the hippocampus, and has also been reported in dorsolateral prefrontal cortex and for cerebellar Purkinje cells. Some studies find that neurons are also more closely packed. Outside the cerebral cortex, extensive cytoarchitectural data are limited to the thalamus, for which there are reports of a loss of neurons from the dorsomedial and anterior nuclei, though the matter remains controversial.

In summary, a range of differences in neuronal structure and organization have been reported to occur in schizophrenia (Table 26.3). The abnormalities sometimes taken to be characteristic of the disorder, V12 disarray, displacement and paucity of hippocampal and cortical neurons, are features which in fact have not been well demonstrated. This undermines attempts to date the pathology of schizophrenia to the second trimester in utero based on their presence (see below).

Table 26.3. Histological findings in schizophrenia

	Weight of evidence
Lack of neurodegenerative lesions (e.g. Alzheimer changes)	+++++
Lack of gliosis	++++
Smaller cortical and hippocampal pyramidal neurons	+++
Decreased cortical and hippocampal synaptic markers	+++
Decreased dendritic spine density	+++
Loss of neurons from dorsal thalamus	++
Abnormalities of white matter neurons	+
Entorhinal cortex dysplasia	+
Disarray of hippocampal neuron orientation	(±)
Loss of hippocampal or cortical neurons	0

Notes:
0: no good evidence. ±: equivocal data. + to +++++: increasing amount of supportive data.
Source: For detailed review and citations, see Harrison (1999a).

Studies of synapses and dendrites

Synapses and dendrites represent a potential site for pathology undetectable using standard approaches. Because they are hard to visualise directly, proteins localised to these parts of the neuron are used as markers for them (Honer et al., 2000).

Markers of presynaptic terminals are generally reduced in the hippocampus in schizophrenia. The magnitude of the loss varies according to the individual synaptic proteins (and hippocampal subfields) studied, implying that the synaptic pathology is not uniform. There is some evidence for preferential decrements in excitatory connections, in keeping with the indications of glutamatergic involvement mentioned above. Presynaptic markers are also reduced in prefrontal cortex, though in this region a subset of inhibitory neurons and terminals appears most affected (Lewis, 1997). Complementing these changes, a decreased density of dendritic spines has been seen in three studies (Glantz & Lewis, 2000). Although unproven, the usual and simplest interpretation is that these changes reflect fewer (or otherwise aberrant) synaptic contacts being formed and received.

Integrating the neuronal and synaptic findings

There is an encouraging convergence between neuronal and synaptic findings in schizophrenia. In particular, the decreases in presynaptic and dendritic markers are in keeping with the smaller neuronal cell bodies, since the size of the latter is proportional to the dendritic and axonal

Table 26.4. Major transmitter systems implicated in schizophrenia

Transmitter	Main supporting evidence
Dopamine (DA)	DA-releasing agents produce psychosis All antipsychotic drugs are DA (D_2 receptor) antagonists Postmortem: Increased levels of D_2 receptors and loss of cortical DA innervation In vivo: Increased basal and amphetamine-stimulated striatal DA levels
Glutamate	NMDA receptor antagonists produce a schizophrenia-like psychosis Postmortem: altered presynaptic glutamate, NMDA and non-NMDA receptors Partial NMDA receptor agonists (e.g. cycloserine) have some therapeutic benefit Roles of NMDA receptors in development and neurotoxicity
5-HT (Serotonin)	5-HT_2 agonists (e.g. LSD) are psychotomimetic Postmortem: Altered cortical 5-HT_{1A} and 5-HT_{2A} receptors 5-HT_2 receptor polymorphisms associated with schizophrenia and clozapine response Atypical antipsychotics have high affinity for several 5-HT receptors Developmental and trophic roles of 5-HT
GABA	Postmortem: loss of cortical GABAergic cells, receptors, and synaptic markers

spread of the neuron. It is also consistent with the findings of increased neuronal density, in that dendrites and synapses are the major component of the neuropil and, if this is reduced, neurons will pack more closely together (Selemon & Goldman-Rakic, 1999). Moreover, it also corresponds with the results of proton magnetic resonance studies which have shown reductions of the neuronal marker *N*-acetyl-aspartate (NAA), as one would predict if the neurons are on average smaller and have less extensive projections (Bertolino et al., 1998).

Postmortem studies are limited to chronic schizophrenia, so it is impossible to prove that cytoarchitectural abnormalities are not the result of the illness or its treatment. However, several lines of evidence suggest that this is not the case. First, as the structural brain abnormalities and lower NAA signals occur in unmedicated and first-episode schizophrenia, it is reasonable to assume that the cytoarchitectural differences are also present then. Secondly, no correlations with duration of disease or medication exposure have been seen in postmortem studies. Thirdly, although antipsychotic treatment does have morphological consquences, the effects are largely restricted to the basal ganglia (Harrison, 1999b).

Where and what is the pathology?

Most of the positive findings reported in schizophrenia are in the hippocampal formation, dorsolateral prefrontal cortex and cingulate gyrus. However, this may be merely a sign that these areas have been the most intensively studied. Few studies have included a comparison region (e.g. striate cortex) and those which have do not provide a clear picture as to the uniformity vs. selectivity of cerebral involvement in schizophrenia. Neither are any of the individual histological abnormalities specific or pathological in the sense that a neurofibrillary tangle or Lewy body is. Rather, at present the favoured interpretation of the structural pathology as a whole is that it is a quantitative deviation of normal neuronal parameters, probably arising during development and putatively affecting functional connectivity between various brain regions. These hypotheses are elaborated below. However, it is important to remain critical of the empirical data, which could equally lead to the conclusion that, though brain structure is clearly altered in schizophrenia, its location, nature, origins, and consequences remain unknown.

Pathophysiology

Neurochemistry and neuropharmacology

A wide range of neurochemical parameters have been investigated in schizophrenia, both postmortem (Reynolds, 1995) and in vivo (Bigliani & Pilowsky, 1999; Soares & Inins, 1999), and a diverse collection of abnormalities reported. These especially affect monoamine and amino-acid neurotransmitter systems (Table 26.4).

Dopamine

The dopamine hypothesis of schizophrenia has been preeminent for over 30 years (Bennett, 1998). It proposes that the symptoms of schizophrenia result from dopaminergic overactivity, whether due to excess dopamine, or to an elevated sensitivity to it, e.g. because of increased numbers of

dopamine receptors. The hypothesis originated with the discovery that effective antipsychotics were dopamine (D_2) receptor antagonists, and that dopamine-releasing agents such as amphetamine produce a paranoid psychosis. It received support from various postmortem findings of increased dopamine content and higher densities of D_2 receptors in schizophrenia. However, despite its longevity it has proven difficult to refine or refute the hypothesis, for two reasons. First, because antipsychotics have marked effects on the dopamine system, confounding all studies of medicated subjects, hence making postmortem studies problematic. Secondly, molecular biology has revealed a large and complex dopamine receptor family, increasing the potential sites and mechanisms of dysfunction.

Much attention has focused on D_2 receptors. Overall, the studies show an increased density in schizophrenia, but it has been difficult to distinguish what proportion of this is not attributable to antipsychotic medication (Zakzanis & Hansen, 1998). Most PET studies of unmedicated patients have not shown a change in D_2 receptors. However, recent evidence suggests that there may in fact be a genuine increase of D_2 receptors in schizophrenia, the uncertainty being due to methodological issues and perhaps an altered receptor conformation (Seeman & Kapur, 2000). Altered expression of D_1 and D_3 receptors has also been reported but this is either unconfirmed or contradicted by other studies. Particular controversy has surrounded the D_4 receptor, following a report that it was up-regulated several fold in schizophrenia; it has also been a candidate receptor to explain the unique therapeutic profile of the atypical antipsychotic drug clozapine. However the result appears to have been due to a 'D_4-like site' not the true D_4 receptor, and the status of the latter in schizophrenia is unknown (see Harrison, 1999c).

In contrast to the equivocal evidence about dopamine receptors, strong evidence for a functional abnormality of dopamine neurons in schizophrenia is emerging. Several PET and SPET studies have shown elevated striatal dopamine release in response to amphetamine, implying a dysregulation and hyper-responsiveness of dopamine neurons (Laruelle & Abi-Dargham, 1999). Importantly, the dopamine release abnormality is present in untreated patients, and is only present during an acute episode, suggesting that a hyperdopaminergic state may underlie the florid, positive symptoms – dopamine as the 'wind for the psychotic fire' (Laruelle & Abi-Dargham, 1999). Dopamine synthesis may also be increased (Lindström et al., 1999). Finally, a new study shows that dopamine levels and D_2 receptor occupancy are elevated in schizophrenia (Abi-Dargham et al., 2000), providing the best evidence yet for an underlying hyperdopaminergia in the disorder (Harrison, 2000). The position of dopaminergic abnormalities in the pathogenesis of schizophrenia is unknown, though one model envisages them as a consequence of a developmental pathophysiology affecting corticostriatal connections (Grace, 2000).

5-HT (Serotonin)

Suggestions of 5-HT involvement in schizophrenia arose because the hallucinogen lysergic acid diethylamide (LSD) is a 5-HT agonist. Recently, interest has focussed on the 5-HT_{2A} receptor (Harrison, 1999c). A high affinity for the receptor may explain the therapeutic advantages of atypical antipsychotics, and variants in the gene are a minor risk factor for schizophrenia and for non-response to the antipsychotic drug clozapine. Many studies have found lowered 5-HT_{2A} receptor expression in frontal cortex in schizophrenia, and there is a blunted neuroendocrine response to 5-HT_2 agonists. Elevated cortical 5-HT_{1A} receptors are also a replicated finding. Hypotheses to explain the role of 5-HT in schizophrenia include the trophic functions of the 5-HT system in neurodevelopment, interactions between 5-HT and dopamine neurons, and impaired 5-HT_{2A} receptor-mediated activation of prefrontal cortex (Kapur & Remington, 1996).

Glutamate

The observation that phencyclidine and other non-competitive antagonists of the NMDA subtype of glutamate receptor produce a psychosis resembling schizophrenia has driven hypotheses of glutamatergic dysfunction in the disorder. There is now some evidence in schizophrenia itself to support this proposal. For example, in medial temporal lobe, glutamatergic markers are decreased, with reduced expression of non-NMDA glutamate receptors (Meador-Woodruff & Healy, 2000). However, a different pattern is seen in other brain regions and affecting other glutamate receptor subtypes, precluding any simple conclusion. Mechanisms proposed to explain glutamatergic involvement in schizophrenia centre on its interactions with dopamine, and subtle forms of glutamate-mediated neurotoxicity (Tamminga, 1998).

Cerebral metabolic activity

Cerebral metabolism in schizophrenia has been extensively investigated using PET to measure regional cerebral blood flow (rCBF) and glucose utilization. SPET and fMRI have been applied as well (Du & McGuire, 1999).

Hypofrontality has been the most widely reported abnormality. Initially it was thought to be a reliable feature of schizophrenia, present in the resting state. However, whilst hypofrontality does occur in unmedicated subjects, it is not invariable, being seen most clearly when subjects are performing tasks which require activation of the

frontal lobes (Andreasen et al., 1997; Spence et al., 1998). The interpretation of hypofrontality is still debated, notably the causality of its relationship to the undoubted impairment of schizophrenics on prefrontal working memory tasks (Weinberger & Berman, 1996).

The most comprehensive analysis correlating regional cerebral activity with clinical features is by Liddle and colleagues, who showed that the three subsyndromes of chronic schizophrenia which they had previously identified have characteristic patterns of rCBF (Liddle, 1996). For example, subjects with psychomotor poverty (a concept allied to negative symptoms) are hypofrontal whereas those with prominent positive symptoms have increased rCBF in the temporal lobe, especially in the hippocampus. Other studies show that the latter region does not activate normally during cognitive tasks, and that superior temporal gyrus activity has a relationship with auditory hallucinations.

Neurophysiology

Two aspects of sensorimotor functioning in schizophrenia are relevant to its neurobiology. First, sensory evoked potentials are altered. In particular, the P300 component is reduced and delayed in response to auditory stimuli, indicative of impaired sensory processing and further implicating the temporal lobes (Ford, 1999). The P300 alterations are also a trait marker of genetic vulnerability to schizophrenia (Blackwood, 2000). Secondly, there is a high rate of eye movement abnormalities in schizophrenia (Hutton & Kennard, 1998), especially affecting smooth pursuit tracking, suggesting impairment in the pathways subserving oculomotor control.

Together, the neurochemical, functional imaging and neurophysiological data illustrate the range and complexity of cerebral dysfunction which occurs in schizophrenia. Like the structural findings, they point to widespread abnormalities which cannot be reduced to a single locus or transmitter system. These uncertainties lead on to consideration of the two main pathogenic neurobiological theories of schizophrenia: as a disorder of neurodevelopment, and as a disorder of neural connectivity.

Pathogenic theories

Schizophrenia as a neurodevelopmental disorder

The neurodevelopmental model of schizophrenia in essence states that the disorder is due to abnormalities during maturation of the brain. It has become the prevailing pathogenic hypothesis (see Weinberger, 1995; Harrison, 1997; Waddington et al., 1999). A range of evidence is adduced in support of it (Table 26.5).

Table 26.5. Evidence for a neurodevelopmental origin of schizophrenia

- Structural brain changes present at or before onset of symptoms, and largely static thereafter
- No gliosis or other pathological signs of progressive or degenerative disease process
- Environmental risk factors are mostly pre- and perinatal
- Neurological, social and intellectual abnormalities seen in preschizophrenic children
- Increased prevalence of minor physical anomalies and abnormal fingerprint patterns, suggestive of intrauterine growth disturbance
- Increased prevalence of septum cavum pellucidum

A 'strong' version of the theory is that the pathology of schizophrenia originates in the second trimester in utero. An earlier timing is excluded since overt brain abnormalities would be seen if neurogenesis were affected, whilst the lack of gliosis is taken to mean that the changes must have occurred prior to the third trimester. However, this form of the neurodevelopmental model is weak on two neuropathological grounds. First, because of the limitations of the absence-of-gliosis argument mentioned earlier. Secondly, the types of cytoarchitectural disturbance adduced in favour (neuronal disarray and malpositioning) are those suggestive of aberrant neuronal migration, a process which occurs at the appropriate gestational period. Yet, as mentioned (Table 26.3), these cytoarchitectural abnormalities have not been unequivocally shown to be present in schizophrenia. By comparison, the seemingly more robust cytoarchitectural findings (e.g. alterations in neuronal size, synapses and dendrites) could originate much later, such parameters being modifiable throughout life.

Other forms of the neurodevelopmental theory advocate a much wider and later time frame and include many maturational processes (e.g. cell adhesion, apoptosis, myelination and synaptic pruning), or suggest that it applies only to a subgroup of cases, or that neurotoxic processes are involved as well (DeLisi, 1997; Lieberman, 1999). Overall, a parsimonious view is that the data are indicative merely of an essentially developmental, as opposed to degenerative, disease process, rather than as pointing to a particular mechanism or timing. A simplified illustration of the neurodevelopmental model is shown in Figure 26.1.

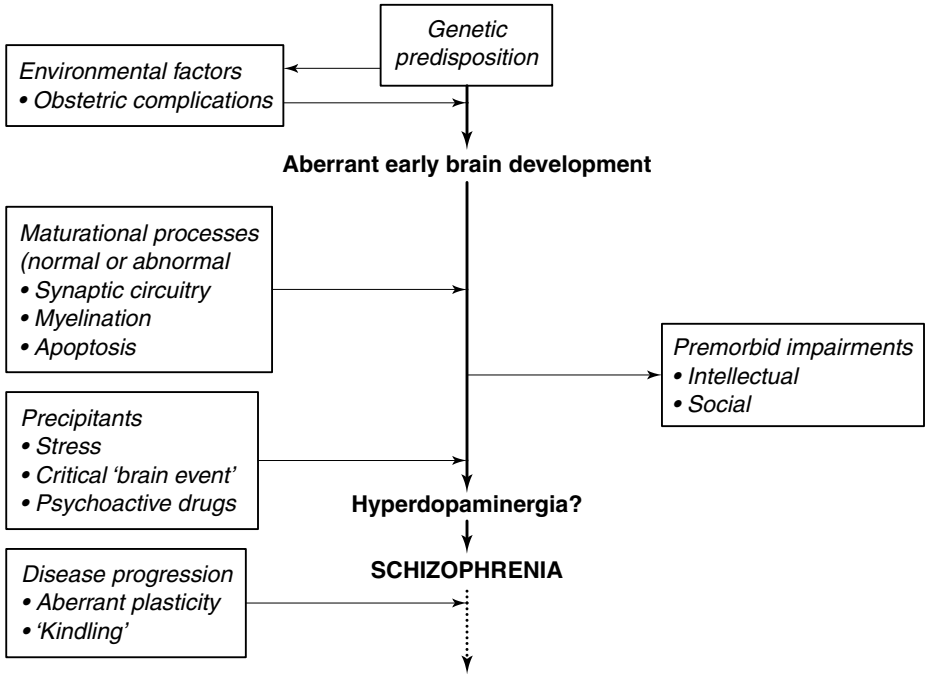

Fig. 26.1. Schematic representation of the neurodevelopmental model of schizoprenia.

Schizophrenia as a disorder of neural connectivity

Bleuler, who coined the term schizophrenia 90 years ago, proposed that the key symptoms are those of 'psychic splitting'. This view now has its counterpart in theories of aberrant functional connectivity between brain regions as the putative mechanism of psychosis (McGuire & Frith, 1996). One model advocates involvement of a circuit between frontal cortex, thalamus, striatum and cerebellum (Andreasen, 1999); another implicates fronto-temporal cortical connections. The conceptual and empirical basis for these proposals originated mainly in the functional imaging studies which show different patterns of activation and deactivation in schizophrenics. The cytoarchitectural features of schizophrenia described above may represent the neuroanatomical basis of this aberrant functional connectivity (Harrison, 1999a).

Treatment

The mainstay of schizophrenia treatment continues to be antipsychotic medication, which is effective in treating acute episodes in 60–70% of patients, and which markedly reduced relapse rates during maintenance therapy (Kane, 1999). However, the drugs cause many and severe side effects, and they have at most minimal efficacy against negative symptoms, depressive symptoms or cognitive deficits. The only drug which is unequivocally more effective than other antipsychotics is clozapine (Wahlbeck et al., 1999), and it is also free of extrapyramidal side effects. Unfortunately, its use is restricted because of the risk of agranulocytosis and the consequent need for regular blood tests.

Clozapine is the prototypical 'atypical' antipsychotic. The term was originally applied to drugs which in rodents were predictive of antipsychotic efficacy but which did not produce catalepsy; it is now often used just to refer to all recently introduced antipsychotics. The main controversy in schizophrenia therapy is whether these new drugs are, like clozapine, more effective and/or cause fewer side effects than conventional antipsychotics. A recent systematic review concluded that atypical antipsychotics as a group (other than clozapine) do cause less extrapyramidal side-effects, but their overall efficacy and tolerability is not clearly superior (Geddes et al., 2000). However, the trials have not adequately examined other outcomes, such as cognitive functioning, suicide rates, quality of life, and rates of tardive dyskinesia; it may well be in these domains that the atypical antipsychotics have their main advantages (e.g. Purdon et al., 2000).

Psychosocial treatments are an integral aspect of management (McGrath & Emmerson, 1999). Family interventions, cognitive therapy aimed at residual psychotic symptoms, and psychological therapy to increase medication compliance have all been shown to be effective (Huxley et al., 2000). In many countries, most patients are looked after by multidisciplinary mental health teams, which in addition to psychiatrists, psychologists and psychiatric nurses include social workers, occupational therapists and others. This range of skills and input is necessary given the range of difficulties and needs which many patients with schizophrenia have.

As yet, there have been few clear therapeutic improvements arising from the various advances in understanding schizophrenia, and the complexity of the disorder makes incremental progress more likely than fundamental advances in the near future. However, there are noteworthy efforts under way, such as trials to enhance glutamatergic functioning (Goff et al., 1999), early intervention to improve outcome (Birchwood et al., 1997) and even discussions about prevention (Tsuang et al., 2000).

In conclusion, considerable progress has been made in revealing the relationship between schizophrenia and the brain. Twenty-five years ago, even the existence of this relationship was doubted (Weinberger, 1995). Nevertheless, there has been no critical breakthrough in terms of identifying a specific biochemical or pathological marker for the disorder, nor a causative gene, and hence the understanding remains in many ways rudimentary. Equally, treatment continues to rely on dopamine-blocking antipsychotic drugs and complementary psychosocial interventions. Currently attention is focused on providing stronger evidence as to the origins and precise details of the molecular neurobiology which underlies this complex and heterogeneous syndrome.

[2]Department of Psychiatry, Massachusetts General Hospital and Harvard University, Boston, MA, USA

Introduction

Obsessive–compulsive behaviour has long been described; religious scrupulosity is documented in medieval texts (Adams, 1973), repetitive hand washing as symbolic of guilt has been depicted by playwrights (Shakespeare: Macbeth) and 'obsessive–compulsive neurosis' generated by unconscious conflict was a cornerstone of psychodynamic theory (Freud, 1973). More recently, however, a new paradigm has emerged; obsessive–compulsive behaviour is now viewed as symptomatic of a highly prevalent medical disorder, characterized by specific psychobiological dysfunctions. Indeed, obsessive–compulsive disorder (OCD) is arguably one of the most incisive exemplars of a neuropsychiatric disorder, insofar as clear models now exist of how its characteristic psychopathology is mediated by specific neuroanatomical circuits and neurochemical systems. This chapter aims to provide a comprehensive review of the current state of knowledge on OCD, including epidemiology, clinical features, neurobiology and management.

Epidemiology

Prevalence

Until the 1980s OCD was viewed as a rare disorder, which only affected 0.005% of the population. These figures were based on a study by Rudin, which looked at the prevalence of OCD in a psychiatric in-patient population (Rudin, 1953). The Epidemiological Catchment Area (ECA) study of 1980–1984 radically changed views of the prevalence of OCD (Karno et al., 1988). Undertaken in five US communities, this study found lifetime prevalence rates for OCD to be 1.9–3.3%, making it the fourth most common psychiatric disorder, with a prevalence that was 25–60 times higher than previously believed. These figures were subsequently confirmed in similar studies in Canada (Kolada et al., 1994), Taiwan (Hwuh & Chang, 1989), and several other countries (Weismann et al., 1994), demonstrating that OCD is a disorder with a similar prevalence across nationalities.

The ECA figures, however, have been challenged. The ECA and cross-national study used the Diagnostic Interview Schedule (DIS); a structured interview designed for trained lay interviewers, to arrive at diagnoses. Several later studies have questioned the validity of DIS diagnoses. Nelson and Rice (1997) examined the 1-year temporal stability of the DIS and found it to be low, with only 19.2% of those who were originally diagnosed with OCD having this diagnosis confirmed on follow-up interview. Two follow-up studies of the ECA, using semistructured interviews conducted by psychiatrists (Antony et al., 1985; Helzer et al., 1985), supported these findings. However, these studies have been criticized in view of their small sample size and failure to use objective instruments to ascertain the diagnosis of OCD. More carefully designed studies, using standard rating scales followed by clinician rated diagnostic interviews have confirmed the ECA findings (Rasmussen & Eisen, 1998).

If OCD is so prevalent, why then has its prevalence been underestimated for so many years? In part this is perhaps due to reluctance on the part of sufferers to seek help, whether because of shame about symptoms or because of a lack of awareness of effective treatments. For example, survey of OCD patients found that the mean age of onset was 14.5 years and that professional help was only sought some 10 years later (Hollander et al., 1997a, b). The development of patient advocacy groups in the area of anxiety

disorders and OCD, will hopefully contribute to increased awareness and earlier treatment.

Also important, however, is the problem of clinical misdiagnosis: in this study, the correct diagnosis was made only 6 years after professional help was sought (Hollander et al., 1997a, b). Patients with OCD may present to a range of different clinicians (e.g. to dermatologists for chapped hands following excessive washing, to primary medical practitioners for somatic obsessions, to internists for repeated concerns about AIDS, or to dentists for gum lesions from excessive tooth-brushing), and the diagnosis may be missed in these settings (Hollingsworth et al., 1980; Rapoport, 1989).

Demographic variables

Gender

In epidemiological samples of adults OCD appears to have equal prevalence between males and females (Karno et al., 1988; Valleni Basile et al., 1996; Zohar, 1999). Male gender may be associated with earlier age of onset, comorbid tics, and increased likelihood of perinatal trauma (Bogetto et al., 1999; Lensi et al., 1996).

Race

The ECA study found significantly fewer blacks presenting with OCD (Karno et al., 1988). However, this feature was observed in nine other mental disorders, and is probably a reflection of sociocultural issues, rather than representing a genetic difference in propensity to OCD. Similarly, although studies in Africa (Carothers, 1953; German, 1972) have found the prevalence of OCD to be lower than that described for the US, significant methodological problems exist with many of these studies (failure to use structured clinical interviews, lack of standardized diagnostic criteria). The Cross-National Epidemiological study (Weismann et al., 1994) found prevalence in Korea and Japan to be similar to the US, as did studies of OCD in India (Khanna et al., 1986) and Puerto Rico (Canino et al., 1987)

Socioeconomic status

In the ECA study (Karno et al., 1988) patients with OCD were more likely to be of lower socioeconomic status, and unemployed. However, in two epidemiological studies of children and adolescents, patients presenting with OCD were more likely to be of higher socioeconomic class (Thomsen, 1994; Valleni Basile et al., 1996). It is plausible that the lower socioeconomic status of adults with OCD reflects the impact their disease has on their ability to function in society.

Marital status

OCD sufferers are more likely to be single or divorced than the general population, a likely reflection of the degree of impairment associated with the disorder. Small clinical studies have suggested that the degree of impairment in sexual and marital functioning in OCD is not appreciably different from major depression (Staebler et al., 1993; Coryell, 1981) and panic disorder (Staebler et al., 1993).

Religion and culture

While the prevalence of OCD across different cultures appears to be similar, culture and religion may influence the content of obsessions and compulsions. Several studies in strictly religious communities (primarily Orthodox Jewish and Muslim), have found an increased prevalence of religious obsessions and scrupulosity (Greenberg & Witzum, 1994). Raphael et al. (1996) found more religious affiliation among patients with OCD than other psychiatric patients, but this was not specific to a single religion, and there is little evidence to suggest that increased religiousness is a predisposing factor to develop OCD (Greenberg & Witzum, 1994).

Quality of life and OCD

The enormous negative impact of OCD on patient's lives is reflected in the World Bank and WHO Global Burden of Disease study (Murray & Lopez, 1996), which found OCD to be among the ten most disabling conditions worldwide. The costs of OCD are enormous, reduced or lost productivity from OCD in the US alone has been estimated at $5.9 billion dollars a year (Dupont et al., 1995). Misdiagnosis may cost several billions of dollars a year in the USA (Hollander et al., 1997b).

Quality of life is a concept that is becoming increasingly important in health care and encompasses dimensions such as physical and social role functioning, interpersonal relationships, perceived health and mental well being. Studies of OCD show that it has significant impact on quality of life. Koran et al. (1996b) in a study of medication free patients, for example, found instrumental role performance (i.e. work, homemaking or student role functioning) and social functioning to be worse than that of the general population and of patients with type II diabetes.

These findings underscore the need for effective treatment of OCD. Both retrospective (Stein et al., 1996; Hollander et al., 1997b) and prospective (Bystritsky et al., 1999; Emmelkamp et al., 2000) studies have fortunately indicated that current treatments result in significant improvement in the quality of life in OCD patients.

Clinical features and diagnosis

Age of onset

The ECA study found a mean age of onset of OCD between 21 and 25 years, a figure that has been confirmed by several later studies (Kolada et al., 1994; Rasmussen & Eisen, 1998). However, a significant proportion of patients has onset of symptoms several years prior to the development of the full disorder. The Zurich cohort study (Degonda et al., 1993) reported that 70% of patients developed symptoms before the age of 20 and this has been confirmed in other studies. As noted earlier, there may be significant gender differences in the onset of OCD. Several studies have found males to have an earlier age of onset (17–19 years) than females (19–22 years) (Rasmussen & Eisen, 1990; Degonda et al., 1993).

Natural history and course of disease

OCD has typically been viewed as a chronic progressive unremitting disease. However, the picture may be more complex. Skoog and Skoog (1999) followed 144 patients over 40 years, with average length of follow-up from onset of 47 years. Eighty-three per cent of patients improved, with complete recovery in 20% and subclinical symptoms in 28%. Early age of onset, the presence of both obsessions and compulsions, magical obsessions and compulsive rituals, low baseline functioning and initial chronic course were associated with a worse course. What makes this study particularly interesting is that only 17 patients received medication and in 14 this was instituted after more than 30 years of OCD.

Studies in adolescents also suggest that OCD may improve over time. Flament et al. (1988) in a study of high school students, found that, of 12 students with OCD at baseline, only 5 still had clinical symptoms at 2 year follow-up; and Valleni Basile (Valleni Basile et al., 1996) found that in adolescents with OCD, the most common transition was from the more severe to the less severe category of OCD. While these studies paint a less gloomy picture of the course of OCD it must be emphasized that a significant proportion of patients continue to have disease after many years.

Symptomatology

The hallmark of OCD is the presence of obsessions and compulsion. While the spectrum of obsessions and compulsions is vast, the majority can be grouped into one of the following clusters (Rasmussen & Tsuang, 1986; Rettew et al., 1992).

Contamination fears

These are the most common of obsessions, and are often coupled with avoidance, checking and handwashing. Patients experience intense anxiety about being contaminated, often going to great lengths to avoid the feared object(s). It is interesting to note that, while the symptom structure has remained relatively constant, the actual feared object has changed over time, from the plague to syphilis and now AIDS (Rachman & Hodgson, 1980).

Checking

These patients experience intense worry that something terrible will happen because they failed to check something completely. Often they acknowledge that their fears are absurd, but experience intense anxiety if they do not perform their checking. They often experience a sense of 'incompleteness' (Janet, 1904) until their specified ritual is performed a certain number of times, when the anxiety stops. These patients show the experience of pathological doubt in its purest form. Leckman et al. (1997) found that checking was highly correlated with sexual, religious and somatic obsessions and that the strongest correlations were between aggressive impulses and checking rituals.

Sexual and aggressive obsessions

Some patients suffer from recurrent, unacceptable sexual thoughts or actions, which as Janet (1904) noted, are often the ones calculated to cause the most horror to the patient. For example, a deeply religious woman will have recurrent sexual thoughts of Jesus, or a mother will experience impulses to harm her children. Patients may experience severe guilt and anxiety, often coupled with the need for continual forgiveness or reassurance.

Symmetry and precision

Patients with obsessions about symmetry and precision may line objects up, straighten things, or perform ordering rituals. This may be accompanied by magical thinking; such patients worry that, unless things are ordered or symmetrical, a potential disaster may occur. Symmetry and ordering obsessions have been found to be associated with chronic tic disorders (Leckman et al., 1997).

Obsessional slowness may also occur as a result of symmetry and ordering concerns. Alternatively, however, obsessional slowness may reflect avoidance (for example, patients with contamination concerns may move slowly to avoid exposure to dirt). Patients with obsessional slowness tend to have more neurological soft signs (Hymas et al., 1991), and may represent a subgroup of patients with more severe illness (Veale, 1993).

Somatic obsessions

Somatic obsessions (for example, that a particular part of the body is misshapen or dysfunctional) occur in many disorders and differential diagnosis includes hypochondriasis, body dysmorphic disorder (BDD), and major depression with somatic features. Patients with OCD, however, tend to have multiple obsessions and compulsions.

Hoarding

Hoarding is defined as the acquisition of, and failure to discard possessions that are useless or have limited value (Frost & Gross, 1993). It may occur in response to several different kinds of obsessions e.g. fear of throwing something out by mistake, fear of misfortune occurring. It is a common symptom of OCD, present in up to 18% of patients (Rasmussen & Tsuang, 1986). It has been suggested that hoarding is associated with less insight (Greenberg, 1987; Frost & Gross, 1993), is found more frequently in patients with comorbid tic disorders, and is a predictor of worse response to SRIs (Black et al., 1998; Mataix-Cols et al., 1999).

OCD subtyping

Although advances in OCD demonstrate that it is a specific neuropsychiatric entity, the available data also indicate a degree of heterogeneity. Research interest has recently been directed at finding homogenous OCD subgroups with prognostic and therapeutic implications. Subtyping OCD by means of symptomatology (as above) provides a preliminary approach, to be supplemented by more sophisticated factor analytic techniques.

One of the first factor analyses (Hodgson & Rachman, 1977) used the Maudsley Obsessive Compulsive Inventory and yielded four factors 'checking', 'cleaning', 'slowness' and 'doubting'. However, the Maudsley is biased towards checking and cleaning items. Furthermore, over time patients' symptoms have been shown to evolve from one of these symptom clusters to another.

Rasmussen and Eisen (1991) have proposed three core subtypes of OCD: abnormal risk assessment, pathological doubt, and incompleteness. They argued that these subtypes cut across symptom clusters. In their work, symptoms involving incompleteness were more often associated with tics and compulsive personality features, whereas those without incompleteness were more likely to be associated with high levels of anxiety and comorbid anxiety disorders.

Baer (1994) in factor analysis of the Y-BOCS have provided data partially consistent with this hypothesis. Three factors best summarized the major symptoms: symmetry/hoarding, contamination/checking, and 'pure' obsessions, such as sexual, aggressive and religious obsessions. They noted similarities between symmetry/hoarding and incompleteness, a feature frequently found in Tourette's Syndrome. Symmetry/hoarding was significantly correlated with comorbid Tourette's Syndrome. Several later studies largely confirmed these findings but found symmetry and hoarding to be two different factors (Leckman et al., 1997).

Neuroimaging studies suggest that these factors may have different neuroanatomical correlations. Rauch and colleagues (Rauch et al., 1998a) found that pure obsessions correlated with bilateral striatal activity, symmetry and ordering negatively correlated with right caudate activity, and washing and cleaning symptoms correlated with orbitofrontal and anterior cingulate cortical activity.

These factors also appear to have clinical implications, for example cleaning/checking may respond best to behavioural treatment (Ball et al., 1996), while as we noted earlier, hoarding is associated with comorbid tic disorders and more likely to require the addition of neuroleptic medication (McDougle et al., 1993, 1994).

The relationship between OCD and tic disorders may provide particular insight into the subtyping of OCD. OCD is common in tic disorders and vice versa. Similarly, family studies have found higher rates of OCD in Tourette's syndrome probands, and higher rates of TS in OCD probands, suggesting a genetic link between the two disorders (Pauls et al., 1995).

Patients with and without tics may have phenotypic differences. For example, OCD patients with tics have male predominance, earlier age at onset, and higher frequency of tic-like compulsions such as the need to touch, tap, or rub items, blinking and staring rituals, as well as symmetry obsessions and feelings of incompleteness. Patients with tics are also more likely to experience sensory phenomena, such as bodily sensations, mental urges and a sense of inner tension (Miguel et al., 2000).

OCD patients with tics differ from those without tics in their response to treatment as well. A retrospective case controlled analysis found fluvoxamine to be less effective in patients with tics (McDougle et al., 1993). Furthermore, in one study patients with tics were more likely to respond to typical neuroleptic augmentation (McDougle et al., 1994). Such data suggests that patients with OCD and tics may represent a neurobiologically distinct subgroup. However, contrary to expectations, a recent controlled trial of risperidone (McDougle et al., 2000) found no significant difference in response between patients with and without tics.

Other aspects of the neurobiology of OCD may provide

an alternative basis for subtyping. Increased neurological soft signs have been found in OCD patients as compared to normal controls (Hollander et al., 1990), and in some but not all studies, this has been a predictor of poorer response to pharmacotherapy (Hollander et al., 1992; Thienemann & Koran, 1995). Similarly, the group of OCD patients with symptom onset in the context of streptococcal throat infection (see below) may represent a distinct subgroup. Thus, several possible ways of integrating data on symptoms, neurobiology and treatment into meaningful subgroups of OCD have been proposed, but further work is required to consolidate these approaches.

Diagnosis

DSM-IV (American Psychiatric Association, 1994) has provided diagnostic criteria for OCD. Like earlier versions, DSM-IV requires patients to experience either obsessions or compulsions which cause marked distress and significantly interfere with the person's social and/or occupational functioning. However, DSM-IV differs from earlier versions in two important ways: The need for insight and the presence of mental rituals.

The DSM-IV field trial (Foa et al., 1995) found that the large majority of patients were uncertain about whether or not their symptoms were unreasonable, and as result the need for insight was de-emphasized and a subcategory 'with poor insight' was added. Furthermore, the majority of patients were found to have mental rituals, and the definition of compulsions was changed to indicate that these are not necessarily physical actions.

Differential diagnosis

Other psychiatric disorders can present with phenomena similar to OCD. Patients with OCD spectrum disorders often experience recurrent, intrusive thoughts or behaviours but these are limited to a specific context (e.g. preoccupation with appearance in body dysmorphic disorder, hair pulling in trichotillomania, or excessive fears of having an illness as in hypochondriasis.) Similar distinctions occur with other anxiety disorders: social or specific phobia is characterized by preoccupations that are limited to a particular feared object or situation, while generalized anxiety disorder is characterized by excessive worry which involves real life situations.

Patients with dementia may display excessive list making, hoarding, counting and other behaviours that resemble compulsive rituals but are compensatory mechanisms. Patients with major depression may show somatic or paranoid ruminations, and patients with schizophrenia can display contamination concerns and hoarding behaviours. These patients however, typically have other symptoms as well, and the form of their symptoms may differ from the classical pattern of ego-dystonicity that characterizes OCD.

Tics and stereotyped movements must be distinguished from compulsions. The key differences are that they are not performed in response to an obsession and the patient does not attach meaning to these movements. However, it is important to bear in mind that the diagnosis of OCD and a tic disorder often coexist.

OCD must also be distinguished from obsessive compulsive personality disorder (OCPD). Unless they have a coexisting diagnosis of OCD, patients with OCPD do not have obsessions or compulsions, but rather their personality is characterized by a pervasive pattern of preoccupation with orderliness, perfectionism and control.

Superstitions and rituals are commonly encountered among a wide variety of people, but a diagnosis of OCD should only be considered if these behaviours are ego-dystonic, and cause significant distress or functional impairment.

Neurological disorders involving lesions of the frontal lobe, basal ganglia (particularly the caudate nucleus) or both, should be excluded. In a review of the relationship between frontal lobe degeneration and repetitive behaviours Ames et al. (1994) found 78% of patients showed some type of repetitive or compulsive behaviour. Similarly, many patients with lesions of the striatum develop behaviours that are consistent with a diagnosis of OCD. Case reports attest to a wide variety of etiologies for such lesion ranging from neurodegenerative disorders such as Huntington's disease, to infarction, to toxins like carbon monoxide or manganese (Cummings & Cunningham, 1992). There are also a few reports of temporal lobe lesions leading to OCD (Jenike & Brotman 1984; Zungu-Dirwayi et al., 1999).

Comorbid conditions

Comorbid conditions are frequent in OCD, with studies reporting that at least 50% of patients have a comorbid Axis I disorder and at least 40% of patients also meet criteria for personality disorder(s) (Piggot et al., 1994).

Axis I disorders

Major depressive disorder is the most common comorbid disorder in OCD, with at least 30% of patients meeting the criteria for a concurrent major depressive episode and lifetime prevalence as high as 70% (Piggot et al., 1994). Depression usually occurs secondary to OCD, with most patients reporting an onset of depressive symptoms after the onset of OCD. However, others report a separate course for their depressive symptoms vs. those of OCD, suggesting

that in a subgroup of patients the disorders are unrelated or at least separate.

The relationship between OCD and mania has been less well studied, but recent evidence suggests that a significant number of patients have both disorders. Chen and Dilsaver (1995) found that 21% of subjects with bipolar disorder in the ECA survey had comorbid OCD while Kruger et al. (1995) found an incidence of 35%. Perugi et al. (1999) found that 16% of patients with OCD had comorbid bipolar disorder (mainly bipolar II). They found that these patients had a more gradual onset, more episodes of major depression and a higher rate of sexual and religious obsessions and fewer checking obsessions.

A substantial cohort of patients (40–60%) with OCD also have comorbid anxiety disorders, with the most common being panic disorder (12–15%), simple phobia (22–27%), and social phobia (11–18%). It has been suggested that the anxiety disorders represent states of altered risk assessment, and the high rates of comorbidity point to shared pathophysiological mechanisms (Piggot et al., 1994).

A substantial number of patients with OCD also have eating disorders, with lifetime rates of anorexia nervosa of 10–17% and rates for bulimia nervosa of 5–20% (Piggot et al., 1994). Similarly, patients with anorexia nervosa and bulimia nervosa have been reported to have a high incidence of obsessional features. This may have therapeutic implications with some studies suggesting that SSRI's may have preferential efficacy in these patients.

Axis II disorders

Due to changes in the conceptualization and diagnostic criteria of personality disorders, the co-morbidity of personality disorders with OCD has been difficult to elucidate. Nevertheless, in studies using DSM-III or IIIR criteria, personality disorders have been found to be very common in patients with OCD with some studies reporting that over 50% of patients meet the criteria for at least one personality disorder. Avoidant, dependent, histrionic or obsessive compulsive personality disorders appear to be the most common comorbid diagnoses (Piggot et al., 1994).

The relationship between OCD and OCPD has been an area of special interest. For many years the Freudian concept of the 'anal erotic character' dominated thinking about the relationship between OCD and OCPD. Here the disorders were viewed as existing along a continuum; with OCD being the final most severe form of the disorder. More recent evidence suggests that significant differences exist between the two disorders. OCD may be a predisposing factor for the development of OCPD. It has been suggested that patients may develop OCPD as an adaptive mechanism to deal with disorder (Baer & Jenike, 1992), a possibility supported by the observation that OCD often predates the development of OCPD (Baer & Jenike, 1992). Obsessive–compulsive personality disorder occurs less frequently in OCD than previously thought but is still more common in OCD than in either the general population or in patients with major depression or panic disorder.

The role of personality disorders as predictors of outcome has received some study. Concomitant schizotypal personality disorder in particular has been consistently associated with poorer response to medication and behavioural therapy, and in some studies has been shown more likely to be associated with a response to typical neuroleptic augmentation (Ravizza et al., 1995). This is in keeping with studies reflecting dopamine dysfunction in schizotypal personality disorder (Siever, 1994). However, a trial of risperidone did not find a difference in response between those with and without schizotypal personality disorder (McDougle et al., 2000).

Etiology and pathophysiology

OCD is a complex disorder, in which several pathophysiological processes may be involved:

The genetics of OCD

Current data suggest that OCD has a substantial genetic component. Twin studies show concordance rates of approximately 80% in monozygotic twins and only 47–50% in dizygotic twins (Inyoue, 1965; Carey & Gottesman, 1981). Furthermore, several studies have found a greater prevalence of OCD and subsyndromal OCD in parents and first-degree relatives of OCD probands as compared to parents of psychiatrically normal controls (Black et al., 1992; Pauls et al., 1995).

Family studies have also borne out a link with Tourette's syndrome with greater prevalence of OCD in first-degree relatives of probands with Tourette's syndrome regardless of OCD comorbidity. Pauls et al. (Pauls & Leckman, 1986; Pauls et al., 1990) in two studies of Tourette's syndrome probands found familial patterns of Tourette's syndrome, chronic tics, and OCD that were consistent with an autosomal mode of transmission with incomplete penetrance. Two later studies replicated these findings (Van de Wetering, 1993; Eapen et al., 1993).

Taken together, these findings suggest that the risk for developing OCD is heritable and point to at least one form of OCD that is characterized by early onset and association with tic disorders.

Neuroanatomical models of OCD

The current neuroanatomical model of OCD emphasizes the role of cortico-striato-thalamo-cortical (CTSC) circuitry. Alexander et al. (1986, 1990) conceptualized this as being organized into multiple, parallel segregated circuits, which project from the cortex to corresponding striatal subterritories, from there to the basal ganglia, and via the thalamus back to the prefrontal regions from which they originated. Very briefly, these systems function to filter out extraneous input to the cortex, to ensure refined output and to mediate stereotyped rule-based processes without these reaching consciousness.

Modern imaging studies confirm the role of cortico-striato-thalamo-cortical circuitry in OCD.

Structural studies

Several volumetric studies of the caudate have shown structural abnormalities. The nature of the abnormalities described has been inconsistent, with some studies showing increased volume and others decreased volume; it is possible that caudate volume changes over time, with increased volume in the aftermath of streptococcal infection (Giedd et al., 2000), and later shrinkage.

Volumetric changes in the orbital frontal and anterior cingulate regions have been less well studied. Of three studies reported so far, only one (Szezsko et al., 1999) found structural abnormalities (reduced bilateral orbital frontal and amygdala volumes). Functional imaging studies, however, provide more robust evidence for involvement of these structures (see below).

White matter reductions in OCD have been reported and a subsequent replication study confirmed overall white matter reduction but increased opercular volume, which correlated with both severity of OCD and nonverbal immediate memory (Jenike et al., 1996). Finally, thalamic volumes normalize after treatment with paroxetine but not behaviour therapy, perhaps pointing to a different mechanism of action for the two modalities (Rosenberg et al., 2000a).

Studies using magnetic resonance spectroscopy (MRS) have also demonstrated striatal abnormalities. Two studies have found decreased *N*-acetyl-aspartate (NAA) levels in the striatum (Ebert et al., 1997; Bartha et al., 1998), suggesting decreased density of healthy neurons in this region. Furthermore, one of these studies failed to find significant differences in striatal volumes (Bartha et al., 1998), underscoring the purported greater sensitivity of MRS–NAA over current morphometric MRI methods.

Rosenberg's group has also demonstrated abnormalities in a pediatric population. Decreased NAA levels were found in right and left medial thalami, with the decreased levels in the left medial thalamus correlating with increased severity of disease (Fitzgerald et al., 2000). In addition caudate glutamatergic levels were found to be increased in children with OCD (Rosenberg et al., 2000b), but this was found to normalize after treatment with paroxetine, perhaps suggesting that paroxetine treatment is mediated by a serotonergically modulated reduction in fronto-striatal glutamatergic concentration.

Functional studies

Neutral state studies have implicated hyperactivity in the prefrontal cortex and less consistently striatal and cingulate involvement (Baxter et al., 1988; Nordahl et al., 1989; Swedo et al., 1989c; Benkelfat et al., 1990; Machlin et al., 1991; Rubin et al., 1992; Perani et al., 1995). Pre/posttreatment studies also point to involvement of these areas. Decreased activity after medication was found in the medial frontal cortex (Hoehn-Saric et al., 1991), and orbitofrontal cortex (Benkelfat et al., 1990; Swedo et al., 1992c), with one study correlating treatment response to activity in the right frontal cortex. Changes in the caudate and cingulum have also been reported (Benkelfat et al., 1990).

Baxter et al. (1992) found decreased right caudate activity in a group receiving medication as well as a different group receiving behaviour therapy. This was subsequently replicated in a second study of behaviour therapy, which also confirmed correlation between orbitofrontal and caudate activity pretreatment that disappeared posttreatment (Schwartz et al., 1996). These studies confirm that effective treatment of OCD, whether pharmacotherapeutic or psychotherapeutic in nature, is accompanied by specific changes in CTSC circuits.

Why should dysfunction in CTSC circuits lead to OCD symptoms? There is increasing evidence that striatal function is associated with the development, maintenance and selection of motoric cognitive and procedural strategies, this has been variously described as 'habit system' 'response set' and 'procedural mobilization'. Thus, it may be argued that striatal lesions can lead to the inappropriate release of genetically programmed sequences (such as hand-washing, hoarding, etc.).

An early heuristic model (Baxter et al., 1990) postulated that different circuits may be involved in the mediation of different kinds of OCD symptom. According to such a 'striatal topography model', the cognitive symptoms of OCD are mediated by the caudate, motoric symptoms by the putamen, and affective symptoms by paralimbic CTSC circuits. More recent evidence shows involvement of a range of CTSC circuits in OCD; nevertheless it may still be suggested that projections to specific fields or cells mediate different kinds of OCD symptoms.

Rauch et al. have suggested that the intrusive events that are the hallmark of OCD and related disorders represent failure of filtering at the level of the thalamus (Rauch et al., 1985). Information can be processed in two ways explicitly (i.e. consciously) and implicitly (i.e. unconsciously), with implicit operations being primarily processed via cortico-striatal systems. In OCD, pathology in the cortico-striatal pathways may allow this information to gain access to consciousness, presenting as intrusive phenomena. Rauch et al. has shown that the striatum is usually recruited during an implicit sequence learning task, but that in patients with OCD, this fails to occur and instead, medial temporal structures, usually associated with conscious information processing, are recruited (Rauch et al., 1985, 1997, 1998b).

In this model compulsions or tics may represent a compensatory mechanism. These repetitive behaviours may serve to recruit viable cortico-striatal-thalamic circuits, thereby facilitating filtering at the level of the thalamus. The repetitions required would reflect the inefficiency of such mechanisms. This is also consistent with clinical observation that patients often suddenly no longer experience the urge to perform a behaviour, 'as if a switch were turned off'. Presumably, once sufficient repetitions have been performed, a threshold level of filtering is reached and the intrusive stimuli no longer reach consciousness. Rauch et al. (1998a, b) have also demonstrated in functional imaging studies a characteristic pattern of thalamic deactivation with striatal recruitment.

Neuropsychology of OCD

Neuropsychological studies of OCD have demonstrated that the following domains of cognitive functioning are most consistently affected in patients with OCD: visuospatial skill, non-verbal memory, and executive abilities.

Visuospatial skills describe the patient's mental capacity to perceive and manipulate objects in two and three dimensional space (Lezak, 1995). Patients with OCD have been found to be impaired on a number of tests that purport to measure visuospatial memory (Flor-Henry et al., 1979; Insel et al., 1983; Behar et al., 1984; Head et al., 1989; Hollander et al., 1990, 1993; Boone et al., 1991; Christenson et al., 1992; Aronowitz et al., 1994, Savage et al., 1995).

Non-verbal memory refers to the ability to learn and recall new visual objects and images, preferably ones not easily described with words. Again, patients with OCD show impairment on several tests of nonverbal memory (Boone et al., 1991; Zielenski et al., 1991; Christenson et al., 1992; Savage et al., 1993, 1995; Aronowitz et al., 1994; Dirson et al., 1995; Cohen et al., 1996). In particular, their ability to encode new non-verbal information appears particularly affected (Boone et al., 1991; Zielenski et al., 1991; Savage et al., 1993, 1995; Aronowitz et al., 1994; Cohen et al., 1996). Deficits in the ability to retrieve previously stored non-verbal memories have also been described. To put it another way, patients with OCD have difficulty learning new non-verbal material, and once having learnt it, have problems in retrieving that memory.

Underlying both these deficits may be impairment of executive function. Executive function refers to the high-level control processes that modulate more elementary sensory, motor, cognitive, memory and affective functions. It requires the ability to take the overall context of the situation into account and use this knowledge to set priorities, implement strategic behaviour and shift behaviour appropriately as the situation changes (Lezak, 1995).

In general patients with OCD appear to have most difficulty in this last component of executive function, that is, they have trouble changing their behaviour appropriately as the situation changes (Malloy, 1987; Christenson et al., 1992).

This is reminiscent of the symptoms of OCD (Savage, 1998). Take as an example a compulsive checker. The excessive fear that something may happen if he fails to check may be linked to failure to appreciate the overall context of the situation. Checking may also be related to difficulty planning and implementing strategic actions. Continued checking in the face of its failure to reduce anxiety may be related to difficulty in flexibly modifying behaviour

This deficit in executive functioning may underlie the problems with non-verbal memory. If a person has poor executive function, and hence organizational problems, it is likely that they will not be able to break down visual structures into easily recognizable components, and hence find them more difficult to remember. Savage et al. demonstrated exactly this in a study that examined OCD patients' performance on the Rey–Osterreith complex figure test. Patients (and matched controls) were asked to copy a complex figure and then draw it immediately after the figure was removed and 30 minutes later. Patients with OCD showed impairment both in the organizational approach used to copy the figure as well as recall after the figure was removed (both immediate and delayed). Recent work also suggests impaired organizational strategies may mediate deficits in verbal memory as well (Savage et al., 2000).

These findings tie in well with evidence of fronto-striatal dysfunction demonstrated in imaging studies of patients with OCD. Studies of patients with Parkinson's disease and Huntington's disease, both disorders involving striatal degeneration, show evidence of executive dysfunction leading to memory and spatial deficits in these patients,

with deficits in organizational approach similar to those found in OCD (Ogden et al., 1990; Grossman et al., 1993)

Autoimmune pathology in OCD

In a series of landmark studies (Swedo et al., 1989b, 1993), Swedo and colleagues confirmed earlier observations that OCD symptoms were common among children with Sydenham's chorea, and often preceded motor manifestations of the disease. Later work (Swedo et al., 1998) demonstrated that a subgroup had OCD symptoms of abrupt onset, and showed exacerbations that often were associated with demonstrable group A β-hemolytic streptococcus infection. In addition, a subset of children with OCD shows antineuronal antibodies.

Together, these finding have led to the designation of Pediatric Autoimmune Neuropsychiatric Disorders Associated with Streptococcal infections (PANDAS) (Swedo et al., 1998). Specific criteria include: (i) presence of OCD and/or a tic disorder, (ii) prepubertal onset, (iii) episodic course of symptom severity, (iv) association with group A β-hemolytic streptococcus infection (v) association with neurologic abnormalities.

Autoimmune basal ganglia damage has been identified as an important pathogenic mechanism in Sydenham's chorea (Husby et al., 1976). Furthermore, acute changes in striatal volume parallel the clinical course of PANDAS (Gibofsky et al., 1991). These findings therefore strengthen the case for striatal damage as a pathogenic mechanism for OCD.

Susceptibility to rheumatic fever and hence PANDAS (Gibofsky et al., 1991) may be inherited as an autosomal recessive trait. The B lymphocyte antigen d8/17 appears to serve as a marker for susceptibility to rheumatic fever, occurring in 100% of rheumatic fever sufferers (Khanna et al., 1989), with significantly higher expression in the rheumatic fever patients than in either unaffected first degree relatives or normal controls. As increased D8/17 has not been reported in poststreptococcal glomerulonephritis, it may indicate specific vulnerability to developing rheumatic fever and related complications. Elevated D8/17 expression has been described in patients with childhood onset OCD, Tourette's syndrome and autism, but not in trichotillomania (Swedo & Leonard, 1992; Niehaus et al., 1996; Murphy et al., 1997; Swedo et al., 1997; Chapman et al., 1998).

Neurochemistry and neuropharmacology

A number of neurotransmitter systems appear to play a role in mediating OCD symptoms.

Serotonin and OCD

The serotonergic hypothesis of OCD was first prompted by the observation that serotonergic reuptake inhibitors were more effective in alleviating the symptoms of OCD (Fernandez-Cordoba & Lopez-Ibor, 1967; Zohar & Insel, 1987; Greist et al., 1995b). Whether SSRI's work by correcting some fundamental abnormality on the serotonergic system or whether they modulate an intact system to compensate for underlying abnormalities in OCD is not yet known.

An interesting set of preclinical studies have found that, in order to desensitize the 5-HT1D autoreceptor in orbitofrontal cortex, the administration of relatively high doses of SSRI's for relatively long periods is required (low doses, short duration, and ECT does not have an effect) (Mansari et al., 1995). This work is reminiscent of clinical findings in OCD (see below), and suggests that this receptor may therefore have a particularly important role.

There is also work suggesting that 5-HT-2 receptors are important in OCD. Case reports suggest that certain hallucinogens (psilocybin and LSD), that are potent stimulators of the 5HT2A and 5HT2C receptors, can decrease OCD symptoms (Delgado & Morena, 1998). Conversely, ritanserin, a 5-HT-2 antagonist results in the exacerbation of OCD symptoms (Ergovesi et al., 1992). Arguably, enhancement of neurotransmission through 5HT2A or 5HT2C receptors may be a common pathway for drugs with therapeutic effect in OCD.

Studies of indirect measures of central serotonergic function (such as platelet receptor binding and CSF concentrations of 5HT metabolites) in OCD have been inconsistent. There is somewhat more consistency in studies of serotonergic agonists; OCD symptoms are exacerbated by mCPP (a 5HT1A and 5HTC agonist) (Zohar et al., 1987; Hollander et al., 1991; Piggot et al., 1993) and perhaps by sumatriptan (a 5HT-1D agonist) (Stein et al., 1999). Administration of sumatriptan during functional imaging demonstrated a significant association between symptom exacerbation and decreased frontal activity, arguably consistent with a role for the 5-HT1D receptor in OCD (Stein et al., 1999). Nevertheless, findings with both mCPP (Charney et al., 1988; Ho Pian et al., 1998; Goodman et al., 1996) and sumatriptan (Pian et al., 1998) have not always been consistent, and sumatriptan has poor blood–brain barrier penetration, so that additional work in this area remains necessary.

Dopaminergic systems and OCD

Preclinical studies demonstrate that stereotypic behaviour can be elicited by the administration of dopamine agonists, and decreased by dopamine blockers. Similarly,

complex repetitive behaviours have been described in stimulant abusers (Ellinwood, 1967; Schiorring, 1975). Furthermore cocaine, which potentiates the effects of dopamine by blocking presynaptic uptake has been reported to exacerbate symptoms in patients with OCD and to induce such behaviour in subjects with a family but not personal history of OCD.

As noted earlier, there is also a strong association between OCD and Tourette's syndrome, a disorder for which a dopaminergic basis is well elucidated. For example, the principal dopamine metabolite homovanillic acid (HVA) is decreased in the CSF of patients with Tourette's syndrome (McDougle et al., 1989), and dopamine blockers are a standard form of treatment in TS. Recent imaging studies have demonstrated a significant increase in the number of striatal presynaptic dopamine carrier sites in the caudate and putamen in Tourette's patients (Singer et al., 1991; Malison et al., 1995; Wolf et al., 1996).

Pharmacologic studies in OCD support a potential role for the dopamine system. Only around 50–60% of patients respond to SSRIs, and patients with comorbid tics are particularly likely not to respond (McDougle et al., 1994). However, augmentation of SSRIs with dopamine blockers has been shown effective in both open (Jacobsen, 1995; Stein, 1997b) and controlled trials (McDougle et al., 2000). Typical neuroleptics are particularly effective in OCD patients with comorbid tics (McDougle et al., 1994), while the atypicals appear useful in OCD patients both with and without tics (Stein et al., 1997a, b; McDougle et al., 2000).

Neuropeptides and OCD

Preclinical evidence has linked neuropeptides to repetitive behaviour in animals and initial clinical investigations in OCD patients suggest that they may play a role in modulation of the disorder. Neuropeptides implicated in OCD include arginine vasopressin (AVP), oxytocin, adrenocorticotropic hormone (ACTH), corticotropin releasing factor (CRF), somatostatin, and the opioid system.

Preclinical studies have linked AVP with enhancement of memory acquisition and retrieval and with grooming behaviours. AVP may also inhibit extinction, decreasing the likelihood of changing a behavioural pattern once it has been established. Altemus et al. (1992) found OCD patients had significantly elevated basal levels of AVP and secreted more AVP into plasma in response to hypertonic saline. However, this was not found in a subsequent study (Leckman et al., 1994a). Nevertheless, in children and adolescents with OCD, a negative correlation between symptom severity and AVP levels was found (Swedo et al., 1992a).

Preclinical studies have shown that oxytocin administration markedly increases grooming behaviour. Furthermore, oxytocin has been shown to induce maternal behaviour in female rats, but only in animals primed with estrogen (Insel, 1992). This may be relevant to explaining the increased risk for onset or exacerbation of OCD in pregnancy or the puerperium. Elevated levels of oxytocin (and estrogen) may induce OCD symptoms in a vulnerable subgroup of women. Higher CSF oxytocin levels have been found in adult patients with no family or personal history of tic disorders and oxytocin levels were significantly correlated with Y-BOCS scores (Leckman et al., 1994b). In children, the AVP/oxytocin ratio was negatively correlated with symptom severity (Swedo et al., 1992a). Administration of oxytocin to adults with OCD has, however, had no consistent therapeutic effect (Epperson et al., 1996).

ACTH and CRF are both noted to increase self-grooming in animals. In humans, both basal plasma ACTH and the increase following CRF administration was found to be less in adults with OCD than controls (Bailly et al., 1994). Studies of CRF levels have been inconsistent, with initial reports of elevated CRF in OCD patients not being confirmed in replication studies. In children, no correlation has been found between either CSF ACTH or CRF levels and symptoms severity (Swedo et al., 1992a). As both ACTH and CRF are released in response to stress, it is possible that any elevations found may be a non-specific response to the stress of a chronic illness.

In animals, somatostatin delays the extinction of active and passive avoidance behaviours (which may be similar to the persistent repetition of OCD) and can also produce stereotypic behaviours (Vecsei et al., 1986; Vecsei & Widerlov, 1988). Studies of both adults and children with OCD have found higher CSF somatostatin as compared to normals (adults) and conduct disordered children (Kruesi et al., 1990; Altemus et al., 1993).

Opioids mediate reward signals and it has been postulated that they may be involved in mechanisms that signal successful task completion. Deficiencies in these mechanisms may potentially explain the 'self-doubt' experienced by many patients with OCD. OCD patients have elevated serum antibodies for the dynorphin precursor prodynorphin (Roy et al., 1994). In Tourette's syndrome CSF dynorphin was found to correlate with OCD (but not tic) symptom severity (Leckman et al., 1988). However, no correlation was found between dynorphin levels and symptom severity in children with OCD. Furthermore, challenges with opioid antagonists in OCD have produced inconsistent results (Insel & Pickar, 1983; Keuler et al., 1996).

In summary, preclinical evidence suggests that various neuropeptides may play a role in the pathogenesis of OCD. Differences between results in adult and pediatric popula-

tions suggest developmental factors impact the functioning of the different neuropeptides. However, clinical studies so far have generally produced inconsistent results, and further studies are warranted to elucidate fully the role of these peptides.

OCD spectrum disorders

In recent years a group of disorders has been hypothesized to overlap phenomenologically and neurobiologically with OCD, the so-called OCD spectrum disorders (Hollander, 1993). These potentially include a broad range of conditions including disorders usually first diagnosed in childhood, infancy, or adolescence (Tourette's disorder, autistic disorder, stereotypic movement disorder), somatoform disorders (body dysmorphic disorder, hypochondriasis), and disorders of impulse control not otherwise specified (trichotillomania, pathological gambling). Nevertheless, the characterization of so varied a range of disorders as OCD related remains contentious, with some authors warning against premature and overinclusive classifications (Rasmussen, 1994).

Neurobiological data so far has pointed to several similarities between some of these disorders. Several of the OCD spectrum disorders have shown a selective response to serotonergic agents. Clomipramine has been shown to be superior to desipramine in a range of repetitive behaviours including hair-pulling (Swedo et al., 1989a), nail-biting (Leonard et al., 1991), stereotypic behaviours (Castellanos et al., 1996) and obsessive–compulsive symptoms in autistic disorder (Gordon et al., 1992). Data also indicates the selective efficacy of serotonin reuptake inhibitors (SRIs) for symptoms of body dysmorphic disorder (Hollander, 1993), obsessive–compulsive symptoms in Tourette's (Scahill et al., 1997), and self-injurious behaviour in mental retardation (Mikkelson et al., 1997). Augmentation of SRIs with dopamine blockers may also be useful in some of the disorders. Nevertheless, it should be remembered that SRIs may be selectively effective in disorders with markedly different phenomenology from OCD (such as premenstrual dysphoric disorder (Eriksson et al., 1995)).

There may also be neuroanatomical overlap between OCD and some of the putative OCD spectrum disorders. For example, in Tourette's disorder magnetic resonance imaging (MRI) studies have found abnormalities of the basal ganglia (including the putamen, Singer et al., 1993), and functional imaging studies have demonstrated abnormal activity in frontal-striatal regions. Findings are not precisely those found in OCD, but OCD symptoms in TD may correlate with increased metabolism in orbitofrontal cortex and putamen (Braun et al., 1995). Furthermore, in patients with obsessive–compulsive symptoms, regional cerebral blood flow patterns differed depending on whether a family history of TD was present, and patterns were similar to those seen in TD in patients from TD families (Moriarty et al., 1997).

In trichotillomania there is only limited brain imaging data. The data that does exist suggests that the caudate is not involved (O'Sullivan et al., 1997; Stein et al., 1997b), but that the left putamen may be smaller in trichotillomania than in controls (O'Sullivan et al., 1997). On functional imaging, however, patients with trichotillomania were found to have increased cerebellar and right superior parietal glucose metabolic rates compared to normal controls (Swedo et al., 1991). These authors also found that anterior cingulate and orbital-frontal metabolism correlated negatively with clomipramine response, a result they previously found in OCD. Increased orbital-frontal metabolism may conceivably comprise a compensatory response in both disorders.

Genetic overlap between OCD and TD has been of particular interest in the context of OCD spectrum disorders. Tics are more common than expected in the families of OCD probands, and OCD is more common in the families of TD patients than in those of controls. Furthermore, preliminary work on dopamine receptor polymorphisms suggests differences in OCD patients with and without tics (Nicolini et al., 1998). While trichotillomania and OCD may be more common in the families of trichotillomania probands than in the general population, this seems to be a relatively subtle finding (Lenane et al., 1992). Also, there was no increased prevalence of pathological gambling or eating disorders in families of OCD probands compared with controls (Black et al., 1994).

Neuroimmunological studies also point to the existence of a spectrum of disorders. Swedo et al. (1998) note that in the aftermath of β-hemolytic streptococcal infection, patients may present not only with OCD, but also with a range of other symptoms including tics and hair-pulling (Swedo et al., 1992b). Also, expression of the D8/17 lymphocyte marker appears increased in childhood-onset OCD and Tourette's (Murphy et al., 1997), and in autism (Hollander et al., 1997a), although not in trichotillomania (Niehaus et al., 1996).

Some authors (Stein & Hollander, 1993a, b) have suggested that one way of looking at the OCD spectrum may be in terms of the dimension of compulsivity and impulsivity. This perspective is based on the notion that compulsivity may reflect harm avoidance, whereas impulsivity reflects risk-seeking. Thus OCD falls on the compulsive end of an OCD spectrum, whereas impulsive disorders fall on the impulsive end, with disorders such as

Tourette's, trichotillomania, and obsessive–compulsive personality disorder demonstrating both compulsive and impulsive characteristics.

Serotonin receptor studies appear to provide some evidence in support of this. Whereas OCD appears to be characterized by hyperresponsivity of at least some serotonergic receptors, impulsivity has been strongly associated with serotonergic hypofunction. Similarly, whereas OCD is characterized by frontal hyperactivity on functional imaging, impulsivity is known to be associated with the loss of prefrontal function. Closer examination suggests, however, that such a distinction is overly simplistic. OCD patients may in fact demonstrate impulsive-aggressive symptoms and impulsive patients may have OCD symptoms. Furthermore, patients with OCD may demonstrate serotonergic hypofunction (Barr et al., 1992), and patients with frontal hypofunction may also demonstrate stereotypic symptoms.

One way of reconciling these data may be the presence or absence of compensatory responses. In OCD it is speculated that compensatory neurobiological changes such as upregulation of some serotonin receptors and frontal hyperfunction may occur. In contrast, in impulsive disorders, there is serotonin or frontal hypoactivity, with no compensatory response. Thus, whereas OCD patients characteristically demonstrate resistance to their symptoms, impulsive patients are able only to experience regret or shame after acting out their symptoms. Putative OCD spectrum disorders may involve both compulsive and impulsive features.

Further work is still needed to delineate fully the concept of an OCD spectrum of disorders. Currently, the most convincing evidence is for an overlap between Tourette's and OCD, with that for the other disorders remaining more speculative. In the interim, it may be useful to employ this construct as heuristic in both clinical and research settings.

Treatment of OCD

Treatment options for OCD fall into two main categories: behavioural therapy and medication.

Behavioural therapy

Behaviour therapy for OCD is not new, it was arguably described by Janet in the nineteenth century. The core features of behaviour therapy for OCD are exposure and response prevention, i.e. the subject is exposed to the feared stimulus and is then helped to resist the urge to carry out the compulsion.

The clustering of fears in OCD patients around certain themes (contamination, aggression etc) has been proposed by Seligman to represent 'prepared phobias' (Seligman, 1971) i.e. fears that we are highly prepared to acquire as they were probably linked to improved survival in earlier periods of human history. This ties in with findings suggesting that the basal ganglia are important in the development, maintenance and selection of cognitive and procedural strategies.

The theoretical basis from which exposure and response prevention operates was first proposed by Mowrer (Deese & Hulse, 1967), who stated that anxiety occurred in response to a specific event by classical conditioning. Rituals are engaged in to decrease the anxiety and if successful are reinforced and more likely to occur in the future (operant conditioning). Ritualistic behaviour preserves the fear response by preventing the person from remaining in contact with the anxiety provoking stimulus long enough to habituate. A vicious cycle of anxiety leading to rituals and back to anxiety is set up. As the disease evolves both the anxiety and the rituals becomes generalized to other stimuli.

Outcome studies of behavioural therapy have found it to be effective in the treatment of OCD. Meyer et al. (1974) in a study of 15 inpatients with OCD showed improvement in all, and of 12 followed up only 4 had experienced periods of relapse. Rachman et al. (Foa & Goldstein, 1978) in a crossover trial proved behavioural therapy to be superior to relaxation therapy. These findings have been replicated in USA, Greece and the Netherlands (Boulougaris, 1977; Emmelkamp, 1982; Baer & Minicheiello, 1988), suggesting cross cultural efficacy. Also, gains may be maintained over time. More recently, studies showing that behavioural therapy can be conducted using computer instruction have been undertaken. There is also a growing interest in more cognitive techniques.

Not all patients respond to behaviour therapy. Poor compliance is perhaps the most common predictor of failure; an unsurprising finding given that behavioural therapy demands a great deal of discipline from the patients. Other patients who are likely to have a poor response include those with pervasive checking rituals, overvalued ideation, obsessional slowness and schizotypal personality disorder. (Quality Assurance Project, 1985).

How does behaviour therapy compare to medication? The Quality Assurance Project meta-analysis looked at 71 trials conducted between 1961 and 1984. They found similar effect sizes for behavioural therapy and clomipramine. More recently Van Balkom et al. (1994) replicated and updated this meta-analysis and found equal efficacy for behavioural treatments and SSRIs (Chouinard, 1992).

Pharmacotherapy

Since the differential response of OCD to serotonergic agents was first noted, these have become the mainstay in the pharmacological management of OCD. Two main classes of agents have been found to be effective, clomipramine and the selective serotonin reuptake inhibitors.

Clomipramine is the most serotonergic of the tricyclic antidepressants and was in the fact the first agent shown to have differential efficacy in OCD. Clomipramine has been considered the standard therapy of OCD for years, and remains a useful agent. It is, however, associated with significant cholinergic and adrenergic side effects, which has limited its utility in clinical practice. Fluoxetine, fluvoxamine, sertraline, paroxetine and citalopram have all proven to be superior to placebo in controlled trials, and all are licensed in some parts of the world for use in patients with OCD (Chouinard, 1992; Montgomery et al., 1993; Wheadon et al., 1993; Tollefson et al., 1994; Greist et al., 1995a; Goodman et al., 1996).

Clinical experience suggests that the SRIs are needed in higher doses and for longer periods to produce an effect in OCD. However, in controlled trials the evidence for a dose–response relationship is only partial. Only paroxetine showed a significant dose–response relationship (Wheadon et al., 1993). Citalopram, fluoxetine and sertraline show a trend of better response at higher doses (Wheadon et al., 1993; Montgomery et al., 1993; Greist et al., 1995a), but this was not statistically significant and no dose response relationship was found for fluvoxamine.

The standard regimen is to treat for 10–12 weeks at the maximally tolerated dose. Initial response may take as long as 8 weeks, and maximal response as long as 20 weeks. Once a therapeutic response is achieved, therapy should be maintained for 6 months to a year. Medication should be tapered slowly and restarted should symptoms reoccur. There is some evidence that once a response is achieved patients can be maintained on somewhat lower doses (Pato et al., 1990; Ravizza et al., 1996; Mundo et al., 1997).

Relative efficacy

Meta-analytic studies have suggested that clomipramine is more effective than SSRIs in OCD (Bisserbee et al., 1995; Greist, 1995b; Piccinelli et al., 1995; Stein et al., 1995; Koran et al., 1996a). However, clomipramine was the first agent to be introduced for the treatment of OCD, and subsequent studies may have included more refractory patients, so resulting in a bias against the SSRIs in the meta-analyses. Indeed, direct head to head comparisons of fluoxetine, fluvoxamine, sertraline and paroxetine have shown equal efficacy of SSRIs with clomipramine, with the SSRIs being better tolerated (Piggot et al., 1990; Bisserbee et al., 1995; Koran et al., 1996a, Zohar & Judge, 1996).

Treatment resistance

Up to 60% of patients with OCD do not respond or experience only partial remission (Goodman et al., 1992). Treatment resistance can be defined as having failed an adequate 10–12 week trial of 2 different SSRIs or clomipramine at maximally tolerated doses. Several strategies have been proposed for the management of treatment resistant patients. Augmentation strategies, using tryptophan, lithium, clonazepam, buspirone and inositol, have all been used with varying degrees of success, but there are few positive controlled augmentation studies of these agents (Goodman et al., 1992; Fux et al., 1996).

Augmentation with neuroleptics has been proven effective in controlled studies. As noted earlier, augmentation of an SSRI with haloperidol produced a significant effect in treatment of refractory patients with co-morbid tic disorders and schizotypal personality predicting a response to neuroleptic augmentation (McDougle et al., 1994). The atypical neuroleptics may be effective also in patients without tics (McDougle et al., 2000), and in view of their superior side effect profile, are increasingly being used as augmenting agents.

Intravenous clomipramine has also been used as a strategy in treatment-resistant patients. Both open and controlled trials have shown benefit in patients previously refractory to oral clomipramine, with response being maintained after subsequent treatment with oral clomipramine (Fallon et al., 1992, 1998). Furthermore, intravenous pulse loading with clomipramine has been suggested to produce a faster response than either oral pulse loading or gradual intravenous dosing (Koran et al., 1997, 1998). However, further work is needed to determine the place of intravenous clomipramine in the treatment of OCD.

In pediatric patients, especially those who fulfill the criteria PANDAS, immunomodulatory treatment has been proposed. Several case reports (The Guillain Barré Study Group, 1985; Barron et al., 1992; Allen et al., 1995; Tucker et al., 1996) and a controlled trial (Perlmutter et al., 1999) have suggested that both plasmapheresis and intravenous immunoglobulin produce improvement in OCD symptoms. However, questions remain as to the generalizability of the results (the children studied are not representative of the pediatric population with OCD) and this treatment currently remains in the experimental phase.

Electroconvulsive therapy is generally not thought to be useful in OCD, but there are a few case reports of its efficacy in the elderly and in some treatment refractory patients (Casey & Davis, 1994; Maletzky et al., 1994; Rabheru &

Persad, 1997). Preliminary reports of the efficacy of transcranial magnetic stimulation (Greenberg et al., 1997) suggest that this modality may also have a place in the treatment of OCD, but at this stage it is still an experimental treatment.

Neurosurgery

Neurosurgery is generally limited to patients with severe, intractable OCD who have not responded to an exhaustive array of other available treatment. The four most common procedures used are: cingulotomy, capsulotomy, limbic leucotomy and subcaudate tractotomy (Jenike, 1998). In a review of the literature, Jenike (1998) found that at least partial relief can be obtained by surgery in some patients with malignant OCD. There is some evidence that right sided lesions are more effective. Lippitz et al. (1997, 1999) found that, in patients who had undergone capsulotomy, good outcome was associated with a lesion in small area within the middle of the right anterior limb of the internal capsule. There was no correlation between left sided lesions and outcome.

There is, however, a lack of controlled data about the efficacy of neurosurgery. This is due, in part to the ethical difficulties in finding an acceptable 'placebo' surgery. However, with the newer gamma knife techniques, which do not require craniotomy, such studies may now be feasible. Neurosurgery is not without risks, but these compare favourably with that of stereotactic operations for non-psychiatric indications (Blaauw & Braakman, 1988). The risk of postoperative seizures is estimated at less than 1% (Ballantine, 1985; Jenike et al., 1991). In severely ill patients who have not benefited from any other intervention, neurosurgery should be considered as a treatment option.

Deep brain stimulation is another technique that may be useful in the treatment of severely ill patients with OCD. As with functional surgery for movement disorders, the use of deep brain stimulation is emerging as a possible alternative to ablative lesions for psychiatric indications as well (Nuttin et al., 1999)

Conclusion

OCD is a fascinating and complex disorder that has a markedly disruptive impact on the lives of those who suffer from it. It is comparatively recently that we have begun to unravel the mechanisms underlying this disorder, and much remains to be discovered. Nevertheless, we now know OCD to be a disorder mediated by particular neuroanatomical circuits, and to respond to specific interventions. Future work will undoubtedly extend and better integrate neuroanatomic, neurochemical, neurogenetic and neuroimmunological findings.
