Dipyridamole has been compared with control in 15 trials (over 5700 patients). There was no clear evidence of benefit: the 16% reduction in the odds of vascular events was only marginally significant (95% CI, 3%–28%) (Antithrombotic Trialists' Collaboration, 2000). This suggests that dipyridamole alone may not be an effective antiplatelet agent. The most recent analyses based on 25 trials (10 400 patients) showed that the combination of dipyridamole and aspirin was associated with a non-significant 6% reduction in serious vascular events (95% CI, 6% increase to 17% reduction) compared with aspirin alone and a 24% reduction in the relative odds of non-fatal stroke (99% CI, 2%–42%) (Antithrombotic Trialists' Collaboration, 2000). In a subgroup analysis of patients with a TIA or minor stroke, the addition of dipyridamole produced an 18% reduction in the relative odds of a vascular event ($2P = 0.01$), and a 29% reduction in non-fatal stroke ($2P = 0.002$).

The ESPRIT trial is now comparing aspirin with aspirin plus dipyridamole with oral anticoagulant (INR 2–3), in 4200 patients with TIA and ischemic stroke, so additional data will become available about the combination of dipyridamole and aspirin (de Schryver & Algra, 2000).

The data at present suggest that dipyridamole alone is not particularly effective, and until ESPRIT is completed, it is unclear how much benefit there is from adding dipyridamole to aspirin. Because of the cost and extra adverse effects, e.g. headache, we would not use the combination as first-line therapy. However, if a patient who already takes aspirin has a recurrent vascular event, we tend to add dipyridamole.

Secondary stroke prevention for people in atrial fibrillation

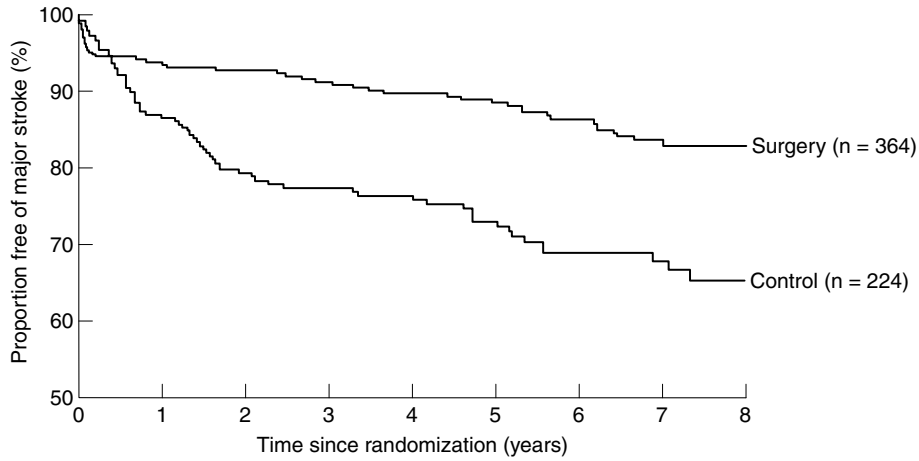
Atrial fibrillation (AF) increases the risk of stroke by about five times, mainly as a consequence of emboli from the fibrillating left atrium. Patients in AF who have had a TIA or minor ischemic stroke are at considerable risk of recurrent stroke. A meta-analysis of data from two trials recruiting 485 people in AF and a previous TIA or minor ischemic stroke found that anticoagulants (INR 2.5–4.0) reduced the risk of recurrent stroke by two-thirds (odds ratio 0.36, 95% CI 0.22–0.58) and also reduced the risk of all vascular events by almost half. No intracranial bleeds were reported among patients given anticoagulants (Koudstaal, 2000).

Fixed minidose warfarin regimens, either alone or in combination with aspirin, have not been adequately evaluated for secondary prevention. Their lack of effect in the primary prevention trials suggests that further randomized trials, to identify the lowest effective anticoagulant intensity for secondary prevention of stroke, would not be worthwhile.

For long-term secondary prevention after TIA or ischemic stroke in patients in AF, we would routinely attempt to use moderate-intensity oral anticoagulants (INR 2–3) rather than antiplatelet drugs. However, there are some patients for whom anticoagulation may be contraindicated, e.g. uncontrolled hypertension, recent gastrointestinal bleeding, liver disease, confusion or dementia, tendency to falls. Clinicians must ensure that the risks of treatment do not outweigh the benefit, and also that patients are prepared to accept the inconvenience of regular blood tests and the increased risk of bleeding. It is unclear how soon after ischemic stroke anticoagulants should be started: we tend to wait for at least 2 weeks, as this may minimize the risk of hemorrhagic transformation of the infarct.

Most of the trials have tested only a few years of anticoagulants, so it is unclear whether the balance of risk and benefit alters with prolonged therapy, although the risk of bleeding does appear to increase with increasing duration of treatment (Levine et al., 1998). Further research is required to determine the optimum duration of anticoagulation. If the patient remains at high risk from stroke, if no bleeding has occurred, and if no new risk factors for bleeding have developed, e.g. falls or dementia, we tend to continue anticoagulants.

If a physician feels that the risks of anticoagulation outweigh the benefits, or if the patient is not prepared to accept the inconvenience and risks of anticoagulation, then aspirin is often prescribed as an alternative. The only trial which has compared aspirin with placebo in patients with AF and a previous ischemic stroke or TIA found a non-significant reduction in the risk of recurrent stroke from 12% per year to 10% per year (odds ratio 0.89, 95% CI 0.64–1.24) (European Atrial Fibrillation Trial Study Group, 1993). Further work is probably required to confirm whether or not aspirin is definitely beneficial, but in the meantime, we prescribe aspirin if anticoagulation is contraindicated.



Number at risk

Surgery	364	335	326	306	286	249	195	143	100
Control	224	189	172	165	158	128	92	63	43

Fig. 86.6. Kaplan–Meier survival curves to show survival free of major stroke (with non-stroke deaths occurring more than 30 days after surgery censored) in surgery and control patients with 80–99% stenosis of the symptomatic carotid artery (With permission from *Lancet* 1998 and European Carotid Surgery Trialist's Collaboration.)

A systematic review of the six trials (3874 patients) with cardio- and cerebsovascular disease found that the addition of aspirin to anticoagulants doubled the risk of intracranial hemorrhage (Hart & Benavente, 1999). For most patients, the combination should be avoided. However, some patients are at particularly high risk of thromboembolism, e.g. those with mechanical prosthetic valves, so the greater antithrombotic benefit of the combination may outweigh the extra bleeding risk (Loewen et al., 1998).

Angiotensin converting enzyme (ACE) inhibitors

The findings of the Heart Outcomes Prevention Evaluation study suggest that the benefits of inhibition of the angiotensin converting enzyme, with ramipiril, are greater than might be expected from its effect on blood pressure reduction (Heart Outcomes Prevention Evaluation Study Investigators, 2000a,b,c). These data suggest that activation of the renin–angiotensin system may be an independent risk factor for cardiovascular disease and that ACE inhibitors might have protective effects on the arterial wall. Further work is required in this area.

Oral contraceptives and hormone replacement therapy (HRT)

Young women who have a stroke of any pathological type whilst on oral contraceptives should stop them, and other vascular risk factors should also be addressed, e.g. smoking.

It is unclear whether HRT should be discontinued in the event of a stroke or TIA. Observational epidemiological data suggest that, amongst women free of vascular disease when they start treatment, HRT is more likely to prevent coronary heart disease events than cause breast or uterine cancer, and may also reduce the risk of limb bone fractures. There are several ongoing randomized trials of HRT in primary and secondary prevention of vascular disease.

Carotid endarterectomy for symptomatic carotid stenosis

Endarterectomy of recently symptomatic severe carotid stenosis almost completely abolishes the high risk of ischemic stroke ipsilateral to the operated artery over the subsequent 2 or 3 years, and this effect probably lasts for at least 8 years (European Carotid Surgery Trialists' Collaborative Group, 1998; Mayberg et al., 1991; Barnett et al., 1998). Even after taking into account the early risk of surgery, the balance of surgical risk and long-term benefit is in favour of surgery (Fig. 86.6).

On average, there is clearly an advantage to surgery when the symptomatic stenosis exceeds about 80% diameter reduction of the arterial lumen using the European Carotid Surgery Trial method, which is equivalent to about 70% using the North American Carotid Surgery Trial method. The risk of surgery is unrelated to the severity of stenosis and because the unoperated risk of stroke in patients with less than 60% (ECST) stenosis is so low, the

Table 86.3. Models to predict ipsilateral ischemic stroke (the medical model) and surgical stroke or death (the surgical model) derived from the European Carotid Surgery Trial

Prognostic variable	Hazard ratio	(95% CI)	*P*	Predictive points
Medical model				
Cerebral vs. ocular events	2.45	(1.09–3.71)	0.02	1
Plaque surface irregularity	2.09	(1.21–3.62)	0.008	1
Any events within the last 2 months	1.82	(1.02–3.18)	0.04	1
Carotid stenosis (per 10% stenosis)	1.30	(1.10–1.40)	0.001	0–2
Surgical model				
Female sex	2.05	(1.29–3.24)	0.002	−0.5
Peripheral vascular disease	3.48	(1.51–4.13)	0.0004	−0.5
Systolic BP > 180 mmHg	2.21	(1.39–3.79)	0.004	−0.5

Notes:
Medical model: a Cox's proportional hazards model for ipsilateral carotid territory major ischemic stroke (i.e. fatal or lasting longer than 7 days) on medical treatment derived from the 857 patients with 0–69% stenosis randomized to no-surgery in the European Carotid Surgery Trial.
Surgical model: a multiple logistic regression model for any major stroke (i.e. fatal or lasting longer than 7 days) or death from other causes within 30 days of carotid endarterectomy derived from the 1203 patients with 0–69% stenosis randomized to surgery in the European Carotid Surgery Trial.
In the risk factor model, which is applied to the 70–99% stenosis group, surgical predictive points are subtracted (i.e. become negative) and their weighting is reduced by 50%.

risk of surgery outweighs the benefit. For patients with between 60% and 80% (ECST) stenosis there is still some uncertainty because there may be a few patients at high enough risk of stroke who would gain from surgery. At present, it is unclear what these risks are for individuals but we do have an approximate idea of what the risks may be in groups of individuals. By adding risk 'points' from a 'medical' model predicting stroke without surgery, and subtracting the 'risk' points from a 'surgical' model predicting the risk of surgery, a score can be calculated which may be clinically useful (Table 86.3). In the 16% of patients in the ECST, with recently symptomatic and severe carotid stenosis and a score above 3.5, there was an advantage to surgery. In patients with a lower score, there was no clear advantage to surgery and even net harm. This approach must be validated in other data sets before it can be widely recommended, but it may reduce the 'numbers-needed-to-treat' to avoid a stroke from 10 to about three (Rothwell et al., 1999b).

It is important to remember that the risk of stroke declines with time after a TIA or ischemic stroke. If the diagnosis is delayed for several months, then the risk of surgery may no longer be justifiable. Ideally, patients should be investigated quickly and efficiently to minimize the problem.

A few patients with a lacunar ischemic stroke or lacunar TIA have an ipsilateral severe carotid stenosis. The question then arises whether the stenosis is 'asymptomatic' (i.e. the stenosis is a coincidental bystander and the infarct was really due to intracranial small vessel disease). There are so few patients in the randomized trials that it is unclear whether or not surgery is beneficial (Boiten et al., 1996). Observational studies show that severe stenosis is about equally rare in the symptomatic and contralateral carotid arteries, which supports the idea of the ipsilateral stenosis being coincidental, but the numbers are too small to be sure (Mead et al., 2001). We would probably recommend surgery, particularly if the stenosis is very severe (>90%), because even if the artery was 'asymptomatic' the risk of stroke without surgery is probably high enough to justify the risk of surgery. The same arguments probably apply if there is also a major coexisting source of embolism from the heart (such as non-rheumatic atrial fibrillation), in which case the patient may reasonably be offered surgery as well as anticoagulation.

It is uncertain whether carotid endarterectomy should precede, follow or be combined with coronary artery bypass surgery in patients who have both cerebrovascular and cardiac symptoms severe enough to require surgery.

Carotid angioplasty and stenting

The one reasonably large randomized trial of carotid angioplasty so far available suggests that the procedural stroke complication rate is similar to carotid endarterectomy (albeit with wide confidence intervals) and that there are few strokes in the long term (with even wider confidence intervals), although the risk of minor morbidity, e.g. neck hematomas and cranial nerve palsies, was lower in patients randomized to angioplasty (CAVATAS, 2000). Larger trials are now being planned to establish both the safety and durability of angioplasty and stenting compared with surgery (Crawley et al., 2000a).

If the benefits do turn out to be greater than the risks, angioplasty, with or without stenting, may be applicable not just to patients presently eligible for carotid endarterectomy but also to those who are unfit for surgery, for stenoses too distal for direct surgery, and for other causes of arterial stenosis such as irradiation and fibromuscular dysplasia.

Surgery and angioplasty for vertebrobasilar ischemia

There are no large randomized trials of surgery or angioplasty for patients with vertebrobasilar ischemia (Crawley et al., 2000b), so at present, we cannot recommend such treatments.

In conclusion, our role as doctors is to ensure that individuals at high risk of stroke and those who have already had TIAs and stroke receive optimal treatment and advice to reduce their risk of serious cerebrovascular and cardiovascular events. Also, whenever possible, we should put pressure on politicians to facilitate healthy changes in the lifestyle of the whole population, which will, ultimately, have a much bigger impact on the burden of stroke disease in the population.

Primary brain tumours in adults

John Laterra[1] and Henry Brem[2]

[1] Department of Neurology, Johns Hopkins Medical Institutions, Baltimore, MD, USA
[2] Department of Neurosurgery, Johns Hopkins Medical Institutions, Baltimore, MD, USA

Approximately 29 000 primary benign and malignant central nervous system tumours are diagnosed in the United States each year (CBTRUS, 1998). Histological diagnosis, location, biological tendency to infiltrate into surrounding brain, surgical resectability, and patient age at diagnosis are strong determinants of their associated morbidity and mortality. Although primary brain tumours are generally resistant to cytotoxic therapies, recent advances in chemotherapy, radiation therapy, and drug delivery in conjunction with more novel therapeutics based upon molecular and cellular biological mechanisms have created new opportunities for prolonging life and preserving the quality of life for brain tumour patients. Even though primary tumours occur infrequently (less than 2%) relative to more common systemic neoplasms such as breast, lung and prostate, they contribute substantially to cancer morbidity because they present at early- to mid-adult life and can rapidly cause neurological disability.

The World Health Organization (WHO) has established a histopathological classification system that divides primary brain tumours into nine separate categories on the basis of routine histochemical and immunohistochemical criteria intended to identify the cell of tumour origin (Table 87.1) (Kleihues et al., 1993). This classification scheme is a standard for pathological diagnosis and clinical decision making. It is generally recognized that all classification schemes available to date have many limitations and need to incorporate molecular and genetic criteria that reflect cellular origins and distinct pathways of transformation. The WHO category of Tumours derived from neuroepithelial tissue consists of nine subcategories that include the most common glial tumours: astrocytoma, oligodendroglioma, ependymoma, and mixed glioma. In adults, gliomas represent the largest proportion of primary brain tumours, accounting for approximately 50% of the total. Meningiomas are the next most common comprising approximately 20–25%, followed by pituitary adenomas, nerve sheath tumours and primary CNS lymphoma that each represent less than 10% of all primary brain tumours (CBTRUS, 1998). A brief summary of the most common gliomas and meningiomas follows. A more comprehensive and detailed description of primary brain tumours can be found in *Tumors of the Central Nervous System* (Burger & Scheithauer, 1994).

Astrocytomas

Astrocytomas are the most common of the gliomas. These tumours have a predilection for the cerebral hemispheres and occur in a range of aggressiveness or tumour 'grade' that, along with patient age at diagnosis, strongly predicts the tumour's biological behaviour and patient survival (Figs. 87.1 and 87.2). The World Heath Organization established a system that divides the infiltrative astrocytomas into three grades (II–IV) of increasing malignancy on the basis of the presence or absence of nuclear atypia, cellular mitoses, micovascular proliferation, and necrosis (Table 87.2) (Kleihues et al., 1993). Low grade astrocytomas (grade II) contain nuclear atypia without other features; anaplastic astrocytomas (grade III) display nuclear atypia and mitoses; and glioblastomas (grade IV) display the additional features of endothelial proliferation and/or necrosis. WHO grade I designates a distinct type of well-demarcated resectable and surgically treatable astrocytoma that includes pilocytic astrocytoma, which is more common in children than in adults, and the subependymal giant cell astrocytoma associated with tuberous sclerosis. The St. Anne-Mayo system uses three histologic features similar to those in the WHO system, but combined in a non-hierachical fashion to generate four tumour grades that are similar, although not always identical, to those defined by the WHO system (Daumas-Duport et al., 1988). Low grade

Table 87.1. World Health Organization classification of CNS tumours

I	Tumours of neuroepithelial tissue
	A. Astrocytic tumours
	1. Astrocytoma
	2. Anaplastic astrocytoma
	3. Glioblastoma
	4. Pilocytic astrocytoma
	5. Pleomorphic xanthoastrocytoma
	6. Subependymal giant cell astrocytoma
	B. Oligodendroglial tumours
	1. Oligodendroglioma
	2. Anaplastic oligodendroglioma
	C. Ependymal tumours
	1. Ependymoma
	2. Anaplastic ependymoma
	3. Myxopapillary ependymoma
	4. Subependymoma
	D. Mixed gliomas
	1. Mixed oligo-astrocytoma
	2. Anaplastic oligo-astrocytoma
	E. Choroid plexus tumours
	1. Choroid plexus papilloma
	2. Choroid plexus carcinoma
	F. Neuroepithelial tumours of uncertain origin
	G. Neuronal and mixed neuronal–glial tumours
	H. Pineal tumours
	I. Embryonal tumours
II	Tumours of cranial and spinal nerves
	A. Schwannoma
	B. Neurofibroma
	C. Malignant peripheral nerve sheath tumour
III	Tumours of the meninges
	A. Tumours of meningothelial cells
	1. Meningioma
	2. Atypical meningioma
	3. Anaplastic (malignant) meningioma
	B. Mesenchymal, non-meningothelial tumours (benign and malignant)
	C. Primary melanocytic lesions
	D. Tumours of uncertain origin
	1. Hemangiopericytoma
	2. Capillary hemangioblastoma
IV	Hemopoietic neoplasms
V	Germ cell tumours
VI	Cysts and tumour-like lesions
VII	Tumours of the anterior pituitary
VIII	Local extensions from regional tumours
IX	Metastatic tumours

Table 87.2. Histologic grading of astrocytic tumours

Features used for grading	
atypia	
mitoses	
endothelial proliferation	
necrosis	
World Health Organization (WHO) system	
Grade II	nuclear atypia only
Grade III	nuclear atypia and mitoses
Grade IV	nuclear atypia, mitoses and either endothelial proliferation or necrosis
St Anne–Mayo (Daumas–Duport) system	
Grade 2	any single feature
Grade 3	any two features
Grade 4	any three or all four features

astrocytoma (WHO grade II) is often referred to as 'benign', which is somewhat of a misnomer since low grade astrocytomas are generally not surgically resectable and frequently progress to higher 'malignant' grade tumours (WHO grades III and IV) over time.

Oligodendroglioma

Oligodendrogliomas are very cellular infiltrative gliomas composed of predominantly oligodendroglial cell types. These tumours are best recognized by the classic appearance of uniform collections of cells with round nuclei and a distinctive perinuclear halo that occurs as an artefact of tissue handling. Like astrocytomas, oligodendrogliomas arise most frequently in the cerebral hemispheres, but they differ from astrocytomas in their predilection for cortical grey matter, a high frequency of calcification, and somewhat clearer demarcation from surrounding brain. Their involvement with cortex and tendency to grow slowly explains their frequent association with partial seizure disorders in otherwise asymptomatic patients. Low grade oligodendrogliomas are more likely than low grade astrocytomas to show some enhancement on CT or MR imaging. Mixed oligoastrocytomas are histological variants containing a mixture of regions with oligodendroglial and those with astroglial features. Survival for patients with well-differentiated oligodendroglioma is longer than that for well-differentiated astrocytoma. Whether the presence of astroglial features reduces patient prognosis relative to pure oligodendroglioma remains controversial. Malignant or anaplastic oligodendrogliomas can present *de novo* or progress from previously well-differentiated

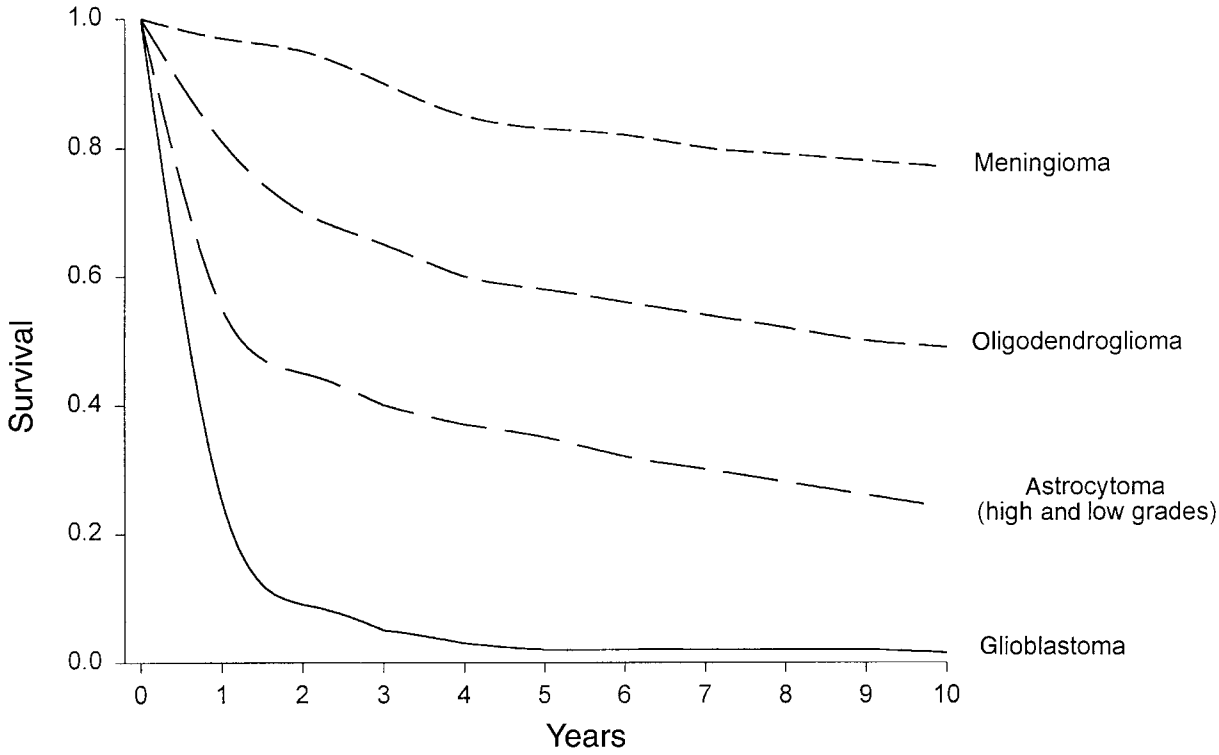

Fig. 87.1. Relative survival for adults according to histologically confirmed brain tumour type. (Modified from Davis et al., 1998.)

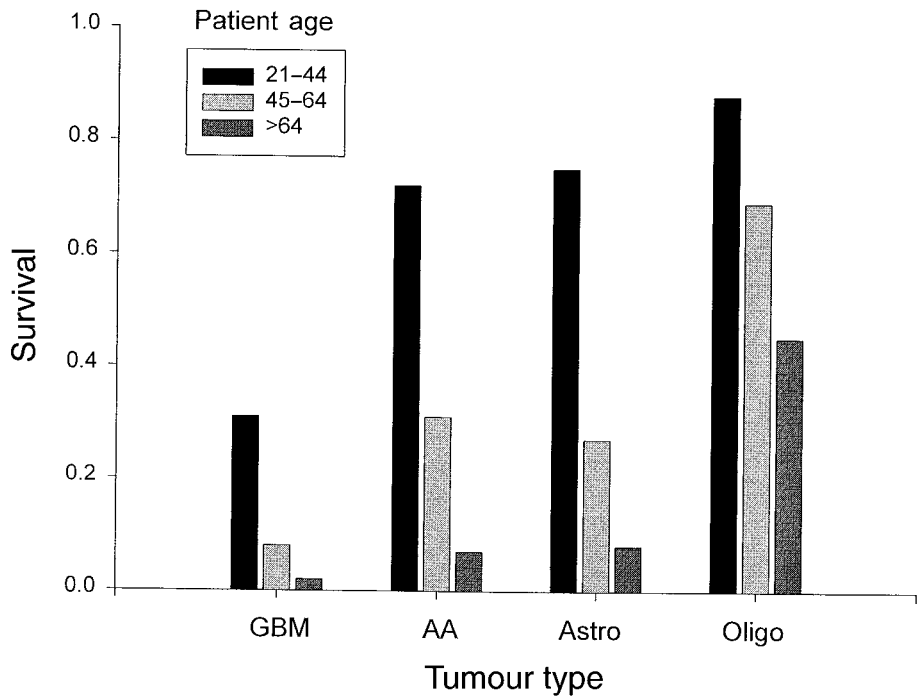

Fig. 87.2. Two-year relative survival for patients with specific brain tumours according to patient age at time of diagnosis (from SEER program of the National Cancer Institute, 1973–1994). (Modified from Wrensch *et al.*, 2000.)

oligodendrogliomas. Anaplastic oligodendrogliomas have many of the malignant features associated with the high grade astrocytomas, although an objective grading system remains to be established. These features include hypercellularity, cellular atypia, mitoses, vascular proliferation and necrosis. The combined loss of chromosomal segments 1p and 19q has recently been associated with prolonged survival and enhanced chemoresponsiveness in oligodendroglioma and anaplastic oligodendroglioma.

Ependymoma

Ependymomas are gliomas derived from the lineage of ependymal cells that line the ventricular system and central spinal canal. These tumours can develop throughout the neuraxis most commonly as intraventricular masses or within brain parenchyma next to the ependymal lining. Intracranial ependymomas arising within the posterior fossa are most commonly found in children. Ependymomas in adults most commonly present at supratentorial and spinal locations. Intracranial and true spinal cord ependymomas present with a spectrum of grades from well differentiated to anaplastic or progress over time from well differentiated to malignant. Anaplastic ependymomas display hypercellularity, mitoses, vascular proliferation, perivascular pseudorosettes and necrosis. Ependymomas of the filum terminale and sacrum are typically of the myxopapillary variant that is a benign, very well-differentiated lesion that rarely progresses to higher grade.

Meningioma

Meningiomas warrant inclusion in this overview, since they represent the second most common primary brain tumour. In contrast to the majority of gliomas diagnosed in adults, most meningiomas are well-circumscribed benign tumours that are frequently cured with surgical resection. Nevertheless, significant morbidity and mortality can result from histologically benign meningiomas that recur and progressively enlarge at sites from which they cannot be removed completely (e.g. cavernous sinus region, skull base) or from relatively rare invasive or malignant histological types. Meningiomas are derived from meningothelial cells of the arachnoid villi at their association with dural membranes. The most common locations are the parasagittal falx cerebri, lateral convexity, and sphenoid ridge, and less frequently tentorium, tuberculum (suprasellar), olfactory groove, and optic nerve sheath are affected. Intraventricular meningiomas occasionally arise from meningothelial cells of the choroid plexus of the lateral ventricles.

A large number of benign histologic variants of uncertain prognostic significance exist. The meningothelial (syncytial), fibrous and transitional meningiomas are the most common of these histological forms. Although described as discrete types, these histological forms are often seen together within single tumours. Meningothelial meningiomas consist of lobules of meningioma cells containing oval nuclei, solitary nucleoli, and nuclear–cytoplasmic inclusions. Indistinct cellular borders give the appearance of a syncytium. Fibrous meningiomas consist of elongated spindle-shaped cells with abundant extracellular collagenous matrix. Transitional meningiomas display both meningothelial and fibrous features and also contain prominent whorls and psammoma bodies consisting of laminated acellular mineral deposits.

Certain gross and histologic criteria are associated with an increased risk of progressive meningioma growth or recurrence (Perry et al., 1997). The majority of meningiomas are amenable to gross total surgical resection, and totally resected classic benign meningiomas have a low 10-year recurrence rate of about 20%. Obviously incomplete resection due to tumour location or involvement of vascular structures, or of cranial nerves, substantially raises the risk for subsequent growth. Histologic features associated with early recurrence include mitotic rates of $\geqslant 4$ per 10 high-powered fields, sheet-like growth, hypercellularity and cellular atypia. Meningiomas with these features are considered 'atypical'. Features of malignancy include invasion into adjacent brain, cellular anaplasia, necrosis, and the acquisition of sarcomatous features. Subtypes likely to pursue a more aggressive course are clear cell, choroid, rhomboid and papillary.

Cellular and molecular pathogenesis

It is now well recognized that cancer develops most commonly as a series of discrete molecular/genetic events that result in the stepwise accumulation of abnormalities in fundamental cell regulatory pathways (Vogelstein & Kinzler, 1993). Many of these defects act on growth factor signalling pathways that tightly regulate cell division, cell survival, differentiation, cell–cell and cell–matrix interactions, and angiogenesis that under normal circumstances control tissue growth, differentiation and response to injury. Dysregulation of these same growth factor pathways through the direct or indirect involvement of proto-oncogene or tumour suppressor gene products results in oncogenic transformation, uncontrolled cell growth and cancer.

The discovery that certain retroviruses cause oncogenic transformation in mammalian cells led to the detection of

specific viral oncogenes and ultimately to the identification of closely related normal cellular genes (proto-oncogenes) from which the viral oncogenes were derived. Mutational activation or overexpression of these proto-oncogenes is now recognized to play a fundamental role in cancer formation and malignant progression in humans. Proto-oncogenes code for a diverse array of gene products that include cell surface receptors such as the epidermal growth factor receptor erb2 and the scatter factor/hepatocyte growth factor receptor c-met, second messenger signaling molecules such as src and ras, and transcription factors that directly regulate gene expression such as fos, jun, and myc (Bos, 1989; Bottaro et al., 1991; Cantley et al., 1991; Wasylyk et al., 1998; Wong et al., 1987). Conversely, tumour suppressor genes coding for proteins that down-regulate oncogenic pathways under normal circumstances have been identified. Loss of expression or inactivation of tumour suppressor genes is equally important to proto-oncogene activation in the multistep process of initiation and progression of brain tumours (Fig. 87.3). The interplay between the increasing number of recognized tumour suppressors and proto-oncogenes is complex and the subject of numerous comprehensive reviews (Bronchud et al., 2000). Those pathways presently considered to be of particular importance are briefly summarized below.

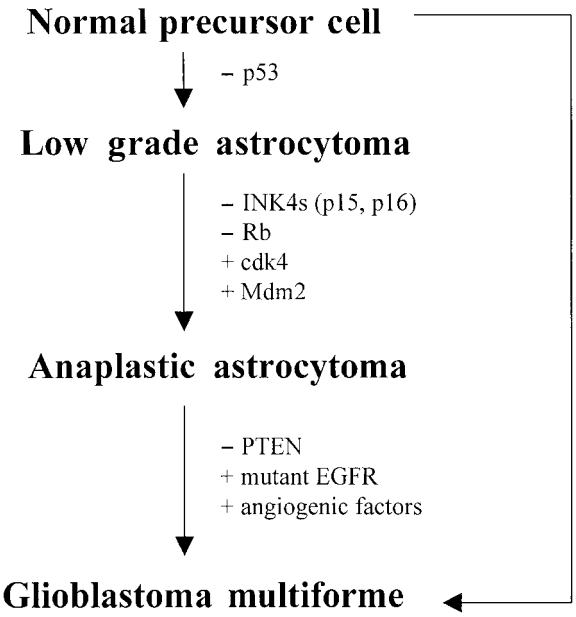

Fig. 87.3. Sequential loss of tumour suppressor and gain of tumour promoter functions commonly involved in the development and malignant progression of astrocytic tumours.

Tyrosine kinase receptor pathways

Numerous growth factors associated with tumour formation and malignant progression are now known to signal target cells via transmembranous cell surface tyrosine kinase receptors. Examples include epidermal growth factor, fibroblast growth factors, insulin-like growth factors, platelet-derived growth factor, scatter factor/hepatocyte growth factor, and vascular endothelial growth factor (Doolittle et al., 1983; Fleming et al., 1992; Friesel & Maciag, 1995). Depending upon receptor and receptor ligand expression patterns, such growth factors can function in an autocrine and/or paracrine fashion to enhance tumour growth and malignancy. For example, the malignant progression of solid tumours including gliomas from relatively low to high grades is linked to the emergence of an angiogenic phenotype that results from expression by tumour cells of angiogenic growth factors, some of which act exclusively upon vascular endothelial cells, i.e. vascular endothelial growth factor, VEGF (Bicknell et al., 1997; Senger et al., 1993). In contrast to VEGF, other glioma cell-derived growth factors, e.g. scatter factor/hepatocyte growth factor, act both in an autocrine fashion directly upon receptor-expressing tumour cells and in a paracrine fashion upon receptor-expressing endothelial cells (Abounader et al., 1999; Laterra et al., 1998). In certain circumstances, such as in the case of the epidermal growth factor receptor, somatic mutations result in expression of a truncated receptor that is constitutively activated in the absence of growth factor binding (Steck et al., 1988; Wong et al., 1992).

Growth factor binding to the extracellular domains of dimerized tyrosine kinase receptors results in the initiation of cytoplasmic signaling cascades mediated by a series of highly specific protein phosphorylation events (Weiss & Schlessinger, 1998). These cascades are initiated by receptor autophosphorylation at tyrosine residues within discrete cytoplasmic amino acid sequences. Phosphorylation creates binding sites for the recruitment and activation of proteins containing SH2 (src-homology 2) domains (Songyang et al., 1993). Binding and activation of these intermediate signalling proteins, in turn, selectively activate specific downstream enzymatic cascades that elicit specific cell responses. Examples of SH2 proteins are phospholipase C, the p85 subunit of phosphatidylinositol 3-kinase, Grb2, and the p120 Ras GTPase-activating protein. There is substantial interdigitation of the downstream signalling pathways activated by distinct receptor tyrosine kinases, which results in the ability of individual receptors typically to influence multiple pathways (Fig. 87.4) (Kazlauskas, 1994). Discrimination of downstream signaling events and their effects upon cellular physiology and

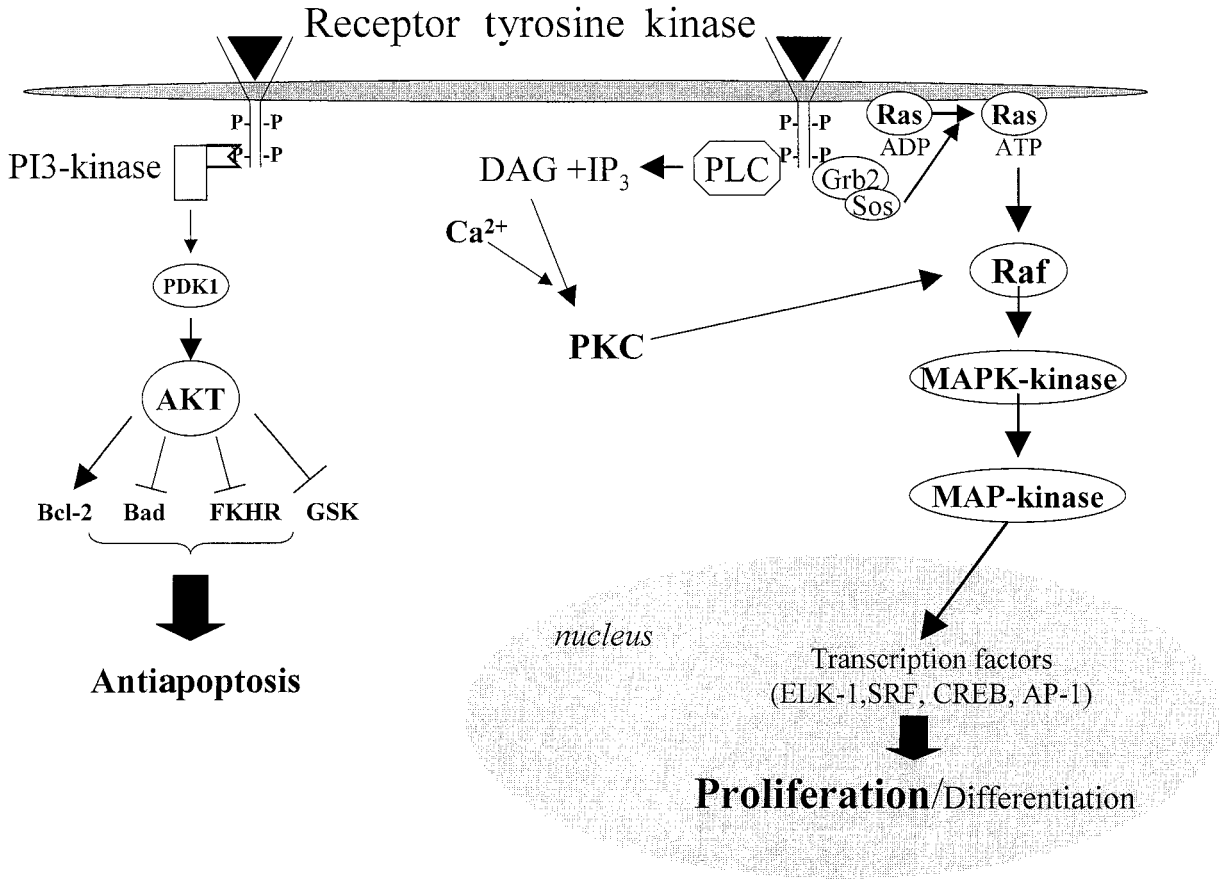

Fig. 87.4. Signalling pathways activated by extracellular ligand-binding to receptor tyrosine kinases in gliomas. PI3-kinase (phosphatidylinositol 3-kinase), PLC (phospholipase C), IP_3 (inositol-triphosphate), DAG (diacylglycerol), PKC (protein kinase C), MAPK (mitogen-activated protein kinase), FKHR (forkhead transcription factor), GSK (glycogen synthase kinase), SRF (serum-response factor), CREB (cyclic-AMP response element binding protein), AP-1 (activator-complex protein-1).

gene expression are influenced by receptor type, receptor number and degree of activation, cell type and the cell's overall environmental context.

The mitogen-activated protein kinase (MAP-kinase) pathway is one of the most prominent and well-characterized pathways activated by receptor tyrosine kinases (Lewis et al., 1998). Activated receptors bind the Grb2: SOS complex that activates Ras, a membrane-bound GTP/GDP exchanger that plays a pivotal role in regulating cell survival, proliferation, and differentiation responses to extracellular signals (Egan et al., 1993; Feldkamp et al., 1997; Rozakis-Adcock et al., 1993). Although mutations resulting in permanently activated Ras are associated with numerous cancers, they appear to play a minimal role in glioma oncogenesis and progression (Bos, 1989). There is great interest in developing pharmacological inhibitors of Ras, however, because of its central role in multiple signalling pathways involved in brain tumour malignancy (Guha et al., 1997). Activated Ras recruits the serine/threonine kinase Raf, which via intermediate kinases leads to the activation of MAP-kinase (Lewis et al., 1998). MAP-kinases are final effector cytoplasmic proteins that upon phosphorylation and activation translocate to the nucleus (Lenormand et al., 1993) where they activate gene expression through the activation of specific transcription factors such as Elk-1, serum response factor (SRF) and cyclic-AMP response element binding protein (CREB), and activator-protein-1 (AP-1) (Gille et al., 1995; Ginty et al., 1994).

Phosphatidylinositol 3-kinase (PI3-kinase) can be activated by binding directly to phosphorylated tyrosine kinase receptors via its p85 regulatory subunit or indirectly through activated RAS (Carpenter & Cantley, 1996). PI3-kinase-dependent RAS and MAP-kinase activation also occurs. PI3-kinase activation ultimately results in the acti-

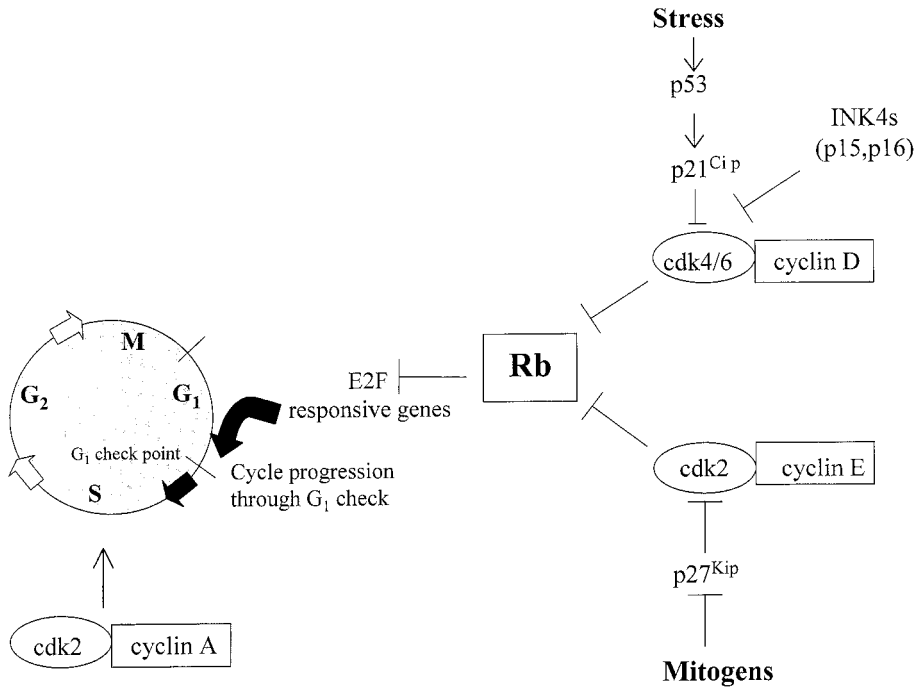

Fig. 87.5. Cell cycle regulatory pathways commonly altered in gliomas. Rb (retinoblastoma protein), cdk (cyclin-dependent kinase), INK (inhibitor of cyclin-dependent kinase).

vation of proteins containing pleckstrin homology domains (Lemmon et al., 1996). One of the most important is AKT (protein kinase B), an intermediate antiapoptotic signal that enhances tumour cell survival and resistance to cytotoxic therapies (Bowers et al., 2000; Downward, 1998). Just how AKT activation enhances brain tumour cell survival is not totally understood, but it appears to involve multiple effector pathways such as induction of Bcl-2, the inhibition of the proapoptotic factor Bad, activation of β-catenin, and phosphorylation of the forkhead family of transcription factors (Datta et al., 1997; Tang et al., 1999). Phospholipase-C (PLC) is activated by binding directly to phosphorylated receptors. Activated PLC catalyses the formation of inositol triphosphates and diacylglycerol from membrane phospholipids, resulting in elevation of free calcium and activation of protein kinase C (PKC) (Nishizuka, 1992). PKC feeds into the MAP-kinase pathway to activate immediate early response genes and subsequent AP-1-dependent gene expression.

The cell cycle

Normal somatic cell replication occurs as a cycle consisting of a sequence of tightly regulated events that control DNA replication (S phase) and the correct segregation of replicated chromosomes to duplicate daughter cells during cell division (mitosis, M phase). Gap phases G_1 and G_2 reside immediately before S phase and between S phase and mitosis, respectively. Quiescent cells reside in G_0 outside the cell cycle. Uncontrolled error-prone cell replication is a fundamental and prominent feature of cancer cells. Recent discoveries in the molecular biology of cell cycle regulation point to multiple control mechanisms altered in cancer. These range from genetic mutations to aberrant activation of growth factor signalling pathways that alter the expression and function of specific cell cycle regulatory proteins (Fig. 87.5) (Sherr, 2000).

Cells residing in G_1 are stimulated to complete a cell cycle and replicate by multiple environmental cues including growth factors, cell–cell interactions, and cell–matrix interactions. If proliferative signals are strong enough to drive cells beyond a certain point in late G_1, i.e. the restriction or check point, the cells commit to complete a full cycle and divide. Progression through the cell cycle is regulated by specific cyclin-dependent kinases (CDKs), their regulatory subunits known as cyclins, and cyclin-dependent kinase inhibitors (Morgan et al., 1985; Sherr, 1993; Sherr & Roberts, 1995). One of the key regulators of cell cycle progression beyond the restriction point is the growth suppressor Rb, the retinoblastoma protein. Under

conditions of relative mitogen deprivation, Rb forms complexes with and inhibits E2F transcription factors, thereby repressing the expression of E2F-responsive genes required for DNA synthesis and cell cycle progression (Nevins, 1998). Growth factor stimulation results in activation of cyclin D-associated CDKs (cdk4/cdk6) that phosphorylate Rb, releasing E2F transcription factors; these then translocate from cytoplasm to nucleus and transactivate S-phase-dependent genes, including cyclins E and A. Cyclin E-cdk2 complexes further amplify Rb phosphorylation and mediate passage through the G_1 check point independent of continued cell stimulation by mitogens and mitogen-dependent cyclin D-cdk4/6 activity (Hatakeyama et al., 1994). Cyclin A-cdk complexes mediate cell cycle progression in late G1 and S phases. Two families of cdk inhibitors, Cip/Kip and INK4 oppose cdk action and slow cell cycle progression (Cheng et al., 1999; Ruas & Peters, 1998). In unstimulated quiescent cells, levels of the cyclin E inhibitor $p27^{Kip1}$ are relatively high. Sequestration of p27 by cyclin D-cdk4/6 complexes facilitates activation of cyclin E-cdk2 and cyclin E-dependent cell cycle progression. Cyclin D-cdk4 inhibition by $p21^{Cip}$ plays an important role in p53-mediated G1 arrest that occurs in response to DNA damage (el-Deiry et al., 1993). The INK4 (inhibitors of cdk4) proteins slow cell cycle progression by binding and inhibiting cyclin D-cdk4/6 complexes, thereby releasing Cip/Kip proteins that in turn bind to and inhibit cyclin-dependent kinases. Overexpression of cdks and loss of cyclin-dependent kinase inhibitor expression play important roles in the malignant progression of numerous cancers, including the gliomas (Biernat et al., 1997) (Fig. 87.3).

p53 pathways

Loss of p53 function often occurs early in the course of glioma development (Chen et al., 1995; von Deimling et al., 1992). Possibly the most frequently mutated tumour suppressor gene in human cancer, p53 normally plays a fundamental role in preventing DNA injury and subsequent oncogenesis through two major actions: inhibition of the cell cycle and induction of apoptosis (Vogelstein et al., 2000). Under normal conditions, cellular levels of p53 remain very low because of its very rapid degradation via specific targeting to proteolytic degradation pathways (Kubbutat & Vousden, 1997; Maki & Howley, 1997). Activation of p53 through protein stabilization occurs in response to cellular stress signals associated with DNA damage and dysregulated cell proliferation. The mechanism by which p53 activation directs cells to either arrest growth or die is not completely clear, but it appears to depend upon the type and degree of cell injury (Vogelstein et al., 2000). Certain findings suggest that the preferential pathway is one of cell cycle arrest to allow subsequent DNA repair. Excessive DNA damage or uncorrectable mutations causing uncontrolled cell proliferation may tilt the response in favour of apoptosis (Chen et al., 1996). p53 exerts most of its effects through its ability to bind to gene regulatory sequences and act as a transcription factor. Activated p53 mediates G1 and G2 cell cycle arrest through the induction of the cyclin-dependent kinase inhibitor $p21^{Cip1}$ (el-Deiry et al., 1993). p53-inducible genes involved in the apoptosis response include the proapoptotic protein Bax, the cell surface death receptor Fas, and antagonists to certain cell survival factors (Fig. 87.6).

The accumulation and activation of p53 protein occurs through its stabilization in response to cell stress signals described above. Mdm2 and $p14^{ARF}$ are two proteins that play important and opposing roles in activation and stabilization of p53 (Kubbutat et al., 1997). Mdm2 binds to p53, blocks p53 transcriptional activity, and directs p53 to cytoplasmic degradative pathways. Mdm2 induction by p53 serves as a negative feedback loop to ensure against uncontrolled p53 activation. Expression of $p14^{ARF}$ is regulated by the E2F1 transcription factor that is activated under conditions of uncontrolled cell proliferation. $p14^{ARF}$ reverses Mdm2-mediated p53 inactivation and inhibits Mdm2-mediated p53 degradation (Bates et al., 1998; Ichimura et al., 2000; Newcomb et al., 2000). Thus $p14^{ARF}$ limits uncontrolled cell cycle progression even in the presence of Mdm2 expression. Genetic mutations leading to excessive Mdm2 activity and loss of $p14^{ARF}$ function are common in human gliomas (Reifenberger et al., 1993).

Angiogenesis and blood–brain barrier

Angiogenesis, the formation of new blood vessels from existing vessels, is necessary for the growth of solid tumours, including malignant brain tumours (Carmeliet & Jain, 2000; Guerin & Laterra, 1996). The extent to which angiogenesis contributes to the growth of highly infiltrative tumours such as gliomas that may obtain their blood supply from pre-existing brain vessels relative to that of non-invasive brain tumours such as meningioma has not been resolved (Wesseling et al., 1997). Blood vessel density increases concurrent with the malignant progression of brain tumours and glioblastoma multiforme is one of the most vascular of solid tumours (Brem et al., 1980; Brem, 1976). A number of angiogenic growth factors play a role in brain tumour angiogenesis, including vascular endothelial growth factor (VEGF), fibroblast growth factor (FGF),

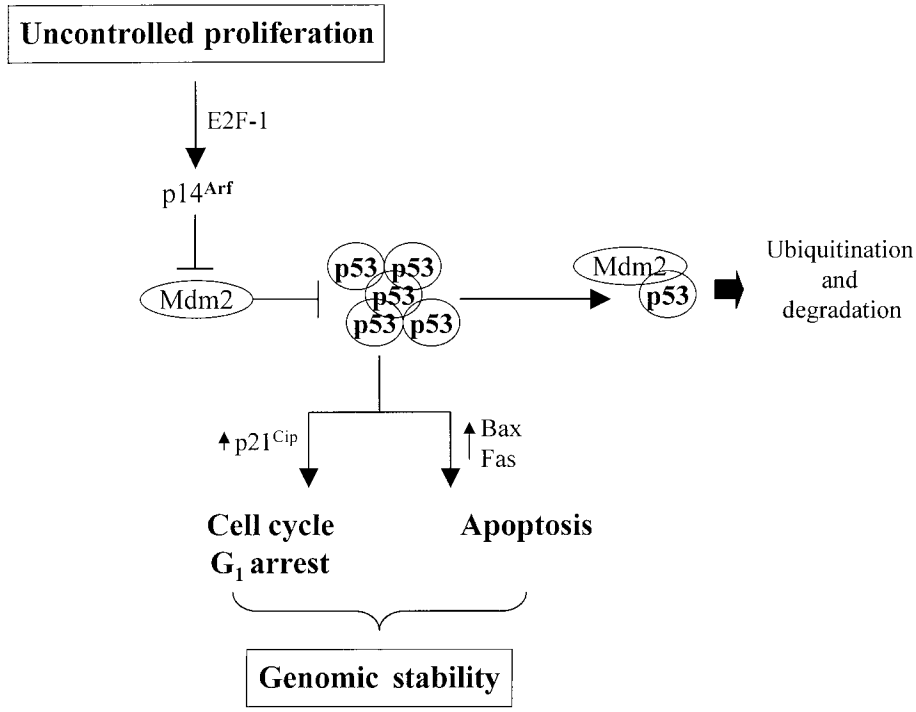

Fig. 87.6. Regulation of cell proliferation and survival by Mdm2-dependent p53 protein degradation.

and scatter factor/hepatocyte growth factor (SF/HGF) (Abounader et al., 1999; Plate et al., 1992; Schmidt et al., 1999). Endothelial cells express specific angiogenic growth factor receptors which, when activated, induce the expression of genes that stimulate otherwise quiescent endothelial cells to invade the perivascular extracellular matrix and proliferate. These genes include proteolytic enzymes such as plasminogen activators and matrix metalloproteinases and specific cell surface adhesion molecules such as integrin$_{\text{alpha v beta 3}}$ (Hsu et al., 1995; Landow et al., 1994; Liotta et al., 1991; Varner, 1997). Tissue invasion is accompanied by endothelial cell proliferation and ultimate reorganization into functional vascular loops that enhance nutrient delivery to the growing tumour. The mechanism by which VEGF expression is induced as low grade gliomas progress to malignant glioma is particularly well understood (Plate & Risau, 1995). As tumour growth rates increase, the tumour cells become relatively hypoxic due to an increasingly insufficient blood supply. Hypoxia results in the induction of hypoxia-inducible factor (HIF), a transcription factor that regulates many physiological and pathophysiological responses to hypoxia (Semenza et al., 2000). The VEGF promoter contains specific HIF-binding sites that, when complexed with HIF, enhance VEGF gene expression. The tumour cells surrounding zones of necrosis within malignant gliomas are the most hypoxic and likewise express the highest levels of VEGF (Plate et al., 1993). Recently, specific angiogenic inhibitors such as angiostatin and endostatin have been identified within tumours, but at concentrations inadequate to control the local pathological angiogenic response (O'Reilly et al., 1994, 1997). These naturally occurring angiogenesis inhibitors and pharmacologic inhibitors of the angiogenic growth factors or their receptors are currently under intense investigation for anti-angiogenic antitumour therapy.

The vasculature of gliomas differs substantially from vessels of the surrounding normal brain in its organization and degree of endothelial cell differentiation. Normal brain microvasculature is composed of highly differentiated endothelial cells, smooth muscle-like pericytes, and well-developed perivascular basement membrane, all ensheathed by perivascular astrocytic foot processes. The endothelial cells of normal brain express a number of characteristics specific to brain that collectively comprise the blood–brain barrier (Laterra et al., 1998). These consist of highly complex interendothelial tight junctions, reduced transendothelial vesicular transport, enzyme systems that limit the non-selective movement of substances from blood to brain and conversely, the up-regulation of specific biochemical transporters and enzymes that enhance the

entry of specific nutrients such as glucose and amino acids from blood to brain. These endothelial specializations are believed to result at least in part from the trophic influence of the perivascular astrocytes (Rubin et al., 1991). As gliomas progress from low to high grade, the vascular–astrocytic complex becomes increasingly disorganized as the normal perivascular astrocytes are displaced by increasingly malignant glioma cells. Glomeruloid bodies consisting of hypertrophied unperfused collections of endothelial cells are characteristic of glioblastoma. Underperfused and retrograde perfused tumour vessels lead to zones of hypoxia and inefficient systemic drug delivery (Carmeliet & Jain, 2000; Jain & Baxter, 1988). The endothelial cells of malignant glioma vessels lose their brain-specific structural and biochemical specializations required for blood–brain barrier function (Guerin et al., 1992a,b). The enhanced permeability to blood-borne substances, including proteins such as albumin, results in tumour-associated vasogenic brain edema and mass effect. Contrast-enhanced brain imaging is based on the ability of intravenously administered contrast agents to leak passively across the highly permeable tumour vessels.

Clinical features

The clinical manifestations of primary brain tumours can be attributed to their local and/or generalized effects on brain function. Early signs or symptoms can result from relatively small tumours if localized within eloquent areas such as within motor cortex, causing contralateral weakness or within speech areas, causing aphasia. Small tumours in such locations can produce more profound deficits than much larger tumours located in relatively silent brain regions, such as the anterior frontal lobes. Localized symptoms most typically result from compressive mass effect, but can also result from the more diffuse invasion of vital structures by glioma cells. Brain tumours, particularly those involving cerebral cortex, can be epileptogenic and cause focal symptoms manifested by either simple or complex partial seizures with or without secondary generalization. In the setting of an intraparenchymal brain tumour, seizures may occur at any time and do not necessarily indicate tumour growth. Spontaneous hemorrhage within a glioma occurs infrequently and can result in the acute or subacute onset of localized symptoms, including seizures or generalized symptoms of increased intracranial pressure if the hemorrhage is large or if it extends into the ventricular system.

Diverse mechanisms can produce increased intracranial pressure and generalized symptoms such as headache, diminished level of consciousness, incontinence, ataxia and vomiting. Masses adjacent to the Sylvian aqueduct or fourth ventricle frequently obstruct flow of cerebrospinal fluid, resulting in ventricular enlargement and obstructive hydrocephalus. Rare tumours residing within a lateral ventricle can obstruct CSF outflow through the foramen of Monro, causing either chronic or intermittent enlargement of a lateral ventricle. Communicating hydrocephalus can result from leptomeningeal spread of primary brain tumours, or from the malabsorption of CSF due, for instance, to elevated CSF protein derived from focal tumours residing within the subarachnoid space. Tumours growing in silent brain regions such as the anterior frontal lobes frequently remain asymptomatic until they compress and compromise adjacent brain, increase intracranial pressure or cause a seizure.

Stereotypic herniation syndromes can develop as a result of the expansion of a mass from one intracranial fossa to an adjacent one (Plum & Posner, 1982). For example, a growing mass within the anterior fossa may force the cingulate gyrus medially beneath the falx cerebri (i.e. cingulate or subfalcine herniation). Concurrent compression and displacement of the internal cerebral vein and ipsilateral anterior cerebral artery lead to ischemia and vascular congestion ipsilateral to the mass. These secondary events enhance the tumour-associated edema and may even cause cerebral infarction. Unilateral temporal lobe masses within a middle cranial fossa can expand medially and inferiorly through the tentorial notch to produce uncal herniation. An early sign of uncal herniation is an asymmetric enlarged ipsilateral pupil resulting from ipsilateral compression of the third cranial nerve. As uncal herniation worsens, false localizing ipsilateral pyramidal signs develop from compression of the opposite cerebral peduncle (‘Kernohan’s notch’). Central transtentorial herniation results from expanding bilateral supratentorial masses causing displacement of the diencephalon, midbrain and upper brainstem. Classical early signs of central herniation are diminished consciousness, miosis and Cheyne–Stokes respirations followed by progressive descending brainstem signs. Both uncal and central herniation can compress posterior cerebral arteries, causing occipital lobe ischemia, and compromise the medial perforating branches of the basilar artery, causing brainstem ischemia and infarction with potential reperfusion hemorrhage.

Imaging

The evaluation of primary brain tumours relies heavily on non-invasive imaging characteristics and most impor-

tantly on subsequent histopathological assessment of tissue specimens obtained from either diagnostic biopsy or larger resections. Major advances have been made in structural, functional and biochemical brain imaging since the 1980s. Computerized tomography (CT) and magnetic resonance imaging (MRI) are complementary approaches for imaging the brain in patients suspected on clinical grounds to have a brain neoplasm. Tumour calcification, which is more common in certain tumours, such as meningioma and oligodendroglioma, is more reliably assessed by CT. In general, however, MRI is the preferred technique because it can distinguish between more diverse tissue properties, and its greater sensitivity increases the quality of surgical and subsequent therapeutic planning (Fig. 87.7).

Contrast enhancement after intravenous administration of contrast agent is a key component of brain tumour imaging. Iodinated contrast agents for CT and gadolinium-based agents typically used in MRI do not cross the normal intact blood–brain barrier. Contrast enhancement resulting from the intraparenchymal accumulation of contrast agent identifies regions containing overly permeable blood vessels that are characteristic but not diagnostic of neoplastic lesions. Contrast enhancement is uniformly present in the most malignant tumours such as glioblastoma multiforme and is typically absent in lower grade tumours such as grade II astrocytoma and well-differentiated oligodendroglioma. Certain benign tumours such as pilocytic astrocytoma and meningioma typically enhance after administration of contrast dye. T_2-weighted MRI sequences are most sensitive for detecting peritumoural edema. Meticulous comparison between MR imaging and histopathology of postmortem brains from patients with gliomas has demonstrated that regions of peritumoural edema match the regions of brain infiltrated by glioma cells (Burger et al., 1988). This is the scientific

basis for including the entire volume of peritumoural T2 abnormality during standard fractionated radiotherapy for glioma.

Positron-emission tomography (PET) and magnetic resonance spectroscopy (MRS) are relatively non-invasive methods for assessing the metabolic state of brain lesions. These imaging techniques can distinguish between neoplastic and non-neoplastic lesions and aid in assessing the malignancy of primary brain tumours. PET indirectly localizes sites of positron emission by directly detecting high energy photons that result from positron–electron annihilation (Phelps et al., 1982). Various positron-emitting radioligands designed to detect specific metabolic pathways or receptor–ligand interactions can be used in PET. The most common neuro-oncological application of PET is the imaging of glucose metabolic rates after systemic administration of ^{18}F-2-deoxyglucose (FDG), a substrate for hexokinase that upon phosphorylation is trapped within cells (Coleman et al., 1991). Malignant tumour cells are hypermetabolic and accumulate FDG-6-phosphate at excessive rates. FDG PET imaging can distinguish grade II from malignant grade III–IV gliomas and malignant gliomas from post-therapy radionecrosis (Di Chiro, 1987; Doyle et al., 1987). Practical limitations of PET include the technical difficulty in synthesizing radiolabelled ligands, poor spatial resolution and frequent false negatives, particularly because of the difficulty in distinguishing malignant tumours from metabolically active cerebral cortex. The specificity and sensitivity of FDG PET is enhanced by concurrent ^{82}rubidium PET for colocalizing regions of excessive blood–brain barrier permeability.

The hypermetabolic anerobic state of malignant gliomas produces elevated levels of lactate within the tumour. In addition, gliomas are rich in choline, a result of rapid membrane turnover, and relatively depleted of *N*-acetylaspartate in comparison to neuron-rich brain regions. Proton MRS can be used to quantify tissue lactate, choline and NAA relative to creatine and thereby distinguish neoplasms from non-neoplastic lesions (Vigneron et al., 1997) (Fig. 87.8). Advantages of MRS are that it is relatively accessible, has high spatial resolution, and does not require radioisotopes. False-positives are not uncommon, however, because of elevated choline levels in certain non-neoplastic lesions such as demyelinating plaques. Functional MRI (fMRI), a technique that detects regions of increased neuronal activity based upon changes in blood-flow and deoxyhemoglobin concentration, can be useful in determining the relationship between tumour and eloquent regions of brain subserving language and motor functions. This information can be important in surgical planning.

Diagnosis and therapy

All brain lesions suspected to be neoplastic on the basis of imaging characteristics and clinical symptomatology require pathological diagnosis preferably by craniotomy and resection. In addition to the probable benefits to survival, aggressive resection provides optimal amounts of tissue for the accurate histopathological analysis of what are frequently histologically heterogeneous tumours. Diagnostic biopsy through either a stereotaxic approach or after craniotomy is reserved for tumours that are either too deep or located in eloquent regions not amenable to aggressive resection.

The principles underlying the treatment of growing brain tumours revolve around the initial goal of reducing and, if possible, eliminating tumour burden. Aggressive resection with attention to minimizing surgical morbidity is the quickest way to eliminate symptoms and the toxicity associated with prolonged exposure to glucocorticoids used to treat tumour-associated edema. Aggressive resection is the treatment of choice for certain primary brain tumours (e.g. meningioma, pilocytic astrocytoma, and subependymoma) that can be cured through surgery alone. Unfortunately, most gliomas diagnosed in adults have poorly defined tumour margins due to their tendency to infiltrate surrounding brain and are therefore not amenable to complete resection. Although somewhat controversial, numerous studies have found a survival advantage from gross-total as opposed to partial resection even for infiltrative gliomas (Berger et al., 1994). This understanding has led to the use of increasingly sophisticated MRI-guided neurosurgical approaches to maximize tumour resection.

External beam gamma radiation is standard postsurgical therapy for all high grade gliomas including anaplastic astrocytoma (grade III), glioblastoma (grade IV) and anaplastic oligodendroglioma. This is supported by a randomized prospective trial showing that surgery plus radiation increases survival at 1 year from 3% to 24% when compared to surgery alone in patients with high grade astrocytoma (Walker et al., 1978). Radiation therapy for high grade glioma consists of 60 Gy delivered over 6 weeks in 30 fractions directed to tumour and peritumoural edema as defined by elevated T_2-weighted MRI signal plus an additional 2 cm margin. The relative benefit of early vs. delayed radiation therapy for patients with newly diagnosed low grade glioma is more uncertain. Two randomized prospective studies are currently under way comparing immediate postoperative with delayed radiation therapy. Preliminary data suggest that, in the absence of other progressive neurological symptoms, it is safe to postpone radiation

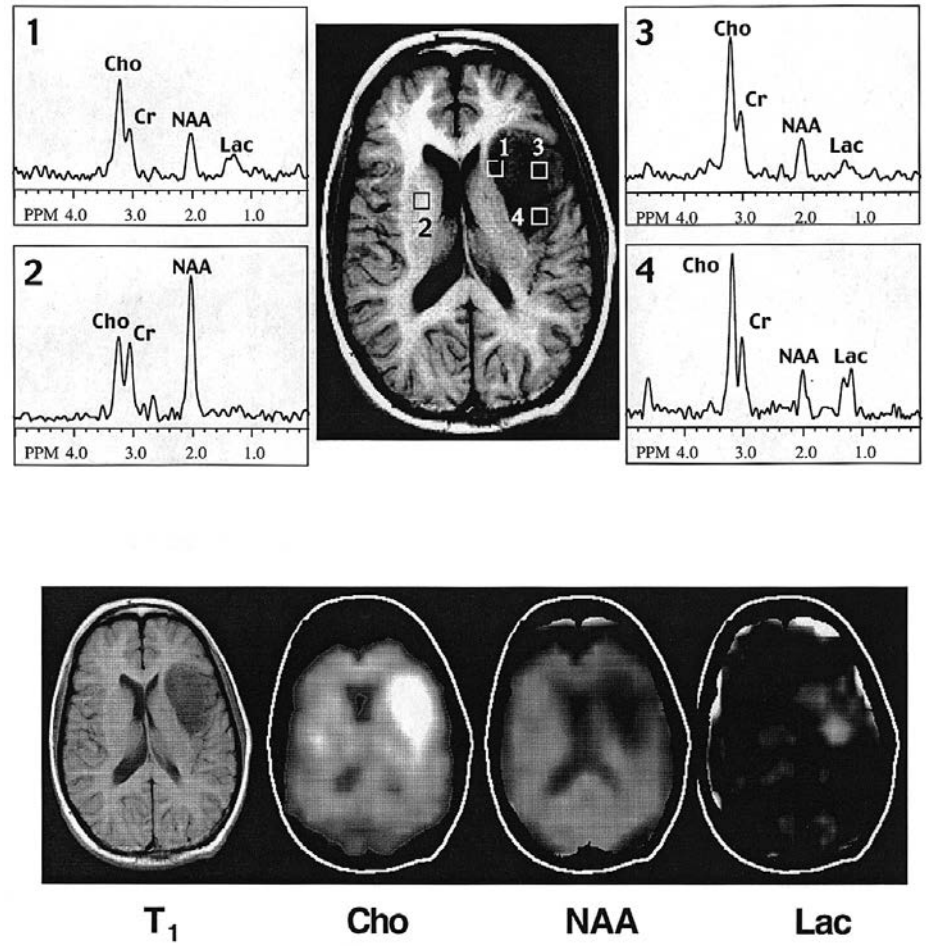

Fig. 87.8. Magnetic resonance spectroscopy of glioblastoma multiforme. (*Upper panel:* Single pixal spectrographs (1 to 4) corresponding to regions sampled within tumour (regions 1, 3 and 4) and contralateral normal brain (region 2) as shown in T_1-weighted magnetic resonance image. Normal brain (region 2) contains high *N*-acetylaspartate (NAA) relative to choline (Cho) and creatine (Cr), and no detectable lactate (Lac). All regions within tumour show elevated choline, elevated lactate, and diminished *N*-acetyl aspartate relative to creatine. *Lower panel:* Magnetic resonance spectroscopic imaging of same tumour depicting diffusely elevated choline, diffusely diminished *N*-acetylaspartate, and multifocally elevated lactate within tumour. (Courtesy of Peter Barker, PhD, Johns Hopkins School of Medicine.)

therapy until there is evidence for tumour growth in patients with low grade gliomas identified incidentally or following a seizure (Karim et al., 1998). The radiotherapy dose for progressive low grade gliomas is generally 54 Gy in 30 daily fractions. Significantly higher doses increase risk of radiation toxicity without any clearly defined benefit in survival.

The majority of gliomas recur within 2 cm of the original resection site and they frequently progress to a higher grade of malignancy at the time of tumour recurrence. Repeat resection of symptomatic recurrences is warranted if it is expected to improve performance status. Chemotherapy is useful for recurrent malignant glioma (Fine et al., 1993; Lesser & Grossman, 1994). Nitrosoureas, such as intravenous BCNU, oral procarbazine, or oral temozolamide, permeate the blood–brain barrier and are proven to have a modest therapeutic benefit in randomized studies (Lesser & Grossman, 1994). It has been proposed that combination therapy with procarbazine, CCNU, and vincristine (PCV) is of particular benefit to patients with anaplastic astrocytoma and anaplastic oligodendroglioma, although data from controlled trials directly comparing PCV to other regimens are not yet available (Smith *et al.*, 2000). Anaplastic oligodendrogliomas characterized by loss of chromosomal segments

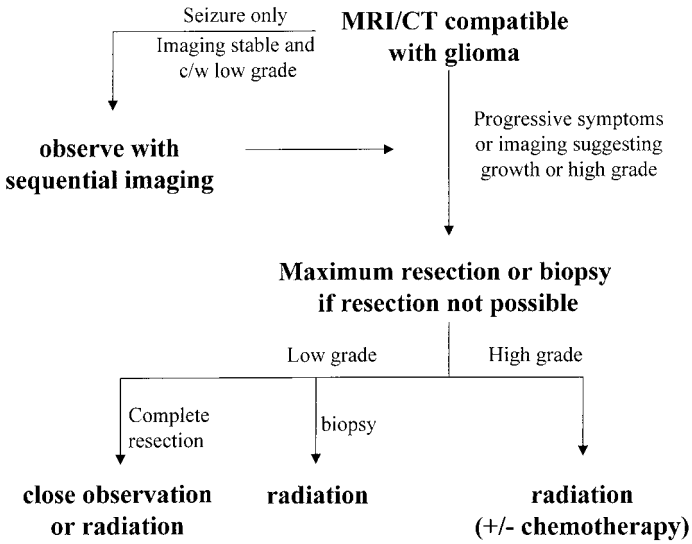

Fig. 87.9. General guidelines for treating adults with symptoms/signs and brain imaging consistent with glioma.

1p and 19q have recently been shown to be particularly sensitive to chemotherapy. The high frequency of local tumour recurrence supports the use of local interstitial chemotherapy administered at the time of tumour resection. A double blind placebo-controlled trial in which biodegradable polymers containing BCNU (Gliadel®) were implanted within the resection cavity of recurrent glioblastoma demonstrated a survival benefit (Brem et al., 1995; Valtonen et al., 1997). Delivery of chemotherapy locally directly within brain eliminates the systemic toxicity (e.g. bone marrow suppression) associated with intravenous chemotherapy. There is no proven role for cytotoxic chemotherapy in the initial treatment of low grade gliomas. A general approach to patients with newly diagnosed gliomas is summarized in Fig. 87.9.

Multiple factors contribute to the resistance of primary brain tumours to cytotoxic chemotherapy and radiation therapy. Neoplastic cells are inherently resistant to death signals due to activation of antiapoptotic pathways. Blood flow to solid tumours and hence drug delivery is inherently inefficient because of elevated interstitial pressures within tumours and their abnormal microvascular anatomy that causes stasis and retrograde perfusion. This also results in tumour hypoxia, reducing the effectiveness of cytotoxic therapies that require oxygen to generate DNA damage (i.e. gamma radiation, nitrosoureas) (Kayama et al., 1991). The blood–brain barrier restricts many chemotherapeutic compounds from reaching the tumour target cells, and tumour cells can express the cell surface transporter *p*-glycoprotein that actively pumps chemotherapeutic compounds out of cells (Henson et al., 1992). Glioma cells express enzymes such as glutathione-s-transferase and O^6-methylguanine-DNA methyltransferase (MGMT) that increase drug metabolism and repair nitrosourea-induced DNA methylation (Schold et al., 1989). Methylation and inactivation of the MGMT promoter in human gliomas predicts chemosensitivity to nitrosoureas such as BCNU (Esteller et al., 2000). Therapeutic trials are under way to overcome these resistance mechanisms (Rhines et al., 2000).

Because of the extremely poor prognosis associated with malignant gliomas numerous alternate therapeutic modalities continue to be developed and tested. Examples that have not fulfilled initial expectations include intra-arterial chemotherapy, chemotherapy concurrent with blood–brain barrier disruption, interstitial brachytherapy, and boron–neutron capture therapy. There is currently great emphasis in applying recent discoveries in molecular/cellular oncology to the development of genetic medicines and small synthetic compounds engineered to target specific molecules that regulate processes such as angiogenesis, apoptosis and the cell cycle that are linked to neoplasia. Present directions point to the therapeutic benefits of using these molecular/biological therapies to enhance the cytotoxic response to conventional chemotherapy and radiation therapy.

[2] Division of Oncology/Hematology, University Children's Hospital, Zurich, Switzerland

Classification

Brain tumours are the most common solid tumours in children and the primary cause of cancer-related morbidity and mortality during childhood (Gurney et al., 1995; Hamilton et al., 1995). The intracranial location and histological type of childhood brain tumours differ markedly from patterns seen in adults. The majority of adult brain tumours arise in the cerebral hemispheres; more than half of all brain tumours in children older than 1 year are found infratentorially. Even for supratentorial locations, tumours of the optic pathway, hypothalamus, and pineal region are relatively uncommon in adults but not in children. Histological differences are also prominent. Whereas the majority of primary brain tumours in adults are malignant gliomas and meningiomas, the majority of childhood tumours are low-grade astrocytomas, primitive neuroectodermal tumours (PNET) and craniopharyngiomas (Table 88.1). The World Health Organization (WHO) Classification of Tumours of the Nervous System (International Agency for Research on Cancer, 2000) proposed brain tumour classifications based on standard light microscopy and tumour location but not on immunohistochemical or other molecular characteristics. The diagnostic categories of childhood brain tumours for which there is a relatively high level of interobserver diagnostic consistency include PNET and medulloblastoma, ependymoma, germinoma, teratoma, craniopharyngioma and pilocytic astrocytoma. By contrast, the diagnosis of astrocytoma, oligodendroglioma and mixed glioma may be more problematic and less consistent (CBTC, 1998).

Table 88.1. Distribution of common brain tumours in children, by location and histology

Location and tumour histological type	Percentage of tumours
Infratentorial	48
PNET/medulloblastoma	20
Low-grade cerebellar astrocytoma	15
Ependymoma	5
Malignant astrocytoma	3
Low-grade brainstem astrocytoma	3
Other	2
Supratentorial hemispheric	38
Low-grade astrocytoma	15
Malignant astrocytoma	8
Mixed glioma	4
Oligodendroglioma	2
Ependymoma	3
Choroid plexus tumours	2
PNET	1
Other	3
Supratentorial midline	14
Low-grade astrocytoma	5
Craniopharyngioma	5
Germ cell tumour	2
PNET	1
Others	1

Epidemiology and pathogenesis

Brain tumours represent 24% of all malignancies in children (Gurney et al., 1995). The incidence of childhood

primary brain tumours in the United States increased by 35% from 1973 to 1994 (Ries et al., 1998). Improvements in brain tumour detection and reporting coincident with the availability of high-resolution neuroimaging may contribute to this reported increase (Smith et al., 1998); however, serious concerns remain that environmental factors may play a significant contributory role.

Factors responsible for the initiation and progression of childhood brain tumours remain poorly understood. A model of tumour progression, proposed for malignant gliomas in adults (International Agency for Research on Cancer, 2000), is unlikely to apply to infants and children. In that model, EGFR amplification, CDKN2A deletion, and MDM2 amplification are common in adult malignant gliomas but not in similar childhood tumours (Sung et al., 2000). Furthermore, malignant transformation for low-grade astrocytoma to malignant glioma is uncommon in children but not in adults. The high incidence of tumours in the first year of life suggests that tumour suppressor genes, which are involved in normal development, play a major role in CNS tumourigenesis (Biegel, 1997). In primitive neuroectodermal tumours (PNET) including medulloblastoma (MB), the most common childhood malignant tumour, putative tumour suppressor locations have been identified on chromosome 17p and 9q. Nearly 40% of all PNETs exhibit a deletion of the short arm of chromosome 17 (Rorke et al., 1997). Another possible tumour suppressor gene is located on the long arm of chromosome 9 where allelic losses have been described in 10–18% of PNET (Schofield et al., 1995). This region also contains the locus of nevoid basal cell carcinoma syndrome (NBCCS), which has been mapped. The gene responsible for this syndrome has been identified as the human homologue of the *Drosophila patched* gene (*PTCH*). The incidence of posterior fossa PNET among NBCCS patients is nearly 5% and mutations in *PTCH* have been demonstrated in approximately 12% of sporadic PNET/MB (Raffel et al., 1997).

Several inherited genetic diseases are associated with an increased risk of brain tumours during childhood. The most frequent association is with the phakomatoses. In children with neurofibromatosis type 1 (NF1), astrocytomas are the most common CNS tumours. They may arise in any brain region; however, the most common sites include the optic nerves and, to a lesser extent, the brainstem and the posterior fossa (Riccardi, 1992). Neurofibromatosis type 2 predisposes to bilateral vestibular schwannomas (acoustic neuromas) and to a lesser extent to trigeminal schwannomas, ependymomas and meningiomas (Riccardi, 1992). Brain tumours in tuberous sclerosis are relatively common and are typically histologically characterized as subependymal giant cell astrocytomas. In patients with Von Hippel–Lindau disease, central nervous system hemangioblastomas (cerebellar, brainstem, spinal) occur at an increased frequency (Friedrich, 1999).Turcot's syndrome, a germline mutation in the adenomatous polyposis coli gene (chromosome 5q21–22), is characterized clinically by the concurrence of primary brain tumours and multiple colorectal adenomas. The predominant brain tumour in Turcot's syndrome is the posterior fossa PNET (Hamilton et al., 1995). Germline mutations in the TP53 gene (chromosome 17p13.1) are responsible for the majority of cases of Li-Fraumeni syndrome (Frebourg & Friend, 1992). This familial cancer syndrome is characterized by a high risk of breast cancer, soft tissue sarcomas, osteosarcomas, leukemia and brain tumours. The most common brain tumours that have been reported in children from such cancer-prone families include astrocytoma, PNETs and ependymoma (Avigad et al., 1997). Inherited genetic disorders of the immune system such as Wiskott–Aldrich syndrome and ataxia telangiectasia are associated with an increased risk of primary CNS lymphoma and other brain tumours.

The most important exogenous risk factor for childhood brain tumours is ionizing radiation. Prenatal diagnostic X-ray exposure has been related to CNS tumours in childhood (Shu et al., 1994). Various other reports identify an increased incidence of gliomas, meningiomas and other brain tumours in children who received radiation therapy to the head for tinea capitis or for prior malignancies (Shore et al., 1976; Relling et al., 1999). The estimated cumulative risk of a second malignant brain tumour after childhood ALL is 0.3% by 5 years from 3-year survival and 0.5% by 10 years (Jenkinson & Hawkins, 1999). Cranial radiation, when combined with some chemotherapeutic agents (e.g. methotrexate) may have a synergistic interaction to increase the incidence of glial tumours.

Diagnosis and treatment

The following sections address diagnostic and treatment issues for childhood brain tumours that pose unique or characteristic problems different from those in adults and discussed in Chapter 87. These will include PNET, brainstem glioma, low grade astrocytomas, germ cell tumours, ependymomas and brain tumours in infants. Accordingly, childhood supratentorial malignant gliomas, oligodendrogliomas, meningiomas and other tumours more commonly found in adults will not be addressed here specifically. A comprehensive assessment of these tumours in childhood can be found in recent reviews and monographs (Cohen & Duffner, 1994; Allen & Siffert, 1997: Pollack, 1999; Packer, 1999).

PNET/medulloblastoma

Primitive neuroectodermal tumours represent a group of malignant small-cell brain tumours, which include medulloblastoma (i.e. cerebellar location), pineoblastoma (i.e. pineal location), ependymoblastoma (ependymal rosette formation), and supratentorial PNETs. The classification of medulloblastoma is the subject of long-standing controversy. Because these tumours are essentially indistinguishable histologically, Rorke suggested that they be grouped together as primitive neuroectodermal CNS tumours (PNET) based on the assumption that they each arise from neoplastic transformation of pluripotent, uncommitted neuroectodermal precursors (Rorke et al., 1997; Rorke, 1983). Immunohistochemical analysis of these tumours supports this approach. By contrast, the WHO classification favoured subdividing the tumours by location based on the premise that, despite the histological similarity, these lesions arise from cells already committed to a location-specific pathway of differentiation.

Primitive neuroectodermal tumours, as a group, constitute nearly 25% of all pediatric brain tumours and are the most common malignant brain tumour in childhood (Gurney et al., 2000). Approximately 85% originate in the cerebellar vermis and are termed medulloblastoma (PNET/MB). Pineal and supratentorial PNETs constitute 10 and 5%, respectively, of all childhood PNETs (Rorke, 1999; Jakacki, 1999).

The midline cerebellar location of PNET/MB typically causes obstructive hydrocephalus. Accordingly, the clinical presentation of PNET/MB is dominated by signs and symptoms of increased intracranial pressure: headache, nausea and vomiting; drowsiness and other behaviour changes; and ataxia. These features are usually indistinguishable from other posterior fossa tumours, including ependymoma and cerebellar astrocytoma. Neuroimaging diagnostics emphasize the use of MRI. The MRI characteristics of PNET/MB include a high T1 signal precontrast, large-area, predominantly uniform contrast enhancement, and a high *N*-acetyl aspartate to choline ratio on proton magnetic resonance spectroscopy. Computer-based neural networks that combine data from neuroimaging studies with patient clinical data have a higher degree of accuracy in distinguishing PNET/MB from other posterior fossa tumour types (e.g. ependymoma, astrocytoma) than experienced neuroradiologists (Arle et al., 1997). However, the diagnosis of non-brainstem posterior fossa tumours requires direct histological confirmation in all cases.

Assessment and treatment of increased intracranial pressure is the most important aspect of preoperative management. Patients with papilledema and significant visual impairment require immediate placement of an external ventricular drain or emergency tumour resection. Prolonged delay between ventricular decompression and tumour resection increases the risk of transtentorial upward herniation. For patients with less severe signs and symptoms of increased intracranial pressure, corticosteroids and acetazolamide may be used to relieve symptoms, reduce tumour swelling, and permit further surgical planning.

The therapeutic management of PNET/MB can be considered in three distinct phases: surgical treatment; postoperative tumour staging; radiation and chemotherapy. The surgical objectives in PNET/MB treatment require that sufficient tissue be obtained to permit accurate histopathological diagnosis. Tumour removal should be as complete as possible since complete tumour removal favourably influences prognosis (Zeltzer et al., 1999). Finally, every effort should be made to re-establish normal CSF flow. The majority of children with PNET/MB will not need a permanent ventriculoperitoneal shunt. The incidence of tumour dissemination to the abdomen by ventriculoperitoneal shunt is uncommon and the clinical significance of this unusual complication has probably been exaggerated (Berger et al., 1991). Postoperative neurological complications of posterior fossa surgery include aseptic meningitis, pseudomeningocele formation and cerebellar mutism. The syndrome of aseptic meningitis occurs in up to 5% of patients undergoing posterior fossa surgery and is not limited to those with PNET/MB. Symptoms of fever and meningismus, ranging from mild to severe in intensity, typically develop 5–10 days after surgery. Although this complication may occur more frequently in patients with large postoperative pseudomeningoceles under tension, there are no reliable clinical features that distinguish this syndrome of presumed chemical meningitis from that of bacterial meningitis. Therefore, analysis and culture of cerebrospinal fluid is essential. If no infectious cause is identified, this complication is effectively treated with corticosteroids.

The syndrome of cerebellar mutism after resection of posterior fossa tumours was noted in the early 1980s (Hirsch et al., 1979; Wisoff & Epstein, 1984). It is characterized clinically by complete or near-complete loss of speech typically beginning 24–48 hours after surgery and is accompanied by severe lower cranial nerve, cerebellar, visual (Lui et al., 1998) and motor dysfunction (Liu et al., 1998; Kedar, 1997). Subsequent reports indicate that this syndrome is not rare, and occurs in up to 15% of children with large midline cerebellar tumours (Pollack, 1997). Cerebellar mutism is often found in cases of aggressive surgi-

cal pursuit of PNET/MB adherent to, or invading, the brainstem. Most patients with this syndrome recover functional speech within several weeks to months after surgery. Permanent residual speech, lower cranial nerve, and motor coordination dysfunction are common.

Clinical prognostic factors determine the postsurgical therapeutic strategy for all PNETs; therefore, postoperative tumour staging is an essential part of PNET/MB clinical management. Staging studies include: neuraxis staging evaluation by spinal MRI (preoperatively or 10–14 days after surgery) to identify metastatic tumour aggregates; CSF cytological examination (intraoperatively or 10–14 days after surgery) to identify leptomeningeal tumour spread; and postoperative neuroimaging to assess residual tumour. The most important clinical prognostic factor for PNET is the metastatic stage, followed by residual tumour bulk, tumour location (i.e. supratentorial vs. infratentorial) and patient's age at diagnosis (Albright et al., 1996; Cohen et al., 1995). Based on results of current staging studies, PNET/MB patients are separated into two groups. Standard-risk patients are limited to those without any evidence of metastatic disease, less than 1.5 cm^2 residual tumour, supratentorial location, and patient age younger than 3 years at diagnosis. Current clinical prognostic factors distinguish high risk patients from all others, but are not sufficiently powerful to identify low risk PNET/MB patients who may benefit from significantly different therapy regimens than standard- and high-risk PNET/MB. It is unlikely that additional clinical prognostic factors will be identified in the future. Therefore, the identification and use of biologically based prognostic factors may improve the accuracy of patient stratification and lead to better risk-adapted therapies. Recent retrospective studies indicate that high TrkC mRNA expression predicts a favourable outcome better than current clinical factors (Grotzer et al., 2000). Other potential biological prognostic factors include HER2/HER4 coexpression (Gilbertson et al., 1997), GFAP expression (Janss et al., 1996) and *MYC* amplification (Scheurlen et al., 1998). Large, prospective studies are planned to determine if these new biological factors will supplement or supplant current clinical prognostic factors in the determination of PNET/MB treatment.

The current treatment strategies for PNET/MB reveal several distinct trends. High-risk patients are treated with involved-field radiation to the posterior fossa, craniospinal radiation, and chemotherapy. To reduce major treatment-associated toxicities, standard-risk patients receive chemotherapy and an identical radiation dose to the tumour but less intensive craniospinal radiation. Infants and children less than 3 or 4 years of age are often treated with intensive chemotherapy alone to postpone or avoid the neurotoxic effects of radiation on the developing brain. Newer protocols combine systemic and intrathecal chemotherapy with highly focused conformal radiation therapy to the tumour bed. For patients with recurrent PNET/MB, the use of high-dose chemotherapy followed by peripheral blood stem cell (PBSC) rescue results in apparently increased survival rates, especially for patients with minimal residual disease before high-dose chemotherapy. The prognosis for recurrent PNET/MB remains very poor.

Radiation therapy is the foundation of PNET/MB treatment. A cumulative radiation dose to the tumour of 56 Gy is typically used. Doses less than 50 Gy are less effective (Silverman et al., 1982). In patients older than 3 or 4 years at diagnosis, the entire craniospinal axis should be treated, regardless of metastatic stage (Jenkin, 1996). Treatment with craniospinal and local radiotherapy (total tumour dose of 54 Gy) without adjuvant chemotherapy results in long-term disease control in approximately 60% of children with standard risk PNET/MB (Evans et al., 1990). However, after whole-brain radiotherapy, many children will have significant long-term neuro-cognitive sequelae, including a demonstrable decline in cognitive function.

Recognition of the severe late effects of radiotherapy on the developing nervous system prompted efforts to reduce craniospinal radiation therapy doses in standard-risk PNET/MB. A prospective single-arm study was recently completed in children with standard-risk PNET/MB. Treatment included lower-dose craniospinal radiation (23.4 Gy), standard local radiotherapy (55.8 Gy) and adjuvant vincristine, CCNU, and cisplatin chemotherapy administered during and after radiotherapy (Packer et al., 1999). The progression-free survival for 68 children aged 3 to 10 years with non-disseminated PNET/MB was 86 $\pm$ 4% at 3 years. The lowest craniospinal radiotherapy dose reported in clinical trials is 18 Gy in 10 fractions with 50.4–55.8 Gy to the posterior fossa in combination with chemotherapy during and after radiation. With a median follow-up time for living patients of 6.3 years, survival for these standard risk PNET/MB patients at 6 years was 70 % (Goldwein et al., 1996). These results suggest that a subset of PNET/MB patients can be cured with chemotherapy and reduced doses of craniospinal irradiation. However, the optimal craniospinal radiation dose remains to be determined.

PNET/MB are responsive to a variety of chemotherapeutic agents, including cisplatin, cyclophosphamide, vincristine, CCNU, and busulfan (Friedman et al., 1991). Chemotherapy plays a major role in the treatment of high-risk PNET/MB, a conclusion that has been supported by large prospective studies (Evans et al., 1990; Packer et al.,

1994b; Bailey et al., 1995). Use of cisplatin, CCNU and vincristine in a postradiation chemotherapy regimen for high-risk patients resulted in 5-year survival rates higher than 80% (Packer, 1990). However, the role of chemotherapy in standard-risk PNET/MB has not been demonstrated directly in clinical trials. Indirect evidence which demonstrated significantly higher survival rates for standard-risk patients treated with radiation therapy and chemotherapy (cisplatin, CCNU and vincristine) than for similar patients treated with radiation alone provided strong support for the use of effective adjuvant chemotherapy for all PNET/MB patients (Packer, 1990).

For patients with relapsed PNET/MB, use of high-dose chemotherapy with peripheral stem cell rescue has shown encouraging results (Kalifa et al., 1999). Several groups reported significant reduction in the size of recurrent tumours of children with recurrent PNET/MB using this strategy (Kalifa et al., 1992). More recently, prolonged survivals after recurrence have been reported. Finlay and colleagues treated more than twenty children with recurrent PNET/MB with high-dose chemotherapy (HDCT) consisting of carboplatin, thiotepa and etoposide followed by peripheral stem cell rescue. With a median follow-up interval of 54 months, nearly one-third of treated patients remain free of tumour recurrence (Dunkel et al., 1998). These results are superior to previously reported outcome statistics for recurrent PNET/MB patients. However, prospective collaborative clinical trials are needed to evaluate different HDCT regimens with respect to survival outcomes as well as to toxicity and quality of life.

Ependymoma

Ependymomas constitute approximately 7% of all childhood brain tumours and arise in the posterior fossa as well as in supratentorial periventricular regions. These tumours generally behave as localized, slow-growing, and relatively non-invasive neoplasms. The primary challenge in the treatment of childhood ependymoma is local control, since metastatic relapses occur rarely (Vanuytsel & Brada, 1991). In the posterior fossa, ependymomas typically arise from the floor of the fourth ventricle. Despite the infrequency of deep infiltration of the brainstem, efforts at complete resection of these tumours often result in major morbidity. Accordingly, complete removal is achieved in less than 50% of the patients. The frequency of gross total resections can be increased by sophisticated technologies including ultrasonic tissue dissociation, argon lasers and robotic localizing devices, by experience of the operator with children and by the intent and preoperative plan to perform a radical surgical resection (Allen et al., 1998). In future, the availability of the intraoperative neuroimaging may provide immediate confirmation of the degree of resection and allow the surgeon to reoperate, immediately, if necessary (Wirtz et al., 2000).

Several studies confirm the importance of complete surgical resection as a predictor of survival outcomes in patients with newly diagnosed ependymomas (Sutton et al., 1991; Robertson et al., 1997; Evans et al., 1996). For children with neuroimaging confirmation of gross total resections the 5-year progression-free survival rate ranges from 60% to 80%. For patients with incomplete resections, survival ranges from 0 to 30% (Pollack et al., 1995; Vanuytsel & Brada, 1991). Surgical management of residual tumour after the first operation remains controversial and includes the option to attempt re-resection immediately after the postoperative MRI reveals residual tumour. Alternatively, a second operation may be deferred until after the child recovers and completes radiation therapy or chemotherapy. The merits of these alternatives have not been formally studied.

Routine postoperative tumour staging for children with intracranial ependymomas is identical to that for PNET/MB; that is, postoperative neuroimaging of the tumour resection site to determine the presence or extent of residual tumour, complete spinal cord imaging by contrast-enhanced MRI to identify possible leptomeningeal metastasis, and lumbar cerebrospinal fluid cytological analysis to detect malignant cells. Unlike PNET/MB in which more than one-third of cases have leptomeningeal tumour spread at the time of diagnosis, metastatic spread of ependymomas is relatively uncommon.

Standard treatment for children older than 3 years at initial diagnosis involved field radiotherapy. Early studies of childhood ependymoma treatment reported a high rate of leptomeningal tumour dissemination. Based on these observations, 'prophylactic' craniospinal radiation was recommended for all children with ependymoma.Using this approach, a 50% 5-year overall survival rate was reported in children with ependymoma (Robertson et al., 1997). Large cooperative studies failed to confirm these findings and also noted that the incidence of isolated neuraxis relapse in ependymoma was also less than 5% (Goldwein et al., 1991). Accordingly, current therapy reserves craniospinal radiation for those patients with proven leptomeningeal metastases at diagnosis. The use of stereotaxic radiosurgery, either as a primary therapy or as a radiosurgical boost after conventional fractionated radiation therapy may improve local tumour control or improve survival outcomes in children with postoperative residual tumour (Grabb et al., 1996).

The role of chemotherapy for childhood ependymoma has been the subject of considerable study and generally

disappointing results. Ependymomas are generally regarded as chemotherapy-resistant tumours, and collaborative studies using postoperative chemotherapy (CCNU and vincristine) failed to show a survival advantage for combined modality treatment (Evans et al., 1996). More recently, a study of 19 children with newly diagnosed ependymoma reported a 74% 5-year progression-free survival for children with residual ependymoma who were treated with standard radiotherapy and *cis*-platinum-based chemotherapy (Needle et al., 1997). These results are higher than most published results for patient with postoperative residual ependymoma treated with radiotherapy alone and comparable to published results for children with completely resected tumours. Based on this provocative finding, current clinical trials use chemotherapy for patients whose postoperative imaging studies are positive for residual tumour.

The therapeutic options for patients with recurrent ependymoma are generally poor and cure after recurrence is exceedingly rare. When possible, re-resection represents a reasonable palliative strategy for patients in whom maximal radiation has been administered. Standard and experimental chemotherapy have been of modest or no proven benefit for these patients and the use of high dose chemotherapy with autologous stem cell rescue has not improved progression-free survival for children with recurrent ependymoma (Mason et al., 1998).

Brainstem glioma

Brainstem gliomas represent 8–12% of all childhood brain tumours and are considered to have among the lowest survival rates. Prior to the widespread availability and use of magnetic resonance imaging, brainstem tumours were considered to be a single group that was uniformly fatal despite the most intensive therapies. The majority of children with brainstem tumours die from progressive tumour within 18 months of diagnosis; however, it was also recognized that some patients had extremely indolent tumours and continuous progression-free survival in excess of 5 years (Greenberger et al., 1977). To assist in the prospective identification of good- vs. poor-risk groups, the MRI and clinical characteristics of a large group of brainstem tumours were analysed retrospectively (Barkovich et al., 1990). Results from these studies demonstrate that there are two major classes of brainstem gliomas. First and most common are the diffuse intrinsic brainstem gliomas, typically located within the pons and upper medulla. These carry a uniformly poor prognosis. Second are the focal brainstem gliomas, typically located in the upper midbrain or lower medulla. By contrast, these less common variants often have an excellent prognosis.

Intrinsic pontomedullary brainstem gliomas constitute approximately 70% of all brainstem tumours. The clinical presentation of diffuse pontomedullary brainstem gliomas typically includes one or more of the following abnormalities: cranial nerve palsies, typically VI and VII; ataxia; long tract signs, including hyperreflexia and extensor plantar responses. The prediagnostic symptomatic interval is usually less than 3 months. On MRI, these tumours show a diffuse infiltrative enlargement of the pons and rostral medulla (Albright et al., 1986). T_1-weighted MRI images usually demonstrate mass effect and low signal intensity when compared with the normal brainstem. T_2 MRI sequences reveal high-signal regions of tumour infiltration with rostral extension into the midbrain and brachium pontis and lateral extension into the cerebellar peduncles. Brainstem enlargement may be unilateral and is often asymmetrical at initial diagnosis. The fourth ventricle is usually distorted; however, obstructive hydrocephalus is distinctly uncommon at initial presentation.

Efforts to correlate the histological features of intrinsic brainstem tumours with their clinical outcome provided the impetus for biopsy and autopsy evaluations. These studies showed that a limited surgical procedure, either stereotaxic or open biopsy, can be accomplished safely with little added morbidity (Epstein & McCleary, 1986). However, biopsy results were not an accurate predictor of clinical outcome, possibly due to the difficulty of obtaining a sufficiently large, representative sample (Jennings et al., 1996). Standard diagnostic management of intrinsic brainstem tumours eliminated routine diagnostic biopsies when the clinical and neuroimaging features typical of diffuse pontomedullary brainstem gliomas are identified. Diagnostic biopsy may be indicated for brainstem lesions with an unusual MRI appearance or an atypical clinical course potentially indicative of a low-grade tumour, brainstem encephalitis, brainstem abscess or demyelinating disease.

But for rare circumstances, there is no defined role for resection of diffuse intrinsic brainstem gliomas. Early in the clinical course, tumour cells infiltrate widely throughout brainstem structures but still permit neurological function to remain at normal or near-normal levels. Consequently, removal of tumour is likely to result in severe neurological deficits. Some diffuse intrinsic brainstem gliomas may have cystic projections dorsally or laterally. Although these surface projections may provide a limited opportunity for tumour resection, it is uncommon that more than 50% of the tumour can be removed and there is no evidence that partial debulking affects progression-free or total survival. The incidence of leptomeningeal spread from diffuse intrinsic pontomedullary gliomas

is distinctly uncommon and routine tumour staging studies are not warranted

Diffuse brainstem gliomas are one of the childhood brain tumours most resistant to radiation therapy. Standard radiation treatment consists of 55 to 59 Gy external beam radiation administered to the local tumour region in single daily fractions of approximately 1.8–2 Gy. This approach results in median survival of 9–13 months from diagnosis (Jennings et al., 1996). Single institution reports suggested prolonged progression-free survival for children treated with multiple daily (i.e. hyperfractionated) radiation treatments in which total radiation doses reached 78 Gy. Subsequent large cooperative trials failed to demonstrate a significant advantage for hyperfractionated radiation and substantial toxicity was observed (Packer et al., 1994a,b; Kaplan et al., 1996; Mandell et al., 1999). Radiation implants (brachytherapy) are not appropriate for these tumours and the role of stereotaxic radiosurgery is uncertain, at best.

Chemotherapy trials have yielded similarly disappointing results. Single-agent or combination chemotherapy, when administered prior to radiation therapy, infrequently produces objective response rates that approach 25% (Jennings et al., 1996) It is unlikely that even these limited response rates will translate into significantly longer survival. A large multi-institution phase III trial using CCNU, vincristine and prednisone after radiation therapy failed to show a survival advantage for adjuvant chemotherapy when compared with radiation therapy alone (Jenkin et al., 1987). Even when the most aggressive chemotherapy strategies are used, such as high-dose chemotherapy followed by peripheral stem cell reinfusion, results are usually limited to relatively brief duration responses and few instances of significant tumour reduction lasting 12 months or longer (Bouffet et al., 2000). Based on these findings, it is difficult to justify the routine use of chemotherapy in brainstem gliomas outside the setting of formal cooperative group studies. However, the extremely poor prognosis for these patients justifies an aggressive search for more effective antitumour strategies.

Dorsally exophytic tumours represent one of the three more clinically benign brainstem tumour variants. These tumours arise from the floor of the fourth ventricle, often completely fill the ventricle, and may produce neurological signs for many years before causing obstructive hydrocephalus. Magnetic resonance images typically demonstrate a well-demarcated lesion that has low paramagnetic signal on T_1-weighted images, high signal on T_2-weighted images. In contrast to diffuse intrinsic pontomedullary gliomas, these tumours often enhance after gadolinium administration. Dorsally exophytic gliomas are characteristically low-grade astrocytomas. Upon evidence of clinically significant tumour growth or symptomatic ventricular obstruction, a complete or near-complete surgical tumour removal is often sufficient therapy. Use of local radiation therapy or chemotherapy should be limited to those uncommon cases of malignant histology or evidence of significant tumour growth after surgery (Pollack et al., 1993).

Cervicomedullary tumours are found in the inferior two-thirds of the medulla and the upper part of the spinal cord. These typically low-grade astrocytomas extend from the epicentre in conformance with the anatomical barriers (Robertson et al., 1994). Intratumoural cysts are infrequent. The clinical features of these tumours include lower cranial nerve and motor dysfunction and symptoms are often present for several years. In contrast to their dorsally exophytic relatives, obstructive hydrocephalus is rare. Surgical resection of cervicomedullary tumours may be considered upon clinical or neuroimaging evidence of significant symptomatic tumour growth. Although near-total resection is possible in some cases, the poorly defined interface between tumour and normal brainstem usually precludes complete surgical removal of these tumours. Long-term follow-up indicates that many patients will not have evidence of any growth for 5 years or so. When present, the rate of cervicomedullary tumour growth is often extremely slow, and malignant transformation has not been observed. Therefore, a conservative management approach is justified.

Cystic nodular brainstem tumours may be found in any region of the brainstem but are most often found in the midbrain. These tumours have a radiographic appearance that is identical to their cerebellar counterparts, and their histology typically proves to be pilocytic astrocytoma. Again, conservative management is warranted and therapeutic intervention should be limited to those cases of clinically and radiographically significant persistent tumour growth. When intervention is required, surgical resection of the mural nodule is often curative.

Optic nerve and hypothalamic astrocytomas

Low-grade astrocytomas occur anywhere within the brain (CBTC, 1988). For cerebellar astrocytomas, the predominant histology is pilocytic. For optic nerve and hypothalamic gliomas, the predominant histology is fibrillary. Optic nerve and hypothalamic gliomas are classified by location as: those anterior to but not involving the chiasm; chiasmal tumours with extension posteriorly along the optic radiations; and chiasmal/hypothalamic tumours for which the initial site of tumour growth cannot be determined.

Prechiasmatic optic nerve gliomas present clinically with progressive visual loss and/or proptosis. Their appearance on CT and MR imaging studies is usually sufficiently characteristic that, like brainstem gliomas, routine biopsy is not necessary. Prechiasmatic optic nerve tumours are often indolent tumours that should be treated conservatively. Progressive tumour growth yielding painful or disfiguring proptosis together with severe visual loss may warrant surgical resection and sacrifice of the affected optic nerve. Surgical resection is curative and no further therapy is required.

Chiasmal and chiasmal/hypothalamic gliomas account for 60–85% of optic pathway/hypothalamic tumours. These tumours, especially the very large chiasmal/hypothalamic glioma, often become clinically apparent at 5 years of age with symptoms of visual loss, and hydrocephalus. The symptom complex of older children is more likely to include visual disturbances and endocrine dysfunction. Children younger than 2 years of age may present with a diencephalic syndrome characterized by frequent vomiting, anorexia and failure to thrive (Gropman et al., 1998). In children with chiasmal tumours involving the optic nerve, the diagnosis of these tumours is frequently made by radiographic criteria alone. Especially in children with NF-1, diffuse enlargement of the optic chiasm, with extension posteriorly along the optic radiations to the geniculate bodies and beyond, is often sufficiently characteristic to permit reliable diagnosis without histological confirmation. However, for large tumours with hypothalamic extension, surgical biopsy is recommended. Though diagnostic confusion is not common, these tumours may have a clinical and neuroimaging appearance similar to other suprasellar tumours including solid craniopharyngiomas and germ cell tumours.

Most chiasmal and chiasmal/hypothalamic gliomas are not 'cured' by surgery, radiation therapy or chemotherapy, either alone or in combination. The slow and often erratic growth of these tumours may blur recognition of the fact that these 'benign' tumours may eventually be fatal. Decisions to initiate treatment should be based on clinical or radiographic evidence of tumour growth from serial observations rather than routinely initiating treatment at the time of tumour diagnosis. Whereas some patients show significant changes in visual acuity or neuroimaging scans within weeks or months of initial diagnosis, many others remain stable for months or years without interval treatment.

Chiasmal and chiasmal/hypothalamic gliomas cannot be resected without sacrifice of visual function and the risk of panhypopituitarism. There is, however, growing recognition that surgical debulking of large chiasmal/hypothalamic gliomas may provide rapid relief of symptoms caused by mass effect and hydrocephalus, delay the need for radiation therapy in young children, result in years of clinical stability without tumour growth, and improve the effectiveness of subsequent radiation therapy (Wisoff, 1992).

Radiation therapy has been shown to be effective in arresting tumour growth and reducing tumour volume in chiasmal and hypothalamic gliomas (Pierce et al., 1990; Erkal et al., 1997), but complete tumour regression after radiation therapy is rare. Because more than 90% of patients with optic pathway/hypothalamic gliomas survive longer than 10 years (Horwich & Bloom 1985), the late effects of radiation therapy, including damage to neuropsychologic function, endocrinopathy, optic nerve injury, and radiation-induced second neoplasms are important considerations. These concerns provided the impetus for clinical trials of alternative treatment approaches, including chemotherapy (Janss et al., 1995).

The role of chemotherapy in the treatment of optic pathway and hypothalamic gliomas is now well established. In a multi-institutional trial of carboplatinum and vincristine, 60% of progressive low-grade glioma patients had a significant reduction in tumour volume, and an additional 30% had prolonged stabilization of progressive tumours (Packer et al., 1997). Other chemotherapy regimens have been evaluated, including the use of procarbazine, 6-thioguanine, dibromodulcitol, CCNU and vincristine. Similar to results noted above for carboplatinum and vincristine, this strategy yielded long periods of disease stabilization with a median time to tumour progression of 132 weeks in children with low-grade gliomas (Prados et al., 1997). At the present time, it is not known whether the duration of clinical responses produced by chemotherapy is equal to that of radiation therapy. However, the ability of chemotherapy to produce durable responses in young children with optic pathway and hypothalamic tumours allows any consideration of subsequent radiation therapy to be postponed until a later age when the neurocognitive and other late effects may be less prominent. Currently used chemotherapy regimens for optic pathway tumours are generally well tolerated, can be administered in the outpatient setting, and do not have a high incidence of serious late effects. The successful use of chemotherapy in younger children has prompted efforts to extend use of these strategies to older children. However, it remains to be proven that the duration of progression-free survival for patients treated with chemotherapy is comparable to that for radiotherapy.

The incidence of optic pathway tumours in NF-1 patients is significantly greater than in the general population.

Nearly 15% of children in whom the diagnosis of NF-1 is confirmed have optic pathway tumours when they undergo screening neuroimaging (Listernick et al., 1989). The majority of these are anterior to the optic chiasm. However, only 52% of the children who have radiographically identifiable optic pathway tumours eventually develop clinically significant signs or symptoms of their tumours. When studied systematically, these tumours behave in a more benign fashion than in children who do not have NF-1. However, low-grade gliomas in children with NF-1 can be erratic in their natural history, at times showing signs of rapid growth followed by periods of spontaneous growth arrest. Treatment of anterior optic nerve glioma is necessary when there is persistent and significant evidence of tumour progression. Screening neuroimaging of asymptomatic NF1 patients is no longer recommended (Listernick et al., 1997). Because optic pathway tumours nearly always arise in children younger than 7 years of age (Listernick et al., 1994), current recommendations indicate that children with NF1 should have yearly ophthalmologic evaluations and assessment of growth to identify early signs of precocious puberty.

The management of children with NF-1 and optic pathway or hypothalamic gliomas is determined primarily by tumour location. Anterior optic nerve gliomas do not extend posteriorly into the optic chiasm. As noted earlier for non-NF1 patients, management for these patients depends entirely on the clinical symptoms. In most cases, chiasmatic gliomas can be observed conservatively by means of neuroimaging studies and ophthalmologic evaluations for a period of time (Listernick et al., 1997). Progressive tumours may be treated by surgery, radiotherapy or chemotherapy in individualized approaches (Pierce et al., 1990; Sutton et al., 1991; Packer et al., 1999).

Germ cell tumours

Germ cell tumours (GCT) as classified in two broad groups: germinomas (atypical teratomas); non-germinomatous germ cell tumours including typical and teratoid teratomas, teratocarcinomas, embryonal carcinomas, endodermal sinus tumours and choriocarcinoma. Intracranial germinomas are most common, representing approximately two-thirds of all intracranial germ cell tumours. Germ cell tumours characteristically occur during early adolescence. In addition to their unusual age distribution, they also show an unusual geographic distribution; that is, germ cell tumours constitute nearly 16% of all childhood brain tumours in Japan but only 3–5% in United States and Western European countries (Kretschmar, 1997).

Table 88.2. CSF and serum tumour markers for germ cell tumours (GCT)

	AFP	β-HCG
Germinoma	−	±
Non-germinomatous GCT		
Embryonal carcinoma	±	±
Yolk sac tumour	++	−
Choriocarcinoma	−	++
Teratoma, mature	−	−
Teratoma, immature-malignant	±	±
Mixed germ cell tumour	±	±

The majority of GCT is found in the pineal region, about one-third in the suprasellar region. Pineal tumours frequently obstruct the posterior aspect of the third ventricle and aqueduct of Sylvius, causing acute hydrocephalus with headaches, papilledema, nausea, vomiting and lethargy. As tumours grow anteriorly, the midbrain tegmentum and quadrigeminal plate are compressed, resulting in Parinaud's syndrome: paralysis of upward gaze, diminished pupillary response to light and retractory or convergence nystagmus. The clinical presentation of suprasellar GCT includes panhypopituitarism, diabetes insipidus, and visual disturbances with prediagnostic symptomatic intervals often exceeding 1 year.

Biochemical markers of germ cell tumours play an important role in the diagnosis and management of pineal and suprasellar region germ cell tumours (Table 88.2). When a germ cell tumour is suspected, CSF and serum should be evaluated for elevation of alpha-fetoprotein (AFP) and human chorionic gonadotropin (β-HCG). AFP is highly expressed during normal fetal development. It is produced initially by the fetal yolk sac and later by hepatocytes. Normal infants have high expression levels of AFP, which do not drop to adult values until 8 months of age or later. Detection of elevated levels of AFP in a brain tumour patient indicates the activity of primitive yolk sac elements and points to a diagnosis of malignant teratoma (Kretschmar, 1997). β-HCG is a specific marker for germ cell tumours with syncytiotrophoblast activity. Pure germinomas may express very low levels of β-HCG; however, the highest levels of this hormone are found in patients with choriocarcinomas. Placental alkaline phosphatase (PLAP) is a tumour marker that is characteristically expressed in patients with germinomas (Shinoda et al., 1988). Routine evaluation of PLAP levels in the CSF are not generally available; however, use of PLAP in immunohistochemistry eval-

uation of biopsy specimens has proven clinically valuable in germinoma diagnosis (Kretschmar, 1997).

The neuroimaging characteristics of germ cell tumours are not diagnostic in themselves and biopsy of these tumours is necessary (Kang et al., 1998). The diversity of tumour histologies in the suprasellar and pineal regions underscores the importance of adequate biopsy samples for accurate diagnosis. Small samples obtained from stereotaxic biopsy may not identify mixed tumour types. When possible, an open surgical biopsy approach is preferred. Intraoperative assessment of tumour histology by frozen section influences surgical management. For example, complete resection is curative for well-differentiated teratomas, whereas chemotherapy and radiation therapies are generally ineffective. Conversely, the extent of surgical resection is often of little importance for germinomas, which are quite sensitive to chemotherapy and radiation therapy.

Radiation treatment approaches differ according to germ cell tumour histological type. Germinomas are exquisitely sensitive to radiation. In the past, 'diagnostic' low doses of radiation therapy (e.g. 10–30 Gy) were administered to unbiopsied suprasellar or pineal region tumours. If significant tumour reduction was observed, the tumour histology was assumed to be a germinoma and radiation therapy was continued to doses ranging from 40 to 56 Gy. This strategy is unacceptable in modern clinical practice since patients with highly radiation-resistant tumours will be treated unnecessarily. Non-germinomatous or mixed GCT may show an early partial response radiotherapy; however, as the true diagnosis will not be known, the radiation dose administered is likely to be inadequate or may not include craniospinal radiotherapy which is standard for choriocarcinoma, endodermal sinus tumours, and other non-germinomatous germ cell tumours. Finally, there is growing evidence that non-germinomatous or mixed GCT benefit from chemotherapy and radiotherapy.

Craniospinal radiation is standard treatment for patients with germinoma and leptomeningeal metastases. However, the incidence of leptomeningeal metastasis in germinoma is up to 11% (Jennings et al., 1985) and its use for patients without MRI or CSF evidence of leptomeningeal spread is controversial. For patients with pure germinomas treated with radiation therapy alone, the 5-year recurrence-free survival rates are excellent and exceed 90% (Matsutani et al., 1997). Non-germinoma germ cell tumours (choriocarcinoma, embryonal carcinoma, yolk sac tumours and malignant teratomas) have a high incidence of leptomeningeal metastasis (Jennings et al., 1985) and craniospinal radiation therapy and radiation are important components of their treatment plan. Well-differentiated teratomas are generally unresponsive to radiation and use of radiation therapy is limited to unresectable recurrent or progressive teratomas in many centres. For these cases, stereotactic radiosurgery may prove to be of greater therapeutic benefit.

Chemotherapy has an established role in the treatment of many germ cell tumours. Germinomas are highly chemotherapy-responsive tumours, especially to regimens incorporating platinum chemotherapy compounds. Chemotherapy for pure germinomas is currently being studied with the specific objective of reducing the overall dose of radiation and therefore the late effects of radiation. However, chemotherapy alone for pure germinomas is less effective than radiation therapy alone for pure germinomas. The prognosis for non-germinomatous germ cell tumours ranges widely; however, all are considerably worse than pure germinomas (Matsutani et al., 1997). Accordingly, current studies attempt to improve survival in non-germinomatous GCT by use of intensive chemotherapy (Balmaceda et al., 1996), together with craniospinal radiation. Results from these efforts are very encouraging and a 4-year progression-free survival rate of 74% has recently been reported for patients with non-germinoma GCT treated with chemotherapy and radiation therapy (Robertson et al., 1997).

Brain tumours in infants

Approximately 20% of all childhood brain tumours occur in children younger than 3 years of age. Significant tumour differences are seen in this age group when compared with older children. During the first 6–12 months of life supratentorial tumour location predominates. By the second year, infratentorial tumours are more common. Tumour histologies are also different in infant brain tumours. Ependymomas, malignant gliomas, atypical teratoid/rhabdoid tumours and choroid plexus tumours are more commonly seen in infants than later in childhood. Unfortunately, the survival outcomes in this age group are significantly less favourable compared with older children, both overall and for specific tumour types (Kun, 1997).

Infants are at high risk for severe radiation-induced late effects, including mental retardation, growth failure, and leukoencephalopathy (Suc et al., 1990; Duffner et al., 1993). To address this problem, current therapy for children 3 years or older uses multiagent chemotherapy alone to postpone radiation therapy for 1 or more years or even to eliminate the need for radiation therapy. It is now apparent that some infants with PNET/MB can be effectively treated with chemotherapy alone. Nearly two decades ago, a group of infants with PNET/MB or ependymoma were treated

with a multiagent chemotherapy including mechlorethamine, vincristine, procarbazine and prednisone (MOPP). Eight of 12 children with PNET/MB and two of five children with ependymoma survived. Children treated with chemotherapy alone had normal growth and normal cognitive function (Ater et al., 1997). These encouraging results prompted a large collaborative study of chemotherapy in infant brain tumour patients sponsored by the Pediatric Oncology Group. Results of this study confirmed that the objective of delaying radiation therapy for one or more years was possible in nearly 40% of cases. Unfortunately, infants with PNET/MB had lower progression-free survival rate than expected; only 42% at 1 year and 34% at 2 years (Duffner et al., 1993).

Subsequent clinical trials increased the intensity of multiagent chemotherapy for infants with brain tumours. However, survival results have not improved substantially and it is apparent that the effectiveness of currently available chemotherapy is lower than that for combined chemotherapy and radiation therapy. Current cooperative group studies continue to evaluate chemotherapy dose intensification and the addition of intrathecal chemotherapy (Geyer et al., 1994). Advances in radiation therapy techniques allow the administration of a more restricted treatment volume to the tumour, significantly limit the radiation exposure of normal brain tissue, and may reduce the late toxic effects of radiation.

Brain metastases

Roy A. Patchell

Department of Neurology, University of Kentucky Medical Center, Lexington, Kentucky, KY, USA

Brain metastases are tumours that originate in tissues outside the brain and spread secondarily to involve the brain. Metastases to the brain are the most common intracranial tumours and outnumber primary brain tumours by at least ten to one. The treatment of these tumours is one of the few areas of Neuro-oncology where true progress has been made during the last 15 years. Although the development of brain metastases still usually indicates a poor prognosis for the patient, it is now possible to reverse most of the symptoms of brain metastases and give patients a meaningful extension of useful life.

Frequency

The frequency of brain metastases is difficulty to determine with precision. Older estimates, based on historical neurosurgical series, suggested that metastases made up only about 10–15% of the total number of intracranial tumours (Dunlap, 1932). However, due to the reluctance of surgeons in the past to operate on patients with known systemic cancer, older neurosurgical series grossly underestimated the actual occurrence of brain metastases. With modern neuroimaging techniques and more careful autopsy studies on cancer patients, it is now known that metastases to the brain as a group are actually the most common intracranial tumours and outnumber primary brain tumours in the general population (Cairncross & Posner, 1983; Walker et al., 1985; Posner, 1992). At present, the frequency of brain metastases in cancer patients is estimated to be 20–40% (Cairncross & Posner, 1983; Posner, 1992). These numbers may increase in the future as the ability to detect small tumours with magnetic resonance imaging (MRI) improves. The frequency of brain metastases may also be rising, due to the longer survival of cancer patients in general.

Table 89.1. Frequency of brain metastases by primary tumour type[a]

Primary tumour	Number of patients	Percentage
Lung	270	48
Breast	82	15
Melanoma	50	9
Colon	26	5
Other known primary	72	13
Unknown primary	61	11
Total	561	100

Note:

[a] Pooled data from references (Markesbery et al., 1978; Cairncross et al., 1980; Zimm et al., 1981).

The histological type of primary tumour is strongly associated with the frequency and pattern of intracranial spread (Table 89.1). In adults, the most common sources of brain metastases are the lung, breast, gastrointestinal tract, genitourinary tract, and skin (malignant melanoma) in that order. In patients less than 21 years old, brain metastases arise most often from sarcomas (osteogenic sarcoma, rhabdomyosarcoma and Ewing's sarcoma), and germ cell tumours (Vannucci & Baten, 1974; Graus et al., 1983; Bouffet et al., 1997; Tasdemiroglu & Patchell, 1997).

Cerebral metastatic disease in children is less frequent than the 20–40% reported in adults. Four retrospective studies have estimated the occurrence to be 6–10% (Vannucci & Baten, 1974; Graus et al., 1983; Bouffet et al., 1997; Tasdemiroglu & Patchell, 1997). The most common childhood solid tumours (other than primary brain tumours) are neuroblastomas and a variety of sarcomas including embryonal rhabdomyosarcoma, Wilm's tumour, Ewing's sarcoma and osteogenic sarcoma. In children

older than 15 years, germ cell tumours have the highest incidence (Graus et al., 1983). The clinical presentation and neurological manifestations of cerebral metastases in children are similar to those seen in adults, and the approach to diagnosis and treatment is the same.

Method of spread and distribution

Most tumour cells reach the brain by hematogenous spread, almost always through the arterial circulation. Most commonly, the metastasis originates in the lung from either a primary lung cancer or from a metastasis to the lung. A small proportion of tumour cells may reach the brain via the vertebral venous system (Batson's plexus). Batson (1942) suggested that this plexus provides a pathway for pelvic and retroperitoneal cancers to spread to the spine and proximally to the intracranial space; he noted an increased proportion of posterior fossa metastases with such tumours, often without other evidence of systemic spread. However, studies have not supported this theory. A retrospective study (Delattre et al., 1988) did not find an increased frequency of skull and spinal lesions in patients with abdominal or pelvic primary tumours, nor was there a corresponding decrease in the percentage of pulmonary metastases in such patients. The 'fertile soil' hypothesis suggests that certain tissues (in this case, brain) have characteristics that support the growth of metastases that are lacking in other organs (Cairncross & Posner, 1983; Delattre et al., 1988). This theory has been proposed to explain the observed distribution.

Within the brain, metastases most commonly are found in the area of the grey/white junction (Delattre et al., 1988; Hwang et al., 1996). This is due to a change in the size of blood vessels at that point; the narrowed vessels act as a trap for emboli. Brain metastases tend to be more common at the terminal 'watershed areas' of arterial circulation (the zones on the border of or between the territories of the major cerebral vessels) (Hwang et al., 1996). The distribution of metastases among the large subdivisions of the central nervous system follows roughly the relative weight and blood flow to each area. Accordingly, about 80% of brain metastases are located in the cerebral hemispheres, 15% in the cerebellum, and 5% in the brainstem (Cairncross & Posner, 1983; Delattre et al., 1988).

Older studies, using computerized tomography (CT) scan data, indicated that metastases to the brain are multiple in slightly more than 50% of cases (Cairncross & Posner 1983; Delattre et al., 1988). More recent experience with MRI indicates that the proportion of multiple metastases is higher and is in the range of two-thirds to three-fourths of patients with brain metastases (Sze et al., 1990). It is probable that, with the widespread use of MRI and new improvements in MRI contrast agents and resolution, the proportion of multiple metastases will be found to be even higher in the future. A note on terminology is in order here. The phrase 'single brain metastasis' refers to those patients with an apparent single cerebral lesion; no implication is made regarding the extent of cancer elsewhere in the body. On the other hand, the phrase 'solitary brain metastasis' is properly used to describe the relatively rare subgroup of patients who have a single brain metastasis that is the only known site of metastatic cancer in the body. Metastases from colon, breast and renal cell carcinoma are often single, while malignant melanoma and lung cancer have a greater tendency to produce multiple cerebral lesions (Delattre et al., 1988).

Clinical presentation

Metastases to the brain are usually symptomatic, and more than two-thirds of patients with brain metastases have some neurological symptoms during the course of their illness (Posner, 1974, 1980; Cairncross & Posner, 1983). Brain metastases may be detected at the same time the primary is diagnosed (synchronous presentation) or more commonly the diagnosis of the primary antedates the development of the brain metastasis (metachronous presentation). Over 80% of brain metastases present some time after the diagnosis of systemic cancer has been made.

The clinical presentation of brain metastases is similar to that of other mass lesions in the brain (Tables 89.2 and 89.3). Headache is a common presenting symptom, and this may be followed after an interval of days or weeks by other focal symptoms or signs. However, the headache may be mild and is rarely of localizing value. Early morning headache (usually thought to be associated with raised intracranial pressure) is a presenting symptom in only 40% of patients with brain metastases (Posner, 1980). Headaches are more common with multiple metastases or with posterior fossa lesions. Raised intracranial pressure (and the accompanying headache) is associated with the clinical sign of papilledema. Since the advent of modern cranial imaging techniques, the frequency of papilledema in patients presenting with brain metastases is less than 25% (Posner, 1974, 1980, 1992).

Seizures, either focal or generalized, occur in approximately 10% of patients at presentation. They are more common in patients with multiple metastases (Posner,

Table 89.2. Symptoms of brain metastases[a]

Symptom	Number of patients	Percentage
Headache	163	42
Focal weakness	107	27
Mental change	121	31
Seizure	80	20
Gait ataxia	65	17
Sensory disturbance	24	6
Speech problems	40	10

Note:

[a] Pooled data from references (Cairncross et al., 1980; Zimm et al., 1981).

Table 89.3. Signs of brain metastases[a]

Sign	Number of patients	Percentage
Altered mental status	139	35
Hemiparesis	174	44
Hemisensory loss	36	9
Papilledema	36	9
Gait ataxia	49	13

Note:

[a] Pooled data from references (Cairncross et al., 1980; Zimm et al., 1981).

1980). Occasionally the seizure will be focal in origin, and this has localizing value. Abnormalities of higher mental functions may take the form of a non-focal encephalopathy (1 to 2% of patients with metastases) or may relate to localized dysfunction (e.g. aphasia). Focal weakness is second only to headache in frequency as a presenting symptom.

Five to 10% of patients may present with acute neurological symptoms caused by hemorrhage into the tumour or cerebral infarction from embolic or compressive occlusion of a blood vessel (Cairncross & Posner, 1983). Hemorrhage into a metastasis is particularly common with choriocarcinoma and melanoma (Mandybur, 1977; Nutt & Patchell, 1992). An unusual presentation of brain metastasis is episodic loss of function suggestive of a transient ischemic attack. Such symptoms may be manifestations of focal seizures that go unrecognized by the patient. However, the signs and symptoms related to cerebral lesions are varied, and the suspicion of brain metastases should be raised in all patients with known systemic cancer in whom new neurological findings develop.

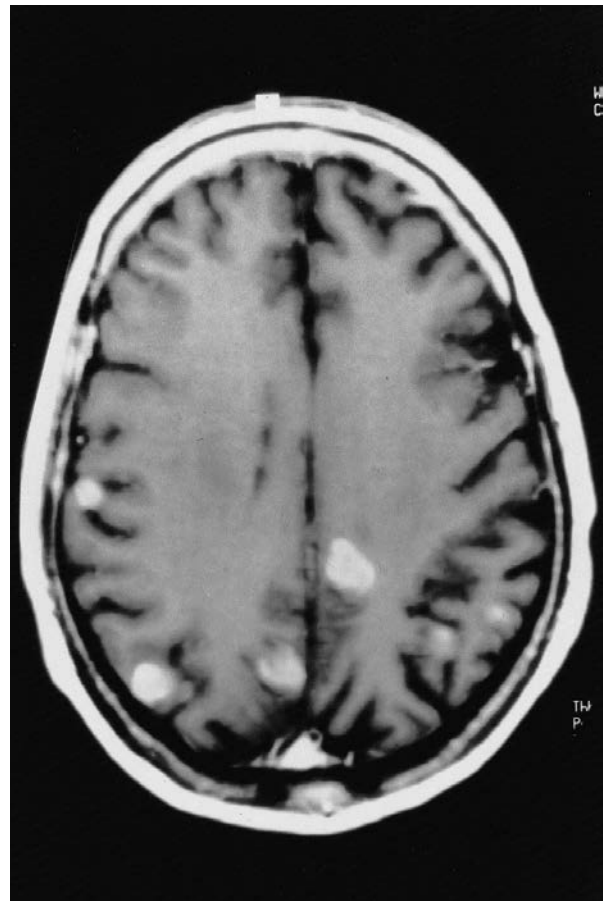

Fig. 89.1. T1 gadolinium-enhanced MRI of a patient with multiple enhancing brain metastases.

Diagnosis

The best diagnostic tests for brain metastases are contrast enhanced MRI (Fig. 89.1) and (to a lesser extent) CT (Sze et al., 1990; Davis et al., 1991). If the clinical history is typical and lesions are multiple, usually there is little doubt surrounding the diagnosis. However, it is important that metastases be distinguished carefully from primary brain tumours (benign or malignant), abscesses, and cerebral infarction and hemorrhages. It is equally important to identify those patients with single metastases whose subsequent management may be different.

Contrast enhanced MRI is more sensitive than enhanced CT scanning (including double dose delayed contrast) or unenhanced MRI in detecting lesions in patients suspected of having intracranial metastases (Sze et al., 1990; Davis et al., 1991). For both CT and MRI, multiplicity of lesions is a useful finding that usually distinguishes metas-

tases from gliomas or other primary tumours. Other imaging findings that favour metastases include a grey/white junction location, relatively smooth lesion margins, and a small tumour nidus with a large amount of associated vasogenic edema (Williams, 1985).

Although T_2-weighted sequences in MRI are sensitive in demonstrating the vasogenic edema as areas of increased signal intensity, not all metastatic lesions have sufficient edema to be identified (Price et al., 1990). In these cases, the lesions are typically less than 5 mm in diameter, may lie adjacent to a larger metastatic lesion, and may be located in the temporal lobes or in the cortical and subcortical areas. However, a study has shown that the false-positive rate, even when using contrast MRI for the diagnosis of single brain metastases, is approximately 11% (Patchell et al., 1990). Other diagnostic tests, such as arteriography or biopsy, may be needed to establish the diagnosis firmly.

The question often arises as to how far to pursue investigation in the patient with a brain mass demonstrated on a CT or MRI and with no previous history of systemic cancer. Because most metastases reach the brain by hematogenous spread through the arterial circulation, the lung is an important source of brain metastases. If the primary tumour is not pulmonary, it has probably spread to the lung before seeding into the arterial circulation and reaching the brain. More than 60% of patients with brain metastases will have a mass demonstrated on chest radiograph that is caused by either a primary lung cancer or a lung metastasis from the primary located elsewhere (Bentson et al., 1988; Delattre et al., 1988; Saphner et al., 1989). Therefore, careful radiographic examination of the chest is one of the most important diagnostic tests in patients with suspected brain metastases (Latief et al., 1997). When the chest radiograph fails to demonstrate a lesion, CT or MRI of the lung may show lesions and suggest the cause of the neurologic disorder. A CT or MRI of the abdomen occasionally will show an unsuspected renal or colon cancer. Further search for a primary tumour is almost never fruitful, especially if there are no positive findings on physical examination and no features of the history are suggestive of a specific primary tumour. In the few patients with brain metastases but no identifiable lesions in the lung, the pathogenesis of the brain metastases may be spread through Batson's vertebral venous plexus, tumour emboli through a patent foramen ovale (paradoxical embolus), or tumour filtered through the lungs with only local or microscopic growth.

Treatment

Newly diagnosed brain metastases

The optimum therapy of brain metastases (whether single or multiple) is still evolving. Several methods of treatment are available for patients with intracranial metastases. Corticosteroids, radiotherapy and surgical therapy all have an established place in management, and as a result of recent randomized trials, the role of radiosurgery is also becoming clearer. In addition, chemotherapy is useful in some patients with chemosensitive tumours. There are several things to be considered when determining the best treatment for each patient, including the extent of systemic disease, neurological status at diagnosis and the number and site of metastases

Brain metastases are associated with a poor prognosis regardless of treatment. Untreated patients have a median survival time of only about 4 weeks (Ruderman & Hall, 1965; Horton et al., 1971; Markesbery et al., 1978). Nearly all untreated patients die as a direct result of the brain tumour, with increasing intracranial pressure leading to obtundation and terminal cerebral herniation. The survival figure quoted here must be interpreted with caution because the information comes from retrospective studies done before the modern age of CT and MRI neuroimaging. Also, in the past as now, the patients who receive no treatment for their brain metastases are usually those with poor performance status, extensive systemic disease, and generally very poor prognoses. It is likely that the average patient diagnosed today would live longer than 1 month, even if untreated.

Anticonvulsants

Seizures occur in about 25% of patients with brain metastases and are the presenting complaint in 10–15% of patients (Posner, 1980, 1992; Cairncross & Posner, 1983; Glantz et al., 2000). Two randomized trials (Glantz et al., 2000) have shown that prophylactic anticonvulsants do not reduce the frequency of first seizures in patients with newly diagnosed brain metastases. Therefore, anticonvulsants should only be given to patients who have actually had seizures and should not be given routinely at the time of diagnosis of brain metastasis to all patients whether they have had seizures or not (Glantz et al., 2000).

Corticosteroids

Almost all patients with brain metastases should be started on corticosteroid (steroid) therapy at the time of diagnosis.

(Patients with small, completely asymptomatic lesions may not need steroids; however, steroids may reduce the side effects of cranial radiation and are rarely harmful in most patients for short periods of time.) The mechanism of action of corticosteroids is not completely understood, although a reduction in the edema surrounding the metastatic tumours is a frequent finding (Fishman, 1975). Dexamethasone is the preferred form of corticosteroid because it has minimal mineralocorticoid affect and a relatively low tendency to induce psychosis (Fishman, 1975; Ehrenkranz & Posner, 1980). More than 70% of patients improve symptomatically after starting steroids (Ehrenkranz & Posner, 1980). Symptoms reflecting generalized neurological dysfunction or brain edema respond more consistently than do focal symptoms such as hemiparesis.

The beneficial effects of steroids are noticeable within 6 to 24 hours after the first dose and reach maximum effect in 3 to 7 days (Gutin, 1975). The median survival time of patients treated with steroids alone is approximately 2 months (Horton et al., 1971; Chang et al., 1992), although much longer lengths of survival have been reported (Gottlieb et al., 1972; Gutin, 1975; Chang et al., 1992).

The usual starting dose of dexamethasone is 4 mg four times daily given either orally or intravenously. Occasionally, patients require higher doses. With stabilization of symptoms and the completion of more definitive treatment, the dose of dexamethasone should be tapered gradually over several weeks and then stopped to minimize long term toxicity. About 10% of patients do not tolerate the reduction in steroids and redevelop the signs of brain edema. In these patients, the lowest effective dose should be continued indefinitely.

Radiotherapy

Radiotherapy is the treatment of choice for most patients with brain metastases. Since the initial report of the use of ionizing radiation for palliative benefit in 1954 (Chao et al., 1954), there have been several studies that have attempted to determine the optimal treatment regimen. Unfortunately, there is still no consensus on the optimum radiation dose and schedule for the treatment of brain metastases.

Most patients are treated with whole brain radiotherapy (WBRT). This is because over two-thirds have multiple metastases at the time of diagnosis, which usually makes surgical treatment impossible. The best available data on the effect of dose and schedule for the treatment of brain metastases comes from several large scale multi-institutional trials conducted by the Radiation Therapy Oncology Group (RTOG) (Borgelt et al., 1980; Gelber et al., 1981; Kurtz et al., 1981). These studies have shown that there appears to be no significant difference in the frequency and duration of response for total radiation doses ranging from 2000 cGy over 1 week to 5000 cGy over 4 weeks. Regimens of 1000 cGy in a single dose, or 1200 cGy in two doses were less effective and are no longer in use.

Currently, typical radiation treatment schedules for brain metastases consist of short courses (7 to 15 days) of whole brain irradiation with relatively high doses per fraction (150 to 400 cGy per day) with total doses in the range of 3000 to 5000 cGy. These schedules minimize the duration of treatment, while still delivering adequate amounts of radiation to the tumour. Increased focal irradiation to the tumour site in the brain has not been demonstrated to be beneficial. A retrospective study has shown that giving a boost dose to the tumour site is no better than whole brain radiotherapy alone in preventing neurological recurrences or increasing length of survival (Hoskins et al., 1990).

Radiation cell sensitizing agents have been used in an attempt to increase tumour cell death. The rationale was based on the observation that hypoxic cells (often found centrally in a tumour) are more resistant to the effects of ionizing radiation. Agents such as misonidazole have the potential to increase cell sensitivity to irradiation. However, none of the radiation cell sensitizers tested to date has been shown to provide any additional benefit over conventional radiotherapy (Eyre et al., 1984; Komarnicky et al., 1991; Berk, 1995).

Whole brain radiotherapy increases the median survival to 3 to 6 months (Deeley & Edwards, 1968; Order et al., 1968; Horton et al., 1971; Berry et al., 1974; Markesbery et al., 1978; Cairncross et al., 1980; Zimm et al., 1981; Cairncross & Posner, 1983; Berk, 1995). Data from large retrospective studies has shown that more than half of patients treated with whole brain radiotherapy die ultimately of progressive systemic cancer and not as a direct result of brain metastases (Cairncross et al., 1980; Cairncross & Posner, 1983; Berk, 1995).

Retrospective studies on large numbers of patients treated in RTOG brain metastasis protocols have identified patient subgroups that were more likely to respond to whole brain radiotherapy (Deiner-West et al., 1989). More favourable outcome is associated with (i) Karnofsky performance scores (Karnofsky & Burchenal, 1949) in the range of 70% or above, (ii) absent or 'controlled' primary tumour, (iii) patient age less than 60 years, and (iv) metastatic spread limited to the brain. Building on these results, a recursive partitioning analysis (RPA) was applied to a combined group consisting of patients from several past RTOG radiotherapy studies (Gaspar et al., 1997). Three distinct prognostic groups were identified. The most favour-

able prognostic group was designated RPA class 1 and consisted of patients whose Karnofsky scores were 70% or higher, age was 65 years or less, primary tumours were 'controlled', and no extracranial metastases were present. RPA Class 3 patients had the worst prognoses; these patients had Karnofsky scores less than 70% (with or without other unfavourable factors). RPA Class 2 patients included patients who did not fit into Class 1 or 3 (i.e. patients who had Karnofsky scores 70% or higher but also had one or more of the other unfavourable factors). Performance status at the time of treatment for brain metastases is the most important prognostic factor.

Radiotherapy has complications. Almost all patients experience a temporary loss of hair; hair usually returns 6–12 months after completing therapy. Also, in the short term, patients may have a transient worsening of neurological symptoms while receiving therapy (Sheline et al., 1980; Cairncross & Posner, 1983). Many physicians believe that maintaining patients on steroids during radiotherapy will minimize radiotherapy complications, although conclusive proof of this has not been forthcoming. During initial days of treatment, mild symptoms such as nausea, vomiting, headache and fever are common. This acute reaction may relate to distorted cerebrovascular autoregulation or increased capillary permeability (Olsson et al., 1975). Rarely, radiation-induced parotitis and loss of taste may also occur with cranial irradiation (Cairncross & Posner, 1983).

The long-term side effects of radiotherapy are usually not a significant issue in the treatment of patients with brain metastases because of the relatively short survival time of these patients. However, reports (DeAngelis et al., 1989a,b; Paleologos et al., 1991; Crossen et al., 1994) have suggested that over 10% of long-term survivors (>12 months) will develop symptoms such as dementia, ataxia, and urinary incontinence. In these patients, imaging studies show cortical atrophy and hyperdense white matter changes. Although the pathogenesis of such alterations is unknown, it is speculated that high dose/large fractionation schedules may be a factor (DeAngelis et al., 1989a,b). Therefore, in patients with anticipated long length of survival, a more prolonged course of radiotherapy with smaller doses per fraction should be used. A reasonable schedule for patients with a good prognosis would be a total dose of 4500 to 5000 cGy given in daily fractions of no more than 200 cGy.

Surgery

Surgical therapy is usually not an option for most patients with brain metastases because of the presence of multiple lesions or extensive systemic cancer. However, in the subgroup of patients whose only metastatic disease is in the brain, it has been shown that death is more likely to be due to the brain metastases than to progressive systemic disease (Zimm et al., 1981). Therefore, in patients with controlled systemic cancer in whom brain metastases develop, the treatment of the brain disease is the factor that will most likely determine the length of survival. It is in this group that the question of more aggressive therapy, particularly surgery, for the brain metastases is usually raised. There have been several advances over the past 20 years that have decreased the risks associated with the surgical approach. Safer anesthesia, the widespread use of corticosteroids, the development of modern non-invasive cranial imaging technology and the introduction of stereotactic approaches have been foremost among these changes.

There are theoretical reasons for believing that the combination of surgical treatment followed by postoperative radiotherapy may be more effective than whole brain radiotherapy alone. Radiotherapy is most successful when used against small tumour volumes. In larger tumours, radiation is usually effective at the periphery of the tumour where cells are relatively small in number and well oxygenated. However, in the centre of the tumour, where tumour cells are more numerous and more hypoxic conditions exist, radiation may fail to destroy the tumour completely. Although there are documented reports of sterilization of brain metastases by radiotherapy alone (Cairncross et al., 1979), in most instances, residual tumour remains. Surgical treatment is most successful in removing large volumes of tumour, but small numbers of malignant cells may be left behind. Rational treatment plans combining surgical debulking and radiotherapy have been developed to overcome the deficiencies of both types of treatment (Bergonie & Tribondeau, 1959; Suit & Todoroki, 1985), and combined therapy has shown promise in patients with a variety of tumour types (Hellman, 1980).

There have been three prospective randomized trials assessing the value of surgical removal of single brain metastases (Table 89.4) (Patchell et al., 1990; Vecht et al., 1993; Mintz et al., 1996) These studies have had a similar design and have compared surgery plus postoperative WBRT with WBRT alone. In a trial (Patchell et al., 1990) performed at the University of Kentucky, there was a statistically significant increase in survival in the surgical group. In addition, the time to recurrence of brain metastases, freedom from death due to neurologic causes, and duration of functional independence were significantly longer in the surgical resection group. A second study (Vecht et al., 1993) conducted as a multi-institutional trial in the

Table 89.4. Surgery for single brain metastases: randomized trials

	N	Median survival (wks)	Length of functional independence (wks)	CNS death
S + WBRT				
Patchell[a]	25	40	38	29
Vecht[b]	32	43	33	35
Mintz[c]	41	24	8	46
WBRT ONLY				
Patchell[a]	23	15	8	50
Vecht[b]	31	26	15	33
Mintz[c]	43	27	9	63

Notes:
WBRT = Whole brain radiotherapy.
[a] = Patchell et al. (1990).
[b] = Vecht et al. (1993).
[c] = Mintz et al. (1996).

Netherlands, found that survival was significantly longer in the surgical group. There was also a non-significant trend toward longer duration of functional independence in the surgically treated patients. No data concerning recurrence of brain metastases were given. A third randomized trial, conducted in Canada by Mintz et al. (1996) failed to find a benefit from surgical treatment. No difference was found in overall survival. There was also no difference in causes of death or quality of life.

It is unclear why the Canadian study was not in agreement with the other two trials. In all three studies, the control arms (the radiation alone arms) had median lengths of survival in the 3–6 months range, well within the expected range for patients treated with radiotherapy alone. The major difference in the studies was the poor results obtained in the surgical arm of the Canadian trial. That study contained a higher proportion of patients with extensive systemic disease and lower performance scores. Also, the Canadian health care system sometimes discourages aggressive and expensive systemic treatment for patients with disseminated cancer. It is possible that these factors resulted in more patients dying of their systemic cancer before a long-term benefit of surgery was seen.

Although the data supporting surgery for single brain metastases were derived from relatively small randomized trials that were not uniformly positive, the results have generally been interpreted to show that the surgical resection is of benefit in selected patients. Surgical therapy plus postoperative WBRT is now the treatment of choice for patients with surgically accessible single brain metastases (Posner, 1990, 1992; Barr et al., 1992).

The value of surgery in the management of multiple metastases remains to be demonstrated. Two retrospective studies (Bindal et al., 1993; Hazurka et al., 1993) have come to opposite conclusions regarding the safety and efficacy of surgical removal of more than one brain metastasis. These two studies suggest that the postoperative morbidity and mortality rates for patients with multiple metastases treated with surgery are relatively low and are comparable with those reported in patients with single surgically resected metastases. However, it is difficult to draw firm conclusions regarding the efficacy of surgery for multiple metastases from the studies published to date. Current practice is to treat multiple metastases with WBRT alone. Currently, surgery is sometimes performed on patients with multiple metastases who have one life-threatening brain lesion. The intent of surgery in these cases is to remove the single life-threatening lesion without taking out the other lesions. Although this approach is speculative, long survival times have been achieved occasionally.

Despite the advantage of surgery in selected patients, WBRT alone remains the treatment for most patients with brain metastases. Single metastases occur in less than one-quarter of patients, and unfortunately, nearly half of patients in this group are not surgical candidates due to inaccessibility of the tumour, extensive systemic disease, and other factors (Patchell et al., 1986). Therefore, at most, only about 10–15% of all patients with brain metastases will benefit from surgical resection. The rest should be treated with radiotherapy.

The best results from surgery are seen in those patients with a single surgically accessible lesion and either no remaining systemic disease (true solitary metastasis) or with controlled systemic cancer limited to the primary site only. A study (Burt et al., 1992) from Memorial Sloan-Kettering Cancer Center has suggested that, in patients undergoing resection of brain metastases from non-small cell lung carcinoma, survival is significantly increased in those patients with complete resection of the primary lung disease. There was no correlation of survival with initial cancer stage *per se*. Also, surgical treatment may be indicated in those patients without known systemic cancer (to obtain a tissue diagnosis) and in patients with impending herniation due to pressure effects.

A point of controversy has been whether postoperative radiotherapy needs to be given as WBRT (as opposed to focal radiation) or whether radiotherapy is even necessary at all after a 'complete resection' of a single metastasis. There is no doubt that radiation therapy, when given as the

only treatment for brain metastases, results in longer survival. Postoperative WBRT is felt to be of benefit because there may be residual disease in the tumour bed or at distant microscopic sites in the brain. However, brain metastases tend to be discrete masses that are theoretically capable of being removed totally, and so postoperative WBRT may not be necessary.

Retrospective studies (Dosoretz et al., 1980; Smalley et al., 1987; DeAngelis et al., 1989a,b; Hagen et al., 1990; Armstrong et al., 1994; Skibber et al., 1996) that examined the role of postoperative radiotherapy in the management of single brain metastases failed to answer the question because of conflicting results. Only one randomized trial (Patchell et al., 1998) has addressed the question of postoperative radiotherapy. In that study, 95 patients who had single brain metastases that were completely resected (as determined by postoperative MRI scans) were randomized to treatment with postoperative WBRT (50.4 Gy) or to observation with no further treatment of the brain metastasis (until recurrence). Recurrence of tumour anywhere in the brain was less frequent in the radiotherapy group than in the observation group (18% vs. 70%, $P<0.001$). Postoperative radiotherapy prevented brain recurrence at the site of the original metastasis (10% vs. 46%, $P<0.001$) and at other sites in the brain (14% vs. 37%, $P<0.01$). As a result, patients in the radiotherapy group were less likely to die of neurologic causes than patients in the observation group (6 of 43 who died [14%] vs. 17 of 39 [44%]; $P=0.003$). There was no significant difference between the two groups in overall length of survival or in the length of time that patients remained functionally independent. The lack of difference in overall survival and quality of life may be explained by the fact that of the 32 patients in the observation group who had recurrence of tumour, 29 (91%) of them received WBRT at recurrence. This diluted the effect of WBRT given immediately postoperatively by most likely improving survival and quality of life in the observation group.

Several conclusions can be drawn from the randomized study. Radiotherapy prevents recurrence of tumour and reduces death from neurological causes. In addition, postoperative MRI scanning is relatively unreliable at detecting residual disease in the operative bed and at other sites in the brain. These factors justify the routine use of WBRT, even after apparently complete resections.

Radiosurgery

Stereotactic radiosurgery, a method of delivering intense focal irradiation using a linear accelerator (LINAC) or multiple Cobalt-60 sources (Gamma Knife), has been used with increasing frequency to treat single and multiple brain metastases. Radiosurgery does not replace conventional radiotherapy to the brain but may offer a substitute for surgical therapy in patients with lesions less than 3 cm in diameter.

To date, much of our information on radiosurgery comes from non-randomized studies. For single metastases, the combined results of many retrospective reports (Loeffler et al., 1990; Mehta et al., 1992; Auchter et al., 1996; Flickinger et al., 1996) suggest that radiosurgery prevents (or controls) local recurrence of 80–90% of treated metastases with about a 5–10% risk of radiation necrosis or new neurologic deficits. Despite these apparently promising results, it is important to note that, at present, radiosurgery has not been unequivocally established as an effective treatment in the management of single metastases. Prospective randomized clinical trials are still needed and are currently under way to determine the role of radiosurgery both in the initial treatment of patients with single metastases and in the management of recurrent brain metastases.

The role of radiosurgery in the treatment of multiple metastases has recently been the subject of three randomized trials. The first randomized trial on the subject was reported by Kondziolka et al. (1999). This study had only 27 patients in it and used non-standard endpoints. As a result, this study was uninterpretable. A second study reported by Chougule et al. (2000) contained methodological errors that made it impossible to draw firm conclusions from the data.

The RTOG has reported the results of a larger randomized study (Sperduto et al., 2000) involving patients with multiple brain metastases. This study (RTOG 9508) contained 144 patients with two or three brain metastases who were randomized to treatment with either WBRT (37.5 Gy) plus radiosurgery or WBRT (37.5 Gy) alone. There was no significant difference in local failure rates in the brain with 21% in the radiosurgery arm and 37% in the WBRT alone arm ($P=0.107$). There was also no significant difference in the length of survival of the two groups (median, 5.3 months for radiosurgery and 6.7 months for WBRT alone). Most noteworthy was the lack of significant difference between the fraction of patients in each group who died of neurological causes (33% radiosurgery vs. 35% WBRT alone). Lower post-treatment Karnofsky scores and steroid dependence were more common in the WBRT alone patients. Nevertheless, this was a completely negative trial with regard to the major endpoints of tumour control in the brain, overall survival, and prevention of death due to neurological causes.

The results of RTOG 9508 have forced a major re-evaluation of the use of radiosurgery in the treatment of

brain metastases. This was the largest and best trial done to date, and it failed to show a benefit of radiosurgery in the treatment of multiple brain metastases when radiosurgery was given in the initial management of newly diagnosed tumours. Treatment with WBRT alone would now appear to be the treatment of choice in these circumstances. However, radiosurgery may still have a place as salvage treatment in patients who have recurrent brain tumours after treatment with WBRT, but this remains to be demonstrated. There have been no definitive randomized trials of radiosurgery in the upfront management of single brain metastases, but RTOG 9508 has a second part evaluating radiosurgery in the management of single metastases that is still ongoing and will hopefully further define the use of radiosurgery in the future.

Interstitial brachytherapy

The use of interstitial brachytherapy, a technique involving the placement of radioactive implants within the area of tumour has been advocated in selected patients. The implants allow delivery of high dose focal radiation to the tumour while minimizing the risk of significant radiation exposure of the surrounding normal brain tissue because of the rapid fall-off of radiation intensity at the margins of the precalculated target area. Both permanent and removable implants have been in use. The placement may be accomplished stereotactically or during open surgery. The procedure is limited to relatively small metastases that are located in surgically accessible regions of the brain.

The role of brachytherapy in the primary management of brain metastases has yet to be determined. Preliminary studies (Heros et al., 1988; Prados et al., 1989; Alesch et al., 1995; Ostertag & Kreth, 1995; McDermott et al., 1996) have been inconclusive and the procedure has potentially serious complications. The major complication is radiation necrosis that may present with the clinical and imaging picture of an expanding mass months after treatment. Sometimes, a biopsy is required to differentiate tumour necrosis from recurrence, while steroids and, occasionally, a surgical resection help to reverse the neurological symptoms secondary to the radiation necrosis. The frequency of this complication varies with the amount of radiation given (Heros et al., 1988).

At present, brachytherapy cannot be recommended as initial therapy for brain metastases. However, this technique may offer an additional treatment option for patients with unresectable metastases or those who have received a prior maximum dose of whole brain radiotherapy.

Chemotherapy

The efficacy of chemotherapy in the management of brain metastases has not been demonstrated, although evidence has been accumulating that suggests that chemotherapy may have a role in the treatment of selected patients. Since more than half of the patients with brain metastases who are treated with surgery or radiotherapy will subsequently die of progression of the systemic disease, a chemotherapeutic agent that is effective against both systemic and brain disease is highly desirable. However, most systemically administered chemotherapeutic agents that have proven effective against the primary sites of cancer have been ineffective against cerebral metastases from the same cell population (Greig et al., 1983; Greig, 1984; Lesser, 1996; Korfel & Thiel, 1999). Drug delivery to the brain is a problem. The transport of material between the blood stream and cerebral tissue differs from other organs in the body. Tight intercellular junctions allow only the more lipid soluble materials to diffuse across capillaries within the brain. The blood–brain barrier is thought to be one of the major reasons that systemically administered anticancer agents do not reach cerebral metastases in adequate concentrations, or for adequate periods of time, to ensure effective tumour cell death. However, drug delivery cannot be the sole cause of the disappointing results in brain tumours. It is known that the blood–brain barrier is usually broken down at sites of brain tumours, and other factors must, therefore, contribute to the relative chemotherapeutic resistance seen with brain metastases (Greig et al., 1983). Tsukada et al. (1983) have suggested that the blood–brain barrier may increase the incidence of brain metastases following systemic chemotherapy by inducing a relative ‘pharmacological sanctuary’ within the central nervous system.

Chemotherapy has been used in the treatment of brain metastases from a variety of primary tumours; however, the results have generally been unimpressive (Greig, 1984; Hildebrand, 1988; Seigers, 1990; Lesser, 1996; Korfel & Thiel, 1999). Although some small uncontrolled series of patients with certain highly chemosensitive tumours (e.g. breast, small cell lung cancer, germ cell tumours) have been reported (Rosner et al., 1986; Hildebrand, 1988; Kleisbauer et al., 1988; Kristjansen & Pedersen, 1989; Seigers, 1990; Lesser, 1996; Korfel & Thiel, 1999; Boogerd et al., 1992). Chemotherapy is not usually the primary therapy for most patients and is seldom the only therapy.

At present, a reasonable use for chemotherapy for brain metastases would be in those patients with small, asymptomatic tumours from primaries that are known to be chemosensitive. If progression occurs with the patient

receiving chemotherapy alone, more definitive treatment with surgery, radiosurgery, or radiotherapy may be given.

Follow-up

There is no set standard for the follow up of brain metastases after treatment. MRI or CT scans are indicated at any time after therapy that patients develop new neurological symptoms. How frequently asymptomatic patients need follow up scans is controversial. For patients treated with surgery, a contrast MRI scan should be performed within 5 days after surgery to detect residual disease. This is especially important if consideration is being made to forgo postoperative radiation therapy. If residual disease is present, patients should be given WBRT. For all patients treated with WBRT, follow-up scans should be obtained at regular intervals after treatment. In general, it takes about 6 weeks after WBRT for a definite change to take place in the scan, and so, patients usually do not need scans immediately following the completion of radiotherapy. A reasonable schedule of follow-up scanning would be to get a scan 3 months after completion of last therapy (either WBRT or surgery) and then about every 4 months for the first year following treatment. The length of time between scans can then be gradually stretched out so that asymptomatic patients are scanned only once per year.

Paraneoplastic syndromes

Jerome B. Posner

Department of Neurology, Memorial Sloan–Kettering Cancer Centre, New York, NY, USA

The term 'paraneoplastic syndrome' refers to a group of disorders that are caused by a cancer but do not result from invasion of the affected organ by the tumour. Although indirect effects of cancer or its treatment, such as vascular disorders, infections, nutritional or metabolic dysfunction, can be considered paraneoplastic (Posner, 1995), most neurologists restrict the term paraneoplastic syndromes involving the nervous system to disorders of unknown cause that are also termed 'remote effects of cancer on the nervous system' (Brain & Norris, 1965). It is these remote effects of cancer on the nervous system that are addressed in this chapter (Table 90.1). Syndromes that are clinically and pathologically identical to paraneoplastic syndromes also occur in patients without cancer, but at a lesser incidence.

Table 90.1. Some paraneoplastic syndromes of the nervous system

Most affected structure	Example(s)
Cerebral hemisphere(s)	Limbic encephalitis
Cerebellum	Purkinje cell degeneration
Brainstem	Opsoclonus/myoclonus
Retina	Carcinoma associated retinopathy
Spinal cord	Necrotizing myelopathy ?Stiff person syndrome
Dorsal root ganglia	Sensory neuronopathy
Peripheral nerve	Sensory neuropathy Autonomic neuropathy
Neuromuscular junction	Lambert–Eaton myasthenic syndrome
Muscle	Dermatomyositis

General considerations

Incidence

Paraneoplastic syndromes can be considered either relatively common or quite rare, depending on how they are defined. If one examines patients with known cancer looking for a mild abnormality of nervous system function, either by clinical or electrophysiological examination, one finds abnormalities frequently. For example, Croft and Wilkinson (1965) reported neurologic paraneoplastic syndromes in 6.6% of 1465 patients with cancer. The majority had proximal muscle weakness and/or a mild peripheral neuropathy. Even higher figures are achieved when one uses quantitative sensory examinations or electrophysiologic assessment of peripheral nerves. Many (but not all) of these mild and subclinical abnormalities may be a result of metabolic or nutritional disturbances associated with far advanced cancer. If one considers only patients with clearly defined and significantly disabling neurological disorders, the incidence is much lower. In the same 1465 patients examined by Croft and Wilkinson there were only three with cerebellar degeneration, three with a myelopathy and none with sensory neuronopathy. It is likely that with the exception of the Lambert–Eaton myasthenic syndrome (LEMS), which affects about 3% of patients with small-cell lung cancer (Sculier et al., 1987), paraneoplastic syndromes affect fewer than 1% of patients with cancer.

Pathogenesis

Increasing evidence suggests that most, if not all, paraneoplastic syndromes affecting the nervous system are caused by an autoimmune reaction engendered by the cancer:

Table 90.2. Antineuronal antibody-associated paraneoplastic disorders[a]

Antibody antigen	Associated cancer	Syndrome	Antigen
Anti-Yo	Gyn, breast	Cerebellar degeneration	Cytoplasm, Purkinje cells 34, 62, kDa
Anti-Hu	SCLC neuroblastoma	Encephalomyelitis, sensory neuronopathy	All neuronal nuclei 35–40 kDa
Anti-Ri	Breast, Gyn, SCLC	Cerebellar ataxia, Opsoclonus	Neuronal nuclei CNS, 55, 80 kDa
Anti-CAR	SCLC, others	Photoreceptor degeneration	Retinal photoreceptor 23 kDa
Anti-amphiphysin	Breast cancer	Stiff-person encephalomyelitis	Synaptic vesicles 128 kDa
Anti-VGCC	SCLC	Lambert–Eaton myasthenic	Presynaptic VCGG
Anti-MysB	SCLC	Lambert–Eaton myasthenic	Presynaptic VCGG
Anti-Ma	Multiple	Cerebellar, brainstem dysfunction	Neuronal nuclei and cytoplasm, 37, 40 kDa
Anti-Ta	Testicular cancer	Limbic encephalitis, brainstem dysfunction	Neuronal nuclei and cytoplasm 40 kDa
Anti-Tr	Hodgkin lymphoma	Cerebellar degeneration	Cytoplasm neurons and Purkinje cells, spiny dendrites
Anti-CV2	SCLC, others	Encephalomyelitis cerebellar degeneration	Glia (subset) 66 kDa

Note:
[a] Modified from Dalmau & Posner (1998).

Antigens normally restricted to the nervous system (Voltz et al., 1999a) (or nervous system and testis (Dalmau et al., 1999), are expressed in a cancer. The immune system, recognizing the antigen in the tumour as foreign, directs an immune response at the tumour; the immune response is misdirected against the shared antigens or epitopes in the nervous system, causing neurological dysfunction. This immune response may be sufficient to retard tumour growth (Carpentier et al., 1998), explaining why so many tumours associated with paraneoplastic syndromes are small and often hard to detect. The evidence for the autoimmune hypothesis is best for the Lambert–Eaton myasthenic syndrome (LEMS) (Newsom-Davis, 1998a) but, as indicated in the next paragraph, current evidence suggests that other paraneoplastic syndromes are also immune-mediated.

Antibody positive paraneoplastic syndromes

In recent years the autoimmune hypothesis has been supported by identification of antibodies in the serum and CSF of some but not all patients with paraneoplastic syndromes (Dalmau & Posner, 1998). These antibodies react with both the target neurological tissue and the underlying tumour. The antibodies often identify patients with a specific clinical syndrome and a specific underlying tumour (Table 90.2). However, there are exceptions: patients with the same paraneoplastic antibody may have different clinical findings and different tumours. Conversely, patients with the same clinical findings may express different antibodies. For example, the anti-Yo antibody is almost always found in patients with paraneoplastic cerebellar degeneration (PCD) and gynecological tumours (Cao et al., 1999) and not in patients with gynecologic tumours who do not have PCD or PCD associated with non-gynecological tumours. However, the antibody is occasionally found in a male with a different tumour (Krakauer et al., 1996), and PCD similar to that in anti-Yo patients may be associated with other antibodies (Mason et al., 1997). Paraneoplastic antibodies typically occur at high titres in the serum; the relative activity is higher in the CSF, at least for those paraneoplastic disorders that clinically affect the CNS. In some instances low titres of the antibody are found in patients with the appropriate cancer but without a paraneoplastic syndrome (Graus et al., 1997).

The antibodies serve as markers indicating that a patient with an unknown neurological diagnosis has cancer as the cause. Particular antibodies also strongly suggest the histologic type of cancer. Thus, the finding of an autoantibody in a patient with a neurological disorder may help identify an occult and potentially curable underlying cancer.

Only a subset of patients with paraneoplastic syndromes have antibodies in their serum. What about the antibody negative patients? There are at least two possibilities. The first is that the antibody negative patients are truly antibody negative and that the disorder may not be immune mediated. The second and more likely possibility is that the disorders are immune mediated and that antibodies are present but have not been identified by current techniques. A good example is the LEMS. Standard histochemical and immunoblotting techniques do not identify an antibody; only by the special techniques of electron microscopic histochemistry or immune precipitation can the

P/Q type calcium channel be identified (Motomura et al., 1995). These findings give one some hope that, using better techniques, antibodies may likewise be found in some currently antibody-negative paraneoplastic syndromes.

Diagnosis

Clinical clues that suggest a diagnosis of a paraneoplastic syndrome include the following.

(i) Most paraneoplastic syndromes evolve subacutely. Many evolve over days or weeks and stabilize by the time the neurologist first sees the patient.

(ii) Paraneoplastic syndromes are usually severe. Most patients have substantial disability at the time they are first seen by the neurologist. Mild or waxing and waning neurological disorders are more likely to have another cause.

(iii) The syndromes are often characteristic. PCD (see below) is so characteristic that it is difficult to consider any other cause for the disorder. However, none of these syndromes, even the most characteristic, is invariably associated with cancer. Thus, only about two-thirds of patients with a LEMS have cancer (almost always a small-cell lung cancer). Probably more than half of patients with subacute cerebellar degeneration have cancer whereas cancer is less common in dermatomyositis and Guillain–Barré syndrome. (Although not all patients with even characteristic paraneoplastic syndromes are found to have cancer, one must evaluate negative reports with care since the neoplasms are often very small and may be overlooked even at autopsy.)

(iv) Paraneoplastic syndromes are often accompanied by CSF pleocytosis, elevated protein and increased IgG levels.

(v) Paraneoplastic syndromes often affect one particular portion of the nervous system with additional subtle or minor findings suggesting dysfunction outside that area. For example, many patients with PCD, in addition to severe ataxia, dysarthria and nystagmus, will be found to be mildly demented and have extensor plantar responses. It is these widespread changes that have led to the use of the term 'encephalomyelitis' when the central nervous system is involved and to the use of the term 'neuromyopathy' when the peripheral nervous system and muscle are involved.

Treatment

Some paraneoplastic syndromes, e.g. LEMS, respond to immunosuppression or the treatment of the underlying cancer (Table 90.3). Some syndromes resolve spontaneously (Mason et al., 1997) but, in general, treatment has been unrewarding (Uchuya et al., 1996) and most patients with paraneoplastic syndromes are left with severe neurological disability. Most of the therapies tried have been forms of immunosuppression, particularly for those syndromes that are associated with autoantibodies. It is possible that the rapid onset of these syndromes does not allow sufficient time for accurate early diagnosis and for treatment to begin before irreversible neuronal damage has occurred. With earlier diagnosis, e.g. specific laboratory tests for antibodies, therapy may be more successful.

Specific treatment (when available) of the individual paraneoplastic syndromes is considered in the sections that follow (Table 90.4).

Specific syndromes

Brain and cranial nerves

Paraneoplastic cerebellar degeneration

The disorder may complicate any malignant tumour but is most common with lung cancer (especially small-cell), gynecological neoplasms and Hodgkin's disease (Cao et al., 1999; Mason et al., 1997; Peltola et al., 1998). Males and females are both affected and the age of incidence reflects the age distribution of the cancer. Neurological manifestations precede detection of the associated tumour in over one-half of patients, rarely by up to 4 years. Alternatively, PCD may develop after diagnosis of the neoplasm. In some instances, the tumour is not found until autopsy. Typically, the disorder begins as gait ataxia that over a few days to months progresses to severe truncal and appendicular ataxia with dysarthria and often nystagmus. The nystagmus is frequently downbeating. Vertigo with, or without, nausea and vomiting is common and many patients complain of diplopia. The cerebellar signs are bilateral but may be asymmetrical. A more rapid onset within a few hours or days or a slower progression sometimes occurs. The cerebellar deficit usually stabilizes but, by then, the patient is often incapacitated. Spontaneous improvement sometimes occurs, particularly when associated with Hodgkin's disease.

The signs and symptoms are frequently limited to cerebellar or cerebellar pathway dysfunction but, in as many as 50% of the patients, other neurological abnormalities, usually mild, may be found on careful examination (Hammack et al., 1990; Peterson et al., 1992), including sensorineural hearing loss, dysphagia, hyperreflexia with or without extensor plantar responses, extrapyramidal

Table 90.3. Treatment of paraneoplastic neurological syndromes[a]

Syndrome	Treatment
Paraneoplastic syndromes that usually respond to treatment	
LEMS	Tumour therapy, plasma exchange, IVIg, 3, 4 diaminopyridine
Myasthenia gravis	Tumour therapy, plasma exchange, IVIg, immunosuppressants
Dermatomyositis	Steroids, immunosuppressants, IVIg
OM (pediatrics)	Steroids, ACTH, tumour
Carcinoid myopathy	Tumour therapy, cyproheptadine
Neuropathy (osteosclerotic myeloma)	Tumour therapy, radiation
Paraneoplastic syndromes that may respond to treatment	
Vasculitis (nerve/muscle)	Steroids
OM (adults)	Steroids, tumour, protein A column, clonazepam, diazepam, baclofen
PCD (Hodgkin's disease)	Tumour therapy
Opsoclonus/ataxia (anti-Ri)	Steroids, cyclophosphamide
Guillain–Barré (Hodgkin's disease)	Tumour therapy, plasma exchange, IVIg
Stiff-man	Tumour therapy, steroids, diazepam, baclofen, IVIg
Neuromyotonia	Plasma exchange
Paraneoplastic syndromes that usually do not respond to treatment	
Paraneoplastic cerebellar degeneration (PCD)	
SCLC (irrespective of anti-Hu)	
Anti-Yo antibodies (cancer of ovary, breast)	
Paraneoplastic encephalomyelitis/sensory neuronopathy	
Limbic encephalopathy (steroids)	
Cerebellar degeneration	
Brainstem encephalopathy	
Myelopathy	
Sensory neuronopathy	
Autonomic dysfunction (central or peripheral)	
Cancer-associated retinopathy	
Paraneoplastic syndromes that may improve spontaneously	
Acute motor neuronopathy and lymphoma	
PCD associated with Hodgkin's disease	
Acute polyradiculopathy associated with Hodgkin's disease	
Limbic encephalopathy	
OM (pediatric and adult population)	

Notes:
Abbreviations: LEMS: Lambert–Eaton myasthenic syndrome; OM: opsoclonus/myoclonus; PCD: paraneoplastic cerebellar degeneration; SCLC: small-cell lung cancer
[a] Modified from Dalmau & Posner (1998).

signs, peripheral neuropathy, dementia, and other cognitive abnormalities. One study, however, using formal cognitive testing found that dementia was not typical when testing was controlled for impaired motor and speech production, suggesting that perceived clinical changes in intellectual function may be more apparent than real (Anderson et al., 1988). Despite this finding, positron emission tomography (PET), performed in a few patients, has revealed hypometabolism in all areas of the neuraxis including the cerebral cortex, cerebellum, and brainstem (Anderson et al., 1988).

The CSF may be normal, but early in the illness usually shows a mild pleocytosis. The protein concentration remains. Elevated protein IgG concentration is increased and oligoclonal bands are present. Cytological examination of the CSF and contrast-enhanced MRI of the neuraxis rules out leptomeningeal metastases. MR scans typically are normal early but later show signs of progressive cerebellar

Table 90.4. Paraneoplastic syndromes affecting brain and cranial nerves

Subacute cerebellar degeneration
Opsoclonus–myoclonus
Limbic encephalitis and other dementias
Brainstem encephalitis
Optic neuritis
Retinal degeneration

atrophy with prominent cerebellar folia and a dilated fourth ventricle.

The pathologic hallmark of PCD is loss, often total, of Purkinje cells (Verschuuren et al., 1996), affecting all parts of the cerebellum. Less striking changes in the cerebellar cortex may include thinning of the molecular layer with microglial proliferation and astrocytic gliosis, proliferation of Bergmann astrocytes and slight thinning of the granular layer with decreased numbers of granule cells. Basket cells and tangential fibres are usually intact. Changes in the cerebellar white matter reflect loss of Purkinje axons, resulting in loss of myelinated fibres and reactive gliosis in the cores of the cerebellar folia and in the white matter surrounding the dentate nucleus. The deep nuclei of the cerebellum and the brainstem nuclei with cerebellar connections are well preserved except in cases with an associated encephalomyelitis.

Some patients with PCD have more widespread pathological abnormalities, including degeneration of spinocerebellar tracts, dorsal columns and corticospinal tracts, patchy demyelination, neuronal degeneration, microglial proliferation and perivascular lymphocytic infiltration in the brainstem, spinal cord and, sometimes, in the dorsal root ganglia. Lymphocytic infiltration may be confined to the dentate nuclei and the surrounding cerebellar white matter. Mild degrees of lymphocytic meningeal infiltration are observed. By contrast, inflammatory cell infiltration in the cerebellar cortex is rare.

When typical, the clinical picture of PCD is almost pathognomonic. When atypical, the disorder must be distinguished from a cerebellar tumour (primary or metastatic) and from leptomeningeal metastases (by MRI and CSF examination, respectively), from late-onset, non-paraneoplastic cerebellar degenerative disorders (Ropper, 1993), cerebellar hemorrhage and infarction, abscess, prion diseases, cerebellar ataxia related to 5-fluorouracil or high-dose cytarabine, and metabolic disorders, especially alcoholic cerebellar degeneration. In alcoholic cerebellar degeneration, the ataxia predominantly involves the lower extremities; dysarthria and nystagmus are unusual.

There have been occasional reports of a partial or near-complete remission of PCD following treatment of the primary tumour. The presence of ocular flutter or opsoclonus indicates a better chance of improvement but this may be a different paraneoplastic syndrome (see below). Only rarely is immunosuppression beneficial (Batocchi et al., 1999) and most patients do not respond. It is possible that, if begun early in the illness, before Purkinje cells are irreversibly damaged, plasmapheresis and immunosuppressive drugs might have a beneficial effect. Symptomatic improvement in the ataxia occurs in a few patients with clonazepam in doses varying from 0.5 to 1.5 mg daily. Buspirone may also give modest relief (Trouillas et al., 1997).

Antibody positive (anti-Yo) paraneoplastic cerebellar degeneration

Several different antibodies reacting with Purkinje cells have been reported in the serum of patients with PCD. The most common is an antibody designated anti-Yo (Table 90.2) (Cao et al., 1999). This antibody is found in the serum of patients with gynecologic or breast cancer and, rarely, other cancers, including those in men (Greenlee et al., 1999; Krakauer et al., 1996). The antibody reacts with the cytoplasm of Purkinje cells and with the tumour causing the disorder (Greenlee et al., 1999). It can be identified both histochemically and on Western blot. The genes coding for the antigen have been cloned and sequenced. One of the proteins (CDR2) appears to down-regulate the function of the *C-myc* gene. This down-regulation may promote apoptosis in Purkinje cells (Okano et al., 1999). In patients with anti-Yo positive PCD, activated, cytotoxic T-lymphocytes that recognize the antigen are found in both blood and CSF (Albert et al., 1998, 2000). One study, however, failed to detect cytotoxic T-cell activity against Yo protein (Tanaka et al., 1998). One report indicates that anti-Yo positive Japanese patients are HLA-A24 positive (Tanaka & Tanaka, 1996). We have not found a consistent HLA genotype in patients in the US.

A second antibody found in patients with pure paraneoplastic cerebellar degeneration is the anti-Tr antibody, named after John Trotter, who reported the first such patient in 1976 (Trotter et al., 1976). This antibody associated with Hodgkin's disease reacts with the cytoplasm of Purkinje cells and produces a characteristic punctate pattern in the molecular layer of the cerebellum (Graus et al., 1998). The antigens cannot be identified on Western blot and the gene has not been cloned. Unlike anti-Yo paraneoplastic cerebellar degeneration, the cerebellar degeneration in this disorder is sometimes reversible.

The anti-Hu antibody (discussed in detail in the next section) may also be associated with PCD but usually is part of a more diffuse encephalomyelitis (Mason et al., 1997).

The anti-Ri antibody (discussed in the section on opsoclonus) is associated with paraneoplastic cerebellar degeneration, usually as part of the opsoclonus/myoclonus syndrome.

Other less well-characterized antibodies have been reported in individuals or a few patients with relatively pure cerebellar degeneration. These include antibodies against glutamate receptors (Smitt et al., 2000). We have been unable to identify glutamate receptor antibodies in our patients with paraneoplastic cerebellar degeneration (Degenhardt et al., 1998). Other antibodies often associated with different paraneoplastic syndromes are occasionally associated with PCD (Honnorat et al., 1999; Mason et al., 1997).

Opsoclonus–myoclonus (OM)

Opsoclonus, a disorder of eye movements consisting of almost continuous arrhythmic, multidirectional, involuntary, high-amplitude conjugate saccades that are often accompanied by synchronous blinking of the lids is a paraneoplastic syndrome complicating neuroblastoma in children and a variety of tumours in adults (Digre, 1986). The movements usually persist when the eyes are closed and during sleep. Opsoclonus is exacerbated by attempts at visual pursuit or voluntary refixation. Opsoclonus may be an isolated neurologic sign but is often accompanied by myoclonus of the trunk, limbs, head, diaphragm, larynx, pharynx and palate, and ataxia. When opsoclonus is a paraneoplastic syndrome of adults it may be accompanied by PCD. OM is also associated with viral infections, postinfectious encephalitis, trauma, intracranial tumours, hydrocephalus, thalamic hemorrhage and toxic encephalopathies from thallium or lithium, amitriptyline overdose and diabetic hyperosmolar coma. Opsoclonus occurs in about 2% of children with neuroblastomas. Neurological symptoms precede identification of the neuroblastoma at least 50% of the time and the tumour often is not obvious on examination; thus, recognition of the neurological syndrome is an important clue to the presence of a neuroblastoma. When a neuroblastoma is associated with OM, there is a higher than expected incidence of intrathoracic tumours and of tumours with a benign histology. The prognosis of the neuroblastoma is better if OM is associated than when there is no neurological complication, an observation not explained by earlier diagnosis when neurological symptoms are present. The neurological disorder responds to ACTH and to intravenous immunoglobulin (Borgna-Pignatti et al., 1996) but not prednisone (Hammer et al., 1995). One report describes a combination of dexamethasone and intravenous immunoglobulin as effective when either alone was not (Veneselli et al., 1998). However, most patients suffer residual neurological damage, usually cognitive (Hammer et al., 1995).

OM is less common in adults. Nevertheless, about 20% of adult patients reported with OM probably have an underlying cancer (Digre, 1986). The most common tumour is lung cancer, but other cancers also cause the syndrome (Berger & Mehari, 1999; Corcia et al., 1997; Ducrocq et al., 1999). The neurological symptoms usually precede diagnosis of the tumour and commonly progress over several weeks although more rapid or slower progression may be observed. Opsoclonus often is associated with truncal ataxia, dysarthria, myoclonus, vertigo and encephalopathy. The CSF may show a mild pleocytosis and a mildly elevated protein. The MRI is usually normal but brainstem abnormalities have been reported.

Neuropathological findings have been variable. In some patients there are no identifiable abnormalities. In others, the changes resembled those of PCD with a loss of Purkinje cells, inflammatory infiltrates in the brainstem (Scaravilli et al., 1999), Bergmann gliosis and loss of cells from the granular layer of the cerebellum. Those patients with pathological changes in the cerebellum may have suffered from PCD as well as opsoclonus. The absence of neuropathological changes in some patients with clearly established opsoclonus and myoclonus suggests that the site of the pathology has not yet been identified.

The prognosis for recovery or partial remission of the neurologic disorder is better for paraneoplastic OM than it is for PCD. Improvement may follow treatment of the underlying tumour, and spontaneous partial remissions occur. Remissions have been reported to follow treatment of the tumour or immunosuppressive treatment including immunoadsorptive therapy using a protein A column (Batchelor et al., 1998a,b).

Antibody positive (anti-Ri) OM

Connolly and colleagues (Connolly et al., 1997) found that children with OM, whether or not caused by cancer, had antibodies that bound to the cytoplasm of Purkinje cells and some axons in the white matter. Western blot analysis revealed several bands including one at 210 kD, the site of the high molecular weight subunit of neurofilament. Our own (unpublished) observations have not identified neurofilament antibodies in any children with paraneoplastic OM, but have found autoantibodies that react with

the nervous system in children with neuroblastoma. These antibodies are more frequent in those with OM than in those without the disorder but none are specific.

Several autoantibodies have also been described in the small number of adults with the syndrome. The best characterized is the anti-Ri antibody (Luque et al., 1991). Histochemically, the antibody reacts with the nuclei of central nervous system neurons, giving an appearance virtually identical to that of the anti-Hu antibody. However, it does not react with neurons of the dorsal root ganglia or other peripheral neurons (Graus et al., 1993). On Western blot, using extracts of cortical neurons, the antibody gives two bands, one at 55 and one at 80 kd. The gene that codes for the antigen recognized by anti-Ri sera has been cloned, sequenced and named *Nova* by Darnell and his colleagues (Buckanovich et al., 1993). *Nova* is a family of genes that are neuron-specific RNA binding proteins. Different members of the family are expressed in different areas of the nervous system. Nova-1, expressed primarily in the brainstem, reacts with an inhibitory glycine receptor. Knockout of Nova-1 in mice yields a fatal clinical syndrome reminiscent of OM. The hypothesis is that the anti-Ri serum binds to the Nova-1 protein, interfering with normal function or synthesis of an inhibitory glycine receptor thus leading to uninhibited activity of the eyes and other muscles. The crystal structure of Nova-1 and 2 has been determined (Lewis et al., 1999) and how the Nova protein specifically binds to RNA has also been determined (Lewis et al., 2000).

Other antibodies have also been reported to be present in some patients with paraneoplastic OM. These include the antiamphiphysin antibody (Saiz et al., 1999). The role of these other antibodies in production of the disease seems less clear than the anti-Ri antibody.

Limbic encephalitis

Limbic encephalitis may occur as an isolated finding or as a more extensive encephalomyelitis (Dalmau et al., 1992; Gultekin et al., 2000). The neurologic symptoms often precede diagnosis of the tumour by up to two years; sometimes the cancer is not detected until autopsy. Symptoms usually progress over several weeks but the course may be more insidious. Anxiety and depression are common early symptoms but the most striking feature is a severe impairment of recent memory (Gultekin et al., 2000). Other manifestations include agitation, confusion, hallucinations, partial or generalized seizures, and hypersomnia. Progressive dementia usually occurs but there occasionally may be a spontaneous remission. The CSF commonly shows a pleocytosis and an elevated protein concentration. MR scans are usually normal but medial temporal abnormalities have been reported (Dalmau et al., 1992; Fakhoury et al., 1999).

Pathological changes affect the grey matter of the hippocampus, cingulate gyrus, pyriform cortex, orbital surfaces of the frontal lobes, insula and the amygdaloid nuclei (Scaravilli et al., 1999). In some patients the caudate nucleus, putamen, globus pallidus, thalamus, hypothalamus and subthalamic nucleus are affected. The pathologic changes consist of: (i) extensive loss of neurons, (ii) reactive gliosis and microglial proliferation and, (iii) perivascular lymphocytic cuffing which may be less prominent in long-standing cases. In a few patients who have been reported with the clinical picture no pathological changes have been found.

No treatment has proved uniformly beneficial although occasional spontaneous remissions have been reported and some patients have improved after treatment of the underlying tumour (Brennan & Craddock, 1983; Nokura et al., 1997).

The anti-Hu antibody (also called ANNA-1 (Lennon, 1994)) can be found in patients with isolated limbic encephalitis but more commonly is associated with a more widespread encephalomyelitis. The full blown anti-Hu syndrome consists of a sensory neuronopathy resulting from inflammatory damage to the dorsal root ganglia, and a widespread encephalomyelitis causing limbic encephalitis, brainstem encephalitis (see below), PCD, myelopathy, an autonomic neuropathy and sometimes other findings (Davis et al., 1991). The antibody reacts with a protein that binds messenger RNA and probably stabilizes it. How that finding relates to the disease is unknown. Other antibodies found in patients with limbic encephalitis include the anti-Ta antibody (Voltz et al., 1999), anti-Ma (Dalmau et al., 1999) and anti-CV2 (Honnorat et al., 1999).

Brainstem encephalitis

Paraneoplastic brainstem encephalitis often is associated with clinical and pathological evidence of encephalomyelitis elsewhere within the central and peripheral nervous systems but may occur as the dominant or an isolated clinical finding (Batchelor et al., 1998a,b; Heckmann et al., 1999; Voltz et al., 1999a,b). It is commonly associated with small-cell lung cancer but an identical clinicopathological syndrome may be seen in the absence of malignancy.

The clinical features vary according to the brainstem structures involved in the pathological process. Common manifestations include vertigo, ataxia, nystagmus, vomiting, bulbar palsy, oculomotor disorders and corticospinal tract dysfunction. Less common clinical features include deafness, myoclonus of the branchial musculature, hypo-

ventilation, and movement disorders including chorea or Parkinson's syndrome.

Neurological symptoms may develop before or after discovery of the malignancy. The pathological changes are identical to those observed in other forms of paraneoplastic encephalomyelitis including lymphocytic perivascular cuffing, gliosis, microglial proliferation and loss of neurons. No form of treatment, including treatment of the underlying tumour, has altered the course.

Visual loss

Paraneoplastic syndromes can affect retinal photoreceptors, either rods or cones (Jacobson & Thirkill, 1995) or both. It can cause a retinal vasculitis (Remulla et al., 1995) or optic neuropathy (Antoine et al., 1993; Blumenthal et al., 1998; Lieberman et al., 1999; Malik et al., 1992). Paraneoplastic retinal degeneration, also called cancer-associated retinopathy, usually occurs in association with small-cell cancer of the lung (Goldstein et al., 1999), melanoma (Boeck et al., 1997; Gittinger & Smith, 1999) and gynecological tumours. Typically, the visual symptoms include episodic visual obscurations, night blindness, light-induced glare, photosensitivity, and impaired colour vision. Visual symptoms usually precede the diagnosis of cancer. The symptoms progress to painless visual loss. They may begin unilaterally but usually become bilateral. Visual testing demonstrates peripheral and ring scotomas and loss of acuity. Funduscopic examination may reveal arteriolar narrowing and abnormal mottling of the retinal pigment epithelium. The electroretinogram is abnormal. CSF is typically normal, although elevated immunoglobulin levels have been reported. Inflammatory cells are sometimes seen in the vitreous by slit-lamp examination.

Pathologically, a loss of photoreceptors and ganglion cells with inflammatory infiltrates and macrophages is usually noted. The other parts of the optic pathway are preserved, although a loss of myelin and lymphocytic infiltration of the optic nerve may occur.

Serum autoantibodies that recognize several proteins have been described in visual paraneoplastic syndromes. These include antibodies that recognize the photoreceptor protein recoverin (Adamus et al., 1997), a retinal-specific protein that is a member of the *Tubby* gene family and enolase-α (Adamus et al., 1998a,b) as well as several others not entirely characterized. Antirecoverin antibodies have been reported to induce apoptosis of photoreceptor and bipolar cells in vivo (Adamus et al., 1998a,b).

Treatment of cancer-associated retinopathy is usually unsuccessful, although a recent report describes improvement in some patients with the use of intravenous immunoglobulin (Guy & Aptsiauri, 1999).

Spinal cord and dorsal root ganglia (Table 90.5)

Necrotizing myelopathy

This is an extremely rare remote effect of cancer (Handforth et al., 1983; Hughes et al., 1992). An identical syndrome may occur with a variety of other diseases and in previously healthy individuals (Katz & Ropper, 2000). Some authors suggest that an association with cancer may be coincidental. The initial symptoms may be asymmetric, but eventually signs become bilateral and symmetric. Back or radicular pain may precede other neurological signs. Cerebrospinal fluid abnormalities may include an elevated protein and a mild pleocytosis. Swelling of the spinal cord may be apparent on MRI. Typically, the neurological deficit progresses rapidly over days or a few weeks, ultimately leading to respiratory failure and death. There is no effective treatment.

Pathologically, there is widespread necrosis of the spinal cord, often most marked in the thoracic segments. The necrosis involves all components of the spinal cord with white matter usually more affected than grey matter.

Motor neuron disease (amyotrophic lateral sclerosis)

All of the subcomponents of amyotrophic lateral sclerosis, progressive muscular atrophy and primary lateral sclerosis may be paraneoplastic (Rosenfeld & Posner, 1991). Gordon and colleagues (Gordon et al., 1997), report the association of motor neuron disease and a variety of lymphoproliferative disorders, including Hodgkin's disease, multiple myeloma, chronic lymphocytic leukemia and other lymphomas. Paraneoplastic syndromes include: (i) amyotrophic lateral sclerosis with both upper and lower motor neuron dysfunction (Rowland, 1997), (ii) progressive muscular atrophy, a pure lower motor neuron syndrome that is sometimes reversible (Schold et al., 1979) and also

associated with lymphoproliferative disorders, and (iii) primary lateral sclerosis, a pure upper motor neuron syndrome associated with solid tumours as well as lymphoproliferative disorders (Forsyth et al., 1997; Rowland, 1997). The clinical and pathological characteristics differ little from non-paraneoplastic motor neuron disease save for the fact that the paraneoplastic disorders are often more rapid in onset and evolution, sometimes reverse spontaneously and, at autopsy, may be more inflammatory than a non-paraneoplastic disorder.

The occurrence of these paraneoplastic syndromes, primarily in patients with lymphoproliferative disorders, suggests the possibility that opportunistic infection may play a role in pathogenesis. The pure lower motor neuron disorder is similar to an anterior horn cell degeneration in a strain of mice infected with the murine leukemia virus (Andrews & Gardner, 1974), although recent evidence suggests that neuronal damage can occur without direct viral invasion (Stoica et al., 2000).

Myelitis

Paraneoplastic myelitis is usually a part of the encephalomyelitis syndrome with inflammatory lesions elsewhere in the brain and dorsal root ganglia as well as spinal cord. The clinical picture is characterized by patchy wasting and weakness of muscles, sometimes combined with fasciculations. The upper extremities are often more severely affected than the legs, reflecting predominant involvement of the cervical spinal cord. There may be striking weakness of neck and intercostal muscles, resulting in respiratory failure. Sensory symptoms, if present, usually are a manifestation of an associated sensory neuronopathy, but patients with severe changes in the posterior horns may present with a clinical picture resembling syringomyelia. Corticospinal tract signs may reflect lesions in the spinal cord or in the brainstem. Autonomic dysfunction results from involvement of autonomic neurons.

Sensory neuronopathy

In contrast to the common axonal or demyelinating sensory neuropathies, paraneoplastic sensory neuronopathy (PSN) where the dorsal root ganglion is the site of pathology is a rare syndrome. The clinical picture of pure sensory loss often does not allow clinical distinction from the more peripheral disorder. Sensory neuronopathy can occur in previously healthy individuals and those with a variety of underlying autoimmune conditions including Sjogren's syndrome. It can also be caused by heavy metal intoxication, including the chemotherapeutic agent cisplatin. At least two-thirds of patients with paraneoplastic sensory neuronopathy have small-cell lung cancer. Symptoms typically begin before the cancer is identified, with dysesthetic pain and numbness in the distal extremities or occasionally in the arm(s), face or trunk. The symptoms may be asymmetrical at onset but progress over days to several weeks to involve the limbs, trunk, and sometimes the face, causing a severe sensory ataxia. All sensory modalities are affected, distinguishing this disorder from cisplatin neuropathy, in which pin and temperature sensation are spared. Deep tendon reflexes are lost, but motor function is preserved. The CSF is typically inflammatory. Sensory nerve action potentials are low in amplitude or absent, whereas motor nerve action potentials are normal and electromyographic (EMG) evidence of denervation is absent.

Early pathological changes are limited mostly to the dorsal root ganglia, in which both a loss of neurons and the presence of lymphocytic inflammatory infiltrates are noted. As the disease progresses, the inflammatory process may advance to the dorsal root, posterior columns, and peripheral nerve. PSN can occur as a pure syndrome or as part of a more diffuse encephalomyelitis. About 50% of patients with PSN have pathological changes that may be clinically inapparent in other regions of the nervous system. In most patients, treating the underlying tumour or removal of the autoantibody by plasmapheresis or immunosuppressive therapy does not alter the course of the neurological disease (Uchuya et. al., 1996), although there are isolated reports of responses to immunotherapy (Oh et al., 1997). Occasional patients have a mild and indolent neuropathy (Graus et al., 1994).

Peripheral nerves (Table 90.6)

Sensory and sensorimotor neuropathy

Peripheral neuropathies (PN), particularly mild distal sensorimotor neuropathies, are quite common in patients with cancer. In one study of lung cancer the incidence was 16%. The incidence is even higher if one defines the disorder by electrical evidence in clinically asymptomatic patients. However, many patients may have suffered from the metabolic or nutritional ravages of late cancer and would not be considered by the definitions here to have true paraneoplastic syndromes.

Some patients not known to have cancer, and who are not evidently systemically ill, present to the neurologist with a PN which may be quite severe and disabling. It is estimated that in those patients whose initial evaluations do not reveal an obvious cause (e.g. vitamin deficiency,

Table 90.6. Paraneoplastic syndromes affecting peripheral nerves

Subacute or chronic sensorimotor peripheral neuropathy

Mononeuritis multiplex and microvasculitis of peripheral nerve
Brachial neuritis
Autonomic neuropathy
Peripheral neuropathy associated with myeloma

amyloidosis, diabetes), about 10% will eventually prove to have cancer as the underlying reason for the peripheral neuropathy. Therefore, one should seriously consider a cancer diagnosis in such patients.

Subacute sensorimotor neuropathy is predominantly a distal symmetrical polyneuropathy, more marked in the lower extremities, with weakness, glove-and-stocking sensory impairment to all modalities, and a loss of tendon reflexes. Bulbar involvement is exceptional. A few patients with paraneoplastic sensorimotor neuropathy follow the remitting and relapsing course typical of chronic inflammatory demyelinating polyneuropathy. These patients may respond to corticosteroid therapy. The CSF is typically acellular, with normal or slightly elevated protein concentration. Nerve conduction studies are consistent with an axonal neuropathy, with low-amplitude or absent sensory nerve action potentials and normal or decreased motor nerve conduction velocities. A few patients have marked slowing of motor conduction velocities consistent with a demyelinating process. Pathologically, there is usually axonal degeneration; in a few patients demyelination is prominent. Spinal cord demyelination and lymphocytic infiltrates of peripheral nerves have also been reported.

A particular sensorimotor neuropathy has been associated with breast cancer. Peterson and colleagues have described 9 patients with a slowly progressive sensorimotor, predominantly sensory, neuropathy, some of whom had additional features suggesting a myopathy (e.g. proximal weakness) or CNS dysfunction (e.g. hyperreflexia and extensor plantar responses) (Peterson et al., 1994). The disorder progressed very slowly over many years, was not disabling, and was frequently heralded by itching or muscle cramps. In one patient, itching, initially over the left breast and later diffusely, preceded identification of the cancer by 18 months. Most patients remained fully functional as neither the neuropathy nor the breast cancer was disabling (Peterson et al., 1994).

A relatively pure paraneoplastic sensory neuropathy (not neuronopathy) occurs with a variety of malignancies but cannot be distinguished from other causes of sensory neuropathy. In one series, when no cause of the sensory neuropathy was identified, cancer was subsequently identified as the cause in approximately one-third of patients. Mean time to cancer diagnosis was more than 2 years (Camerlingo et al., 1998).

Peripheral neuropathy due to microvasculitis is rare as a paraneoplastic syndrome. The disorder has been reported as part of the anti-Hu syndrome (Blumenthal et al., 1998). It also appears without obvious antibody involvement in patients with a variety of cancers (Oh et al., 1991). Vasculitic neuropathy can either present as a diffuse polyneuropathy or as a mononeuritis multiplex. The disorder can involve both peripheral and cranial nerves. The importance of making a diagnosis, which may require nerve biopsy, is that the condition may respond to corticosteroid treatment. PN may be associated with multiple myeloma and Waldenstrom's macroglobulinemia (Simmons, 1999). With the rare osteosclerotic form of myeloma, PN is present in about 50% of patients. Successful treatment of the myeloma often leads to amelioration of the neurological symptomatology. Amyloidosis associated with myeloma can also cause a PN that responds poorly to treatment.

Acute polyradiculoneuropathy is an uncommon remote effect with a striking association with Hodgkin's disease (Lisak et al., 1977). The clinical and pathological features and elevated CSF protein are typical of the Guillain–Barré syndrome (GBS). Symptoms may begin when the tumour is in remission, during active disease, or the PN may presage a relapse of Hodgkin's disease. The course of the neuropathy is independent of the Hodgkin's disease and may, like idiopathic GBS, respond to plasmapheresis or IVIg. This patient improved with steroids.

Brachial neuritis

Acute brachial neuritis (clinically undistinguishable from the idiopathic variety) occurs with increased frequency in patients with Hodgkin's disease (Lachance et al., 1991). Brachial neuritis should be differentiated from other causes of a brachial plexopathy in cancer, namely tumour infiltration, radiation fibrosis and radiation-induced tumours.

Autonomic neuropathy

This rare paraneoplastic syndrome usually is associated with lung tumours (Ahmed & Carpenter, 1975), especially small-cell cancers, but may occur with other neoplasms. It may precede or follow diagnosis of a malignancy. Typically,

Table 90.7. Paraneoplastic syndromes affecting neuromuscular junction and muscle

Lambert–Eaton myasthenic syndrome (Chapter 69)
Myasthenia gravis (Chapter 69)
Dermatomyositis, polymyositis, acute necrotizing myopathy (Chapter 70)
Neuromyotonic and stiff-person syndrome (Chapter 48)

there is subacute onset of intestinal hypomotility, postural hypotension, neurogenic bladder dysfunction, pupillary abnormalities, impotence and anhidrosis in varying combinations. Some cases are associated with PSN. The CSF shows an elevated protein without pleocytosis. The initial course is rapidly progressive but later may stabilize, although the patient often is severely disabled by the time this stage is reached. The autonomic neuropathy may improve following treatment of the underlying tumour. Nicotinic acetylcholine receptor antibodies may be found. Autonomic neuropathy also occurs as part of the anti-Hu syndrome.

Neuromuscular junction and muscle (Table 90.7)

Paraneoplastic disorders of the neuromuscular junction include the Lambert–Eaton myasthenic syndrome and myasthenia gravis. These disorders have a common pathogenetic mechanism, i.e. they are caused by antibodies against ion channels, and, whether paraneoplastic or not, they respond to immunological treatment. Another ion channel disorder included in this section is neuromyotonia, which is not confined to the neuromuscular junction. Finally, because of its similarity to neuromyotonia, the stiff-person syndrome is also included in this section. The stiff-person syndrome is discussed in detail in Chapter 48. Recent reviews of these disorders have appeared (Brown & Marsden, 1999; Newsom-Davis, 1998a; Vincent, 1999).

Lambert–Eaton myasthenic syndrome (LEMS)

LEMS results from a reduced release of acetylcholine at presynaptic nerve terminals. The same P/Q-type voltage-gated calcium channels are found in small-cell lung cancers. Interestingly, the richest source of P/Q-type voltage-gated calcium channels is the cerebellum, perhaps explaining the occasional relationship of paraneoplastic cerebellar degeneration and LEMS (Voltz et al., 1999a,b).

LEMS is a classic autoimmune disease (see Chapter 69) in that the binding of circulating IgG antibodies to the voltage-gated calcium channels reproduces the electrophysiologic abnormalities in experimental animals; removal of IgG antibodies from humans with the disorder improves neurological function (Vincent, 1999). LEMS is paraneoplastic in about 60% of patients. It is almost always associated with small-cell lung cancer. Antibodies that react with P/Q-type voltage-gated calcium channels are found in patients with or without paraneoplastic syndromes (Vincent, 1999). LEMS can be treated either by immunosuppression or by treatment of the underlying cancer when present (Newsom-Davis, 1998b). Patients with small-cell lung cancer associated with LEMS have a better prognosis than patients with small-cell lung cancer who do not develop a paraneoplastic disorder (Maddison et al., 1999).

Myasthenia gravis

Myasthenia gravis (MG) occurs in 30% of patients with thymomas, and approximately 10% of patients with MG are found to have a thymoma. Myasthenia is discussed in Chapter 69.

Polymyositis and dermatomyositis

These common inflammatory, probably autoimmune, muscle diseases are discussed in detail in Chapter 70 (Callen, 2000). Only a minority of patients suffering from these disorders have an underlying malignancy as their cause (Naschitz et al., 1999), particularly older patients. Dermatomyositis with typical cutaneous changes is more likely than polymyositis to be paraneoplastic. Females and males are affected in approximately equal numbers. Symptoms of the muscle weakness generally precede identification of the cancer. The tumour may be at any site, but breast, lung, ovarian, and gastric malignancies are the most common. Hodgkin's disease and prostate and colon cancer are also reported offenders.

The clinical and laboratory findings in dermatomyositis/polymyositis associated with malignancy resemble those in the idiopathic disease, although cancer patients often have more striking abnormalities on muscle biopsy. Patients characteristically present with proximal muscle weakness, elevated levels of serum creatine kinase (CK), and EMG evidence suggesting a myopathic process rather than nerve disease. A muscle biopsy specimen showing inflammatory myopathy confirms the diagnosis. Although laboratory findings do not distinguish paraneoplastic from non-paraneoplastic varieties, the presence of autoanti-

bodies, particularly common in the disorder associated with lung disease, is less common in patients with the paraneoplastic disorder. No laboratory test is absolutely diagnostic. Normal CK levels are occasionally found even in patients with profound muscle weakness, with or without malignancy; abnormal CK levels indicate a poor prognosis for the muscle disease. Weakness of respiratory and pharyngeal muscles may contribute to death. The prognosis is worse for the paraneoplastic disorder than for the non-paraneoplastic disorder.

Corticosteroids, cyclosporine and other immunosuppressants have been used successfully. Other reports suggest that high-dose intravenous immunoglobulin is useful in patients unresponsive to other forms of immunosuppression (Dalakas, 1999).

Neuromyotonia and stiff-person syndrome

Muscle cramps are a common complication of cancer, sometimes related to electrolyte imbalance or induced by chemotherapy. A much rarer but clinically significant paraneoplastic disorder is acquired neuromyotonia (Vincent, 1999). The disorder is characterized by muscle stiffness, cramps and obviously rippling and twitching muscles, sometimes leading to sustained abnormal postures. Relaxation after voluntary contraction is delayed. Symptoms persist during sleep, but are abolished by curare. Sudden prolonged bursts of high frequency involuntary repetitive muscle action potentials are seen on electromyography.

The muscle spasms and rigidity are sometimes precipitated by activity, forcing patients to become sedentary. The disorder arises from peripheral nerves and is sometimes a part of the encephalomyelitis syndrome. The disorder is usually non-paraneoplastic, but may be associated with cancer including thymomas and small-cell lung cancer. Antibodies against voltage-gated potassium channels are often positive. Plasma exchange improves the patient's condition. Some patients respond to anticonvulsants. Injection of IgG from affected patients into experimental animals can reproduce the syndrome.

The stiff-person syndrome may superficially resemble neuromyotonia, but has a central origin. It is clinically characterized by stiffness and rigidity with episodic spasms of axial muscles (see Chapter 48). A variant of the syndrome affects the limbs. Painful reflex spasms can occur in response to tactile stimuli or startle. Normal appearing muscle action potentials are found on electromyography, but the activity is continuous and excessive and increased by voluntary activity. The disorder is usually not associated with cancer, but in some patients the underlying syndrome is paraneoplastic. In those cases, the disorder is not associated with the typical antibodies against glutamic acid decarboxylase found in patients with the non-paraneoplastic syndrome. Instead, amphiphysin or antibodies that react with cerebellum may be found (Antoine et al., 1999; Saiz et al., 1999). Both the paraneoplastic and the non-paraneoplastic disorder may respond to immunosuppression. Some patients respond to drugs that enhance GABA neurotransmission, such as diazepam, gabapentin and baclofen. In the non-paraneoplastic disorder, antibodies against glutamic acid dehydrogenase, the rate-limiting enzyme for the synthesis of gamma aminobutyric acid, suggest that the disease is the result of interference with GABA metabolism.

Harmful effects of radiation on the nervous system

Jeremy H. Rees[1] and Michael Brada[2]

[1] Institute of Neurology, The National Hospital for Neurology and Neurosurgery, London, UK
[2] Institute of Cancer Research, The Royal Marsden NHS Trust, Sutton, Surrey, UK

Radiotherapy (RT) is the mainstay of treatment of primary brain tumours which are not resectable and is the only treatment modality which has been demonstrated to prolong survival in patients with malignant gliomas. It is a potentially toxic treatment and therefore adequate controls must be in place to monitor the dose administered. This chapter describes the basic physical principles underlying the cellular and molecular mechanisms of RT-induced cell death and then discusses the harmful effects of radiation on the nervous system.

Physical principles of radiation

Radiotherapy is the use of electromagnetic radiation usually in the form of photons to produce cell damage and thereby destroy tumours. Electromagnetic radiation acts principally by ionizing molecules in irradiated tissues. Radiation energy is either absorbed directly into the DNA or indirectly via the generation of free radicals in the aqueous cytosol which produce further molecular damage. The end result of irradiation is DNA damage in the form of inter- and intrastrand cross-links, strand breaks and damage to nucleotide bases. The cellular repair capacity may not be sufficient to repair all DNA lesions, particularly double strand breaks and these may ultimately lead to cell death. The majority of human cells that sustain DNA damage die a mitotic rather than an apoptotic cell death.

The principal biological effect of radiation at tissue level is to inhibit cell proliferation thereby affecting dividing tumour cells rather than non-proliferating normal tissue cells. This results in tumour control, which equates with cure in some tumours, but only minimal damage of normal brain at conventional doses. The balance between tumour control and normal tissue damage is described as the therapeutic ratio. Maximum therapeutic ratio is achieved through exploiting biological differences between tumours and normal tissue (largely by fractionation) and by physically focusing high radiation doses to tumour while sparing surrounding normal brain.

In conventional external beam radiotherapy, radiation is usually given in the form of high energy X-rays (photons) generated by a linear accelerator or as gamma rays (also photons) from an external cobalt source. Radiation can also be delivered by insertion of small radioactive sources directly into a tumour and this is described as brachytherapy or interstitial radiotherapy. Electrons, generated by linear accelerators, are particularly useful for the treatment of superficial lesions and are rarely used for the treatment of CNS tumours. Cyclotron generated protons have been employed in the treatment of some deep-seated tumours but this technique is only available in a handful of centres worldwide.

Radiation sensitivity of tumours and tissues is defined by the ability of constituent cells to survive a given dose of radiation. This is measured in vitro with a clonogenic cell survival assay. The proportion of tumour cells surviving a dose of 2Gy is described as SF2 (surviving fractions of cells after radiation dose of 2Gy). Gliomas have relatively high SF2 while embryonal tumours, germ cell tumours and lymphomas have low SF2. While it is possible to increase tumour cell kill with higher doses per fraction, increased damage to tumour is usually associated with increased damage to normal tissue. The biological differences between radiation sensitivity of tumour cells and normal tissue are seen at lower doses and can be exploited by fractionation giving a number of repeated small doses over a period of time. The result is damage to tumour cells and recoverable damage to normal tissue therefore sparing the normal brain.

Conventional fractionation schedules for the treatment of intracranial tumours deliver radiation on a daily basis 5 days per week in 1.8–2Gy fractions over 6 weeks. Alternative

fractionation schedules which increase treatment intensity include accelerated and hyperfractionated schedules. Conversely, hypofractionated schedules (larger doses per fraction to lower total doses over a shorter time) generally deliver less intensive treatment usually for the purpose of palliation.

Within the central nervous system, the most sensitive normal tissues are oligodendroglia and vascular endothelial cells. The time to expression of damage is determined by the lifespan of the mature cells and ranges from months to years after irradiation. The severity of damage is related to the proportion of surviving cells and the consequent tissue viability and function. Small doses per fraction, adequate time interval between fractions allowing for cellular repair and total doses below tolerance of critical tissues minimize the damage to normal brain.

Pathological effects of radiation

There are three hypotheses to explain the mechanism of RT-induced damage to the CNS, which are not mutually exclusive. RT is most likely to be directly toxic to nervous system tissue, particularly the white matter and myelin-producing cells (oligodendrocytes and Schwann cells). It also damages vascular endothelium and leads to islands of endothelial proliferation, luminal occlusion and subsequent tissue ischemia and necrosis. Damage may also occur via a hypersensitivity reaction to intracellular contents released as a consequence of glial toxicity. This immune response in turn causes tissue necrosis and vascular damage. Experimental data in vivo suggests that both oligodendroglia and endothelial cells are targets of damage and the differential effect may be dose-dependent. Cellular damage with cytokine release may be responsible for further damage.

The tissue consequences of radiation injury range from histologically recognized and expressed necrosis to less well-defined encephalomalacia as well as minor functional deficit without obvious structural defect following lower radiation doses.

High doses of radiation beyond tolerance lead to necrosis largely confined to the white matter with damage to oligodendrocytes and endothelial cells. In the acute phase, radiation damage is expressed as hemorrhagic coagulation necrosis. Delayed radiation necrosis is characterized by fibrin exudation which may lead to either calcification or classical fibrinoid necrosis.

Necrotic lesions may commence as multiple foci, which later coalesce. The lesions are either resorbed by macrophages and evolve into cysts or remain as discreet white matter necrotic foci. Necrosis is commonly found within malignant gliomas and this is likely to represent the desired effect of radiation contributed to by inadequate blood supply to the tumour. It should not be considered a damaging consequence of radiation as seen in normal tissue.

Very high doses of radiation delivered by interstitial radiotherapy or radiosurgery (often in association with conventional high dose external beam radiotherapy) frequently cause localized necrosis as the doses used go well beyond the known radiation tolerance of the CNS.

The pathological features associated with late radiation effects, characterized by cognitive impairment and occasionally leading to dementia, are less well defined. White matter lesions predominate and include demyelination, white matter spongiosis and occasional small foci of necrosis. Children may develop mineralizing microangiopathy following low dose irradiation combined with chemotherapy. Radiation-induced vasculopathy may also be a contributing factor to late radiation effects.

Changes seen in the spinal cord following irradiation have been well described in experimental animals and mirror those seen in the brain. Excessive doses of radiation cause depletion of oligodendrocytes and damage to vascular endothelium leading to radiation necrosis. Radiation myelopathy expressed as progressive paraparesis is usually characterized by white matter atrophy and demyelination.

As can be seen, no part of the nervous system is immune from RT-induced damage. The nature, timing and severity of this damage is dependent on radiation-related factors including dose fractionation, total dose and target volume as well as host factors such as age, pre-existing systemic disease, particularly vasculopathy, and the use of concurrent chemotherapy.

Diagnosis of radiation damage to the nervous system

The development of neurological symptoms and signs in a patient should only be ascribed to the damaging effects of RT if the following conditions are met.

(i) The anatomy of the clinical signs corresponds to the radiation portals.
(ii) The dosage and fractionation are sufficient to damage that particular area of the nervous system.
(iii) The time elapsed between RT and the development of the neurological syndrome is compatible with the known effects of RT on the nervous system.
(iv) Tumour recurrence has been excluded, particularly in the brain where the clinical and radiological features of RT necrosis can be indistinguishable.

(v) Other differential diagnoses, e.g. intramedullary metastasis, paraneoplastic myelitis have been excluded.

Time course of RT-induced damage to the CNS

RT-induced damage to the brain and spinal cord is categorized according to the time at which the clinical syndrome is manifest into: (i) acute toxicity which occurs during RT; (ii) early-delayed toxicity which occurs within weeks of the completion of RT; (iii) late toxicity which occurs months to years following treatment.

As a general rule, acute and early-delayed toxicity are reversible and improve spontaneously or following the administration of corticosteroids, while late toxicity is largely irreversible. RT to the spinal cord is rarely associated with acute toxicity (Millburn et al., 1968; Tefft et al., 1969).

Specific syndromes

Acute brain toxicity

Acute toxicity is due to increasing brain edema caused by probable disruption of the blood–brain barrier and is rare with current dose fractionation protocols (1.8 to 2.0 Gy/day). It occurs most commonly in the presence of preexisting mass effect from a tumour that has not been debulked. The clinical manifestations are worsening focal deficit, fever and pressure symptoms of headache, drowsiness and vomiting. The syndrome responds to corticosteroids and, in rare instances where there is life-threatening raised intracranial pressure, mannitol may be helpful. It occurs more frequently following higher dose fractions. Acute toxicity has been reported in 50% of patients with brain metastases receiving 15 Gy in 2 fractions over 3 days (Young et al., 1974) and a large proportion of patients receiving a single fraction of 10 Gy (Hindo et al., 1970). Acute encephalopathy, responding to corticosteroids, has also been reported in children given low-dose cranial RT with concomitant intrathecal methotrexate as part of prophylaxis of meningeal leukemia (ALL) (Oliff et al., 1978).

Early-delayed brain toxicity

This usually occurs within 3 weeks to 3 months after the completion of RT and is postulated to be due to acute demyelination resulting from damage to oligodendrocytes. This may be due to either direct RT toxicity on myelin turnover or to the release of toxic radicals due to tumour cell lysis. In one patient who died 12 weeks after irradiation and 1 week after the onset of bulbar symptoms, postmortem examination of the brainstem revealed punched out areas of demyelination and perivenular inflammation that resembled the changes observed in acute multiple sclerosis (Lampert & Davis, 1964).

The most frequent manifestations are excessive fatigue and anorexia with occasional transient worsening or reappearance of a pre-existing deficit. In the immediate post-RT period it has been described as the somnolence syndrome (Faithfull & Brada, 1998). The symptoms peak 2 weeks and 6–8 weeks after RT and cause great concern because they may simulate tumour progression. The clinical deterioration occurs over several days to weeks and gradually resolves. In addition, transient tumour swelling following RT may exacerbate particularly focal symptoms. An awareness of this syndrome is important to avoid making therapeutic decisions regarding adjuvant chemotherapy within the first 2–3 months of RT (Hoffman et al., 1979). Imaging shows increased contrast enhancement and more pronounced surrounding edema, which resolve spontaneously, unlike the situation with tumour progression. The failure of the patient or scan to improve within 2 to 3 months of RT therefore does not necessarily imply treatment failure.

The somnolence syndrome was originally described following low dose (18–24 Gy) prophylactic whole brain irradiation (PCI) in childhood acute lymphoblastic leukemia (ALL) (Freeman et al., 1973; Littman et al., 1984). The incidence is 40–60% (Berg et al., 1983). The clinical features consist of headache, nausea, vomiting, anorexia and occasionally fever and papilledema. Investigations reveal diffuse slowing of brain activity on EEG, increased protein concentration and pleocytosis in CSF and white matter lesions characteristic of demyelination on MRI scanning. It usually resolves within 3 to 6 weeks and may be helped by a course of corticosteroids.

On rare occasions, patients develop a syndrome of bradykinesia, tremor and progressive cognitive decline within a few months of RT. This Parkinsonian state is characteristically dopa-resistant (Vigliani et al., 1999).

Imaging reveals cerebral atrophy, ventriculomegaly and white matter attenuation, which on postmortem examination is due to myelin loss and reactive astrocytosis (Asai et al., 1989). The development of a focal brainstem encephalopathy, characterized by ataxia, dysarthria, diplopia, has also been reported 8–11 weeks after high dose RT to extracranial structures. Most patients recover within 6 to 8 weeks, although it can be fatal.

Late brain toxicity

Late effects occur months to years after cranial RT and range from asymptomatic white matter signal change on MRI scanning to dementia, cerebrovascular disease, the development of second malignancies and radiation necrosis.

Radiation dementia

In a study of bone marrow transplant patients, subtle changes in brain volume were detectable one week after total body irradiation with a relatively small dose of 14.4Gy (Jager et al., 1996). This is an asymptomatic process but radiation encephalopathy, manifested by gradual intellectual decline and personality change, may progress to a full-blown dementia. In many patients treated with lower doses, memory loss is mild and non-progressive. Patients who progress to dementia may have initially mild impairment of recent memory, starting months to years after treatment. This is followed by gradual disorientation, progressive gait ataxia and urinary incontinence. The physical signs are variable but the patient is usually dysarthric, apraxic and has brisk reflexes with extensor plantar responses. CT/MRI scanning reveals generalized atrophy with ventricular enlargement and confluent subcortical white matter changes.

Cranial irradiation in children is associated with late cognitive impairment and the incidence and severity are related to age at the time of irradiation, RT volume and dose. Very young children are at greater risk (less than 4 years) as the CNS is still in an anatomically and functionally immature state.

A necrotizing leukoencephalopathy is seen in up to 15% of children receiving combined RT and methotrexate for ALL (Fig. 91.1) and in adults with primary CNS lymphoma treated with combined regimens where there is a short interval between chemotherapy and RT. Very delayed encephalopathy occurring decades after treatment has also been described (Duffey et al., 1996).

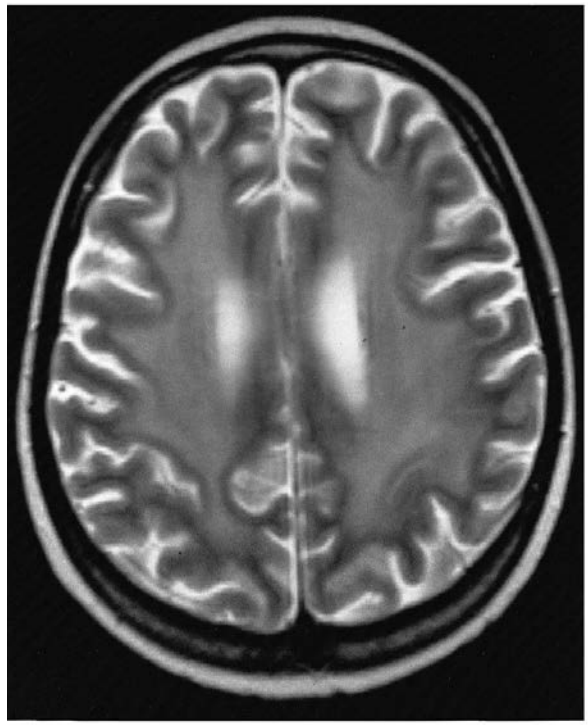

Fig. 91.1. Axial T2W MRI brain showing radiation leukoencephalopathy and generalized cortical atrophy. 19-year-old girl with Philadelphia positive ALL post bone marrow transplant (matched unrelated donor) who had received whole brain RT as part of the conditioning protocol and subsequently methotrexate. She presented with a 3-month history of personality change, withdrawal, perserveration, incontinence and abulia, and the MRI scan showed confluent high signal change throughout subcortical white matter. She died 2 weeks later.

Radiation necrosis

Delayed radiation necrosis is a recognized complication of treatment for primary brain tumours as well as extracranial tumours, particularly nasopharyngeal carcinoma where high dose radiation may lead to temporal lobe necrosis (Lee et al., 1998). It presents insidiously with headache, confusion, focal deficits and seizures several months to years following treatment. It is an uncommon complication of conventional localized external beam radiotherapy, occurring in 3–5% of patients receiving 50 Gy and 5–15% of patients receiving 60 Gy at ≤2 Gy per fraction. Small increments above 60 Gy are associated with an increased likelihood of necrosis. Clinical studies of the incidence of necrosis at different dosages have established the basis for standard RT for intracranial tumours. Benign or low-grade tumours receive ≤ 55 Gy in 30 fractions which carries virtually no risk of radionecrosis while malignant gliomas receive 55–60 Gy in 30 fractions, which is associated with a 3% risk of necrosis.

Radiation necrosis is currently seen more commonly in patients with malignant brain tumours treated with high dose focal treatments such as stereotactic radiosurgery and interstitial RT. High localized doses are given either as a radiation boost with the aim of improving local tumour control or at the time of recurrence. While high precision localized treatment techniques are postulated to avoid

damage to healthy tissue, there is almost invariably some normal brain within the high dose region. Radiation necrosis is also recognized following single fraction radiosurgery for AVMs (Brada & Kitchen, 2000) and for benign tumours and the frequency is volume and dose dependent.

In brain tumour patients, the appearances of radiation necrosis on CT/MRI scanning may be indistinguishable from recurrent tumour demonstrating an irregularly enhancing mass lesion with surrounding edema. Although FDG-PET scanning (DiChiro et al., 1988) and Magnetic Resonance Spectroscopy (Chong et al., 1999; Chan et al., 1999); may help to distinguish necrosis from tumour recurrence, the only sure way of making a diagnosis is by surgical biopsy. Treatment is by excision of necrotic material which shows hyalinization and fibrinoid necrosis together with demyelination and axonal loss. Steroids are only of temporary benefit. Hyperbaric oxygen therapy (Chuba et al., 1997) and anticoagulation (Glantz et al., 1994) are currently under investigation as a potential therapy.

Mineralizing microangiopathy

This usually occurs in children following PCI for ALL and is diagnosed by the presence of basal ganglia calcification and presents with headache, seizures, behavioural changes and ataxia. Histopathologically the small vessels are occluded by calcium deposits with the surrounding brain being mineralized and necrotic (Price & Birdwell, 1978).

Vascular disease

Radiation may affect vessels of any size. Small vessel occlusion is a component of radiation necrosis. Larger vessels may be occluded by an arteriosclerotic type occlusion. Vessel wall damage may lead to aneurysms. The pathology of large vessel stenosis and occlusion includes accelerated atherosclerosis, thought to be mediated by endothelial damage and necrotizing vasculitis of the vasa vasorum leading to ischemic lesions within the vessel wall (Zidar et al., 1997). Clinically, patients are usually younger than those with spontaneous atherosclerosis, do not have coexisting vascular disease in other circulations, and may have multiple lesions within the intracranial and extracranial vessels. The angiographic features of a RT-induced large vessel stenosis are variable. There may be a smooth, tapering occlusion, accelerated atherosclerosis with extensive plaque formation or a focal severe stenosis (Fig. 91.2). In cases of slowly progressive vascular occlusive disease, there is time for the development of a collateral circulation in a stenosed artery, giving rise to moyamoya disease. This has been reported particularly in children who had radiotherapy for optic nerve or hypothalamic gliomas (Beyer et al., 1986). In adults, the clinical picture is usually a thrombotic occlusion causing a stroke, which may be heralded by TIAs. This occurs after neck irradiation for lymphoma or head and neck tumours, particularly in the presence of hyperlipidemia, hypertension and pre-existing vascular disease. Increased incidence of CVA has also been reported in patients with pituitary adenoma (Rosen & Bengtsson, 1990). Although the etiology is multifactorial, radiation is likely to be one of the causative factors (Brada et al., 1999). Treatment is empirical and consists of the same medical and surgical options as in spontaneous atherosclerotic cerebrovascular disease. The role of antiplatelet agents and anticoagulants is uncertain both in treatment and prophylaxis.

Fig. 91.2. MR angiogram of extracranial carotids showing focal severe stenosis of the left internal carotid artery. 59-year-old woman with left amaurosis fugax and loud left carotid bruit. She had received radiotherapy to her neck 25 years previously for metastatic tongue cancer. She also had a left brachial neuropathy.

Radiation-induced malignancies of the central and peripheral nervous systems

Radiation is recognized to be associated with increased risk of second malignancy and this has been described following systemic as well as cranial irradiation. Radiation for non-neoplastic conditions and benign tumours should therefore be used with considerable caution. The commonest RT-induced tumours include meningiomas, gliomas, cranial osteosarcomas, soft tissue sarcomas, schwannomas and peripheral nerve sheath tumours (PNSTs). They have been described following RT for tinea capitis (Ron et al., 1988), PCI for ALL (Neglia et al., 1991) and RT for pituitary adenoma (Brada et al., 1992).

Second tumours tend to lie within the radiation field, usually within lower dose regions and develop from a few years to many decades after irradiation. The reported median time to the development of gliomas is 7 years. Sarcomas develop with a longer lag time and meningiomas may be seen 30 or 40 years later. The histology is identical to spontaneous tumours although meningiomas are more likely to contain atypical features and have a worse prognosis. The treatment is the same as spontaneously occurring tumours and depends on a good histological examination. RT-induced meningiomas should be completely excised where possible, and adjuvant radiotherapy given only if it can be safely administered taking into consideration previous radiotherapy.

Cranial neuropathies

The cranial nerves are considered more resistant to RT than brain parenchyma and are rarely damaged by conventional irradiation. Transient anosmia and dysgeusia are well recognized and usually recover. The commonest cranial neuropathy, albeit rare, is optic neuropathy seen in patients treated for pituitary adenomas, craniopharyngiomas and nasopharyngeal tumours. It is characterized by painless monocular or bilateral visual loss, associated with an altitudinal field defect. The optic disc is usually normal, but may be swollen with telangectasiae and peripapillary and macular hemorrhages, cotton-wool spots and attenuation of the retinal arterioles. The condition is usually irreversible although steroids should be tried. Following pituitary irradiation to 45 Gy at $\leq$1.8 Gy per fraction the incidence is 1–2% (Brada et al., 1993). The likelihood of visual loss is increased by concomitant diabetes, previous tumour compression or chemotherapy and is particularly high following single fraction radiosurgery (Leber et al., 1998). Stereotactic radiosurgery may cause abrupt visual loss with swelling and enhancement of the optic nerves on MRI scanning (Girkin et al., 1997).

There is no specific treatment for radiation optic neuropathy, although it is important to exclude other causes such as arteritic ischemic optic neuropathy which may present in a similar way and respond to corticosteroids.

Other cranial nerves are less frequently affected. Facial and trigeminal neuropathy occur in patients with acoustic neuromas treated with single fraction stereotactic radiosurgery. (Miller et al., 1999; Flickinger et al., 1996). Permanent sixth nerve palsies have been noted after re-irradiation for nasopharyngeal carcinoma and lower cranial nerves may be damaged by high dose RT for head and neck tumours.

RT-induced spinal cord damage

Spinal cord damage following therapeutic radiation which includes the spinal cord follows the same pattern as radiation-induced brain damage with acute, early delayed and late syndromes. The most devastating is late radiation myelopathy, which is an uncommon complication of RT usually seen after treatment of paraspinal tumours. Unlike radiation encephalopathy it is not usually complicated by the presence of a spinal cord tumour. Patients with epidural spinal cord compression who deteriorate during RT either have progressive disease or suffer vascular occlusion from persistent or progressive tumour. However there have been reports of a fatal acute myelopathy following accidental local radiation overdose associated with a normal MRI scan in the acute phase despite neurological deficits (Alfonso et al., 1997).

Early-delayed myelopathy

As with early-delayed brain toxicity, a transient benign myelopathy occurs three to five months after radiotherapy to the spinal cord. The common clinical situations in which this occurs are mantle radiotherapy for Hodgkin's disease when the cervical or thoracic cord is included within the radiation portals and following head and neck and lung cancer irradiation. It has been reported in up to 15% of Hodgkin's disease patients (Word et al., 1980) and the incidence increases with radiation dose. The patient describes electric shock like sensations in the trunk and limbs, mainly provoked by neck flexion (Lhermitte's sign).

On the basis of circumstantial evidence (no postmortem data exist), it is thought that spontaneous discharges are generated by demyelinated sensory axons in the posterior

columns. The symptoms tend to resolve within a year, although some patients may continue to complain for years. There is no evidence that early-delayed myelopathy predisposes to a late-delayed myelopathy.

Late-delayed myelopathy

Delayed radiation myelopathy is slowly progressive and usually starts 1–4 years after RT. The main risk factors are older age and dose/fractionation parameters. The initial symptoms are sensory and usually start as a hemicord Brown–Séquard syndrome with paresthesiae and weakness in one leg and spinothalamic sensory loss in the other. Pain is uncommon. There is a distal to proximal progression up to the level of the irradiated segment and this eventually progresses to paraplegia or tetraplegia due to a complete 'transverse lesion' of the cord. Abrupt aggravation of symptoms and periods of temporary stabilization are common (Dynes & Smedal, 1960). Spontaneous remissions or recovery have not been described. The diagnosis is usually made after MRI scanning has excluded intramedullary or epidural tumour. Very rarely, patients can present with a subacute necrotic myelopathy as a paraneoplastic neurological syndrome, but this is an unlikely diagnosis as it usually presents before the cancer is diagnosed (Ojeda, 1984). CSF examination is usually normal or shows a high protein concentration. The MRI scan may show cord swelling acutely and occasionally complete spinal block with contrast enhancement but in the later stages the cord is atrophic and non-enhancing. Once the diagnosis is made, it is worthwhile treating with corticosteroids as remissions have been described (Godwin-Austen et al., 1975).

The pathological changes are centred on the white matter tracts with confluent areas of necrosis followed by fibrinoid necrosis and luminal occlusion in blood vessels. Areas of demyelination may be seen below the irradiated part of the cord, not associated with vascular changes, suggesting that vascular and glial damage occur independently (Schultheiss et al., 1988). Abnormal blood vessels are found only within the beam of radiation.

Lower motor neuron syndrome

A pure motor syndrome has been described following pelvic RT for testicular tumours (Fossa et al., 1969) and Hodgkin's disease (DeGreve et al., 1984). It is without sensory or sphincter disturbance and, as its name implies, is characterized by atrophy, fasciculations and areflexia confined to the lower limbs. It may remain restricted to one leg. The course is usually subacute and progressive followed by periods of stabilization with sufficient strength to maintain ambulation. The EMG shows denervation but normal motor conduction suggesting an anterior horn cell disease. The CSF protein concentration is elevated but is otherwise unremarkable as are imaging studies. The main differential diagnoses include subacute motor neuronopathy, a paraneoplastic neurological syndrome associated with non-Hodgkin's lymphoma (Schold et al., 1980), an isolated monomelic motor neuropathy or motor neuron disease.

Radiation-induced plexopathy

The major sites of peripheral nerve damage are the brachial plexus, after treatment for breast or lung cancer and the lumbosacral plexus after treatment for pelvic and lower abdominal malignancies. Most cases are late-delayed but early-delayed reversible reactions have been described (Salner et al., 1981; Enevoldson et al., 1992).

Brachial plexopathy following RT for breast cancer is a common clinical problem and the differential diagnosis lies between radiation-induced injury and neoplastic infiltration. There are no absolute criteria which can distinguish one from the other although tumour infiltration is more frequently characterized by severe and persistent pain. Other useful pointers towards a RT plexopathy are the rarity of an associated Horner's syndrome, the presence of paresthesiae as a predominant symptom and fasciculations or myokymia on the EMG (Lederman & Wilbourn, 1984). Similarly, in patients with lumbosacral plexopathy, slowly progressive weakness was usually the initial symptom of RT-induced plexopathy while pain marked the onset of tumour infiltration (Thomas et al., 1985). Radiation cases almost all went on to develop bilateral weakness while tumour patients typically had painful unilateral weakness. CT or MRI scanning is essential to exclude recurrent tumour and in cases with equivocal imaging surgical exploration may be necessary.

In conclusion, radiation is an important and effective treatment modality in the management of systemic and intracranial malignancies. Its use is associated with a recognized set of radiation-induced side effects. Modern radiation therapy offers treatment to the levels of radiation tolerance of the brain and spinal cord associated with a small risk of complications. In some circumstances higher doses of irradiation and shorter fractionations are used. This is possible either with localized irradiation techniques which minimize the dose to normal brain or with increasing doses

aimed at improving tumour control with an accepted increased risk of toxicity. While radiation is relatively safe, it is not devoid of side effects and these require recognition and appropriate management. Attempts are also being made to define the genetic predisposing factors, which may predict higher risk of damage to allow for individual tailoring of radiation doses.

Immune mechanisms in neurological disease

Hans-Peter Hartung,[1] Klaus V. Toyka[2] and Bernd C. Kieseier[1]

[1] Department of Neurology, Heinrich-Heine-University, Düsseldorf, Germany
[2] Department of Neurology, Julius-Maximilians-University, Würzburg, Germany

The following chapter reviews principles of immunology to provide an understanding of how components of the nervous system are recognized by the immune system, how an autoimmune response is mounted, how immune cells and mediators enter the nervous tissue, and how tolerance against neural antigens is induced, maintained, and broken. Most of the general principles have been discovered since the 1980s but only with the new technology of targeted deletions and mutations (permanent and conditional knockout, knockin) can these principles be systematically explored at the molecular level. A brief discussion of multiple sclerosis, the Guillain–Barré syndrome, and myasthenia gravis will follow, while clinical aspects and disease-specific pathomechanisms of immune-mediated neurological disorders are presented in greater detail in individual chapters. Therapeutic consequences based on immunological principles are discussed in Chapter 93.

Categories of the immune response

The immune system is a multifaceted system of cells and molecules with specialized tasks in defending the organism from external agents, infectious or toxic. Moreover, the immune system plays a pivotal role in maintaining antigenic homeostasis in the body. Two types of responses to invading organisms can take place: an acute response launched within hours, and a delayed response occurring within days. The immediately responding system is termed innate immune system, and it evolves stereotypically and at the same magnitude regardless how often the infectious agent is encountered. In contrast, a more delayed response is delivered by the adaptive or acquired immune system and provides a more specific immunologic reaction which improves in efficiency on repeated exposure to a given infective agent, capitalizing on the formation of immunological memory. The immune system has traditionally been divided into innate and adaptive systems, each containing different cellular and molecular components. The main distinction between these two systems lies in the mechanisms and receptors used for immune recognition. These two systems are not separated, but are functionally connected allowing for intensive interactions (Carroll & Prodeus, 1998; Ochsenbein & Zinkernagel, 2000).

The innate immune system

During evolution, the innate immune system appeared before the adaptive immune system, and some form of innate immunity probably exists in all multicellular organisms. Characteristically, innate immune responses consist of all the immune defence mechanisms that do not require immunologic memory. Genetically, the molecular mediators and their receptors are highly conserved between species as far apart as *Caenorhabditis elegans*, *Drosophila*, and mammals.

The strategy of the innate immune response may not be to recognize every possible antigen, but rather to focus on a few highly conserved structures present in large groups of microorganisms. These structures are referred to as pathogen-associated molecular patterns, and the corresponding receptors of the innate immune system are called pattern-recognition receptors (Janeway, 1992). Examples of pathogen-associated molecular patterns are bacterial lipopolysaccharide, peptidoglycan, and bacterial DNA. Although chemically quite distinct, these molecules share common features: they are only produced by microbial pathogens, and not by their host, they represent in general invariant structures shared by large classes of pathogens, and they are usually relevant for the survival or pathogenicity of microorganisms (Medzhitov & Janeway, 2000).

Pattern-recognition receptors are encoded in the germ line, thus their specificity is genetically predetermined, evolved by natural selection. Structurally, these receptors belong to several families, and functionally they can be differentiated into three classes: secreted, endocytic, and signalling (Fearon & Locksley, 1996). They are expressed on many effector cells of the innate immune system, most importantly on macrophages, dendritic cells, and B-lymphocytes: all professional antigen-presenting cells. The total number of receptors involved in the innate immune response is thought to be in the hundreds, in contrast to the approximately 10^{15} somatically generated immunoglobulin and T-cell receptors of the adaptive immune response.

Once the pathogen-associated molecular pattern has been identified by a receptor, immediately signal transduction pathways are activated within the effector cell to induce the expression of various immune-response genes, such as costimulatory signals, inflammatory cytokines and chemokines. The effector cell is triggered to generate an immediate immune response rather than to proliferate, which accounts for the rapid kinetics of the innate immune system. The response of the innate immune system results in the recruitment and activation of antigen-specific lymphocytes and the subsequent initiation of adaptive immune responses, in concert with circulating antibodies and complement.

The adaptive immune system

The adaptive immune response is based on two classes of highly specialized cells, T- and B-lymphocytes. Each of these cells expresses a single kind of structurally unique receptor, resulting in a broad and extremely diverse repertoire of antigen recognition.

Both B- and T-lymphocytes are derived from primordial stem cells in primary lymphoid tissues such as bone marrow and fetal liver. Their development is guided by interactions with stromal cells, such as fibroblasts, and cytokines, including various colony-stimulating factors. However, the early phase of lymphocyte development is not dependent on the presence of any antigen, but once these cells express a mature antigen receptor, their further differentiation and survival becomes antigen dependent.

B-lymphocytes

The development of B-lymphocytes is characterized by successive steps in the somatic rearrangement and expression of immunoglobulin genes, and by changes in the expression of cell surface and intracellular molecules. In the bone marrow B-cell development proceeds in the absence of an antigen until a complete IgM molecule is expressed on the surface of the cell, which is defined as an immature B-cell. This cell population is subject to selection for self-tolerance and ability to survive in the periphery, a complex regulatory mechanism still not fully elucidated. After this selection, immature B-cells enter the periphery and access lymphoid follicles. The surviving cells form part of the long-lived pool of mature peripheral B-cells. These lymphocytes, coexpressing IgM and IgD, recirculate through the lymphoid organs, until they encounter their specific antigen. Once the immunoglobulin receptor on the B-cell surface interacts with a specific antigen, the B-cell will be activated. This process requires a series of additional stimulatory signals besides the direct contact between antigen and B-cell receptor. Some antigens, such as bacterial lipopolysaccharides can stimulate B-cells directly, and therefore are termed Type 1 T-cell-independent antigens. Type 2 T-cell-independent antigens containing repeating epitopes that cross-link B-cell antigen receptors similarly do not require cognate T-cell help but other soluble factors or cellular interactions to trigger B-cell mitogenesis. In contrast, most proteins and peptides depend on additional signals provided by T-helper cells, and are called T-cell-dependent antigens. After antigen recognition the B-cell is activated to divide. Selected B-cells will differentiate into plasma cells, which secrete large amounts of immunoglobulins, or into long-lived memory cells, which contribute to lasting protective immunity.

Besides synthesizing specific antibodies, B-lymphocytes are capable of binding, internalizing, and digesting antigen, and can re-express the digested protein fragments on their cell surface in the context of major histocompatibility complex (MHC) proteins. As such, B-cells can act as specific antigen-presenting cells as well.

B-cell receptor and soluble antibodies

The unique feature of B-lymphocytes is their ability to express and secrete antibodies. Antibodies or immunoglobulins consist of two identical heavy chains and two identical light chains that are held together by disulfide bonds. The N-terminal of each chain possesses a variable domain that binds antigen through three hypervariable complementarity-determining regions. The C-terminal domains of the heavy and the light chains form the constant regions, which define the class and subclass of the antibody and govern whether the light chain is of the κ or

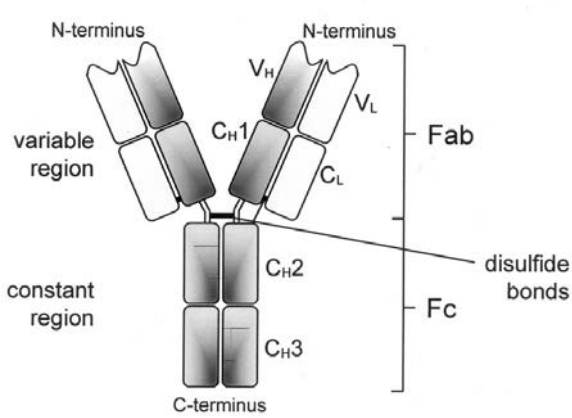

Fig. 92.1. Basic structure of an immunoglobulin molecule. Each immunoglobulin molecule consists of two heavy and two light chains, linked by disulfide bonds. The amino-terminal domain of each chain is variable in sequence (Fab fragment), whereas the remaining domains are constant (Fc fragment). Antibodies recognize conformational epitopes via the Fab fragment whereas the Fc fragment mediates binding to Fc receptors on immunoinflammatory cells and activates the classical complement pathway.

λ type (see Fig. 92.1). Five different classes of antibodies (IgD, IgM, IgG, IgA and IgE), four subclasses of IgG, and two subclasses of IgA are known, each of which exhibiting different functional properties (see Table 92.1). Each type of antibody can be produced as a soluble circulating immunoglobulin molecule or as a cell surface molecule anchored through a transmembrane domain in the B-cell membrane, where it acts as the B-cell receptor.

Most resting B-lymphocytes express IgD and IgM molecules on their surface. The antigen response starts with binding of the antigen to IgM-expressing B-cells resulting in the production of antibodies of the same specificity. After antigen contact, class switching will occur and most B-cells will produce IgG immunoglobulins. During a secondary response to the same antigen, a relative increase in IgG is observed. Depending on their environment, some B-cells will synthesize IgA (preferentially in the gut) or IgE (especially in the lung and the skin). The determinants of class switching are not completely understood.

Antibody genes continually change as B-cells encounter antigen and proliferate. Certain portions of the hypervariable regions are active sites of mutations, resulting in a continuous change of the antibody repertoire. Besides the increase in number of antibodies secreted, the affinity of individual antibodies against the stimulating antigen will increase over time, as B-cells expressing higher-affinity receptors on their surface are selectively activated. Moreover, the total binding force for antigens during this maturational process is termed antibody avidity. This process increases both the efficiency and the specificity of the immune response. A distinctive minor subset of B-cells termed B-1 cells, many of which carry the CD5 antigen, express a more limited V gene repertoire. They spontaneously secrete IgM antibodies that frequently bind microbial polysaccharides and some self antigens (Ochsenbein & Zinkernagel, 2000). These so-called natural autoantibodies may gain pathogenic significance if polyclonal activation raises their concentrations above the normal low levels. $CD5^+$ B-cell-derived IgM antibodies have been implicated in the pathogenesis of autoimmune neuropathies (Gold et al., 1999).

In various immune-mediated neurological diseases the entire functional spectrum of antibody responses can be observed. For example, in multiple sclerosis antibody

binding to the myelin sheath results in complement activation and, consequently, tissue destruction (Storch et al., 1998). In other diseases, such as myasthenia gravis or the Guillain–Barré syndrome and its Miller–Fisher variant, a direct blocking effect of antibodies on nerve conduction or neuromuscular transmission has been demonstrated (Buchwald et al., 1998, 2001; Drachman et al., 1982). Other mechanisms of humoral immunity are also involved in the pathogenesis of neuroimmunological diseases. The recognition of antibody-coated peptides by accessory effector cells triggers the activation of macrophages resulting in the release of inflammatory mediators in the surrounding tissue, thus perpetuating local inflammation. Moreover, antibodies binding to target antigens can activate, via Fc receptors, a toxic programme called antibody-dependent cell-mediated cytotoxicity (ADCC), directing an antigen-specific attack by an effector cell through the cellular release of cytoplasmic granules containing granzymes or perforins. Such mechanisms are critically involved, e.g. in the Guillain–Barré syndrome (Archelos & Hartung, 2000).

Antibodies may form immune complexes when binding circulating or tissue antigens. These can ignite complement and Fc receptor-dependent pathways of tissue damage. Immune complex-induced injury has been implicated in the pathogenesis of the vasculitides.

Major histocompatibility complex

The task of displaying the antigens of cell-associated microbes for recognition by T-lymphocytes is performed by specific molecules that are encoded by genes comprising the major histocompatibility complex (MHC). The physiological function of MHC molecules is the presentation of peptides to T-cells. Two types of MHC gene products can be distinguished, class I MHC molecules and class II MHC molecules, which differ functionally. Each MHC molecule consists of an extracellular peptide-binding cleft, or groove, and a pair of immunoglobulin-like domains, containing binding sites for the T-cell surface markers CD4 and CD8. By transmembrane domains MHC molecules are anchored to the cell surface. MHC molecules exhibit a broad specificity for peptide binding, whereas the fine specificity of antigen recognition resides in large parts in the T-cell receptor. Peptides from the cytosol are expressed by MHC class I molecules and presented to $CD8^+$ T-cells, whereas peptides generated in vesicles are bound to MHC class II molecules and recognized by $CD4^+$ T-lymphocytes. The two classes of MHC molecules are expressed differentially on cells. All nucleated cells exhibit MHC class I molecules, although hematopoietic cells express them at highest densities. MHC class II molecules, in contrast, are normally only expressed on professional antigen-presenting cells, such as macrophages, dendritic cells, and B-lymphocytes. The levels of both class I and II molecules can be markedly upregulated by cytokines, in particular IFNγ and TNFα.

A separate lineage of antigen-presenting molecules, structurally akin to MHC class I gene products, are the *CD1* molecules. They represent a class of related receptors, expressed by thymocytes, dendritic cells, and some B-lymphocytes, and are involved in the presentation of non-peptide (lipid and glycolipid) bacterial antigens to some T-cells (Schaible & Kaufmann, 2000).

T-lymphocytes

Cells destined to become T-cells, so-called *prothymocytes*, continuously migrate from the bone marrow to the thymus, where they develop into T-lymphocytes within the given microenvironment (Kruisbeek, 1999) and are subjected to a series of selection procedures (Anderson et al., 1996). Whereas antibodies detect an antigen in its native confirmational state, the T-cell receptor (of the α/β type) recognizes only short linear peptide fragments in the context of MHC molecules on the cell surface. Thus, part of the T-cell receptor recognizes the foreign peptide, and part of it recognizes the self MHC molecule. Only a minority of T-cells are able to perform this task, and a rigorous process of selection is necessary to determine those T-cells which can form the pool of lymphocytes to be exported from the thymus. This process is called thymic education and involves both positive and negative selection (Rathmell & Thompson, 1999; Sakaguchi, 2001; Sebzda et al., 1999). T-cells that do not recognize self-MHC molecules need to be eliminated, whereas those cells that have various affinities for binding self-MHC molecules are positively selected. However, many of these cells exhibit a high affinity to self-antigens, which makes them potentially harmful. Therefore they are eliminated as well (clonal deletion). As a result of the selective processes, more than 90% of T-cells in the thymus die, usually through apoptosis.

During thymic education the expression of various T-cell surface molecules is induced. Of specific interest is the expression of the surface molecules CD4 and CD8.

$CD4^+$ T-cells usually act as helper T-(T_H) cells and recognize preferentially extracellular peptide antigens presented by MHC class II molecules, whereas $CD8^+$ T-cells are usually cytotoxic and recognize cytosolic antigens presented by MHC class I molecules (see Fig. 92.2). The latter are expressed on all nucleated cells. Thus any infected cell can signal to $CD8^+$ T-cell and be destroyed, removing sites of pathogen replication. MHC class II molecules are expressed on the surface of professional antigen present-

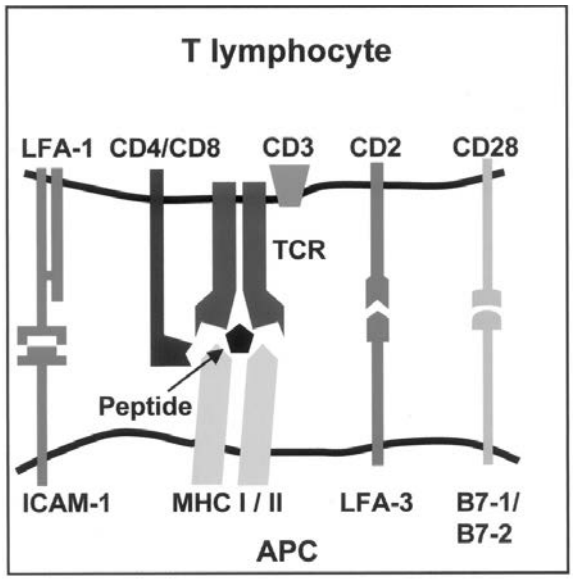

Fig. 92.2. Trimolecular complex. T-cell activation requires cognate dual recognition of peptide-MHC complex and costimulatory molecules displayed on antigen-presenting cells (APCs). T-cell–APC interaction is further strengthened by reciprocal recognition of accessory molecules.

ing cells only. Once a naive $CD4^+$ T-lymphocyte encounters a specific antigen on the surface of a professional antigen-presenting cell in the context of costimulatory molecules, such as CD80 or CD86, it gets activated, proliferates and differentiates into an armed effector T_H-lymphocyte (Abbas & Sharpe, 1999). Recently, a new serial encounter model of antigen recognition invokes a dynamic physical contact with T-cells literally crawling over and scanning the surface of multiple APCs (Friedel & Gunzer, 2001).

Three types of such effector T_H-cells can be distinguished: T_H1-cells manufacturing effector molecules that activate macrophages and T_H2-cells generating B-cell activating effector molecules. The third group, so-called T_H0-cells, from which both these functional classes derive also secrete molecules of both spectrums and may therefore have a distinct effector function (see Fig. 92.3). IFN-γ is the signature cytokine of T_H1-cells, which primarily act in phagocyte-mediated defence against infections, activated by macrophages or dendritic cells. In contrast, T_H2 populations produce IL-4 and IL-5 in response to helminthes and their principal effector functions can be seen in IgE and eosinophil/mast cell-mediated immune reactions. Thus, effector T-cells are critically involved in executing effector

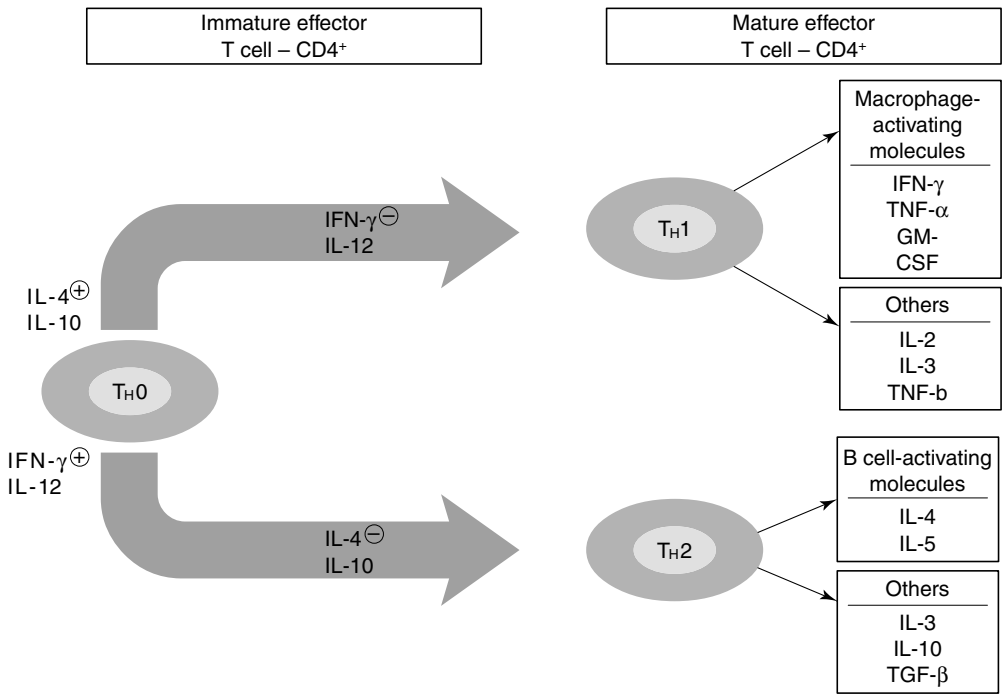

Fig. 92.3. T-cell activation. Once a naive CD4+ T-cells encounters its specific antigenic epitope displayed in the context of MHC class II gene products and sufficient levels of costimulatory molecules on an appropriate antigen-presenting cell, it starts to proliferate and differentiates into an immature effector cell, termed T_H0. This cell type carries the potential to become either a T_H1- or a T_H2-cell, which differ in their spectrum of cytokine production.

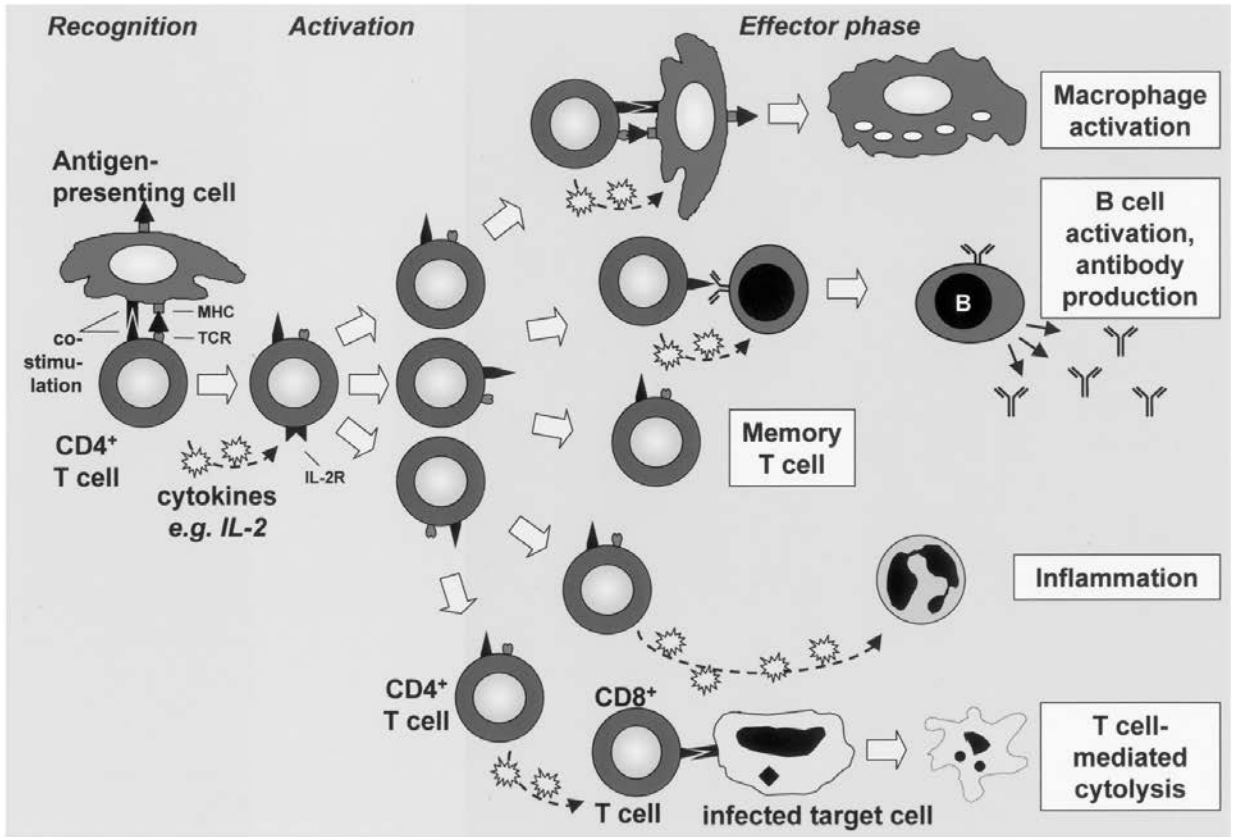

Fig. 92.4. The different stages of T-cell responses. T-cell activation first requires contact with processed antigenic epitopes associated with MHC class II molecules displayed on antigen-presenting cells and perception of additional costimulatory molecules. Up-regulation of IL-2 receptors (IL-2R) occurs and IL-2 drives T-cells into clonal proliferation during the activation stage. The effector stage is diverse. Multiple pathways lead to activation of macrophages and B cells. CD8 cells cause MHC class I restricted target cell lysis. CD4-driven responses can culminate in inflammatory tissue injury.

functions of the adaptive immune response (see Fig. 92.4). The cytokines produced by the individual subclass of T_H-cells not only determine their effector function but also regulate the development and expansion of the respective subset. For example, IFN-γ, produced by T_H1-cells, promotes further T_H1 differentiation and inhibits the proliferation of T_H2-cells. On the other hand IL-4, secreted by T_H2-lymphocytes, promotes T_H2 differentiation, whereas IL-10, also produced by T_H2-cells, inhibits activation of T_H1-lymphocytes. Thus, each T_H subset amplifies itself and down-regulates the reciprocal subset. Other factors, besides cytokines, affecting the development of T_H-cells are the avidity of MHC–peptide–TCR interaction, which is dependent on the type of antigen-presenting cell involved, the dose of the antigen, the affinity of peptide–MHC interaction, and on costimulatory molecules. Moreover, genetic factors appear to also modulate this process.

CD8 T-lymphocytes are instrumental in launching cytotoxic attacks on targets. They destroy them primarily by the release of cytotoxic granules, perforin and granzymes. A second mechanism of delivering a lethal hit, though in all likelihood more commonly utilized by a small proportion of CD4 cytolytic T-cells, involves up-regulated expression of Fas ligand and its interaction with Fas (CD95) exhibited on the recognized target (Suda et al., 1993).

T-cell receptor

Unlike antibodies, T-cell receptors are produced as transmembrane molecules only. They are composed as heterodimers and consist of an α- and a β- or a γ- and a δ-chain. Each chain contains a variable and constant domain. Similar to the immunoglobulins, the variable domains contain three complementarity-determining regions (CDR) (see Fig. 92.5). In the case of the α/β T-cell receptor these regions recognize a complex formed by a peptide seated within the groove of an MHC molecule. In contrast, most γ/δ T-cells do not recognize antigen in the form of

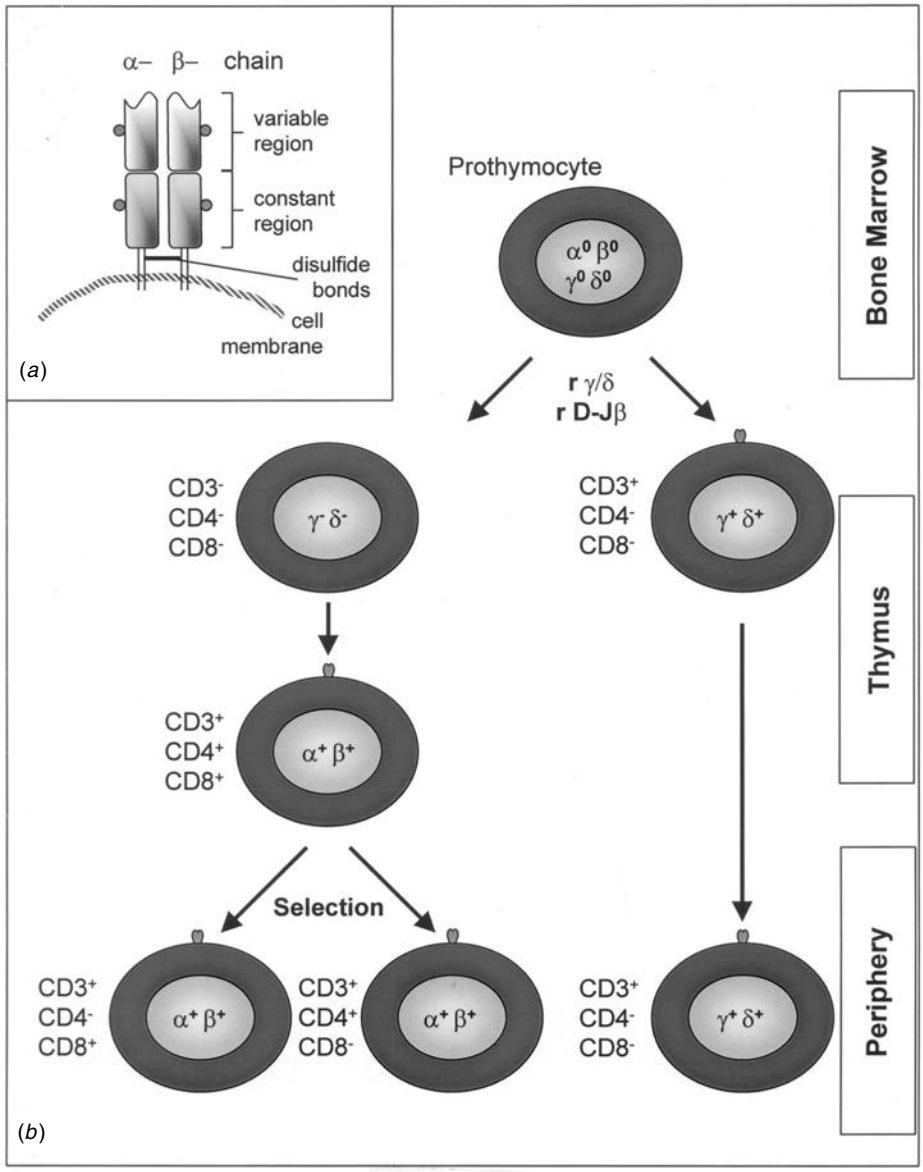

Fig. 92.5. Structure of the T-cell receptor and its distribution during T-cell development. The T cell receptor, expressed on the cellular surface only, is a heterodimer composed of two transmembrane glycoprotein chains, the α- and the β-chain. Both consist of a variable and a constant domain, and carry carbohydrate side chains. An alternative type of T-cell receptor is made up of different polypeptides designated γ and δ. During T-cell development various types of T-cells are selected.

peptide–MHC complexes. The antigen specificity of the T-cell receptor is determined by certain amphipathic amino acids in the antigen-binding cleft of the receptor. However, various different peptides can bind to the same T-cell receptor, and various T-cell receptors, produced by different genes, can exhibit similar peptide-binding capabilities ('degenerate' or 'promiscuous' antigen recognition) (Eisen, 2001; Hemmer et al., 1998). Thus, antigen specificity is not predictable on the basis of gene family expression. In contrast to the B-cell receptor, no further recombination or diversification of the T-cell receptor repertoire occurs once T-cells have matured. Paradoxically, the actual diversity of expressed γ/δ T-cell receptor is very limited, for unknown reasons. Functions of the γ/δ T-cells and molecular targets of γ/δ T-cell receptor recognition remain largely unresolved. One hypothesis holds that γ/δ T-cells are specialized to recognize antigens frequently encountered at epithelial boundaries (Hayday, 2000).

How does the immune system achieve the diversity of the antigen receptor repertoire? It has been estimated that

lymphocytes are capable of producing around 10^{15} different T-cell receptor variable regions and a similar number of antibody variable regions. Notably, this diversity is based on less than 400 different genes. Thus, multiple recombination processes that cut, splice, and modify the variable-region genes provide the large diversity of the B- and T-cell receptor repertoires (Tonegawa, 1983). The random generation of such a highly diverse repertoire of antigen receptors allows the adaptive immune system to recognize virtually any antigen. The price of this diversity, however, is the potential inability to distinguish foreign antigens from self antigens.

Binding of the antigen-specific T-cell receptor and either the CD4 or CD8 coreceptors to peptide–MHC complexes triggers an internal programme activating the effector T-cell (Bromley et al., 2001). The signalling events and functional consequences of T-cell antigen recognition may be altered by changing some of the T-cell receptor contact residues of a peptide antigen. Peptides eliciting responses different from those to native peptide ligands are termed altered peptide ligands (APL). They may be important in the regulation of T-cell activation in physiological or pathological situations. The T-cell response elicited by these peptides can induce only partial activation, while some APLs even deliver negative signals to the cell that inhibit their responses. Thus, APLs represent a mechanism by which T-cell activation can be regulated. This concept opens new avenues for therapeutic interventions (for details cf. Chapter 93).

Macrophages

Macrophages are bone-marrow derived cells that exhibit pleotropic functions in the immune system. They are the mature form of monocytes, which circulate in the blood and differentiate continuously into macrophages upon migration into the tissues.

Macrophages represent a cellular component of the innate immune system and as such do not exhibit specific antigen receptors, such as B- or T-lymphocytes, but possess receptors for carbohydrates and therefore can, to some degree, discriminate between 'self' and 'foreign' molecules. Moreover, they carry receptors for antibodies and complement. Opsonization ('coating') of pathogens with antibodies and/or complement will enhance macrophage activity. In some circumstances, macrophages are able to destroy pathogens by phagocytosis without the need for T-cell delivery of activating signals. However, in many clinically important settings $CD4^+$ T-cells are required to stimulate macrophages. The latter are rendered activated by membrane-bound signals issued by activated T_H1-cells as well as by the potent macrophage-activating cytokine interferon (IFN)-γ secreted by them. Once activated, macrophages can kill intracellular and ingested bacteria. Moreover, macrophages can also cause local tissue damage by the release of toxic oxygen free radicals, nitric oxide, metabolites, proteases, glutamate and a host of other proinflammatory mediators (Hartung et al., 1995; Pouly et al., 2000; Smith et al., 1999).

Antigen-presenting cells

Antigen presentation is crucial in triggering an effector T-cell response. The most important professional antigen-presenting cells are macrophages, B-lymphocytes and dendritic cells. Macrophages, as outlined before, are antigen-presenting cells that phagocytose antigens and present processed peptide fragments on their cellular surface. They exhibit MHC class II molecules at low levels, but their expression is inducible by IFN-γ. Thus, besides T-cell activation, IFN-γ enhances antigen presentation.

B-lymphocytes bind protein antigens with their receptors, internalize them and present fragments of the antigen to T_H-cells. The antigen-presenting function of B-cells is essential for T_H-cell-dependent antibody production.

Among professional antigen-presenting cells, dendritic cells are the most effective in initiating T-cell-dependent immune responses, a process also termed priming. Dendritic cells are derived from bone marrow precursors and most are related to the mononuclear phagocytic lineage. They are competent in presenting antigens to both $CD4^+$ as well as $CD8^+$ T-cells. By virtue of their anatomic location, they are often the first cells of the immune system to encounter foreign antigens. After antigen exposure, dendritic cells migrate to lymphoid organs, such as lymph nodes, the thymus, and the Peyer's patches, where they present the antigen to B- and T-cells. Moreover, dendritic cells are supposed to exhibit immunoregulatory functions by participating in the T_H1/T_H2 subtype-polarization, and by inducing T-cell anergy as well as T-cell apoptosis.

Other than these immune cells, the nervous system contains intrinsic cellular populations which have the potential to act as antigen presenters.

In the CNS, cells participating in the formation of the blood–brain barrier, specifically perivascular microglia or pericytes but also endothelial cells, can serve as competent antigen-presenting cells by up-regulation of class II MHC molecules. Microglia are the dominant parenchymal antigen presenters whereas the relevance of astrocytes in unclear (Antel & Becher, 1998; Aloisi et al., 2000). MHC class II inducibility in microglia cells appears to be regulated by neurotrophins released by electrically active neurons (Neuman et al., 1998), assigning an immunoregulatory function to neuronal cells within the CNS.

In the PNS, Schwann cells, besides forming the myelin sheath, can express MHC class II antigens and have been shown in vitro to present antigen to autoreactive T-cells. They also exhibit MHC class I antigens which mark them as targets for T-cell-mediated cellular cytotoxicity. Schwann cells can generate toxic and immunosuppressive mediators, such as leukotrienes, prostanoids and nitric oxide. This raises the possibility that these cells act as antigen presenters as well as immunoregulators within the PNS.

Complement

Complement is part of the innate immune system and represents one of the main effector mechanisms of antibody-mediated immunity. The complement systems encompasses more than 30 different proteins, all named by number in historical order, which, once activated, initiate a cascade generating bioactive components with various functions. The complement systems exhibit three main physiological activities: host defence against infections, acting as an interface between innate and adaptive immunity, disposal of immune complexes and neutralization of the products of inflammatory injury (Barrington et al., 2001; Walport, 2001). These effector functions can be activated through three different pathways: the classical pathway, triggered by an antibody, the mannan-binding lectin pathway, initiated by binding of a serum lectin, and the alternative pathway, triggered directly on pathogen surfaces. Once activated, all pathways converge at the point of cleavage of C3, eventually resulting in the formation of the membrane–attack complex (C5b–9) and subsequent lysis of the pathogen (see Fig. 92.6). Moreover, components of complement can opsonize pathogens for uptake by phagocytes or can act as chemoattractants recruiting immunocompetent cells to sites of infection.

It has become apparent that the activation of complement in disease may be harmful as well as helpful. In several immune-mediated disorders of the nervous system activation of the complement system plays a key role in the pathogenesis of the disease. In demyelinating diseases of the central as well as the peripheral nervous system, such as multiple sclerosis and the Guillain–Barré syndrome, respectively, complement activation results in myelin breakdown and axonal damage (cf. e.g. Jung et al., 1995; O'Hanlon et al., 2001; Storch et al., 1998). In myasthenia gravis, antibodies targeting the acetylcholine receptors on the postsynaptic membrane induce complement-mediated lysis (Engel, 1999). Similarly, in dermatomyositis and vasculitic disorders activation of the complement cascade results in severe tissue damage (Dalakas, 1998).

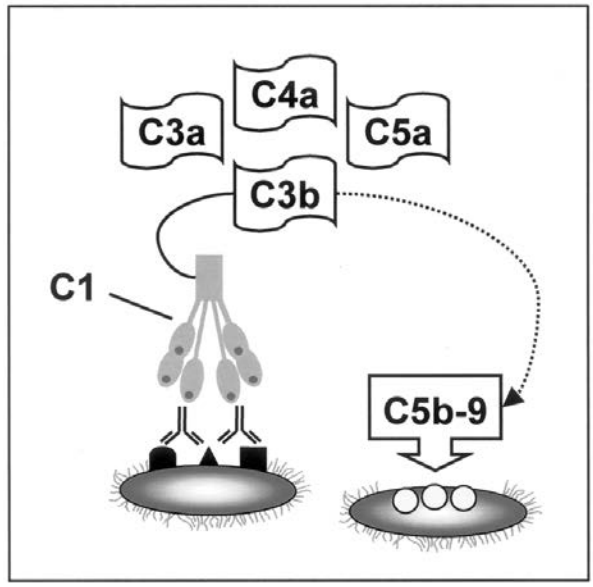

Fig. 92.6. Complement activation. The complement system can be activated by various pathways. In the classical pathway, C1 is activated by antibodies binding (e.g. to a microbial surface) or a surface molecule of a target structure (e.g. myelin sheath). This initiates a cascade of enzymatic cleavage processes generating larger and smaller fragments of various complement factors ('a' and 'b'). The larger C5b complex triggers the assembly of a membrane-attack complex (C5b-9), which can result in the lysis of a pathogen or as in the demyelinating disorders, of the myelin sheath.

Inflammatory mediators

Activation of the immune system results in the generation of an array of immunologically active mediators which primarily act locally and regulate the immune response. Some of these mediators, critically involved in immune-mediated disorders of the nervous system, will be discussed in the following section.

Cytokines

Cytokines represent a group of soluble low molecular mass proteins secreted by one cell to modulate the properties of the cell itself or of another cell in an autocrine or paracrine manner. They act as messengers both within the immune system but also in its dialogue with the nervous system, forming an integrated network that is intimately involved in the regulation of immune responses (Oppenheim & Feldman, 2001). Cytokines are synthesized *de novo* by all three types of effector T-cells and their effect depends on the target cell. T_H1- and T_H2-cells release different but overlapping sets of cytokines, which define their distinct

Table 92.2. Major cytokines and their function

Cytokine	Size (number of amino acids) and form	Producer cell	Actions
IFN-γ	143, heterodimer	T-cells, NK cells	Macrophage activation, increased expression of MHC molecules and antigen processing components, Ig class switching
TNF-α	157, trimers	Macrophages, NK cells, T cells	Local inflammation, endothelial activation
TNF-β	171, trimers	T-cells, B-cells	Killing, endothelial activation
TGF-β	112, homo- and heterotrimers	Chondrocytes, monocytes, T-cells	Inhibits cell growth, anti-inflammatory
IL-1	153 and 159, monomer	Macrophages, epithelial cells	Fever, T-cell activation, macrophage activation
IL-2	133, monomer	T-cells	T-cell proliferation
IL-4	129, monomer	T-cells, mast cells	B-cell activation, IgE switch suppresses T_H-cells
IL-5	115, homodimer	T-cells, mast cells	Eosinophil growth, differentiation
IL-10	160, homodimer	T-cells, macrophages	Macrophage suppression
IL-12	197 and 307, heterodimer	B-cells, macrophages	Activates NK cells, induces $CD4^+$ T-cell differentiation to T_H1-cells
IL-13	132, monomer	T-cells	B-cell growth and differentiation, inhibits macrophage inflammatory cytokine production and T_H1-cells
IL-18	157, monomer	Activated macrophages	Induces IFN-γ production by T- cells and NK cells, favours T_H1 induction

Notes:
IFN = interferon, TNF = tumour necrosis factor, TGF = transforming growth factor, IL = interleukin, NK cell = natural killer cell.

actions in immunity (O'Garra, 1998). T_H2-cells secrete, among others, interleukin (IL)-4 and IL-5, which activate B-lymphocytes, and IL-10, which inhibits macrophage activation. T_H1-cells secrete interferon IFN-γ, tumour necrosis factor (TNF)- α, and lymphotoxin (LT-α or TNF-β), potent proinflammatory molecules, which activate macrophages, inhibit B-cells and are directly cytotoxic for some cells.

Cytokines exhibit their action via receptors, which can be classified into equivalent families based on their distinctive structure. These families of cytokines and their receptors are also characterized by functional similarities. The specific functional effect of the individual cytokines is dependent on intracellular signalling events that are triggered by the binding of cytokines to their specific receptor. Their pleiotropism and redundancy make a simple statement about the function of individual cytokines difficult, although studies in knockout mice helped to clarify the physiologic role of certain cytokines (see Table 92.2).

One telling example of how a cytokine orchestrates the immune response and links innate and adaptive immunity is IL-12. This heterodimer is critical for initiating a sequence of responses involving macrophages, NK cells, and T-lymphocytes resulting in the eradication of the microbe. Macrophages and dendritic cells in response to the antigen produce IL-12. Secreted IL-12 stimulates NK cells as well as T-lymphocytes to produce IFN-γ, which then activates macrophages to kill the phagocytosed microbes. Moreover, IL-12 induces the differentiation of T-lymphocytes into IFN-γ-producing T_H1-cells, which express high affinity IL-12 binding, in contrast to T_H2-lymphocytes with low affinity IL-12 binding properties. Finally, IL-12 enhances the function of $CD8^+$ cytolytic T-cells and NK cells. This example demonstrates how immune mediators, especially cytokines, can regulate the immune response. Importantly, microglia, astroglia and Schwann cells are also sources of cytokines.

Chemokines

The burgeoning family of chemoattractant cytokines, so-called chemokines, comprises a large and diverse group of 8 to 10 kDa proteins that display between two and four NH_2-terminal cysteine amino acid residues. Based on the relative position of these cysteine residues in the mature protein, chemokines are divided into the CXC (or α), CC (or β), C (or γ), and CX_3C (or δ) subfamilies. So far, over 50 different chemokines have been recognized (Luster, 1998; Zhang et al., 2000; Zlotnik & Yoshie, 2000).

Secreted by a wide variety of leukocytes and other cell types, chemokines are functionally characterized by their capacity to induce the directional migration and activation of leukocytes. Furthermore, they promote humoral and cell-mediated immune reactions, regulate cell adhesion, leukocyte trafficking, and homing.

Chemokines induce their activity by binding to homologous transmembrane G protein-coupled receptors on target cells. To date, four human CXC chemokine receptors, eight human CC chemokine receptors, and one human CX_3C chemokine receptor have been identified. All receptors are expressed on various types of leukocytes: some appear to be restricted to certain cell types, whereas others are more widely displayed. Furthermore, in some cell types chemokine receptors are found to be constitutively expressed, whereas they are inducible on others. This diversity is also reflected in the expression pattern noted on T-helper cells: T_H1-cells preferentially express CXCR3 and CCR5, whereas T_H2-cells preferentially express CCR4 and CCR3. The migratory responsiveness is mirrored by the chemokine receptor expression pattern identifiable on these cell subtypes (Baggiolini, 1998; Cyster, 2000; Mackey et al., 1999; Ransohoff et al., 1997).

Matrix metalloproteinases

The matrix metalloproteinases (MMPs) comprise a large group of endoproteinases that share some structural features in the N-terminal catalytic domains. At least 25 members are known which can be categorized into the subfamilies of the collagenases, gelatinases, stromelysins, matrilysin, and membrane-type metalloproteinases (Nagase & Woessner, 1999; Yong et al., 1998).

With the exception of the membrane type MMPs, which are bound to the cellular surface, all other MMPs are secreted into the extracellular space by a wide range of cell types as latent proenzymes requiring activation by proteolytic cleavage of an amino-terminal domain to expose the active catalytic site. Since MMPs can catalyse the degradation of all protein components of the extracellular matrix, their finely tuned regulation is of critical importance to prevent tissue destruction (Birkedal-Hansen, 1995).

In recent in vitro studies the spectrum of MMP substrates was extended to proforms of MMPs, enzyme inhibitors, cell-membrane bound adhesion molecules, cytokine precursors, and cytokine receptors (Chandler et al., 1997). Shedding of the pro-form of the proinflammatory cytokine TNF-α is achieved by TNF-α converting enzyme (TACE), a unique disintegrin metalloproteinase with notable sequence identity to the adamalysin family of metalloproteinases (Black et al., 1997; Moss et al., 1997).

Termination of the immune response

To control the massive expansion of cellular and soluble immune mediators certain mechanisms must operate with high fidelity to regulate the immune response. Once the target antigen has been eliminated, or in the absence of infection, the activated effector cells are no longer needed. The cessation of the antigenic stimulus prompts the cells to undergo programmed cell death or apoptosis (Gold et al., 1997; Zipp et al., 1999).

The survival of lymphocytes depends on a delicate balance between death-promoting and death-inhibiting factors. Apoptosis is inhibited by some members of the intracellular Bcl-2 family, which block mitochondrial swelling, a process that leads to cell death (Chao & Korsmeyer, 1998; Hengartner, 2000). On the other hand, various mechanisms can induce apoptosis, e.g. through the interaction of the cell surface receptor Fas on T-cells with its ligand Fas ligand, a member of the TNF family (Krammer, 2000). Glucocorticoids promote T-cell apoptosis as well, an observation with therapeutic implications (Gold et al., 2001).

Tolerance and autoimmunity

The random generation of a highly diverse repertoire of B- and T-cell receptors allows the adaptive immune system to recognize virtually any antigen, including autoantigens, often referred to as self-reactive T-cells or autoantibodies. Tolerance is the process that eliminates or down-regulates such autoreactive cells (see Table 92.3). Consequently, a breakdown in this system can cause an autoimmune response or even autoimmune disease (see Table 92.4).

B-cell tolerance

Autoantibodies are characteristic for several autoimmune diseases of the nervous system, the prototype being myasthenia gravis. Autoantibodies bind to surface molecules or receptors leading to functional impairment of the affected cell. They can also bind to intracellular antigens and may thereby cause disease (Matsumoto et al., 1999).

The immune system has several mechanisms at hand to filter autoreactive B-lymphocytes out of the B-cell pool: (i) by clonal deletion of immature B-cells in the bone marrow (Nemazee & Burki, 1989), (ii) by deletion of autoreactive B-lymphocytes in the T-cell zones of secondary lymphoid organs, such as lymph nodes or the spleen (Rathmell et al., 1996), (iii) by induction of cellular anergy ('functional inactivation') (Goodnow et al., 1988), and (iv) by a process called 'receptor editing' which changes the

Table 92.4. Mechanisms of autoimmunity

Loss of tolerance to self by:
Increased/aberrant expression of class II or costimulatory molecules
Molecular mimicry
Decreased activity of regulatory/suppressor cells
Defect in apoptosis
Superantigen-induced activation of autoreactive T-cells
Bystander activation of T/B-cells
Release of sequestered antigens

receptor specificity once an autoantigen has been encountered (Nemazee, 2000). At present, it remains unclear to what extent these mechanisms are of relevance in preventing autoimmune disorders in the nervous system.

T-cell tolerance

The basic principle of T-cell tolerance is the deletion of self-reactive T-lymphocytes in the thymus (van Parijs & Abbas, 1998). During the process of thymic education self-reactive T-lymphocytes are eliminated by complex mechanisms consisting of positive and negative selection. To delete all self-reactive cells, the presence of all autoantigens is required in the thymus. However, this is not always the case (Huseby & Goverman, 2000; Kamradt & Mitchison, 2001, Klein & Kyewski, 2000). Further, some autoreactive T-cells escape thymic education and enter the systemic immune compartment. Several mechanisms are required to keep T-cells in check and maintain peripheral tolerance (see Fig. 92.7).

Immunologic ignorance

Several mechanisms can cause immunologic ignorance: antigens may be physically isolated from self-reactive T-cells due to the separation in different biological compartments, e.g. by the blood–brain barrier marking the central nervous system as a potential immunologically privileged site (Barker & Billingham, 1977). Also, the level of antigen expressed might be below a certain threshold required for T-cell activation (Akkaraju et al., 1997; Ferber et al., 1994) or the physical encounters with APCs are not sufficiently frequent (Friedl & Gunzer, 2001). If tissues lack professional antigen presenters, resident antigens fail to activate T-cells and are therefore ignored. Importantly, autoreactive T-cells in such a setting remain functionally intact.

Peripheral clonal deletion

If abundant self-antigens in the periphery continually stimulate autoreactive T-cells, these may succumb to activation-induced cell death through apoptosis. The lack of growth factors may also lead to elimination of autoreactive T-cells.

Inhibition

T-cells require the presence of co-stimulatory molecules when detecting antigens presented by an MHC molecule. CD152 (or CTL-4) on T-cells binds the costimulatory molecules CD80 (or B7–1) and CD86 (or B7–2) with a higher affinity than the costimulatory receptor CD28. Thus, CD152 inhibits T-cell activation (Chambers & Allison, 1999) and results in anergy, i.e. functional unresponsiveness.

Anergy

If T-cells recognize antigens presented without adequate levels of costimulatory molecules, they are rendered unresponsive and cannot even launch a response when restimulated by antigen presenters expressing sufficient amounts of costimulators. This state is termed anergy. T-cell anergy can also be induced by altered peptide ligand which contains modified T-cell receptor contact residues.

Suppression

Regulatory T-cells, by the production of inhibitory cytokines such as IL-10 or transforming growth factor (TGF)-β inhibit or suppress the activation of T-lymphocytes. These inhibitory cells are called suppressor T-cells (T_S). However, attempts to isolate these $CD8^+$ lymphocytes or to purify and characterize the suppressor factors secreted have been extremely difficult. It is conceivable that suppression is exerted by different cell types and mediated by a variety of molecules (Chen et al., 1994; Powrie et al., 1996; Shevach, 2000).

Breakdown of tolerance

If one of the regulatory mechanisms outlined earlier fails, the specific immune response is mounted against self-

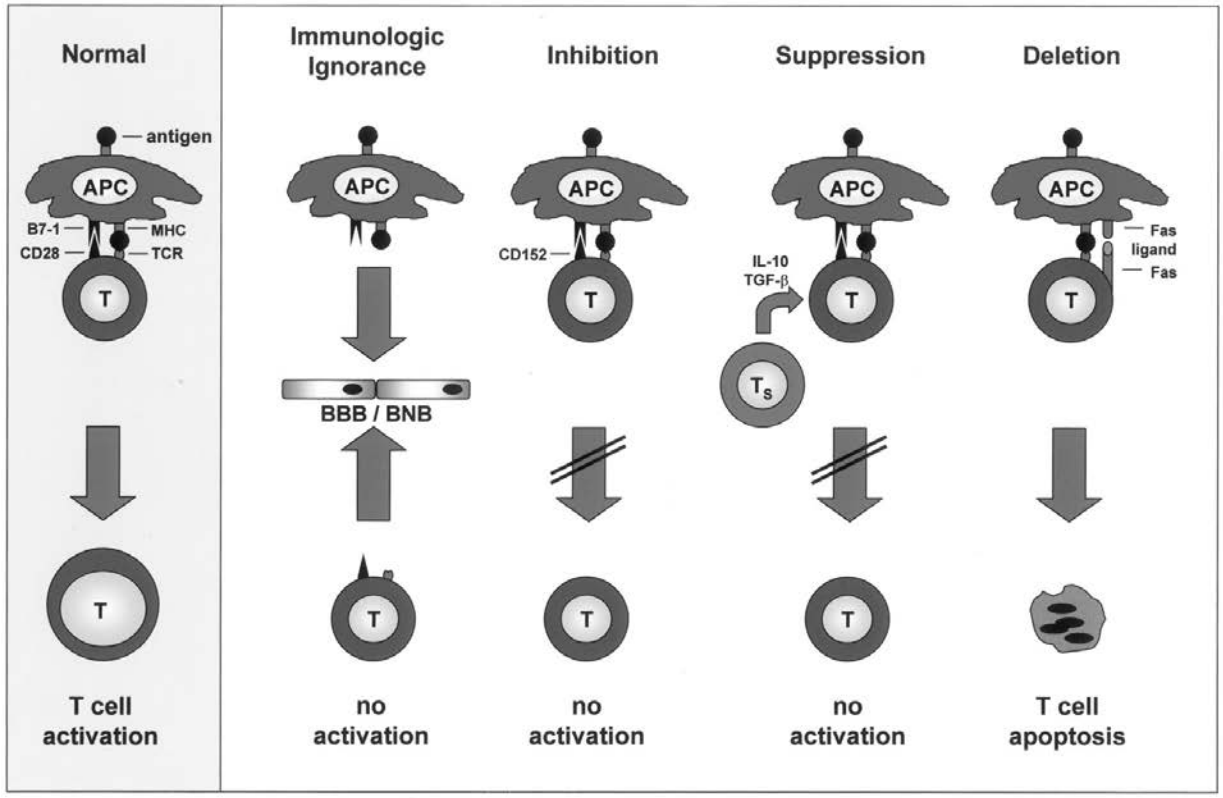

Fig. 92.7. Peripheral T-cell tolerance. Since self-reactive T-lymphocytes can escape thymic education, various mechanisms control the activity of these potentially autoreactive cells in the periphery. See text for details. BBB = blood–brain barrier, BNB = blood–nerve barrier.

antigens which leads to expansion of autoreactive effector T-cells, generation of autoantibodies through T-cell help, or both, and may give rise to severe tissue damage; a scenario which Ehrlich termed horror autotoxicus. Autoaggressive responses eventuate autoimmune disease. The autoimmune response persists because the immune system is not able to remove the offending autoantigen from the body, even worse, new hitherto hidden autoantigens could be released to amplify the response and broaden its epitope specificity, a process termed epitope spreading. The mechanisms of tissue damage in autoimmune diseases are essentially the same as those operative in other inflammatory disorders.

Various mechanisms are operative to promote or prevent tissue damage once an autoimmune reaction has started. Recruitment of large numbers of host monocytes/macrophages and T-cells and the release of cytotoxic cytokines and chemokines would serve to augment the injurious tissue reaction. Autoantibodies, either directly with the mediation of complement or via ADDC, are also active partners. Conversely, a suppressive/inhibitory local environment with only few or not fully competent APCs, anatomical distance of autoreactive cells to target structures, antiinflammatory cytokines or inappropriate antibody concentrations may help to defend against autoimmune tissue destruction. Finally, induction of apoptosis in activated T-cells may eliminate the autoreactive T-cells before the full inflammatory cascade is set in motion.

In most neurological autoimmune disorders the ultimate cause has not been established. One hypothesis holds that the extent of intrathymic deletion varies (Klein et al., 2000) and as such may not provide sufficient central tolerance. Another mechanism is the peripheral activation of potentially self-reactive T-lymphocytes in the normal repertoire by infectious agents. In autoimmune diseases such as multiple sclerosis or the Guillain–Barré syndrome (GBS) several lines of evidence implicate infection as a potential cause of the disease (Hafler, 1999; Karlsen & Dyrberg, 1998; Rose, 1998; Sheik et al., 1998). Alternatively, the release of sequestered autoantigens through tissue damage could provoke or perpetuate ongoing immune

reactions and, parenthetically, broaden their specifity (Miller et al., 1997, 2001). Another possible role in the genesis of autoimmunity has been attributed to a group of peptides derived from viral and bacterial pathogens, so called superantigens. They have a distinct mode of binding to MHC molecules that enables them to activate large numbers of T- or B-cells (Perron et al., 1997; Silverman, 1998). Bystander activation implicating the 'accidental' activation of effector immune cells may also play an important role (Infante-Duarte et al., 2000; Tough et al., 1997).

Alternatively, structural similarities between microbial and self-antigens could activate autoreactive T-cells, a mechanism termed molecular mimicry (Albert & Inman, 1999; Wucherpfennig & Strominger, 1995). T-lymphocytes can recognize microbial as well as self-peptides with similar amino acid sequence (Fujinami & Oldstone, 1985; Jahnke et al., 1985; Karlsen & Dyrberg, 1998). On the other hand, a single T-cell receptor can recognize several peptides with various degrees in sequence homology (Grogan et al., 1999; Hemmer et al., 1998; Maier et al., 2000). The first human autoimmune disorder proposed to result from such misguided T-cell cross-reactivity was rheumatic fever and its associated CNS disorder, Sydenham chorea, after infection with hemolytic streptococci. The principle of molecular mimicry has also been invoked in the pathogenesis of GBS following infection with *Campylobacter jejuni* or certain viruses (Hartung et al., 1998c; Hughes et al., 1999).

Several neurological disorders provide evidence that autoimmunity caused by autoreactive T-cells can be self-limited. Examples are monophasic diseases such as acute disseminated encephalomyelitis (ADEM) and GBS (Hartung & Grossman, 2001; Hartung et al., 1998b). Other forms of autoimmune diseases are episodic but persistent, such as relapsing–remitting forms of multiple sclerosis (MS), or chronic and progressive, such as primary or late stages of MS or chronic inflammatory demyelinating polyradiculoneuropathy (CIDP). Which mechanisms determine the duration and extent of the autoimmune response remain unclear but apoptosis of autoaggressive T-cells or restoration of a disturbed Th1/Th2 balance have been proposed as underlying mechanisms.

Genetic control

It has long been established that autoimmunity is under genetic control. Clinical evidence points to hereditary susceptibility factors linked to MHC haplotype, immunoglobulin genes and others (cf. e.g. Compston, 1999). Genetic susceptibility was traditionally studied in animal models such as EAE or EAN where resistant and highly susceptible strains exist. In the resistant strains, experimental tools were developed to break tolerance and set off a fulminant autoimmune reaction.

Table 92.5. Witebsky's postulates: criteria for autoimmune diseases

A human disease can be assumed to be autoimmune in origin based on:
Demonstration of autoantibodies or autoreactive T-cells
Demonstration of immunoglobulin deposited on target structures
Reproduction of disease in experimental animals by immunization with putative autoantigens or passive transfer of autoantibodies/autoreactive T-cells
Disease should respond to immunosuppression or immunomodulation

Autoimmunity in the nervous system

To establish that a human disease is autoimmune in origin several criteria need to be met to satisfy Witebsky's postulates, the equivalent of Koch's postulates for an autoimmune pathogenetic sequence: (i) The existence of autoantibodies or autoreactive T-cells should be demonstrable, (ii) binding of autoantibodies should be detectable at target structures, (iii) experimentally, characteristic features of the disease should be reproducible by active immunization with putative autoantigen, passive transfer of autoantibody or autoreactive T-cells, (iv) the disease should respond to immunosuppression/modulation (Rose & Bona, 1993) (see Table 92.5).

The nervous system has long been considered an immunologically privileged site. This concept was based on the premise that (i) there is a more or less strict anatomic separation between the systemic immune compartment (blood) and the neural tissue, (ii) MHC molecules required for antigen presentation are absent under normal circumstances, (iii) there is no lymphatic drainage, and (iv) immune surveillance by T-cells is lacking. It is now obvious that most of these assumptions are not tenable. The blood–brain and the blood–nerve barrier do restrict access of immune cells and soluble mediators to a certain degree, however, this restriction is not complete, neither anatomically (e.g. the blood–nerve barrier is absent or relatively deficient at the roots, in the ganglia, and the motor terminals) nor functionally (Antel & Owens, 1999; Gold et al., 1999). Activated T-lymphocytes can penetrate intact barriers irrespective of their antigen specificity, and, under certain circumstances, release cytokines that up-regulate

Table 92.6. Immune-mediated disorders of the nervous system

Disorder	Target autoantigens (candidates)	Histopathology/pathomechanisms
CNS		
Multiple sclerosis	Myelin/oligodendrocyte proteins (e.g. MBP, MOG, MAG, PLP, αB cristallin)	Heterogeneous: multifocal inflammation, demyelination, axonal loss, loss of oligodendrocytes, colocalization of IgG and complement in the lesion
Stiff-person syndrome	GAD (glutamic acid decarboxylase) containing GABAergic neurons	No significant observations
Rassmussen's encephalitis	Glu-receptor-3 on neurons	Inflammation and neuronal loss
Neuromuscular junction		
Myasthenia gravis	Postsynaptic acetylcholine receptors (AChR); MuSK in some cases	Reduced folding and AChR density; deposition of IgG and complement
Lambert–Eaton myasthenic syndrome	Presynaptic voltage-gated calcium channels	Loss of calcium channels at the motor nerve terminal
Neuromyotonia (acquired)	Voltage-gated potassium channels	Heterogeneous
PNS		
Guillain–Barré syndrome	Gangliosides, such as GM1 (esp. axonal form), GQ1b (Miller–Fisher variant) and related glycolipids	Macrophage-mediated multifocal demyelination, axonal loss, IgG and complement deposition
CIDP	P0, glycolipids	Like Guillain–Barré syndrome
Multifocal motor neuropathy	Ganglioside GM1	Focal demyelination, deposition of IgM at the nodes of Ranvier
Monoclonal gammopathy associated neuropathies	MAG (myelin associated glycoprotein), also unknown targets	Segmental demyelination without inflammatory infiltration, IgM and complement deposition on the myelin sheath
CNS/PNS		
Paraneoplastic syndromes	Various, e.g. Hu, Ri, Yo	Neuronal loss, gliosis, perivascular inflammatory infiltration
Muscle		
Dermatomyositis	Unknown	Complement mediated vasculopathy, perimysial and perivascular infiltration with $CD4^+$ T-cells and B-cells
Polymyositis	Unknown	Endomysial infiltrates consisting of $CD8^+$ cells

Notes:
CIDP = chronic inflammatory demylinating polyradiculoneuropathy; CNS = central nervous system; GAD = glutamic acid decarboxylase; Glu = glutamat; MAG = myelin-associated glycoprotein; MBP = myelin basic protein; MOG = myelin oligodendrocyte glycoprotein; MuSK = muscle specific kinase; PLP = proteolipid protein; PNS = peripheral nervous system.

the expression of MHC class II molecules. Moreover, professional and non-professional antigen-presenting cells are abundantly distributed within the nervous tissue (Antel & Owens, 1999; Hartung et al., 1998a).

In the following section principal mechanisms underlying autoimmune disorders of the nervous system will be outlined. Table 92.6 enlists a range of neurological diseases considered to be autoimmune in nature or immune mediated and summarizes candidate antigens and potential pathogenic mechanisms. Detailed aspects of clinical presentation and treatment can be found in the individual chapters assigned to these diseases.

Immune cell trafficking

To mediate a local immune response within the CNS or PNS activated immunocompetent cells need to cross anatomically tight interfaces that separate the systemic

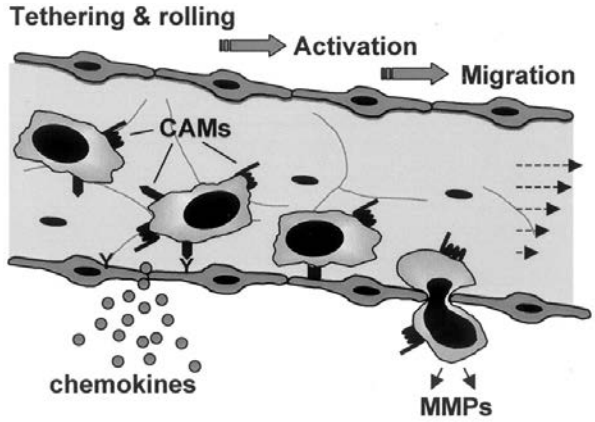

Fig. 92.8. Immune cell migration. The mechanism of immune cell trafficking is a multistep process occurring in an ordered sequential fashion. Leukocytes in the bloodstream become tethered to endothelial cells and start to crawl slowly downstream, facilitated by the interaction with various cellular adhesion molecules (CAMs). Probably by scanning the endothelial cell surface, rolling leukocytes respond to chemokines, which activate these cells and provide directional signals. The process of migration through the anatomical barrier separating the nervous system from the systemic compartment (blood–brain or blood–nerve barrier) is mediated by the release of matrix metalloproteinases (MMPs).

immune compartment from the nervous tissue, the blood–brain barrier (BBB) in the CNS and blood–nerve barrier (BNB) in the PNS.

This mechanism of transendothelial migration is a multistep process occurring in an ordered sequential fashion (see Fig. 92.8). In the first step, cellular adhesion molecules (CAMs) are expressed on the leukocytes and the vascular endothelium, resulting in a slowing and attachment of the circulating leukocytes along the vessel wall ('tethering' and 'rolling'). The flowing blood quickly dislodges cells that touch the vessel wall, thus adhesion molecules act as mechanical anchors, but also function as tissue-specific recognition molecules. Based on structural differences, CAMs can be categorized into four groups: the immunoglobulin superfamily, selectins, integrins and cadherins, all of which are involved in lymphocyte recruitment and extravasation. The specific function of individual CAMs has been elucidated by blocking their action with specific monoclonal antibodies in various animal models or by generating knock-out animals for the corresponding gene of a particular CAM.

The extravasation of leukocytes into the CNS parenchyma is facilitated by the expression of CAMs on both leukocytes and cerebral vascular endothelial cells (Archelos et al., 1999). The latter display various CAMs, of which two, vascular adhesion molecule-1 (VCAM-1) and E-selectin, are expressed only on activated endothelial cells. VCAM-1 can also be found on macrophages, dendritic cells, and epithelial cells and displays a prolonged expression on the endothelium after activation. Its counter-receptor on leukocytes is the very late antigen-4 (VLA-4). Another CAM important in mediating the attachment of lymphocytes to myelinated regions of the CNS is L-selectin (Archelos et al., 1998). It is expressed on various cell types, especially lymphocytes and neutrophils. Crucial in T-cell activation and enabling lymphocyte migration through vessel walls is the intercellular adhesion molecule-1 (ICAM-1). It binds to a T-cell integrin called lymphocyte function-associated antigen-1 (LFA-1) and is expressed on endothelial as well as antigen-presenting cells.

The coordinated up-regulation and expression of various CAMs along the endothelium within the blood vessel wall and on activated leukocytes increases their adhesive interaction. Initially, tethers are formed by CAMs, thus, circulating leukocytes within the bloodstream slow down, start rolling along the vessel wall and finally attach to it. This initially unstable interaction gets strengthened through the interaction of other CAMs, such as ICAM-1 with LFA-1, and VCAM-1 with VLA-4, respectively.

After interaction with the corresponding ligand various CAMs are shed or cleaved from the cell surface (Gearing & Newman, 1993). Thus they circulate within body fluids and are thought to regulate cellular interactions and to promote de-adhesion.

In the second step, chemokines come into play, providing signals to direct leukocyte migration into and within the extravascular space. Since lymphocytes must be positioned correctly to interact with other cells, the pattern and distribution of chemokines within the target tissue as well as the types of chemokine receptors expressed on the cell surface become critically important in orchestrating the ongoing immune responses (Campbell et al., 1998; Gerard & Rollins, 2001; Lindhout et al., 1999; Moser & Loetscher, 2001; Taub & Oppenheim, 1994).

Finally, in the third step, MMPs are secreted by the leukocytes in order to disrupt the BBB or BNB, thus facilitating the migration into the parenchyma of the nervous system (Bianchi et al., 1997; Kieseier et al., 1999).

Immune-mediated demyelination of the CNS

Multiple sclerosis (MS) is an immune-mediated neurological disease characterized by multifocal inflammatory demyelination and axonal damage in brain and spinal cord. Whereas the primary trigger of the abnormal

Table 92.7. Animal models for antigen-induced demyelination

Model	Antigens	Time course/ histopathology/ pathomechanisms
Lewis rat		
Active EAE	CNS myelin, MBP, MOG, PLP	Acute; T-cell inflammation, axonal damage, secondary demyelination
Adoptive-transfer EAE	MBP, S-100	Acute; T-cell inflammation, axonal damage (MBP)
Active EAN	PNS myelin, P2, PMP22	Acute; T-cell inflammation, strong demyelination
Adoptive-transfer EAN	P2, P0	Acute; T-cell inflammation, moderate demyelination
Congenic Lewis rat		
Active EAE	MOG	Relapsing–remitting disorder, mimicking the histopathology of MS
Murine EAE		
Active EAE	MBP, MOG, PLP	Relapsing–remitting and chronic courses; demyelination, axonal damage
Adoptive-transfer EAE	MBP, PLP	
Marmoset/ Rhesus monkey		
Active EAE	MOG, MBP	Acute; demyelination, T-cell inflammation

Notes:
CNS = central nervous system; EAE = experimental autoimmune encephalomyelitis; EAN = experimental autoimmune neuritis; MBP = myelin basic protein; MS = multiple sclerosis; MOG = myelin–oligodendrocyte glycoprotein; PLP = proteolipid protein; PNS = peripheral nervous system.
Sources: For details, cf. Gold et al. (2000).
Transgenic EAE models are reviewed in Owens et al. (2000).

immune reaction in MS remains unknown, collective evidence points to myelin-directed T-lymphocytes as key drivers of this complex process. Much progress in the understanding of immunological mechanisms involved in inflammatory demyelination of the CNS has been made through the investigation of experimental autoimmune encephalomyelitis (EAE), an animal model of MS. In principle, autoimmune model diseases can be induced by immunization with putative autoantigens in combination with non-specific immunostimulants (e.g. Freund's adjuvant); passive transfer of autoreactive T-cell lines or clones retrieved from diseased animals and propagated in vitro in the presence of autoantigen; by impairment of normal immunological function (e.g. irradiation or thymectomy, T-cell transfer to syngeneic T-cell-deficient mice); by infection (e.g. Theiler's virus-induced encephalomyelitis); or by genetic manipulation (transgenic models). Most commonly, EAE is induced in susceptible animals either by immunization with myelin components, such as myelin basic protein (MBP), proteolipid protein (PLP) or myelin oligodendrocyte glycoprotein (MOG), or adoptive transfer of $CD4^+$ T-cells specific for myelin antigens (see Table 92.7) (Gold et al., 2000; Martin et al., 1992; Steinman, 1999). The adoptive transfer experiments clearly established that EAE is a primarily T-cell-mediated autoimmune disease. More recently, transgenic overexpression or disruption of genes coding for T-cell receptors, cytokines and chemokines in the CNS of mice and rats allowed to reproduce different MS-related pathology and to dissect relevant immunopathogenic pathways (Owens et al., 2001).

Encephalitogenic T-cells are part of the normal T-cell repertoire and are not selected during thymic education (Schlüsener & Wekerle, 1985). Also healthy human individuals carry such autoreactive T-lymphocytes in their repertoire but these appear to be silenced (Hellings et al., 2001). The initial activation of these cells occurs in the systemic immune compartment outside the CNS, where T-lymphocytes encounter a specific autoantigen presented by MHC class II molecules and simultaneously perceive additional costimulatory signals, such as CD80 and CD86, on the cell surface of antigen-presenting cells (Kuchroo et al., 1995). Such autoreactive T-cells may reside quiescently in the systemic immune compartment where they cannot develop their autoaggressive potential. An external trigger, possibly an infective illness, most likely a viral infection, renders these cells active (Noseworthy et al., 2000; Soldan & Jacobson, 2001; Stohlman & Hinton, 2001; Talbot et al., 2001). Potential mechanisms include molecular mimicry, superantigen-driven broad T-cell proliferation, or cytokine-mediated bystander activation (Brocke et al.,

1998; Liblau & Gautam, 2000; Wingerchuk et al., 2001). To initiate a local immune response within the CNS, circulating T-cells, activated in the periphery, need to cross the BBB. Once within the CNS the T-cells encounter the specific autoantigenic epitopes displayed in the context of MHC and costimulatory molecules, e.g. on microglia, again, and, in consequence, become reactivated and expand clonally in situ and amplify the immune response by recruiting further immunocompetent cells through additional secretion of chemokines and cytokines. $CD4^+$ T-cells can be found in large numbers within the MS lesion (Raine, 1997), which can functionally be differentiated into two subsets of T-helper cells: T_H1 and T_H2. These trigger, based on the different profile of cytokines released, a polarized immunological response (Romagnani, 1997). Excess production of T_H1 cytokines and relatively deficient synthesis of T_H2 cytokines have been linked to acute exacerbations (Liblau et al., 1995).

It has been suggested that defective T-cell Fas function with subsequent lack of T-cell apoptosis is key in the failure to contain the autoaggressive T-cell response (Comi et al., 2000).

Once the BBB is damaged, passage into the CNS of soluble factors, such as circulating antibodies, which are supposed to contribute to the inflammatory demyelinative process, is greatly facilitated.

A pivotal role in this effector phase of the disease is played by macrophages/microglia (Benveniste, 1997). These cells act as local antigen presenters and as effector cells that effectively participate in and perpetuate immune-mediated demyelination by phagocytosis and the release of cytokines, proteases, and toxic mediators including glutamate (Bö et al., 1994; Brosnan et al., 1994; Hartung et al., 1995).

A vigorous inflammatory reaction within the CNS targeting the myelin sheath will also lead to axonal transection, which is supposed to be the pathologic correlate of the irreversible neurologic impairment in MS (Trapp et al., 1998) (see Fig. 92.9).

MS lesions contain $\alpha\beta$TCR- and in much smaller numbers $\gamma\delta$TCR-carrying T-lymphocytes (Battistini et al., 1995). These have been suggested to attack oligodendrocytes expressing heat shock proteins. The identification of MS-specific T-cell autoantigens has been one of the central issues in MS research over the last years. Based primarily on studies in EAE, MBP, a major protein component of myelin, was considered a prime candidate autoantigen for MS. Studying the human T-cell response against MBP revealed a rather complex recognition pattern (Martin et al., 2000). Certain MBP sequences were recognized more frequently than others ('immunodominant epitopes'); however, the antigen-specific receptors expressed by these reactive T-cell clones were also heterogeneous in their epitope specificity (Meinl et al., 1993; Pette et al., 1990).

It is now commonly accepted that many other myelin proteins, such as PLP, MOG, and myelin-associated glycoprotein (MAG) (Wallström et al., 1998) and even a non-myelin autoantigen, S100β, a calcium-binding protein of astroglia could be additional major autoantigens in MS (Gilden et al., 2001; Hartung & Rieckmann, 1997; Kojima et al., 1994; Martin et al., 2000; Pender et al., 2000; Schmidt et al., 1997).

B-cells are certainly also involved in the pathogenesis of MS. In patients with oligoclonal bands in the cerebrospinal fluid, plasma cells could be detected within white matter plaques (Farrell et al., 1985). In EAE the administration of MOG-specific antibodies resulted in widespread demyelination (Linington et al., 1988). In MS patients antibody responses against MBP, MAG, MOG, PLP, and αB crystallin have been identified in blood and CSF, and autoantibody binding in situ has been demonstrated (Archelos et al., 2000; Cross et al., 2001; Reindl et al., 1999; Steinman, 1996). Currently, MOG located on the surface of the myelin sheath is considered the most attractive candidate for an aberrant B-cell response culminating in demyelination (Wekerle, 1999). Given the heterogeneity of the pathology of MS lesions (Lucchinetti et al., 2000), it presently appears likely that the underlying pathogenetic pathways of tissue damage are multiple and diverse.

Immune-mediated demyelination of the PNS

Immune-mediated inflammatory disorders of the PNS are characterized by cellular infiltration, demyelination and axonal loss in the affected part of the nerve.

Most of these changes can be reproduced in the model disorder, experimental autoimmune neuritis (EAN). EAN can be elicited in susceptible animals by active immunization with whole peripheral nerve homogenate, myelin, myelin proteins P0 and P2 or peptides thereof, and galactocerebroside. It can also be produced by adoptive transfer of P2, P2 peptide-specific, P0, and P0 peptide-specific T-cell lines (see Table 92.7) (Gold et al., 2000; Linington & Brostoff, 1993).

The pathological hallmark of EAN is the infiltration of the PNS by lymphocytes and macrophages, which results in multifocal demyelination of axons predominantly around venules. Macrophages actively strip off myelin lamellae from axons, induce vesicular disruption of the myelin sheath, and phagocytose both intact and damaged myelin, as shown by electron microscopy (Griffin et al.,

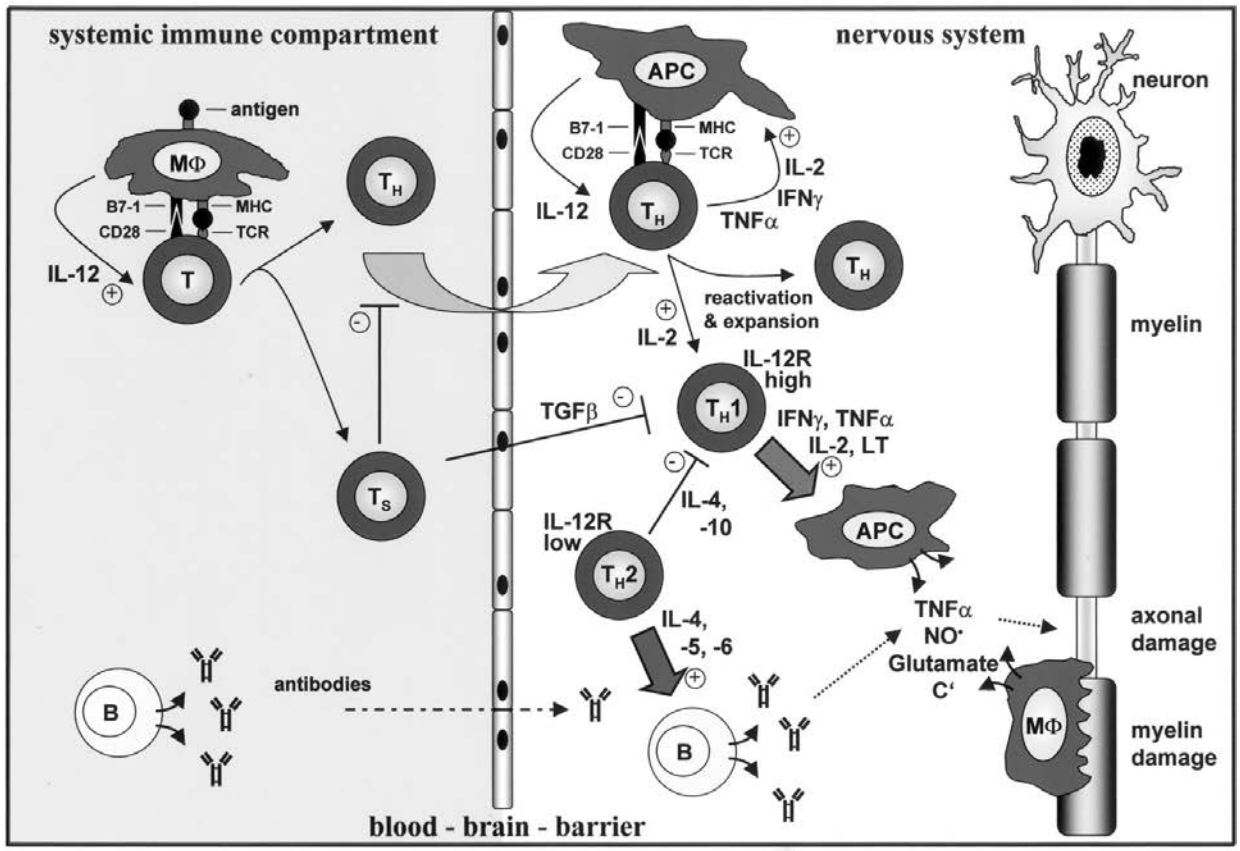

Fig. 92.9. Pathogenesis of immune-mediated inflammatory demyelination. Autoreactive T cells in the systemic circulation upon activation and guided by adhesion molecules on the blood–brain barrier can, attracted by chemokines, migrate into the CNS. Matrix metalloproteinases (MMPs) are utilized to penetrate the basal membrane. In the CNS, autoreactive T-cells when recognizing their antigen on an antigen-presenting cell displaying additional recognition and costimulatory molecules in a permissive cytokine microenvironment are reactivated, proliferate and secrete various cytokines. These can, in turn, activate microglia, macrophages or astrocytes to elaborate noxious inflammatory molecules. Cytokines can also impede impulse propagation. Autoreactive B-cells and autoantibodies can also be detected in blood and CSF. They can pass through a damaged blood–brain barrier and, upon activating the complement system with ensuing formation of the membrane attack complex, damage myelin. Antibodies can also bind to macrophages and stimulate them to antibody-dependent cytotoxicity. APC = antigen-presenting cell; Mϕ = macrophage; C = complement. See text for further explanation.

1993). Macrophages represent the predominant cell population in the inflamed PNS, and they reside in spinal roots as well as in more distal segments of the affected nerves (Hartung et al., 1998b; Kiefer et al., 2001). The fundamental need for this cell group in the pathogenesis of the disease, both in the induction and effector stage, was demonstrated by depletion experiments: macrophage elimination by intraperitoneal injection of silicon dust prevented all clinical, electrophysiologic, and histologic signs of EAN.

Crucial to the pathogenesis of inflammatory demyelination is the early invasion of the PNS by leukocytes. Circulating autoreactive T-cells need to be activated in the periphery in order to cross the BNB and to incite a local immuno-inflammatory response similar to the situation in the CNS. Breakdown of the BNB is one of the earliest morphologically demonstrable events in lesion development in EAN (Gold et al. 1999).

One pathogenic mechanism of special relevance to autoimmune neuropathies is molecular mimicry. In a proportion of patients with GBS epitopes shared between the enteropathogen *Campylobacter jejuni*, or *Cytomegalovirus (CMV)* or *Haemophilus influenzae* and nerve fibres have been identified as targets for aberrant cross-reactive B-cell responses (O'Leary & Willison, 2000). In a recent study,

antibody responses to the ganglioside GM1 were linked to axonal and motor injury, as seen in one clinical variant of GBS, in an experimental model induced in rabbits by active immunization with this glycoconjugate (Yuki et al., 2001). However, these observations cannot explain the entire clinical spectrum and laboratory findings of this disorder. Therefore GBS should be defined as an organ-specific immune-mediated disorder emerging from a synergistic interaction of cell-mediated and humoral immune responses to still incompletely characterized peripheral nerve antigens (Hahn, 1998; Sheikh et al., 1998).

Immune disorders of synaptic transmission

The neuromuscular junction (NMJ) is a prominent target for an autoimmune attack. Myasthenia gravis (MG) and the Lambert–Eaton myasthenic syndrome (LEMS) represent the two most common disorders of the NMJ, both mediated by an autoantibody-induced dysfunction of neuromuscular transmission. The pathomechanisms involved in these disorders are well elaborated (Patrick & Lindstrom, 1973; Toyka et al., 1975). In MG autoantibodies target muscle nicotinic acetylcholine receptors (AChR) on the postsynaptic membrane. Plasma exchange, removing circulating antibodies, results in a substantial albeit transient improvement in muscle strength lasting for several weeks. AChR antibodies in patients with the disease are IgG but heterogenous in light chain, subclass, and in their reactivity with the antigen, although the majority is directed against the so-called major immunogenic region located on the alpha subunit (Lindstrom, 2000). There is no evidence of T-cell infiltration in the NMJ, however, anti-AChR antibodies induce severe damage through complement-dependent lysis of the postsynaptic membrane and occasional macrophage infiltration. Moreover, the antibodies are able to cross-link the AChRs on the membrane surface, resulting in their accelerated internalization and degradation ('antigenic modulation') (Drachman, 1994; Engel, 1999). Thirdly, antibodies can inhibit AChR function directly.

The origins of the autoimmune response in MG remain uncertain. MG is an autoantibody-mediated disorder; as outlined before, B-cell responses are mostly T-cell controlled, thus the critical mechanism of loss of tolerance to the self-AChR could involve aberrant T-cell function. Autoreactive $CD4^+$ T-cells have been isolated from MG patients (Hohlfeld et al., 1984). In many patients, MG is associated with thymic hyperplasia or more rarely thymoma. Moreover, thymectomy is partially and transiently effective in treating the disease. Since the thymus is the major site of thymic education of T-lymphocytes, any alteration in thymic function would appear, at least in theory, to be potentially involved in the pathogenesis of MG. Thymic myoid cells express AchR epitopes and could sensitize CD4 T-cells whose epitope specificity would broaden once they exit the thymus. These lymphocytes probably interact with anti-AchR B-cells and precipitate the secretion of pathogenic autoantibodies.

Alternatively, cross-reactivity of antibodies against other antigens, particularly those shared with thymoma tissue, should be considered.

In about 15% of patients with MG, AChR antibodies are not detectable, and many of these patients have antibodies to another neuromuscular junction protein, muscle specific kinase (MuSK) (Vincent et al., 2001). MuSK is a receptor tyrosine kinase representing an essential component of the developing neuromuscular junction. At present its function in the fully developed NMJ remains elusive; however, a role in maintaining the high density of AChRs at the NMJ has been suggested (Hoch et al., 2001).

In LEMS, patients develop autoantibodies against presynaptic voltage-gated calcium channel proteins (VGCC). These antibodies reduce the number of active zone particles. In more than 60% LEMS is associated with a small-cell lung cancer (Dalmau et al., 1999). In this setting, VGCC detected on cancer cells apparently evoke an antibody response that cross-reacts with calcium channels at the NMJ (see Fig. 92.10) (Vincent, 1998). Some patients harbour antibodies to synaptotagmin which can reduce the quantal content of endplate potential (Takamori et al., 2000).

Yet another autoimmune disorder resulting from antibodies to some subtypes of voltage-gated potassium channels (VGPC) is neuromyotonia. These antibodies play an important role in the pathogenesis of the nerve hyperexcitability that characterizes the disease.

Inflammation and neuroprotection

Immune reactions in the nervous system may not be entirely destructive. Recent evidence suggests that immune responses can also be protective or aid in the repair of damaged neural tissue (Hohlfeld et al., 2000; Schwartz et al., 1999). For example, autoreactive T-cells may synthesize neurotrophic factors such as nerve growth factor (NGF) or brain-derived neurotrophic factor (BDNF) and deliver them at the lesion site (Kerschensteiner et al., 1999). However, spontaneous cellular immune responses do not exert sufficient protection

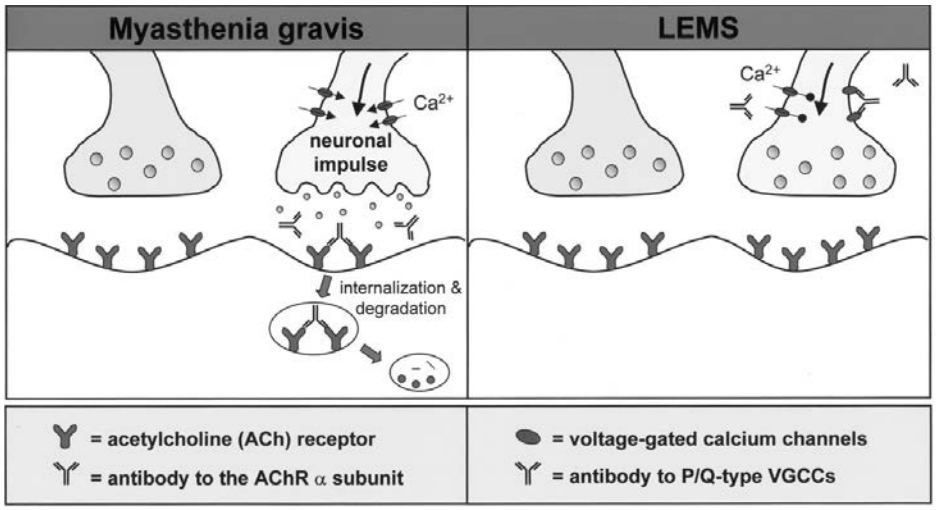

Fig. 92.10. Immune-mediated disorders at the neuromuscular junction. In myasthenia gravis autoantibodies bind to postsynaptic acetylcholine receptors (AChR) causing receptor internalization and degradation. In the Lambert–Eaton myasthenic syndrome (LEMS) autoantibodies target presynaptic calcium channels, thus inhibiting calcium influx required for the release of ACh into the synaptic cleft.

to cause significant improvement after neural injury (Schwartz & Moalem, 2001). The precise mechanisms underlying such neuroprotective effects are under current investigation.

The basis of immunotherapy in neurological disease

Reinhard Hohlfeld

Institute for Clinical Neuroimmunology and Department of Neurology, Klinikum Grosshadern, University of Munich, Germany

The first part of this chapter covers some general aspects of immunotherapy. In the second part, the mechanisms and side effects of the most widely used immunosuppressive and immunomodulatory agents are reviewed. The final part provides a brief overview of the most promising future strategies and therapeutic developments.

Principles of immunotherapy

Practical issues and general rules

Commencing with the trials of corticosteroids for treatment of rheumatoid arthritis in the late 1940s, numerous agents have been employed in many diseases with suspected or established autoimmune pathogenesis to abrogate excessive immunoreactivity. Unfortunately, the lack of specificity of these agents and their concurrent toxicities have limited their effectiveness. However, many formerly fatal or intractable diseases characterized by aberrant immunity can now be considered responsive to manipulation of the underlying defects in immune regulation. When making the decision to employ one of these agents, one should know as much as possible about the nature of the immune abnormality to be corrected and of the ability of a given drug to influence this process. Furthermore, the adverse effects of the agent should be weighed against the possible benefits (Machkhas et al., 1997).

The goals of treatment seem simple enough: to improve clinical deficits and to stop or slow progression of the disease process while keeping side effects to a minimum. Before initiation of any form of immunotherapy, and during therapy, a number of important points need to be considered and checked (Table 93.1). The diagnosis should be unequivocally established. Baseline variables (such as muscle strength, vital capacity, walking distance, etc.) should be documented so they may be measured on follow-up examinations to help in quantifying improvement. Certain medical conditions (e.g. chronic or undiagnosed infections, diabetes) must also be considered. Another major consideration before initiation of therapy is patient compliance. Usually, the risks associated with non-compliance outweigh the benefits of treatment, and non-compliance is a contraindication of immunosuppression. Regarding the duration of therapy, it is important that adequate dosages are given over a sufficient period of time. Otherwise, the agent is terminated prematurely and labelled a 'treatment failure', and will probably never be used again, even though in retrospect it is felt that incorrect dosages or insufficient duration of treatment were used. On the other hand, it is equally important that the effectiveness and tolerance of any immunomodulatory treatment is regularly assessed, and that the treatment is stopped if it turns out to be ineffective or accompanied by unacceptable side effects.

Implications of disease heterogeneity

In neuroimmunological as well as in other diseases, rational treatment depends on a thorough understanding of the disease's etiology and pathogenesis. MS provides a good example: Research into the pathogenesis of MS and especially the rapidly growing number of different animal models are beginning to reveal a remarkable heterogeneity and complexity of the pathogenetic mechanisms of inflammatory demyelinating CNS disease. In view of these developments, it seems likely that more refined classifications can be developed in the future for the disease we today call MS (Lucchinetti et al., 2000). This will increase the possibility of a more differentiated therapeutic approach. The evidence for an immunopathogenesis of

Table 93.1. General rules for immunotherapy

Checklist before treatment
Consider immunomodulatory treatment only if the diagnosis has been firmly established.
Attempt to tailor treatment to the individual patient.
Carefully weigh the risks versus potential benefits: In patients with a pronounced clinical deficit, immunosuppressive and immunomodulatory treatments are associated with increased risk and reduced benefit.
If several agents are indicated, begin with the least toxic.
Consider that not all immunomodulatory treatments can be combined, since one agent may depend on immune mechanisms suppressed by the other.
Do not underestimate the risks of long-term steroids.
Assure compliance by informing the patient in detail about the side effects and possible complications.
In case of cytotoxic immunosuppressive treatments, specifically mention the risks of infection and cancer, and emphasize the need for contraception.
Obtain written informed consent if necessary.
Check for agent-specific contraindications and perform appropriate laboratory tests to exclude conditions that might interfere with treatment (e.g. exclude IgA deficiency before treatment with i.v. IgG).
Before starting immunomodulatory therapy, make a treatment plan and have a concept of how to proceed if the therapy fails.
Provide the patient with an emergency passport that should be always carried and should indicate the diagnosis and medication.
Checklist during treatment
Re-evaluate the need for the therapy and for the present dose at regular intervals in all patients.
Always optimize symptomatic treatment before and during immunomodulatory treatment.
Remember that the clinical response is the single most important criterion for success or failure.
Monitor lab values (e.g. blood count, liver function) at regular intervals for early detection of side effects.
Treat infections early and efficiently and consider preventive measures in immunosuppressed patients.
Reconsider the diagnosis in treatment-resistant cases.

MS is strong, but indirect, because much of it has been derived from autoimmune animal models (Wekerle et al., 1994; Lassmann & Wekerle, 1998). Experimental support has accumulated for a variety of distinct autoimmune mechanisms, and it is likely that different human autoimmune diseases (and different forms of MS) are triggered by different mechanisms. In addition, different mechanisms may operate at different stages of the same disease. The identification of the etiology in individual cases is not an academic problem, but of the utmost relevance for therapy. Further, it is still unclear whether virus(es) or other infectious agents play a role. Although numerous viruses have been incriminated over the years, most of these claims have not been substantiated. This is not surprising as it is extremely unlikely that a single virus would be involved in all forms of MS. It is possible, however, that subtypes or 'variants' of MS are related to viral infection. For appropriate treatment it is essential to identify these cases.

Phase-specific immunotherapy

Common sense and clinical judgement suggest that the sooner immunotherapy is initiated, the better the chances are to prevent permanent deficits. Arguments against very early treatment include the high cost of long-term therapy and adverse reactions, which could diminish or abolish therapeutic effectiveness at a later stage when therapy is urgently needed. At the other end of the clinical spectrum, patients with severe impairment have an increased risk for various adverse reactions to immunotherapy. Furthermore, immunotherapy cannot be expected to reverse a pre-existing, stable chronic deficit, at least not in autoimmune diseases of the CNS. Therefore, patients with advanced CNS disease are bad candidates for immunotherapy, and aggressive immunosuppressive treatments are usually contraindicated.

Ideally, the intensity of immunosuppressive or immunomodulatory treatment should be adjusted to disease

activity. How can disease activity be measured? Again, consider MS as an example. One of the first lessons learned from MRI studies was that clinical activity is a very poor indicator of disease activity. It is probably unrealistic to assume that the currently available MRI techniques alone can provide reliable and feasible indicators of disease activity for therapeutic monitoring. However, the various imaging techniques have an enormous potential, and it is conceivable that they can in the future be developed into practical and reliable tools for assessing disease activity (McDonald, 1998). As regards laboratory markers of MS disease activity, none of the proposed 'activity markers' has yet proven suitable for routine monitoring of disease activity. There are many reasons for this, mostly related to limitations of the feasibility, reliability, sensitivity and specificity of the various assays. In spite of the unsolved problems, it is likely that more dependable and feasible laboratory tests of disease activity will soon be developed.

There are presently no reliable criteria for predicting the individual course and severity of MS. Such criteria are crucial for deciding whether and when to initiate immunomodulatory treatment. There is no need to treat benign MS, but MS cases with poor prognosis should be treated early. There is some evidence that imaging studies may help assess the prognosis in individual cases, but a precise prediction is not possible (Kappos et al., 1999). It is also unclear whether the clinical course provides helpful criteria to define subtypes of MS for differentiated therapy. The published clinical trials have differentiated (more or less rigorously) between relapsing–remitting and progressive MS, excluding primary progressive MS. More results are needed to decide whether such a distinction is meaningful.

Combination therapy

It seems logical to consider combining different immunotherapies that work via different mechanisms. Striking examples for the effectiveness of such therapy are provided by the combination of antiviral therapies in HIV infection and the combination of the immunosuppressive regimes routinely used in transplantation. The difficulty is to select the right agents to combine, as well as the right type of disease or disease type. An important general problem is that the different immune mechanisms targeted by different agents may depend on each other, so that one agent depends on the intactness of mechanisms inhibited by another agent. Clinical trials need to carefully look for such adverse interactions, which are difficult to predict.

Neuroprotective side effect of inflammation: Relevance for immunosuppressive therapy?

It has been proposed that inflammatory cells are not necessarily always harmful but under certain conditions even protective. For example, the intraperitoneal injection of MBP-specific T-cells protected optic nerve axons and retinal ganglion cells after experimental crush injury of the optic nerve (Moalem et al., 1999). The transferred T-cells were shown to home to the crush lesion. The exact mechanism of T-cell-mediated neuroprotection is still unknown. Unexpectedly, activated human immune cells express the classical neurotrophic factor, brain-derived neurotrophic factor (BDNF), in vitro and in inflammatory brain lesions of multiple sclerosis (Kerschensteiner et al., 1999). Therefore, it has been proposed that the functional neuroprotective effect of T-cells seen in the optic nerve crush experiments (Moalem et al., 1999) is related to the focal production of neurotrophic factor(s) by autoimmune T-cells (Hohlfeld et al., 2000).

Until recently, neurons were considered the major cellular source of BDNF in the nervous system (Hofer et al., 1990; Lewin & Barde, 1996). BDNF has potent effects on neuronal survival and plasticity during development and after injury. Considering that inflammation is a universal tissue reaction crucial for defence and repair, it is interesting to learn whether the immune cells accumulating in traumatic, degenerative, ischemic, infectious, and autoimmune lesions of the nervous system might provide an external source of BDNF. Activated human CD4+ T-cells, CD8+ T-cells, B-cells, monocytes as well as myelin antigen-specific T-cell lines produce BDNF (Kerschensteiner et al., 1999). The immune cell-derived BDNF supports neuronal survival in vitro. Furthermore, BDNF is expressed in inflammatory infiltrates in the brain of patients with acute disseminated encephalitis and multiple sclerosis. In a broader perspective, the expression of BDNF by immune cells provides a striking example for the close functional integration between the immune and nervous systems (Steinman, 1993; Neumann & Wekerle 1998).

The novel concept of 'protective autoimmunity' has far-reaching implications. Inflammatory reactions are very common not only in infectious and autoimmune diseases but also in ischemic, degenerative, traumatic, and metabolic lesions of the nervous system and muscle (e.g. stroke, Duchenne muscular dystrophy, adrenoleukodystrophy). It now appears that these lesions represent an attempt (often futile) of the immune system to protect the nervous system. An important implication for immunotherapy is that non-selective immunosuppressive treatments are likely to eliminate the neuroprotective autoimmune cells

along with the autoaggressive offenders. This may be one of the reasons why treatment with nonselective immunosuppressive agents often fails to have a convincing clinical benefit.

Immunosuppressive and immunomodulatory agents

Glucocorticosteroids

Glucocorticosteroids (GCS) are the most widely and frequently used immunomodulatory agents. For some indications treatment with GCS is limited to a short period of time (as in, e.g. multiple sclerosis), for others it is extended over many years (as in, e.g. giant cell arteritis). In principle, both short-term and long-term treatment with GCS can be associated with severe adverse reactions. As a general rule, however, side effects depend on the daily dose, dosing frequency, and duration of treatment. When GCS treatment becomes mandatory, efforts must focus on minimizing GCS side effects while maintaining therapeutic efficacy. Generally, these goals can be at least partially attained by using short-acting GCS medications at the lowest possible dose and the greatest dosing interval for the shortest period of time (Katz, 2000).

The anti-inflammatory and immunosuppressive effects of glucocorticosteroids have several compounds. First, steroids profoundly influence the distribution and trafficking of leukocytes. For example, steroids induce peripheral blood neutrophilia, whereas T-cells, monocytes and eosinophils are depleted from blood. Secondly, steroids alter the functional properties of T-cells and monocytes. Thirdly, steroids act on the synthesis and secretion of cytokines and immune mediators. Fourthly, steroids have an effect on microvascular permeability, which may contribute to the effects on leukocyte migration.

GCS bind to cytoplasmic receptors. After binding, the GCS–receptor complex traverses nuclear pores, binds to DNA at specific sites, leads to change in the transcription rates of GCS-sensitive genes, and results in regulation of proteins participating in the inflammatory response. The profound (but transient) effects of GCS on leukocyte trafficking differ depending on cell type. Due to both redistribution and deletion there is a rapid decrease of lymphocytes and monocytes. T-lymphocytes, in particular CD4+ T-helper cells, are more severely affected than B-cells. Natural killer cells are similarly resistant. At the same time, neutrophil numbers increase due to release from bone marrow and decreased egress from the circulation to inflammatory sites. Antibody-mediated responses including allergic reactions are suppressed as well as graft rejections. However, although total lympoid tissue shrinks during prolonged treatment, both cellular and humoral immunity are still functional at a reduced level.

Besides influencing the number and distribution of immune cells, GCS down-regulate the secretion of several lymphokines, including various interleukins, interferon-γ, and tumour necrosis factor-α. The antiinflammatory effects of GCS include the suppression of the secretion of arachidonic acid metabolites such as prostaglandins and leukotriene, the decrease of capillary dilatation, edema, fibrin deposition and the blockade of lysosomal enzyme degranulation.

Prolonged therapy with oral GCS is usually started as a single morning dose of a relatively short-acting GCS such as prednisone, prednisolone and methyprednisolone. These agents have a biologic half-life of approximately 12–36 hours, and can thus be considered as relatively short-acting GCS (Katz, 2000). By comparison, betamethasone and dexamethasone are long-acting CGS with a biologic half-life of 36–54 hours. The once-daily oral regime is maintained until the disease is stable or improved. At this time, therapy is tapered to an alternate-day regime. This approach permits a return to normal hypothalamic–pituitary–adrenal axis function while reducing the risk of side effects. High dose i.v. GCS pulse therapies (e.g. 500 or 1000 mg methylprednislone per day for 3 to 5 consecutive days), as are frequently used for acute exacerbations of multiple sclerosis, are sometimes efficacious in other situations and diseases, even when superimposed on a daily GCS regime. It is possible that such high dose pulse therapy with GCS has additional immunosuppressive effects, for example, by inducing apoptosis of inflammatory cells (Gold et al., 1997).

GCS have a large array of potential side effects. Therefore, steroid therapy must be managed with care, by clinicians experienced in its use. For some indications, it is advisable to hospitalize patients for initiation of steroid therapy. For example, patients with generalized myasthenia gravis may experience a transient steroid-induced exacerbation of myasthenic weakness.

The continued administration of GCS carries the risk of side effects for which patients should be closely monitored (Table 93.2). Hypothalamic–pituitary–adrenal axis suppression may occur with less than 2 weeks of systemic therapy. The most important side effects with long-term treatment are osteoporosis, hypertension, exacerbation or precipitation of diabetes, obesity, gastrointestinal ulcers, cataracts and occasional opportunistic infections. Typical signs of infection may be masked by GCS treatment. Blood pressure, weight, serum electrolytes and glucose level should be closely followed and adequately treated. Regular

Table 93.2. Side effects of glucocorticosteroid therapy

Characteristic early in therapy: essentially unavoidable
Insomnia
Emotional lability
Enhanced appetite or weight gain or both
Common in patients with underlying risk factors or other drug toxicities
Hypertension
Diabetes mellitus
Peptic ulcer disease
Acne vulgaris
Anticipated with use of sustained and intense treatment: minimize risk by conservative dosing regimens and steroid-sparing agents when possible
Cushingoid habitus
Hypothalamic–pituitary–adrenal suppression
Infection diathesis
Osteonecrosis
Myopathy
Impaired wound healing
Insidious and delayed: likely dependent on cumulative dose
Osteoporosis
Skin atrophy
Cataracts
Atherosclerosis
Growth retardation
Fatty liver
Rare and unpredictable
Psychosis
Pseudotumour cerebri
Glaucoma
Epidural lipomatosis
Pancreatitis

slit lamp examinations (every 6 months) help to detect cataracts early. In patients with a history of ulcer, histamine H2 receptor antagonists such as ranitidine, or H^+, K^+-ATPase inhibitors such as omeprazole should be given to protect the upper gastrointestinal mucosa from ulceration and bleeding.

GCS-induced osteoporosis is especially problematic in older individuals, particularly those who are estrogen deficient. To minimize steroid-induced osteoporosis, the single most effective measure is reduction of dosage or, if possible, complete discontinuation of the GCS. Calcium supplementation and postmenopausal estrogen repletion are helpful. The 24-hour urine calcium output should be measured after 1–3 months of GCS therapy and oral calcium and vitamin D should be given, based on the level of urinary calcium excretion. Cyclical, oral bisphosphonates prevent GCS-induced loss of bone mineral density in the spine and hip. Potassium replacement is necessary only in patients who develop hypokalemia.

Immunosuppressive and cytotoxic agents

Azathioprine and mycophenolate mofetil

Azathioprine has been used for many years for immunosuppressive treatment of neuroimmunological disorders. Because of its efficacy and tolerability, AZA remains one of the mainstays of immunosuppressive treatment.

The action of AZA is predominantly due to conversion into its metabolite 6-mercaptopurine. This completes with its analogue, hypoxanthine, a central component of nucleic acid synthesis and therefore has widespread effects on DNA and RNA synthesis. AZA acts primarily on proliferating lymphocytes and induces both B- and T-cell lymphopenia (Anstey & Lear, 1998). In vitro studies have demonstrated effects on both T- and B-cell functions, in particular the inhibition of surface receptor expression (for example CD2), blocking of mitogen-driven responses and antibody responses. Antigen- and mitogen-induced in vitro proliferative responses of T-cells are less inhibited by AZA than by cytotoxic agents like cyclophosphamide. AZA also has mild antiinflammatory properties, probably due to the inhibition of promonocyte cell division.

AZA is frequently used as an adjunct, e.g. to reduce the dose of CGS, but may be used alone. It is relatively easy to use as a therapeutic agent. Two major disadvantages of AZA are the following. First, up to 10% of patients show an acute idiosyncratic reaction, with general malaise, fever, skin reactions, and GI symptoms of nausea and vomiting. In this situation, the drug should be discontinued immediately. Secondly, the immunosuppressive effects develop slowly over several months. For this reason, 6 to 12 months of treatment are usually required to judge the efficacy of AZA treatment.

The incidence of serious side effects of azathioprine is relatively low. The most frequent adverse reactions encountered during long-term treatment in 104 patients with severe generalized MG in decreasing order of frequency were reversible marrow depression with leukopenia, gastrointestinal complications, infections and transient elevation of liver enzymes (Hohlfeld et al., 1988). The most serious observation, which may possibly have been related to 6 years of treatment with azathioprine, was renal lymphoma in one patient.

Mild intestinal discomfort, reported relatively commonly, can usually be alleviated by splitting the dose into

three or more divided doses, taking the drug after meals, starting treatment with a bedtime dose, and reducing the dose temporarily. A serious gastrointestinal complication is AZA-related pancreatitis. Elevation of liver enzymes up to three times the baseline is also common and may be tolerated, since it is usually reversible after the dose has been reduced. The risk of developing malignancies, especially lymphoma, is not certain, but seems to be lower in patients with MG than in organ transplant recipients. By contrast to what might be expected from experience in transplantation medicine, serious infections are rarely a problem in AZA-treated patients with neuroimmunological disease (Hohlfeld et al., 1988). Azathioprine is potentially teratogenic and mutagenic. Patients should be advised to use contraceptive measures during treatment and for at least several months after its completion. Data available from mothers treated with azathioprine for kidney transplant have not shown an increased rate of birth defects in their children, but no data on the actual risk are available.

Patients should be monitored carefully for side effects during treatment. Complete blood counts should be obtained at least weekly during the first 2 months, and monthly thereafter. If the total white blood count (WBC) is reduced to less than 3000/μl, the medication should be discontinued for a few days and treatment continued at a lower dose after the WBC returns to more than 3500/μl. The long-term dose can be adjusted to maintain the WBC around 4000/μl, and lymphocyte counts ranging between 800 and 1000/μl. However, it is not certain whether the immunosuppressive efficacy of AZA therapy in autoimmune diseases is directly correlated to the WBC or lymphocyte count.

In patients receiving AZA and steroids, the total WBC is usually elevated because of steroid-induced neutrophilia (see section on glucocorticosteroids). Therefore, the above suggestions for monitoring treatment by total WBC do not apply in patients who are concomitantly treated with GCS. During combined treatment, a WBC of approximately 6000 to 8000/μl can be used as the lower tolerable limit. Alternatively, the lymphocyte count, which is less markedly altered by corticosteroids, can be used for monitoring.

Another measure of drug effect is the mean corpuscular volume (MCV) of red cells, which is usually but not invariably elevated (up to 15%) during long-term treatment. This may be useful in situations when there is doubt about the compliance of patients in taking their medication.

Up to 10% of the population has a genetically reduced activity of the enzyme thiopurine-5-methyltransferase. In these patients, AZA metabolism is reduced and AZA toxicity increased. Mutations of the enzyme can be detected (ruled out) by PCR before treatment.

An important drug interaction occurs with allopurinol. Inhibition of xanthine oxidase by allopurinol impairs the conversion of azathioprine to 6-thiouric acid which accumulates and eventually leads to myelosuppression. If allopurinol must be administered concurrently, the dose of azathioprine must be reduced to 25% of the regular dose (approximately 0.5 mg per kg body weight) and the WBC should be closely monitored.

Mycophenolate mofetil is another immunosuppressive agent acting on DNA metabolism. In transplantation medicine, mycophenolate mofetil has proved useful and seems more powerful than AZA (Lipsky, 1996). In patients with neuroimmunological disease, e.g. myasthenia gravis, mycophenolate mofetil has been tried if AZA is not tolerated or contraindicated (Chaudry et al., 2001). Mycophenolate mofetil inhibits inosine monophosphate dehydrogenase and thereby depletes guanine nucleotides, leading to inhibition of DNA synthesis. Its adverse effects include gastrointestinal symptoms, gastrointestinal hemorrhage, leukopenia and infection. Compared to AZA, its hepatotoxicity is low, but its risk of secondary lymphoma seems slightly higher (Lipsky, 1996). In contrast to AZA, the combination of mycophenolate mofetil and allopurinol is not problematic.

Immunophilin-binding agents (cyclosporin, sirolimus and tacrolimus)

Cyclosporin, sirolimus (rapamycin) and tacrolimus (FK506) form the trinity of immunophilin-binding drugs. The immunophilin-binding drugs form complexes with abundant intracellular proteins called immunophilins: cyclosporin with cyclophilin (CP), and tacrolimus and sirolimus with the tacrolimus-binding protein (FKBP). The cyclosporin–CP and tacrolimus–FKBP complexes inhibit the phosphatase calcineurin and its substrate, the transcription factor NFAT, thus preventing the transcription of messenger RNAs for key cytokines, such as interleukin-2. The rapamycin–FKBP complex binds to a kinase called the target of rapamycin (TOR). TOR controls the phosphorylation of proteins involved in regulation of the cell cycle (Abraham, 1998).

Since NFAT is a validated target for two clinically important immunosuppressive drugs, interference with NFAT regulation might be expected to yield additional avenues for immunosuppression in the future (Kiani et al., 2000).

The immunophilin-binding agents very efficiently suppress transplant rejection, but presently are only rarely used in neuroimmunological disease. Cyclosporin was demonstrated to be effective in myasthenia gravis (Tindall et al., 1993), but has remained a second-line agent, mainly owing to its nephrotoxicity and high cost. A trial in multi-

ple sclerosis showed only modest benefit, and was associated with significant nephrotoxicity (The Multiple Sclerosis Study Group, 1990). It is likely that in the future immunophilin-binding agents will gain more importance in the treatment of neuroimmunological diseases. In addition to their immunosuppressive action, some of these substances or their derivatives seem to have neurotrophic effects (Steiner et al., 1997).

Cyclosporin is a cyclical undecapeptide isolated from two species of soil fungi. It targets the immune system more specifically than azathioprine or cyclophosphamide. Since its immunosuppressive effects were first noted, it has revolutionized transplant surgery leading to a dramatic increase in graft survival after cardiac, kidney, liver or pancreas transplants. The effects of cyclosporin focus on T-lymphocytes; B-cells and macrophages are apparently spared. The only appreciable effect of cyclosporin on accessory cells seems to be the disruption of lymphokine-dependent T-lymphocyte/macrophage interactions. Clinical improvement usually begins in 2–4 weeks.

Major side effects of cyclosporin include nephrotoxicity and hepatic disorders. In addition, cyclosporin can affect other organs such as the pancreas, CNS, bone and skeletal muscle. Further adverse reactions include arterial hypertension, tremor and hirsutism. Most of the adverse effects correlate with the dose and duration of treatment. Optimal dosage is monitored by measuring 'trough' drug levels, 12 hours after the last dose (i.e. first thing in the morning). For example, if the creatinine level increases by 50% over baseline levels or to more than 1.5 mg per 100 ml during treatment, the dose should be reduced or the drug discontinued. A more sensitive indicator of nephrotoxicity is the measurement of creatinine clearance. The encephalotoxicity of cyclosporin is discussed in Chapter 129. Cyclosporin must be discontinued if idiosyncratic or allergic reactions develop. The risk of late malignancies is not established, but may be similar to that of azathioprine.

Methotrexate (MTX)

Methotrexate is a chemotherapeutic drug used in oncology. For patients with neuroimmunological disease, it is used as a second-line immunosuppressive treatment, for example for treating inflammatory myopathies and, with limited success, advanced multiple sclerosis. For these indications, MTX is given orally at a dose from 10 to 20 mg 1 day each week.

MTX is a structural analog of folic acid acting as a folic acid antagonist. MTX inhibits the enzyme dihydrofolate reductase leading to a partial depletion of tetrohydrofolate cofactors and, as a consequence, inhibits purine and thymidilate synthesis. Due to its mechanism of action, MTX acts on rapidly dividing cells. Given satisfactory renal function and adequate hydration, MTX is excreted unchanged mainly in the urine within 12 hours of administration. Chronic extended use can lead to liver fibrosis and cirrhosis. Further adverse effects include bone marrow suppression, gastrointestinal complications, cystitis, lung fibrosis, alopecia and cutaneous vasculitis. Concurrent application of folate may reduce the incidence of side effects without significant reduction of therapeutic efficacy. Non-steroidal anti-inflammatory agents and trimethoprinsulfamethoxazole can potentiate the toxicity of MTX.

Cyclophosphamide

Cyclophosphamide (CTX) has been used as an immunosuppressive agent in vasculitis and neuroimmunological diseases refractory to other forms of immunosuppressive therapy. CTX belongs to the group of alkylating agents due to its ability to intercalate into the DNA helix. It is therefore primarily acting upon rapidly dividing cells from the lymphoid, gastrointestinal, urothelial systems, the hair follicles, ovarian and testicular tissue and certain tumour cells. The desired actions (i.e. immunosuppression and decrease of tumour growth) as well as the adverse effects (i.e. leukopenia, hemorrhagic cystitis, amenorrhea, oligospermia and transient alopecia) are caused by its effect on DNA. CTX acts upon the immune system in a number of different ways including the decrease of T-cells of various subclasses and, even more, B-cell numbers and function. Its efficacy in lupus nephritis, Wegener's granulomatosis and various vasculitides has led to its use in MS (Weiner et al., 1995) and other neuroimmunological disorders.

Cyclophosphamide may have serious side effects. The major and often limiting side effect is bone marrow suppression affecting leukocytes more than erythrocytes and platelets. The active metabolites are concentrated in the urine. This may damage the epithelium of the bladder (hemorrhagic cystitis, malignant transformation). This kind of toxicity can be reduced by a high fluid intake and, during pulse administration of high doses intravenously, by the simultaneous use of a uroprotective agent (mesna). In this connection, even microhematuria is an alarming sign that requires intense investigation to exclude a bladder tumour.

Patients should be informed that during prolonged therapy serious side effects may develop, and should be instructed to report signs and symptoms without delay. Permanent infertility may occur in both male and female patients. Alopecia may develop with short- and long-term therapy but is mild and reversible after treatment is stopped. Additional, rarer side effects include myocardial

damage and pulmonary fibrosis. After prolonged treatment, the potential for the development of leukemia, lymphoma, and urological cancers is of particular concern. Tumours can occur many years after therapy with CTX was stopped. The risk of malignancy depends on the cumulative dose, which should not exceed 85 grams. Like other cytotoxic agents, cyclophosphamide is potentially teratogenic and should be avoided during pregnancy, especially in the first trimester.

Cyclophosphamide is given orally at a dose of 1 to 2 mg per kg body weight per day, or by intermittent i.v. pulse theraphy (0.5–1.0 g/m^2). The i.v. pulses are repeated monthly for 6 months, and later in 3-month intervals for 1 to 2 years. If possible, therapy with CTX should be limited to 2 or 3 years because of its cumulative toxic and carcinogenic effects.

Mitoxantrone (MIX)

Mitoxantrone (MIX) is a synthetic anthracycline derivative that has been tested with promising results in relapsing and in chronic progressive MS (Hartung et al., 1999). The drug acts on both DNA and RNA synthesis. However, its molecular action is not yet fully defined. The interference with nucleic acid synthesis explains its influence on rapidly dividing and metabolically active cells such as tumour cells and immune cells. Mitoxantrone is given as a single infusion (12 mg/m^2 in 250 ml of 0.9% sodium chloride or 5% dextrose) over 30 min. Antiemetics (ondansetron or tropisetron) should be coadministered to prevent nausea. To maintain immunosuppression over longer periods of time, MIX has to be administered every 3 months. Although the acute toxicity is lower than that seen in patients treated with high dose cyclophosphamide, MIX like other anthracycline derivatives (doxorubicin and daunorubicin) is cardiotoxic. Congestive heart failure and decreased left ventricular ejection fraction have been observed with cumulative doses of 140 mg and higher. Patients with preexisting cardiac problems should therefore not be treated with MIX. In addition, each patient should be evaluated with an electrocardiogram and echocardiography before initiation of therapy and after one year of therapy. Frequent analysis (every other day during the first 2 weeks after therapy and then weekly) of laboratory values including blood counts, liver enzymes, uric acid and renal laboratory values should be obtained, because myelosuppression occurs within a few days after therapy. Patients who were treated with MIX for a tumour, e.g. breast cancer, have an approximately tenfold risk for later development of a secondary hematopoetic malignancy.

Patients should be informed that a bluish discoloration of urine and of the sclera occurs within 24hrs after administration. Besides cardiac problems, adverse reactions include bleeding, nausea and vomiting, jaundice, infections, renal failure, alopecia, seizures and headaches, cough and dyspnea and allergic reactions. The risks of administration must therefore be carefully weighed against the desired effects. Mainly because of its cumulative cardiotoxicity, MIX can only be applied for a relatively short time span, thus limiting its use in a chronic disease like MS. Patients should be carefully informed about the potential risks and benefits of this treatment.

Immunomodulatory agents

In contrast to immunosuppressive drugs, immunomodulatory agents do not globally suppress, but rather modulate immune functions in a complex way. They may even enhance certain immune functions. It is the overall effect on the immune system that translates into a clinical benefit. Interferon-beta can be considered the prototype of an immunomodulatory agent.

Interferons

Three different preparations of recombinant interferon-β (IFN-β) have been approved in different countries for treatment of MS, interferon-β-1b (Betaferon, Betaseron), interferon-β-1a (Rebif), and interferon-β-1a (Avonex). Initially, interferons were tested in MS for their antiviral effect (for review see Jacobs & Johnson, 1994). A pilot trial of systemic recombinant IFN-γ resulted in a sharp increase of clinical exacerbations (Panitch et al., 1987). In contrast, IFN-β turned out to have a beneficial effect, which has meanwhile been corroborated in several large controlled trials (Sibley et al., 1995; Jacobs et al., 1996; Ebers, 1998; Kappos, 1998).

Different trials of IFN-β showed a 30% reduction of the exacerbation rate, and/or a delay in time until sustained clinical progression. The precise mechanisms of the effects of IFN-β are unknown. Antiviral and antiproliferative actions might contribute, although immunomodulatory effects such as reduced transcription of MHC class II molecules are considered more important. Consistent with this notion, type I interferons are also effective in EAE.

Interferons have antiproliferative and various immunomodulatory effects (Arnason & Reder, 1994; Weinstock-Guttman et al., 1995; Yong et al., 1998; Hall et al., 1997). IFN-α is part of a multigene family, whereas IFN-β and IFN-γ are encoded by single genes. Because IFN-α and IFN-β share components of the same receptor, they are referred to as type I interferons. IFN-γ uses a separate receptor and is referred to as type II interferon. The receptor for type I IFNs is composed of at least two chains

Table 93.3. The many effects of interferon-beta

Process	Effect	Process	Effect
Activation		*Tissue damage*	
Major histocompatibility complex (MHC) class I expression	↑	Lymphotoxin production by TH1 cells	↓
MHC class II expression	↑↓	Tumour necrosis factor alpha production by macrophages	↓[b]
B7.1 expression on B cells	↓	Macrophage cytolytic activity	↑↓[b]
B7.2 expression on monocytes	↑	Release of mitogen and oxygen intermediates by macrophages	↑↓[b]
Suppressor cell function	↑[a]	CD14 expression on macrophages	↓[b]
Recruitment		*Recovery*	
Circulating lymphocyte numbers	↓	IL-10 production by macrophages	↑[b]
Lymphocyte entry to lymph nodes	↑	Transforming growth factor beta-1 production by peripheral blood mononuclear cells	↑[b]
Expansion		Prostaglandin E_2 release from macrophages	↓[b]
Interleukin (IL)-2 production by TH1 cells	↑[b]		
IL-2 receptor expression	↓[b]	*Other*	
T-cell proliferation	↓[b]	Antibody synthesis	↑
		Cytotoxic T-cell function	↑
Trafficking		Cytotoxic natural killer cell function	↑
Lymphocyte exit from lymph nodes	↓	Cytostasis	↑

(IFNAR-1 and IFNAR-2). The receptor for IFN-γ is composed of at least two transmembrane chains, IFNGR-1 and IFNGR-2. Although the surface receptors are different, several components of the intracellular signalling pathways are shared between type I and type II IFNs. Thus, the signalling pathways of the different IFNs partially overlap (Darnell et al., 1994; Briscoe et al., 1996). Additional IFNs have been discovered, but they have not been as well characterized.

Type I interferons, the IFN-α family and IFN-β, are produced by almost all mammalian cells upon stimulation. One (but not the only) inducer of interferon synthesis is double-stranded RNA, which is part of the infectious cycle of most viruses, but is not found in mammalian cells. IFNs trigger the synthesis of many host-cell proteins that contribute to the inhibition of viral replication, and are believed to mediate most of the biological effects of the IFNs. Like IFN-γ, type I interferons increase expression of MHC class I and therefore enhance the ability of virus-infected cells to present viral peptides to CD8+ T cells. In contrast to IFN-γ, however, IFN-α and IFN-β do not induce but suppress the synthesis of MHC class II proteins. This effect may be important for the immunomodulatory activity of type I interferons (Weinstock-Guttman et al., 1995; Yong et al., 1998; Hall et al., 1997). The exact mechanism of IFN-β-mediated MHC class II inhibition is not completely understood. It appears that IFN-β reduces the activity of the class II transactivator CIITA, a factor necessary for IFN-γ-induced MHC class II transcription (Lu et al., 1995).

Apart from the inhibition of MHC class II expression, numerous other immunomodulatory effects of type I interferons have been described (Table 93.3). For example, IFN-β has been shown to up-regulate interleukin-10 expression and secretion by T-cells and monocytes (Rudick et al., 1996, 1998a; Rep et al., 1996; Weber et al., 1999), indicating that part of the clinical effects of IFN-β are in fact mediated by interleukin-10. Both IFN-β-1a and IFN-β-1b induce the production of IL-10 in MBP-specific CD4+ T-cell lines, but inhibit proliferation and production of lymphotoxin (Weber et al., 1999). Furthermore, IFN-β inhibits T-cell migration across basement membrane in vitro, presumably by decreasing the secretion of matrix-degrading enzymes

(Leppert et al., 1996; Stüve et al., 1996). This IFN-mediated inhibitory effect on the secretion of matrix metalloproteinases, as well as other consequences of IFN cellular responses, may be pertinent for the suppression of inflammation (i.e reduced numbers of enhancing MRI lesions and lessened CSF pleocytosis) observed in IFN-treated MS patients. Potential mechanisms include increase in soluble VCAM-1 (Calabresi et al., 1997b) and concomitant down-regulation of the corresponding partner adhesion molecule VLA-4 on peripheral blood lymphocytes (Calabresi et al., 1997a). Increased soluble VCAM-1 and decreased cellular VLA-4 would tend to block leukocyte–endothelial adhesion at the blood–brain barrier. Leukocytes also require stimulation by chemoattractants, called chemokines, during extravasation, and several chemokines are increased in the CSF of patients with relapses of MS. It is interesting that IFNs up-regulate the expression of chemokines by numerous cell types, including hematopoietic cells. Elevated levels of chemokines in the circulation would tend to reduce transvascular chemokine gradients, favouring the entry of cells into the CNS.

A myriad of other effects of IFN-β have been described (Table 93.3). The relative importance and mutual interdependence of this bewildering variety of actions are not well understood, so that at the present time the mechanisms of IFN-β treatment of MS remain unknown.

There is evidence that recombinant IFN-α also reduces exacerbation frequency (Durelli et al., 1994) and MRI activity (Myhr et al., 1999) in relapsing–remitting MS. Its efficacy as regards MRI activity was comparable to that observed in trials of IFN-β (Myhr et al., 1999). The profile of side effects was similar to that of IFN-β (see below). In addition, however, there was a high incidence of moderate to severe (reversible) hair loss (40% in the high dose group after 6 months) (Myhr et al., 1999). Whether IFN-α will ever be as important in MS treatment as IFN-β now seems doubtful. However, it should be noted that although IFN-β and IFN-α bind to the same receptor, they interact with the receptor in different ways. These differential binding modes of IFN-α and IFN-β result in differential cytoplasmic signalling and perhaps, different clinical effects.

The major short- and medium-term side effects of IFN-β observed in MS trials include 'flu-like symptoms and (usually mild) laboratory abnormalities (Walther & Hohlfeld, 1999). Skin necrosis at injection sites occurred in up to 5% of patients in trials of subcutaneous IFN.

Initially up to 75% of patients experience 'flu-like symptoms such as fever, myalgia, headache, fatigue, and chills. The reaction begins 3–6 hours after injection and usually improves within 24 hours. The individual pattern and intensity of these symptoms vary greatly from patient to patient and even from injection to injection. These transient 'flu-like symptoms are probably related to a temporary up-regulation of inflammatory cytokines such as interleukin-6 (IL-6), tumour necrosis factor alpha (TNF-α), and IFN-γ (Dayal et al., 1995; Brod et al., 1996). The flu-like reactions usually resolve during the first 3 months of treatment. Patients should be advised to take the injection before bedtime in order to 'sleep off' most of the side effects and to take non-steroidal antiphlogistics (NSAIDs) as comedication. Oral prednisone (10 mg per day) with or without NSAIDs is highly effective in reducing 'flu-like symptoms, if NSAIDs alone are not sufficient.

Many patients experience a transient worsening of pre-existing MS symptoms, especially increased spasticity. This usually appears within the complex of 'flu-like symptoms, especially in the first 12 weeks of treatment, and is probably similar in nature to the functional deterioration of the neurological status of MS patients as a consequence of stress, heat, fever, or inflammatory mediators. Symptoms typically appear 3–24 hours after IFN injection and can last between several hours to several days. Comedication with NSAIDs and, sometimes, antispasticity medication (e.g. baclofen) is helpful.

Neither IFN-β-1a nor IFN-β-1b has been associated with significant hepatic or renal dysfunction or bone marrow suppression. The most commonly observed laboratory abnormalities are lymphopenia, neutropenia, leukopenia, and raised liver aminotransferase values. These changes were seldom serious and always reversible during clinical trials and postmarketing surveillance. Complete blood counts should be obtained each month as well as serum chemistries with liver function tests in the first three months, and quarterly thereafter. If significant laboratory changes occur, the dosage should be temporarily reduced or discontinued. Once the parameters have normalized, it is usually possible to gradually increase the dosage of IFN without any complications. Although no evidence for any drug interactions has emerged so far, the concomitant administration of IFN-β and other potentially hepato- or myelotoxic medications such as anticonvulsants, antidepressants, or ticlopidine should be closely monitored.

Preclinical studies with both IFN-β-1b and IFN-β-1a in rhesus monkeys demonstrated that high doses of IFN-β were not teratogenic for the embryo, but they had a dose-dependent abortive effect. It is, however, not known if IFN-β is teratogenic in humans. It is generally recommended that interferon therapy should be discontinued before a planned pregnancy, and then during pregnancy. However, IFN-β therapy is not necessarily an indication for inducing

an abortion of an intact pregnancy once the drug has been discontinued until delivery. It is not known whether IFN-β is secreted into breast milk. Although the protein is most likely degraded in the acidic environment of the infant's stomach, therapy should nevertheless be discontinued during nursing for safety reasons. To lower the risk of a relapse postpartum, one can consider early weaning and begin treatment with IFN-β soon after delivery.

Symptoms of depression are frequent in MS patients. Up to 50% of patients who begin IFN-β therapy have unrealistically optimistic treatment expectations, and consequently their compliance is significantly less than that of patients with more realistic expectations. These facts should be taken into account when evaluating the significance of IFN-β in depression (Ebers et al., 1998). If depression and mood disorders appear during therapy with IFN-β, they should be treated like all other depressive syndromes, i.e. with antidepressant medication and psychotherapy. The individual pros and cons of IFN-β treatment in light of the actual course of the disease must be openly and critically discussed with the patient in order to decide whether IFN-β should be continued.

The incidence and character of injection site complications depends on the route of administration. Cutaneous reactions range from mild irritation to necrosis (IFNB Multiple Sclerosis Study Group, 1995; Jacobs et al., 1996; Ebers et al., 1998; Kappos et al., 1998). Generally, intramuscular injection causes less skin reactions, and so far no necroses have been reported. On the other hand, however, i.m. injection may be complicated by abscess formation.

The development of other autoimmune diseases is a rare but documented side effect of IFN-α therapy. Several cases of similar complications recently reported for IFN-β include myasthenia gravis, hyper- and hypothyroidism, Raynaud's phenomenon, autoimmune hepatitis, rheumatoid arthritis, and lupus erythematosus. Since autoimmune complications may be serious, other immunoactive drugs should be considered for MS patients with known autoimmune thyroid dysfunction or other autoimmune diseases.

A single case of a capillary-leak syndrome (CLS) associated with a pre-existing C1-esterase-inhibitor (C1-INH) deficiency and a monoclonal gammopathy in a patient treated with 8 MIU IFN-β-1b has been reported. The patient died within 80 hours postinjection due to shock and multiorgan failure (Schmidt et al., 1999). IFN-β should not be prescribed in MS if the patient's history or blood tests suggest a concomitant disease with abnormalities of the complement system or increased B-cell activation (e.g. monoclonal gammopathy of unknown significance).

Both IFN-β-1b and IFN-β-1a may be associated with a worsening of psoriasis vulgaris. Very rarely, anaphylaxis or shock may occur.

During therapy with IFN-β, patients may develop antibodies that neutralize its biological effects. Such neutralizing antibodies have been observed in MS patients treated with IFN-β-1b and in patients treated with IFN-β-1a (Jacobs et al., 1996; IFNB Multiple Sclerosis Study Group and UBC MS/MRI Analysis Group 1996; Ebers et al., 1998; Kappos et al., 1998; Khan & Dhib-Jalbut, 1998; Yong et al., 1998; Rudick et al., 1998b). The clinical significance of the neutralizing antibodies remains uncertain. It seems clear that they may attenuate or abolish the treatment effect. However, the following points should be considered. First, although the reported incidence of neutralizing antibodies varies between trials, the results of different trials are definitely not directly comparable because of different assays, cut-off levels and/or methods for confirmation of antibody positivity. Secondly, there are no reliable criteria to predict whether individual patients will develop neutralizing antibodies. Thirdly, antibody titres may fluctuate widely in individual patients. Notably, the antibodies may completely disappear despite continued treatment. Fourthly, some antibodies to IFN-β may serve as carriers, prolonging the half-life for biologic activity and enhancing the bioactivity.

Copolymer-1 (COP-1; glatiramer acetate)

Copolymer-1 (COP-1) is a rather unique immunomodulatory agent used for treatment of patients with relapsing MS. It is a synthetic basic random copolymer of L-glutamic acid, L-lysine, L-alanine, and L-tyrosine in a milar residue ratio of 0.14:0.34:0.43:0.1 and an average molecular mass of 4700–11 000 Da. COP-1 was originally studied along with other basic copolymers in an attempt to simulate the activity of MBP in inducing EAE, but was then found to suppress EAE in various species including the guinea pig, rabbit, mouse, rhesus monkey, and baboon (for review see Arnon et al., 1996).

It has been proposed that COP-1 competes with MBP and perhaps, other myelin autoantigens for binding to MHC class II molecules expressed on antigen-presenting cells (APC) (Arnon et al., 1996). COP-1 binds promiscuously to purified HLA-DR molecules (Fridkis-Hareli & Strominger, 1998). This would place COP-1 in the category of MHC inhibitors. Since D-COP-1, a stereoisomeric form of COP-1, binds as efficiently to MHC class II molecules as COP-1 but does not inhibit EAE, MHC binding seems to be a necessary but insufficient step that must be followed by a more specific step such as induction of regulatory cells or T-cell receptor antagonism.

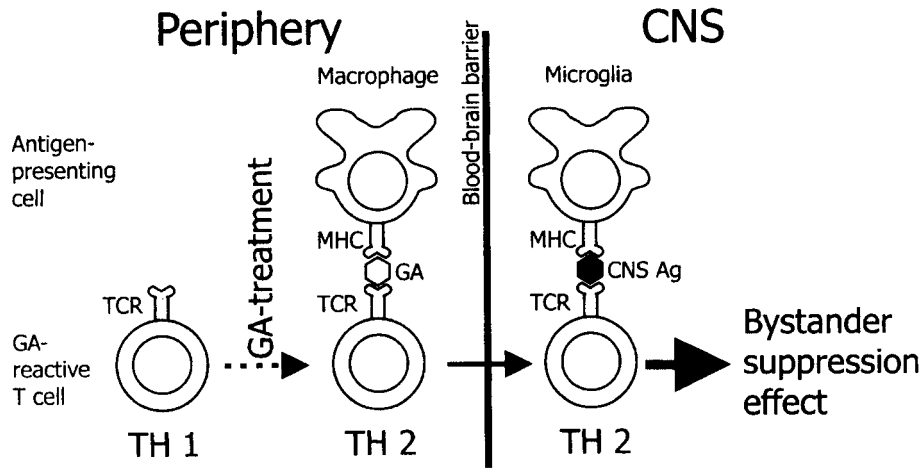

Fig. 93.1. Schematic view of the putative mechanism of action of glatiramer acetate (GA) (Neuhaus et al., 2001). In the periphery, outside the CNS, GA initially stimulates a population of TH1-like T-cells. During treatment, the properties of the GA-stimulated T-cells change, and they become more TH2-like (dotted arrow). The activated GA-specific T-cells enter the CNS, where they encounter CNS antigens like MBP bound to MHC class II and presented on the surface of microglia cells. The GA-reactive T-cells are stimulated to secrete down-modulatory cytokines like IL-4, which exert a bystander suppressive effect on other T-cells. TCR = T-cell receptor; MHC = major histocompatibility complex; Ag = antigen.

It is difficult to understand how COP-1 can compete with myelin antigens for MHC binding at the subcutaneous injection site. In this regard, the actions of COP-1 in MS may differ from those in EAE. In MS, COP-1 is abundantly available at subcutaneous injection sites. It is unlikely, however, that COP-1 peptides reach the brain. On the other hand, the repeated subcutaneous 'immunization' with COP-1 seems to induce a population of COP-1-reactive regulatory T-cells of the so-called TH2 type (Neuhaus et al., 2000). Since activated T-cells can traverse the blood–brain barrier (Wekerle et al., 1986), these COP-1-reactive regulatory cells should be able to reach the brain parenchyma and particularly, MS lesions. Here, they will be confronted with myelin degradation products, including MBP peptides bound to MHC molecules expressed on the surface of perivascular microglia and secondarily recruited macrophages. It can be further postulated that upon recognition of cross-reactive MBP, the COP-1 reactive 'suppressor' T-cells are activated (or modulated) to exert their down-regulatory functions. The suppressive effect might extend to T-cell responses against other myelin antigens, e.g., PLP ('bystander suppression; Fig. 93.1) (Neuhaus et al., 2001).

Conversely, systemically circulating MBP-reactive T-cells might be altered (e.g. down-regulated, 'tolerized', or shifted in cytokine profile) after recognition of cross-reactive components of COP-1 in the periphery. Indeed, there is some evidence that COP-1 peptides can act as 'altered peptide ligands' (APL) or 'T-cell receptor antagonists' on MBP-specific T-cells (Aharoni, et al., 1999). In vitro, human T-cells specific for MBP epitope 82-100 were inhibited when they were cocultured with APC pulsed with MBP and APC pulsed with COP-1, suggesting a TCR-antagonistic effect of COP-1 (Aharoni et al., 1999). Note that in contrast to MHC competition and TCR antagonism, APL-like effects do not require the simultaneous exposure of T-cells to both COP-1 and MBP. Therefore, APL effects could occur in the periphery at subcutaneous injection sites. After exposure to COP-1 in the periphery, MBP-specific T-cells might be altered in their properties and respond differently when they encounter their original antigen MBP in the brain (O. Neuhaus et al., unpublished data).

The therapeutic effects of COP-1 are reviewed in Chapter 99.

Intravenous immunoglobulins

Intravenous immunoglobulins have been widely used for therapy of neuroimmunological diseases, including neuromuscular disorders and multiple sclerosis (Said, 2000). Based on the first experience of i.v. Ig in idiopathic thrombocytopenic purpura, i.v. Ig is usually given as a cycle of 5 consecutive days of 0.4 g/kg body weight (summing up to a total of 2 g/kg body weight) in acute neuromuscular disorders (like Guillain–Barré syndrome). Whether a reduction of the dose or shortening of the cycle

Source: From Voltz and Hohlfeld (1996).

would be similarly efficacious, has not been tested in controlled studies. In chronic treatment (like for CIDP), however, there is no reason why i.v. Ig should be given in 5-day cycles. Instead, impairment should be assessed in regular intervals, e.g. every 6 weeks (or less or more often, depending on the course) and at these intervals the dose should be adjusted according to the clinical course and individual response. In this manner, the dose of i.v. Ig is 'titrated' to the individual need of the patient.

The mode of action of i.v. Ig is still incompletely understood. Several early and long-term effects are considered, like blockade of Fc receptors, neutralization of circulating antibodies, or increased clearance of immune complexes. Which of these play a role in a given disease is still unknown.

Generally, i.v. Ig therapy is well tolerated and considered safe. However, there are reports of mild side effects in 1–15% of patients treated. In addition, occasional severe side effects including nephrotoxicity have been reported, which must be closely monitored in patients treated with i.v. Ig (list of reported side effects in Table 93.4a (Voltz & Hohlfeld, 1996)).

To minimize the risk of hepatitis C infections, anti-HCV-positive donors must be identified and excluded because chronic hepatitis C infection may be undiagnosed in potential donors. In the third generation of i.v. Ig preparations an additional virus inactivation step is included which does not alter the functional activity of the product. If fructose intolerance or diabetes is known in a patient, a choice may be made from different i.v. Ig preparations with different fructose or glucose contents.

Before treatment with i.v. Ig, the laboratory tests shown in Table 93.4b should be obtained: renal function, hepatitis serology, and other tests which will be distorted by i.v. Ig (Voltz & Hohlfeld, 1996). Because of the possibility of severe hemolytic anemia due to hemolytic antibodies, it has been advised to cross-match all patients' blood with the i.v. Ig preparation to be used. If IgA deficiency is suspected (i.e. when ataxia telangiectasia is present), IgA should be measured. If IgA deficiency is present (incidence about 1:1000), there is a 30% risk of having anti-IgA antibodies. The actual risk of developing anaphylactic reactions to i.v. Ig is not known. Whether to give i.v. Ig or switch to another treatment option, must be weighed individually.

Mild side effects may be abolished just by slowing the infusion rate. If severe side effects occur, i.v. Ig must be stopped and an alternative treatment considered. If necessary, immunomodulatory treatment with i.v. Ig can be continued through pregnancy.

Invasive immunomodulatory procedures

Plasmapheresis

During the 1980s, plasmapheresis (therapeutic plasma exchange) was tested and used in many neurological and neuroimmunological disorders. More recently, therapy with i.v. Ig has replaced plasmapheresis for many of the original indications, owing mainly to the better tolerability and more convenient application of i.v. Ig.

There are two major techniques of therapeutic plasmapheresis: plasma separation by a centrifugal plasma separator, and plasma separation by membrane filtration. A typical plasmapheresis protocol employs three to five exchanges of one or 1.5 plasma volumes per week until the patient shows satisfactory improvement. Usually, plasma exchange therapy is combined with immunosuppressive treatment, e.g. a combination of corticosteroids and azathioprine.

In the treatment of autoimmune diseases, plasmapheresis aims at the removal of circulating autoantibodies, inflammatory mediators, or both. One of best-established indications for therapeutic plasma exchange is the critical deterioration of generalized weakness in patients with myasthenia gravis (Hohlfeld et al., 1996). In MG, early clinical effects of plasmapheresis are occasionally observed in less than 24 hours. Such immediate improvement is probably due to the removal of those autoantibodies that have a direct functional effect on the ACh receptor. Often, the effects of plasmapheresis are more delayed and become obvious only after 2 or more days. This delayed improvement is usually due to the removal of antibodies that act indirectly, for example by increased receptor turnover or by complement-mediated lysis of the postsynaptic membrane.

Although there is practically no age limit for plasmapheresis if the patient is in good general health, it is the elderly patient with multiorgan disease who carries an increased risk for developing severe complications. The complications of plasmapheresis include cardiovascular systemic reactions, electrolyte disturbances, and infections. Thrombophlebitis, thromboses, pulmonary embolism, and subacute bacterial endocarditis have been observed, particularly in patients who have had arteriovenous shunts or grafts placed for vascular access. Bacterial respiratory tract infections are a common problem in myasthenic crisis. Immunoglobulin depletion after plasmapheresis may further decrease resistance to infection. In patients with infection, i.v. Ig is the preferred treatment for imminent or manifest myasthenic crisis.

Early administration of appropriate antibiotics is recommended in patients who develop infections during or after plasma exchange therapy. Intravenous immunoglobulins of both IgG and IgM isotype should be replaced in these patients. Serious infections may occur after plasma exchange in patients who were severely immunosuppressed, e.g., with cyclophosphamide. It is important to note that the removal of clotting factors during plasmapheresis results in impairment of hemostasis for about 24 hours.

As an alternative to standard plasmapheresis, selective immunoadsorption by tryptophan-linked polyvinylalcohol gels has been introduced. In MG, this procedure is as efficient as plasmapheresis (Yeh & Chiu, 2000). Since there is negligible adsorption of albumin, protein substitution is not required.

Thymectomy

Thymectomy is a form of invasive immunomodulatory treatment used in myasthenia gravis. Although there has never been a prospective controlled clinical trial of thymectomy in MG, this form of treatment has been found useful empirically and is widely applied. Because controlled studies are lacking, many questions regarding thymectomy cannot be answered conclusively. A recent survey reflects the limits of our knowledge and the present clinical practice in carrying out thymectomy (Gronseth & Barohn, 2000). Most reports did not show any correlation between the severity of myasthenic symptoms before surgery and the timing or degree of improvement after surgery. The time of the beginning of clinical improvement after thymectomy was relatively variable, and many patients improved only after several years. Most studies report better responses when thymectomy is performed early in the disease but the mechanism which produces benefit in MG is still uncertain (Gronseth & Barohn, 2000).

There is no consensus about the lower and upper age limits for thymectomy, the indication for thymectomy in pure ocular myasthenia, or the benefit of early or late thymectomy as compared with the natural course of MG (Lanska, 1990). However, a number of clinical recommendations seem reasonable in light of the available experience.

(i) The best results may be expected in patients between 10 and 40 years of age with relatively recent onset of MG (within 3–5 years).
(ii) Men have about the same chance to improve as women.

(iii) Improvement usually begins months to years after thymectomy, although it occasionally may become apparent within days or weeks. Rarely, late relapses occur in patients who experienced remission after thymectomy. It is possible that this is related to immunological activity or regrowth of thymic tissue that may not have been completely removed at surgery.
(iv) Children between 1 and 5 years are usually not submitted to thymectomy. There is no consensus about thymectomy in children between 6 and 10 years of age (Lanska, 1990).
(v) Patients with pure ocular myasthenia are usually excluded from thymectomy unless other therapies have proved unsuccessful or generalized symptoms appear. However, one study reported that thymectomy resulted in significant improvement in 80% of patients with MG confined to the ocular muscles (Schumm et al., 1985).
(vi) Patients older than 60–65 years are usually not thymectomized, except for thymoma.
(vii) Thymoma is generally considered an absolute indication for thymectomy.

The most widely performed surgical approach to the thymus is transsternal. A transcervical approach is not recommended because it does not ensure the removal of ectopic thymic tissue that may be widely distributed in the neck and mediastinum. When properly performed, thymectomy has a low mortality rate that is essentially that of anesthesia. However, it should be performed in a center with extensive experience and a neuromuscular consultant available. In patients with stable disease and after appropriate preparation (see above sections), the operation is very safe, and severe perioperative complications are virtually absent (less than 1%).

Bone marrow and stem cell transplantation

Recent advances in immunobiology and transplantation medicine have made it possible to mobilise, isolate and successfully transplant autologous hematopoetic stem cells. Prior to transplantation, the immune system of the recipient is ablated by aggressive chemotherapy. In the best and most experienced centres, the acute mortality of this procedure is now below 5%. For this and other reasons, autologous blood and marrow stem cell transplantation has been considered as a treatment option for autoimmune diseases. For example, international guidelines have been developed for autologous stem cell transplantation in MS (Comi et al., 2000). However, this approach faces not only clinical but also conceptual problems. For example, several reports have shown that after allogenic BMT, MS can exacerbate or even develop de novo in the transplant recipients (Jeffery & Alshami, 1998; Kelly et al., 1996). Needless to say, transplantation may be followed by serious early and late complications such as infections and tumours (Anderson et al., 1990). Further, one should consider the possibility that the transplanted autologous stem cells reconstitute not only the normal immune functions, but also the autoimmune component. For all these reasons, great scepticism and extreme caution are necessary when considering autologous stem cell transplantation as a treatment for MS.

Future developments

Advances in biotechnology have promoted the development of a new class of biotechnological products for immunotherapy and even immunological gene therapy. These biotechnological agents are used to manipulate the immune system by selectively mimicking, inhibiting, or otherwise interacting with naturally occurring polypeptides or oligonucleotides. A comprehensive review of these agents is beyond the scope of this chapter. Recent overviews on the subject may be found in (Hohlfeld, 1997; Compston et al., 1998; Weilbach & Gold, 1999; Hohlfeld, 1999) (Table 93.5). Some of the new biotechnological agents hold the promise of an unprecedented selectivity of action. However, these agents also present a number of specific problems, ranging from inconvenient application (by s.c., i.m., or i.v. injection) to immunogenicity (stimulation of neutralizing antibodies). Thus, it is obvious that biotechnological agents are not necessarily superior to chemical immunomodulators.

Ideally, immunotherapy would not have to be applied indefinitely, but only for a limited, short time to achieve a permanent result. Such tolerance-inducing therapy has indeed been achieved in experimental situations, especially in transplantation. These experiments demonstrate that it is possible to achieve a state of permanent and selective immune tolerance by combining different immunological manipulations. By analogy, it may be possible to 'silence' an ongoing immune reaction permanently by combining different immunotherapies. Possible approaches include combinations of antileukocyte differentiation antigens, combinations of anti-costimulatory agents, and various strategies for 'immune deviation' (Hohlfeld, 1997).

The introduction of interferon-β for the treatment of multiple sclerosis heralds a new era of immunomodulatory phamacotherapy. Interferon-β is the first approved cytokine therapy for any human autoimmune disease. However, the initial hope that the success of this agent would usher in a multitude of new cytokine therapies not been fulfilled so far.

Table 93.5. Biotechnological agents and experimental approaches for the immunomodulatory therapy of MS

Immunosuppressive agents
Anti-CD3 mAbs
Anti-CD4 mAbs
Anti-CD53 mAb (Campath-1H)
Anti-interleukin-2 receptor α-subunit mAbs (e.g. Daclizumab, Basiliximab)

Cytokines and cytokine inhibitors
Interferons
Interferon β-1a
Interferon β-1b
Interferon-α
Other interferons

TNF inhibitors
*TNF-receptor-IgG soluble dimeric p-55 (Lenercept^{R})
*Anti-TNF human/murine chimeric mAb cA2
Metalloprotease inhibitors (e.g. BB-3644)

Down-regulatory cytokines
Interleukin-1 inhibitors
Interleukin-4
Interleukin-10
Interleukin-13
*TGF-β2(BetaKine^{R})

Chemokine antagonists and -receptor blockers
Neurotactin antagonist
MCP-1 receptor antagonist
CXCR3 receptor antagonist
CCR1 receptor antagonist
CCR5 receptor antagonist

Therapies directed at cell interaction molecules
Adhesion molecules
Humanized anti-CD11/CD18 mAb (Hu23F2G)
Antagonistic peptide inhibitors of integrins
Anti-VLA-4 and anti-α4 integrin mAbs or peptide inhibitors
Anti-ICAM-1 (CD54) mAb

Costimulatory molecules
Anti-CD2 mAb
Anti-LFA-3 (CD58) mAb
Anti-CD154 mAb
CTLA4-Ig
Anti-CD45 mAb

Immunotherapies targeting the 'trimolecular complex'
Copolymer-1
MHC blockers
Altered peptide ligands (so far mostly MBP analogues)
*Oral tolerance (oral bovine myelin)
Other strategies of tolerance induction by modification of antigen presentation
Vaccination with T-cells or TCR peptides
Anti-TCR mAbs

Agents affecting both the immune and nervous systems (see Chapter by Scolding)
e.g. Neurotrophic factors

Notes:
Most treatments are experimental.
FDA-approved agents are printed in bold.
*Asterisk denotes treatments that were shown to be ineffective or unfavourable, or had unacceptable toxic effects.
Source: From Hohlfeld (1997); Weilbach and Gold (1999).

None of the other cytokines tested in pilot trials was truly promising, let alone superior to interferon-β. On the contrary, not only were trials with a soluble receptor for tumour necrosis factor-(TNF-)-α, and with an antibody against TNF-alpha, negative, but they showed clear evidence of treatment-induced exacerbation (Arnason et al., 1999). These results were completely unexpected in light of existing evidence that TNF-α is involved in MS pathogenesis, and that anti-TNF therapies previously worked in animal models (Arnason et al., 1999).

Selective, antigen-specific immunotherapies target the trimolecular complex (TMC) of T-cell stimulation, which is part of the 'immunological synapse' (Fig. 93.2). In principle, each component of the TMC can be targeted. The major histocompatibility (MHC) molecule could be blocked by anti-MHC antibodies or 'blocking peptides'; the antigen (or antigenic peptide) could be applied in such a way that the autoreactive T-cells are inhibited rather than stimulated; and the T-cell receptor (TCR) could be targeted with anti-TCR antibodies or by T-cell or TCR peptide vaccination. Although such antigen-selective immunotherapy may seem very promising, it poses a number of special problems. For example, it has been shown that the T-cell response to various candidate CNS autoantigens is much more complex in humans than it is in certain inbred rodent strains. This implies that selective immunotherapy needs to be 'individualized' (tailored for individual patients). Furthermore, there is growing evidence that the auto-

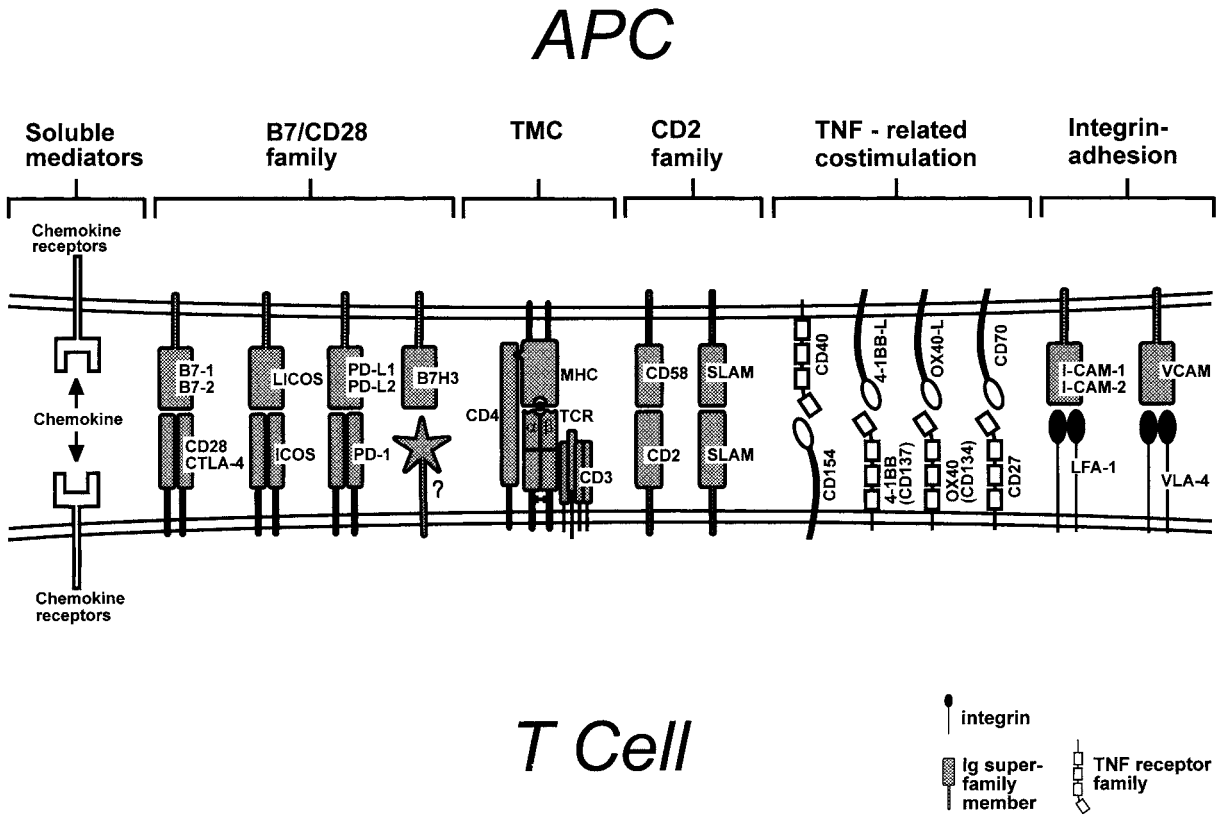

Fig. 93.2. Schematic view of the 'immunological synapse' (Molecular interactions at the interface between a CD4+ T-cell (bottom) and an antigen-presenting cell (APC; top); Hohlfeld, 1997). Antigen-specificity is conferred by the clonotypic T-cell receptor (TCR) that recognizes an antigen peptide (black dot) bound to an MHC class II molecule (trimolecular complex, TMC; centre). Signal transduction is mediated by the invariant proteins of the CD3 complex associated with the TCR. In addition to antigen-specific signalling via the TCR/CD3 complex, various costimulatory signals are transmitted by interactions between costimulatory molecules and their ligands (e.g. CD40 and CD40-L; CD28/CTLA-4 and B7-1/B7-2), or between cytokines and their receptors (left). Large arrows indicate direction of signalling. Interactions between various adhesion molecules strengthen the contact between the T-cell and the APC (right). Most adhesion and costimulatory molecules belong to either the integrin or immunoglobulin family.

immune response is not static but dynamic. For example, the autoimmune response may spread to include new autoantigens over time ('epitope spreading').

Thus far, copaxone is the only approved agent in the category of (semi)-selective, antigen-directed agents (Neuhaus et al., 2001). The synthesis of COP-1 was modelled after myelin basic protein (MBP), a prime candidate autoantigen of MS. Other agents in the same category of selective immunomodulators include an altered peptide ligand (APL) of MBP, soluble complex of MBP-peptide bound to the MS-associated HLA molecule DR2, and oral myelin preparations for induction of oral tolerance. Except for COP-1, none of these putatively selective therapies has so far proven a truly convincing clinical benefit to MS patients (Hohlfeld & Wiendl, 2001). On the contrary, two phase II trials of an APL called CGP77116 or NB 5788, derived from MBP peptide 83–99, had to be halted prematurely because of allergic reactions and clinical exacerbations of MS (Kappos et al., 2000; Bielekova et al., 2000).

For the future, it is to be hoped that new techniques will continue to advance our understanding of the immunopathogenesis of neurological autoimmune disorders, and that these advances in knowledge can be rapidly translated into therapeutic applications.

Vasculitis of the central nervous system

David B. Hellmann[1] and John H. Stone[2]

[1]Johns Hopkins Bayview Medical Center, Johns Hopkins University School of Medicine, Baltimore, MD, USA
[2]Johns Hopkins Vasculitis Center, Johns Hopkins University School of Medicine, Baltimore, MD, USA

Vasculitis of the CNS presents one of the great diagnostic and therapeutic challenges in neurology. Diagnosing CNS vasculitis is difficult because the most common presenting symptoms, headache and mental status changes, are nonspecific. Moreover, almost any CNS abnormality including isolated dementia and intracerebral hemorrhage can occasionally be the result of CNS vasculitis. No imaging study is specific for CNS vasculitis, and even brain biopsies can be falsely negative in this condition. Designing treatment for CNS vasculitis is also difficult, as the rarity of the diagnosis has prevented the large treatment trials needed to define optimal therapy. Despite all of these challenges, the last two decades have yielded substantial information about the diagnosis and treatment of this disease. Guidelines are now possible to help physicians know when to suspect the disease, how to recognize the limits of imaging studies, how to identify the disorders that can mimic CNS vasculitis, and how to initiate therapy.

Classification and definition of terms

CNS vasculitis is not one disease but a collection of disorders (Calabrese et al., 1997; Lie, 1997; Moore, 1988). Traditionally, the classification of CNS vasculitis (Table 94.1) recognizes two main groups: primary disorders, which have no known cause, and secondary disorders, which are associated with identifiable diseases such as systemic lupus erythematosus or infection (Calabrese et al., 1997; Lie, 1997). Many designations have been applied to primary CNS vasculitis (Table 94.2), all of which have inevitable flaws. The term granulomatous angiitis of the central nervous system, for example, is inaccurate because less than half of the cases of primary CNS vasculitis demonstrate granulomas (Lie, 1997).This chapter bows to tradition and employs the term primary angiitis of the central nervous system (PACNS).

Table 94.1. Classification of vasculitis of the CNS

I.	Primary
	A. Histologically defined angiitis of the CNS
	B. Angiographically defined angiopathy of the CNS
II.	Secondary (e.g. SLE, Wegener's granulomatosis)

Table 94.2. Designations used in the medical literature for primary CNS vasculitis[a]

Name	Abbreviation
Primary angiitis of the CNS	PACNS
Isolated angiitis of the CNS	IACNS
Granulomatous angiitis of the CNS	GACNS
Benign angiopathy of the CNS	BACNS
Angiographically defined angiopathy of the CNS	ADACNS
Histologically defined angiitis of the CNS	HDACNS
Non-infections granulomatous angiitis of the CNS	
Granulomatous angiitis of the nervous system	GANS
Idiopathic granulomatous angiitis of the CNS	IGAMS

Note:
[a] From Woolfenden (1998); Lie (1997).

However, even this term has shortcomings: it has been applied both to cases that are biopsy proven and also to cases defined only by angiographic abnormalities. Since no angiographic abnormality is absolutely specific for vasculitis, and because cases of PACNS diagnosed by biopsy differ in important ways from those diagnosed angiographically (Calabrese et al., 1997), this chapter acknowledges these differences by also using the terms angiographically defined angiopathy of the CNS (ADACNS) and histologically defined

angiitis of the CNS (HDACNS), as proposed by Woolfenden (Woolfenden et al., 1998).

Historical perspective

The first cases of CNS vasculitis were described in 1922 (Harbitz, 1922). This report concerned two patients: a 26-year-old woman with headaches, encephalopathy, and ataxia whose condition worsened over 2 years to stupor, coma, and death; and a 46-year-old man with mental status changes and hallucinations progressing to coma and death over 9 months. Postmorten examination in both cases demonstrated granulomatous angiitis of the leptomeningeal arteries and veins (Harbitz, 1922). Nearly four decades later, Cravioto and Feigin first recognized that PACNS constituted a separate form of vasculitis and were the first to delineate its distinct features (Cravioto & Feigin, 1959). As recently as 1986 there had been only 46 cases of PACNS described in the medical literature, emphasizing how rarely the disorder was diagnosed (Calabrese, et al., 1997; Younger et al., 1997).

Increasing awareness of the disorder and advances in neuroimaging resulted in a total of approximately 200 cases reported in the medical literature by 1997 (Calabrese et al., 1997). Still, the relative rarity of CNS vasculitis is indicated by the fact that PACNS accounted for 1.2% of 2680 cases of all types of vasculitis at one centre (Lie, 1997).

Etiology and pathogenesis

The cause of PACNS is unknown (Calabrese et al., 1997; Lie, 1997; Moore, 1988; Younger et al., 1997). Efforts to define the pathogenesis have been hampered by the disorder's rarity and the infrequency with which histopathological specimens are obtained. Most theories about the etiology and pathogenesis of PACNS have focused on infections, altered immunity, and environmental toxins (Calabrese & Mallek, 1987; Calabrese et al., 1997; Lie, 1997). A variety of bacteria, fungi, and viruses are capable of causing vasculitis of the CNS (see below) (Arthur & Margolis, 1977; Calabrese et al., 1997; Reyes et al., 1976). However, in most PACNS cases no infection is identifiable by culture, immunochemical stains, or polymerase chain reaction (PCR) (Calabrese et al., 1997; Lie, 1997). The occurrence of CNS vasculitis in association with Hodgkin's disease suggested that immunodeficiency states might cause some cases of PACNS (Calabrese et al., 1997). It is recognized now, however, that immunodeficiency simply permits infections (especially with varicella-zoster virus), which are the usual case of CNS vasculitis associated with Hodgkin's disease (Calabrese et al., 1997). The association of CNS vasculitis with other rheumatic diseases, including systemic lupus erythematosus, Wegener's granulomatosis, and Cogan's syndrome, has suggested autoimmunity as a cause of PACNS. The presence of granulomatous inflammation implicates cellular immune processes. Immune complexes and autoantibodies have not been found in tissue samples (Moore, 1989b; Moore, 1995). Unspecified environmental toxins have been implicated by the number of cases associated with drug use, particularly cocaine, ephedrine, and amphetamines (see below) (Calabrese et al., 1997; Lie, 1997; Younger et al., 1997).

Pathology

PACNS affects medium- and small-sized arteries and arterioles of the brain and spinal cord. Veins are infrequently involved. Although the lesions can be distributed widely, the leptomeninges and cerebral cortex are involved most frequently (Calabrese et al., 1997; Lie, 1997; McCormick & Neuberger, 1958; Moore & Fauci, 1981). Vasculitic lesions contain predominantly lymphocytes, with variable numbers of eosinophils, neutrophils, histiocytes, and plasma cells (Lie, 1997). No immunohistological studies of the inflammatory infiltrates in PACNS have been reported, so the precise nature of the lymphocytic infiltrate remains undefined. Inflammatory cells infiltrate all layers of the arteries and cause fibrinoid necrosis in some specimens (approximately 25%) (Lie, 1997). Fewer than half of the lesions in PACNS demonstrate granulomatous inflammation with Langhans or foreign-body type multinucleated giant cells (Lie, 1997). The inflammation spreads along the vessel in a discontinuous fashion, characterized by skip lesions (Lie, 1997). Variable degrees of inflammation and healing (as manifested by intimal fibrosis) can often be demonstrated in different sites within the same biopsy specimen, indicating that the lesions develop or progress at different rates (Lie, 1997). Aneurysmal formation occurs much less often in PACNS than in polyarteritis nodosa. Thrombosis and vessel rupture can lead to infarction and hemorrhage of the CNS (Lie, 1997).

Clinical features

Symptoms and signs

Several authorities have argued persuasively that the clinical features of HDACNS differ from those of ADACNS

Table 94.3. Clinical and laboratory features of PACNS based on the method of diagnosis[a]

	HDACNS	ADACNS	*P*
Sex, no. (%)			
Males	78 (69.0)	17 (30.8)	<0.001
Females	38 (31.0)	38 (69.1)	
Age, mean ± SD	46 ± 17	33 ± 14	<0.001
Headache, no. (%)			
Yes	63 (55.8)	43 (78.2)	
No	50 (44.3)	12 (21.8)	
Stroke, no. (%)			
Yes	13 (13.5)	15 (32.6)	<0.008
No	83 (86.5)	31 (67.4)	
Seizure, no. (%)

No	100 (88.5)	50 (90.9)	
Diffuse neurologic dysfunction, no. (%)			
Yes	77 (68.1)	26 (47.3)	<0.009
No	36 (31.9)	29 (52.7)	
Decreased cognition, no. (%)			
Yes	64 (83.1)	20 (76.9)	
No	13 (16.9)	6 (23.1)	
Days from symptom onset to diagnosis, mean ± SD	170 ± 261	46 ± 73	<0.001
Abnormal CSF (%)	80–90	50–53	<0.005

Notes:

[a] An abnormal cerebrospinal fluid (CSF) sample had >5 cells/mm^3 and/or protein >55 mg%. PACNS = primary angiitis of the central nervous system.

HDACNS: histologically defined angiitis of the CNS.

ADACNS: angiographically defined angiopathy of the CNS.

Source: (Modified from Calabrese, 1997; p. 1190 Table. 2).

(Calabrese et al., 1997; Lie, 1997; Vollmer et al., 1993; Younger et al., 1997). Therefore, these two entities are discussed separately (Table 94.3).

HDACNS preferentially affects middle-aged men. Men are affected about twice as often as women (Calabrese et al., 1997). Although HDACNS may strike at any age, the mean age at onset is 46. Headaches and diffuse neurologic dysfunction as manifested by encephalopathy constitute the most common presenting features (Calabrese et al., 1997; Ferro, 1998; Moore, 1989a; Vollmer et al., 1993). Focal neurological deficits eventually develop in about half of the patients; yet strokes are present in less than 20% at onset of the disease and are almost always accompanied by diffuse neurologic dysfunction (Vollmer et al., 1993). Strokes in the absence of diffuse cortical dysfunction are distinctly unusual for HDACNS (Vollmer et al., 1993). Brainstem or cranial nerve dysfunction develops in 40% of HDACNS patients, and seizures in 25% (Vollmer et al., 1993). Isolated dementia rarely develops in HDACNS (Vollmer et al., 1993). Spinal cord disease, manifested by myelopathy, develops in about 15% (Calabrese et al., 1997; Vollmer et al., 1993). The neurological manifestations of HDACNS typically unfold over 5–6 months before the diagnosis is made, but some cases develop more acutely (Calabrese et al., 1997). Only 20% of patients with HDACNS develop systemic symptoms or signs such as fever, weight loss, or sweats (Vollmer et al., 1993).

Common diagnostic tests are normal or yield non-specific abnormalities in HDACNS. Abnormalities of the serum hemoglobin level, the peripheral white blood cell count, and the erythrocyte sedimentation rate (ESR) occur in 17%, 42% and 65% of cases, respectively (Calabrese et al., 1997). The cerebrospinal fluid (CSF) is abnormal in approximately 88% of cases (Calabrese et al., 1997; Hellmann et al., 1992; Stone et al., 1994; Vollmer et al., 1993). The mean CSF protein level is 177 mg/dl, with a median of 100. A CSF lymphocytosis develops in about 65–75% of patients, with a mean cell count of 77/mm^3 (Calabrese et al., 1997). The CSF pleocytosis in HDACNS rarely exceeds 250 cells/mm^3 (Vollmer et al., 1993). Oligoclonal bands and increased CSF IgG synthesis have been reported in some patients with PACNS, but their diagnostic value has not been evaluated (Calabrese et al., 1997). Non-specific electroencephalogram (EEG) abnormalities occur in 93% of patients (Vollmer et al., 1993).

In comparison to HDACNS, ADACNS more frequently develops in young women (Table 94.3) (Calabrese et al., 1997). Some authors have speculated that the pathophysiology of ADACNS may relate more to a vasospasm-induced angiopathy than to true vasculitis (Calabrese et al., 1997). This has led to the occasional reference to 'benign' angiopathy of the CNS in the literature, an inappropriate term because the manifestations of ADACNS may include cerebrovascular accidents and other serious neurological events (Woolfenden et al., 1998). ADACNS is more likely to present with acute strokes (Table 94.3), but diffuse cortical dysfunction and CSF abnormalities occur less often than in HDACNS (Calabrese et al., 1997).

Imaging studies

Magnetic resonance imaging (MRI) almost always reveals abnormalities, albeit non-specific ones, in PACNS. Most

Fig. 94.1. MR in CNS vasculitis. Axial SE MR image (1500/30) shows high signal intensity in the left parietal cortex, subcortical white matter (*black arrows*), and in the left putamen (*white arrow*). (From Pomper, 1999 with permission.)

series report 100% sensitivity (Greenan et al., 1992; Harris et al., 1994; Vollmer et al., 1993; Woolfenden et al., 1998), but false-negative MR studies have been reported (Alhalabi & Moore, 1994; Pomper et al., 1999). Thus, a person with a completely normal MRI is unlikely to have PACNS. Having both a normal MR study and a normal CSF cell count and protein level virtually excludes the diagnosis (Hellmann et al., 1992; Stone et al., 1994). In general, CT is much less sensitive than MRI, detecting abnormalities in 50–68% of cases (Vollmer et al., 1993; Younger et al., 1997). However, CT is better than MRI at detecting hemorrhage (Harris et al., 1994).

On average, patients with PACNS have at least 3 MR lesions that are predominantly supratentorial and bilateral (Pomper et al., 1999) (Fig. 94.1). The most commonly involved regions are the subcortical white matter, followed by the deep grey matter, the deep white matter, and the cortex (Pomper et al., 1999). White matter lesions in PACNS are usually more irregular than those of multiple sclerosis which have an ovoid appearance and develop in the perivascular zones. Functional MRI has not been extensively studied but may be useful in separating vasculitic infarction from other processes. Yuh et al., suggest that perfusion imaging can assess microcirculating vasculopathy, and diffusion-weighted imagery may detect acute infarction, even when not visible on conventional T_2-weighted scans (Yuk et al., 1999; Miller et al., 1987). A minority of the MR lesions enhance after administration of contrast agents (Harris et al., 1994; Pomper et al., 1999). MR angiography is not usually helpful in evaluating patients with CNS vasculitis because the technique's resolution remains inadequate for the size of blood vessels typically affected by PACNS. The roles of SPECT and PET scanning have not been studied.

A variety of angiographic abnormalities occur in PACNS (Alhalabi & Moore, 1994; Calabrese et al., 1997; Ehsan et al., 1995; Hellmann et al., 1992; Hurst & Grossman, 1994; Pomper et al., 1999; Stein et al., 1987; Stone et al., 1994; Wynne et al., 1997). The most common abnormalities are alterations in the calibre of the arteries, including constriction, irregularity, and dilatation (Hurst & Grossman, 1994). 'Beading', produced by lesions of constriction or dilatation interspersed with normal areas, is the classic sign of PACNS (Fig. 94.2) (Hurst & Grossman, 1994). Stenoses range in length from a few millimetres to 3 centimetres (Alhalabi & Moore, 1994). Vasculitis of the CNS may also cause threadlike narrowing of vessels, cutoff signs, slowing of the circulation time, and delayed emptying of the arteries (Hurst & Grossman, 1994). Occlusions develop often, but microaneurysms are seen infrequently (Alhalabi & Moore, 1994). Over time, collateral vessels may develop. The most frequent sites of involvement are the middle and anterior cerebral arteries and their branches (Alhalabi & Moore, 1994). Posterior cerebral involvement occurs somewhat less often. Abnormalities proximal to the supraclinoid segment of the internal carotid artery occur rarely. Most cases demonstrate multiple, bilateral though not necessarily symmetrical lesions (Alhalabi & Moore, 1994). Lesions may be far more extensive than suggested by clinical findings (Alhalabi & Moore, 1994). Angiographic lesions are often more widespread than suggested by MR; only about half of the lesions seen on angiography have a corresponding lesion identified on MR (Pomper et al., 1999).

The sensitivity of angiography in PACNS has been reported to vary from 50–80% (Calabrese et al., 1997; Duna & Calabrese, 1995; Harris et al., 1994; Vollmer et al., 1993). Therefore, a normal CNS angiogram does not exclude the diagnosis of PACNS. Furthermore, unfortunately, even 'positive' angiograms are not specific for PACNS. Many conditions and disorders, including vasospasm, infection, emboli, radiation damage, hypercoagulable states, severe hypertension, pre-eclampsia, and drugs such as cocaine

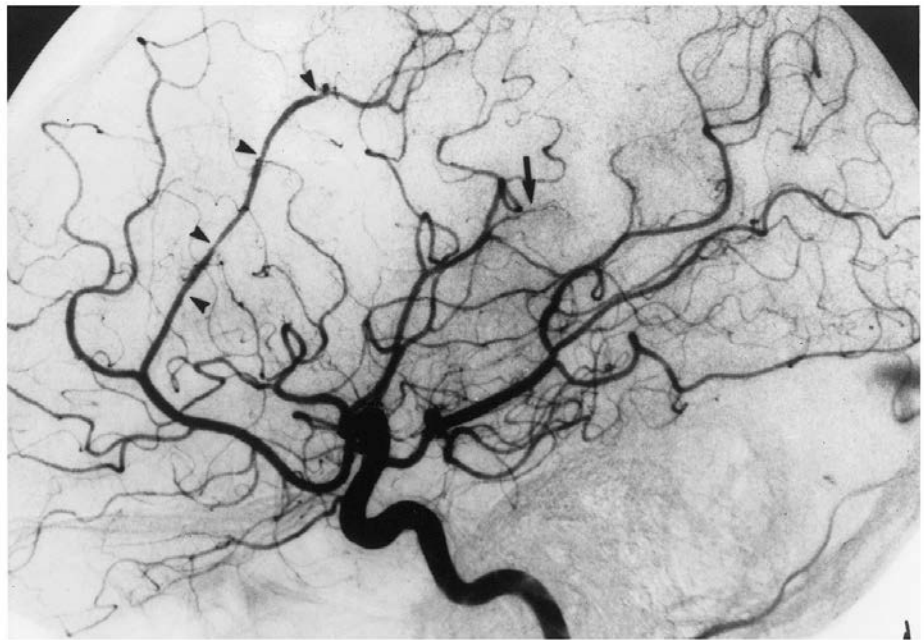

Fig. 94.2. Angiogram of the right internal carotid artery shows lesions in the ACA (pericallosal) (*arrowheads*) and severe narrowing of the distal MCA (*arrow*). (From Pomper, 1999, with permission.)

and amphetamines can produce similar angiographic findings (Alhalabi & Moore, 1994; Calabrese et al., 1997; Duna & Calabrese, 1995).

As an invasive test, angiography carries some risk. For patients suspected of having CNS vasculitis, angiography is associated with an 11.8% risk of a transient neurologic deficit and a 0.8% risk of permanent damage from a stroke (Hellman et al., 1992).

Brain biopsy

Because of the focal segmental distribution of lesions in PACNS, brain biopsies are falsely negative in approximately 25% of cases confirmed histologically by second biopsy or autopsy (Calabrese et al., 1997; Lie, 1997). For reasons of safety and optimal yield, the non-dominant temporal lobe tip is the most common biopsy site (Calabrese et al., 1997). Biopsies should sample the leptomeninges, as well as the brain parenchyma, because the leptomeninges are involved commonly in this disease (Calabrese et al., 1997). Stereotactic biopsies of deeper brain regions are of lower yield in some studies (Vollmer et al., 1993) but not in others (Alrawi et al., 1999). Brain biopsy carries a risk of serious morbidity ranging from 0–2% (Alrawi et al., 1999; Harris et al., 1994). In addition to histological examination, stains and cultures for bacteria, fungi, and viruses should be performed. Because of the relative inaccessibility of pathologic tissue in PACNS, a portion of the sample should be snap frozen for later investigations whenever possible. Although the yield of biopsy has been questioned, in one study of 61 patients with possible CNS vasculitis, brain biopsy established the diagnosis of PACNS in 22 (36%), an alternative diagnosis in 24 (39%), and no diagnosis in 12 (25%) (Alrawi et al., 1999). Alternative diagnoses were infectious encephalitis (7), primary CNS lymphoma (6), brain abscess (3), non-lymphomatous tumour (2), multiple sclerosis (2), and single cases of sarcoidosis, sterile infarct, and arteriovenous malformation (Alrawi et al., 1999).

Diagnostic criteria

The diagnosis of PACNS cannot be based entirely upon any individual part of the evaluation, but rather requires a comprehensive analysis of all clinical, laboratory, and radiological data. Criteria for the diagnosis of PACNS proposed by Woolfenden et al. (1998) include:

(i) History of clinical findings of an acquired neurologic deficit that is consistent with CNS vasculitis (e.g. headache, focal or multifocal neurologic deficit, encephalopathy, or seizure).

Table 94.4. Differential diagnosis of primary angiitis of the central nervous system[a]

Category	Examples
Rheumatic disorders	Systemtic lupus erythematosus, Wegener's granulomatosis, polyarteritis nodosa, Takayasu's arteritis, temporal arteritis, Behçet's disease, Sjögren syndrome, Cogan syndrome
Infections	Bacteria (e.g. endocarditis, bacterial meningitis, tuberculosis, syphilis, Lyme disease), fungi (e.g. histoplasmosis, aspergillus), viruses (e.g. *H. Zoster*, human immunodeficiency virus, hepatitis C)
Drugs	Cocaine, ephedrine, amphetamine, allopurinol, phenylpropanolamine, heroin
Vasculopathies	Atherosclerosis, antiphospholipid antibody syndrome, cerebral amyloid angiopathy, moyamoya, radiation-induced vasculopathy, vasospasm associated with severe hypertension or hemorrhage, arterial fibromuscular dysplasia, cardiac myxoma embolism, cholesterol embolism, pregnancy and postpartum-associated vasculopathy, sickle cell anemia, thrombotic thrombocytopenic purpura
Malignancy	Vascular lymphoma, Hodgkin's disease, small cell lung cancer
Heritable disorders	Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL)
Other inflammatory disorders	Sarcoidosis, inflammatory bowel disease, celiac disease
Metabolic disorders	Pheochromocytoma

Note:
[a] From Lie (1997); Razavi (1999); Williamson, (1999); Younger (1997); Calabrese, (1997); Calabrese & Mallek (1987).

(ii) No evidence of systemic vasculitis or any other condition that could cause the clinical and pathologic features, despite a thorough evaluation.

The diagnosis of PACNS may be considered definite if these two criteria are met and there is histologic confirmation of vasculitis. The diagnosis may be regarded as probable if, in the absence of a positive biopsy, the CNS angiogram demonstrates abnormalities characteristic of vasculitis in multiple intracranial vessels, assuming the absence of atherosclerosis in proximal cervical arteries. With angiographic abnormalities that are less convincing, the diagnosis should be classified as possible (Woolfenden et al., 1998).

Differential diagnosis

The differential diagnosis of PACNS is challenging because of the myriad of secondary forms of CNS vasculitis, and the numerous non-vasculitic conditions that may mimic the clinical or radiographic features of PACNS (Table 94.4).

Several rheumatic disorders can cause CNS vasculitis or CNS vasculopathy, but rarely mimic PACNS convincingly. Although many rheumatic disorders are included in the differential diagnosis of PACNS, only a few cause CNS vasculitis with any frequency, namely, lupus and polyarteritis nodosa. In unusual cases, Wegener's granulomatosis also causes vasculitis of the brain parenchyma, but typically involves blood vessels below the resolution of conventional angiography. Cogan's syndrome and Churg-Strauss syndrome are very rare causes of CNS vasculitis, as are scleroderma, Sjögren's syndrome and rheumatoid arthritis. Takayasu's arteritis and temporal arteritis involve extracranial vessels, and intracranial involvement is exceptional. Finally, although Behcet's disease commonly involves the CNS (see Chapter 96), the CNS pathophysiology in Behcet's does not appear to be vasculitic in nature. In nearly all cases, rheumatic diseases that cause CNS vasculitis are accompanied by symptoms, signs, and serologic abnormalities that indicate systemic involvement and permit their distinction from PACNS

Chronic infections can cause vasculitis either by infecting vascular cells and inciting inflammatory responses or by contiguous spread from other CNS tissues (Table 94.4). CNS vasculitis secondary to infection should be suspected when the patient has: (i) systemic features (e.g. fever, weight loss) (Yanker et al., 1986); (ii) an immunodeficiency state (e.g. HIV, Hodgkin's disease, diabetes, alcoholism) (Greco et al., 1976; Rewcastle & Tom, 1962); (iii) extensive arteritis of the base of the brain with prominent cranial nerve involvement (often features of arteritis caused by fungi and tuberculosis (Stone et al., 1998); or (iv) a CSF monocytosis exceeding 250 cells/mm^3 (Vollmer et al., 1993).

One infection that mimics PACNS closely is varicella-zoster virus (VZV). Vasculitis of the CNS is a well-described

complication of VZV infections (Blue & Rosenblum, 1983; Bourdette et al., 1983; Doyle et al., 1983; Gilden et al., 2000; MacKenzie et al., 1981; Ojeda et al., 1984; Reshef et al., 1985; Reyes et al., 1976; Rosenblum et al., 1978; Vilchez-Padilla et al., 1982; Walker et al., 1973). Two forms occur: a large-vessel arteritis that chiefly affects immunocompetent individuals, and a small-vessel arteritis that affects patients with immunodeficiency states, such as Hodgkin's disease, leukemia, or the acquired immune deficiency syndrome (AIDS) (Gilden et al., 2000). Classically, the large artery variant presents in patients over 60 years old who develop an ipsilateral stroke (with contralateral hemiplegia) some weeks to months (mean 7 weeks) following an episode of zoster in the distribution of the trigeminal nerve (Gilden et al., 2000). Angiography reveals beading of the middle and anterior cerebral arteries (Gilden et al., 2000; MacKenzie et al., 1981). Microscopic examination demonstrates granulomatous inflammation, VZ antigen, Cowdry A inclusion bodies, and herpesvirus particles (Gilden et al., 2000). PCR studies confirm VZV DNA in affected arteries (Gilden et al., 2000). Although, the vasculitis can be confined to the same side as the trigeminal zoster, bilateral vasculitis does occur (Gilden et al., 2000). In addition, VZ-induced granulomatous vasculitis can occur without an antecedent rash (Gilden et al., 2000).

The smaller vessel variant of VZV-induced CNS vasculitis generally develops in immunodeficient patients. Clinical presentations include hemiplegia, aphasia, headache, vomiting, encephalopathy, and seizures (Gilden et al., 2000). MR demonstrates small infarctions, hemorrhages, or both, often involving the bilateral cortical and subcortical grey and white matter (Gilden et al., 2000; Lipton & Ma, 1996). The white matter lesions are smaller and less confluent than those in progressive multifocal leukoencephalopathy (Gilden et al., 2000). Thus, VZ-induced CNS vasculitis should be suspected in a patient with a recent episode of zoster or state of immunodeficiency. The diagnosis can be suggested by the characteristic radiological features, by positive VZV PCR in the CSF and confirmed by demonstrating VZV infection on brain biopsy (Gilden et al., 2000). Successful treatment has been reported with prednisone (60–80 mg/day for 3–5 days) accompanied by acyclovir administered for 2 weeks (or longer in severely immunosuppressed patients (Gilden et al., 2000).

A detailed drug history and toxicology screen helps identify patients with drug-induced CNS vasculopathy (Table 94.4). Cocaine, amphetamines, and ephedrine derivatives are the most common culprits (Bostwick, 1981; Glick et al., 1987; Kaye and Fainstat, 1987; Kessler et al., 1978; Rumbaugh et al., 1971a,b; Scully et al., 1993; Weiss et al., 1970; Wooten et al., 1983; Yu et al., 1983). In contrast to patients with PACNS, patients with drug-induced vasculitis are more frequently male, tend to be a decade younger (onset in the 20s or 30s), and more likely to demonstrate hemorrhage (either intracranial or subarchnoid) (Scully et al., 1993; Wooten et al., 1983). The angiographic abnormalities of drug-induced CNS vasculitis are similar to those of PACNS (Scully et al., 1993; Wooten et al., 1983). Normal angiograms with vasculitis documented on biopsy have been reported, especially with cocaine (Scully et al., 1993). Though the number of histopathologically proven cases is small, medications are capable of inducing frank vasculitis (Wooten et al., 1983). Whereas PACNS involves chiefly a lymphocytic infiltrate with giant cells and granulomas centred on the adventitia, drug-induced vasculitis is usually associated with a polymorphonuclear cell infiltrate focused on the intima, without giant cells or granulomas (Wooten et al., 1983).

A number of other conditions cause angiographic changes that resemble those of PACNS (Table 94.4) (Calabrese et al., 1997; Razavi et al., 1999). Atherosclerosis occasionally mimics PACNS, but usually is distinguishable by the presence of risk factors for atherosclerosis (e.g. advanced age, hypertension, hyperlipidemia, smoking) and by eccentric narrowing of the proximal and extracranial carotid arteries (Calabrese, 1997; Calabrese & Mallek, 1987).

Pregnancy history is also important because vasculopathy that clinically and angiographically mimics PACNS sometimes develops during pregnancy and the puerperium (Calabrese et al., 1997; Farine et al., 1984; Glick et al., 1987). In some of these patients, the disorder appears to be part of pre-eclampsia (Farine et al., 1984) and may be caused by vasospasm or severe hypertension. Other patients may have a true vasculitis since they have no history of pre-eclampsia, develop the symptoms weeks to months after delivery, and demonstrate vasculitis on biopsy (Glick et al., 1987). In these latter cases, the true relationship of vasculitis in the event of pregnancy is difficult to confirm.

Rarely, cerebral amyloid angiopathy (CAA) mimics PACNS. In CAA, amyloid is deposited in the walls of blood vessels in the leptomeninges and cerebral cortex (sparing the white matter), resulting in a wide range of vasculopathic changes such as cracking, 'double-barreling', fibrinoid necrosis, aneurysm formation, vascular ectasia, vessel occlusion, and perivascular inflammation (Fountain & Eberhard, 1996; Greenberg, 1998; Greenberg & Vonsattel, 1997; Mandybur, 1986; Scully et al., 1991; Vonsattel et al., 1991; Yamada et al., 1996). In addition to mimicking PACNS, CAA may also coexist with PACNS. Indeed, one study estimated that 10% of patients with PACNS also have

Table 94.5. Comparison of cerebral amyloid angiopathy (CAA) with PACNS[a]

	CAA (n=140)	PACNS (n=63)
Clinical feature		
Mean age (range)	76 (34–97)	44.8 (3–79)
Headache	36%	63%
Hemorrhage (CT, MRI)	nearly universal	rare
Angiography		
Concentric narrowing	rare	common
Biopsy	Amyloid deposition	Granulomatous inflammation

CAA (Fountain & Eberhard, 1996), raising the question of whether one condition contributes to the pathogenesis of the other.

The greatest risk factor for CAA is ageing: moderate to severe CAA rarely occurs before age 65, but is present at autopsy in 2.3% of those aged 65–74 and in 12.1% of those older than 84 (Greenberg, 1998). Only an Icelandic variant occurs before the age of 50. Most causes of CAA are asymptomatic (Fountain & Eberhard, 1996). Among those who become symptomatic, the most common presentation is acute intracranial hemorrhage (Greenberg, 1998). In contrast to hypertension, which predisposes to bleeding in the basal ganglia, thalamus, pons, and cerebellum, CAA-related hemorrhage (like vascular amyloid itself) favours the cerebral cortex (Greenberg, 1998). Pathologic studies reveal that vascular deposits in CAA can consist of β-protein amyloid, AL amyloid, AP amyloid or other proteins (Yamada et al., 1996). Rarely, CAA can present as dementia of acute onset accompanied by leukoencephalopathy in the absence of lobar hemorrhage.

Often, CAA and PACNS are readily distinguishable on clinical, radiological and pathological grounds (Table 94.5). In the absence of biopsy evidence of coexisting vasculitis, CAA is treated with measures to reduce the likelihood of hemorrhage, i.e. avoidance of anticoagulation. When PACNS and CAA coexist, immunosuppressive therapy has been reported to be beneficial (Greenberg, 1998).

Malignancies, particularly disseminated intravascular lymphoma, can mimic the clinical and angiographic features of PACNS (Calabrese, et al., 1997; Lie, 1997; Williams et al., 1998). In some series, mental status changes and fever are the most common presenting features (DiGiuseppe et al., 1994). A dramatic improvement following corticosteroids may further suggest PACNS. However, in the absence of a correct diagnosis and prompt initiation of intensive chemotherapy, most patients with intravascular lymphoma relapse rapidly and die (DiGiuseppe et al., 1994).

Finally, the disorder termed 'cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy' (CADASIL) may be mistaken for PACNS (Williamson et al., 1999). Detailed questions about family history of neurologic disease are therefore essential in the evaluation of patients with possible PACNS

Treatment and course

In the absence of treatment, almost all patients with HDACNS die of progressive neurological deficits (Younger et al., 1997). With corticosteroid therapy, cyclophosphamide treatment, or both, most patients stabilize or improve (Calabrese et al., 1997). Recent studies indicate mortality for either definite or probable PACNS has dropped to less than 5% (Calabrese et al., 1997). Although some studies suggested that cyclophosphamide plus prednisone gave superior results to prednisone alone (Calabrese & Mallek, 1987), these differences may be due to ascertainment biases caused by the fact that older cases in the literature were identified chiefly at autopsy (Calabrese et al., 1997). Some authors suggest that cyclophosphamide or other immunosuppressive drugs should be reserved for histologically proven cases that progress despite corticosteroid therapy (Calabrese et al., 1997). Typically, prednisone is administered at 40–60 mg/d for 3–6 months and then tapered to complete a 12 month course (Moore, 1989a). Pulse corticosteroid therapy (i.e. 1000 mg of methylprednisolone intravenously daily for 3 days) followed by daily oral prednisone (1 mg/kg) has been used as initial therapy for patients who have deteriorated rapidly. Monthly, intravenous pulse cyclophosphamide (750–1000 mg/m^2) is less likely than daily oral cyclophosphamide (2 mg/kg) to cause infections and hemorrhagic cystitis. However, oral daily cyclophosphamide may be more effective for certain forms of systemic vasculitis (Langford, 2001). Data comparing daily oral with monthly pulse cyclophosphamide in the treatment of CNS vasculitis are not available.

Treatment of ADACNS is also not well defined. Because some of these patients may have a vasculopathy related more to vasospasm than to arteritis, treatment with calcium channel blockers and prednisone (e.g. 30–60 mg/d) for 3–6 weeks may be sufficient therapy (Calabrese et al., 1997). Avoidance of drugs that promote thrombosis

or vasoconstriction (e.g. oral contraceptives, nicotine, and sympathomimetic drugs) is also recommended (Calabrese et al., 1997).

A substantial number of HDACNS patients may respond sufficiently to steroids alone, which may be tapered successfully over 6 months or more. Some ADACNS patients may do well with shorter courses of steroids and a longer course of treatment with a calcium channel blocker. Predicting which patients will fare well with less intense immunosuppression is difficult. Patients with severe deficits at presentation or radiologic evidence of vital brain regions at risk should probably be treated with the combination of cyclophosphamide and steroids from the onset.

Few studies have reported the neurological outcomes of patients with PACNS. In one study of 21 patients, 10 (48%) demonstrated some recovery (Alrawi et al., 1999). The recovery rate with ADACNS is probably higher (Calabrese et al., 1997).

Sarcoidosis of the nervous system

John Zajicek

Derriford Hospital, Plymouth, Devon, UK

This chapter considers the often difficult diagnosis of neurosarcoidosis, its prevalence, pathology, differential diagnosis, treatment and prognosis. Although advances in imaging techniques have alerted clinicians to this potential diagnosis more frequently than in the past, there is still no definitive non-invasive investigation to provide certain confirmation of clinical suspicion. The diagnosis is one which should always be treated with a healthy degree of scepticism, as even typical granulomas may have alternative causes.

Epidemiology

Prevalence rates for intrathoracic sarcoidosis vary from greater than 50 per 100 000, for example in African–Americans and Irish, to under 10 per 100 000 (James & Hosoda, 1994). Much higher prevalence rates were obtained when consecutive postmortems were performed on approximately 60% of all deaths in an area of Sweden, when evidence of sarcoidosis was found in 43 individuals, only three of whom were known to have sarcoidosis during life, yielding a prevalence of 641 per 100 000 (Hagerstrand & Linel, 1964). The clinical significance of these findings is uncertain, but they suggest that the pathological process is far commoner than we recognize, although this may be limited to subclinical disease in most cases. Intermediate estimates for the prevalence of systemic sarcoidosis of 10–20 per 100 000 are likely for caucasians in London and New York.

Previous data from large series of patients with sarcoidosis have estimated that approximately 5% of such patients will have clinical involvement of the nervous system (Maycock et al., 1963; Stilzbach et al., 1974; Delaney, 1977; Stern et al., 1985), although postmortem studies suggest that antemortem diagnosis is only made in 50% with nervous system involvement (Iwai et al., 1993). Conservatively, we can therefore estimate that about 5 to 10 patients per million population will have clinical neurosarcoidosis, although this figure will vary according to local prevalence rates.

Clinical aspects of neurosarcoidosis

As with any rare disease, information concerning natural history, prognosis and treatment strategies is seldom based on large prospective cohort analysis, let alone on randomized trials.

Because nervous system sarcoidosis is relatively rare, few large series exist in the literature; the largest has been a British series of 68 patients (Zajicek et al., 1999). In assessing the available data it is important to be aware of how each series has been compiled. For example, there is no prospective analysis of consecutive cases and most series will either have been compiled from patients in a sarcoidosis/chest clinic or from neurology departments. These factors have inevitably led to referral bias so that data from thoracic departments are more likely to show pulmonary abnormalities, whilst patients presenting to neurologists may not have had any previous evidence of systemic disease. Variation also exists in the degree to which individual clinicians pursue a diagnosis, for example, although facial nerve paresis is a relatively common manifestation of neurosarcoidosis, 'Bell's palsy', on the other hand, is considered to have a generally benign clinical course, and such cases may not be fully investigated for neurosarcoidosis. A recent series of 265 cases of acute facial nerve palsy found 11% had abnormal cerebrospinal fluid, mostly due to Ramsey–Hunt syndrome, HIV or Lyme disease (Kohler et al., 1999), with only one case identified with sarcoidosis.

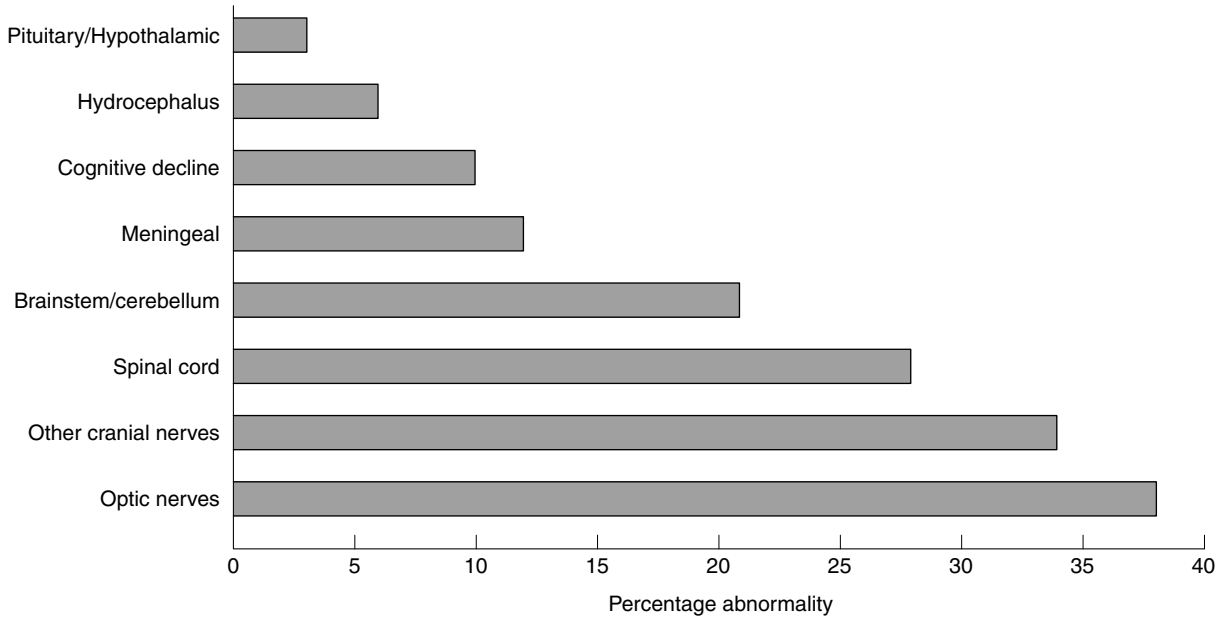

Fig. 95.1. Clinical presentations of neurosarcoidosis in 68 patients (Zajicek et al., 1999).

Allowing for these caveats, some useful information can be obtained by comparing some of the largest series in the literature (James & Sharma, 1967; Delaney, 1977; Stern et al., 1985; Oksanen, 1986; Chapelon et al., 1990; Zajicek et al., 1999). The total number of cases in these series is 247 and although the average percentage of cases with peripheral nerve and muscle involvement in all except the most recent series was in the order of 30%, Zajicek et al. found no cases with peripheral nervous system involvement. It certainly appears that such manifestations are rare in peripheral nerve clinics in the UK (P.K. Thomas, personal communication) and this may reduce one's tendency to obtain a tissue diagnosis using peripheral tissue.

There is no obvious sex difference in prevalence rates, and the mean age of presentation is around 40 years. In patients presenting with neurosarcoidosis to neurology clinics, there is an approximate 40% chance of their having had previous disease in other organs, most commonly chest or anterior uvea. Details of clinical features at presentation from one large series are summarized in Fig. 95.1.

Optic nerve disease is a very common presentation of neurosarcoidosis and up to 38% of patients may have evidence of a lesion at this site, approximately two-thirds of whom will have clinical evidence of unilateral and one-third bilateral disease. The characteristic picture is often an atypical optic neuritis, subacute in onset, which might recover following steroids or cause permanent visual impairment. Initial steroid sensitivity is occasionally followed by dependence, with symptoms deteriorating below a certain dosage level. In a prognostic analysis of patients with optic nerve disease who were followed up for lengthy periods, most of whom received corticosteroid treatment, there is an approximate 40% chance of appreciable recovery over 18 months or more.

When investigating patients for neurosarcoidosis, a full neuro-ophthalmological workup is therefore indicated, including a search for both anterior and posterior segment disease with slit lamp examination and fluorescein angiography, as well as seeking clinical and/or visual evoked potential evidence for optic nerve disease. Unfortunately, optic nerve disease has a tendency to be severe with profound impairment of visual acuity being all too common.

The propensity for sarcoidosis to produce a meningeal reaction probably explains the predominance of cranial nerve palsies in most series (see Fig. 95.2). If optic nerve disease is also taken into account, then around 60% of patients present with cranial nerve palsies in the combined series of 247 patients (see above). Approximately one-third of patients will have facial nerve paralysis, most commonly unilateral, although bilateral simultaneous or sequential paralysis carries a higher index of suspicion.

Facial nerve palsies are a classical manifestation of neurosarcoidosis and have been reported as carrying a good prognosis in previous publications (Delaney, 1977),

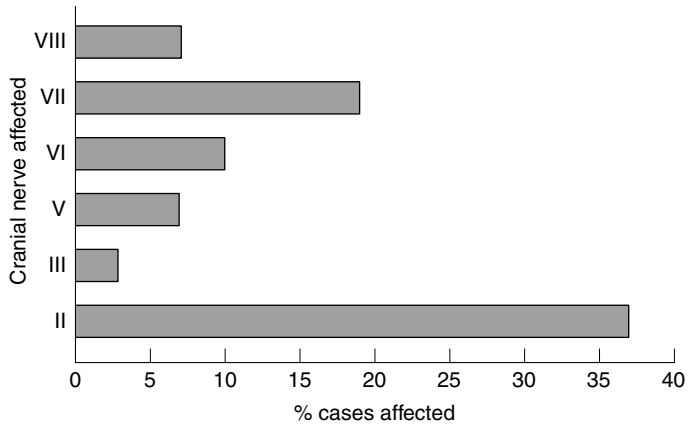

Fig. 95.2. Cranial nerve involvement in a series of 68 patients with neurosarcoidosis (Zajicek et al., 1999)

although this may not always be the case (Zajicek et al., 1999). There may well be a difference in prognosis depending on where the facial nerve is affected along its course. Certainly, examples of CSF abnormalities in cases of apparently pure facial palsy suggest that the lesion may result from a meningitic reaction, but the classical explanation for facial palsy in neurosarcoidosis is that it is secondary to inflammation in the parotid gland, although many early authors also noted the lack of temporal correlation between parotitis and facial palsy (Wilson, 1940). More detailed prospective studies are clearly needed to assess the site and significance of such palsies.

Spinal column disease has previously constituted up to 10% of large series of neurosarcoidosis cases (Oksanen, 1986; Stern et al., 1985; James & Sharma, 1967). Syndromes ranged from intramedullary tumour-like presentations to meningitic–radicular syndromes (for review see Zajicek, 1990). Zajicek et al. described 28% of patients with clinical signs of spinal cord disease. In ten patients this was clinically confined to the cord whilst nine patients also had clinical disease elsewhere in the neuraxis. Fifteen cases with spinal cord disease were followed up for more than 18 months, and 11 of these deteriorated (73%). These results suggest that such a presentation carries a poorer prognosis than certain other manifestations of neurosarcoidosis.

Brainstem and/or cerebellar presentation occurs in about 20% of patients, who principally exhibit limb or gait ataxia and eye movement abnormalities such as failure of vertical gaze. Internuclear ophthalmoplegia and central vomiting have also been reported with neurosarcoidosis. A small percentage (<10%) of cases may present with cognitive decline and a similar number may have a meningitic type illness at presentation.

Pathology and pathogenesis of sarcoid granulomas

The fundamental histological feature characterizing sarcoidosis is the presence of non-caseating epithelioid cell granulomata. Whilst the presence of such granulomata may seem pathognomonic of sarcoidosis, other disease processes are capable of provoking a granulomatous reaction, and it is only in the correct clinical context, when alternative explanations have been excluded, that the clinician may tentatively accept a diagnosis of sarcoidosis. This particularly applies in the nervous system where access to tissue is more difficult and clinical syndromes tend to be less clear cut (see Table 95.1).

Mononuclear phagocytes, including blood-borne monocytes, tissue macrophages, brain microglia and epithelioid cells (which may amalgamate to produce giant cells), constitute the predominant cell types in a granuloma. Well-formed granulomata usually contain macrophages with varying degrees of maturity, including

activated and non-activated cells. An example of meningeal sarcoidosis is demonstrated in Fig. 95.3, see colour plate section.

Macrophages in areas of early granuloma formation express the calcium-binding protein calgranulin Mac 387, which is an antigen shared by granulocytes and circulating monocytes but only a small proportion of tissue macrophages (Chilosi et al., 1990). This suggests that local recruitment from blood-borne monocytes is important in granuloma formation. Epithelioid cells retain macrophage markers within granulomas, confirming their lineage (Poulter, 1983). They also strongly express MHC class II molecules and act as antigen-presenting cells (van der Oord et al., 1984). Epithelioid cells possess numerous well developed cytoplasmic organelles containing material which is of intermediate electron density on electron microscopy. There is no evidence that these organelles contain fragments of microorganisms but it has been postulated that the epithelioid cells found in tuberculosis contain more prominent rough endoplasmic reticulum and fewer lysosymes, whereas the reverse may be true in sarcoidosis (Epstein, 1991).

As well as phagocytic cells, sarcoid granulomas also contain high numbers of lymphocytes, reflecting their importance in immunopathogenesis. Inorganic foreign body granulomas, for example those induced by silica, consist almost entirely of macrophages with very few lymphocytes. The inorganic material is resistant to degradation within macrophages and may induce cell death, leading to giant cell formation, but under these circumstances there is little evidence of T-cell activation, and these granulomata therefore do not resemble immunologically induced granulomata commonly found in sarcoidosis. Most lymphocytes found within sarcoid granulomata are CD4+ T-cells, found particularly at the centre of the lesion. CD8+ cells and B-cells tend to occur towards the periphery of a granuloma (Modlin et al., 1984), but $\gamma\delta$-T-cells may also play a role in the inflammatory process, and cell numbers may be raised both systemically and locally at the site of granuloma formation (Balbi et al., 1990).

Not surprisingly when investigators have looked at the cytokine and adhesion molecule profile within granulomata, a large array of molecules can be found. LFA-1 and ICAM-1 appear to be two of the major adhesion molecules expressed (Semenzato et al., 1994). IL-1 and γ-interferon are preferentially expressed at the granuloma centre and the overall pattern of cytokine involvement is skewed towards the proinflammatory T_H1 (TNF-α, Il-1, Il-2) rather than T_H2. It is beyond the scope of the present chapter to provide great detail on granuloma formation and this can be found elsewhere (Semenzato et al., 1994), but the end result of such granulomata is often fibrosis and scar formation which is not necessarily specific to sarcoidosis. Numerous proteins may be released which promote this process including PDGF, IGF-1, TGF-β as well as tissue breakdown products including collagenases and free oxygen radicals.

The fundamental question concerning the driving stimulus behind granuloma formation remains controversial and unanswered. Most observers would accept that there is undoubtedly an exaggerated immune response to an as yet unidentified antigen. The histological similarity between tuberculous and sarcoid lesions has led to a prolonged search for mycobacteria within granulomata. Whilst some investigators have detected mycobacterial DNA by polymerase chain reaction (PCR) in sarcoidosis tissue (Saboor et al., 1992; Mangiapan & Hance, 1995), others have been unable to do so (Vokurka et al., 1997).

The possibility that sarcoidosis may be caused by an abnormal reaction to other infectious agents has also been widely explored. Human herpes virus 8 (HHV-8) has been implicated in the development of Kaposi's sarcoma (KS) and other malignancies in HIV-related disease, and recently Alberti et al. (1997) reported HHV-8 DNA in biopsy specimens from eight patients with sarcoidosis, although others were unable to find serological evidence for HHV-8 infection in sarcoidosis patients, whilst such evidence was found in patients with HIV-related KS. Ishige et al. (1999) reported the presence of DNA from either *Propionibacterium acnes* or *Propionibacterium granulosum* in all lymph node samples from 15 patients with sarcoidosis, but only 2/15 patients with tuberculosis and 3/15 controls. The significance of these findings is uncertain as *Propionibacteria* can be present in tissue without pathological effects.

Genetic factors almost certainly govern disease susceptibility in sarcoidosis, and it has been argued that affected individuals possess a genetic predisposition to an exaggerated immune response which is able to eradicate the microorganisms early and thus make identification very difficult. Certainly familial cases of sarcoidosis have been described, and there appears to be a higher incidence in monozygotic rather than dizygotic twins (British Thoracic and Tuberculous Association, 1973). The recognition of varying prevalence rates in different ethnic groups has long been quoted as evidence for genetic predisposition in sarcoidosis and associations between human leukocyte antigens (HLA) of the major histocompatibility (MHC) group and sarcoidosis, has provided more concrete support for this hypothesis. Notable associations exist between HLA-B8 in British, Italian and Czech populations (Smith et al., 1981; Martinetti et al., 1995) and HLA-DR17 in Scandinavians

(Berlin et al., 1997). Because these associations have been inconsistent, they have recently been explored further by examining other genes around the MHC including the transporter associated with antigen processing (TAP) genes (Foley et al., 1999). Significant differences have been found between UK and Polish populations in susceptibility at these loci, and there appeared to be independent associations at the TAP and HLA-DPB1 loci. A recent study has also suggested that polymorphisms in the C-C chemokine receptor 2 gene (a major receptor for the monocyte chemoattractant protein (MCP) group of C-C chemokines) may confer susceptibility to sarcoidosis (Hizawa et al., 1999). These studies illustrate the importance of distinguishing populations when examining disease susceptibility. Although the causes of sarcoidosis remain unknown, as in other CNS inflammatory conditions (notably Multiple Sclerosis, MS), there is emerging consensus which supports the belief that sarcoidosis results from exposure of genetically susceptible individuals to specific environmental agents (American Thoracic Society 1999).

The diagnosis of neurosarcoidosis

An accurate diagnosis is the cornerstone of treatment, yet defining the diagnosis of neurosarcoidosis with certainty is often difficult. Most series in the literature rely on the presence of recognized neurological phenomena in the context of a granulomatous multisystem disease, so that tissue diagnosis is often made from organs such as the liver, lung or skin. However, this is really inadequate to be certain of CNS involvement in the same process. There are many reports of systemic sarcoidosis being identified, and the apparent CNS component of the illness being treated, yet the true CNS diagnosis may be entirely different and emerge only later. Histological diagnosis from the CNS is often an early feature in neurological series, particularly if biopsy is performed on the expectation that an alternative diagnosis is present. When early presentation occurs to the neurological clinic, systemic disease is less likely to be obvious, and once a tissue diagnosis from the CNS is obtained, clinicians are less liable to search for systemic disease. Certainly CNS histology is preferable to relying on systemic histology, but even here granulomatous reactions can exist around other pathologies, falling short of a 'gold standard' diagnostic test. There are those who argue that one cannot make a diagnosis of neurosarcoidosis in the absence of systemic disease, but in reality clinicians may be faced with sick patients, a histological diagnosis and pressure to treat, which often outweighs the desire to perform further investigations.

All this influences the confidence with which we can make a diagnosis of neurosarcoidosis, and we must accept that until the pathology is fully understood, errors in diagnosis will occur (some of which have already entered the literature and will continue to do so). Clinicians therefore make estimates of probability of disease and must manage patients according to these probabilities. Similarly, when cases are defined from the literature, there is an inevitable leap of faith that these cases do indeed suffer from neurosarcoidosis and are broadly representative of clinical practice.

The investigation of patients with possible neurosarcoidosis

It has been suggested that a definite diagnosis of neurosarcoidosis can only be made if nervous system histology is positive within a suitable clinical context (Zajicek et al., 1999). A greater precision in diagnostic definition not only allows for accurate prospective analysis of prognostic indicators, and better assessment and validation of indirect indicators of disease, but also enables therapeutic trials to be conducted in a meaningful fashion. However, biopsy of CNS tissue (Fig. 95.4) is required to make a definite diagnosis of neurosarcoidosis according to these criteria, and even in the largest series, this was only achieved in less than 20% of cases. When the patient is seriously ill with rapidly progressive disease in several parts of the neuraxis, it is important to achieve a diagnosis as quickly as possible in order that appropriate therapy can be commenced; under these circumstances guided stereotactic or open biopsy is often performed, either of meninges and/or of parenchymal lesions. With less severe disease and/or a more gradual course, it is often more appropriate to perform indirect investigations to look for systemic disease and treat accordingly (see below).

Retrospective analysis of the usefulness of biopsy to assess the specificity and sensitivity of any other single investigation inevitably introduces bias, as biopsy is undertaken selectively, e.g. on mass lesions, where the possibility of neoplasia has been raised, in patients with severe and rapidly progressive disease, or in cases where histology is relatively easy to obtain. The lesion site (which influences the decision to biopsy) will also influence the clinical presentation, for example, cortical lesions may be more likely to present with epilepsy and be biopsied, thus interpretation of the clinical presentation of this group of patients must be cautious. Another major difficulty with interpreting data from these patients is their lack of completeness, as investigations are often halted once tissue

diagnosis is achieved. Establishing the diagnosis of neurosarcoidosis is often difficult and the only way to acquire firm evidence for the value of any single investigation is to perform a prospective study using appropriate investigations in all patients, especially those in whom a definite histological diagnosis has been obtained. The understandable tendency not to perform further investigations once the diagnosis has been obtained has limited our knowledge on the usefulness of non-invasive methods for investigating neurosarcoidosis.

Most patients being investigated for neurosarcoidosis have a chest radiograph which at presentation to neurologists can be expected to be abnormal between one-third and two-thirds of the time, the most common abnormality being bilateral hilar lymphadenopathy, occasionally with additional pulmonary abnormality. Previous studies utilizing chest CT suggest it may assist in targeting transbronchial biopsy.

Historically, one of the most useful investigations in sarcoidosis is the Kveim antigen skin test, which is positive in around 85% of patients with neurosarcoidosis. This compares favourably with rates of positivity in other patients with systemic sarcoidosis (Scadding & Mitchell, 1985). The usefulness of this test compared to tissue diagnosis by other means has previously been assessed (Mitchell et al., 1980). That study reviewed the procedures by which histological confirmation was obtained in 79 patients with a final diagnosis of sarcoidosis. Transbronchial lung biopsy was performed in 42 cases and showed sarcoid-type granulomata in 37. Kveim tests were performed in 44 and were interpreted as being positive in 19 and equivocal in 11. Thus, whilst rates of granulomatous 'positive' Kveim test responses are usually lower than those obtained by appropriate tissue biopsy, a positive Kveim test can be regarded as comparable to that of finding granulomas in a biopsy of a site remote from that principally affected. Recent questions concerning safety of the test and particularly the idea that it may transfer sarcoidosis have been vigorously refuted (DuBois et al., 1993). However, since the appearance of variant CJD, it has become even more difficult to obtain Kveim antigen in the UK and the USA, and the lack of availability makes the routine use of this test problematical. A further major problem with the Kveim test lies in the 4–6 week time interval required to elapse before biopsy can be performed. This period may be crucial to the timing of intervention in the disease process, particularly when lesions occur in clinically critical sites. Concomitant use of corticosteroids may reduce systemic granuloma formation including the site of Kveim antigen insertion, and this is a likely explanation for negative Kveim results observed in cases of biopsy proven disease. In some series, all Kveim negative patients were being treated with systemic corticosteroids. Hence, although the Kveim test is an invaluable aid in the diagnosis of neurosarcoidosis, up to 3% may be false-positive, negative results may occur with concomitant corticosteroid therapy and lack of availability means alternative means of making a diagnosis are usually required.

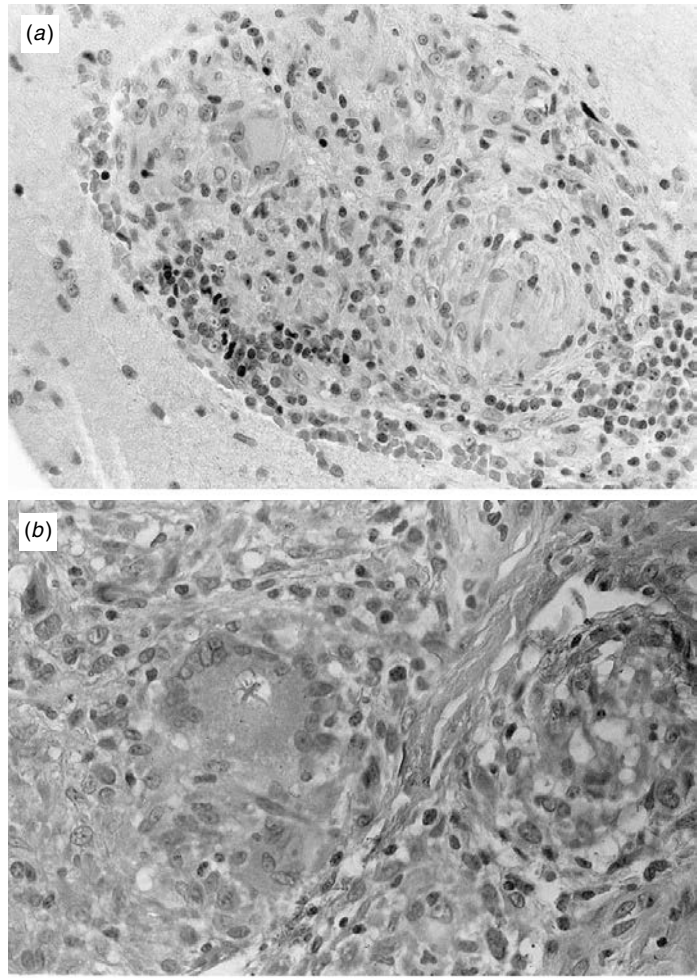

Fig. 95.4. (*a*) Photomicrograph of an intraparenchymal non-caseating sarcoid granuloma of the brain (×200). (*b*) Photomicrograph of a sarcoid granuloma in brain, demonstrating a multinucleated giant cell (×400) (From Aminoff, 2001, with permission.)

The usefulness of performing 'blind' biopsies from other organs, including liver and lung, in patients with suspected neurosarcoidosis, is uncertain. Whilst tissue diagnosis from sites outside the nervous system has previously been considered sufficient to establish the diagnosis of neurosarcoidosis in the context of an appropriate clinical syndrome, this should still only be considered as evidence for

systemic disease which by itself is insufficient to be certain of neurological involvement by granulomatous tissue.

CSF abnormalities are common in neurosarcoidosis and are present in over 80% of cases at presentation. The most common abnormality is an elevation in protein, sometimes to very high levels and around half of all cases will show a CSF lymphocytosis, with occasional rare neutrophils and monocytes. A similar proportion of patients may have CSF oligoclonal bands on immunoelectrophoresis: one-third of these cases providing evidence for systemic synthesis (the so-called 'mirror' pattern of similar oligoclonal bands in CSF and serum), the remainder fulfilling the criteria for local synthesis, with only a small proportion of this latter group of patients having normal CSF protein levels, which may be a way of helping to distinguish them from those patients with multiple sclerosis. If there is definite evidence for multisystem disease in the context of neurosarcoidosis, one is more likely to see a 'mirror' pattern and intrathecal local synthesis is less likely to be present (V. Chamoun, personal communication).

The significance of raised CSF ACE levels in the context of elevated protein concentrations or CSF cell counts remains uncertain, and this investigation is probably of little use. Any usefulness may be principally confined to that small number of patients where levels are raised out of proportion to the protein concentration, when the CSF does not contain large numbers of inflammatory cells and the serum ACE is not elevated. Other biochemical indices are generally unhelpful in establishing a diagnosis; serum calcium and erythrocyte sedimentation rate are rarely elevated.

Whole body Gallium scanning remains a useful indicator of systemic disease, which although again is a relatively non-specific measure, adds diagnostic probability to a case. Ga67 citrate is taken up at sites of active sarcoidosis and also by other inflammatory and malignant diseases, including tuberculosis and lymphomas, but the pattern of uptake among patients with active sarcoidosis is well recognized. Accordingly, as a component of the investigations relevant to the diagnosis of extrathoracic sarcoidosis it can be very helpful although constrained by the limitations imposed by subjective interpretation. In a consecutive unpublished series of 42 such patients a definite pattern of uptake was obtained in 18 (42%), whilst the pattern of uptake was considered equivocal in eight and negative in 16. In the British series, 45% of patients in whom this investigation was performed proved to have increased uptake which was usually in the salivary glands or chest.

MRI has greatly aided the investigation of patients with inflammatory brain disease and has consistently proved to

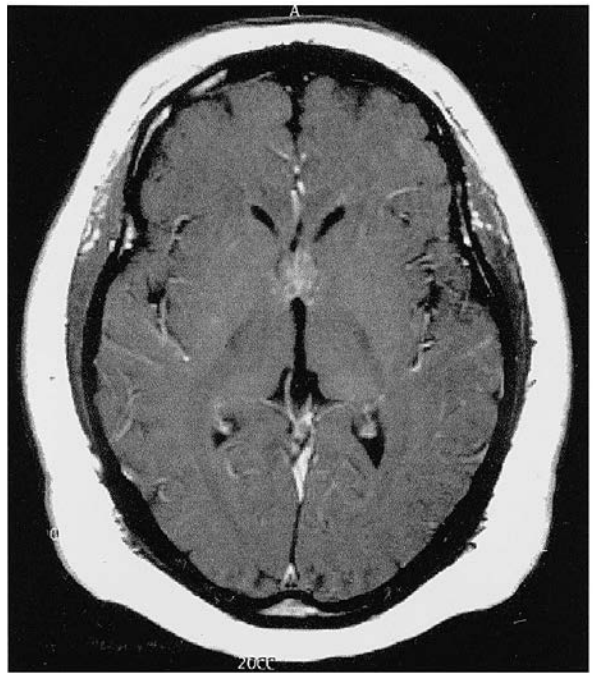

Fig. 95.5. Contrast-enhanced axial MRI scan demonstrates modularity around the optic chiasm, and anterior borders of the third ventricle in a patient with neurosarcoidosis.

Fig. 95.6. Coronal MRI demonstrating hydrocephalus. (Courtesy of Dr J.C. McArthur.)

be more sensitive than CT. Although MRI does not provide a great deal of specificity, its sensitivity is around 82%. Multiple white matter lesions and leptomeningeal enhancement with gadolinium, are the most common MRI findings, occurring independently in about 40% of cases. MRI abnormalities have been well described in previous series (Miller et al., 1988; Seltzer et al., 1991; Zajicek et al., 1999; Christophoridis et al., 1999) and although there are no specific features distinguishing neurosarcoidosis from MS, meningeal enhancement or persistent enhancement (more than a few weeks) of parenchymal lesions are much more suggestive of a granulomatous process and are not expected in MS (see Figs. 95.5, 95.6).

An overall plan for the investigation of a patient in whom the diagnosis of neurosarcoidosis is being considered is shown in Table 95.2. The essential decision which the clinician needs to make is whether evidence of systemic disease is sufficient to justify treatment of an associated neurological syndrome, or whether neurosurgical biopsy should be sought. In the present era, when the morbidity of carefully conducted leptomeningeal or parenchymal biopsy is low, serious consideration must be given to such procedures, particularly if the clinician is considering the use of potentially toxic drugs.

Table 95.2. The investigation of patients with possible neurosarcoidosis

Investigations for systemic disease
Chest X-ray (possible chest CT if high index of suspicion)
Lung function tests
Gallium scan
Blood investigations (including ESR, serum calcium, liver function, urea, electrolytes, autoantibodies, anti-neutrophil cytoplasmic antibody, complement, complete blood count, serum ACE, and other tests depending on differential diagnosis.
Consider tissue biopsy via bronchoscopy, liver, skin or conjunctival biopsy depending on abnormality.
Investigations for eye/nervous system disease
Ophthalmological assessment, including slit lamp examination, fluorescein angiography, electroretinograms and evoked potentials.
MRI of brain and possibly spine, with gadolinium contrast administration, consider repeating after an interval to look for prolonged contrast enhancement.
Lumbar puncture, CSF analysis for glucose, protein, cells, cytology, immunoelectophoresis (with paired blood)
Consider leptomeningeal and/or parenchymal biopsy

Treatment of neurosarcoidosis

Prolonged follow-up, ideally under randomized controlled conditions is necessary to draw valid conclusions concerning treatment schedules in neurosarcoidosis. Forty-seven patients were followed up for at least 18 months in the series of Zajicek et al. (1999), 34 of whom received corticosteroids alone, usually as a combination of long term oral prednisolone with or without intravenous methylprednisolone boluses. Ten/34 (29%) improved or stabilized whereas 24/34 (71%) deteriorated. Other therapies were tried only as steroid treatment was becoming ineffective or side effects were too severe; such treatments included methotrexate, azathioprine and hydroxychloroquine. The number of patients treated with any other single regime was too small to draw firm conclusions. Cyclosporin was used in three instances and was associated with improvement in one. Cranial irradiation was used in two instances, in one case after cyclosporin had failed and in one case after corticosteroids proved ineffective. Intravenous cyclophosphamide was used at high dosage (400 mg/day until the peripheral white cell count fell to below 4×10^6/ml) in three cases, who all improved.

The absence of large prospective trials and the paucity of existing data renders it very difficult to identify those patients in whom early aggressive immunotherapy would be beneficial. Analysis of the available data would suggest that disease presenting in the spinal cord or optic nerve, together with epilepsy, carry a poorer prognosis than facial nerve palsies. Most patients are treated with systemic corticosteroids which often carry significant side effects as dosages tend to be high and prolonged. Although some patients improve on this treatment, many continue to have troublesome disease. It is often the case that symptoms tend to recur at doses of prednisolone less than 20–25 mg/day or the equivalent in other corticosteroid types, making cessation of corticosteroids difficult. The incidence of steroid-related side effects is extremely high with such prolonged treatment, and all patients should be considered for osteoporosis-prevention treatment if prolonged steroid administration is anticipated. Concomitant anticonvulsant therapy which induces hepatic microsomal enzymes may reduce prednisolone concentration and efficacy, necessitating even higher oral doses. Bolus pulsed intravenous methylprednisolone gives a high initial loading dose of corticosteroid, and may help to avoid side effects associated with long term oral treatment.

Even fewer data exist concerning the efficacy of other forms of immunomodulatory therapy. The use of chlorambucil (Kataria, 1980), methotrexate (Lower & Baughman, 1990; Soriano et al., 1990), chloroquine (Morse et al., 1961), cyclosporin (Kavanaugh et al., 1987; Cunnah et al., 1988; Stern et al., 1992), radiotherapy (Grizzanti et al., 1982; Bejar et al., 1985; Gelwan et al., 1988) and cyclophosphamide, have all been reported. Thalidomide has been used in the treatment of generalized, particularly cutaneous, sarcoidosis, but its use in neurosarcoidosis awaits assessment.

Several regimes of immunotherapy can be used and some of these are described in Zajicek et al. (1999). Methotrexate, usually used weekly in a dose of 10 mg, may be of value in maintaining optimal suppression together with i.v./oral prednisolone and this is often used as a first-line steroid-sparing agent. Hydroxychloroquine has also proved to be a very useful adjunct to steroids and at a dose of 200 mg/day. This can be used daily for up to about a year and is worth considering as a first-line agent together with methotrexate. Cyclosporin, cyclophosphamide and fractionated radiotherapy all need further assessment. One regime for the management of neurosarcoidosis consists of initiating treatment with 1g i.v. methylprednisolone for 3 days together with at least 25 mg of oral prednisolone or equivalent per day. i.v. methylprednisolone 1 g is then continued on a weekly basis for a number of weeks, allowing a reduction of oral prednisolone to 15–20 mg/day. During this period, oral methotrexate and hydroxychloroquine may be added, especially with severe disease or a poor initial response to steroids. In severe cases, the i.v. methylprednisolone may be continued for some months, with a gradually increasing interdose interval.

None of these recommendations can be considered to have withstood serious scientific scrutiny in clinical trials, to gain such information requires collaboration on a wide scale, which would not only allow for the refinement of diagnostic criteria, but also provide for better analysis of prognostic factors. At present we can only conclude that neurosarcoidosis is often difficult to diagnose, that if the illness doesn't respond to early corticosteroid therapy then it can also be problematical to treat, and furthermore the prognosis appears to be worse than other manifestations of the condition.

Collagen–vascular disease and the nervous system

Michael J. Regan[1] and John H. Stone[2]

[1] Division of Rheumatology, Johns Hopkins University School of Medicine, Baltimore, MD, USA
[2]Johns Hopkins Vasculitis Center, Johns Hopkins University School of Medicine, Baltimore, MD, USA

The collagen–vascular diseases represent the systemic expression of the immune system gone awry. In many cases, combinations of immune system dysregulation and nervous system involvement lead to some of the most challenging clinical conundrums in the neurosciences. In this chapter, we review the collagen–vascular diseases and their impact on the brain and peripheral nervous system.

Systemic lupus erythematosus

Systemic lupus erythematosus (SLE) is the prototype of autoimmune diseases. The condition occurs throughout the world and is more prevalent in women (particularly during the reproductive years), with a female:male ratio of 9:1 (Gladman & Urowitz, 1998). To meet inclusion criteria for research studies as an SLE patient, a patient must demonstrate a minimum of 4 out of the 11 American College of Rheumatology (ACR) criteria (Table 96.1) (Tan et al., 1982). The criteria demonstrate the protean nature of SLE, which is capable of affecting any organ system. However, some patients clearly fit the spectrum of SLE yet do not fulfil minimum ACR criteria. Among the many neuropsychiatric manifestations of SLE, only seizures and psychosis were included in the 1982 criteria.

A 1999 nomenclature system for neuropsychiatric SLE (NPSLE) expanded the neuropsychiatric section of the ACR criteria, defining 19 neuropsychiatric syndromes associated with SLE. These are listed in Table 96.2 (ACR Ad hoc Committee, 1999). Usage of the terms 'CNS lupus', 'lupus cerebritis', 'CNS vasculitis', 'lupus headache', 'lupoid sclerosis', 'brief reactive psychosis', and 'organic brain syndrome' is discouraged. Neuropsychiatric manifestations may occur in up to two-thirds of patients with SLE (West, 1994) and range from anxiety, mood disorders, cognitive dysfunction and delirium to depression, frank psychosis, stupor and coma (Kovacs et al., 1993; Boumpas et al., 1995). Several conditions must be excluded before the attribution of neurological findings to NPSLE.

Pathogenesis

The pathogenesis of NPSLE remains elusive. It is probably more accurate to regard the 'disease' of SLE as a complex, heterogeneous group of disorders of unknown cause. Autopsy studies of patients with NPSLE have shown no pathognomonic lesions and frequently demonstrated poor correlation between clinical and pathological findings (West, 1994). In a classic 1968 paper, Johnson and Richardson reported that microscopic lesions were more common than macroscopic ones. Microinfarcts, microhemorrhages and increased pericapillary microglia were found in 20 of the 24 patients autopsied (83%) (Johnson & Richardson, 1968). Vasculitis was seen rarely, and inflammatory cells were present in only 3 out of the 24 patients (12.5%). Even some highly symptomatic patients, particularly those with diffuse CNS dysfunction, had few pathological abnormalities. In contrast, pathological abnormalities were found occasionally in patients who demonstrated no overt neurological manifestations of NPSLE during life. Other autopsy studies have provided similar results, the most common findings being a bland vasculopathy with endothelial proliferation, hyalinization, multiple microinfarcts, and microhemorrhages (Ellis & Veroty, 1979; Funata, 1979; Devinsky et al., 1988; Hanly et al., 1992).

Evidence suggests several possible etiological roles for a number of autoantibodies including antiribosomal P antibodies, anti-lymphocyte antibodies, antineuronal antibodies, and antiphospholipid antibodies (aPL). The precise mechanisms of how these antibodies conspire to cause NPSLE is unclear. In the 1980s and 1990s, research focused

Table 96.1. The 1982 revised ACR CRITERIA[a]

Criterion	Definition
Malar rash	Fixed erythema, flat or raised, over the malar eminences, sparing the nasolabial folds
Discoid rash	Erythematous raised patches with adherent keratotic scaling and follicular plugging: atrophic scarring may occur in older lesions
Photosensitivity	Skin rash as a result of unusual reaction to sunlight, by patient history or physician observation
Oral ulcers	Oral or nasopharyngeal ulceration, usually painless, observed by a physician
Arthritis	Non-erosive arthritis involving two or more peripheral joints, characterized by tenderness, swelling, or effusion
Serositis	Pleuritis: convincing evidence of pleuritic pain or rub heard by a physician or evidence of pleural effusion; o*r* Pericarditis: documented by electrocardiogram or rub or evidence of pericardial effusion
Renal disorder	Persistent proteinuria greater than 0.5 g/24 hours or greater than 3+ if quantitation not performed; *or* Cellular casts: may be red cell, hemoglobin, granular, tubular, or mixed
Neurological disorder	Seizures: in the absence of offending drugs or known metabolic derangement, e.g. uremia, ketoacidosis, or electrolyte imbalance; *or* Psychosis: in the absence of offending drugs or known metabolic derangement, e.g. uremia, ketoacidosis, or electrolyte imbalance
Hematological disorder	Hemolytic anemia with reticulocytosis; *or* Leukopenia: less than 4000/mm^3 on more than two occasions; *or* Lymphopenia: less than 1500/mm^3 on more than two occasions; *or* Thrombocytopenia: less than 100 000/mm^3 in the absence of offending drugs
Immunological disorder	Positive LE cell preparation; *or* Anti-DNA: antibody to native DNA in abnormal titre; *or* Anti-Sm: presence of antibody to SM nuclear antigen; *or* False-positive serological test for syphilis, known to be positive for at least 6 months, and confirmed by *Treponema pallidum* immobilization or fluorescent treponemal antibody test
Antinuclear antibody	An abnormal titre of antinuclear antibody by immunofluorescence or an equivalent assay at any point in time in the absence of drug

on intraneuronal antigens, particularly in relation to the complications of psychosis and depression (Bluestein, 1997). Two studies showed moderately strong associations between serum antiribosomal P antibodies and psychiatric manifestations (Bonfa et al., 1987; Schneebaum et al., 1991; Teh & Isenberg, 1994). Schneebaum et al. found serum antiribosomal P antibodies in 51 of 269 patients with SLE (19%) (Schneebaum et al., 1991). Among the 82 patients with NPSLE symptoms, elevated levels of antiribosomal P antibodies were found in 29%, compared to only 14% of the 187 patients without NPSLE manifestations. In those patients with psychosis and depression, 45% and 88% were antiribosomal P antibody positive, respectively (Bluestein, 1997). Further investigations of antiribosomal P antibodies in SLE are indicated before widespread application in clinical practice (Teh & Isenberg, 1994; ACR Ad hoc Committee, 1999).

Serum and cerebrospinal (CSF) fluid IgG antineuronal antibodies have also been investigated (Bluestein et al., 1981; Temesvari et al., 1983; Robbins et al., 1988; Costalla et al., 1990; Matsunaga et al., 1991; Denburg et al., 1994; Wallace & Metzger, 1997). Serum antineuronal antibodies are present in 80% of patients with NPSLE (compared with only 5% of those without NPSLE features). However, CSF antineuronal antibodies have superior sensitivity and specificity for NPSLE (Bluestein et al., 1981; Bluestein & Zvaifler, 1983; Bluestein, 1997; Wallace & Metzger, 1997). Bluestein et al. found CSF antineuronal antibodies in 75% of patients with NPSLE, compared with only 10% in SLE patients without evidence of NPSLE, with the strongest

correlation in those patients with diffuse CNS dysfunction (Bluestein et al., 1981).

Much investigation has also centred on the role of aPL in NPSLE. Intracranial thromboses causing cerebrovascular syndromes are strongly associated with aPL. These antibodies also occur in some patients with Libman–Sacks endocarditis. Embolization from cardiac foci and the formation of thrombi *in situ* cause strokes in some SLE patients. However, as with the other autoantibodies, not all patients with these antibodies have manifestations of NPSLE (Hirohata & Miyamoto, 1990; Susuki et al., 1995; Bluestein, 1997; Khoshbin et al., 1999).

With the exception of aPL, neither serum nor CSF levels of the autoantibodies discussed above have correlated consistently with specific neuropsychiatric syndromes in SLE. Use of these assays should be reserved for investigational use only.

Although no single pathogenetic mechanism currently explains the broad spectrum of NPSLE manifestations, in recent years, the process of apoptosis has attracted considerable attention as one that may explain many aspects of the initiation and propagation of SLE (Andrade et al., 2000). The central hypothesis in this theory is that failure to phagocytose and degrade apoptotic cells, followed by an autoamplification of the inflammatory process, leads to the clinical expression of SLE. In the genetically susceptible individual, a primary immune response directed against certain non-tolerized structures is initiated. In SLE, it is known that autoantigens are clustered and concentrated in the surface blebs of apoptotic cells, where they are modified by apoptosis-specific proteolysis and phosphorylation (Rosen & Casciola-Rosen, 1999). Many of these autoantigens are cleaved specifically by caspases during apoptosis, generating unique fragments. Other autoantigens are cleaved by granzyme B. In general terms, defective clearance of this apoptotic material and abnormal regulation of the immune response are likely susceptibility factors to this initiation phase. Access of the apoptotic material to the class II major histocompatibility complex pathway in the context of antigen-presenting cells may then initiate a primary immune response effectively. Once primary immunization has occurred, the repeated generation of apoptotic material (e.g. by sun exposure, viral infections, or drug triggers) may rechallenge the immune system effectively, leading to flares.

Laboratory testing/imaging studies

In patients suspected of possible NPSLE, a complete history and physical examination are the essential first steps. Laboratory analyses should include a complete blood count with differential; renal and hepatic function profiles; serum complement levels; an anti-dsDNA antibody assay; an erythrocyte sedimentation rate (ESR); and a urinalysis that includes microscopic examination. Assays for aPL (anticardiolipin antibodies and the lupus anticoagulant) are also indicated (see below). Other evaluations for hypercoagulable states may be indicated in patients with histories of vascular thromboses. Because of the frequent use of immunosuppression in SLE, a high index of suspicion for systemic or CNS infections is essential. Blood cultures, echocardiograms, and other studies may be indicated by certain clinical presentations.

Lumbar puncture provides important information in the setting of possible NPSLE. In addition to the cell count (with differential white blood cell count) and levels of protein and glucose, the CSF should also be assayed for cryptococcal antigen and cultured for bacterial, fungal and mycobacterial organisms. In the proper clinical settings, particularly when evaluating SLE patients with multiple sclerosis-like presentations, total IgG and albumin levels, myelin basic protein, and oligoclonal bands may be useful (West, 1994; Wallace & Metzger, 1997).

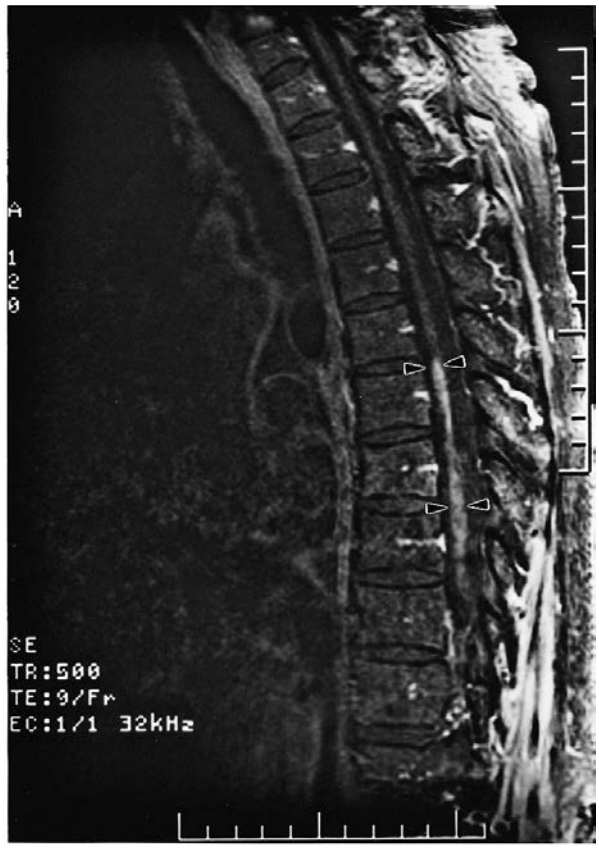

Fig. 96.1. Transverse myelopathy in systemic lupus erythematosus. Note increased signal intensity within the thoracic cord (arrowheads) corresponding to inflammation or ischemia extending over several segments. (Figure courtesy of Dr J.C. McArthur.)

Neuroimaging techniques play an important role in the evaluation of NPSLE patients but by themselves rarely yield diagnostic information. Radiology studies are often most helpful in excluding conditions that may mimic NPSLE, and must always be interpreted in light of the patient's clinical picture. Magnetic resonance (MR) imaging is superior to computerized tomography (CT) scanning for evaluating most NPSLE syndromes (Sibbitt et al., 1999). CT scans can be useful early in the diagnostic evaluation for the exclusion of large infarctions, intracerebral hemorrhages, massive cerebral edema, and mass lesions (e.g. brain abscesses or mycotic aneurysms) (Sibbitt et al., 1999). However, CT is comparatively insensitive to small lesions (infarcts or punctate lesions), diffuse brain injury and chronic white matter disease. Because MR imaging is much more sensitive for these lesions, it is by far the preferred imaging technique in NPSLE (Sibbitt et al., 1999). MR imaging (Fig. 96.1) should be performed promptly in the setting of neurological abnormalities, as some of the lesions associated with diffuse NPLSE disappear rapidly with the institution of glucocorticoid treatment (McCune et al., 1988; Sibbitt et al., 1989).

Headaches

Headache is a common symptom in SLE patients (Wallace & Metzger, 1997; Gladman & Urowitz, 1998). Migraine and tension headaches occur with increased frequency in SLE, and distinguishing these benign headaches from those of more serious etiology is sometimes challenging (Isenberg et al., 1982; Kovacs et al., 1993; Molad & Wysenbeek, 1997; ACR Ad hoc Committee, 1999). In the past, SLE patients with severe, disabling, and persistent headaches were labelled as having 'lupus headaches'. 'Non-specific intractable headaches' is now the preferred term (ACR Ad hoc Committee, 1999).

Benign intracranial hypertension (pseudotumour cerebri) may occur in SLE, with headache and papilledema as the presenting features (Li & Ho, 1989; Greeb et al., 1995). These patients have no focal neurologic deficits or abnormal CSF findings. aPL have been reported in patients with benign intracranial hypertension, but the true relationship between these antibodies and this clinical entity remains poorly defined (Wallace & Metzger, 1997). Benign intracranial hypertension occurs more commonly in adolescent women and is associated with dural sinus thromboses and steroid tapering (Parnass et al., 1987; Wallace & Metzger, 1997).

Acute confusional states

Diffuse CNS dysfunction in SLE may present with symptoms of an acute confusional state (ACS) (ACR Ad hoc Committee, 1999). Synonyms for ACS include 'organic brain syndrome', 'delirium', 'encephalopathy', 'lupus cerebritis', and 'CNS vasculitis'. With regard to the last term, autopsy studies demonstrate that true CNS vasculitis rarely occurs in SLE (Johnson & Richardson, 1968; Ellis & Veroty, 1979). Rather, diffuse CNS symptoms in SLE are much more likely to result from infections or complications of hypercoagulable states than from vasculitis (West, 1994).

The key feature of ACS is a disturbance in consciousness or level of arousal. ACS is characterized by deficits in attention accompanied by disturbances of cognition, mood, affect and/or behaviour, and may range from hyperactivity with delirium to coma. The syndrome typically develops over hours to days, and the patients' mental status may

fluctuate throughout the day. ACS can be complicated by psychosis and seizures. Varying degrees of cognitive deficits may occur, but if they occur without other manifestations of ACS, the term 'cognitive dysfuncton' is more appropriate (Carbotte et al., 1995). Before attributing a patient's symptomatology to ACS, other neurological disorders, drug-induced delirium (due to either prescription drugs or substance abuse), CNS infection and metabolic derangements must be excluded.

Glucocorticoids are the mainstay of therapy of ACS in SLE. Cyclophosphamide may be added in recalcitrant cases. Even following the institution of appropriate doses of immunosuppressive agents, ACS may require weeks or months to resolve.

Psychosis, anxiety and mood disorders

Psychosis, a severe disturbance in the perception of reality (including delusions and/or halluncinations), has been recognized as a manifestation of SLE for many years (Kovacs et al., 1993; Boumpas et al., 1995; ACR Ad hoc Committee, 1999;). Psychosis secondary to NPSLE may be difficult to distinguish from steroid psychosis in patients receiving glucocorticoids (Hall et al., 1979; Ling et al., 1981; Denburg et al., 1995). In this situation, steroids are rarely the cause of CNS dysfunction, and are responsible for less than 10% of psychotic events in SLE patients (Bluestein, 1992). The degree of SLE activity in other organs systems can be useful in separating steroid psychosis from NPSLE. Whereas auditory hallucinations are characteristic of steroid-induced psychoses, tactile hallucinations are more frequent in NPSLE (Bluestein, 1992).

Anxiety and depression commonly occur in SLE. Careful clinical evaluations, often with psychiatric consultation, will determine if anxiety and depression are reactive phenomena or true manifestations of NPSLE. In most SLE patients, anxiety is a reactive phenomenon rather than a direct manifestation of NPSLE. Depression may be severe in NPSLE and requires aggressive antidepressant therapy as well as treatment directed against SLE (Gladman & Urowitz, 1998).

Seizures

Both partial (focal) and generalized (primary/secondary) seizures occur in SLE (Scheuer & Pedley, 1990; ACR Ad hoc Committee, 1999). The frequency of seizures in large SLE series is between 6 and 26% (Wallace & Metzger, 1997). Seizures can occur as isolated events or in association with other neurologic symptoms such as strokes or intracranial hemorrhage (West, 1994). The etiology of seizures in SLE may be multifactorial, attributable to focal ischemia, any of the causes of cerebrovascular syndromes, cardiac emboli, and/or the presence of antineuronal/other autoantibodies. Other causes to consider include glucocorticoid withdrawal, high-dose intravenous glucocorticoid therapy, CNS infection, or chronic scar foci from previous neurologic events (Wallace & Metzger, 1997). Differentiation of seizures that are caused by active SLE, from those induced by treatment of the condition, can prove difficult (Mayes & Brey, 1996; Wallace & Metzger, 1997). Seizures caused by NPSLE respond well to glucocorticoid administration and may not require long-term anticonvulsant therapy (Russell et al., 1951; Presthus & Skulstad, 1957; Wallace & Metzger, 1997).

Myelopathy, optic neuropathy, and demyelinating syndromes

Transverse myelopathy (TM) occurs in only 1–2% of SLE patients, but can lead to the devastating sequelae of paraparesis or paraplegia (Andrianokos et al., 1975; Warren & Kredich, 1984; Kovacs et al., 2000) (Fig. 96.1). TM usually has a rapid onset with bilateral weakness of legs and/or arms, but may be asymmetric. Both sensory and motor deficits may occur, as may bowel and bladder dysfunction (Gladman & Urowitz, 1998; Kovacs et al., 1993, 2000). TM constitutes a medical emergency, and early diagnosis requires a high index of clinical suspicion. A recent retrospective review recorded a total 105 published cases of TM occurring in patients with SLE (Kovacs et al., 2000). This review found that TM often occurs early in the disease process, i.e. accompanying the initial presentation or within 5 years of disease onset.

The pathophysiology of TM in SLE remains elusive. Investigations are hindered by the paucity of pathologic material from these patients. The most commonly offered explanations are vasculitis of the spinal cord (Andrianokos et al., 1975) and thrombosis of the spinal vessels (perhaps mediated by aPL) (Lavelle et al., 1990). Either of these mechanisms (and other ones) may be operative in individual patients. One unusual steroid complication, epidural lipomatosis, may lead to compression of the anterior spinal artery, causing symptoms and signs that mimic TM (Bluestein, 1992).

The occurrence of TM in SLE may be difficult to distinguish from multiple sclerosis (MS). The term 'lupoid sclerosis' has been employed to describe SLE patients presenting with neurological features reminiscent of MS. MS may be associated with ANA (Dore-Duffy et al., 1982; Bluestein, 1992). In addition, an increased prevalence of aPL in SLE patients with TM and optic neuropathy (ON) has been

noted. In a recent review of TM, ON occurred in 48% of 105 cases of SLE patients with TM (Devic, 1894; April & Vansonnberg, 1976; Kinney et al., 1979; Kovacs et al., 2000). In SLE patients without TM, however, the incidence of ON is probably much lower. Occurrence of these symptoms in SLE may represent a combination of the two diseases, perhaps reflecting a shared autoimmune pathogenesis. 'Demyelinating syndrome' may be the best term for these neurologic features in SLE (ACR Ad hoc Committee, 1999).

Early, aggressive treatment of TM may improve patient outcomes (Harisdangkul et al., 1995). The combination of high-dose intravenous ('pulse') methylprednisone for 3 days and monthly intravenous cyclophosphamide is recommended (Kovacs et al., 2000). The benefit of plasmapheresis remains unproven. Unfortunately, residual neurological deficits can be devastating (April & Vansonnberg, 1976; Harisdangkul et al., 1995; Kovacs et al., 2000). In patients with compelling evidence of aPL in disease pathogenesis (e.g. strongly positive aPL titres, and other clinical features of APS), anticoagulation with coumadin is reasonable.

Cerebrovascular disease

Cerebrovascular disease (CVD) in SLE may result from arterial insufficiency/occlusion, venous occlusive disease, or hemorrhage, leading to transient or permanent neurologic deficits. CVD encompasses the following presentations: stroke syndrome, transient ischemic attacks (TIA), chronic multifocal white matter disease, subarachnoid/intracranial hemorrhage, and venous sinus thrombosis (Kelley et al., 1980; Fields et al., 1990; Wallace & Metzger, 1997; ACR Ad hoc Committee, 1999) (see Fig. 96.2). In recent years, there has also been greater awareness of the vasculopathy associated with long-term glucocorticoid use.

Aseptic meningitis

Aseptic meningitis (AS) presents with fever, headache, and meningismus. Lumbar puncture reveals a lymphocytic pleocytosis, most commonly with less than 200–300 WBC/mm^3 (Welsby & Smith, 1977; West, 1994). Nonsteroidal anti-inflammatory agents, commonly used in SLE, may also cause AS (Ballas & Konta, 1982; Hoppmann et al., 1991), as may azathioprine (rarely) (Lockshin & Kagen, 1972; Bluestein, 1992).

Movement disorders

Chorea (Lusius & Szilagyi, 1975; Bruyn & Padberg, 1984), hemiballismus, cerebellar ataxia (Singh et al., 1988; Al-Arfaj & Naddaf, 1995), and rarely Parkinsonism (Miyoshi et al., 1993) may complicate SLE. Of these, chorea is the most common, occurring in 1–4% of SLE patients (Wallace & Metzger, 1997). It can be the presenting feature of SLE, antedating other manifestations by up to 7 years (Donaldson et al., 1971). In a review of 29 cases, the majority of patients were girls (Groothius et al., 1977; Wallace & Metzger, 1997). In a subsequent review of 52 cases, chorea occurred early in the natural history of SLE, did not correlate with other neurological symptoms, lasted a maximum of 3 years, and was associated with pregnancy and the postpartum period (Bruyn & Padberg, 1984). Autopsy studies in SLE have revealed infarctions of the basal ganglia in patients with movement disorders (Wallace & Metzger, 1997). Since the advent of testing for aPL, many associations between chorea and these autoantibodies have been reported (Hadron et al., 1986; Asherson et al., 1987a; Petri, 1997).

Cranial neuropathies

Cranial neuropathies occur in 3 to 16% of SLE patients during the course of their disease (Wallace & Metzger, 1997). They tend to occur during flares of SLE in other organs (McCune & Golbus, 1988; West, 1994). Facial nerve palsies, third and fourth nerve palsies, trigeminal neuralgia, ON, internuclear ophthalmoplegia have all been reported. Other manifestations include tinnitus and vertigo. These usually are transient and respond to treatment with glucocorticoids (West, 1994).

Peripheral nervous system manifestations

The peripheral nerve manifestations of NPSLE include myasthenia gravis, autonomic neuropathy and peripheral neuropathy. Peripheral neuropathies are subdivided into acute inflammatory demyelinating polyneuropathies (Guillain–Barré syndrome), mononeuropathies, plexopathies, peripheral cranial neuropathies, and polyneuropathies (ACR Ad hoc Committee, 1999). Peripheral neuropathy may occur in 2 to 21% of SLE patients (Wallace & Metzger, 1997). Most patients are responsive to glucocorticoids but cytotoxic agents and plasma exchange have been used for refractory cases (Hughes et al., 1982; Wallace & Metzger, 1997).

The antiphospholipid syndrome

A major contribution to understanding the pathogenesis and treatment of many clinical manifestations of SLE has been elucidation of the antiphospholipid syndrome (APS).

Table 96.3. Revised criteria for the antiphospholipid syndrome[a]

Clinical criteria

(i) Vascular thrombosis:
One or more clinical episodes of arterial, venous, or small vessel thrombosis, in any tissue or organ.

(ii) Pregnancy morbidity.

Laboratory criteria

(i) Anticardiolipin antibody of IgG and/or IgM isotype in blood in medium or high titre, on two or more occasions, at least 6 weeks apart.

(ii) Lupus anticoagulant present in the plasma, on two or more occasions, at least 6 weeks apart.

Definite antiphospholipid antibody syndrome is considered to be present if at least one of the clinical criteria and one of the laboratory criteria are met.

Note:

[a] Modified from Wilson et al. (1999).

Criteria for the diagnosis of APS are outlined in Table 96.3 (Wilson et al., 1999). Some clinicians classify patients with this syndrome as having either primary or secondary APS, depending on the absence or presence of an underlying condition, but the clinical features and antibody specificities of primary and secondary APS (as presently understood) are virtually identical (Alarcon-Segovia & Sanchez-Guerrero, 1989; Asherson et al., 1989a; Mackworth-Young et al., 1989; Vianna et al., 1994; Petri, 1997)).

APS is characterized by recurrent vascular thromboses, pregnancy losses and/or thrombocytopenia occuring in association with elevated levels of aPL (Harris, 1987; Petri, 1997; Wilson et al., 1999). The aPL include anticardiolipin antibodies and the lupus anticoagulant. Either or both may be present in individual patients. There is evidence that, in some APS patients, the target antigens are two phospholipid-binding plasma proteins, prothrombin and β_2-glycoprotein-1 (Roubey, 2000).

The spectrum of neurological manifestations in APS is broad (Levine & Welch, 1987; Petri, 1997) and includes strokes, TIAs, transient global amnesia, multi-infarct dementia, ischemic encephalopathy (Asherson et al., 1987b), ocular ischemia (Asherson et al., 1989b; Watts et al., 1990), severe migraines (Levine et al., 1990; Pope et al., 1991), pseudotumour cerebri, chorea (Hatron et al., 1986; Asherson et al., 1987a), apnea (Herkes et al., 1988), seizures, and TM (Harris et al., 1985; Lavelle et al., 1990). APS accounts for 36% of new strokes in those younger than 50 years of age (Kittner & Gorelick, 1992).

APS should be suspected in any SLE patient presenting with thrombosis. Other hypercoagulable states must also be excluded by appropriate testing. Thromboses can occur in any venous or arterial distribution throughout the body. Overall, the most common sites of thromboses are the deep veins, followed by the CNS. Although thrombocytopenia is not part of the APS criteria (see Table 96.3), it is a well-recognized clinical manifestation of the disorder, but other causes of thrombocytopenia in SLE must be excluded (Harris et al., 1986; Petri, 1997). APS has also been associated with leg ulcers, digital ischemia, superficial thrombophlebitis, hemolytic anemia, angina, cardiac valvular disease, pulmonary embolism, pulmonary hypertension, adrenal failure, myocardial infarction and livedo reticularis. Sneddon's syndrome, the occurrence of livedo reticularis and stroke/TIA, is a subset of APS in many cases (Sneddon, 1965; Petri, 1997). Some Sneddon's syndrome patients, however, do not have demonstrable aPL and do not meet criteria for APS (Jonas et al., 1986; Burton, 1988; Petri, 1997).

Occasionally APS patients present with the 'catastrophic antiphospholipid syndrome'. In this devastating complication, thromboses occur at multiple sites, either simultaneously or over a matter of hours, days or weeks (Greisman et al., 1991; Asherson, 1992). On presentation, the differential diagnosis of these critically ill patients includes disseminated intravascular coagulation, thrombotic thrombocytopenic purpura, systemic vasculitis, and sepsis. APL assays are sometimes negative during this overwhelming cascade of clinical events (Drenkard et al., 1989; Greisman et al., 1991).

Following a thrombotic event, the treatment of APS necessitates long-term treatment with warfarin to avert further recurrences (Derksen et al., 1993; Khamashta et al., 1995; Petri, 2000). While some researchers have suggested a low-intensity warfarin schedule, most experts still advocate maintaining the International Normalized Ratio of greater than/equal to 3 (Khamashta et al., 1995).

Sjögren's syndrome

Sjögren's syndrome (SS) is a systemic inflammatory autoimmune disorder that primarily affects the exocrine glands. SS is characterized by lymphocytic infiltration of these glands leading to organ dysfunction and the principal manifestations of keratoconjunctivitis sicca and xerostomia (Tzioufas & Moutsopoulos, 1998). Typically, the syndrome begins with non-specific symptoms and develops slowly. Many patients are symptomatic for years before the diagnosis is made (Maini, 1987). SS can be either

primary (occurring alone), or secondary to other autoimmune conditions, such as systemic lupus erythematosus, rheumatoid arthritis, or systemic sclerosis (Fotini et al., 2000). It occurs at all ages but primarily affects females during the fourth and fifth decades of life. The disorder is nine times more common in women than men (Tzioufas & Moutsopoulos, 1998).

Laboratory testing may reveal a mild anemia of chronic disease, with leukopenia in 10% of cases (Tzioufas & Moutsopoulos, 1998). An elevated ESR and hypergammaglobulinemia is found in nearly 80% of cases and autoantibodies are common, particularly to Ro (SS-A), and La (SS-B), ANA, and rheumatoid factor (Tzioufas & Moutsopoulos, 1998). The cornerstone of diagnosis remains biopsy of a minor salivary gland and demonstration of focal lymphocytic infiltrates (Chisholm & Mason, 1968; Moutsopoulos, 1994). A European multicentre study led to widely accepted diagnostic criteria for primary SS (Vitali et al., 1993, 1996).

The most feared complication of primary SS is the development of B-cell lymphoma (5–10% of all patients, equating to a 44-fold increased risk compared with age-, gender-, and race-matched controls) (Kassan et al., 1978; Tzioufas & Moutsopoulos, 1998; Ioannidis & Moutsopoulos, 1999).

The neurologic manifestations of SS include peripheral neuropathies and, very rarely, CNS disease. Vasculitis, usually manifesting as purpura, urticaria, skin ulcerations and mononeuritis multiplex, occurs in 5% of SS patients (Tzioufas & Moutsopoulos, 1998). The peripheral neuropathy associated with SS is the result of a small vessel vasculitis, and is usually a symmetric, mild, sensory or sensorimotor neuropathy (Kaltreider & Talal, 1969; Mellfren et al., 1989; Andonopoulos et al., 1990). Nerve biopsy usually shows mononuclear cell infiltration (Mellfren et al., 1989). Although it is not clear if the peripheral neuropathy of SS always responds to immunosuppressive treatment, improvement has been reported (Mellfren et al., 1989). Cranial nerve involvement has been reported affecting the trigeminal and optic nerves (Kaltreider & Talal, 1969; Tzioufas & Moutsopoulos, 1998).

The frequency of CNS involvement in SS has probably been over-reported in the past. Reported CNS manifestations associated with primary SS are broad, and include seizures, hemiparesis, TM, AS, cognitive defects, encephalopathy and dementia, suggesting the possibility of both focal and diffuse involvement (Alexander, 1987; Tzioufas & Moutsopoulos, 1998; Niemela & Hakala, 1999). Although a 20–25% prevalence of CNS involvement in primary SS has been reported (Alexander, 1987; Alexander et al., 1994), this series probably suffered from substantial selection bias. Other investigators have sharply revised the estimate of CNS involvement in SS downward (Drosos et al., 1989; Moutsopoulos et al., 1993; Ioannidis & Moutsopoulos, 1999).

Systemic vasculitides: polyarteritis nodosa

Polyarteritis nodosa (PAN), first described by Kussmaul and Maier in 1866 (Kussmaul & Maier, 1866), is defined as necrotizing vasculitis limited to medium-sized arteries (Jennette et al., 1994). Though protean in its manifestations, PAN demonstrates a striking predilection for certain organs, particularly the peripheral nerves (Fig. 96.3, see colour plate section), skin, gastrointestinal tract and kidneys. PAN usually begins with non-specific symptoms that may include malaise, fatigue, fever, myalgias, and arthralgias. Overt signs of vasculitis may not occur until weeks or months after onset of the first symptoms. Renal involvement, nearly universal at autopsy, produces few clinical symptoms during life aside from those related to renin-mediated hypertension caused by arteritic involvement of the medium-sized interlobar renal vessels (Heptinstall, 1992). Cardiac lesions, often striking at

autopsy, are usually subclinical (Cupps & Fauci, 1981). For reasons that are not understood, PAN usually spares the lungs.

The pathological changes in PAN are limited to arteries, sparing veins. In gross specimens, aneurysmal bulges of the arterial wall may be visible (Kussmaul & Maier, 1866). Histologic sections reveal infiltration and destruction of the blood vessel wall by inflammatory cells, accompanied by fibrinoid necrosis (Fauci et al., 1978). Whereas the acute inflammatory infiltrate is composed chiefly of neutrophils, mononuclear cells predominate in later stages. Varying degrees of intimal proliferation and thrombosis also occur. The lesions of PAN are segmental, and favour the branch points of arteries. A critical pathological feature of PAN is the absence of granulomas or granulomatous inflammation. A minority of PAN cases are associated with hepatitis B virus (HBV) infections (Goecke et al., 1970; Guillevin et al., 1995). Other microbial pathogens probably contribute to the remaining cases, but no definitive links with other infectious agents have been established.

A majority of patients with PAN (>80% in some series (Guillevin et al., 1995) have vasculitic neuropathy, typically in the pattern of a mononeuritis multiplex (MM). MM most often affects the peroneal, tibial, ulnar, median and radial nerves, leading to symptoms and signs in the distal extremities (e.g. foot or wrist drop) (Hellmann et al., 1987). Cranial neuropathies and radiculopathies are unusual, but reported. MM almost always causes sensory abnormalities, particularly painful dysesthesias; motor involvement occurs in one-third of patients. On clinical examination, advanced cases of MM may mimic confluent, symmetrical polyneuropathies. In such cases, electrodiagnostic testing may unmask an underlying asymmetry and confirm the presence of multiple axonal neuropathies. CNS disease in PAN usually results from hypertension rather than intracranial vasculitis, but vasculitic involvement of cerebral blood vessels sometimes occurs (Moore & Fauci, 1981; Guillevin et al., 1988).

The diagnosis of PAN requires either a tissue biopsy or an angiogram demonstrating the characteristic microaneurysms (Ewald et al., 1987). Biopsies of asymptomatic organs (e.g. the testicle) are rarely diagnostic (Albert et al., 1988; Dahlberg et al., 1989). In contrast, simultaneous nerve/muscle biopsies (e.g. sural nerve and gastrocnemius), are of high yield if there is clinical evidence of MM. Mesenteric angiography may demonstrate telltale microaneurysms, even in patients without gastrointestinal symptoms.

For patients with idiopathic PAN, prolonged immunosuppression remains the cornerstone of therapy. Approximately one-half of patients with PAN achieve remissions or cures with high doses of glucocorticoids alone (Guillevin & Lhote, 1998). Cyclophosphamide is indicated for patients whose disease is refractory to glucocorticoids or who have serious major organ involvement at diagnosis. Frequent monitoring of the white blood cell count (e.g. every 2 weeks) to avoid neutropenia is essential in order to prevent opportunistic infections. Prophylaxis against *Pneumocystis carinii* pneumonia with trimethoprim/sulfamethoxazole is also advisable.

In recent years, antiviral agents have improved the treatment of HBV-associated PAN substantially. One effective strategy involves the use of prednisone (1 mg/kg/d) to suppress the inflammation (Guillevin et al., 1995). Simultaneously with the start of glucocorticoid treatment, patients begin 6-week courses of plasma exchange (approximately 3 exchanges/week). After 1 week of glucocorticoids, prednisone is tapered off over 3–7 days, and antiviral therapy is started (e.g. lamivudine 100 mg/d).

The 'ANCA-associated' vasculitides

The 'antineutrophilic cytoplasmic antibody (ANCA)-associated' vasculitides (AAV) (Wegener's granulomatosis [WG], microscopic polyangiitis [MPA], and Churg–Strauss syndrome [CSS]) are characterized by pauci-immune, necrotizing vascular inflammation of small and medium-sized vessels (including veins as well as arteries). AAV have a particular tropism for the lungs, kidneys and upper respiratory tract. Among the neurological manifestations of these diseases, vasculitic neuropathy is extremely common (in CSS and MPA>WG) and potentially devastating. It should be noted that, despite rigorous serological evaluations, not all patients with 'ANCA-associated' vasculitis actually have detectable ANCA. Furthermore, the role of ANCA in disease pathogenesis of these conditions remains undefined. Rather than a primary etiological role, current evidence favours an ancillary role for ANCA in amplifying the ongoing inflammatory response (Hoffman & Specks, 1998).

Two types of ANCA tests, immunofluorescence (IF) and enzyme immunoassay (EIA), are now in common use. IF assays are more sensitive than EIAs, but their positive predictive values are low (Rao et al., 1995; Hagen et al., 1998). A host of non-vasculitic systemic illnesses may be associated with ANCA positivity, including infections, malignancies and other rheumatic conditions (Stone et al., 2000). Thus, positive IF assays for ANCA should be confirmed by EIAs for specific antibodies directed against proteinase-3 (PR-3) or myeloperoxidase (MPO), which are more specific for vasculitis (Hagen et al., 1998). ANCA titres are unreliable indicators of disease activity, and no treatment decisions should

be predicated solely upon elevations or declines in antibody titres.

Wegener's granulomatosis

Classic WG includes three pathologic hallmarks: (i) necrotizing granulomas of the upper and/or lower respiratory tract; (ii) vasculitis affecting arteries or veins; and (iii) segmental glomerulonephritis (GN), associated with necrosis and thrombosis of capillary loops, with or without granulomatous lesions (Godman & Churg, 1954). Approximately 90% of patients with WG have nasal involvement (Hoffman et al., 1992a). Cartilaginous inflammation may lead to nasal septal perforation and even to nasal bridge collapse (a 'saddle-nose' deformity). Erosive sinus disease is highly characteristic of WG. Subglottic stenosis, resulting from the predilection of WG to cause scarring inflammation below the vocal cords, may cause hoarseness or respiratory stridor, and sometimes requires a tracheostomy. Conductive hearing loss may result from granulomatous inflammation of the middle ear cavity and serous otitis media. Moreover, middle ear inflammation may compress the seventh cranial nerve as it courses through the middle ear cavity, leading to a peripheral facial nerve palsy. Sensorineural hearing loss occurs less often in WG, and its mechanism is poorly understood (Stone & Francis, 2000). WG has two signature ocular lesions: the retro-orbital mass and necrotizing scleritis.

The pulmonary manifestations of WG range from asymptomatic lung nodules to fulminant alveolar hemorrhage. Hilar and/or mediastinal adenopathy are rare. Renal involvement, the most ominous clinical manifestation of WG, is associated with segmental necrotizing GN and crescent formation, and presents clinically as rapidly progressive GN.

Parenchymal brain involvement has been reported in WG but is rare (Drachman, 1963; Fred et al., 1964), meningeal inflammation is a more common CNS manifestation of this disease. Meningeal WG typically presents with excruciating headaches, a CSF pleocytosis, cranial neuropathies caused by a basilar meningitis, and thickened meninges that enhance on MR imaging (Fig. 96.4). Because of the granulomatous inflammation, meningeal tuberculosis is a common misdiagnosis. MM may accompany WG but is more characteristic of MPA or CSS.

For WG patients with disease that threatens major organs, combined therapy with cyclophosphamide and glucocorticoids is indicated (Hoffman et al., 1992a). For those with 'limited' WG (Hoffman et al., 1992b), weekly methotrexate plus glucocorticoids is an appropriate first-line treatment strategy that avoids the potential toxicities of cyclophosphamide. However, durable remissions are unusual with this alternative regimen (Stone et al., 1999).

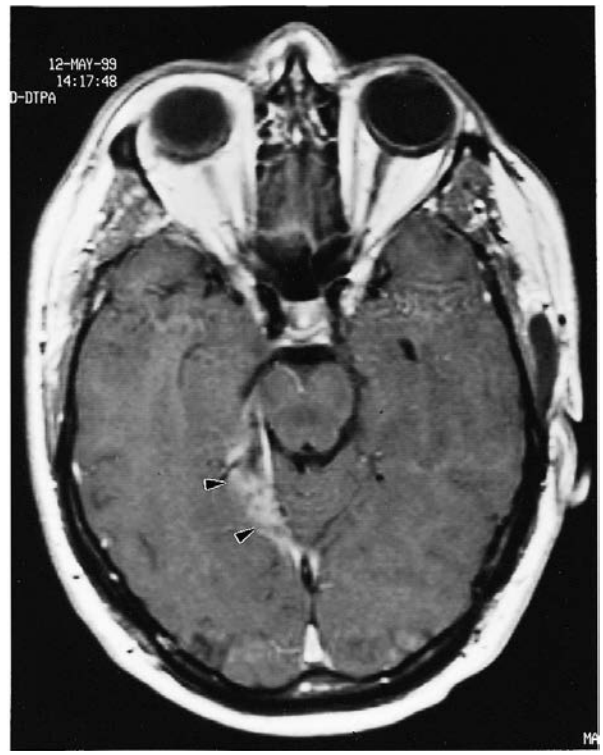

Fig. 96.4. MR in Wegener's granulomatosis: meningeal enhancement along right mesial temporal lobe (arrowheads). (Figure courtesy of Dr J.C. McArthur.)

Microscopic polyangiitis

Davson et al. (1948) proposed the division of PAN patients into two groups based on the presence or absence of GN. The 1994 Chapel Hill Consensus Conference (Jennette et al., 1994) validated the concept of microscopic polyangiitis (MPA) as a disease separate from classic PAN, defining MPA as a pauci-immune, non-granulomatous vasculitis affecting small (and perhaps) medium-sized blood vessels. The distinction between MPA and classic PAN is appropriate for several reasons. MPA, in contrast to PAN: (i) often involves the lung; (ii) may involve veins as well as arteries; (iii) rarely causes severe hypertension; (iv) is commonly associated with ANCA; (v) nearly always requires cyclophosphamide to induce remission; and, (vi) is more likely to flare following remissions.

GN (79%), weight loss (73%), MM (58%), and fever (55%) are the most common manifestations of MPA (Guillevin et

al., 1999a). The upper respiratory tract symptoms in MPA are milder than those of WG, but the cardinal distinction between MPA and WG is the absence of granulomatous inflammation. Approximately 12% of patients with MPA develop alveolar hemorrhage, which may constitute a rapidly evolving life-threatening complication (Guillevin & Lhote, 1998). Vasculitic neuropathy is common in MPA. Vasculitis involving the CNS occurs far less frequently, but is reported.

Churg–Strauss syndrome

Churg–Strauss syndrome (CSS) is a systemic vasculitis associated with eosinophilic infiltration of the blood vessel wall. The Chapel Hill Consensus Conference defined CSS as eosinophil-rich, granulomatous inflammation involving the respiratory tract, vasculitis of small to medium-sized blood vessels, asthma and eosinophilia (Jennette et al., 1994). CSS is often associated with substantial upper respiratory tract involvement in the form of nasal polyps and allergic rhinitis. In contrast to WG, however, the upper respiratory features of CSS are not destructive, and the typical pulmonary manifestation is asthma rather than nodules. Fleeting pulmonary infiltrates occur in up to one-third of patients.

CSS characteristically evolves through three distinct phases: (i) a prodrome accompanied by atopy, which may last from months to years; (ii) a peripheral eosinophilia/tissue infiltration phase, in which up to 60 000 eosinophils/mm^3 appear in the peripheral blood (eosinophils infiltrate the lung, gastrointestinal tract, and other tissues in this phase); and (iii) a vasculitic phase in which systemic vasculitis afflicts a wide range of organs. Greater than 90% of CSS patients have histories of asthma, typically of new onset. Cardiac involvement (usually congestive heart failure) occurs with comparatively greater frequency in CSS than in other AAV, and is a common mode of death (Guillevin et al., 1999b). Renal disease in CSS is less common and less malignant than in WG or MPA, but aggressive renal lesions sometimes occur (Clutterbuck et al., 1990). Finally, MM occurs with a remarkable frequency in CSS (77% in one series)(Guillevin et al., 1999b).

Because a substantial number of CSS patients achieve satisfactory responses with glucocorticoids alone, these agents are a reasonable first approach for many CSS patients. Concomitant cyclophosphamide use is indicated for patients with MM, rapidly progressive GN, or other indicators of severe disease. Interferon-alpha appears promising as a treatment for CSS (Tatsis et al., 1998), but larger studies are required.

Cryoglobulinemia

Cryoglobulins (CG) are antibodies that precipitate from serum under conditions of cold (e.g. refrigeration at 4 °C for several days) and resolubilize upon rewarming (Lamprecht et al., 1999). These proteins occur in association with a number of systemic conditions (e.g. autoimmune diseases and malignancies), and may lead to clinical complications that include vasculitis and hyperviscosity. CG are classified into three types (Types I, II, or III) based on the presence or absence of: (i) monoclonality; and (ii) rheumatoid factor activity (i.e. the ability to bind the Fc portion of IgG) (Table 96.4) (Meltzer & Franklin, 1966; Brouet et al., 1974; Lamprecht et al., 1999). Type I CG, which are monoclonal and lack rheumatoid factor activity, are associated with certain hematopoietic malignancies and often lead to the syndrome of hyperviscosity (addressed elsewhere in this text) rather than vasculitis. In contrast, collagen–vascular diseases are associated with Type II and Type III CG.

CG Types II and III are termed 'mixed' CG because they consist of both IgG and IgM antibodies. The IgM components in Type II and III CG both possess rheumatoid factor activity. Whereas the IgM component in Type II CG is monoclonal, the IgM in Type III is polyclonal. Either type of mixed CG may cause an immune complex-mediated small vessel vasculitis, through the deposition of cryoglobulin-containing immune complexes in blood vessel walls, leading to the activation of complement. Ninety per cent of patients with vasculitis secondary to mixed CG are hypocomplementemic, with C4 levels characteristically more depressed than C3 (Lamprecht et al., 1999). The most common manifestations of cryoglobulinemic vasculitis are recurrent crops of palpable purpura on the legs that sometimes coalesce to form large, painful ulcerations. Other common manifestations are vasculitic neuropathy, GN, arthralgias, malaise, and fatigue (Brouet et al., 1974; Lamprecht et al., 1999). Some patients develop mesenteric vasculitis, Raynaud's phenomenon, livedo reticularis or secondary SS. The typical features of Type II and III CG are virtually indistinguishable, except for the fact that only Type II is associated with glomerulonephritis (Lamprecht et al., 1999). CNS vasculitis occurs in a small minority of patients with CG.

Infection with the hepatitis C virus (HCV) accounts for at least 80% of the vasculitis cases associated with mixed CG (Agnello et al., 1992; Abel et al., 1993; Marcellin et al., 1993; Wener et al., 1996). Compared to serum levels, anti-HCV antibodies and HCV RNA in CG precipitates are concentrated 1000-fold. However, vasculitis occurs in only a minority of HCV patients, even though 50% of patients infected with HCV have demonstrable cryoglobulins. This

Table 96.4. Classification of cryoglobulins, their immunochemical features, and clinical associations

Type	Monoclonal	RF activity present[a]	Clinical syndrome	Disease association
I	Yes (usually IgG)	No	Hyperviscosity	Malignancy
II	Yes (IgM)	Yes	Vasculitis	Hepatitis C
				Rheumatic diseases
				Malignancy
				Idiopathic
III	No	Yes	Vasculitis	Hepatitis C
				Rheumatic diseases
				Idiopathic

Note:
[a] RF = Rheumatoid factor.

probably relates both to host genetic factors and to specific features of the infecting HCV quasi-species.

For CG patients with relatively mild disease (e.g. frequent purpuric lesions, shallow cutaneous ulcers), interferon-alpha (3×10^6 units 3 times per week) alone or combined with ribavirin (1000–1200 mg/d) may be effective; (Di Bisceglie et al., 1995; Poynard et al., 1995; Lamprecht et al., 1999). If antiviral therapy is initiated prior to control of the inflammatory process with immunosuppression, there is some risk of causing a temporary exacerbation of the vasculitic process (probably through alteration of the antigen: antibody ratio). For patients with MM or other manifestations of severe disease, glucocorticoids and cyclophosphamide are required, and plasmapheresis may be a useful adjunctive therapy. In such cases, antiviral therapy starts later.

Behçet's disease

Behçet's disease (BD) is among the forms of primary vasculitis most likely to involve the CNS (Shimizu et al., 1979; Kaklamani et al., 1998; Sakane et al., 1999). The hallmark triad of oral ulcers, genital ulcers and ocular inflammation was first described in 1937 (Behçet, 1937). BD may affect small, medium, and large arteries, and also has an unusual proclivity to involve veins as well as arteries. Most patients are in their third or fourth decade at disease onset. The cause is unknown. BD is most common in people with ancestry along the ancient Silk Route, i.e. the Eastern Mediterranean, Middle East, and Far East (Sakane et al., 1999). Genetic factors (e.g. the HLA-B51 allele) increase disease susceptibility (Mizuki et al., 1999).

The diagnostic criteria for BD and other prominent disease features are listed in Table 96.5 (Sakane et al., 1999). Virtually all patients have multiple, recurrent and often severe oral ulcers. Acute anterior uveitis frequently leads to a hypopyon, and chronically may cause irregular pupils because of synechiae between the iris and lens. Posterior uveitis, which usually results from vasculitis of the retinal veins, may be subclinical but eventually leads to devastating visual loss. Pathergy, the development of pustules at the sites of sterile needle pricks, occurs in only a minority of patients with BD, but is more likely among patients from areas of high disease prevalence (Sakane et al., 1999).

Although not included in the diagnostic criteria for BD, neurological involvement ('neuro-Behçet's') is common and often severe. The percentage of BD patients who develop clinical manifestations of neuro-Behçet's is at least 5% (Serdaroglu et al., 1989). In a large autopsy series, however, 20% of BD patients had pathological evidence of neurological involvement (Lakhanpal et al., 1985). The array of potential neurological complications may be divided into parenchymal and non-parenchymal lesions. The most common syndrome is brainstem inflammation, which often evolves over a period of days. Brainstem involvement may be associated with cranial neuropathies, oculomotor dysfunction, nystagmus, dysarthria, ataxia and bulbar weaknesss. Headache and meningismus usually accompany such brainstem lesions.

Meningoencephalitis is the second most common neurological syndrome in BD. Both spinal cord lesions (TM or the Brown–Sequárd syndrome) and hemispheric signs may complicate this presentation. Meningoencephalitis can also occur without focal signs, leading to a confusional

Table 96.5. Criteria for the diagnosis of Behçet's disease[a]

Finding	Definition
Recurrent oral ulceration	Minor aphthous, major aphthous, or herpeti-form ulcers observed by the physician or patient, which have recurred at least three times over a 12-month period
Recurrent genital ulceration	Aphthous ulceration or scarring observed by the physician or patient
Eye lesions	Anterior uveitis, posterior uveitis, or cells in the vitreous on slit-lamp examination; or retinal vasculitis detected by an ophthalmologist
Skin lesions	Erythema nodosum observed by the physician or patient, pseudofolliculitis, or papulopustular lesions; or acneiform nodules observed by the physician in a postadolescent patient who is not receiving corticosteroids
Positive pathergy test	Test interpreted as positive by the physician at 24 to 48 hours

Notes:

[a] The criteria were drawn up by the International Study Group for Behçet's disease (Sakane *et al.*, 1999).

For the diagnosis to be made, a patient must have recurrent oral ulceration plus at least two of the other findings in the absence of other clinical explanations.

Additional features of BD sometimes include folliculitis; a peripheral arthritis (usually non-deforming, oligoarticular, involving large joints in an asymmetrical pattern); thrombophlebitis (often migratory); gastrointestinal disease (often difficult to distinguish from Crohn's disease); epididymitis; and large artery vasculitis (Sakane et al., 1999; Kaklamani et al., 1998; Zouboulis & Orfanos, 1998).

syndrome that is sometimes chronic and progressive, culminating in dementia, Parkinsonism, pseudobulbar palsy and quadriparesis. Parenchymal lesions in BD are usually associated with an active CSF characterized by a mixed pleocytosis and elevated CSF protein. In contrast to MS (with which neuro-Behçet's is often confused), most studies indicate no evidence of intrathecal immunoglobulin synthesis. MR imaging in BD correlates well with parenchymal lesions, and radiological lesions tend to improve or resolve completely following the resolution of clinical symptoms.

Venous sinus thrombosis is a common type of non-parenchymal complication in BD, and may occur with or without meningitis. Isolated intracranial hypertension (in the absence of dural sinus thrombosis) may also complicate BD and require shunting procedures. Unusual neurological manifestations of BD include peripheral nerve involvement, ON, sensorineural hearing loss and isolated vestibulopathy.

In terms of pathological findings, true vasculitis is rarely demonstrated in neuro-Behçet's. Far more common are acute inflammatory infiltrates within the parenchyma, comprised of neutrophils, lymphocytes, and occasional eosinophils. Patients with brainstem syndromes may have tissue swelling and multiple foci of cellular infiltration, with perivascular cuffing. Chronic cases show areas of necrosis and loss of all tissue elements, accompanied by brainstem atrophy.

Despite the severe nature of many neuro-Behçet's complications, patients may have complete recoveries from acute episodes if treated promptly. Long-term prognosis may be poor for patients who have relapsing neurological symptoms. The treatment of neuro-Behçet's is dictated by the type and severity of the neurological findings (Sakane et al., 1999). High doses of glucocorticoids are the cornerstone of therapy for major CNS involvement, but often these must be supplemented by additional agents either to control refractory disease or to avoid excessive glucocorticoid side effects. Early treatment with azathioprine favourably affects the long-term prognosis in Behcet's disease (Hamuryudan et al., 1997). Thalidomide is effective for the mucocutaneous features of Behcet's disease, but long-term use frequently leads to an irreversible peripheral neuropathy (Hamuryudan et al., 1998). For posterior uveitis and significant brainstem or other CNS lesions, cyclosporin, cyclophosphamide or chlorambucil may be indicated. Because of the potentially severe neurologic side effects of cyclosporin (which may be difficult to distinguish from neuro-Behcet's (Kotake et al., 1999), cyclosporin should be used with great caution in patients with neurological manifestations of the disease.

Giant cell arteritis

Giant cell arteritis (GCA), the most common form of primary systemic vasculitis, principally affects medium-

and large-sized extracranial branches of the carotid artery. For reasons that are not understood, documented intracranial disease in GCA is very rare. GCA occurs with increasing incidence in older patients and has a mean age of onset of 72. The disease virtually never occurs in individuals younger than 50. The disease is most common in Caucasians, particularly those of Northern European ancestry, but occurs in all races.

Headache is the most common feature of GCA (70–90%). The only distinguishing feature of GCA headaches is that they are unusual either in severity or location. Scalp tenderness, polymyalgia rheumatica, and jaw claudication are other classic symptoms of GCA. The most feared complication of GCA is blindness, the usual mechanism of which is anterior ischemic optic neuropathy (AION) caused by infarction of the posterior ciliary artery. Partial visual loss occurs in 10–15% of all patients with GCA, and bilateral blindness may occur. The onset of visual loss from AION is usually abrupt and irreversible. Other neuro-ophthalmological complications of GCA are amaurosis fugax and diplopia, the latter caused by cranial nerve vasculitis.

A substantial portion of patients with GCA present with atypical clinical features. Although intracranial vessels are generally spared by GCA, strokes may occur from thrombosis of, or embolization from, extracranial vessels (Caselli & Hunder, 1993). GCA may also involve the brachial plexus, leading to the sudden onset of pain and inability to abduct the shoulder, mimicking a C5 radiculopathy. Other misleading presentations of GCA include fever of unknown origin (Calamia & Hunder, 1981), persistent nonproductive cough, poorly localized pains in the region of the throat and lingual infarction. Complications of large artery involvement by GCA such as aortic dissection or aneurysm (thoracic>abdominal) may be catastrophic, and sometimes occur years after diagnosis (Evans et al., 1995). One population-based study, large artery involvement (thoracic or abdominal aortic aneurysms) occurred in 17% of the patients (Evans et al., 1995).

The diagnosis of GCA is usually confirmed by temporal artery biopsy. Because of the non-specific nature of many GCA symptoms, and the justification required for the use of a potentially toxic treatment (glucocorticoids), the importance of performing temporal artery biopsies in patients suspected of having GCA cannot be overemphasized. However, treatment should be instituted immediately once the diagnosis is suspected, not delayed until after performance of a biopsy. The diagnosis may be confirmed even after patients have been on glucocorticoid treatment for several weeks (Achkar et al., 1994). (Nevertheless, obtaining biopsies as quickly as possible is prudent.) Negative bilateral temporal artery biopsies have a negative predictive value of 91% (Hall et al., 1983). Arterial segments at least 2 centimetres in length should be removed during the procedure.

The pathological features of GCA are consistent with an antigen-driven T-cell response (Weyand, 2000). Cellular infiltrates are composed of CD4+ T-lymphocytes, macrophages and multinucleated giant cells, but B-cells are typically absent (Martinez-Taboada et al., 1996a). The T-cells are believed to enter the artery via the vasa vasorum in the adventitia, recruited by a specific (but still unknown) antigen or antigens (Martinez-Taboada et al., 1996b). The T-cells orchestrating the inflammatory response in GCA produce interferon (IFN)-γ. This cytokine may be essential in the conversion of polymyalgia rheumatica to GCA (Weyand et al., 1994). Under stimulation by T-cells, adventitial macrophages produce interleukin (IL)-1β and IL-6, but little tumour necrosis factor.

Despite the importance of the adventitia to orchestration of the disease, most of the tissue damage occurs in the media and intima. Macrophages in the media produce not IL-1 or IL-6, but rather matrix metalloproteinases (MMP). These enzymes are capable of digesting arterial wall components, and may contribute to the fragmentation of the internal elastic lamina. MMP are also essential for the mobilization and migration of smooth muscle cells from the media to the intima, where they undergo proliferation. The final step in the pathophysiology of GCA (culminating in luminal occlusion) is a hyperplastic reaction of the intima, driven by platelet-derived growth factor (PDGF) produced by multinucleated giant cells and macrophages situated at the border of the media and intima (Kaiser et al., 1998).

GCA is exquisitely sensitive to treatment with glucocorticoids. The usual starting dose is at least 60 mg/d of prednisone. The goal should be to decrease the patient's dose to 20 mg/d by the end of the second month of therapy, and to taper steroids off completely by 9–12 months. However, flares of disease frequently occur during steroid tapers in at least 50% of cases, and the mean length of prednisone therapy is approximately 2 years. A recent multicentre trial of methotrexate as a steroid sparing agent in GCA found no effectiveness of methotrexate for this purpose (Hoffman et al., 2000).

Takayasu's arteritis

Takayasu's arteritis (TA) is a form of large vessel vasculitis that tends to afflict young females. Because of its predilection for large elastic arteries arising from the aortic arch, TA frequently leads to diminished or absent pulses in the

upper extremities, hence the alternative name 'pulseless disease'. The disease is associated with granulomatous vasculitis focused on the media of the artery, histopathologically indistinguishable from GCA. Two frequently overlapping phases of the disease are described: (i) an inflammatory phase, in which findings of an acute inflammatory state exist (constitutional symptoms, elevated acute phase reactants); and (ii) a stenotic phase, in which damaged elastic arteries become either narrowed, leading to tissue ischemia, or dilated (potentially leading to rupture). The ascending aorta, aortic arch, and branch vessels are most commonly affected, including the carotid, brachiocephalic, subclavian, and vertebral arteries. The descending aorta may also be affected, and renal artery involvement sometimes results in hypertension. The pulmonary vasculature is involved in approximately one-half of all patients with TA, but is asymptomatic in many. Whereas most of the involved arteries become narrowed after some period of inflammation, the ascending aorta frequently dilates, sometimes leading to aortic dissection and aortic regurgitation.

Severe involvement of the extracranial large arteries supplying the brain (the carotids and vertebrals) may lead to cerebrovascular accidents, but intracranial involvement is surprisingly rare, as in GCA. Steal syndromes (e.g. the subclavian steal: Moncada et al., 1998) often result from such large artery involvement. Advanced carotid lesions may be associated with a host of ocular findings in TA. The first TA patient ever described had 'a peculiar, wreath-like sheathing' (Takayasu, 1908) of retinal blood vessels, representing an arteriovenous anastomosis. In addition to arteriovenous anastomosis, ophthalmological findings in TA include microaneurysms, retinal neovascularization and, as an eventual complication of retinal ischemia, vitreous hemorrhage, retinal detachment, and optic atrophy. Approximately 35% of patients in one series had eye findings directly related to TA, but many of these patients had few or no symptoms (Kiyosawa & Baba, 1998). Rare cases of AION (the classic lesion of GCA) have been described in TA (Schmidt et al., 1997). In some cases, retinal lesions such as microaneurysms have undergone dramatic resolution following bypass procedures to restore the patency of large vessel circulation to the head (Kiyosawa & Baba, 1998). Although most of the retinal findings in TA are associated with cerebral hypoperfusion, hypertensive retinopathy may also ensue from renal artery stenosis (Uyama & Asayama, 1976).

Determination of the degree of disease activity may be exceptionally difficult in TA. Forty-four per cent of patients undergoing surgery of stenotic lesions for presumed 'burned out' disease had active arteritis upon pathological examination of the specimens (Kerr et al., 1994). Acute phase reactants are unreliable parameters of disease activity in many patients. MR may have some role in assessing disease activity, but its role needs further investigation. The mainstay of treatment for TA is glucocorticoid therapy. Angioplasty, stenting, and bypass procedures may be indicated in certain patients.

Cogan's syndrome

Cogan's syndrome (CS) is defined by the occurrence of inflammatory eye disease and vestibulo/auditory dysfunction. The classic presentation of the disorder includes interstitial keratitis and sensorineural hearing loss. The interval between the onset of eye and ear symptoms is usually only several months (or less), but intervals of up to 2 years have been reported. This disorder affects young adults, with no gender predominance. In approximately 10% of cases, eye and ear inflammation is associated with arteritis of medium- and large-sized vessels (including aortitis) that mimics Takayasu's arteritis (Haynes et al., 1980; Vollertsen et al., 1986). Although the eye and ear findings in CS are sometimes attributed to vasculitis, their true pathophysiology remains obscure (Schuknecht & Nadol, 1994; St. Clair & McCallum, 1999).

Interstitial keratitis leads to the sensation of ocular irritation, excessive lacrimation and photophobia, and is accompanied by moderate reductions (generally reversible) in visual acuity. Slit-lamp examination of the cornea reveals stromal clouding in the anterior and middle cornea. Pathologically, the cornea shows infiltration of lymphocytes and plasma cells in the deep corneal layers, with varying degrees of neovascularization (Fisher & Hellstrom, 1961; Bernhardt et al., 1976). In addition to interstitial keratitis, many other forms of inflammatory eye disease may occur in CS, including conjunctivitis, uveitis, episcleritis, scleritis, exophthalmos, papilledema, retinal vasculitis, and ON (Haynes et al., 1980; Vollertsen et al., 1986).

The greatest cause of long-term morbidity in CS is the ear involvement. More than half of the patients with CS suffer some degree of irreversible sensorineural hearing loss (Haynes et al., 1980; Vollertsen et al., 1986; St. Clair & McCallum, 1999). A substantial percentage become profoundly deaf in at least one ear. The vestibular manifestations may also be severe, and usually present with the abrupt onset of vertigo, ataxia, tinnitus, nausea, vomiting, and sometimes oscillopsia.

Interstitial keratitis generally responds well to topical steroid therapy. Ear disease in CS must be treated promptly

and aggressively, with high doses of systemic glucocorticoids. Responses usually occur within 2 weeks, and total courses of immunosuppression lasting 2 to 3 months may be sufficient for the ear manifestations. In patients with suboptimal responses to glucocorticoids who still have salvageable hearing, cytotoxic agents (e.g. cyclophosphamide) are appropriate.

Part XIII

Disorders of myelin

97

Myelination, demyelination and remyelination

Alastair Compston

University of Cambridge, Addenbrooke's Hospital, Cambridge, UK

The relationship between injury and repair of the central nervous system is complex. Although long considered incapable of regeneration, the mammalian central nervous system can undergo neurogenesis and gliogenesis re-establishing axon–glial interactions needed for remyelination and safe conduction of the nerve impulse. In health, glia and neurons each exert survival effects on other constituents of the developing and mature central nervous system. Microglia mediate cell injury when activated but damaged tissue may be advantaged by the inflammatory process which delivers growth promoting and neuroprotective molecules to sites of tissue injury. Furthermore, bystander damage is limited whilst degenerate material is removed.

Myelination

Stem cells

Stem cells self-replicate through asymmetric division and differentiate down a variety of fate-committed lineages. They can be identified by surface markers or the behaviour of their progeny in defined environments. The principal source of neural stem cells during development is subventricular zone ependymal cells (Fig. 97.1, see colour plate section). Adult neural stem cells are present especially in the hippocampus and olfactory bulb but also in the neocortex (Maglivi et al., 2000). Embryonic stem cells are even less restricted retaining the ability to maintain the germline and differentiate to a cell-specific fate such as oligodendrocytes or dopaminergic neurons (Thompson et al., 1998). The need to select survivors from cells overproduced in the developing nervous system involves programmed cell death. Caspases cleave proteins supporting the nuclear membrane and cause apoptosis by activation of the endonuclease which digests DNA. Programmed cell death is influenced by the mammalian mitochondrial product *Bcl-2* and other antiapoptotic (*Bcl-X*) and proapoptotic molecules (*Bax*, *Bad* and *Bid*). Apoptosis makes it safe to retain a source of mitotic precursors in the mature nervous system, whilst avoiding uncontrolled growth.

Growth factors for neurones and glia

Acting together or in sequence, growth factors orchestrate development within the nervous system influencing proliferation, migration and differentiation. Many also support survival of fully differentiated cells.

Retinoic acid promotes embryonic cell differentiation down the neural lineage. Further in vitro manipulations yield mixed cultures enriched for oligodendrocytes (Brustle et al., 1999). Murine neural stem cells proliferate in response to epidermal growth factor (EGF). Their default differentiation pathway is gamma aminobutyric acid (GABA)-ergic neurones, but they can be directed towards dopaminergic and non-neuronal fates. EGF and fibroblast growth factor (FGF)-2 act sequentially in regulating neuronal development from stem cells. Glial cell line derived nerve growth factor (GDNF) induces a bias towards glial differentiation within cultured neural crest cells. Neurospheres derived from human embryonic tissue initially expand with fibroblast growth factor (FGF)-2.

There is a continued requirement for specific growth factors and cytokines once cell fate is committed. Many are also active on more primitive cell types. These growth-promoting molecules are produced by neurones, astrocytes and microglia. Platelet-derived growth factor (PDGF) is mitogenic for oligodendrocyte progenitors but they differentiate after a defined number of divisions (Raff et al., 1983); however, FGF-2 indefinitely suspends their maturation and promotes migration. EGF, neurotrophin (NT)-3, thyroxine and T3, retinoic acid and glucocorticoids each also stimulate oligodendrocyte differentiation and maturation from stem cells or committed precursors in vitro. Survival factors for cells of the oligodendrocyte lineage also

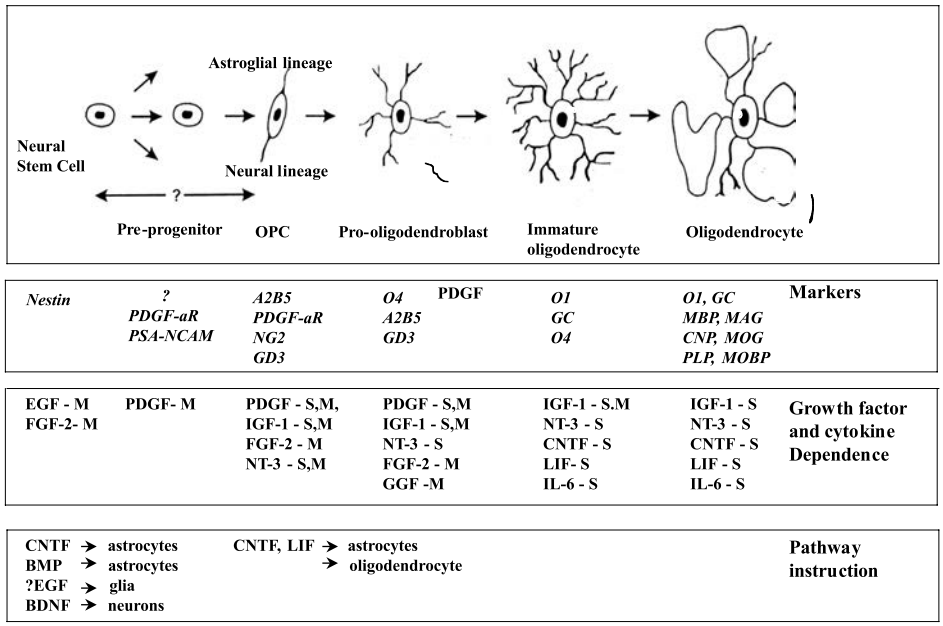

Fig. 97.2. Cells of the macroglial lineage develop under growth factor control acquiring cell surface markers with maturation and responding specifically to factors which orchestrate proliferation, migration, differentiation and survival. (Kindly prepared by Dr Siddarthan Chandran.)

include insulin like growth factor (IGF)-1 and -2, leukemia inhibitory factor (LIF), interleukin (IL)-6, NT-3 and ciliary neurotrophic factor (CNTF: Barres et al., 1992).

Macroglial lineages in the rodent and human nervous system

Astrocytes

Astrocytes contribute to formation of the glia limitans which defines the boundaries of the central nervous system and the blood–brain barrier. They contact cell bodies of neurones and the bare portions of axons and take up potassium following generation of the nerve impulse; astrocytes may also synthesize and insert axonal sodium channels at the node of Ranvier. Astrocyte reactivity in response to tissue injury, marked by increased expression of glial fibrillary acidic protein (GFAP), increases the availability of growth and neuroprotective factors (Komoly et al., 1992; Yao et al., 1995). Eventually, astrocyte reactivity leads to glial scar formation. FGF-2 and EGF stimulate the division of astrocytes. Proliferation is inhibited by transforming growth factor (TGF)-β.

Oligodendrocytes

Human oligodendrocyte precursors are born around the ventricles by 7–9 weeks gestation (Rivkin et al., 1995: Fig. 97.2). In the spinal cord, they increase progressively within the ventral and lateral portions of cervical and then lumbar regions, thereafter populating the lateral and dorsal cord by the time myelination starts at embryonic day 83 (Hajihosseini et al., 1996). The adult human central nervous system contains preoligodendrocytes which express the O4 marker but not galactocerebroside (GalC: Armstrong et al., 1992). Bipolar cells positive for A2B5 but negative for O4 and markers of mature oligodendrocytes or astrocytes, which proliferate and are bipotential in vitro, have also been recovered from the adult human central nervous system (Scolding et al., 1995). Although this adult human progenitor divides on a monolayer of human astrocytes, and neurons improve its survival, it does not proliferate in response to FGF-2, PDGF, IGF, BDNF, NT-3, NT-4/5 (alone or in combination), or rat astrocyte or neuroblastoma cell line (B-104) conditioned medium, stimuli known to promote division of the rat neonatal oligodendrocyte precursor.

Axon–glial interactions and myelination

The migration of oligodendrocyte progenitors is influenced by receptor–ligand adhesions with the extracellular matrix. Integrins are one of several families of molecules which determine cell–cell interactions in the developing and postmature nervous system. Myelination occurs when the membraneous processes of mature oligodendrocytes contact and ensheath axons of diameter 1 μm or more, and compact to form the myelin lamellae needed for saltatory axonal conduction. Stable myelination depends on additional cell surface and extracellular matrix molecules which promote and maintain interactions between myelin and axons. These include janusin, tenascin, laminin and fibronectin.

The axon–glial relationship is reciprocal. Oligodendrocyte progenitors are influenced by their axonal environment. Neurones are mitogenic for cells of the oligodendrocyte lineage. The molecular basis involves both diffusible and membrane-associated signals, which include PDGF. Electrical activity in axons also influences oligodendrocyte progenitor proliferation (Barres & Raff, 1993). Eventually, the number of mature oligodendrocytes is matched to local axon density, survival being orchestrated by the number of axons requiring myelination. Conversely, oligodendrocytes promote the survival, growth and calibre of retinal ganglion cells in the developing optic nerve; and oligodendrocytes secrete a factor needed for sodium channels to cluster at intervals appropriate for the diameter of developing axons in preparation for propagation of the nerve impulse. Neurons show a marked increase in survival when cocultured directly with oligodendrocyte precursors and differentiated oligodendrocytes and this effect is also reproduced using medium conditioned by differentiated oligodendrocytes (Wilkins et al., 2001). Neutralizing antibodies to IGF-1, but not other candidate trophic factors, block the soluble survival effect of oligodendrocytes; cells of the oligodendrocyte lineage produce IGF-1; and recombinant IGF-1 promotes neuronal survival under identical conditions. Neurons exposed to oligodendrocyte conditioned medium show enhanced neurite and axonal length; this effect is reduced by inhibitors of MAPkinase/Erk pathway whereas PI_3kinase inhibition reduces the effect of oligodendrocytes and conditioned medium on neuronal survival (Wilkins et al., 2002)

Once stable axon–glial contact is established, the elongated oligodendrocyte processes form a cup around the axon at the point of contact, extending lengthwise to form a trough whose two lips advance around the circumference of the axon until they meet. One then passes beneath the other to become the inner tongue of the future sheath, which rotates many times around the axon to form the multiple membrane layers or lamellae. During compaction, the cytoplasmic content of all except the inner- and outermost lamellae of the developing spiral sheath is gradually extruded, and the two inner leaflets of the surface membrane lipid bilayer fuse to form the major dense line visible in cross-section (Fig. 97.3). The developing myelin sheath extends lengthwise in both directions along the axon to form an internodal segment. Each layer of the spiral retains a bead of cytoplasm at the advancing edge, where the two inner leaflets of the surface membrane remain separate.

Electrical resistance is low at the node of Ranvier, due to the high concentration of sodium channels, and depolarization is thereby facilitated. In myelinated axons, the action potential generates electrical currents which, in turn, trigger depolarization not at the immediately adjacent myelinated (and insulated) internode, but preferentially at the next node of Ranvier. This saltatory conduction is considerably more rapid than continuous propagation of the nerve impulse.

Demyelination

The best hypothesis concerning events which underlie the pathogenesis of inflammatory brain disease requires extrapolation and integration from a combination of in vitro, experimental, pathological and clinical observations, which necessarily risks contaminating fact with fiction in the attempt to achieve overall coherence.

Cellular infiltration of the central nervous system

The blood–brain barrier prevents the passage of large molecules and cells, even though specific vesicular and other transport mechanisms provide the brain with essential nutrients and permit a degree of cellular traffic. It is composed of a layer of cerebral endothelial cells surrounded by a basement membrane and the Virchow Robin space, itself contained by astrocytes whose foot processes establish endothelial tight junctions.

Penetration of cerebral vessels occurs when endothelial cells extend microvillar processes and entangle inflammatory cells as they pass along the vessel wall. Vascular permeability also depends on alterations in expression of cell surface molecules on activated T-cells together with the secretion of enzymes that degrade the extracellular matrix of lining cells. The constitutive expression of specific molecules that determine immunological recognition and cellular adhesion alters under conditions of inflammatory cell activation, amplifying the steady state cellular surveillance that occurs in health and contributing to the perivenular concentration of inflammatory cells that characterizes most demyelinating diseases (Carrithers et al., 2000). Thus migration results from changes on endothelia and activated lymphocytes. Certain addressins highly concentrated on endothelial cells by the action of locally acting cytokines (IL-1 and tumour necrosis factor [TNF]α) interact with ligands on the surface of circulating lymphocytes or inflammatory cells. Specific receptor–ligand interactions include intercellular adhesion molecule [ICAM]-1 reacting with leukocyte function antigen [LFA]-1, LFA-3, which links exclusively with the T-cell ligand cluster defined [CD]-2, and CD9, which selectively adheres to B-lymphocytes. Other adhesion systems, such as complement activation products and CD44, are ubiquitously expressed and non-specifically enhance contact between

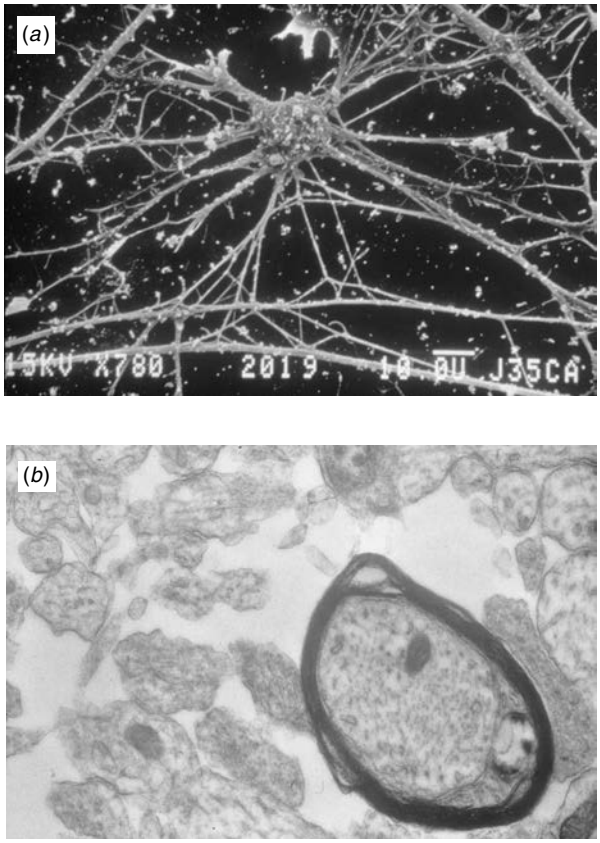

Fig. 97.3. (*a*) Rat O-2A progenitors associate in vitro with several bundles of dorsal rat ganglion axons shown by scanning electron microscopy; (*b*) formation of compact myelin sheaths around axons shown by transmission electron microscopy. (Kindly provided by Dr John Zajicek and reproduced with permission from Zajicek et al., 1992.)

circulating and endothelial cells. Soluble adhesion molecules, such as ICAM, inhibit mononuclear cell migration across endothelial barriers. Migration can be actively prevented by blocking antibodies directed, for example, at the α4 chain of integrins.

The critical factor in determining propagation of the immune response is that only those cells primed against central nervous system antigen persist in the brain, whereas those that do not encounter specific antigen die by apoptosis (Wekerle et al., 1986). Cellular traffic across the blood–brain barrier non-specifically permits a variety of other potentially pathogenic molecules to assemble on the abluminal surface of cerebral vessels, creating the conditions needed for cellular, antibody, complement and macrophage-mediated tissue injury.

Next in the cascade of events is outward migration of cells from the inflammatory nidus. This is largely promoted by local production of chemokines interacting with specific receptors on migrating cells, and by enzymes which degrade tissue barriers and extracellular matrices (Zang et al., 2000). Chemokines specific for T-cells are IP-10 and MIG; neutrophils respond to Gro-α and IL-8; and T-cells and monocytes to RANTES, MCP-1 and MIP-1α. The IP-10 receptor is CXCR3 and CCR5 binds the MIP-1α and RANTES ligands. IL-2-induces the secretion of metalloproteases by T-cells and this enhances their ability to adhere and migrate through endothelial barriers.

The role of microglia

Microglia are primary immunocompetent cells which have antigen-presenting and phagocytic properties (Fig. 97.4, see colour plate section). They can be distinguished phenotypically from brain macrophages by differential expression of CD45 and CD11. Microglia and bone-marrow derived macrophages play a complex and in some respects paradoxical role in development, injury and repair of axon–glial arrangements within the central nervous system.

Microglia and oligodendrocyte survival

Media conditioned by non-activated microglia increase the number of surviving GalC positive oligodendrocytes in vitro (Nicholas et al., 2000a). Survival results from inhibition of endogenous oligodendrocyte precursor apoptosis and promotion of oligodendrocyte differentiation by soluble factors released by non-activated microglia which over-rides the effects on maturation of PDGF and FGF-2 (Fig. 97.5, see colour plate section). These soluble factors act by up-regulation in oligodendrocyte precursors of nuclear factor of kappa-binding (NFk-B). Antiplatelet-derived growth factor antibody abolishes this effect even though PDGFα chain is expressed at similar levels within both non-activated and interferon (IFN)-γ activated microglia and both conditioned media have similar levels of PDGF-α chain bioactivity. However, the soluble factors produced by non-activated microglia recruit phosphatidyl-3-inositol kinase to the PDGFα receptor and synergize with endogenous PDGFα chain to increase NFk-B activation. These effects are not observed with supernatants from microglia treated with IFN-γ.

Therefore, depending on activation state, microglia produce soluble factors that promote oligodendrocyte development through an effect on PDGFα receptor signalling. These appear not to be any one of the many growth factors known to act on cells of the oligodendrocyte

lineage. Conversely, in their activated state, microglia mediate tissue injury. The most potent activators in vitro and perhaps in vivo are bacterium-derived lipopolysaccharide, the T-cell derived cytokine IFN-γ and the colony-stimulating factors (CSFs). Activated microglia change their morphology (becoming amoeboid and motile) and release proinflammatory cytokines, chemokines and mediators which orchestrate their immune functions.

Microglia as antigen-presenting cells

The terms professional and non-professional define antigen-presenting cells, which can initiate antigen-specific primary or secondary immune responses, respectively, reflecting differences in the quality of stimulation required for naive as opposed to memory T-cell activation. The issue of whether antigen presentation occurs exclusively within the central nervous system or uses cells (of peripheral or brain origin), which encounter antigen in draining lymph nodes and stimulate lymphocytes which then migrate into the central nervous system is not fully resolved. The best candidates for a brain-derived antigen-presenting cell are microglia or bone marrow-derived macrophages but astrocytes, cerebral vascular endothelial cells and pericytes are all capable of restimulating lymphocytes, and there is now experimental evidence that dendritic cells can migrate from the periphery and trigger the immune response (Perry, 1998).

The non-professional antigen-presenting role is assigned to the $CD45^{high}CD11b/c^{+}$ perivascular macrophage rather than to the $CD45^{low}CD11b/c^{+}$ parenchymal microglial cell. Unlike perivascular macrophages, microglia fail to produce IL-2, resulting in limited T-cell proliferation and the promotion of apoptosis. Microglia secrete IL-1 and constitutively express class II major histocompatibility complex (MHC) and the B7 accessory molecule following activation. Costimulation is most effectively delivered through CD28 and B7, and/or CD40 and its ligand. These costimulatory molecules are upregulated by IFN-γ and down-regulated by anti-inflammatory cytokines especially the Th-2 associated products IL-4, IL-10 and TGF-ß1. Antigen presentation by microglia to memory T-cells results in cytokine release, which reciprocally activates naive microglia, indicating that recall antigen presentation results in an environment which propagates the immune response (Hall et al., 1999). The effect is predominantly mediated by IFN-γ but amplified by TNFα.

Interactions between microglia and oligodendrocytes

Fully differentiated oligodendrocytes stimulated to divide by exposure to bFGF or nerve growth factor (NGF), transduce the mitotic signal and enter the cell cycle but cannot divide and either enter a resting non-myelinating state or die by apoptosis (Muir & Compston, 1996). Postnatal rat cortical oligodendrocytes, but not their progenitors (or astrocytes), are selectively killed by exposure to NGF, through binding to the p75 receptor when trkA is not co-expressed, whereas no such effect is seen with brain derived nerve growth factor (BDNF) or NT-3 (Casaccia-Bonnefil et al., 1996); p75 receptor may be up-regulated on oligodendrocytes within the lesions of multiple sclerosis. This apparent paradox is not so surprising since the trkA and p75 NGF receptors are part of the cell death pathway involving Fas and the TNFα receptor. Thus, there may be diametrically opposite effects of growth factors on cells of the same lineage depending on the expression of receptors, the signals transduced and their ability to enter the cell cycle.

Oligodendrocytes are especially sensitive to mediators of inflammation but also to anoxia and excitotoxic damage. Cells exposed to sublytic concentrations of complement or perforin show a transient increase in intracellular calcium during which pores forming in the membrane are gathered into vesicles and shed from the cell surface, thereby restoring membrane integrity and leaving the oligodendrocyte metabolically intact (Scolding et al., 1989). Oligodendrocyte recovery correlates with calcium oscillations suggesting that the calcium signal following insertion of the membrane–attack complex stimulates protective mechanisms and repair at the cellular level. This illustrates the principle of reversible oligodendrocyte injury, but the main relevance of complement activation in the context of inflammatory brain disease may be the breakdown of C3, releasing membrane-bound and fluid-phase products, which determine interactions between oligodendrocytes and macrophages or microglia. Differences in histological features of the lesions in multiple schlerosis suggest heterogeneity in the pathogenesis (Luchinetti et al., 1999): one variant (type 2) consists of perivenous demyelination with local deposition of immunoglobulin and terminal complement components within sharply defined lesions also having remyelination; these patients have the phenotype of clinically definite multiple schlerosis with an equal distribution of relapsing and progressive cases. Uptake of myelin by macrophages is enhanced by opsonization with complement, involves the CR3 receptor, induces a rise in intracellular calcium, and is associated with the production of TNFα and nitric oxide by these activated macrophages. The fact that oligodendrocytes possess receptors for TNFα and the related molecule *fas*, provides a basis for signalling events which activate both apoptotic and necrotic death pathways.

IFN-γ up-regulates the expression of an heterogeneous

group of molecules on microglia involved in the phagocytosis of opsonized particles. These include the FcR1 (CD64), FcRII (CD32) and FcRIII (CD16) receptors; complement components C1q, iCR3 and C5a; IL-8, TNF-R1 and the bacterial peptide f-Met–Leu–Phe. The pro-inflammatory responses of microglia are limited by the production of IL-4, IL-10, prostaglandin-E2 and TGF-ß which suppress several behaviours (proliferation, activation, adhesion, migration, phagocytosis, costimulation and mediator production), and by apoptosis of autoreactive T-cells using perforin and the Fas/Fas-ligand pathway. Microglia are themselves killed by apoptotic mechanisms in response to TGF-β and are not protected by Bcl-2. With some variations, the same checks and balances are provided by anti-inflammatory cytokines on the proinflammatory behaviour of astrocytes.

Significant cell death occurs when oligodendrocytes derived from mixed rat cortical glia are cultured without growth supporting factors. Soluble factors released from these cultures are chemotactic in vitro for microglia. This occurs before major cell loss has occurred; microglial chemotaxis is not due to the release of cellular debris since osmotic lysis of freshly plated oligodendrocytes does not reproduce the effect. IFN-γ activation increases the sensitivity of microglia to these chemoattractants (Nicholas et al., 2002a). The initial recruitment of microglia by stressed oligodendrocytes could represent part of a survival response engaged by injured cells.

Activated microglia mainly kill (opsonized) oligodendrocytes by cell–cell contact and local release of TNFα during cell contact (Zajicek et al., 1992). Receptor–ligand interactions allow microglia to recognize and then deliver the lethal signal to target cells. Antibody in low concentration, coating the surface of the oligodendrocyte or its myelin sheath, opsonizes the target cell for lytic damage by microglia using these Fc receptors. Demyelinated axons are coated with antimyelin oligodendrocyte glycoprotein (MOG) antibody in the lesions of acute multiple sclerosis (Genain et al., 1999). The potential role of MOG is further suggested by the high prevalence of intrathecal anti-MOG antibodies, which persist in multiple sclerosis from an early stage in the illness, unlike the evolving pattern of antibody responses to myelin basic protein (MBP).

Oligodendrocytes are resistant to physiological concentrations of soluble TNFα through protection by microglia-derived IGF-2 and CNTF; these growth factors act synergistically to block the oligodendrocyte toxicity otherwise caused by TNFα released by IFN-γ activated microglia (Nicholas et al., 2002b). The activity of c-Jun kinase (JNK) stimulated by TNFα receptor ligation confirms that these factors inhibit TNFα signalling. Irrespective of activation, conditioned media do not induce JNK activity in oligodendrocytes unless CNTF or IGF-2 activity are neutralized (Fig. 97.6, see colour plate section). The TNFα-containing medium of IFN-γ treated, but not non-activated, microglia is then toxic for oliogodendrocytes.

Thus, activation of microglia results in the release of molecules, which are potentially toxic for oligodendrocytes, but these effects are neutralized by simultaneous production of growth factors. In the context of inflammation, this safeguard would limit bystander damage to oligodendrocytes, whilst allowing cell contact-dependent mechanisms of injury to operate appropriately after microglial activation. Growth factor availability within an inflammatory lesion determines the extent of bystander damage. The stressed oligodendrocyte signals its distress and either summons assistance or suicidally attracts activated microglia, but this is a potentially dangerous liaison.

Microglia and neurones

Soluble factors released by activated microglia impair mitochondrial (cytochrome oxidase) activity of neurons in vitro. These functional effects are blocked by antibodies to TNFα. Cell death is prevented by intracellular release of NKk-B. Although this neuronal dysfunction is initially reversible (Nicholas et al., 2001b), a mechanistically different and generally more lethal sequence of events follows prolonged exposure to microglial soluble factors. Inducible nitric oxide synthetase but not its neuronal isoform is implicated in these less reversible events. However, by analogy with the simultaneous production of destructive and protective factors for oligodendrocytes, microglia in both their activated and non-activated states also produce factors which promote the metabolic activity of neurons remote from the immediate arena of nitric oxide-mediated injury (Golde et al., 2002).

Although axons do not generally regenerate in the central nervous system, due to active inhibition by macroglia, macrophages release IL-2 which transiently removes the inhibitory constituents from oligodendrocytes and astrocytes. Neuronal survival in the crushed optic nerve is enhanced if myelin-specific autoimmune T-cells are injected locally, perhaps by a mechanism which involves transient reduction in energy requirements due to reduced nerve activity. The functional advantage of allowing inflammation to enhance axon regeneration is shown by enhanced motor recovery in rats, made paraplegic by complete spinal cord transection, transplanted with macrophages first primed in vitro against peripheral nerve (Rapalino et al., 1998). Neuroprotection after spinal cord injury is also provided experimentally by systemic immunization with myelin basic protein specific autoreactive T-cells (Hauben et al., 2000). Functional recovery is associated with reconstitution of nerve fibres across the

lesion and restoration of motor conduction. No additional repair is achieved by manipulating growth factors within the lesions.

The pathogenesis of multiple sclerosis

The symptoms and signs of multiple sclerosis arise from patchy inflammation and demyelination within the brain and spinal cord. Disability occurs as a direct consequence of this inflammatory process and its relative failure to repair. The disease pattern, characterized by a course which is initially intermittent then episodic with incomplete recovery and eventually followed by slow progression, raises fundamental questions concerning the etiology of inflammatory brain disease and the basis for symptom onset and recovery (Fig. 97.7).

Genetic factors set the scene for events which underlie the clinical features of multiple sclerosis (Compston, 1999). Some, perhaps the majority, influence the immunological behaviour of susceptible individuals. Population studies demonstrate an association between the class II MHC alleles *DR15* and *DQ6* and their corresponding genotypes. Based on systematic searches of the genome, additional regions of interest are provisionally identified on several other chromosomes; some cluster in families which are, and others which are not, linked to the *DR15* haplotype. A major part of future studies in the genetics of multiple sclerosis will be to resolve the question of disease heterogeneity.

Although not yet fully defined, the initiating events culminate in brain inflammation. In addition to the migration of activated lymphocytes across cerebral and spinal endothelial barriers and microglial activation by IFN-γ, proinflammatory cytokines delivered by T-cells and released by microglia interfere directly with the function of myelinated fibres. The evidence partly derives from correlations between abnormalities of evoked potentials and inflammation detected by magnetic resonance imaging (Youl et al., 1991), and from the clinical observation that patients undergoing experimental treatments experience a significant but transient rehearsal of previously experienced symptoms coinciding with acute cytokine release during which conduction block can be demonstrated (Moreau et al., 1996; Coles et al., 1999). Experimental studies demonstrate that nitric oxide can reversibly impair conduction in normal or hypomyelinated spinal cord axons central (Redford et al., 1997), consistent with the in vitro studies. More prolonged exposure causes axon degeneration especially if the nerves are electrically active (Smith et al., 2001). Subsequently, a pentapeptide (Gln–Tyr–Asn–Ala–Asp), able to block sodium channels in human neuroblastoma-glioma NH15-CA2 cells, was shown to be present at ×3–14 concentration in cerebrospinal fluid from patients with multiple sclerosis compared to normal controls (Brinkmeier et al., 2000).

It therefore follows that recovery of function may sometimes merely reflect restoration of conduction following removal of proinflammatory cytokines through myelinated axons, which were never structurally damaged. Even where demyelination has occurred, function may be restored by rearrangement of sodium channels (England et al., 1990), providing a variety of alternative patterns of conduction. This principle is further illustrated by the demonstration that mouse strains susceptible to Theiler's virus which are class I but not class II MHC antigen deficient show few physiological or functional deficits due to increased density of sodium channels and preservation of axons (see below) despite extensive demyelination (Rivera-Quinones et al., 1998). There may also be a contribution to recovery of structure and function in multiple sclerosis from remyelination (Prineas et al., 1993: see below).

Progression and disability in multiple sclerosis are best explained by axon degeneration. Identified in the classical neuropathological literature, this has recently been re-emphasized histologically (see below) and by magnetic resonance imaging or spectroscopy showing atrophy and changes in *N*-acetyl aspartate in lesions (Davie et al., 1995), normal appearing white matter (Evangelou et al., 2000) and brain (De Stefano et al., 1998) and spinal cord lesions (Stevenson et al., 1998). The fate of axons is conditioned by the amount of early inflammation: they may be damaged directly during the initial inflammatory disease process; through exposure non-specifically to inflammatory mediators after demyelination; because nerve fibres have a limited ability to survive prolonged demyelination; or for all three reasons. Immunohistochemical staining for amyloid precursor protein suggests that axonal injury occurs as part of the acute demyelinating lesion (Ferguson et al., 1997; Trapp et al., 1998). Circumstantial evidence suggests that vulnerability of recently demyelinated axons to the inflammatory environment of acute lesions, or secondary degenerative effects of demyelination through loss of trophic support are more likely mechanisms than primary immunological injury to the intact axon by infiltrating mononuclear cells and their mediators. Recent histological assessments draw attention to the presence of axon degeneration not only in inflammatory lesions but also in inactive plaques and in areas of remyelination; the most extensive axonal injury is seen in secondary progressive multiple sclerosis but with surprisingly little typifying the lesions of primary progressive disease; amyloid precursor protein deposition is associated with macrophages and infiltrating CD8 lymphocytes but not TNFα or inducible

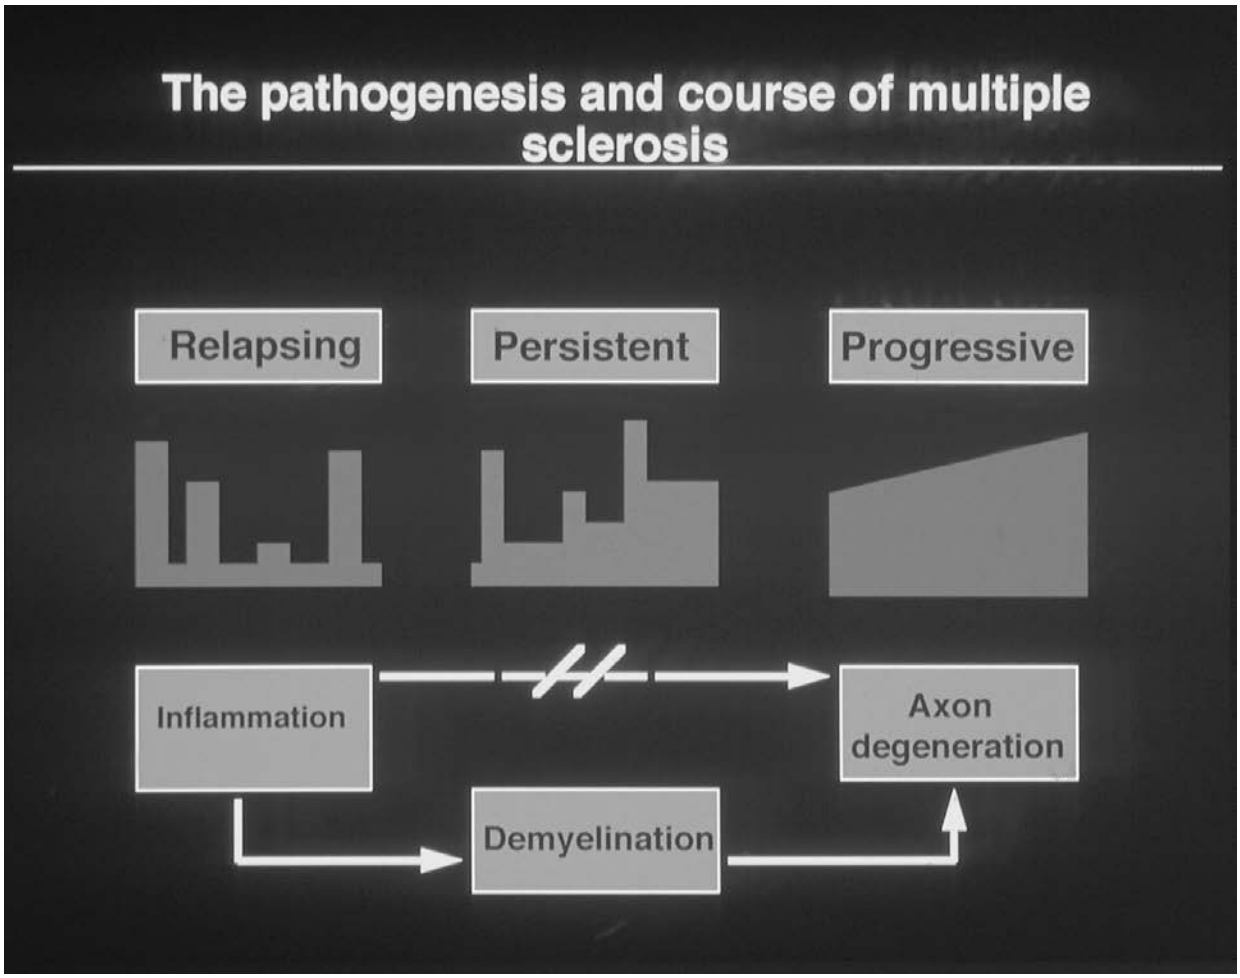

Fig. 97.7. Stages in the clinical course of multiple sclerosis. Inflammation causes transient alteration in conduction through the action of nitric oxide on myelinated fibres, providing one explanation for symptoms which recover. Inflammation drives demyelination, which may improve through remyelination, but otherwise accounts for persistent clinical deficits. There is a major contribution to secondary progression from axon degeneration which results both from inflammation and loss of trophic support from oligodendrocytes.

nitric oxide synthase (Bitsch et al., 2000). This analysis is consistent with experimental evidence that myelin or glia, and electrical activity provide survival factors for axons (Barres & Raff, 1993; Meyer-Franke et al., 1995; Sanches et al., 1996; Wilkins et al., 2001).

Remyelination

The extent to which remyelination is essential for the comprehensive treatment of multiple sclerosis hinges on the issue of when and why axons degenerate. For those axons which degenerate early as a direct result of the inflammatory process, efforts at remyelination may have little to offer; conversely, if the naked axon is resistant to the inflammatory milieu but has poor survival properties, remyelination is an essential part of the overall strategy for treating multiple sclerosis, and its timing is very important. A number of basic questions also arise with respect to the practicalities of repairing demyelinated but viable axons in multiple sclerosis. Can surviving oligodendrocytes remyelinate naked axons or must there be a source of precursor cells? Are stem cells for glia present in the adult human nervous system? If so, can they migrate from germinal centres to sites of injury? Can cells other than oligodendrocytes be used as surrogates for remyelination? Will growth factor therapy prove effective and well tolerated as a means of promoting repair? Will endogenous repair or assisted remyelination restore structure and function of the adult human nervous system? Some answers are already available.

The pioneering experimental studies, involving mechanical and gliotoxin induced demyelination, showed

that remyelination occurs endogenously and restores conduction both in young and adult nervous systems, but the capacity for repair by oligodendrocyte precursors is exhausted by repeated insult. With antigalactocerebroside antibody-mediated demyelination of the feline optic nerve, small glial cells derived from precursors located outside the lesion differentiate into oligodendrocytes and achieve extensive remyelination. They concentrate early at the margins of the lesion, suggesting local origin within the optic nerve (Carroll et al., 1998). This remyelinating cell is beyond reasonable doubt the in vivo counterpart of the oligodendrocyte progenitor, characterized in vitro.

The human preoligodendrocyte and its progenitor have each now been identified in the lesions of multiple sclerosis (Wolswijk, 1998; Scolding et al., 1998), but the fact that progenitors are present within persistently demyelinated lesions suggests that these have not successfully engaged naked axons. Demyelinated lesions of the central nervous system are preferentially repopulated by Schwann cells, but these are not precocious myelinators, mainly because each Schwann only captures a single axon and their territory is limited by host astrocytes. Reactive astrocytes bring to experimental demyelinating lesion cytokines or growth factors which promote repair (Komoly et al., 1992; Yao et al., 1995) as do reactive astrocytes in the lesions of multiple sclerosis (Stadelman et al., 2002).

Because it maximally recapitulates the range and variety of environmental conditions and local signals on which endogenous remyelination depends, transplantation is the preferred method for assessing the myelinating potential of macroglia. Although it was the prospect of clinical intervention which initiated and has since sustained research into remyelination, the main dividend (to date) from experimental studies of glial cell implantation has been an improved understanding of myelination and glial neurobiology (Fig. 97.8).

A source of precursor cells able to proliferate, migrate and differentiate in the vicinity of the demyelinated axon is essential. Postmitotic oligodendrocytes neither divide, differentiate nor remyelinate axons. The cell must proliferate and cell implantation does not achieve remyelination if division is inhibited by X-irradiation. Both findings suggest that the origin of the remyelinating cell is a precursor and not a dedifferentiated mature oligodendrocyte. Embryonic stem cell derived oligodendrocytes myelinate axons in vitro in the dysmyelinating *shiverer* mouse, even at some distance from the site of transplantation (Liu et al., 2000). Other transplanted glia have a limited capacity for migration. CG4 (oligodendrocyte lineage line) cells injected into the intact ventral horn of the rat spinal cord lesioned in the dorsal column, and with high dose X-irradiation in advance of cell implantation, migrate into the lesion as progenitors without undergoing differentiation and then remyelinate naked axons (Franklin et al., 1996). However, without X-irradiation, cell survival is restricted to the inoculation site with no surviving transplanted cells seen elsewhere in the spinal cord. Normal tissue apparently does not favour oligodendrocyte progenitor migration but the reactive change which occurs in and around lesions is sufficient to support both survival and movement of cells, presumably due to the local availability of cytokines and growth factors produced by reactive astrocytes and microglia. However, growth factor supplements appear not to make a substantial difference to histological outcome. Experimentally, remyelination restores conduction (Smith et al., 1981), and glial cell implantation alters structure and function in the central nervous system (Groves et al., 1993; Jeffery & Blakemore, 1997).

Transplantation of human glia using mixed cultures which include oligodendrocyte progenitors confirms that oligodendrocyte lineage cells fail to migrate but survive in clumps within the lesion (Targett et al., 1996). In this situation, oligodendrocytes extend processes, which contact rat axons, but without the formation of myelin sheaths. Instead, the membranes end in terminal loops where the processes abut onto demyelinated axons. Despite these imperfect results of initial attempts at reconstructing glial–neuronal interactions by cell implantation using human material, cells of the human oligodendrocyte lineage transplanted into myelin deficient rodents survive, even after prolonged cryopreservation, and myelinate central axons (Seilhean et al., 1996). Unlike animals injected with ethidium bromide, these *shiverer* mice have normal numbers of astrocytes. This may be important since human oligodendrocyte precursors proliferate and survive in response to astrocyte-derived factors. Given their ability to myelinate the central nervous system, human Schwann cells have been evaluated in experimental rodent models of demyelination (Brierley et al., 2001). Failure to purify the cell implant by immuno-affinity (using human NGF receptor) lead to extensive fibroblast overgrowth and axon degeneration, whereas remyelination was achieved using the enriched population.

Olfactory bulb glia have a permissive role on axon regeneration in adults and form myelin sheaths capable of restoring conduction of the nerve impulse in experimental rodent models of remyelination. Olfactory ensheathing cells have the advantage over Schwann cells of improved migration and the ability to integrate within areas of astrocytosis. Human olfactory ensheathing cells proliferate in astrocyte conditioned medium in vitro and can be identified by expression of the p75 low-affinity NGF receptor. After transplantation in the X-irradiated ethidium bromide gliotoxic lesion of the rat spinal cord, they adopt a remyelinating phenotype and capture a proportion of naked

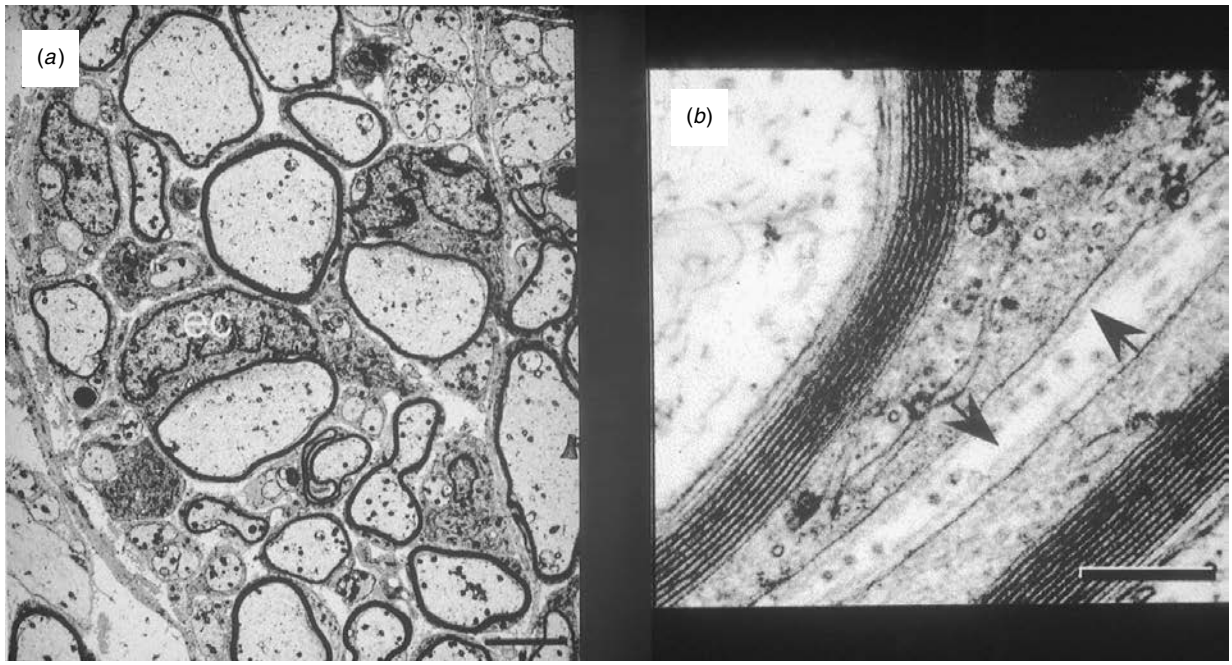

Fig. 97.8. Formation of compact myelin lamellae by human olfactory bulb ensheathing cells. (*a*) 6 weeks after injecting cells into gliotoxin-induced demyelinating lesions, many remyelinated axons are present in semi-thin sections stained with toluidine blue. (*b*) The myelin sheaths are similar to those formed by Schwann cells or olfactory bulb ensheathing cells having the periodicity of peripheral myelin and being surrounded by cytoplasm. (Kindly provided by Dr Robin Franklin and reproduced with permission from Barnett et al. (2000).)

axons with an histological pattern similar to Schwann cell repair (Barnett et al., 2000). Olfactory ensheathing and Schwann cells share the property of low morbidity access as the basis for clinical applications of cell implantation, since either could be obtained from the intended recipient and would therefore be suitable for autotransplantation, with all its immunological and ethical advantages.

Given the potential for endogenous remyelination of the central nervous system by oligodendrocyte progenitors and their progeny, it is reasonable to ask whether enhanced repair might be a dividend from containing tissue injury, the scales being tipped in favour of remyelination once the rate of injury has been restricted. Hints that immunoglobulin might both limit the disease process and promote remyelination come from the observation that spontaneous remyelination is much enhanced in Theiler's murine (demyelinating) encephalomyelitis virus when animals are treated with serum raised by immunization with spinal cord homogenate. The effect depends on IgM antibodies directed specifically against myelin basic protein (Rodriguez et al., 1996). This raises the question of whether increased remyelination is merely the consequence of successful disease suppression, promoting endogenous repair or depends directly on IgM which binds and stimulates cells of the oliogodendrocyte lineage, as suggested by the coassociation of inflammation and remyelination both in experimental lesions and multiple sclerosis. The available evidence suggests that pooled IgG and IgM fractions protect (rat) oligodendrocytes by inhibition of antibody-mediated phagocytosis and termination of the immune reaction by induction of apoptosis in infiltrating T-cells through nitric oxide and TNFα dependent mechanisms rather than by direct stimulation of oligodendrocytes. Hence, enhanced remyelination probably depends on manipulating the relationship between inflammation and repair rather than a direct growth-promoting effect (Stangel et al., 1999, 2000).

So what are the possibilities, based on contemporary experimental evidence, for repair of demyelinated pathways by cell implantation? One strategy is to wait until a therapy is available that can be given systemically and delivered simultaneously to all affected parts of the central nervous system. Another is first to prove that structure and function can usefully be restored in a single informative lesion before tackling the secondary task of making this intervention diffusely available in the central nervous system. If proof of principle involves cell implantation, the most promising present candidates are autologous periph-

eral nerve Schwann cells (Kohama et al., 2001) or olfactory bulb ensheathing cells (Barnett et al., 2000). The ideal lesion would be safely accessible, responsible for clinically significant and stable deficits resulting from persistent demyelination of intact axons, and at a site where the risks of failure would be acceptable through the presence of an intact paired structure or pathway. An unsuitable lesion would be at an inacessible site, where intervention would risk a strategic pathway, with an unstable or clinically irreversible deficit, and evidence for extensive axon degeneration. Attempts to enhance remyelination would need to be combined with adequate suppression of disease activity (Compston, 1996).

Most is known about the spinal cord and this might appear the obvious choice for a first clinical intervention. The symptoms are a major cause of disability, and can to some extent be measured using physiological and imaging techniques. But the risks of failure or increasing deficits within densely packed tracts would be high especially since it would be necessary to avoid patients with established chronic progressive disease and extensive axon degeneration. Magnetic resonance imaging usually shows many lesions in series within the corticospinal tracts so that remyelinating any one would be of limited value. Cord atrophy indicating severe axon degeneration is usually present in patients with stable or progressive deficits. The optic nerve is attractive because the symptoms are clinically eloquent, physiological assessment and imaging are well developed and there is a paired structure. Failure would not compromise vision in the intact eye. However, the natural history of optic neuritis is usually for recovery, which may occur over many months making it difficult to demonstrate that intervention had altered the natural history of visual recovery and the timing would need fine judgement, waiting for the establishment of persistent visual deficits but avoiding transplantation of a nerve with degenerate axons. Although the responsible lesion can usually be identified, this is often long, making for difficulty in placing implanted cells but there is evidence for early atrophy after unilateral optic neuritis despite the expected recovery of vision (Hickman et al., 2000) suggesting a need to protect axons from the loss of trophic support associated with persistent demyelination. The cerebellar peduncle is an alternative since this gives rise to symptoms which can be measured, and at a site where remyelination is known to occur and can be imaged. The typical severe proximal tremor is usually unilateral. It presents early and rarely recovers spontaneously. Failure would not be catastrophic and the pathway which involves the superior cerebellar peduncle and red nucleus has long been the target for stereotactic procedures. The responsible lesion can often be identified and has spectroscopic features, indicating demyelination with preserved axons near normal tissue integrity (C. Brierley, unpublished observations). In making the difficult transition between experimental and applied work, neurologists might feel more comfortable about early intervention here than in either the optic nerve or cerebellar peduncle than the spinal cord.

Many practical, clinical, ethical and biological problems remain to be overcome before remyelination of strategically placed lesions can become a reality for individual patients with multiple sclerosis.

Multiple sclerosis and its pathophysiology

W. Ian McDonald, Maria A. Ron and Gavin Giovannoni

Institute of Neurology, University College, London, UK

Multiple sclerosis is an inflammatory demyelinating disorder and is one of the commonest causes of severe neurological disability in middle life in people of northern European origin. Classically, it begins with relapses and remissions of neurological impairment. In time, the remissions tend to be incomplete, and a phase of insidious progression with or without superimposed relapses, is entered (secondary progressive MS). In a small proportion of patients (approximately 10%) there is steady progression from onset, without clear cut relapses and remissions (primary progressive MS) (Thompson et al., 2000).

Prevalence

The prevalence of MS varies greatly throughout the world and appears to be influenced by a complex interaction between geographic position and genetic background (for reviews see Compston, 1998, 1999). In the temperate zones of northern Europe, North America and Australasia, rates in excess of 100 per 100 000 population have been recorded and have reached 300 per 100 000 in the Orkney and Shetland Islands (Kurtzke, 1993). By contrast, in Asia the prevalence is of the order of 5 per 100 000; fewer than 10 cases have been described in black Africans.

A closer inspection of the epidemiological data reveals a number of important details departing from the overall picture. There are a number of reports that migration from a high prevalence zone (e.g. Northern Europe) to a low prevalence zone (e.g. South Africa) before puberty lowers the risk of MS while migration after this time does not. Migration in the reverse direction has the opposite effect. Another interesting detail is the occurrence of significant local variations in prevalence (see below) and the occurrence of clusters of cases over limited periods of time in confined geographical areas. This has been reported from Iceland, and most strikingly, for the Faroe Islands. The numbers involved in these studies are small, and caution should be exercised in their interpretion. It is of interest that the recent data on MS in Australia does not support the notion of an effect of age at migration on the risk of MS, though it does confirm strikingly the latitudinal gradient which is greater there than in any other country for which data is available (Hammond et al., 2000).

Etiology

The latitude gradient, the influence of migration and the occurrence of clusters of cases have been interpreted as evidence for the involvement of an environmental factor in the etiology of multiple sclerosis. What this might be is uncertain. An infective agent has been postulated (see below), but confirmation of its presence has not been forthcoming.

The geographical prevalence of MS is probably also influenced by genetic factors. In the Northern hemisphere there are genetic clines, one of which is a north–south gradient of frequency of HLA DR15 (formerly DR2), an antigen long associated with multiple sclerosis (see below), the frequency in the Northern hemisphere being higher in the north than in the south (Compston, 1998, 1999). It has become increasingly clear that within the broad north–south gradient of prevalence there are significant local variations. For example in Enna, Sicily, the prevalence is 53 per 100 000 population, whereas in Malta at almost the same latitude it is 4 per 100 000 population. Similar discrepancies are found in Italy and Switzerland. These observations have led to the suggestion that local differences in genetic constitution may be influencing prevalence. A genome survey of European multiple sclerosis is currently addressing this question.

The most convincing evidence for a genetic effect comes from the studies of families. It has long been recognized that the risk of MS is increased in relatives of a proband. In Canada, the overall lifetime risk for MS is 0.2%, 3% for first-degree relatives and 1% for second-degree relatives (Sadovnick, 1994). The risk for adoptive children (Ebers et al., 1995) and marital partners (Robertson et al., 1997) is not increased, whereas the risk to children when both parents have multiple sclerosis is dramatically increased (Robertson et al., 1997). Large twin studies carried out in Canada and the UK have shown that the concordance rate in monozygotic twins is approximately 25% and in dizygotic twins and sibs 2%. These observations provide powerful support for the hypothesis that genetic factors are involved in determining susceptibility to multiple sclerosis, and (because approximately 75% of monozygotic twins are *not* concordant) for the implication of another factor (presumably environmental) as well.

What genes are involved? It is now nearly 30 years since the associations between MS and the HLA system were recognized (for review see Compston, 1999). It is tantalizing that the identity of the genes and their mode of action are still unclear. The field is confusing for the outsider, with different approaches (seeking association vs. linkage), different techniques (serological vs. cellular), conflicting reports, and periodic changes in terminology. Nevertheless, after a period in which little happened, progress is being made again.

The association between MS and *DR15* (formerly *DR2*) (encoded on the sixth chromosome) has been widely confirmed, including in three genome surveys conducted in the United States and France, Canada and the UK. Each of these investigations (and a smaller investigation in Finland) found indications for the involvement of genes on other chromosomes as well; there was however little consistency (for reviews see Compston, 1998, 1999). New surveys with more closely spaced markers are being conducted. A whole genome screen in the UK for association (the first of its kind) has shown four new associations, two of which coincide with previously identified regions of linkage (17q and 10p; S. Sawcer & A. Compston, personal communication). The probability of finding close association and linkage in the same region by chance alone must be low. This raises the possibility that these genes may indeed be involved in susceptibility to MS. Whether they are relevant in other populations remains to be seen. Looking at the evidence overall, it is clear that there is not a single gene which has a major effect on susceptibility to multiple sclerosis and it is probable that several genes with relatively small effects are involved.

A number of attempts have been made to see whether there are specific associations with particular forms of the disease. The only suggestive (albeit unconfirmed) association has come from Japan where MS is rare and more commonly takes the form of an optic–spinal illness than in Caucasians. The optic–spinal form there is associated with a haplotype different from that associated with the Caucasian form, the latter being the same as that commonly found in Northern Europe. There is no confirmed specific association with the primary progressive form of multiple sclerosis. A number of associations have been claimed to influence severity of course of disease (see Chapter 2), but a consistent picture has yet to emerge.

Symptomatology

The mean age of onset of MS is about 30 years and the illness is apporoximately twice as common in women as in men. The course is enormously variable. At one extreme rare cases are fatal in less than a year. At the other, occasional patients have little disability even after 50 years (benign MS; this term is often used to refer to patients with little disability after 10–15 years). Forty per cent of patients require assistance in walking after 15 years (Weinshenker et al., 1989). The median survival from onset is 28 years for men and 33 years for women (Bronnum-Hansen et al., 1994). The frequency of relapses varies widely, though on average it is approximately 0.8–1 per annum. Exceptionally, one, two or even three decades intervene between relapses. Relapses may be precipitated by intercurrent viral infection (Sibley et al., 1985) but the cause of the majority is not apparent.

MS commonly presents with weakness, tingling or numbness in the limbs, vertigo, double vision, unsteadiness or visual loss, reflecting the sites of predilection for lesions (plaques). Each of these features can first appear later in the course of the illness. Some manifestations are more common later. These include bladder and bowel disturbance (often progressing to incontinence), impotence and cognitive dysfunction; the latter is discussed in more detail below. The usual course of a relapse is for symptoms to develop over a matter of days, to persist for several weeks and to resolve gradually over a month or two.

Certain transient symptoms are characteristic of MS. The best known are Lhermitte's symptom (a surge of paresthesiae in the trunk and limbs on neck flexion) and thermolability. Many patients notice that their symptoms are reversibly increased by a hot bath, a hot meal or exercise and conversely that their symptoms are diminished by

a cool ambient temperature. Less commonly, patients may experience tonic spasms or episodes of ataxia. The latter often last a matter of seconds and may be repeated many times in an hour. Characteristically, these episodes are abolished by carbamazepine which is also effective in trigeminal neuralgia, a not uncommon manifestation of multiple sclerosis. Like other manifestations, it commonly occurs in episodes which tend to remit after several weeks. Overall, pain occurs in about one-half of patients and has a variety of causes including muscle spasm and lesions involving central pain pathways (Paty et al., 1997).

Disturbances of cortical function such as epilepsy and aphasia are rare, but well-documented, manifestations. Anosmia and deafness are other infrequent manifestations of the disease.

Clinically isolated syndromes

Three acute or subacute clinical syndromes: optic neuritis, brainstem disturbance and myelopathy, have attracted particular attention because they often herald the onset of MS. The most reliable predictor for the subsequent development of the established disease is the finding of clinically silent abnormalities on MRI scans of the brain at presentation, an observation which has been widely confirmed. In the longest follow-up to date, patients with these three syndromes were grouped together. After 10 years, 80–90% of those with additional abnormalities at presentation had developed multiple sclerosis, compared with 10–20% of those without such abnormalities (O'Riordan et al., 1998). The number and volume of the MRI abnormalities at presentation are predictive of the severity of disability later (Fillippi et al., 1994).

Cognitive and psychiatric abnormalities

There has been much progress in unravelling the cognitive and psychiatric manifestations of MS in the past decade. Accordingly, they are reviewed here at some length.

Cognitive impairment is subtle in patients with clinically isolated syndromes, and subjective symptoms are as a rule absent. Slowing of cognitive processing and impaired auditory attention were first reported in a group of patients with different clinical presentations (i.e. optic neuritis, brainstem or cord syndromes) who exhibited 'silent' MRI abnormalities in other brain regions (Callanan et al., 1989). These findings were later confirmed in a group of patients with optic neuritis who had white matter lesions elsewhere in the brain compared to those who did not (Feinstein et al., 1992b). In addition, impairment of working memory has been described in patients presenting with clinically isolated myelopathy (Pelosi et al., 1997). In this study event-related potential data suggested that both acquisition of memory traces and retrieval processes are impaired.

In patients with clinically definite multiple sclerosis (CDMS), cognitive abnormalities can be detected in 40 to 60% of patients and contribute significantly to the burden of disability (Rao et al., 1991b).

The pattern of cognitive abnormalities is characterized by a decline in intellectual ability, as measured by the difference between current and estimated premorbid IQ, and has been documented in 60% of CDMS patients attending hospital. In addition, memory and executive functions are often impaired to an extent that cannot be explained as a result of the general intellectual decline (Ron et al., 1991).

Impairment in memory tasks is characterized by poor recall, with better preserved recognition and normal forgetting (Rao et al., 1991a). This dissociation has also been reported in Huntington's disease and other conditions predominantly affecting subcortical structures. In some studies verbal memory appeared to be less impaired than visual memory (Ron et al., 1991). A dissociation between memory and attention deficits have been reported (Litvan et al., 1988), suggesting that the former are not a sufficient explanation for memory impairment, which is more likely to result from defective retrieval (Ryan et al., 1996).

Executive function deficits appear to be equally common. Impairment in working memory (Litvan et al., 1988; Grafman et al., 1990; Foong et al., 1997) has been described and may be partly due to decreased information processing speed (Demaree et al., 1999). Impairments in verbal fluency, use of strategy, planning and cognitive estimates have also been described (Foong et al., 1997), although not all executive functions are impaired to the same extent. Foong et al. (1997) have described relative preservation of planning ability with a pattern of deficits reminiscent of that found in HIV dementia, another white matter disease.

Language abilities have traditionally been considered to be spared by the disease, but Kujala et al. (1996) have described subtle abnormalities even in patients with mild cognitive impairment. These abnormalities, which involve semantic and circumlocutory naming errors, could not be explained as resulting from other cognitive abnormalities, which were often absent in this sample.

The natural history of these cognitive deficits is only partially understood. It is well established that cognitive deficits may remain static for many patients during the early stages of the disease (Hohol et al., 1997; Kujala et al., 1996,

1997). A 4-year follow-up study of patients with clinically isolated lesions (Feinstein et al., 1992b) found that cognitive deterioration had only occurred in those who had developed CDMS, and especially in those with secondary progressive disease. In such patients decline in auditory attention and visual memory were observed. Other follow-up studies (Amato et al., 1995) suggest that other deficits (i.e. linguistic disturbances and impaired abstract reasoning) emerge as the disease progresses, although the pattern of impairment varies from patient to patient.

The effects of relapses and remissions on cognitive ability are poorly understood. In a serial study testing patients every 2 weeks, performance on tests of attention and information processing speed declined only in those in whom there was an increase in MRI lesion load (Feinstein et al., 1993). In a group of patients tested during a relapse and again 6 weeks later Foong et al. (1998) described improvements in attention tasks only in those who were mildly impaired at the outset and in whom the volume of gadolinium-enhancing lesions diminished between tests. Memory impairment remained unchanged in all patients, suggesting that, for some patients, cognitive deficits, especially memory impairment, may be permanent.

Cognitive impairment tends to be more severe in those with secondary progressive disease (Ron et al., 1991; Patti et al., 1995; Amato et al., 1995), but cases of early severe cognitive impairment with only mild neurological disability are well documented (Fontaine et al., 1994). Cognitive decline cannot be fully explained as a result of fatigue or depression (Grossman et al., 1994). The pattern of cognitive abnormalities in patients with primary progressive disease does not differ significantly from that of patients with secondary progressive disease, and deficits in verbal memory, attention, verbal fluency and spatial reasoning have also been reported (Camp et al., 1999). Patients with primary progressive MS have been thought to have more severe cognitive deficits than those with secondary progressive disease (Comi et al., 1995), but this has recently been questioned (Foong et al., 2000).

Cognitive impairment has been found to correlate with MRI markers of disease, the most widely used of them being T2 lesion load (Ron et al., 1991), although even at best clinico-MRI correlations are only modest. The lack of neuropathological specificity of T2 abnormalities and the presence of pathology in the normal-appearing white matter (NAWM) probably account for the limited correlations. Other MRI parameters such as T1 lesion load and degree of brain atrophy may be better correlated with cognitive impairment, but reports are contradictory (Rovaris et al., 1998). Other techniques such as magnetization transfer and diffusion tensor imaging, sensitive indices of axonal and myelin integrity, may be more valuable in establishing the neuropathological substrate of cognitive deficits (van Buchem et al., 1998; Filippi et al., 2000; Rovaris et al., 2000).

Attempts to link regional MRI abnormalities (e.g. frontal lesion load) to specific cognitive deficits (e.g. executive functions) have met with variable success (Arnett et al., 1994; Foong et al., 1997) as could be expected in the presence of widespread, multiple lesions and generalized NAWM abnormalities. Strategically placed lesions may have severe cognitive consequences. This may be the case with lesions involving association fibres, especially in the prefrontal areas (Miki et al., 1998; Moriarty et al., 1999). Thus, the results of these studies point to the fact that the burden of the MS lesions, lesion location, severity of pathological damage in individual lesions, and the subtler changes in the NAWM contribute to cause cognitive impairment (Comi et al., 1999). Functional imaging studies hold greater promise to determine the common neural networks disrupted by lesions in different localizations. The PET study of Paulesu et al. (1996) goes some way towards achieving this aim. Decreased glucose metabolism in hippocampi and left thalamus was present in MS patients with memory impairment compared to those without. These changes in brain metabolism, which occurred in the absence of detectable temporal or thalamic lesions, may be caused by more distant or subtle pathology and are likely to represent the common substrate for these deficits. Another study by the same group (Blinkenberg et al., 2000) has found a significant correlation between reduction in cortical metabolism and total load of white matter lesions.

Psychiatric abnormalities in multiple sclerosis

Psychiatric morbidity is not increased in patients with clinically isolated syndromes (Logsdail et al., 1988), and there is little evidence that symptoms of depression or anxiety, without concomitant neurological symptoms or signs, are the presenting features of MS (Skegg et al., 1988). On the other hand, psychiatric morbidity is high in patients with CDMS. The prevalence of depression is close to 50% in hospital attenders (Ron & Logsdail, 1989); this is higher than in patients attending with non-neurological disability (due, e.g. to rheumatoid arthritis) and the lifetime risk of developing depression is of the same order (Sadovnick et al., 1996). A sevenfold increase in suicide has also been reported (Sadovnick et al., 1991).

The presence of depression is not closely related to the duration of illness, degree of disability or cognitive impairment, but may be commoner during relapses or when

neurological disability is progressive. It is uncertain whether there is a genetic predisposition to depression in these patients and while some studies have not found an increased risk for depression in first-degree relatives of depressed MS patients (Sadovnick et al., 1996) others have (Patten et al., 2000). Environmental factors, on the other hand, are clearly important in determining psychiatric morbidity. The degree of social stress and lack of support as perceived by the patients, correlates more closely with the presence of depression than other features of the illness or severity of MRI abnormalities (Ron & Logsdail, 1989).

The early report of increased incidence of depression in patients treated with interferon beta (IFNB Multiple Sclerosis Study Group, 1993) has not been confirmed (Borrás et al., 1999).

The increased rates of psychiatric morbidity in patients with MS and other brain diseases argues in favour of a causative role, although correlations with MRI lesion load have been disappointing (Ron & Logsdail, 1989; Pujol et al., 1997). Recent studies have focused on fronto-temporal circuits known to be relevant in depression and, as with cognitive impairment, a pattern is emerging (Pujol et al., 1997).

Bipolar affective disorder has been reported to occur more often in MS than in the general population (Schiffer et al., 1986), but this remains to be confirmed by appropriate epidemiological studies. A number of intriguing studies have suggested that unsuspected MS may be commoner than would be expected by chance in psychiatric inpatients (see review by McDonald & Ron, 1999).

Short-lived psychotic episodes with schizophrenic or affective symptomatology have also been described (Feinstein et al., 1992a), but they appear to be uncommon. These episodes occurred when neurological disability is well established and temporal lobe lesions appear to be particularly prominent in these patients. This is in marked contrast with the high incidence of schizophrenia-like psychosis in patients with metachromatic leukodystrophy (Hyde et al., 1992), suggesting that the age of onset of white matter disease (i.e. during childhood in the case of metachromatic leukodystrophy) may lead to very different psychiatric manifestations.

Euphoria is an uncommon symptom, best defined as a state of persistent cheerfulness without the motor overactivity of mania and is best considered as the type of personality change akin to that seen in patients with frontal lobe pathology. Its prevalence is around 10%, and is closely associated with the presence of brain pathology and cognitive impairment (Ron & Logsdail, 1989). Also recently, depression has been reported to be less frequent and quality of life less impaired in patients with loss of autobiographical memory (Kenealy et al., 2000). suggesting that even in patients without frank euphoria, specific cognitive deficits may have a mood elevating effect.

Pathological laughing and crying, an abnormal display of emotion not associated with the presence of depression occurs but is equally uncommon (Feinstein et al., 1997).

Pathology

The cardinal features of pathology in multiple sclerosis are (i) demyelination with relative preservation of axons; (ii) astrocytic gliosis; (iii) inflammation; and (iv) axonal loss. The latter, recognized by Charcot (1868) and repeatedly confirmed (Kornek & Lassmann, 1999) has achieved much prominence recently as it has become clear that it is an important factor determining disability. Remyelination occurs but is incomplete (for review see Prineas & McDonald, 2002).

The lesions of multiple sclerosis tend to be periventricular in distribution, though this orientation may be obscured in large, confluent lesions. Any part of the central nervous system can be affected, though there are certain sites of predilection, including the periventricular white matter, the optic nerves, brainstem and spinal cord.

In the past decade, the evolution of the new lesion has been subject to re-evaluation at two levels. First, the dynamics of the MRI visible lesions have been revealed by serial gadolinium-enhanced MRI (for review see Smith & McDonald, 1999). The earliest detectable damage in the majority of lesions in patients with relapsing–remitting and secondary progressive multiple sclerosis is an increase in permeability in the blood–brain barrier in association with inflammation. Demyelination detected by magnetic resonance spectroscopy (MRS) and by delay in evoked potentials occurs at about the same time. In some lesions, it may precede the appearance of gadolinium enhancement. Inflammation and edema resolve over 4–8 weeks. In primary progressive MS, however, only approximately 5% of new lesions enhance (Thompson et al., 1991), in keeping with the observation of a significantly lower level of inflammation at postmortem in primary progressive multiple sclerosis than in secondary progressive disease (Revesz et al., 1994).

It is important to realize that occasional cases classified as primary progressive multiple sclerosis for a number of years may experience a clear-cut relapse, a fact which serves to underline the difficulty of identifying homogeneous subgroups of cases in multiple sclerosis. This difficulty is further enhanced by the fact that patients may

Table 98.1. Histopathological features of different patterns of active multiple sclerosis lesions

	Type I	Type II	Type III	Type IV

forget minor episodes of neurological disturbance which may have preceded by many years the onset of progressive disease. Thus, caution must be exercised in associating particular kinds of lesion with particular patterns of clinical expression. This consideration is relevant to the oft-raised question as to whether multiple sclerosis is more than one disease, and in particular whether primary progressive multiple sclerosis is a specific entity. The failure to identify confirmed specific genetic associations further weakens the case. At present the question remains open.

The second approach to the evolution of the lesion, is histopathological. On the basis of the study of a large number of biopsied lesions and lesions observed at postmortem, Lassmann and his colleagues (Lucchinetti et al., 2000) have postulated that there are four types of lesion (see below and Table 98.1). This has led to the suggestion that there may be four distinct pathogenetic routes by which the classical multiple sclerosis plaque seen at postmortem may arise. How these mechanisms relate to the various clinical patterns of disease remains to be determined.

Pathogenesis and the immunology of multiple sclerosis

The most widely held view of the nature of multiple sclerosis is that it is an organ-specific autoimmune disease (Martin & McFarland, 1995), the hypothetical pathogenesis of which is summarized in Fig. 98.1. The central tenet of the autoimmune theory is that MS is mediated by antigen-specific autoreactive T-cells. Putative autoantigens implicated in MS include the myelin proteins: myelin basic protein (MBP), proteolipid protein (PLP), myelin associated glycoprotein (MAG), and myelin oligodendrocyte glycoprotein (MOG); other potential non-myelin autoantigens include transaldolase, 2′3′-cyclic nucleotide 3′-phosphodiesterases, and αB-crystallin (Steinman, 1995). These antigens, peptides derived from these antigens or the adoptive transfer of specific T-cells reactive to these antigens are capable of inducing experimental allergic encephalomyelitis (EAE), a model of MS, in several animal species (Petry et al., 2000). MS patients have myelin-reactive T-cells in their peripheral circulations that are clonally enriched in MS plaques (Oksenberg et al., 1993). Although

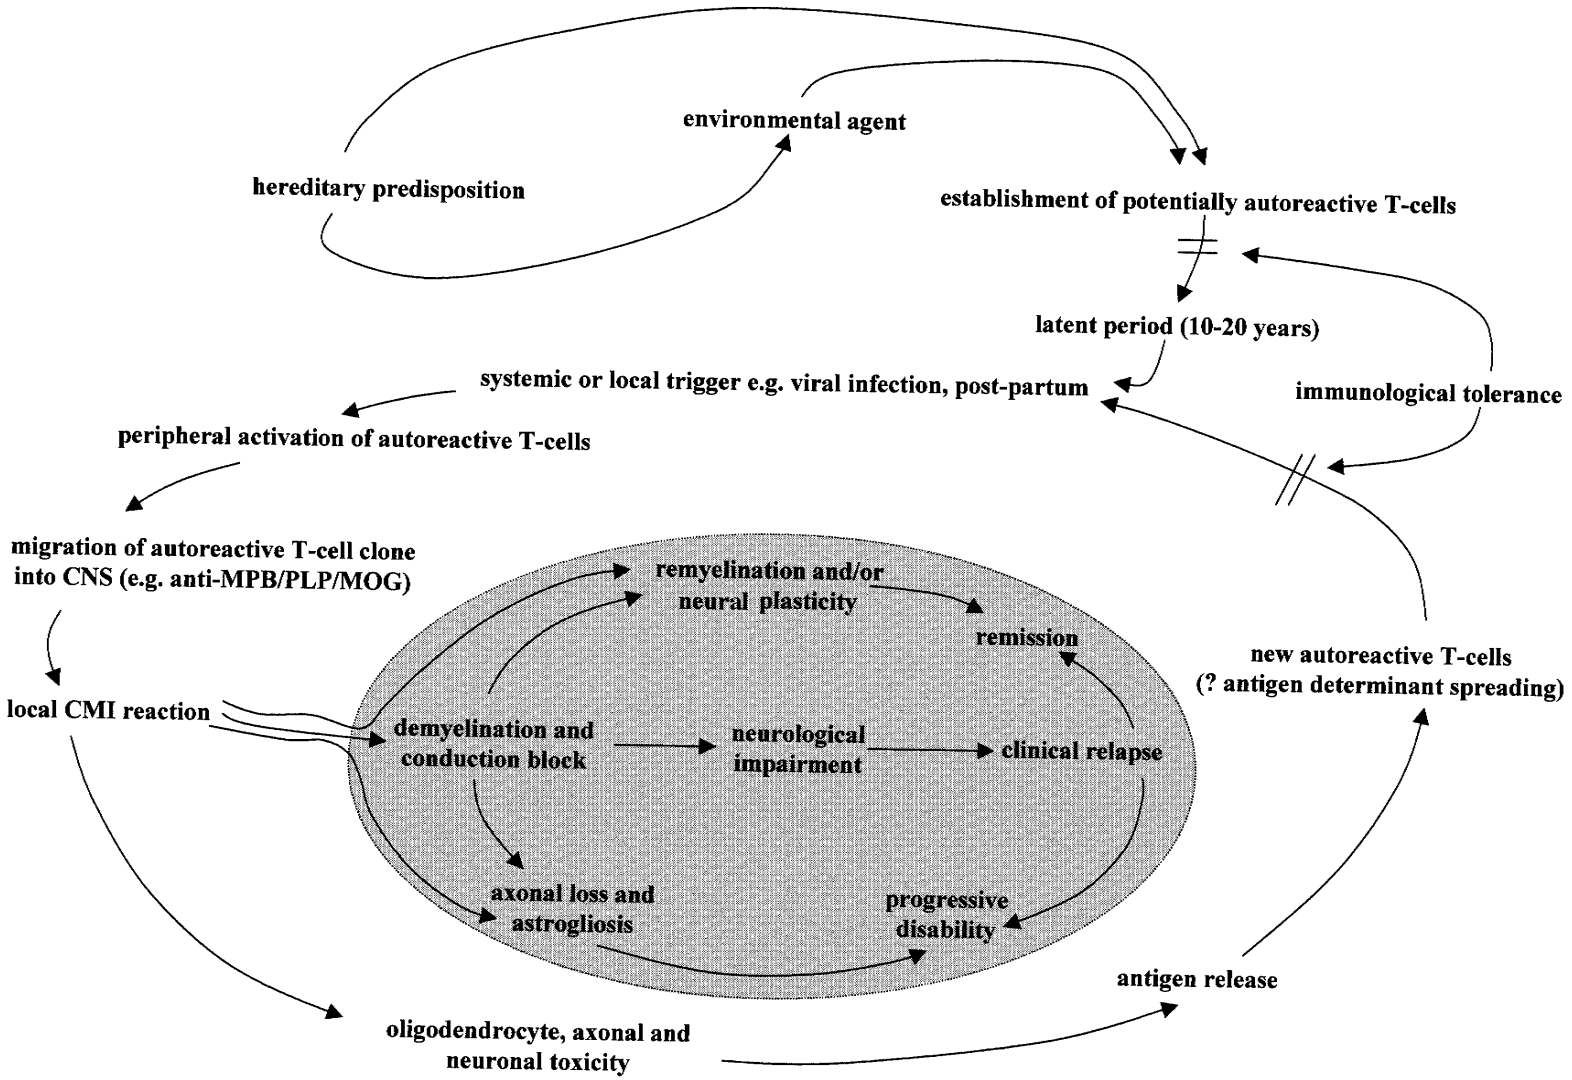

Fig. 98.1. Hypothetical scheme for the pathogenesis of multiple sclerosis. In subjects with a genetic susceptibility, childhood exposure to a putative environmental trigger or triggers induces autoreactive T-cells, which establishes a state of latent autoimmunity with the potential to develop disease. After a period of latency (Wolfson & Wolfson, 1993), estimated to be 10–20 years, a systemic trigger such as a viral infection activates these autoreactive T-cells, possibly as a consequence of molecular mimicry (Gran et al., 1999). Another possibility is exposure to a superantigen, which is capable of non-specifically activating a subset of T-cells. Once activated, these T-cells selectively cross the blood–brain barrier and on re-exposure to their autoantigen initiate a cell-mediated (Th1) inflammatory reaction. The resultant cell-mediated inflammatory cascade results in demyelination and axonal damage. Sequestered CNS antigens, which are then released are hypothesized to initiate further episodes of autoimmune-induced inflammation, by the process of intra- or intermolecular antigenic spreading. Events within the shaded oval represent the clinical correlates of the multifocal inflammatory reaction, which occurs in MS

auto-reactive T-cells are demonstrable in normal subjects, they probably occur at a lower frequency, their T-cell receptor (TCR) usage is generally not restricted and they are less likely to have undergone in vivo activation and proliferation compared to T-cells from MS patients (Hafler et al., 1996; Allegretta et al., 1990; Trotter et al., 1997). Despite these findings it remains a moot point whether or not these autoreactive T-cells are primarily involved in the pathogenesis of MS or occur as a secondary or non-specific phenomenon in response to tissue damage.

Evidence against the autoimmune theory has been the failure of multiple sclerosis to respond, except to a minor degree, to anti-T-cell therapies, including azathioprine (Yudkin et al., 1991), cyclosporin (The Multiple Sclerosis Study Group, 1990) and a depleting anti-CD4 monoclonal antibody (van Oosten et al., 1997). The failure of these therapies in multiple sclerosis should be contrasted with their striking efficacy in EAE and in allogenic solid organ transplant rejection, disorders in which antigen-specific T-cell involvement is well established. It has also not been possible passively to transfer multiple sclerosis to nude mice, i.e. mice lacking an immune system, using autoreactive T-cells derived from MS patients (Hao et al., 1994; Martino et al., 1994; Jones et al., 1995). The clinical observation that the disease course of MS is worsened by immunodeficiency due to HIV-1 Infection (Berger et al., 1989) also questions the role of T-cells in the pathogenesis of the disease. This evidence, however, is based on a very small number of cases and is therefore not conclusive and does not exclude specific T-cell involvement early in the course of the disease.

The immunological events, which are thought to occur within an individual MS lesion, are summarized in Fig. 98.2. Although current evidence supports MS as a disease mediated by Th1–CD4+ $\alpha\beta$T-cells (Martin & McFarland, 1995; Hohlfeld, 1997), additional cell types including CD8+ T-cells (Babbe et al., 2000), $\gamma\delta$T-cell (Borsellino et al., 2000), natural killer (NK) cells (Pouly & Antel, 1999), and B-cells (Archelos et al., 2000) are found in MS lesions have all been implicated in the disease process. CD8+ T-cells, $\gamma\delta$T-cells and natural killer (NK) cells are capable of producing potent cytotoxic mediators, granzyme and perforin, and may be actively involved in the disease process.

The intrathecal synthesis of oligocloncal IgM and IgG is an almost invariable feature of MS in Caucasians (McLean et al., 1990). The site of antigen specific B-cell ontogeny is presumed to be in the deep cervical lymphatics, although secondary lymphoid-like follicles have been seen within MS lesions (Prineas, 1979). Genomic analysis of immunoglobulin heavy chain sequences from MS lesions shows that the variable region IgG preferentially accumulates mutations in the complementary-determining regions relative to framework regions of the molecule (Smith-Jensen et al., 2000). This is a feature of a T-cell dependent antigen-driven response, which also occurs in central nervous system infections, e.g. subacute sclerosing panencephalitis (SSPE) (Smith-Jensen et al., 2000). Autoantibodies, such as anti-MOG are found in the CSF of MS patients and are capable of binding to the myelin and activating complement (Raine et al., 1999).

The focal inflammatory infiltrates produce a host of pro-inflammatory cytokines and non-specific mediators, which are responsible for tissue damage. However, these inflammatory cells are also capable of producing growth or trophic factors which may play a role in the process of tissue repair and remyelination (Hohlfeld et al., 2000). For example, brain-derived neurotrophic factor (BDNF), produced by T-cells, B-cells, macrophages and microglia, is expressed in MS lesions (Kerchensteiner et al., 1999). Similarly, insulin-like growth factor-1 (IGF-1), a survival factor for oligodendrocytes, IFG receptors and receptors for glial growth factor 2 (GGF2), which promote the proliferation and survival of the oligodendrocyte, are up-regulated in MS lesions. Antioxidants, particularly glutathione produced by astrocytes, have an important neuroprotective role in inflammatory CNS diseases (Heales et al., 1999).

As mentioned above, recent work suggests that there may be four distinct routes leading to the demyelinated plaque (see Table 98.1, Lucchinetti et al., 2000). The pathological subtypes appear to be associated with different immunological mechanisms involving antibodies, complement, T-cell cytotoxicity, and macrophage activation. Whether or not these pathological subtypes represent different stages of the disease or autoimmune or toxic/viral variants is speculative and is currently under investigations.

The immunological mechanisms underlying disease progression and the clinical or phenotypic spectrum of MS are unknown. Current proposals include failure of reparative and neuroprotective mechanisms, an imbalance between the Th1 and Th2 cell-mediated immune responses, dysregulated T-cell function, reduced T-cell apoptosis, antigen determinant spreading, pathological heterogeneity, and genetic differences responsible for tissue repair and/or protection against tissue damage. The specific role inflammation plays in disease progression is not well defined.

Immunosuppressive therapies, which are capable of reducing or stopping clinical relapses and suppressing MRI activity, generally do not stop disease progression.

The epidemiological evidence for an infective factor in the etiology of MS has already been mentioned (Kurtzke,

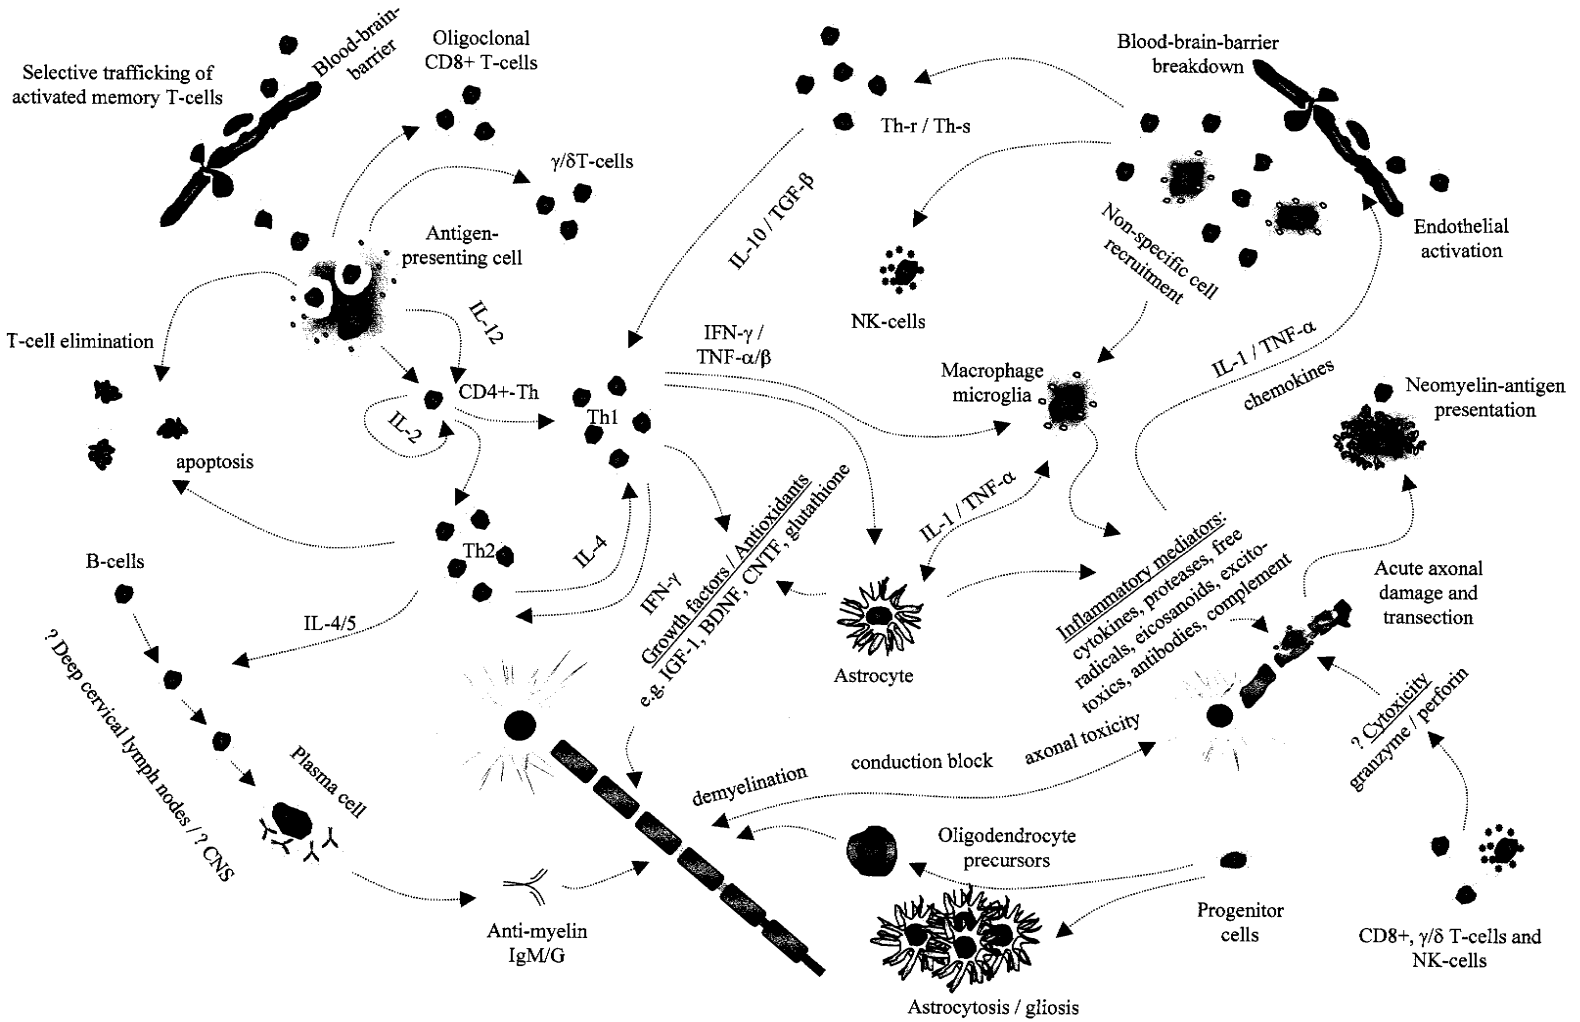

Fig. 98.2. Postulated local mechanisms of inflammation in MS. Activated $CD4^+$ and $CD8^+$ T-cells cross the blood–brain barrier selectively via the interaction of their cell surface adhesion molecules with those expressed on the central nervous system endothelium (Archelos et al., 1999). The T-cells then negotiate a path through the basement membrane and extracellular matrix, by secreting several metalloproteinases (Kieseier et al., 1999). Once within the perivascular space, these cells are activated by professional antigen presenting cells (probably macrophages or microglia). The T-cells then proliferate and produce cytokines. The profile of T-cell cytokines produced depends on the costimulatory signals received during activation (Racke et al., 2000). IL-12 favours Th-1 development and cytokine production (IL-2, IFNγ and TNFα/β). This initiates a classical cell-mediated inflammatory cascade, which activates macrophages, microglia, astrocytes and endothelial cells. Once activated, macrophages/microglia and astrocytes also produce proinflammatory cytokines, which recruit more inflammatory cells by the up-regulation of endothelial cell adhesion molecules and the production of chemokines. A host of toxic substances, including reactive oxygen (superoxide, hydrogen peroxide and the hydroxyl radical) and nitrogen (nitric oxide, peroxynitrite) species, proteases, eicosanoids, excitotoxic factors (kynurenic and quinolinic acid), which in combination with autoantibodies, complement activation and toxic effects of cytokines (particularly TNFα) cause oligodendrocyte cell damage or death by apoptosis with resultant demyelination. These local factors may also be responsible for axonal toxicity and damage and be capable of causing axonal transection (Trapp et al., 1999). Immunomodulatory cytokines (IL4, IL10 and TGFβ) produced by regulator/suppressor (Th-r/Th-s) and Th2 T-cells, growth factors and antioxidants may be important in down-regulating and controlling the inflammation, neuroprotection and stimulating repair.

1993). Numerous candidate organisms have been unsuccessfully implicated as the cause of MS (Johnson, 1994). Epstein–Barr virus (EBV) (Munch et al., 1997), human-herpes-virus-6 (HHV6) (Berti et al., 2000) and the MS-associated retroviruses (Perron et al., 2000) remain potential candidates. The autoimmune and infectious theories are not mutually exclusive and are potentially complementary. For example, following on the acute encephalitic phase of murine Theiler's virus infection, susceptible strains of mice develop an autoimmune demyelinating disease of the CNS, which is not too dissimilar pathologically from MS (Miller et al., 1997). Systemic infection also plays an important role in the induction of acute MS disease activity, presumably via a non-specific stimulation of the immune system. A third of clinical relapses follow an acute viral or bacterial infection (Sibley et al., 1985; Rapp et al., 1995).

In summary, MS is an inflammatory disease of the CNS with evidence of organ-specific cell-mediated autoimmunity directed at myelin components. Whether it is a true 'autoimmune disease' remains to be established. An infectious etiology cannot be excluded. Recent pathological evidence supports disease heterogeneity.

Pathophysiology

The mechanism of symptom production in MS has interested neurologists since the time of Charcot (1868). Experimental work since the 1960s together with the application of evoked potentials to the study of MS since the 1970s and the use of serial MRI since the 1990s, has revealed the probable mechanisms of many of the manifestations of MS; this despite the well-known (though explicable) discrepancies between clinical deficit and hyperintensities on T_2-weighted images. The whole subject has been comprehensively reviewed recently (Smith & McDonald, 1999).

The loss of function occurring in a relapse is a consequence of conduction block which develops partly because of the altered biophysical properties of the nerve fibre, and partly through the action of inflammatory mediators on the process of conduction. There is experimental evidence that nitric oxide, which is produced by macrophages which are abundant in the acute lesion, is implicated. The role of other inflammatory mediators remains to be determined.

Two major factors have so far been identified in the process of remission: resolution of inflammation and the acquisition of the ability of the demyelinated axons to conduct as a result of the insertion of new sodium channels into the denuded axon membrane. Although conduction in these circumstances is an order of magnitude slower than normal, clinical recovery is remarkably good. The usual persistence of conduction delays in adults, despite recovery of function, provides the basis for the use of the evoked potential to detect clinically silent lesions during diagnostic evaluation (Chapter 99). To the extent that remyelination occurs (Chapter 97) it will contribute to the recovery process.

The demyelinated axon has a number of other properties, which help to explain some of the characteristic features of MS. The exquisite vulnerability of conduction in the demyelinated axon to small changes in temperature (a rise of as little as 1 °C can convert intermittent conduction block into persistent conduction block) is likely to contribute to the effect of changes in body temperature on symptoms. The inability of demyelinated axon to conduct long trains of impulses faithfully at physiological frequencies probably contributes to functional impairment, and may contribute to fatigue, though the pathophysiology of this common and often disabling symptom remains to be elucidated fully.

The cerebral cortex in MS

There has recently been renewed interest both in the structure and the function of the cerebral cortex in MS. It has long been known that cortical plaques occur; they are in fact common (Kidd et al., 1999). It is also possible that there are secondary effects on cortical organization deriving from neuronal loss consequent upon axonal degeneration. This is perhaps particularly likely in the visual cortex, given the high frequency of involvement of the visual pathways in MS and the propensity for transynaptic degeneration in the visual symptom. By the same token, changes might also be expected in the retina. These possibilities have yet to be investigated. Clinically, little attention has been given to the contribution of high-level deficits (e.g. apraxia) to disability.

The importance of axonal degeneration in MS raises the question of whether adaptive changes might contribute to functional recovery. That they do so in stroke and are associated with changes in the pattern of cortical activation has been demonstrated by functional imaging (Weiller et al., 1993). Recent fMRI observations provide evidence for extensive changes in the pattern of cortical activation in patients who have recovered clinically from optic neuritis, but still have delayed VEPs. Numerous extrastriae visual areas are activated by a stimulus which normally produces activation confined to the occipital cortex (Werring et al.,

2000). These changes appear to be absent from those with normal latencies. These observations require confirmation. Similar changes have been observed in the motor system (Lee et al., 2000). Whether and to what extent the cortical changes contribute to remission from relapses, and whether they may help to retard the accumulation of neurological deficit in the continuously progressive phase of the disease, remains to be determined.

The diagnosis and management of multiple sclerosis

David H. Miller and Alan J. Thompson

Institute of Neurology, London, UK

The 1990s have seen significant progress in both the diagnosis and management of multiple sclerosis (MS). The widespread use of magnetic resonance imaging (MRI) has enabled an earlier and more accurate diagnosis in many instances. An increasing range of effective strategies for symptom management have evolved as has the widespread introduction of partially effective disease modifying therapies. This chapter summarizes current approaches to diagnosis and management. As MS remains a disabling disease of unknown cause, the chapter concludes with a brief discussion of potential future therapeutic strategies.

Diagnosis

General requirements

The diagnosis of MS is based primarily on clinical features, but in the presence of a characteristic clinical picture, there is a number of laboratory investigations that are very helpful in supporting the diagnosis. The most widely used diagnostic criteria of recent decades have been those of Schumacher et al. (1965) and Poser et al. (1983). These have emphasized the requirement for there to be a history of multiple episodes separated in time, and signs on examination of multiple lesions affecting different parts of the central nervous system (CNS) white matter. Both sets of criteria have applied categories of definite, probable and possible MS, based largely on the completeness for the evidence for dissemination in time and space. An age range at diagnosis of 10–59 years is suggested, although rarely presentation will be seen at a younger or older age. There must be no better explanation for the clinical presentation. The Poser criteria added the results of laboratory investigations to increase diagnostic certainty. Thus, the presence of oligoclonal IgG bands in the cerebrospinal fluid (CSF) but not serum (indicating intrathecal production) could upgrade the diagnosis from clinically probable to laboratory supported definite MS. The presence of clinically silent lesions on MRI or evoked potential testing could be used, along with clinical signs of a single CNS lesion, to satisfy the criterion of dissemination in space.

The Poser criteria were formulated in 1982, when experience with MRI was limited. A new set of criteria incorporating the progress of the last two decades has been recommended by an International Panel in 2001 (McDonald et al., 2001; Tables 99.2–99.4). They represent a considerable simplification in the diagnostic classification. The outcome of a diagnostic evaluation is now 'MS', 'possible MS', or not MS.

Common clinical presentations: relapsing remitting MS

In 85% of patients, the presentation of MS is with episodes of acute and reversible neurological disturbance (relapses and remissions) affecting CNS white matter. Clinically definite MS (or MS on the new criteria) on the Poser criteria is diagnosed when there are at least two episodes, each lasting at least 24 hours and separated in time by at least 1 month, with signs on examination of involvement of two separate parts of the CNS. Relapses will normally last for longer, a typical duration being 2–6 weeks. Many clinicians will also feel more comfortable making a definite diagnosis only when the interval between the two episodes is longer than 1 month, e.g. 3 or 6 months, because the monophasic demyelinating disorder acute disseminated encephalomyelitis, although in practice a much rarer disorder in adults, can occasionally evolve over 1–2 months.

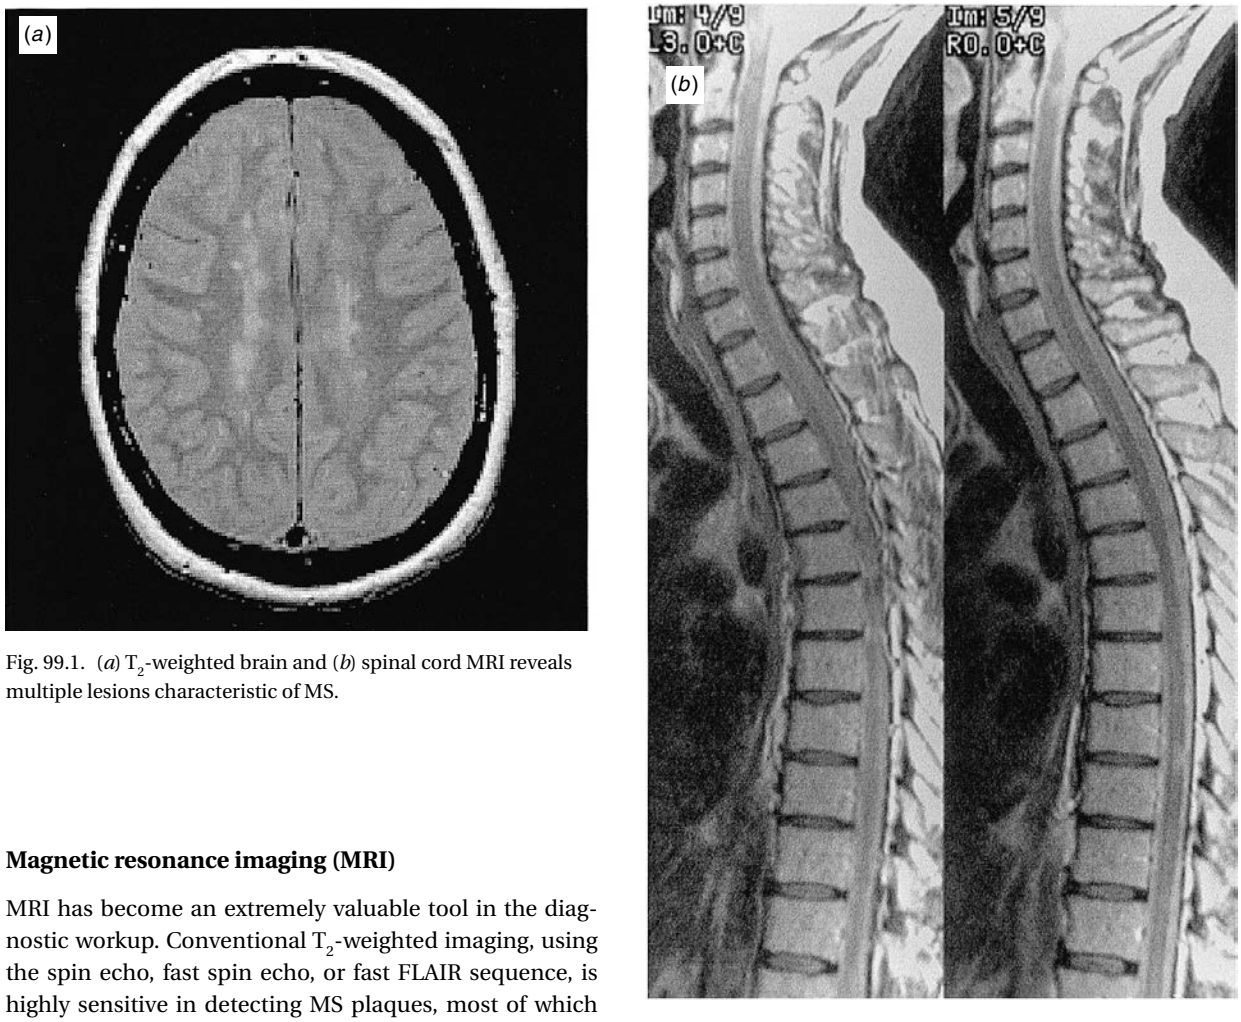

Fig. 99.1. (*a*) T_2-weighted brain and (*b*) spinal cord MRI reveals multiple lesions characteristic of MS.

Magnetic resonance imaging (MRI)

MRI has become an extremely valuable tool in the diagnostic workup. Conventional T_2-weighted imaging, using the spin echo, fast spin echo, or fast FLAIR sequence, is highly sensitive in detecting MS plaques, most of which are clinically silent. Brain MRI is abnormal in 95% of patients with clinically definite MS, and spinal cord MRI reveals lesions in about 75%; together, one or other region will reveal abnormalities in all but a very small number of patients (Fig. 99.1). MRI assists the diagnosis by demonstrating disseminated white matter lesions in space, but also by showing a profile of abnormalities that are characteristic of demyelination. Such characteristic features include the following: predominantly periventricular lesions with asymmetrical and irregular involvement; oval or round shaped lesions; corpus callosum involvement, lesions abutting the corticomedullary junction; brainstem lesions especially in the floor of the fourth ventricle or abutting the subarachnoid surface; gadolinium enhancement for the first few weeks of a lesion's appearance but not thereafter; nodular or ring shaped enhancement sometimes with an open (incomplete) ring; spinal cord lesions of less than 1–2 vertebral segments in length, with partial cross-sectional involvement, often wedge shaped and extending to the subarachnoid surface on axial images.

Despite these helpful features, specificity of MRI is limited and there are many other conditions, which produce white matter lesions (Table 99.1). Sometimes the clinical picture or pattern of MRI abnormalities are clearly such that MS is not part of the differential diagnosis. MRI diagnostic criteria have been developed to improve specificity (Barkhof et al., 1997; Fazekas et al., 1999; Tintoré et al., 2000). Nevertheless, no MRI finding is pathognomonic of MS, and diagnosis remains primarily clinical. A particular problem is that ageing *per se* produces cerebral white matter lesions due to small vessel disease; brain MRI is therefore least specific in older adults. Age-related lesions do not occur in the cord: MRI of this region is especially useful in older patients, or when brain imaging results are normal (Thorpe et al., 1996).

Table 99.1. Causes of white matter lesions on MRI

Common causes	Ageing (small vessel disease)
	Symptomatic cerebrovascular disease
	Multiple sclerosis
Less common	Acute disseminated encephalomyelitis
	Behçet's disease
	Decompression sickness
	Fat embolism
	HIV encephalitis
	HTLV-1 associated myelopathy
	Hydrocephalus
	Irradiation
	Isolated CNS vasculitis
	Leukodystrophies (many types)
	Migraine
	Mitochondrial encephalopathy
	Neurosarcoidosis
	Phenylketonuria
	Progressive multifocal leukoencephalopathy
	Subacute sclerosing panencephalitis
	Systemic lupus erythematosus
	Toxic leukoencephalopathy (several causes)
	Trauma
	Whipple's disease

Evoked potentials

These investigations include visual, brainstem auditory, somatosensory and motor evoked potentials. They are useful, like MRI, in demonstrating subclinical involvement of CNS fibre pathways, or in demonstrating objective CNS abnormality when the clinical features are equivocal. They are less sensitive than MRI and less often required in diagnostic workup. They are most useful when MRI findings are equivocal or negative or in older individuals when brain MRI is least specific. The visual evoked potential is the most useful in practice, and has been incorporated into the new diagnostic criteria (McDonald et al., 2001; Table 99.2). The characteristic abnormality in demyelination is a prolonged latency response with a well-preserved wave form.

CSF examination

The CSF exhibits a mild mononuclear pleocytosis (5–30 cells per mm^3) and mildly raised protein in 40% patients. Intrathecal oligoclonal IgG bands (i.e. not seen in matching serum), occur in 90% with clinically definite MS. CSF examination is most useful when the clinical and MRI findings are equivocal or in older individuals when brain MRI is less specific.

Other investigations

Other multifocal disorders, which produce relapsing CNS syndromes, need to be considered. Blood tests include a full blood count, ESR and autoantibody screen (thinking of SLE or vasculitis), borrelia and treponemal serology. In SLE, white matter lesions often have a subcortical predominance. Sometimes neurosarcoidosis is considered and may lead to chest X-ray, serum ACE, and neuro-ophthalmology assessment; gadolinium-enhanced MRI may reveal meningeal enhancement which is not a feature of MS. If the question of neuro-Behçet's disease arises, CRP and neuro-ophthalmology assessment may be performed; the most common parenchymal CNS syndromes in Behçet's disease involve the brainstem and diencephalon, and striking MRI abnormalities may occur in these regions. MS with prominent and permanent visual loss due to optic neuropathy may lead to a search for the mitochondrial DNA point mutations associated with Leber's disease; the coexistence of Leber's optic neuropathy and MS is rare but well recognized, especially in females (Harding et al., 1992).

Primary progressive MS

In 15% of patients, onset is with a slowly progressive CNS syndrome (primary progressive MS). Most often this is a progressive myelopathy with spastic paraplegia (80%); rarer presentations include progressive ataxia, dementia or visual loss. Because of the progressive and often unifocal onset, the diagnostic criteria used for relapsing remitting MS are less satisfactory. In cases of progressive myelopathy, spinal MRI is mandatory to exclude a surgically treatable compressive lesion or spinal arteriovenous malformation. The differential diagnosis also includes other intrinsic myelopathies including HTLV-1 associated myelopathy, hereditary spastic paraplegia, motor neuron disease, and adrenomyeloneuropathy. The most useful investigations for a diagnosis of primary progressive MS are brain and cord MRI, CSF examination for oligoclonal bands and, in the case of progressive myelopathy, visual evoked potentials. New diagnostic criteria have been published based on clinical and laboratory findings (Thompson et al., 2000; McDonald et al., 2001; Table 99.2). For a definite diagnosis, these require the presence of CSF oligoclonal bands plus the following MRI findings: *either* 9 brain lesions *or* 2 spinal cord lesions *or* 4–8 brain lesions plus one spinal cord lesion.

Clinically isolated syndromes (CIS)

A particularly important diagnostic issue arises in adult patients who present with a CIS, which is typical of MS, e.g.

Table 99.2. New criteria for diagnosis of MS

Clinical presentation	Additional data needed for MS diagnosis
Two or more attacks; objective clinical evidence of two or more lesions	• None[a]
Two or more attacks; objective clinical evidence of one lesion	• Dissemination in space, demonstrated by: → MRI[b] or → 2 or more MRI-detected lesions consistent with MS plus positive CSF[c] or → Await further clinical attack implicating a different site
One attack; objective clinical evidence of two or more lesions	• Dissemination in time, demonstrated by: → MRI[d] or → Second clinical attack
One attack; objective clinical evidence of one lesion (monosymptomatic presentation; clinically isolated syndrome)	• Dissemination in space, demonstrated by: → MRI[b] or → 2 or more MRI-detected lesions consistent with MS plus positive CSF[c] and • Dissemination in time, demonstrated by: → MRI[d] or → Second clinical attack
Insidious neurological progression suggestive of MS	• Positive CSF[c] and • Dissemination in space, demonstrated by: → (i) Nine or more T_2 lesions in brain; or (ii) two or more lesions in spinal cord or (iii) four to eight brain plus one spinal cord lesion or → abnormal VEP[e] associated with four to eight brain lesions, or with fewer than four brain lesions plus one spinal cord lesion demonstrated by MRI and • Dissemination in time, demonstrated by: → MRI[d] or → Continued progression for 1 year

Notes:
If criteria indicated are fulfilled, the diagnosis is MS; if the criteria are not completely met, the diagnosis is 'possible MS'; if the criteria are fully explored and not met, the diagnosis is 'not MS'.

[a] No additional tests are required; however, if tests (MRI, CSF) are undertaken and are NEGATIVE, extreme caution needs to be taken before making a diagnosis of MS. Alternative diagnoses must be considered. There must be no better explanation for the clinical picture.

[b] MRI demonstration of space dissemination must fulfil the criteria in Table 99.3.

[c] Positive CSF determined by oligoclonal bands detected by established methods (preferably isoelectric focusing) different from any such bands in serum or by a raised IgG index.

[d] MRI demonstration of time dissemination must fulfil the criteria in Table 99.4.

[e] Abnormal visual evoked potential of the type seen in MS (delay with a well-preserved wave form).

unilateral optic neuritis, or a partial myelitis. The traditional Schumacher/Poser criteria do not allow a diagnosis of MS until a second clinical episode has occurred. However, it is now clear that many of these patients will develop clinical MS and that MRI findings at presentation identify those most likely to do so. About two-thirds of patients with CIS already have disseminated brain lesions indistinguishable from MS. Follow-up for up to 10 years shows that most of this group (80–90%) will develop MS, whereas only 10–20% with normal brain imaging will do so (O'Riordan et al., 1998). Specific MRI features which increase the likelihood of early development of MS (within 3 years) are 4 or more periventricular lesions, gadolinium-enhancing lesions, corticomedullary junction lesions and infratentorial lesions (Barkhof et al., 1997). The presence of new lesions on a follow-up scan 3 months after presentation with a CIS and an abnormal initial scan have been associated with an increased likelihood of developing clinical MS within 1 year (Brex et al., 2001). Serial MRI in patients with CIS can satisfy the criteria for dissemination in space and time, and have been incorporated in the new diagnostic classification (Tables 99.2–99.4).

Table 99.3. MRI criteria for dissemination in space

Three out of four of the following:
(i) One gadolinium-enhancing lesion or nine T_2 hyperintense lesion if there is no gadolinium-enhancing lesion
(ii) At least one infratentorial lesion
(iii) At least one juxtacortical lesion
(iv) At least three periventricular lesions

Note:
One spinal cord lesion can substitute for one brain lesion
Source: From McDonald et al. (2001).

Table 99.4. MRI criteria for dissemination of lesions in time

(i) If a first scan is 3 or more months after the onset of the clinical event, the presence of a gadolinium-enhancing lesion is sufficient to demonstrate dissemination in time, provided that it is not at the site implicated in the original clinical event. If there is no enhancing lesion at this time, a follow-up scan is required. The timing of this follow-up scan is not crucial, but 3 months is recommended. A new T_2 or gadolinium-enhancing lesion at this time then fulfils the criterion for dissemination in time.
(ii) If the first scan is performed less than 3 months after the onset of the clinical event, a second scan done 3 months or more after the clinical event showing a new gadolinium-enhancing lesion provides sufficient evidence for dissemination in time. However, if no enhancing lesion is seen at this second scan, a further scan not less than 3 months after the first scan that shows a new T_2 lesion or an enhancing lesion will suffice.

Acute disseminated encephalomyelitis (ADEM)

This is monophasic but multifocal demyelinating CNS disorder, which arises in the differential diagnosis when patients present with a first clinical episode of CNS demyelination. It is common in children but rare in adults, the reverse of MS. It is often seen following infections and occasionally after vaccinations. Clinical features more typical of ADEM are obtundation, bilateral optic neuritis and complete transverse myelitis. CSF sometimes shows a marked pleocytosis (e.g. $>$100 white cells per mm^3). MRI findings may be indistinguishable from MS or sometimes show a more distinctive pattern with symmetrical lesions in the cerebellar peduncles and cerebral white matter; on follow-up the MRI lesions show partial or complete resolution and new lesions do not appear, unlike MS where new lesions are frequently found.

Devic's neuromyelitis optica

This is a syndrome in which a combination of optic neuritis and a severe myelitis are seen without clinical involvement of other CNS regions. It may be monophasic or multiphasic. Several clinical, laboratory and pathological features appear to distinguish it from classical relapsing remitting MS (Wingerchuk et al., 1999): a complete transverse myelitis, with sometimes poor recovery; relatively more common in non-Caucasian ethnic groups; brain MRI often normal; spinal cord MRI exhibits extensive lesions over many segments with swelling during the acute phase; CSF may exhibit a neutrophil pleocytosis and is often negative for oligoclonal bands; pathologically, the cord lesions may exhibit necrosis. It is a syndrome with several specific causes (e.g. SLE, ADEM) but in most cases a cause is not identified.

Management

Symptomatic treatment

The wide range of symptoms commonly seen in multiple sclerosis (MS) has already been discussed. It is relevant in this section to emphasize that in many patients some, if

not all, of these symptoms coexist and interact, resulting in complex disability which is often extremely difficult to manage (Thompson, 1998; Leary & Thompson, 2000). Furthermore, drug therapy for one symptom may aggravate another, e.g. the treatment of spasticity or pain with agents may worsen existing fatigue. This complexity argues for a comprehensive and carefully constructed management plan that is specific to the individual patient's needs. This is incorporated within the rehabilitation philosophy, which will be discussed later. In the approach to individual symptoms, it is almost invariably necessary to combine a number of key elements:

(i) education and information for the patient
(ii) therapy input (physiotherapy, occupational therapy, speech and language therapy, etc.)
(iii) drug treatment

Although this section will focus on the third of these essential components, it is important to appreciate that drugs in isolation are very limited in the treatment of common, disabling symptoms such as spasticity and ataxia (Kesselring & Thompson, 1997). It is also sobering to reflect on the paucity of evidence available to support the majority of agents in current clinical use and to underline the need for scientifically sound trials in the area of symptomatic management.

Of the variety of symptoms seen in MS, many, such as spasticity, ataxia, poor balance and sensory disturbance, affect mobility. However, from the patient's perspective, the most disabling symptoms are fatigue and bladder dysfunction, both of which may also limit mobility. Other symptoms, which have, until recently, been underreported, include pain and cognitive dysfunction. Temperature-related symptoms are also both common and disabling, as are bowel and sexual dysfunction. Finally, visual and bulbar symptoms such as speech, swallowing and respiratory difficulties may be extremely incapacitating.

Mobility-related symptoms

Spasticity

This common symptom, which only requires drug therapy if it is truly disabling, is an excellent example of the need to combine patient education, therapy and drug treatment. (Thompson, 2001). The latter may be given orally or by injection (intramuscular, intraneural or intrathecal). Of the oral agents, it is preferable to attempt to manage the symptom with a single agent; baclofen is the most effective, though not always well tolerated. It is a gamma aminobutyric acid (GABA) B agonist which acts on both pre- and postsynaptic terminals. Appropriately for MS, it is thought to be particularly effective for spasticity of spinal origin and in particular flexor spasms. It should be commenced at a low dose (5 mg tid) and increased gradually to between 60 to 80 mg per day. Patients should be monitored carefully by the physiotherapist to avoid problems with low tone, particularly in relation to the trunk muscles, and to identify side effects which, along with hypotonia and weakness, include drowsiness and fatigue. Abrupt discontinuation may result in severe withdrawal symptoms including hallucinations and seizures. Of the alternatives, it has been suggested that tizanidine may not cause so much weakness, though this is not so obvious in clinical practice. It acts by stimulating alpha-adrenergic receptors and has been evaluated in two relatively large randomized, placebo-controlled trials. It should also be started at a low dose (2 mg tid) and increased slowly up to a maximum of between 24 and 32 mg per day. It may also cause fatigue and a dry mouth, and liver function tests should be checked before starting and at monthly intervals for three months as transient hepatotoxicity may occur. Other agents include diazepam and clonazepam, which may be particularly useful for nocturnal spasms. Others, including gabapentin, memantine, and vigabatrin, have undergone small, uncontrolled studies. The use of cannabis has been advocated in a number of quarters, most vociferously by patients themselves, and a large randomized placebo-controlled trial is under way in the UK.

For more severe spasticity, the choice of intervention will depend on whether it is focal or generalized. For the former, intramuscular botulinum toxin or intraneural injection with either alcohol or phenol may be appropriate. A recent study has shown particular benefit from botulinum toxin in adductor spasticity though little functional effect was seen (Hymen et al., 2000). Focal spasticity is relatively uncommon in MS and for more severe genaralized spasticity giving baclofen by the intrathecal route utilizing an externally programmable pump may be useful in carefully selected patients. Because the drug is infused directly into the spinal fluid, only very small quantities are required to provide a powerful effect without systemic side effects. Marked reductions in tone and spasm frequency have been reported though the process is not without complications. If patients are very severely disabled and are not suitable for a pump, giving a single injection of intrathecal phenol could be considered provided the patient no longer has effective bladder and bowel control. Further injections are usually required as the effect tends to wear off.

Ataxia

This is one of the most frustrating and resistant symptoms in MS. It is usually seen in more disabled patients but can also occur early in the condition. The majority of patients

have an intention tremor, which is very disabling. Truncal ataxia can interfere with standing and sitting balance and be both distressing and incapacitating. Therapy has some effect, mainly focusing on improving posture and proximal stabilization and occasionally applying weights. Drug treatment is probably even more ineffective (Alusi et al., 2001a,b). A number of agents have been tried in small studies including isoniazid (with pyridoxine), clonazepam, primidone, propranalol and, more recently, gabapentin and the 5H3 antagonist ondansetron (Alusi et al., 1999). The latter appeared useful when given intravenously but this was not convincingly demonstrated in a subsequent study when it was given orally (Rice et al., 1999).

Surgical intervention, either by thalamotomy or thalamic stimulation, has also been used in MS with variable success, certainly not as effective as in Parkinson's disease (Schuurman et al., 2000; Alusi et al., 2001a,b). There have been no controlled studies of thalamotomy of the ventral intermediate nucleus (VIM) and functional benefit is variable. Serious side effects occur in up to 10% of patients and include hemiparesis, dysphasia and dysphagia. Thalamic stimulation may be more effective and appears to have a lower incidence of side effects, but again there are few controlled studies (Montgomery et al., 1999). Further work is under way to identify more effective targets for this procedure.

Fatigue

Fatigue is considered by most to be the most disabling symptom in MS. This overwhelming feeling of exhaustion must be distinguished from depression, which may often coexist. Common, practical issues such as a poor sleep pattern resulting from painful spasms or nocturia must also be considered. Fatigue management programmes are the cornerstone of treatment though drug treatment may be useful in a minority of patients. Amantadine has been shown to be effective while pemoline has not (Krupp et al., 1995). More recently, promising results have been presented for the 'wake-promoting' agent modafinil given at a dose of 200mg daily (Rammohan et al., 2002). The theoretical potential for the potassium channel blockers 4-aminopyridine and 3,4-diaminopyridine to improve fatigue has never been realized.

Bladder, bowel and sexual dysfunction

These symptoms, which often occur in tandem as a result of spinal cord disease, are extremely disabling (see Chapter 56). Active management is crucial. In relation to bladder disturbance, pelvic floor exercises may have a useful role, particularly in women (Vahtera et al., 1997) and biofeedback may also be considered. The combination of clean, intermittent catheterization and an anticholinergic agent such as oxybutinin (tolteridene tartrate is a useful alternative) is usually sufficient to address the incomplete emptying and hyperreflexia so commonly seen in this condition (Hussain & Fowler, 2000). The use of a bladder stimulator may also improve emptying, particularly in mobile patients. The synthetic antidiuretic hormone desmopressin, given by nasal spray, is useful in the management of nocturia. The anticipated side effect of hyponatremia is rare though needs to be considered more carefully in elderly patients. Finally, in very severe disease, the neurotoxic agent capsaicin, which acts on C fibres, may reduce detrusor hyperreflexia (Fowler et al., 1994). The potential benefits of an ultrapotent capsinoid substance resiniferotoxin and a sublingual cannabinoid preparation are currently being evaluated. Permanent catheterization may eventually be necessary and suprapubic placement is usually the preferred option.

The most common bowel symptoms are constipation and fecal incontinence, which may coexist. There is little evidence to support particular interventions. However, establishing a bowel programme is usually advocated and increasing dietary fibre together with bulk laxatives such as lactulose may be helpful in mild constipation; when more severe, stimulant laxatives such as senna and bisacodyl may have a role. The iso-osmotic laxative movicol has been found to be particularly useful and possibly more effective that lactulose (Attar et al., 1999).

Sexual dysfunction is now acknowledged to be a frequent symptom in MS and the underlying mechanisms are better understood (Zorzon et al., 1999). The recent licensing of sildenafil (Viagra) represents a major breakthrough in the management of erectile dysfunction in men, and a potential role in women is currently being investigated. In a recent randomized, placebo-controlled trial involving 217 men with MS, the ability to achieve and maintain erections was significantly better in the treated group with 92% of that group reporting an improvement of sexual activity (Fowler et al., 1999). Adverse events were mild in nature with headache and flushing the most common (23% and 13.5%, respectively) and there were no cardiac events in the treated group. In relation to intracorporeal pharmacotherapy, papaverine has been replaced by prostaglandin E1 (alprostadil) and more recently this has been developed as a pellet into the urethra via a small applicator.

Pain and other paroxysmal symptoms

Pain is common in MS and can have a major impact on both activity and participation (disability and handicap) (Archibald et al., 1994). It is chronic in nature in about 85% of cases and acute/paroxysmal in the remainder. In the

latter group, trigeminal neuralgia is the most common symptom and carbamazepine is the drug of choice. If this is ineffective or poorly tolerated, other anticonvulsants including phenytoin, lamotrigine and gabapentin may be considered and recent small studies have suggested that the prostoglandin E1 analogue misoprotol may be helpful. In a small proportion of patients, a percutaneous procedure may be necessary and rarely microvascular surgery may be helpful. Other paroxysmal symptoms include paroxysmal dysarthria and ataxia, tonic spasms and sensory symptoms including Lhermitte's symptom. Again, carbamazepine is the most useful therapy but gabapentin may also have a role. Finally, epilepsy occurs in 5% of patients with MS and may, in some cases, relate to cortical/subcortical plaques. Treatment should be with anticonvulsants though drug therapy may not need to be continued indefinitely.

Chronic pain is common, often multifactorial and difficult to treat. Amitriptyline may be useful in chronic dysesthetic pain. Physiotherapy to improve posture in sitting and standing is the cornerstone of management of chronic lumbar pain. Non-steroidal anti-inflammatory drugs, transcutaneous electrical nerve stimulation (TENS) and heat may all play a role. However, referral to a specialized pain clinic may be necessary in more resistant cases.

Visual and brainstem symptoms

Severe reduction in visual acuity may follow serial episodes of optic neuritis or result from progressive visual loss, which may occur late in the condition and requires referral to a 'low vision' clinic. Involuntary eye movement disorders, such as pendular nystagmus, oscillopsia and opsoclonus, may also cause debilitating visual dysfunction. Treatment with prisms or occasionally medications such as baclofen, gabapentin, isoniazid and, most recently, memantine may be useful (Starck et al., 1997).

Vertigo is another disabling symptom. It may be helped by prochlorperazine or cinnarazine, while physiotherapy, including Cawthorne–Cooksey exercises, may be useful if the situation becomes chronic. Dysphagia may occur in up to 45% of patients and symptoms such as coughing when eating, choking and change in swallowing function should alert the clinician. Mild dysphagia can usually be managed by assessment and advice from the speech therapist. If severe, a videofluoroscopy may be indicated and percutaneous gastrostomy may be required if swallowing is obviously unsafe or intake is inadequate. Dysarthria is common and again requires assessment and active management from a speech therapist. Finally, respiratory insufficiency may occur in advanced MS but may also complicate acute episodes, usually resulting from respiratory muscle weakness.

Cognitive, psychiatric and psychological dysfunction

All of these areas may be affected in MS, as has been described in the previous chapter. In relation to the management of cognitive dysfunction, a detailed assessment is crucial to define the deficits (which may often be quite subtle) and plan appropriate management strategies. There is little evidence to support cognitive rehabilitation but a computer-based retraining programme for specific attentional deficits may be beneficial.

Diagnosis of psychiatric disturbances is important as symptoms such as depression may worsen fatigue and cognitive function. Depressive symptoms are usually quite mild and often do not require antidepressant medication. Finally, many patients have great difficulty coping with both the diagnosis and subsequent disability in MS. This may be, in part, abated by education and support but some patients may require counselling or psychotherapy.

Neurological rehabilitation

Patients with MS require comprehensive management that incorporates the expertise appropriate to their symptoms and is sufficiently flexible to respond rapidly to their changing pattern of need. They require information and support to facilitate their involvement in the management of their own condition, retain a sense of control and maximise their independence (Hatch, 1997). The philosophy of rehabilitation, which emphasizes patient education and self-management, is ideally suited to meet the needs of people with this fluctuating, unpredictable and incurable condition. This philosophy must be based on a thorough understanding of the mechanisms underlying disability and recovery in MS (Thompson, 2000a,b). It is translated into practice by carrying out goal-orientated rehabilitation programmes which are based on expert multidisciplinary assessment and evaluated through appropriate clinical outcome measures and monitoring of goal achievement (Rossiter et al., 1998).

Tentative evidence now exists to support the use of components of the rehabilitation process including physiotherapy (Wiles et al., 2001) and aerobic exercise (Petajan et al, 1996). Attempts to evaluate the potential benefit of the full rehabilitation package have focused primarily on the in-patient setting and have attempted to identify which areas are likely to improve and whether that improvement is maintained following discharge into the community. Although recent studies have methodological limitations, they are an improvement on earlier work and, perhaps most importantly, demonstrate that such studies are feasible (Thompson, 2000a,b). Despite small numbers, inpatient rehabilitation resulted in a significant benefit in

disability and handicap in a UK study of patients with progressive MS and benefit in disability and aspects of quality of life in a less disabled Italian cohort (Freeman et al., 1997; Solari et al., 1999). The duration of benefit has not been looked at in a randomized controlled trial, but a single group study suggested that benefits in disability and handicap persist for approximately 6 months, while the positive effect on quality of life and emotional well-being may continue for longer (Freeman et al., 1999). This study emphasized the important link between hospital and community in attempting to provide a continuum of care for patients with MS and their families throughout the course of their condition (Thompson & Freeman, 2000). More recently, this link has been provided by MS nurse specialists (Johnson, 1997). Few studies have attempted to evaluate the different models of care available, but a recent study from Rome has suggested that coordinated multidisciplinary care may be more beneficial when compared to medical care alone (Pozzilli et al., 1999). The development of standards of care for the management of MS is an important first step and should serve to emphasize both patient needs and the paucity of evidence available to guide the way in which they are met (Hatch et al., 1999).

Treatment of acute relapses

Corticosteroids

In placebo-controlled trials, a short course of high dose intravenous methylprednisolone (IVMP; 1 g/day for 3 days or 0.5 g/day for 5 days) has been shown to shorten the duration of functional impairment during relapses of MS (Milligan et al., 1987). Such a treatment is often used to hasten recovery from functionally disabling relapses. A similar beneficial effect has been seen with a 2-week course of ACTH, but this is rarely used nowadays. A 3-week course of oral methylprednisolone in standard dosage was associated with a similar outcome as the use of IVMP in one study, but has not been compared directly with placebo in MS relapses (Barnes et al., 1997). Some clinicians use a short course of oral corticosteriods (up to 3 weeks) as an alternative to IVMP in treating MS relapses. In optic neuritis, oral prednisone alone was not associated with accelerated visual recovery whereas IVMP followed by oral prednisone was (Beck et al., 1992). There is no evidence that the final outcome of relapses is affected by steroid therapy, either in MS or optic neuritis. Because of an increased likelihood of side effects, and lack of evidence for long-term benefits, steroids should not be used chronically in MS.

Plasma exchange

A single small study, with placebo controls, has investigated the use of plasma exchange in patients with severe, disabling relapses due to MS or to similar inflammatory CNS disorders such as Devic's' syndrome, in whom there had been no useful improvement following IVMP (Weinshenker et al., 1999). Significantly more patients treated with plasma than sham exchange experienced a functional improvement.

Disease modifying treatments

The last 10 years have witnessed the first introduction of licensed drugs for modifying the course of the disease. In the USA, the FDA has licensed β interferons, glatiramer acetate (formerly known as copolymer-1) and mitoxantrone. The effects and role of these and other agents is reviewed.

Beta interferons

In relapsing remitting MS, three β interferon preparations (β-interferon-1b 8 mU subcutaneously on alternate days; β-interferon-1a 30 μg intramuscularly once per week; β-interferon-1a 22 μg and 44 μg subcutaneously three time per week) have all been shown to reduce relapse rate in randomized, double-blind, placebo-controlled trials of 2 to 3 years duration (IFNB Study Group, 1993; Jacobs et al., 1996; PRISMS Study Group, 1998). The magnitude of the relapse reduction is around 30%. There is evidence that the severity of relapses is also reduced, along with the number of steroid courses and hospital admission required to treat relapses. A similar effect on relapses, reported as a delay until the development of clinically definite MS, has been found in patients with CIS and brain MRI abnormalities (Jacobs et al., 2000). In two of the three relapsing remitting trials, the proportion of patients developing a confirmed increase in disability (i.e. for at least 3–6 months) was reduced in the β-interferon arm compared to placebo. In all trials, β interferons have been shown to reduce the frequency of new or enhancing MRI lesions by 50–70%, the effect being immediate and sustained.

There have also been three large trials completed in patients with secondary progressive MS. In only one trial was there an effect on progression in disability measured using the Kurtzke expanded disability status scale. In this trial, a higher percentage of patients had a history of superimposed relapses in the two years preceding the trials (European Study Group, 1998). Whereas interferons appear to reduce disability accumulation as a result of incomplete recovery from relapses, they probably have little, if any effect on secondary progression *per se*.

As a result of these trials, β interferons have been widely used as the disease-modifying treatment of choice for ambulant patients with relapsing remitting MS, who are experiencing frequent relapses. They are usually well tolerated. The most common adverse effects are injection site reactions (rarely skin necrosis with subcutaneous preparations), 'flu-like symptoms (which usually subside within a few weeks and can be ameliorated by concurrent use of non-steroidal anti-inflammatory drugs such as ibuprofen or by paracetamol), leukopenia, and abnormal liver function tests. The effects on pregnancy are unknown and treatment should be discontinued in women wishing to become pregnant; they are also contraindicated during lactation. The interferons are expensive treatments, and in some countries their cost effectiveness has been questioned; health economic assessments of these agents are hampered by uncertainties in extrapolating from the duration of the existing randomized trials to the period over which major disabilities most often accrue (see below).

The therapeutic mechanisms of β interferons are not well understood. Potentially important mechanisms include interfering with γ-interferon-mediated up-regulation of class II HLA expression on antigen-presenting cells, and stabilization of the blood–brain barrier. All three available preparations are produced by recombinant DNA technology in tissue culture. β-interferon-1a and 1b have a number of structural differences: the former is glycosylated and has an amino acid sequence identical to that of natural β-interferon; the latter is non-glycosylated and serine is substituted for cysteine at position 17.

The long-term effects of β interferons are unclear. This is an important issue in a disease in which the major disabilities typically evolve over 10–20 years. Particularly crucial questions are: does treatment in early relapsing remitting MS delay the development of secondary progression and major locomotor disabilities? Do neutralizing antibodies, which develop in 20–40% patients, modify the long-term course of the disease? Are there hitherto unrecognized long term adverse effects, for example, could there be an increased risk of neoplasia as occurs with some other therapies which modify the immune system? Because of the variable and unpredictable course of MS, systematic long-term follow-up will be needed to address these issues.

Glatiramer acetate

This therapy is a polymer composed of 4 amino acids: L-alanine, L-glutamic acid, L-lysine and L-tyrosine. It is given in a dose of 20 mg by daily subcutaneous injection. In a single, randomized, double-blind, placebo-controlled trial of ambulant patients with relapsing remitting MS, it was shown to reduce relapse rate by 29% (Johnson et al., 1995). It did not affect the proportion of patients experiencing a confirmed increase in disability during the 2-year trial. A subsequent trial has shown that it reduces the rate of new MRI lesions by about 30%, the effect becoming apparent after several months (Comi et al., 2001). There is currently no data on the effect of glatiramer in progressive forms of MS or CIS. Its mechanism of action is uncertain, there is some evidence that it enhances regulatory T-cell functions. It is being used in some countries as an alternative therapy to interferons for reducing relapse rate. It is well tolerated; a small number of patients experience a systemic but self-limiting reaction with flushing, chest pain, dyspnea and palpitations. Its long term effects are uncertain.

Mitoxantrone

This is an anthrecenedione antineoplastic agent that intercalates with DNA and exerts a potent immunomodulating effect, suppressing both humoral immunity and T-helper cell function. In a group of patients with a relapsing remitting or secondary progressive course, a major increase in disability over the previous year, and with enhancing lesions on MRI, a randomized trial was performed in which patients were given either mitoxantrone 20 mg/month plus IVMP 1 g/month or IVMP 1 g/month alone, over 6 months (Edan et al., 1997). The mitoxantrone arm exhibited a major reduction in the frequency of enhancing lesions, reaching 90% at 6 months; this group also experienced fewer clinical relapses, especially during the second 3 months and an improvement in disability, although the clinical component of the assessments was unblinded. A more recent 2-year trial in secondary progressive MS, in which mitoxantrone was given every 3 months (at doses of 5 mg/m^2 or 12 mg/m^2) and compared with placebo, also reported beneficial effects on clinical and MRI outcomes (H-P. Hartung, personal communication).

The drug has recently been licensed by the FDA, for reducing neurological disability and/or the frequency of relapses in patients with secondary progressive, progressive relapsing or worsening relapsing–remitting MS. Its use should be tempered by potential risks. Cardiac toxicity may occur with cumulative doses. Although no cases of cardiac failure were observed with the doses used in the above two trials, confirmation of a normal left ventricular ejection fraction (LVEF) is required before treatment is started. LVEF should be checked again if the cumulative dose exceeds 100 mg/m^2, and it is recommended that the cumulative lifetime dose should not exceed 140 mg/m^2. It causes marked but temporary leukopenia, maximal about 2 weeks after infusion. It may cause alopecia, amenorrhea, nausea and vomiting, and an increased risk of intercurrent infections. The long-term efficacy and risks (beyond 2 years) are uncertain.

Intravenous immunoglobulins

A single trial of moderate size reported a reduction in relapse rate in relapsing remitting MS, but no clear evidence for an effect on sustained progression in disability (Fazekas et al., 1997). Further studies are needed to define the efficacy of this therapy.

Azathioprine

This therapy has been evaluated in several large randomized trials and in a subsequent meta-analysis (Yudkin et al., 1991). It appears to have a modest effect in reducing relapse rate, but little if any effect on progression. Its use in MS is tempered by moderately frequent short term side effects, and a slightly increased risk of neoplasia in the long term. Anecdotal experience in Devic's neuromyelitis optica suggest that it may reduce relapse frequency in this condition.

Other therapies

Other immunosuppressive therapies have shown an ability to suppress MRI lesion formation, often very substantially. Examples include Campath-1H, an antilymphocyte antibody, cladribine, and peripheral stem cell transplantation. However, the clinical effects are much less clear. In a trial in progressive forms of MS, cladribine had no effect on progression in disability (Rice et al., 2000). A small uncontrolled trial of Campath-1H suggested that relapses could be suppressed but not progression in disability (Coles et al., 1999). Clinical trials of cyclophosphamide have yielded conflicting results; a large randomized, placebo-controlled Canadian multicentre study in chronic progressive MS was negative (Canadian Cooperative Multiple Sclerosis Study Group, 1991).

Future prospects

A striking observation in the recent trials has been an ability of several immunomodulatory or immunosuppressive agents, most notably β interferon, to suppress new enhancing lesions on MRI. These lesions represent inflammatory and demyelinating foci, and their suppression is in accordance with the suppression of relapses, which has been shown by the same agents, albeit to a lesser extent. On the other hand, clear evidence that the phase of slow progression in disability can be modified, be it primary or secondary, is lacking. Both pathological and MR studies, the latter using techniques such as MR spectroscopy, magnetization transfer imaging and measures of atrophy, suggest that a neurodegenerative process with axonal loss is underlying the progressive forms of MS (Miller & Thompson, 1999). The relationship between axonal loss, inflammation and demyelination is unclear. An important area of work is to elucidate the mechanisms of axonal loss, through which new strategies to prevent it can be developed. There is increasing interest in strategies that aim at neuroprotection, repair and remyelination.

Leukodystrophies

Hugo W. Moser[1] and Kunihiko Suzuki[2]

[1]Departments of Neurology and Pediatrics, Johns Hopkins University, Kennedy Krieger Institute, Baltimore, MD, USA
[2]Neuroscience Center, University of North Carolina, USA

The term leukodystrophy was first introduced by Bielschowsky and Henneberg (1928). In his review of the neuropathology of the leukodystrophies, James Powers et al. (2000) recommended that the term leukodystrophy should be applied only to 'those progressive diseases of myelin in which a molecular abnormality is responsible for metabolic defects in myelin sheaths or myelin forming cells resulting in confluent destruction, or failed development, of central white matter'. Since the 1990s, remarkable progress has been achieved in the definition of the biochemical defect and the molecular basis of the leukodystrophies (Table 100.1).

In line with this recommendation, this chapter focuses on those genetic disorders in which central nervous system myelin is affected out of proportion to other elements of the nervous system, a judgement which may be somewhat arbitrary and subject to change as knowledge advances. Van der Knaap and Valk (1995) provide an excellent guide to the differential diagnosis of white matter abnormalities demonstrable on MRI and the acquired and genetically determined disorders of myelin that mimic the leukodystrophies. Experience in tertiary referral centres indicates that more than 50% of patients referred for 'second opinion' have leukoencephalopathies in which the cause cannot be determined utilizing diagnostic techniques that are currently available. The utilization of new neuroimaging techniques, such as magnetic resonance spectroscopy, combined with gene linkage analysis, has led to important recent advances and makes it likely that additional leukodystrophies will be defined in the near future (Alexander, 1949; Brenner et al., 2001; Verloes et al., 1997; van der Knaap et al., 1995, 1999; Topcu et al., 2000; Leegwater et al., 1999).

X-linked adrenoleukodystrophy

Background and general features

X-linked adrenoleukodystrophy (X-ALD) (Moser, 1997; Moser et al., 2000a,b) was described first in 1923. It was at first thought to be a variant of Schilder's disease 'encephalitis periaxialis diffusa' (Schilder, 1924), a disease category which has been analysed retrospectively and shown to be heterogeneous (Poser & van Bogaert, 1956). One of the three patients described by Schilder is now thought to have had X-ALD while the others had subacute sclerosing leukoencephalopathy and multiple sclerosis, respectively. In 1976 it was shown that X-ALD is associated with the abnormal accumulation of very long chain fatty acids (VLCFA) (Igarashi et al., 1976). The defective gene was identified in 1993 (Mosser et al., 1993). X-ALD must be distinguished sharply from neonatal adrenoleukodystrophy (NALD), which is disorder of peroxisome biogenesis that resembles the Zellweger syndrome (Kelley et al., 1986) and has an autosomal recessive mode of inheritance.

Clinical features

X-ALD shows a wide range of clinical manifestations (Moser, 1997). The childhood cerebral form is the most severe. It affects about 35% of the patients with the X-ALD gene defect. It presents most commonly between 4 and 8 years of age. Initial manifestations resemble those of hyperactivity or an attention deficit disorder, but then progress with defects in cognitive function, vision, hearing and later motor disturbances which may lead to total neurological disability within two years and death at varying intervals thereafter. Adrenomyeloneuropathy (AMN) is the most common form of X-ALD and affects 40 to 45%. It presents most commonly in young adults as progressive paraparesis

Table 100.1. Leukodystrophies in which the gene defect has been defined or localized

Disorder	Biochemical abnormality	Enzyme-protein defect	Gene map	Mode of inheritance
Gene defect defined				
adrenoleukodystrophy, X-linked	VLCFA excess	ALDP deficiency	Xq28	X-linked
Alexander		GFAP excess		autosomal dominant
Canavan	NAA excess	aspartoacylase deficiency	17p13-ter	autosomal recessive
Cerebrotendinous xanthomatosis	cholestanol	sterol 27 hydroxylase	2q33-qter	autosomal recessive
Globoid leukodystrophy	psychosine excess	galactocerebrosidase	14q25-31	autosomal recessive
Lipomembranous osteodysoplasia with leukodystrophy		TYRO protein tyrosone kinase		autosomal recessive
Metachromatic leukodystrophy	sulfatide excess	arylsulfatase A	22q13	autosomal recessive
Pelizaeus Merzbacher disease		proteolipid protein deficiency	Xq22	X-linked
Sjogren Larrson		fatty aldehyde dehydrogenase	17p11.2	autosomal recessive
Gene defect localized but not defined				
Vacuolating megalencephalic leukodystrophy with subcortical cysts			22qter	autosomal recessive
Childhood ataxia with diffuse central nervous system hypomyelination/ vanishing white matter disease			3q27	autosomal recessive

and sphincter disturbances, which are often misdiagnosed as multiple sclerosis. It is slowly progressive over a period of decades, and some patients have survived to the eighth decade with only moderate disability. Approximately 40% of AMN patients develop varying degrees of cerebral involvement which in approximately half of these patients is rapidly progressive (Van Geel et al., 2001). Seventy per cent of X-ALD patients have primary adrenocortical insufficiency. Approximately 30% of X-ALD patients have primary adrenocortical insufficiency (Addison disease) without evidence of neurological involvement, but many of these patients develop evidence of AMN in adulthood. The various X-ALD phenotypes often occur in the same kindred or nuclear family. Approximately half of the women heterozygous for X-ALD develop a relatively mild AMN-like syndrome in middle age or later. Only 1% of X-ALD heterozygotes have adrenal insufficiency.

Gene defect

The X-ALD gene has been mapped to Xq 28. It codes for a peroxisomal membrane protein, ALDP, which is a member of the ATP binding cassette (ABC) transporter superfamily (Higgins, 1992). The minimum combined incidence of X-ALD males and females in the United States is 1:16800 (Bezman et al., 2001). More than 200 mutations have been identified (Smith et al., 1999) and are continually updated and listed in the website *www.x.ald.nl.* Many mutations are unique to kindreds. There is no correlation between the nature of the mutation and phenotypic expression.

The mechanism by which the X-ALD gene defect leads to the accumulation of VLCFA has not been determined. When X-ALD cells are transfected with ALDP, they acquire the capacity to degrade VLCFA through mechanisms that have not yet been defined (Steinberg et al., 1999). ABC transporter proteins function as dimers (Higgins, 1992). ALDP is a monomer. The human peroxisome membrane contains four different ABC transporter proteins (Smith et al., 1999). ALDRP, which has been mapped to chromosome 12, is of particular interest since its amino acid composition (Lombard-Platet et al., 1996) and gene structure (Broccardo et al., 1998) bear a close resemblance to ALDP, and it can substitute at least in part for the function of ALDP in respect to VLCFA metabolism (Kemp et al., 1998). The ABC transporters functions as dimers. ALDP can form a dimer either with another ALDP molecule (homodimer) or form a heterodimer with one of the other peroxisomal ABC transporters, such as ALDRP. The existence of such heterodimers has been demonstrated in vitro (Kemp et al., 1998). The extent to which such heterodimers are formed

in vivo is uncertain, since in the nervous system ALDP and ALDRP show different patterns of ontogeny and cellular distribution (Aubourg & Dubois-Dalcq, 2000).

Animal model

A mouse model of X-ALD has been developed by Kobayashi and associates (1997) and in two other laboratories. This mouse model lacks ALDP. VLCFA accumulate in the brain and adrenal gland, and the adrenal gland exhibits lamellar inclusions equivalent to the human disease. The animals do not show clinical evidence of neurological or adrenal dysfunction. At 24 months of age they show statistically significant reductions in peripheral nerve conduction velocity compared to age-matched controls and myelin abnormalities which resemble those in AMN. They do not show evidence of the inflammatory demyelinating process seen in patients with the cerebral forms of X-ALD.

Pathology and pathogenesis

There are two distinct pathological processes: an inflammatory demyelinating process that involves children most frequently and approximately one-third of the adults, and a distal axonopathy that affects adults.

Children and adults with the cerebral forms of the disease show an inflammatory process that affects the central nervous system white matter (Powers et al., 1992). There are confluent symmetric lesions that contain three zones. The lesions occur most frequently in the parieto-occipital regions, and advance caudo-rostrally. In the outermost zone there is an astroglial reaction and the astrocytes in this zone contain tumour necrosis factor alpha. The second zone exhibits a perivascular inflammatory response associated with demyelination and the accumulation of cholesterol esters that contain a high proportion of VLCFA. The perivascular cells include macrophages, T-cells and B-cells, and contrast neuroimaging studies have shown breakdown of the blood–brain barrier. This zone resembles what is seen in multiple sclerosis. In the innermost zone there is extensive gliosis with loss of myelin and reduction or absence of the inflammatory response. Axons are involved to varying degrees in zone 2 and frequently in the innermost zone. The inflammatory response in X-ALD is unique among the leukodystrophies. It is the cause of the rapid progression of the disease. It may be initiated through as yet undefined autoimmune mechanisms, possibly involving reactions to lipids that contain excess amounts of VLCFA, or at times by trauma, and then is maintained and amplified by a destructive cascade which may be cytokine mediated.

Powers et al. (2000) provide strong evidence that AMN is a distal axonopathy that involves mainly the long tracts of the spinal cord. It may be a consequence of the abnormalities in lipid membrane structure and function caused by accumulation of VLCFA (Ho et al., 1995; Whitcomb et al., 1988).

Diagnosis

The most frequently used diagnostic assay is the demonstration of increased levels of VLCFA in plasma or cultured skin fibroblasts (Moser et al., 1999). These assays are reliable for the identification of affected males, provided that they are performed in a qualified laboratory, but a 15% false-negative rate occurs in heterozygotes (Moser et al., 1999). Mutation analysis is the most reliable procedure for the identification of heterozygotes (Boehm et al., 1999). MRI findings in patients with the cerebral form of the disease are often characteristic (van der Knaap & Valk, 1995). They show symmetric, confluent T_2 signals in the white matter of the parieto-occipital region, with a garland of contrast enhancement at the advancing edge of the lesion (Fig. 100.1). MRI findings are atypical in approximately 15% of patients with abnormal MRI. The brain MRI is normal in more than half of the patients with AMN, and in many others who are free of neurological symptoms. MRI abnormalities usually precede symptoms in patients with cerebral involvement, and the brain MRI is of prognostic value (Moser et al., 2000a,b). Abnormalities in magnetic resonance spectroscopy studies often precede MRI changes and appear to be of value in setting prognosis and the selection of patients for bone marrow transplantation.

Therapy

It is essential to monitor adrenal function, which is impaired in approximately 70% of patients, and to provide adrenal steroid hormone replacement therapy when it is deficient. This is mandatory and can be life-saving. Adrenal hormone replacement therapy does not alter the neurological aspects of the disease.

Bone marrow transplantation (BMT) is the most effective therapy for the cerebral forms of the disease, but must be applied in the early stages of the disease. Under these circumstances it can provide long-term stabilization and at times improvement (Shapiro et al., 2000). Selection of patients for BMT requires clinical judgement, because it is a procedure that carries considerable risk. It is not recommended for patients with advanced neurologic involvement, since in these patients the risk of complications and continued disease progression is high. It is not

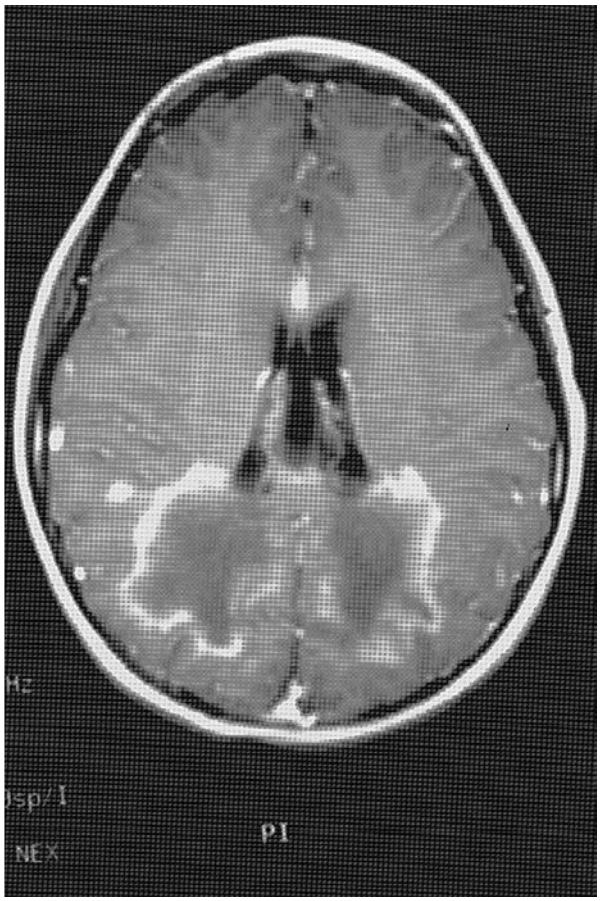

Fig. 100.1. T_1-weighted image with contrast in a 7-year-old boy with childhood cerebral X-ALD. Note symmetrical parieto-occipital lesions with contrast enhancement at margin.

recommended for AMN patients because there is no evidence that BMT benefits the myelopathy. BMT is not appropriate for persons who have the *X-ALD* gene defect, but do not have evidence of neurological involvement by MRI. Natural history data indicate that more than half of these patients will escape the cerebral forms of the disease even without therapy (Moser et al., 2000a,b).

Dietary therapy with a 4:1 mixture of glyceryltrioleate and glyceryltrierucate, referred to as Lorenzo's Oil (Rizzo et al., 1989) has been used extensively. Recent studies suggest that it is not of benefit in patients who are already neurologically symptomatic (van Geel et al., 1999). An international collaborative study, aimed to determine whether administration of the oil to asymptomatic patients can diminish the frequency and severity of subsequent neurologic involvement, will be completed in 2001.

Two new therapeutic approaches have been proposed recently; Lovastatin and 4-phenylbutyrate. Lovastatin has been reported to improve the capacity of X-ALD cells to metabolize VLCFA (Pahan et al., 1998; Pai et al., 2000) and to reduce the inflammatory response (Stanislaus et al., 1999; Pahan et al., 1997). 4-phenylbutyrate increases the capacity to metabolize VLCFA in cultured X-ALD cells and reduces VLCFA levels in the brain and adrenal gland of the X-ALD mouse model. It also increases the expression of ALDRP, which resembles ALDP (Lombard-Platet et al., 1996; Broccardo et al., 1998) and can substitute for its function at least in part. This approach has been proposed as an example of pharmacological gene therapy (Kemp et al., 1998). Therapeutic trials of both agents are planned.

Metachromatic leukodystrophy: sulfatide lipidosis

Background and general features

The key abnormality in metachromatic leukodystrophy is the accumulation of sulfatide (galactosylceramide-3-sulfate). This acidic glycolipid accumulates in the white matter of brain and peripheral nerves and also in the kidney, gall bladder and urine and causes metachromatic staining with aniline dyes. Accumulation of metachromatic lipids in brain tissue was first reported by Perusiniu and Alzheimer in 1910. In 1921 Witte also noted metachromatic lipids in the kidney, and predicted that in vivo diagnosis might be achieved by examination of the urine, and this was accomplished by Austin in 1957 (Kolodny & Fluharty, 1995). Sulfatide accumulation can be caused by three distinct genetic defects. (i) Deficient activity of the lysosomal enzyme arylsulfatase A (ASA) which catalyses the hydrolysis of sulfatide to galactosylceramide. This is by far the most common cause. Its estimated incidence is 1:40 000–1:100 000. (ii) Multiple sulfatase deficiency (MSD). Fifty cases of MSD had been reported by 1995 (Kolodny & Fluharty, 1995). In MSD the activities of at least seven sulfatases are deficient and mucopolysaccharide and steroid sulfate esters accumulate in addition to sulfatide. The gene defect abolishes the posttranslation modification of sulfatases. This modification involves the conversion of a cysteine residue to formylglycine. It causes a change in protein folding and appears to be required for the enzymatic action of all of the sulfatases that are defective in MDS. (iii) The third and least frequent cause of sulfatide accumulation is a genetically determined deficiency of Saposin D (Waring et al., 1998), one of the sphingolipid activator proteins which is required for the biological activity of arylsulfatase A but not the other sulfatases.

Clinical presentation

MLD may present in late infancy, adolescence or adulthood. The late infantile form is the most common. It presents between 1 and 3 years of age, with loss of previously acquired motor skills, such as ability to walk, followed by ataxia, dysarthria and dysphagia and later by impairment of cognitive function, vision and hearing. It is progressive and leads to death after several years. Neurological examination shows evidence of both central nervous and peripheral nerve function as evidenced by the association of hypotonia and diminished deep tendon reflexes with positive Babinski sign, ataxia, dystonic movements and nystagmus. The manifestations of the juvenile form resemble those of the late infantile form but progress more slowly. In the adult form behavioural and cognitive changes precede motor changes by years or even decades. The patients may present with a frontal lobe syndrome, which may include disinhibition, impulsivity, poor judgement, emotional lability, social inappropriateness and poor attention span (Shapiro et al., 1994). MSD patients can be differentiated from late infantile MLD because they show more severely impaired early development, mild coarsening of facial features, and sometimes corneal clouding, hepatosplenomegaly, stiff joints and ichthyosis.

Gene defect

MLD is transmitted as an autosomal recessive trait. The gene that encodes ASA maps to 22q13. More than 40 mutations have been identified. Three are relatively common. Homozygosity for mutations that abolish function completely causes the severe late infantile phenotype. Missense mutations in which up to 3–5% of normal activity is maintained tend to be associated with the adult form of the disease. Patients who are heterozygous for a null mutation and one of the milder missense mutation, often have the juvenile phenotypes (Gieselmann et al., 1998).

Animal model

ASA-deficient mice have been generated by homologous recombination. These animals accumulate sulfatide. Unlike what is seen in humans, the most severe demyelination occurs in the acoustic ganglion and the animals become deaf at 6–12 months (Gieselmann et al., 1998).

Pathology and pathogenesis

The central and peripheral nervous system show demyelination associated with the accumulation of metachromatic bodies with a characteristic lamellar pattern that when viewed under the electron microscope has been likened to tuffstone (Kolodny & Fluharty, 1995). Several factors may contribute to the pathogenesis of the demyelination. These include impaired function and loss of oligodendrocytes and Schwann cells, impaired stability of myelin due to increased sulfatide content, and the accumulation of sulfogalactosylsphingosine, the degradation of which is impaired in MLD. Accumulation of a related compound, galactosylsphingosine, which is also referred to as psychosine, has been shown to be a toxic agent in globoid leukodystrophy (Suzuki, 1998).

Diagnosis

Clinical recognition of the late infantile and juvenile forms is based upon evidence of progressive nervous system dysfunction associated with loss of myelin both in the central and peripheral nervous system. The adult form of the disease is often misdiagnosed as a psychosis in adults. An abnormal MRI often provides the first clue to the existence of a metabolic abnormality. The MRI demonstrates symmetric and confluent high signal in the periventricular anterior and posterior white matter on T_2-weighted images (van der Knaap & Valk, 1995).

Measurement of ASA activity in white blood cells is the most frequently used initial laboratory assay (Kolodny & Fluharty, 1995). If the results of this assay are normal, the diagnosis of MLD can be excluded, except for the rare disorder cited previously in which sulfatide excess is due to deficiency of the saposin D cofactor (Waring et al., 1998). The clinical presentation of saposin D deficiency resembles late infantile or juvenile MLD. Urinary sulfatide excretion (Natowicz et al., 1996) is increased but ASA activity is normal. MSD can be distinguished from MLD because of its earlier onset, and the presence of the additional biochemical abnormalities cited previously (Kolodny & Fluharty, 1995). ASA is the only sulfatase that is deficient in type 1 MLD. In MSD the activities of arylsulfatases B and C and of mucopolysaccharide sulfatases are also deficient (Kolodny & Fluharty, 1995).

Interpretation of diminished ASA activity requires caution. Demonstration of deficient ASA activity is not sufficient for the laboratory diagnosis of MLD. Confirmation of the diagnosis requires clinical or laboratory evidence of sulfatide storage in addition to the diminished enzyme activity. Reduced levels of ASA activity, sometimes equivalent to what is seen in MLD, may also be associated with a condition referred to as pseudosulfatase deficiency (PSD). PSD is a benign and common condition. It is associated with a loss of polyadenylylation signal and

an *N*-glycosylation site in the ASA gene that reduces but does not abolish enzyme activity (Gieselmann et al., 1989). The carrier frequency for the PSD is 7% or higher. Persons with PSD do not have symptoms. Urinary sulfatide excretion (Natowicz et al., 1996) is increased in MLD but not in PSD. Peripheral nerve conduction velocity, which is almost always reduced in MLD, is normal in PSD, and the brain MRI is normal. The molecular changes associated with PSD can be identified by DNA analysis (Gieselman et al., 1989). It is important to recognize that demonstration of this abnormality does not exclude MLD, since PSD is common and persons who are PSD carriers may also have MLD. Identification of MLD carriers requires mutation analysis. Prenatal diagnosis of MLD can be achieved with the ASA assay, but subject to the caution expressed previously. Normal activity excludes fetal involvement, but interpretation of reduced levels may require additional studies such as in vitro sulfatide loading studies and DNA analysis (Kolodny & Fluharty, 1995).

Therapy

Bone marrow transplantation (BMT) can stabilize or diminish the rate of progression of nervous system dysfunction, but does not appear to influence the peripheral nerve involvement (Krivit et al., 1995). Consideration for BMT is recommended only for patients with relatively mild nervous system involvement and particularly in asymptomatic patients identified by tests of at-risk relatives, with care taken to differentiate MLD from PSD. The procedure is not recommended for patients with advanced nervous system involvement, where it is associated with high risk of additional worsening of the disability. Gene therapy is under investigation in cultured cells (Sangalli et al., 1998) and in the animal model, but is not yet ready for human testing. Gall bladder surgery is required occasionally in patients who have sulfatide-containing gallstones.

Globoid-cell leukodystrophy (Krabbe disease: globoid leukodystrophy

Background and general features

Globoid-cell leukodystrophy (GLD) is caused by a genetic deficiency of galactosylceramidase (galactocerebroside-beta galactosidase (GALC) (Suzuki et al., 1995). This lysosomal enzyme normally degrades galactocerebroside to ceramide and galactose. Galactocerebroside is a sphingolipid consisting of sphingosine, fatty acid and galactose and normally is present almost exclusively in the myelin sheath. Accumulation of galactocerebroside leads to the formation of characteristic multinucleated cells which led to the designation of this disorder as globoid cell leukodystrophy.

GALC also catalyses the degradation of psychosine (galactosylsphingosine) to sphingosine and galactose. Psychosine accumulates in patients with GLD and this accumulation is a key factor in the pathogenesis of the disease (Suzuki, 1998). GLD was described first in 1916 by Krabbe in Denmark in two siblings who died of an 'acute infantile diffuse sclerosis of the brain'. The enzyme defect was defined in 1971 by Suzuki (Suzuki & Suzuki, 1970) and the gene abnormality in 1993 (Chen et al., 1993).

Clinical features

The infantile form is most common, with an estimated incidence between 1:100000 and 1:200000. The child, apparently normal during the first few months of life, becomes hyperirritable, hypersensitive to auditory, tactile or visual stimuli and shows some limb stiffness. This is followed by rapid and severe motor and mental deterioration, with marked hypertonicity, optic atrophy, and a decerebrate state. Patients rarely survive beyond 2 years. Juvenile (Krivit et al., 1998) and adult forms also occur. The adult patients may present with progressive spastic paraparesis progressing to tetraparesis followed by optic atrophy, dementia and neuropathy (Suzuki et al., 1995).

Gene defect

GLD is transmitted as an autosomal recessive trait. The gene has been mapped to 14q25–31. The human *GALC* gene is 58 kb in length and consists of 17 exons and 16 introns (Wenger et al., 1997). Sixty-five disease-causing mutations were described by 1999 (Jardim et al., 1999). A 502T/del mutation is the most common. Its origin has been traced to Sweden and it is present in 40% of GLD patients who are of European origin. The mutation consists of a 30 bp deletion in intron 10. It eliminates activity in expression studies. The second most frequent mutation is a C $\rightarrow$T change at nucleotide 1538 (T531M). It is found in approximately 10% of patients with the infantile phenotype. All mutations responsible for the adult forms of GLD are missense mutations located at the 5′ end of the gene. Genotype–phenotype correlations are complicated by the existence of polymorphisms. The most frequent polymorphism, which is present in 35 to 45% of the general population, involves a T$\rightarrow$C change at position 1637, which in COS-1 cell expression studies reduced expression of GALC to 30%.

Animal models

Animal models of GLD have been described in mice, sheep, dogs, and monkeys. The murine model, referred to as the twitcher mouse, and the canine model are being used extensively in studies of pathogenesis and therapy (Wu et al., 2000; Wenger et al., 1999, 2000).

Pathology and pathogenesis

The main histopathological changes are extensive demyelination, gliosis and the presence of characteristic multinucleated cells, referred to as globoid cells. Intracerebral injections of galactocerebroside into rat brain produced cells that are similar to the globoid cells in GLD. Globoid cells are cells of mononuclear phagocytic lineage that become multinucleated as a response to galactocerebroside. The number of oligodendrocytes is greatly decreased. Peripheral nerves show endoneurial fibrosis, proliferation of fibroblasts, segmental demyelination and perivascular accumulation of macrophages containing periodic acid Schiff (PAS) positive material.

While it is well documented that galactocerebroside causes the formation of globoid cells, intracerebral injection of this substance did not lead to severe pathological changes. Galactocerebroside levels are not increased in the small amount of myelin that can be isolated from the brain of patients with GLD. Suzuki and associates have presented strong evidence that the accumulation of psychosine (galactosphingosine) is the principal toxic mechanism (Suzuki, 1998).

Diagnosis

Diagnosis in infants is suspected on the basis of the characteristic clinical presentation and confirmed by assay of GALC activity in white blood cells or cultured fibroblasts (Suzuki et al., 1995). The peripheral nerve involvement leads to diminished conduction velocity and the level of protein in the cerebrospinal fluid is increased. Brain MRI shows high intensity signal in the deep white matter on T_2-weighted images (van der Knaap & Valk, 1995). Diagnosis in juveniles and adults is more difficult since the symptoms of progressive neurological deterioration are less specific. Progressive paraparesis is the most common presenting symptom in adults and MRI abnormalities may be confined to the corticospinal tracts (Fig. 100.2). Demonstration of reduced GALC activity in amniocytes or cultured chorion villus cells permits prenatal diagnosis. Identification of heterozygotes requires mutation analysis.

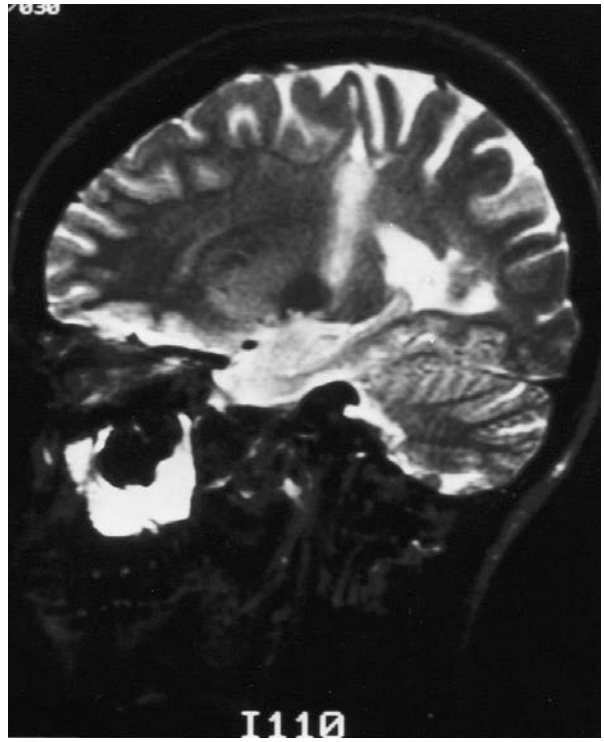

Fig. 100.2. Globoid leukodystrophy. 23-year-old female presents with intact intelligence and progressive hemiparesis since 18 years of age. Male sibling has similar presentation. T_2-weighted sagittal images demonstrate isolated high-signal intensity of corticospinal tract and involvement of occipital regions.

Treatment

Allogeneic hematopoetic stem cell transplant (BMT) has been found to be beneficial in four patients with the juvenile form of the disease (Krivit et al., 1998). All four of the patients showed stabilization or improvement in neurological cognitive function and MRI. Peripheral nerve conduction velocity improved in one patient and remained unchanged in two. BMT is also beneficial in the twitcher mouse model. It increases survival, weight and peripheral nerve function, but falls far short of a cure (Suzuki, et al., 1995). The beneficial effect appears to be due to infiltration of hematogenous lineage cells into the demyelinating central nervous system. In the twitcher mouse this infiltration into the demyelinating regions is greater than in controls, and appears to be related to the expression of chemoattractant proteins in these regions (Wu et al., 2000). BMT so far has not been shown to alter significantly the course of the infantile form, which is the most severe and the most common form of GLD. It is likely that additional approaches will be needed. Gene therapy is being examined

in the canine model of GLD (Wenger et al., 1999) and in cultured cells. The possibility of a different therapeutic approach is suggested by the demonstration that subcutaneous administration of L-cycloserine, an inhibitor of sphingosine synthesis which presumably would also reduce levels of psychosine and galactocerebroside, reduces levels of psychosine and galactocerebroside and slows clinical and pathological progression in the twitcher mouse (Levine et al., 2000).

Pelizaeus Merzbacher disease

Background and general features

Pelizaeus Merzbacher disease (PMD) was recognized initially by Pelizaeus in 1885, who described a family with a progressive neurologic deficit. Merzbacher in 1910 made a report on the same family and noted that deficiency of myelin was a central feature and that the disease affected males predominantly. Seitelberger on the basis of extensive clinical, morphological and epidemiological studies (Seitelberger, 1970) described 'classical' (Type I), 'connatal' (Type II) and 'transitional' (Type III) forms, which he joined together as a single entity on the basis of certain unique patterns of demyelination in postmortem tissue and a sex-linked recessive mode of inheritance. He also included three other types (Types IV to VI), which are now no longer considered part of the spectrum. Important advances in knowledge resulted from neurochemical and genetic studies in mouse mutants. It was shown in 1985 that the gene that codes for proteolipid protein (PLP), one of the major myelin proteins, is located on the X-chromosome, and in 1986 that the *jimpy* mouse, a mutant that had been identified in 1964, is deficient in this protein. PLP deficiency and mutations in this gene were demonstrated in PLP patients in 1987 and 1989, respectively. In 1994 it was shown that X-linked spastic paraplegia (SPG2 MIM 31290) type 2 and PMD are allelic (Saugier-Veber et al., 1994). This has added a new dimension to the understanding and classification of PMD. The designation PMD/SPG2 now encompasses all patients with disease-causing abnormalities that involve the PLP gene.

Clinical presentation

The principal clinical features of classic Type 1 PMD are (i) the presence of abnormal eye movements (horizontal or rotatory) with onset within the first few months of life; (ii) the occurrence of psychomotor deterioration before 2 years of age, and (iii) the appearance of bilateral pyramidal tract signs, dystonia and often ataxia during the first years of life (Boulloche & Aicardi, 1986). Laryngeal stridor also occurs frequently. In the connatal type II, intrauterine movements of the affected fetus are reduced, there is congenital laryngeal stridor, and psychomotor retardation is severe. SPG2 presents with mild spastic paraparesis in the late subteens or early teens. It is slowly progressive over decades. Involvement of upper limbs, ataxia and cognitive dysfunction may occur in the late stage of the illness. Patients with abnormalities of the PLP gene may have phenotypes intermediate in severity between PMD type 1 and SPG2 (MIM 308840).

Gene defect

PMD is transmitted as a sex-linked recessive trait, but with the caveat that some female heterozygotes (Nance et al., 1996) or female animal models (Cuddon et al., 1998) may develop neurological symptoms. The PLP gene is located on Xq22. It is an integral membrane protein with four transmembrane domains. The amino and carboxy terminals are oriented toward the cytoplasmic surface. It is 17 kb in length and comprises 7 exons. PLP contains 276 amino acids. An alternative splicing site leads to the formation of the related protein DM-20, which differs from PLP by the absence of an internal 35-amino acid peptide in the intracellular loop region (Seitelberger, 1970). The cellular mechanisms of classical and connatal forms of PMD have been examined in transfected COS-7 cells (Gow & Lazzarini, 1996). In classical PMD, PLP protein accumulated in the endoplasmic reticulum (ER), presumably due to protein misfolding which interferes with the secretory pathway, whereas the shorter isoform DM-20 was transported normally. In contrast, in cells transfected with mutant genes of patients with the connatal phenotype, there was ER accumulation of both DM-20 and PLP, indicating that the more profound secretory deficit causes the most severe phenotype. Forty different mutations in the PLP gene have been identified, which in the aggregate are present in 25 to 38% of PMD/SGP2 patients. The most frequent abnormality, however, is duplication of the PLP gene. This was demonstrated in 62% of 82 patients with sporacic PMD/SGP2 (Mimault et al., 1999). Duplications are associated with the milder phenotypes (Sistermans et al., 1998). Neurological manifestations in female heterozygotes occur more commonly in those kindreds in whom affected males have relatively mild phenotypes (Sivakumar, et al., 1999).

Animal models

The *jimpy* mouse is a model of the severe forms of PMD. The 'rumpshaker' mouse is a model of SGP2 (Seitelberger,

1970). The 'shaking pup' canine model has a phenotype that is intermediate in severity between the *jimpy* and the rumpshaker mouse and is a valuable model for the evaluation of therapeutic interventions (Cuddon et al., 1998).

Pathology and pathogenesis

Myelin stains reveal a marked myelin deficiency especially in the deeper cerebral parts, and a patchy tigroid appearance due to the presence of somewhat better preserved islands of myelin which often are located around blood vessels. Oligodendrocytes are reduced in number and astrocytes increased. PLP is absent. In the connatal form the myelin deficiency is more widespread (Seitelberger, 1970). The peripheral nerves are intact in all forms. Transgenic mice with two-fold overexpression of PLP protein show hypomyelination and severe neurological deficits. This demonstrates that precise control of the PMP gene is essential for normal oligodendrocyte differentiation (Readhead et al., 1994).

Diagnosis

Suspicion of the diagnosis is based upon the signs of progressive central nervous system impairment as described above in the presence of intact peripheral nerve function. The major confirmatory technique is the application of DNA-based analyses. Search for duplications is of particular importance, because they represent the most frequent gene abnormality (Mimault et al., 1999; Sistermans et al., 1998; Woodhead et al., 1998; Hodes et al., 2000).

Therapy

There is no specific therapy at this time.

Canavan disease

Background and general features

The first complete clinical and pathological description of Canavan Disease (CD) was provided by van Bogaert and Bertram in 1949. Several leukodystrophy patients who excreted large quantities of *N*-acetylaspartate in the urine were reported between 1986 and 1988 by Divry et al. (1988). In 1988 Matalon and colleagues established the association between NAA aciduria and CD and demonstrated that this was due to deficiency of aspartoacylase (ASPA). They cloned the gene in 1993 (Kaul et al., 1993) and in 2000 developed a knockout mouse model (Matalon et al., 2000). ASPA gene replacement therapy in two children with CD has been reported (Leone et al., 2000), the first time that this has been attempted in leukodystrophy patients.

Clinical presentation

Most children become symptomatic between 10 weeks and 4 months of age after an uneventful prenatal and perinatal course (Traeger & Rapin, 1998). Initial manifestations are lack of visual fixation and tracking, poor suck and irritability and delay in acquisition of head control. Macrocephaly (>90th percentile) was noted in 54 of 59 children and nystagmus in 51/58. Feeding difficulties, irritability and seizures are common. Psychomotor development is severely impaired. In a series of 60 patients only one was able to sit unsupported, and only two spoke a few words. Survival in this severely handicapped state ranged from 7 months to 30 years.

Gene defect

The mode of inheritance is autosomal recessive. The gene that codes for ASPA has been mapped to 17p13-ter (Matalon et al., 1995). It codes for a 340 amino acid protein and is expressed in most tissues. Mutations are most frequent in the Ashkenazi Jewish population, where the carrier frequency is 1:37.7, leading to an estimated disease frequency of 1:5000. Two mutations predominate in this population. The *E285A* mutation was found in 84% of alleles, and the *Y231X* in 14%. CD is much less frequent in the non-Jewish population and the mutations are different. An *A305* E mutation was present in 39.5 of alleles, and eight other less frequent mutations were identified in 31 of 38 alleles (Shaag et al., 1995). The nature of the mutation does not correlate with clinical severity.

Animal model

Matalon and associates have developed a knockout mouse in which ASPA is absent and NAA accumulates (Matalon et al., 2000). Homozygous animals develop macrocephaly, tremors, ataxia and impaired mobility and balance. Half of the mice died at age of weaning, but others survived to 9 months. Neuropathological studies showed extensive vacuolization in subcortical white matter, deep cortex, and striatum. Vacuolization was observed in retinal ganglion cells, hippocampus and cerebellum. Increased brain NAA levels were demonstrated by biochemical studies and by magnetic resonance spectroscopy.

Pathology and pathogenesis

The size and weight of the brain is increased. The characteristic microscopic change is widespread vacuolization in the lower layers of the cortex and subcortical white matter, the more central zones being relatively spared. The Purkinje cell layer of the cerebellum is affected early. There is widespread lack of myelin which involves the areas of spongy degeneration and far beyond. Axis cylinders are relatively preserved. Oligodendrocytes are preserved. There is a conspicuous increase in the size and number of protoplasmic astrocytes (Banker & Victor, 1979).

The main biochemical abnormality in CD is the accumulation of NAA. NAA is present in high concentration in normal brain, second only to glutamate in terms of free amino acid concentration (Clark, 1998). It is present in highest concentration in neurons. The enzyme responsible for NAA synthesis is present only in the nervous system, but ASPA, the enzyme which degrades it, and which is deficient in CD, is expressed in many tissues. In the nervous system ASPA is present mainly in white matter. Astroglia contain a specific transport mechanism for NAA (Sager et al., 1999). An understanding of the pathogenesis of CDS requires clarification of the physiological role of NAA. It may play a role in protecting neurons against osmotic stress (Clark, 1998). Baslow has hypothesized the existence of an intercompartmental cotransport of water uphill against a gradient of a hydrophilic osmolyte, and that the metabolic defect in CD leads to a buildup of NAA–water in the extracellular space between the axon-wrapped glial–myelin repeating lamellar membranes (Baslow, 1999). NAA is the precursor of the dipeptide *N*-acetylaspartylglutamate (NAAG). NAAG is present in high concentration in normal brain and appears to play a role in glutaminergic transmission. Levels of NAAG are increased in the urine of CD patients (Burlina et al., 1999). If such an increase also exists in brain this could also contribute to pathogenesis. Acetate and aspartate are the products of NAA degradation and play a role in myelin synthesis (Sager et al., 1999). The deficiency of this degradation in CD may contribute to the failure of myelin formation.

Diagnosis

NAA levels in the urine of CD patients are elevated 80-fold and can be measured accurately by a stable isotope dilution assay (Jakobs et al., 1991). Measurement of NAA levels in amniotic fluid is the most reliable procedure for prenatal diagnosis (Bennett et al., 1993). Mutation analysis (Shaag et al., 1995; Kaul et al., 1994) is reliable when the mutation has been identified in an affected family member. MRI studies show diffuse hypodensity of the white matter of the cerebral hemispheres and cerebellum. The subcortical white matter is involved most severely at all stages of the disease, with relative preservation of central structures. The globus pallidus is often involved with sparing of the caudate nucleus and putamen. MR spectroscopy shows increased levels of NAA (Leone et al., 2000).

Therapy and prevention

Leone et al. (2000) have reported on *ASP* gene transfer in two severely disabled CD patients who were 19 and 24 months old. The gene was condensed using poly-L-lysine and encapsulated with liposomes to form 60–100-nm particles and injected intraventricularly into the lateral ventricle through a burr-hole in combination with the intraveneous administration of mannitol. There were no adverse side effects. ASPA RNA could be detected by reverse transcriptase reaction in the cerebrospinal fluid of one of the children 1 year following the gene injection, but not in the other. Some evidence of mild clinical and radiological improvement was noted in the former child, but the data were insufficient to evaluate clinical efficacy. The recently developed animal model is expected to facilitate the evaluation of this and other therapies. The demonstration that two readily identifiable mutations account for 97% of gene abnormalities in CD patients of Ashkenazi Jewish descent makes it possible to identify CD carriers in this population. This will permit the identification of two-carrier couples and reduction of disease frequency through genetic counselling, analogous to the programs that are now being conducted for Tay Sachs disease.

Other leukodystrophies

Alexander disease

Alexander disease (AD) was first described in 1949 (Alexander, 1949). Infantile, juvenile and adult forms have been described (Johnson, 1996). The infantile form presents during the first or second year with developmental delay, megalencephaly, seizures followed by progressive psychomotor retardation, spasticity and quadriparesis. Death occurs 1 to 10 years after onset. Juvenile and adult forms, often with slower progression, have been described. The most striking and characteristic feature is the accumulation of Rosenthal fibres (RF). These are intracellular inclusions found exclusively in astrocytes, which under the light microscope appear as small round or ovoid bodies up

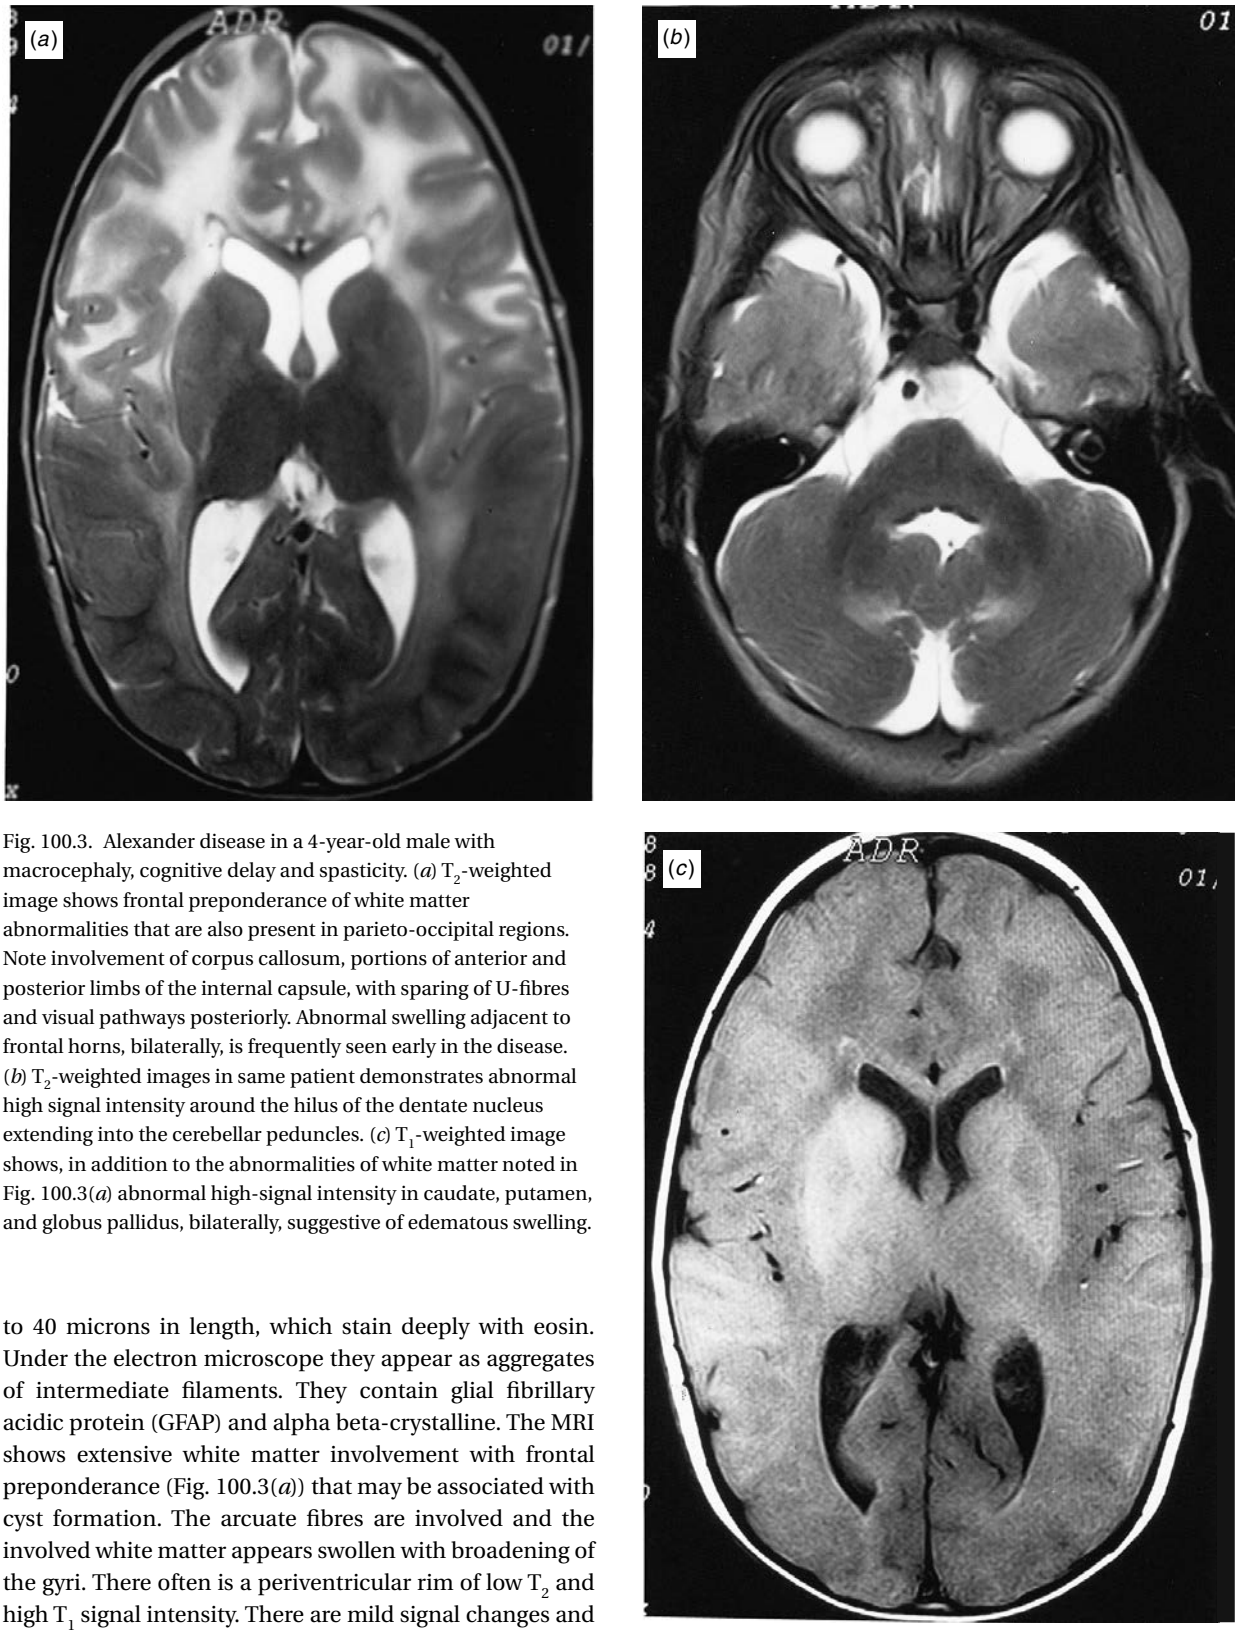

Fig. 100.3. Alexander disease in a 4-year-old male with macrocephaly, cognitive delay and spasticity. (*a*) T_2-weighted image shows frontal preponderance of white matter abnormalities that are also present in parieto-occipital regions. Note involvement of corpus callosum, portions of anterior and posterior limbs of the internal capsule, with sparing of U-fibres and visual pathways posteriorly. Abnormal swelling adjacent to frontal horns, bilaterally, is frequently seen early in the disease. (*b*) T_2-weighted images in same patient demonstrates abnormal high signal intensity around the hilus of the dentate nucleus extending into the cerebellar peduncles. (*c*) T_1-weighted image shows, in addition to the abnormalities of white matter noted in Fig. 100.3(*a*) abnormal high-signal intensity in caudate, putamen, and globus pallidus, bilaterally, suggestive of edematous swelling.

to 40 microns in length, which stain deeply with eosin. Under the electron microscope they appear as aggregates of intermediate filaments. They contain glial fibrillary acidic protein (GFAP) and alpha beta-crystalline. The MRI shows extensive white matter involvement with frontal preponderance (Fig. 100.3(*a*)) that may be associated with cyst formation. The arcuate fibres are involved and the involved white matter appears swollen with broadening of the gyri. There often is a periventricular rim of low T_2 and high T_1 signal intensity. There are mild signal changes and

swelling in the basal nuclei and thalamus (Fig. 100.3(*b*)). The brainstem and cerebellum are involved (Fig. 100.3(*c*)). The pathogenesis and genetics of AD have been clarified recently. Messing and associates developed a transgenic mouse that overexpresses GFAP. These mice showed pathological features that resemble AD (Johnson, 1996). This finding led to a search for mutations in the *GFAP* gene in patients (Brenner et al., 2001). Ten of 11 AD patients, with the infantile, juvenile and adult phenotypes represented, had mutations in the *GFAP* gene, none of which were present in 100 controls. Seven different mutations were identified. No abnormalities were observed in the parents. These results indicate that mutations in the *GFAP* gene are responsible for the majority of AD cases. The gene is autosomal dominant and appears to act as dominant negative. Most cases appear to be due to new mutations in the parental germline or the fetus, consistent with the historical clinical observation that most cases are sporadic.

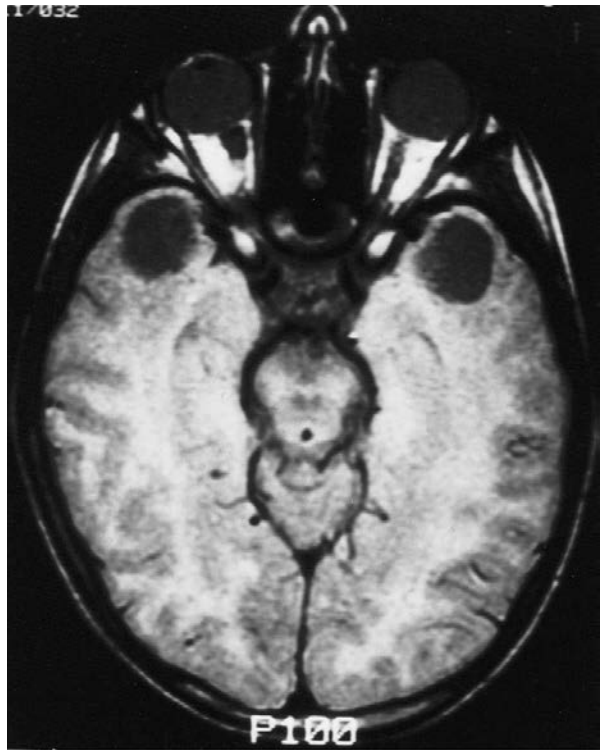

Fig. 100.4. Vacuolating leukoencephalopathy (van der Knaap et al. (1995)): 8-year-old female patient with mild learning disability, macrocephaly and spasticity. Flair images demonstrate diffuse high-signal intensity of white matter, including U-fibres. Note large vacuoles in temporal lobes bilaterally.

Cerebrotendinous xanthomatosis

Cerebrotendinous xanthomatosis (CTX) was described first by Bogaert, Scherer and Epstein in 1937. It presents during the first decade with bilateral juvenile cataracts and diarrhea, followed in the second or third decade by neurological signs and symptoms such as spasticity, ataxia, seizures, mental retardation, dementia, behavioural disturbances and peripheral neuropathy. Tendon xanthomata, often emphasized as a hallmark of the disease, rarely are seen in patients who are less than 20 years old (Verrips, et al., 2000b). Neuropathological abnormalities are widespread and include granulomatous and xanthomatous lesions in the cerebellar hemispheres, globus pallidus and cerebellar peduncles as well as demyelination gliosis in the cerebral hemispheres and the long tracts of the spinal cord and peripheral neuropathy (Federico & Dotti, 1996). The most characteristic abnormality on MRI is a high T_2 intensity lesion in the cerebellum surrounded by a rim with low T_2 intensity. Cerebellar foliae may be prominent, suggesting atrophy. The underlying defect is a deficiency of the mitochondrial sterol 27 hydroxylase, a cytochrome P-450 enzyme which together with two protein cofactors, adrenodoxin and adrenodoxin reductase, hydroxylates steroids at the C27 position. The gene for this enzyme, which maps to 2q33-qter, has been cloned (Cali et al., 1991). Twenty-eight mutations have been identified. Forty-one per cent involve the adrenodoxin and heme protein binding sites (Verrips et al., 2000a). The main biochemical abnormalities are the accumulation of cholestanol in tissues and body fluids demonstrated first by John Menkes in 1968 (Menkes et al., 1968), decreased formation of bile acids, resulting in markedly diminished formation of chenodeoxycholic acid and increased levels of bile alcohols and their conjugates in bile, urine and plasma (Federico & Dotti, 1996). Assay of serum cholestanol levels is the most frequently used diagnostic assay. Mutation analysis is required for carrier detection. Oral administration of chenodeoxycholic acid reduces cholestanol levels and improves neurologic function (Berginer et al., 1984). Simvastatin and plasma exchange have also been used, but require additional appraisal. In theory, liver transplantation might be a curative treatment, but has not been performed in patients with CTX (Federico & Dotti, 1996).

Sjogren Larsson syndrome

Sjogren Larsson syndrome, a disorder in which a leukoencephalopathy is associated with mental retardation, cerebral palsy and ichtyosis, has been shown to be due to a defect in fatty aldehyde dehydrogenase. The defective gene is located at 17p11.2. Thirty-five different mutations have been identified. This syndrome, as well as other inherited disorders of fatty alcohol metabolism, have been reviewed recently (Rizzo, 1998).

Polycystic lipomembranous osteodysplasia with sclerosing leukoencephalopathy

A loss of function mutation in a TYRO tyrosine kinase protein has been reported recently in Polycystic lipomembranous osteodysplasia with sclerosing leukoencephalopathy (MIM 221770) (Paloneva et al., 2000). This is a rare leukodystrophy associated with destructive changes in the skeleton and presenile dementia observed in isolated populations in Finland and Japan (Verloes et al., 1997).

Recently identified leukodystrophies

Analysis and grouping of patients based initially upon MRI findings has led to the identification of three additional leukodystrophies. These are *vacuolating megalencephalic leukoencephalopathy with subcortical cysts* (van der Knaap et al., 1995) (Fig. 100.4) which has been mapped to 22q (Topcu et al., 2000) *leukoencephalopathic vanishing white matter*, also referred to as childhood ataxia with diffuse central nervous system hypomyelination, which has been mapped to chromosome 3q27 (Leegwater et al., 1999) and a *leukoencephalopathy associated with a disturbance in the metabolism* of polyols (van der Knaap et al., 1999).

Part XIV

Infections

101

Host responses in central nervous system infection

David N. Irani[1,2] and Diane E. Griffin[1,2]

[1] Department of Molecular Microbiology and Immunology, The Johns Hopkins University Bloomberg's School of Hygiene and Public Health, Baltimore, MD, USA and [2] Department of Neurology, The Johns Hopkins University School of Medicine, Baltimore, MD, USA

Infections of the central nervous system (CNS) can occur in two anatomically distinct tissue compartments: the subarachnoid and leptomeningeal spaces (meningitis) and the parenchyma of the brain and spinal cord (encephalomyelitis). While an intact blood–brain barrier (BBB) ordinarily deters microorganisms from invading either tissue compartment, it also excludes most circulating components of the immune system, making the CNS susceptible to infection once such invasion does occur. Cells of the immune system can extravasate into the CNS in response to infection, but they appear to do so in a tightly regulated manner. Within the brain, neural cells have restricted immunological function, and the local microenvironment of the CNS can also down-modulate various effector responses of recruited inflammatory cells. In general, a successful host immune response against a CNS infection must overcome these structural and functional barriers to eradicate infectious organisms without causing excessive damage to non-renewable neural cell populations. In some cases, however, the host response is not fully controlled and actually contributes to the neurologic deficits associated with CNS infection. This chapter will review these concepts by citing examples from both human disease states and laboratory-based experimental systems.

Anatomical considerations

There are several anatomical features of the nervous system that influence how local and systemic immune responses are mounted in response to CNS infection. These include: (i) the BBB which stands as a physical barrier against the passage of immune elements from the periphery into the CNS, (ii) the Virchow–Robin spaces immediately surrounding blood vessels that penetrate into the brain where important immunologic reactions can take place, and (iii) cerebrospinal fluid (CSF) recirculation pathways, which may disseminate microorganisms throughout the neuraxis and cause infectious antigens to be carried out of the CNS via particular routes, therefore influencing how they are detected by the immune system in the periphery.

Under normal circumstances, structures that comprise the BBB generally prevent the entry of infectious pathogens, inflammatory cells, and circulating proteins such as antibodies and cytokines into the CNS. Cerebrovascular endothelial cells maintain tight intercellular junctions and very low rates of vesicular transport that differentiate them from the more permeable endothelium found in other tissues. A dense basement membrane ensheathes the cerebrovascular endothelium which is itself surrounded by a network of pericytes and astrocytic foot processes that collectively maintain the integrity of the BBB. In only a few specific locations is the BBB 'fenestrated' and easier to traverse; infectious pathogens circulating in the bloodstream are quite effectively excluded from the brain. Yet once this barrier is breached, many infections take firm hold within the CNS as there is limited intrinsic immune capacity of neural tissues and effective host responses must also surmount the BBB from the periphery.

The Virchow–Robin spaces immediately surrounding many blood vessels that penetrate the surface of the brain are actually extensions of the subpial space (Fig. 101.1). These spaces contain macrophage-like cells with phagocytic and antigen-presenting capacities not found within the brain parenchyma itself. These so-called perivascular macrophages or perivascular microglial cells are of bone marrow origin and actively repopulate themselves within the CNS over the life of the host (Hickey & Kimura, 1988; Hickey et al., 1992). Foreign antigens and lymphocytes also pass through these spaces as they are carried into the lymphatic channels of the head and neck. As a result, the

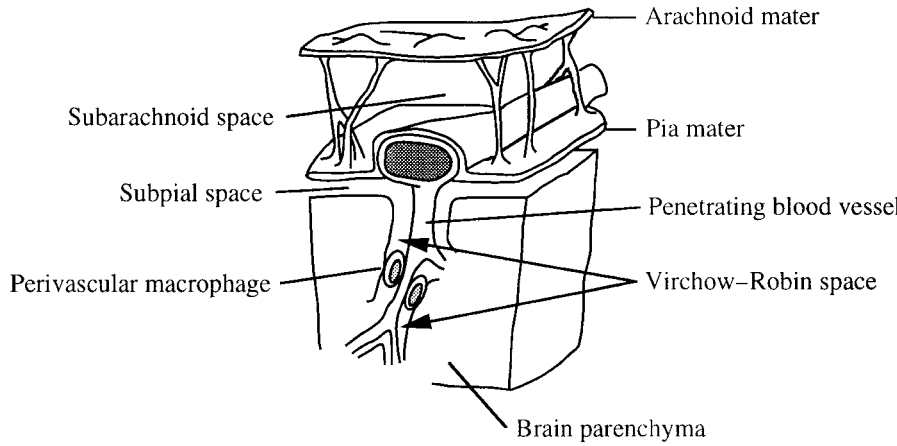

Fig. 101.1. The Virchow–Robin space. These extensions of the subpial space contain perivascular macrophages and can serve as a conduit through which foreign antigens and other leukocytes leave the CNS. Important neuroimmunological reactions occur in these spaces.

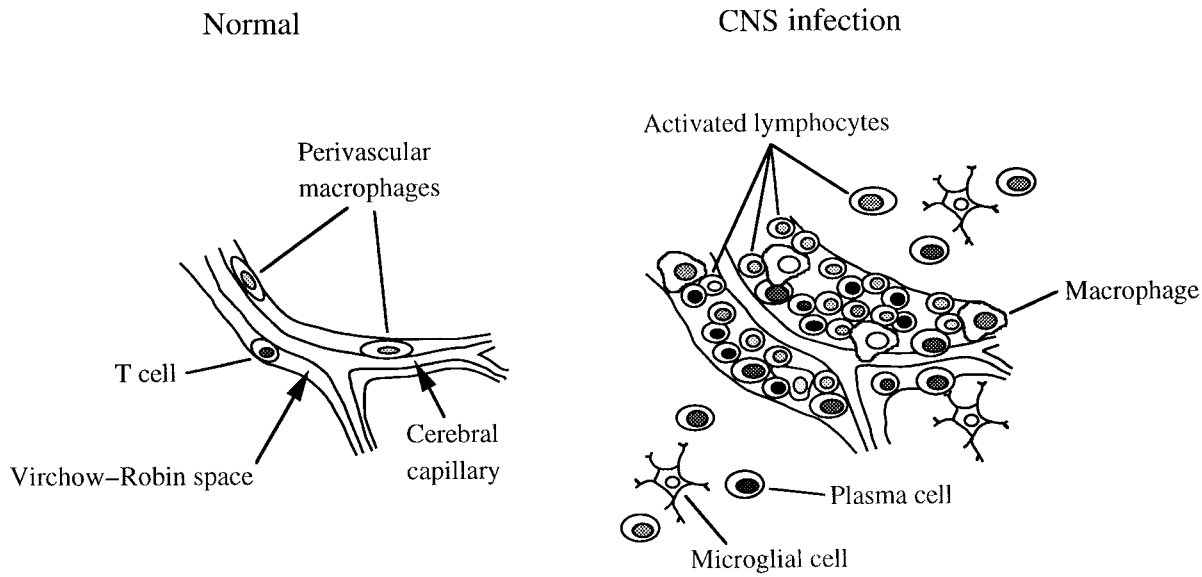

Fig. 101.2. Perivascular inflammation within the Virchow–Robin space. Infections of the CNS can recruit many types of circulating leukocytes across the blood–brain barrier into the Virchow–Robin spaces. These cells (or their products) can then pass into the brain parenchyma itself, allowing for direct interaction with infectious organisms and infected neural cells.

Virchow–Robin spaces form well-defined sites, physically outside of the brain parenchyma itself, where important neuroimmunologic reactions take place (Esiri & Gay, 1990). These spaces become engorged with inflammatory cells during a variety of acute and chronic infections of the CNS (Fig. 101.2).

CSF is produced by cells of the choroid plexus within the ventricles of the brain. Its protein content, including antibodies and complement which are the primary immune mediators present at baseline, is almost entirely derived from the blood. However, these proteins are present in CSF at less than 1% of circulating levels (Fishman, 1992). In contrast, CSF contains abundant nutrients (glucose, amino acids, etc.) that many infectious pathogens can utilize (Fishman, 1992). This fluid normally recirculates within the subarachnoid space which may disseminate

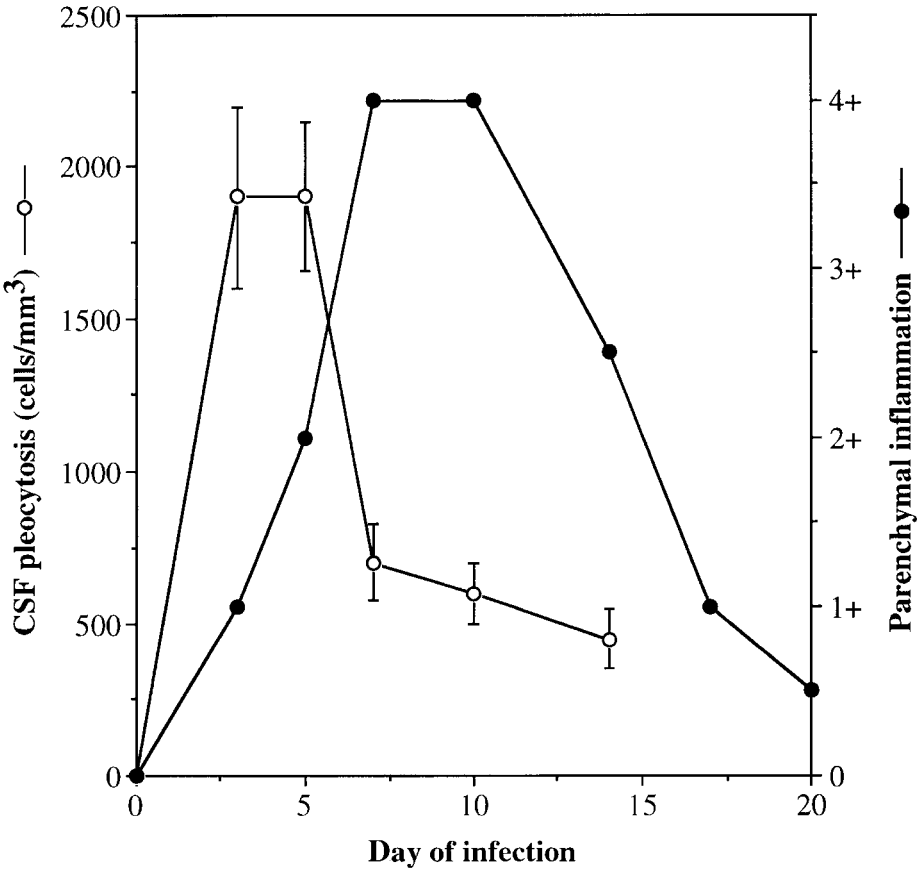

Fig. 101.3. Kinetics of mononuclear leukocyte appearance in the CSF and brain parenchyma of mice with acute Sindbis virus encephalitis. In this infection, cells rapidly infiltrate the CSF before any parenchymal inflammation is seen. CSF cell counts then fall precipitously as cellular infiltration of the brain itself becomes maximal. (Adapted from Moench & Griffin, 1984.)

invading micro-organisms throughout the neuraxis. In addition, protein antigens delivered directly into the CSF of experimental animals elicit enhanced humoral (antibody) and suppressed cell-mediated (T-cell) immune responses compared to when proteins are administered via a peripheral route (Cserr & Knopf, 1992; Gordon et al., 1992). In these models, cervical lymph nodes are an important site where antigen-specific immune responses develop (Harling-Berg et al., 1989; Cserr & Knopf, 1992). Likewise, these lymph nodes also serve as an important site where virus-specific cytotoxic T-lymphocytes (CTL) are generated, following the experimental inoculation of neurotropic viruses into the CNS (Lynch et al., 1989). In this case, however, the degree to which the virus-specific immune response gets skewed in favour of a humoral response, as occurs with more simple protein antigens, remains unknown. Yet, despite any qualitative effects on the elicited immune response, inflammatory cells, antibodies and immunoregulatory cytokines collect within the CSF during many CNS infections. In one experimental model of acute viral encephalitis, the accumulation of mononuclear cells in CSF actually precedes immune infiltration of the brain (Fig. 101.3); CSF inflammation is already subsiding when parenchymal inflammation becomes maximal (Moench & Griffin, 1984). Such differences in the kinetics of leukocyte infiltration suggest that recruited inflammatory cells may either traffic from one CNS compartment to another (i.e. from CSF to brain) or that their capacity to extravasate into each site is controlled by different mechanisms and/or occurs via different pathways. It also implies that, when CSF is sampled diagnostically in viral encephalitis, the findings may not fully reflect the degree of abnormality present in the underlying brain parenchyma itself.

Immune capabilities of neural cells

Most neural cells lack constitutive expression of major histocompatibility (MHC) class I and class II molecules that are necessary for antigen presentation to T-cells. While astrocytes and cerebrovascular endothelial cells can both be induced to express these molecules in vitro (Fierz et al., 1985; Risau et al., 1990), only perivascular macrophages and parenchymal microglial cells are reliably induced to express MHC antigens during CNS infection in vivo (Tyor et al., 1990, 1992a). Even then, MHC Class II expression necessary for antigen presentation to CD4+ T-cells may not be sufficient; ligation of various costimulatory molecules is required to fully activate naive T-cells and drive them to proliferate (Steinman, 1991). Microglial cells, however, can reactivate memory T-cells and induce some antigen-specific cytokine production without stimulating proliferation (Ford et al., 1996). This 'partial' activation is followed by the prompt induction of T-cell death via apoptosis (Ford et al., 1996). In this manner, microglial cells may actually protect the CNS from lymphocytes recruited during infection by allowing them to exert some local effector function but also by discouraging their full activation and limiting their survival.

The issue of whether any neural cell can present infectious antigens to a naive T-cell (i.e. a T-cell that has not yet encountered such an antigen outside the CNS) remains unclear. In early pathogenesis studies, viruses inoculated experimentally into the CSF or the brain parenchyma of animals were introduced in relatively large volumes; this typically produced a rapid viremia thereby allowing specific activation of the immune system in the periphery (Mims, 1959). In a more careful study of this issue, a large volume injection of influenza virus into the brain parenchyma or CSF of mice elicited systemic cellular and humoral antiviral immune responses comparable to those which developed following intranasal challenge (Stephenson et al., 1997). However, when the same amount of virus was delivered directly into the CNS parenchyma in a very small volume, there was no detectable immune response elicited over the first 10 days and less than half of the mice eventually mounted such a response more than 80 days later (Stephenson et al., 1997). Not only does this highlight the fact that infectious pathogens elicit variable local immune responses based on their accumulation in different CNS compartments, but it also demonstrates that the brain parenchyma itself has a surprisingly deficient capacity to initiate a primary immune response. While this may have evolved to minimize the risks of CNS autoimmunity, it may also allow infectious pathogens to remain sequestered behind the BBB and hidden from the immune system.

The CNS, however, is not totally devoid of intrinsic immune function. In a murine model of acute viral encephalitis, transcripts encoding multiple cytokine genes are induced in the brain well before overt inflammation can be detected (Wesselingh et al., 1994). This strongly suggests that endogenous neural cells rapidly produce these mediators in response to infection. Proinflammatory cytokines can be localized within microglial cells and astrocytes from autopsy cases of chronic human CNS infections as well as from experimental CNS infections induced in laboratory animals (Frei et al., 1989; Tyor et al., 1992a; Wesselingh et al., 1993, 1996). A role for these soluble immune mediators as an important component of the acute host response to infection has now been demonstrated; both pharmacological and genetic strategies to inhibit their production in experimental systems lead to enhanced pathogen replication within the CNS and/or more lethal disease (Geiger et al., 1995; Tucker et al., 1996; Byrnes et al., 2000). However, the long-term production of cytokines and other inflammatory mediators within the CNS has been associated with neurotoxicity and severe neurological symptoms such as myelopathy and dementia in chronic diseases such as human immunodeficiency virus (HIV) infection (Tyor et al., 1992a; Wesselingh et al., 1993; Adamson et al., 1996). Nevertheless, endogenous neural cells are now recognized to be immunologically active, at least with regard to their capacity to produce cytokines and other inflammatory mediators during CNS infections. As discussed, this response may work either to the benefit or the eventual detriment of the infected host.

Endogenous cells of the brain may also possess other immunological functions relevant to different CNS infections. Certainly phagocytosis, a function served primarily by macrophage-lineage cells including microglia and perivascular macrophages, can help to control extracellular pathogens such as bacteria. Following their stimulation with inflammatory cytokines, astrocytes can generate a complete, functional complement cascade (through both the classical and alternative pathways) that may participate in the opsonization and killing of infectious pathogens within the brain (Morgan & Gasque, 1996). More recently, certain astrocyte populations have also been recognized to express perforin, a cytotoxic protein previously only found in T-cells and natural killer cells (Gasque et al., 1998). While dysregulation of these endogenous immune pathways has been implicated in a variety of inflammatory and degenerative diseases involving the CNS, their identification also highlights the fact that brain is not entirely the 'immune privileged' site it was once considered to be.

Recruitment of inflammatory cells into the CNS

It is generally assumed that inflammatory cells which accumulate in the perivascular spaces of the brain during various CNS infections do so by extravasating directly from the circulation across the BBB. Such leukocyte extravasation is likely to be a multistep process triggered by chemoattractant signals arising from within the CNS. Once such a signal is detected, circulating leukocytes must then bind to the luminal surfaces of cerebral vessels. In other tissues, this binding occurs via the actions of specific adhesion–ligand pairs (Springer, 1990). Bound leukocytes then traverse the endothelial and basement membrane barriers before they can begin to exert effector functions in response to the eliciting infection. While it is assumed that specific signals are also required to retain inflammatory cells within the brain, the precise mechanisms and routes of cell efflux from the CNS remain poorly understood.

An enlarging number of chemoattractant cytokines ('chemokines') have been identified which signal leukocytes to migrate along a gradient via the actions of specific chemokine receptors. α-Chemokines are the primary attractants for neutrophils, while β-chemokines can modulate both macrophage and T-cell migratory responses (Baggiolini et al., 1994). In general, these molecules operate via redundant pathways to attract overlapping populations of inflammatory cells into various tissue sites. Chemokines can be produced within the CNS by different glial, and possibly even neuronal, cell populations (Glabinski et al., 1995). Their role during CNS infection has been most carefully investigated in chronic disorders such as HIV; the increased number of activated macrophages found within the brains of patients with HIV-associated dementia compared to non-demented control patients has been correlated with higher CSF (and presumably brain) levels of certain β-chemokines (Kelder et al., 1998). The HIV tat protein can directly induce cultured astrocytes to secrete high levels of monocyte chemoattractant protein-1 (MCP-1), the principal β-chemokine associated with HIV dementia (Conant et al., 1998; Kelder et al., 1998). It is likely that chemokines direct the recruitment of inflammatory cells into the CNS during other acute and chronic neurologic infections as well.

In the absence of disease, cerebrovascular endothelial cells express few adhesion molecules making non-activated lymphocytes and circulating monocytes unable to enter the CNS with any efficiency. Following viral infection, however, a variety of adhesion molecules are up-regulated on cerebrovascular endothelial cell surfaces (Irani & Griffin, 1996). This probably occurs via local cytokine production from within the CNS as cultured cerebrovascular endothelial cells can up-regulate various adhesion receptors following cytokine stimulation in vitro (Wekerle et al., 1991). Activated lymphocytes and monocytes, which themselves express higher levels of adhesion molecules compared to resting cells, then bind to cerebrovascular endothelium without regard to their antigenic specificity (Irani & Griffin, 1996). Such binding, although not necessarily sufficient to gain entry into the CNS, is certainly a prerequisite step for circulating inflammatory cells to cross the BBB.

Once bound to the luminal surface of a CNS blood vessel, leukocytes must pass through endothelial cell tight junctions and then traverse the surrounding basement membrane. Like those found in other tissues, the BBB basement membrane is composed of multiple extracellular matrix proteins including type IV collagen, heparin sulfate proteoglycan, laminin, and entactin. Activated lymphocytes produce a matrix-degrading heparan sulfate endoglycosidase and presumably other matrix degradative enzymes as well (Naparstek et al., 1984). Matrix metalloproteinases (MMPs) are a family of zinc-containing endopeptidases that degrade specific components of the extracellular matrix found within the CNS; these enzymes have received significant recent attention because they are made by activated lymphocytes and monocytes and specific MMP inhibitors can block the extravasation of these cells across the BBB (Yong et al., 1998). Endogenous neural cells may also be stimulated to generate MMPs which may contribute to BBB changes seen during chronic CNS infections such as HIV (Power et al., 1993; Maeda & Sobel, 1996). In disease situations where the CNS inflammatory response may actually be detrimental to the neurological function of the host, local CNS production of MMPs may contribute to disease progression. Not only does a damaged BBB make it easier for excessive numbers of circulating leukocytes to enter the CNS, but it may promote exposure of the brain to potentially toxic serum proteins including serine proteases such as thrombin (Turgeon & Houenou, 1997).

Unlike their entry into the CNS, which can occur without regard to antigenic specificity, the retention of lymphocytes within the CNS during infection appears to depend strongly on the antigen that each cell recognizes. Thus, at least during viral infection of the CNS, virus-specific T-cells are selectively retained within the CNS compared to cells of an irrelevant specificity (Irani & Griffin, 1996). In this case, it is assumed that the process of recognizing viral antigens on neural cells induces changes that cause these T-cells to remain in place. How the 'irrelevant' T-cells exit the CNS is now known, and some evidence suggests that they may not actually leave the CNS but instead undergo apoptosis

locally within the brain (Barac-Latas et al., 1995; Irani et al., 1997). Thus, the brain may possess endogenous mechanisms that keep relevant leukocytes within its confines, while causing unnecessary inflammatory elements to either depart or be eliminated. Any breakdown of this system, however, might predispose to immune-mediated neurological injury.

Local regulation of inflammatory cell function within the CNS

In addition to mechanisms that control the recruitment of inflammatory cells into the brain, there is evolving evidence to suggest that the CNS has some capacity to regulate the local effector function of recruited inflammatory cells. Such a capacity may have evolved to prevent overactive immune responses from damaging non-renewable cell populations such as neurons. For example, T-cells that have extravasated into the brain parenchyma may produce cytokines and exert some cytolytic activity, but there is little evidence that they proliferate locally in response to antigenic stimulation. Perivascular and parenchymal lymphocytes do not divide within the brains of animals with viral encephalitis when assayed using in vivo techniques to label DNA in proliferating cells (Irani et al., 1997; Hawke et al., 1998). Furthermore, lymphocytes isolated from the brains of these animals and placed into culture eventually recover the capacity to divide suggesting that the local CNS microenvironment exerts this antiproliferative effect (Irani et al., 1997). While this may in part derive from inhibitory signals generated during local antigen presentation (Ford et al., 1996), it is also clear that neuronal membrane lipids can affect various T-cell responses such as proliferation, cytokine production, and survival (Irani et al., 1996, 1997). Infiltrating T-cells probably encounter these membrane glycolipids once they infiltrate the brain, thereby coming under their local regulatory effect. This provides another potential mechanism to control local T-cell function to the advantage of the CNS.

The brain may also be able to exert local control over the effector functions of leukocytes other than T-cells. Sensory neurons can regulate immunoglobulin secretion by B-cells via the release of soluble factors (Hikawa & Takenaka, 1996), and various neuropeptides have been shown to modulate the production of inflammatory cytokines by human monocytes (Lotz et al., 1988). Astrocytes may also contribute to local immune regulation within the brain by producing immunomodulatory cytokines such as transforming growth factor-β (Wilbanks & Streilein, 1992). This particular mediator has received attention because it is constitutively expressed within the brain, CSF, and aqueous humor of the eye (Streilin, 1993). Based on these and other data, immune privilege within the CNS is now viewed as an active process whereby local tissue factors interact with and alter the functional programs of various cells of the immune system. It remains unclear, however, exactly to what degree such endogenous immunoregulatory pathways are altered during various infections of the CNS.

Host responses against specific types of infectious pathogens within the CNS

Viruses invade the CNS either through hemotogenous dissemination and direct spread across the BBB or through retrograde axonal transport up nerve processes that extend from the periphery into the CNS (Johnson, 1998). As intracellular pathogens, the tropism of viruses for different neural cell populations and their effect on host cell function and survival are major determinants of the severity of disease. The paucity of MHC antigen expression within the CNS, particularly on neurons, can limit direct CTL-mediated clearance of certain viruses and may predispose to chronic or relapsing neurologic infections (Joly et al., 1991). Their capacity to establish latency also allows viruses to avoid detection by the immune system. In other cases, however, T-cell-mediated clearance of viruses from the CNS can occur via the local production of soluble anti-viral mediators such as interferon-γ (Kündig et al., 1993). T-cells can also protect experimental animals from otherwise lethal CNS viral challenges without actually decreasing the amount of infectious virus in the brain (Stohlman et al., 1986). In still other cases, antiviral antibodies can shut off virus production by infected neurons in a non-cytolytic manner (Levine et al., 1991). This strategy is attractive because recovery from disease can occur without cytolytic destruction of non-renewable cells and because the immune system can generate an antigen-specific response that acts without requiring target cell expression of MHC molecules. Such non-cytolytic strategies have their drawbacks, however, as the viral clearance can be incomplete allowing viral nucleic acids to persist long-term within the CNS (Levine & Griffin, 1992). This can be enough to stimulate persistent CNS inflammation which has been hypothesized to predispose the CNS to eventual immune-mediated damage (Tyor et al., 1992b; Hawke et al., 1998). Endogenous neural cells can mount non-specific antiviral responses via the production of cytokines (Tucker et al.,

1996; Byrnes et al., 2000), but as discussed earlier, the long-term generation of mediators such as tumor necrosis factor-α (TNF-α) within the CNS during chronic infections such as HIV may actually promote the development of neurologic systems (Wesselingh, et al., 1993; Tyor et al., 1995).

Bacteria require specific virulence factors to invade the CNS and produce neurological disease. Organisms that cause acute meningitis are usually encapsulated; this inhibits activation of complement through the classical pathway and delays bacterial phagocytosis outside the CNS. As a result, encapsulated bacteria survive longer in the bloodstream, produce more robust bacteremias, and are more likely to invade the CNS (Tunkel & Scheld, 1991). Once within the subarachnoid space, favourable local conditions (i.e. limited intrinsic host defences, abundant nutrients) allow for rapid and unimpeded bacterial multiplication. Inflammatory cytokines, particularly interleukin-1 and TNF-α, are eventually secreted in response to bacterial cell wall products and help induce endothelial expression of adhesion molecules important for neutrophil egress (Springer, 1990). The local production of other chemotactic stimuli including interleukin-8 also recruits neutrophils, but low overall levels of opsonins, antibodies, and complement within the CSF limit bacterial phagocytosis by infiltrating cells. Slow growing bacteria such as mycobacteria have adapted to survive inside macrophages and typically induce mononuclear inflammatory responses in the CSF.

Fungi are generally avirulent pathogens; most individuals with disseminated fungal infections that spread to the CNS have some underlying immune deficiency. The particularly high frequency of these disorders in patients with impaired cell-mediated responses implies that these immune elements serve as the primary host defence against fungal pathogens that invade the CNS. In these hosts, fungi can survive longer in the bloodstream (their presumed route to the CNS), are more likely to cross the BBB, and then grow unchecked in the CSF without eliciting much of an inflammatory response. For *Cryptococcus neoformans*, the ability to produce melanin, which may act as an antioxidant to protect the organism from host immune damage, has been proposed as an important virulence factor (Kwon-Chung & Rhodes, 1986). Once CNS infection has been established, these organisms are difficult to completely eradicate and often require long-term antifungal therapy. Mortality in general is high.

Only a few parasites frequently invade the nervous system. Free-living amebae that cause acute meningoencephalitis likely enter the CNS by direct invasion across the olfactory mucosa. This can occur following aquatic exposure such as swimming in infected water (Cegielski & Durack, 1991). Macrophages, neutrophils, and the complement system all can respond to these organisms, but once CNS invasion occurs, the infection typically overwhelms host defences and is invariably fatal (Cegielski & Durack, 1991). Most other parasites are assumed to enter the CNS from the bloodstream. Intracellular pathogens such as *Toxoplasma gondii* may establish latent CNS infection in the form of inert cysts that evade host immune clearance. Otherwise, various T-cell-derived cytokines are particularly active against these organisms, in part, via their capacity to activate phagocytic macrophages (Dukes et al., 1991). Clinically apparent CNS toxoplasmosis almost always develops in hosts with acquired cellular immune deficiencies such as those caused by chronic HIV infection. In contrast, the cysticerci of *Taenia solium* can induce an intense parenchymal CNS inflammatory reaction. These organisms are eventually killed leaving behind calcified nodules, which themselves can produce neurological symptoms such as seizures. Malaria can induce an acute encephalopathy associated with the adhesion of parasitized erythrocytes to cerebral capillary endothelial cells. In fatal cases, diminished cerebral blood flow and petechial hemorrhages often ensue, although emerging data suggest that the host immune response also contributes to disease pathogenesis. Inflammatory cytokines can be induced within the CNS of patients with cerebral malaria that may serve to up-regulate endothelial adhesion molecules and promote further erythrocyte adhesion (Fujioka & Aikawa, 1996). Brain hypoxia, along with varying degrees of the hypoglycemia that is common in this setting, may be the substrate that underlies the neurological disease.

In conclusion, an effective host immune response to infection of the CNS requires a careful interplay between the nervous and immune systems. This response must overcome a series of structural and functional barriers imposed by the CNS in order to eradicate infectious organisms without causing excessive damage to non-renewable neural cell populations. These barriers have evolved to protect the brain, which certainly can sustain more injury from an activated immune system than from an infection itself. Such a protective system, however, often allows invading organisms to replicate behind the BBB in an unimpeded manner or limits their full eradication from the CNS. Either of these situations may be as detrimental to the host as an overexuberant local immune response. The neuroimmunologic lessons taught by studying host responses during CNS infections have broad relevance to understanding nervous system–immune system interactions in general.

Viral diseases of the nervous system

Larry E. Davis

Neurology Service, New Mexico VA Health Care System, Albuquerque, New Mexico, USA and Department of Neuroscience and Microbiology, University of New Mexico School of Medicine, Albuquerque, New Mexico USA.

Viral routes and host defenses

Many viruses once they reach the central nervous system (CNS) are capable of infecting cells and producing varying types of clinical syndromes. If the virus infects primarily meningeal cells lining the brain, meningitis develops. If the virus widely infects many types of brain cells, such as neurons and glia, encephalitis ensues. Some viruses infect only selective cell types producing specific clinical syndromes. For example, poliovirus infects only neurons of the motor pathway producing a paralytic disease called poliomyelitis. To date, viruses have not been implicated as a cause of brain abscesses or subdural empyemas.

Viral infections of the CNS usually begin with a primary focus of infection associated with their route of entry. Enteroviruses establish an initial infection in the gastrointestinal tract. Mumps virus establishes a primary infection in the respiratory tract. Rabies virus is directly inoculated through the skin via saliva during the bite from an infected animal and establishes a primary infection in the subcutaneous tissue and underlying muscle. Arboviruses are inoculated through the skin by a vector (infected mosquito or tick) and infect subcutaneous tissue and traversing blood vessels. The primary systemic infection usually is asymptomatic but prodromal syndromes can occur (gastroenteritis or upper respiratory infection). As viral replication continues at the primary site of infection, progeny virions spread into adjacent blood vessels or lymphatic channels. A viremia of varying duration then develops seldom causing a CNS infection. For example, less than 2% of susceptible individuals infected with poliovirus develop viral infection of the spinal cord and paralysis (Melnick, 1996).

For a viremia to cause a CNS infection, several important host barriers must be overcome. The reticuloendothelial system (RES) is an efficient filter of viruses circulating in blood. Clearance of small viruses, such as arboviruses, from blood is over 90% within 1 hour. However, some viruses overcome the RES by constantly releasing viral particles into the bloodstream following infection of vascular endothelial cells or lymph nodes (Johnson & Mims, 1968). Other viruses circumvent the RES by infecting circulating blood cells. Mumps virus can replicate within leukocytes and human immunodeficiency virus (HIV) can replicate in T-helper lymphocytes and monocytes/macrophages. In this manner, viruses are protected by RES phagocytosis or circulating neutralizing antibody.

Humoral and cellular immune responses are other defences that effectively terminate viremias. However in a primary infection, several days are required for the host immune system to establish the immune response. The delay may allow the virus to cross the blood–brain barrier and establish the CNS infection.

The final hindrance for a virus to reach the CNS is to overcome the blood–brain barrier. This barrier is usually highly effective in preventing all micro-organisms from reaching the CNS. However, some arboviruses breech the barrer by infecting cerebral capillary endothelial cells, replicating, and exiting directly into the brain (Johnson, 1965). Other viruses, such as mumps, appear capable of penetrating the fenestrated walls of the choroid plexus blood vessels to infect and replicate within the choroid plexus cells and subsequently enter the ventricular cerebrospinal fluid (CSF) (Wolinsky et al., 1976).

A few viruses reach the CNS via peripheral or cranial nerves. Rabies virus appears to infect peripheral sensory nerves in the initially infected muscle and travel retrograde to reach the spinal or trigeminal ganglia and into the spinal cord or brainstem (Murphy et al., 1973). Herpes simplex virus has been hypothesized to reach the brain by spread within sensory fibres of the trigeminal ganglia (Davis & Johnson, 1979).

Table 102.1. Estimated frequency of neurological syndromes in systemic viral infections

Virus	Meningitis	Encephalitis	Myelitis
Enterovirus	+++	++	+
Poliovirus	+++	+	+++
Human immunodeficiency virus	+++	++	++
Arbovirus	+++	+++	++
Herpes simplex			
(congenital)	++	+++	+++
(adult)	++ (type 2)	+ (type 1)	+ (type 1,2)
Varicella-zoster	+	+	+
Epstein–Barr	+	+	+
Cytomegalovirus			
(congenital)	+	+++	+
(immunosuppresssed adult)	++	++	+
Influenza	+	+	+
Parainfluenza	+	+	+
Rubeola (measles)	++	++	+
Rubella			
(congenital)	+	+++	+
(child or adult)	+	++	+
Mumps	+++	++	+
Lymphocytic choriomeningitis	+++	++	0
Reovirus	+	+	+
Dengue	++	++	0
Adenovirus	++	++	0
Parvovirus B19	+	++	0
Rabies		+++	+++
Papovavirus (JC strain)		+++	0
Prions		+++	0
(Creutzfeld–Jakob disease)			

Notes:
+++ = common, greater than 1 per 1000 primary infections.
++ = Less common, less than 1 per 1000 primary infections.
+ = Uncommon, only scattered reports in literature.
0 = No or questionable reports in literature.

The brain is not a homogeneous organ, such as liver. Viral infections directed towards different brain locations or cell types result in differing signs and symptoms. Thus, the neurological signs and symptoms are due to the location of the viral infection in the CNS and not the specific virus. The specific virus determines the severity of the CNS infection and its duration.

This chapter discusses the major neurological illnesses that are caused by viruses. Table 102.1 lists the types of infections that different viruses can cause and their estimated frequency. However, one is referred to major textbooks of infectious diseases for information regarding details of specific viruses and the types of CNS infection they can cause (Mandell et al., 2000; Long et al., 1997; Davis & Kennedy, 2000).

Viral infections of the meninges

Viral meningitis is part of a broader syndrome with similar features called aseptic meningitis. Viral meningitis is characterized by (i) acute onset, (ii) signs and symptoms of meningeal inflammation, (iii) characteristic CSF findings, (iv) absence of organisms when CSF is cultured on routine bacteriologic media, and (v) relatively short and benign clinical course (Davis, 1997). Aseptic meningitis has

similar clinical characteristics to viral meningitis but the meningitis is not always brief or benign. Non-viral causes of aseptic meningitis include drugs, biologic products, unusual bacterial or parasitic agents, systemic or immunologically mediated diseases, neoplastic diseases, and parameningeal conditions (Table 102.2).

Etiologies and epidemiology

Worldwide, enteroviruses (coxsackieviruses and echoviruses) and mumps virus are the most common causes of viral meningitis. In countries administering mumps vaccine to children, enteroviruses account for over 80% of cases. In the United States, the Centers for Disease Control and Prevention report over 10 000 cases of aseptic meningitis each year (Centers for Disease Control and Prevention 1992). However, the true incidence likely is much higher as many cases are not reported to state agencies. Recent studies of enterovirus meningitis suggest that over 75 000 such cases occur annually (Rotbart, 1995). In epidemiology studies, the incidence of aseptic meningitis has been estimated to be about 18 cases per 100 000 population per year but can locally increase during seasonal epidemics (Modlin, 1999). The majority of cases occur in children, with a peak incidence occurring in summer and early fall when epidemics of enteroviruses prevail.

Clinical manifestations

Prodromal illnesses may preceded the viral meningitis. The characteristics of the prodromal illness are usually vague and mild and consist of gastrointestinal distress, rashes or 'flu-like symptoms (Table 102.3). However, meningitis from mumps virus may be preceded by parotitis or orchitis and from herpes simplex virus by genital vesicles.

Table 102.4 lists the signs and symptoms of viral meningitis. The onset of symptoms is usually quite abrupt and patients reach marked symptoms within hours of onset. Marked lethargy or seizures suggests viral invasion of the brain parenchyma and the development of meningoencephalitis. The presence of coma, papilledema or focal neurologic signs is rare in viral meningitis and raises the possibility of a CNS mass from a different cause.

Laboratory findings

The hemogram is usually normal or has a mild leukocytosis (usually lymphocytosis). Other blood tests vary depending on the etiology. Table 102.5 lists the common CSF abnormalities. In uncomplicated viral meningitis, the electroencephalogram and neuroimaging are usually normal.

Differential diagnosis

The major causes of aseptic meningitis are listed in Table 102.2. It is important to distinguish the patient with viral meningitis from patients with pyogenic bacterial, tuberculosis, or fungal meningitis. Distinguishing features between viral and bacterial meningitis are listed in Table 102.5. Of note, occasional patients with proven viral meningitis (especially mumps and herpes simplex viruses) may have CSF obtained in the first day of the illness that contains predominately neutrophils and mildly depressed glucose. However, patients with viral meningitis should not have markedly depressed CSF glucose levels (below 20 mg/dl) or bacteria seen by Gram stain of the CSF sediment. In patients with atypical viral meningitis, repeat lumbar puncture 12–24 hours later usually demonstrates a CSF with a normal or near normal glucose level and predominance of lymphocytes (Sells et al., 1975).

Diagnosis

The etiology of viral meningitis is established if there is: (i) a characteristic prodrome (such as parotitis or genital vesicles), (ii) isolation of virus from CSF, stool or throat secretions, (iii) positive polymerase chain reaction (PCR) assay for viral nucleic acid in CSF, or (iv) a four-fold rise in antibody titre to a specific virus between the acute and convalescent serum samples. Table 102.3 lists the most common methods to diagnose each virus. The ease of culturing viruses from CSF depends on the etiology. Viruses most often are isolated from CSF in the first 12–24 hours of symptoms. However, isolation of the virus from the gastrointestinal tract or throat often occurs for days. Use of PCR assays in CSF to establish the diagnosis of enterovirus or herpes simplex virus (HSV) meningitis is becoming widely used (Read & Kurtz, 1999; Riding et al., 1996). PCR assays for enteroviruses have primers and probes directed against a conserved 5′ non-coding region of the viral genome and thus detect most enterovirus strains. The newer PCR assays report over 90% sensitivity and 100% specificity for enteroviruses. A similar sensitivity and specificity is reported for HSV PCR assays. PCR assays for mumps and other viruses may soon be available (Poggio et al., 2000). Studies are under way to determine whether a battery of PCR assays can be used to detect several infectious agents in CSF (Read & Kurtz, 1999; Hosoya et al., 1998).

Management

The first step is to determine that the patient has aseptic meningitis, likely due to a virus, and not acute pyogenic

Table 102.2. Major causes of aseptic meningitis

Viruses
Enteroviruses (echovirus and coxsackievirus)
Mumps
Herpes simplex, types 2 and 1
Arboviruses (Eastern equine encephalitis, Western encephalitis, Venezuelan encephalitis, St. Louis encephalitis, Powassan, California, Colorado tick fever, West Nile, and many strains found outside of the United States
Human immunodeficiency virus
Lymphocytic choriomeningitis virus
Poliovirus
Varicella-zoster virus
Parvovirus B19
Epstein–Barr virus
Adenovirus
Rubeola virus (measles)
Rhinovirus
Cytomegalovirus
Vaccine viruses (mumps, measles, rubella, poliovirus)

Other infectious agents
Borrelia Burgdorferi
Treponema pallidum (syphilis)
Taenia solium (cysticercosis)
Leptospira sp.
Brucella sp.
Bartonella sp. (cat scratch fever)
Agents of bacterial endocarditis
Toxoplasma gondii
Mycoplasma pneumonia
Trichinella spiralis (trichinosis)
Rickettsia rickettsii (Rocky mountain spotted fever)
Rickettsia prowazekii (typhus)
Ehrlichia chaffeensis
Agents of human granulocytic ehrlichiosis
Babesia sp.
Chlamydia trachomatis
Angiostrongylus cantonensis and Baylisacaris procyonis (eosinophilic meningitis)

Parameningeal conditions
Sinusitis
Epidural or subdural empyema
Mastoiditis
Dermoid or epidermoid cyst
Cranial osteomyelitis
Brain abscess
Infection or inflammation related to ventricular shunts
Posterior fossa surgery

Drugs
Trimethoprim-sulfamethoxazole
Ibuprofen, Sulindac, Tolmentin, Naproxen
Azathioprine
Sulfasalazine
Ciprofloxacin
Amoxicillin
Isoniazid
Carbamazepine
Chemical meningitis from drugs or radiographic agents instilled in CSF

Biological products
Murine monoclonal antibody OKT3
Intravenous gammaglobulin (IVIg)
Influenza vaccine (killed virus)

Systemic or immunologically mediated diseases
Systemic lupus erythematosus
Rheumatoid arthritis
Polyarteritis nodosa
Granulomatous arteritis
Mixed connective tissue disease
Sjogren syndrome
Lymphomatoid granulomatosis
Wegener granulomatosis
Sarcoidosis
Behçet disease
Kawasaki disease
Mollaret meningitis
Vogt–Koyanagi–Harada syndrome
Familial Mediterranean fever
Status epilepticus

Neoplastic diseases
Leukemia
Carcinoma
Lymphoma
Craniopharyngioma
Teratoma
Astrocytoma
Meduloblastoma

Source: Table was modified from Davis (1997).

Table 102.3. Prodromes and methods of diagnosis of CNS viruses

Virus	Prodromes	Virus isolation	Polymerase chain reaction and serology
Enterovirus	None or mild gastroenteritis, pharyngitis syndrome or hand–foot–mouth syndrome for 1–3 days	**CSF, throat, stool**	**PCR assay available** Acute, convalescent sera
Mumps	Parotitis or occasional orchitis for 2–10 days	**CSF, throat**	PCR assay is research **Acute, convalescent sera**
Herpes simplex	Genital vesicles for 1–7 days	**Genital lesions** CSF	**PCR assay available** Acute, convalescent sera for primary type 2 infection
Arboviruses	Fever, rash, malaise, myalgia for 1–5 days	–	**Acute serum IgM antibody capture enzyme immunoassay** **Acute, convalescent sera**
Human immunodeficiency	'Flu-like' syndrome with arthralgia, myalgia, maculopapular truncal rash, lymphadenopathy 2–6 weeks after HIV exposure	CSF, blood	**PCR assay available** **Serology positive 4–6 weeks after primary infection**
Lymphocytic choriomeningitis	Fevers, 'flu-like' syndrome for 5–21 days	CSF, blood	PCR assay is research **Acute, convalescent sera**
Poliovirus	Gastroenteritis, myalgia for 1–2 days	**Stool, throat**	**Acute, convalescent sera**
Varicella-zoster	Chickenpox or zoster rash for 1–5 days	**Skin vesicles** CSF	**PCR assay available,** **Acute, convalescent sera**
Parainfluenza	Cough, myalgia for 1–4 days	CSF, throat	Acute, convalescent sera
Rotavirus	Gastroenteritis for 1–5 days		**Stool, CSF for rotavirus antigen immunoassay**
Adenovirus	Cough, pharyngitis, pneumonia, conjunctivitis for 1–4 days	CSF, **throat**	PCR assay, experimental Acute, convalescent sera
Rubeola	Cough, coryza, conjunctivitis, rash for 1–7 days	**Throat,** blood lymphocytes	**Acute, convalescent sera**

Notes:
Boldface indicates the most common methods of making diagnosis.

bacterial, tuberculous, or fungal meningitis. Once the illness is determined to be an aseptic meningitis, efforts should be made to determine the etiology (see Tables 102.2 and 102.3).

The decision whether to hospitalize the patient or treat the patient as an outpatient varies. Experience in emergency rooms has shown that the diagnosis of aseptic meningitis can usually be correctly made and the older child or adult can be managed as an outpatient (Waisman et al., 1999). In general, hospitalization should be considered in neonates, infants, elderly, or immunosuppressed individuals in which the clinical features of more serious forms of meningitis may be masked. As noted above, patients with CSF containing predominantly neutrophils or depressed glucose levels are usually hospitalized and treated for possible bacterial meningitis for the first day until the repeat lumbar puncture shows the typical pattern of viral meningitis or the PCR assay for enterovirus or mumps virus returns positive. Detection of enterovirus RNA in CSF by PCR assay often allows for shortening of hospital stays.

The majority of cases of viral meningitis are brief, self-limited and do not benefit from antiviral treatment. Patients with severe meningitis from herpes simplex virus, type 2, respond to acyclovir at an oral dose of 200 mg/day five times a day for 5 days (DeBiasi & Tyler, 2000). For maximum benefit, the acyclovir must be started as early as possible in the clinical course. However, most patients with herpes simplex viral meningitis do well without acyclovir treatment. Pleconaril is a new antiviral drug designed to block enteroviruses from attaching and entering a host cell

Table 102.4. Signs and symptoms of viral meningitis

Common
Fever
Headache
Stiff neck
Anorexia, nausea, vomiting
Photophobia
Irritability
Relative preservation of mental status
Uncommon
Lethargy
Seizures
Rare
Focal neurological signs
Papilledema
Babinski sign
Stupor or coma

Table 102.5. Distinguishing CSF features between viral and bacterial meningitis

CSF feature	Viral meningitis[a]	Bacterial meningitis[a]
White blood cells	Predominantly mononuclear	Predominantly neutrophils
Protein	Normal to mildly elevated	Elevated
Glucose	Normal to minimally depressed	Depressed
Gram stain of sediment	Negative	Positive
Bacterial culture	Negative	Positive

Notes:

[a] These CSF features are usually present but all the features will not necessarily be present in every patient.

(Pevear et al., 1999). Pleconaril is currently in clinical trials to determine its efficacy for the treatment of severe cases of enteroviral meningoencephalitis, especially in hypogammaglobulinemic patients.

If the headache is severe, use of analgesics may lessen the discomfort. Narcotics should be given cautiously as they may induce nausea and vomiting. If nausea or vomiting is prolonged and severe, antiemetics orally or rectally may help. Fever may be reduced by acetaminophen.

Prognosis

Most patients fully recover within 1 to 3 weeks (Sells et al., 1975; Lepow et al., 1962). Complications are rare. Obstructive hydrocephalus, deafness and cortical blindness have been reported in mumps meningitis (Thompson, 1979). Neonates and infants under 3 months have been reported to develop intellectual impairment, transient speech delay, or hyperactivity (Sells et al., 1975; Lepow et al., 1962).

Specific viral meningitis syndromes

Enterovirus meningitis

Enteroviruses comprise about 67 different strains, with a limited number of strains predominating each year in the United States, and account for over 80% of cases of viral meningitis in the United States (Rotbart, 1995). Enteroviruses are stable at room temperature, stable at acidic pH as low as 3.0, and resistant to lipid solvents because they lack a lipid envelope. These viruses are therefore well suited to survival in water and sewage. Infection

occurs by a fecal–oral route with primary replication occurring in the gastrointestinal or upper respiratory track (Jubelt, 1984; Rotbart, 1995). Most infections are asymptomatic or cause mild upper respiratory tract symptoms, rashes, gastroenteritic or hand–foot-and-mouth disease. Although transient viremia is common, only in about 1–5% of individuals does the virus cross the blood–CSF barrier to infect meningeal cells. The infected meningeal cells elicit an immune-mediated lymphocytic inflammatory response. Humoral and cellular responses to the virus usually eliminate the virus in CSF within 1–3 days. The exceptions are individuals with agammaglobulinemia who have difficulty eradicating the virus and experience a meningoencephalitis with prolonged viral persistence in CSF and stool (McKinney et al., 1987). While most enteroviruses cause only viral meningitis, a few strains such as enterovirus 71, are becoming recognized to cause a severe meningoencephalitis that can be fatal (Huang et al., 1999; Komatsu et al., 1999). Most causes of severe meningo encephalitis occur in infants less than 2 weeks of age. Spinal cord infections producing a flaccid limb paralysis occasionally are produced by enteroviruses (Figueroa et al., 1989).

The diagnosis of enterovirus meningitis is best done by PCR assay of CSF. The PCR test detects most strains of enterovirus, is recognized to have a sensitivity and specificity about 90%, and is considerably more sensitive than viral culture of CSF (Rotbart, 1995). Acute and convalescent serological studies are difficult to perform because of the many different strains of enteroviruses.

Herpes simplex virus, type 2 meningitis

HSV type 2 is the most common cause of neonatal herpes simplex encephalitis (Whitley, 1988). However, in adults this virus is mainly associated with viral meningitis that may be recurrent (DeBiasi & Tyler, 2000). In patients with primary genital herpes viral infection (usually from type 2 virus), viral meningitis develops in 11 to 36%. The virus becomes latent in sacral sensory ganglia and about 20% of patients with one episode of herpes simplex meningitis experience subsequent meningitic episodes that are usually milder and shorter in duration. This diagnosis should be suspected in sexually active adults with genital vesicles or in which the meningitis occurs in the winter or spring (periods when enterovirus infections are less common).

Viral infections of the brain

The term encephalitis implies a diffuse inflammation of the brain parenchyma. Viral infections represent the most common cause of encephalitis. In the United States, herpes simplex virus and arboviruses account for most cases, but other viruses also cause encephalitis (Table 102.1).

Table 102.6. Signs and symptoms of viral encephalitis

Common
Fever
Headache (dull), nausea, vomiting, malaise
Mental changes, confusion, delirium, lethargy, stupor
Seizures: generalized or focal
Hyperreflexia, Babinski signs, spasticity
Mild stiff neck
Less common
Coma
Tremors of arm or face, Parkinsonism
Hemiparesis
Aphasia
Cranial nerve palsies
Ataxia
Papilledema
Visual loss
Rare
Peripheral neuropathy

Epidemiology

Viral encephalitis occurs in all seasons but peaks in summer and early fall. The summer peak represents cases of arbovirus encephalitis from the bite of infected mosquito or tick. These vectors disappear in the winter as do cases of arbovirus encephalitis. The Centers for Disease Control and Prevention report from 1000 to 5000 cases of encephalitis per year with the number of cases varying depending on whether epidemics of arbovirus encephalitis developed. Viral encephalitis can occur at any age but the elderly and infants tend to have more severe encephalitis.

Clinical manifestations

The onset is usually abrupt, with the clinical course rapidly progressing over 1 to 3 days (Table 102.6 lists the most common signs and symptoms. The clinical features are similar for all forms of viral encephalitis but some distinguishing features can be recognized (Table 102.7). The strain of encephalitic virus determines the severity of the signs and symptoms (Table 102.8).

Table 102.7. Characteristic features of viral encephalitis in North America

Virus	Characteristic features
Most common causes	
Herpes simplex virus type 1	Sporadic, any season, all ages
La Crosse strain of California virus	Geographic restriction to upper midwestern and eastern states, occurs mainly in children, occurs summer and early fall, follows bite of infected *Aedes triseriatus* mosquito
St Louis encephalitis virus	Geographic restriction to midwestern and eastern states, occurs summer and early fall, follows vite of infected *Culex tarsalis* mosquito.
Western equine encephalitis virus	Geographic restriction to western states, occurs summer and early fall, follows bite of infected *Culex tarsalis* mosquito
Enteroviruses, esp. enterovirus 71	Prodromal rash, gastroenteritis, herpangina
Less common causes	
Eastern equine encephalitis	Geographic restriction to East and Gulf Coast, occurs summer and early fall, follows bite of infected *Culiseta melanura* mosquito
Colorado tick fever	Geographic restriction to Rocky mountain area, occurs spring and summer, follows bite of *Dermacentor andersoni* tick
Venezuelan equine encephalitis virus	Geographic restriction to Central America and south western states, follows bite of *Aedes* and *Culex* mosquitoes
Mumps virus	Parotitis and/or orchitis, often occurs during mumps epidemics in winter or spring in children who have not received mumps vaccine
Varicella-zoster virus	Often follows shingles by weeks, occurs in immunosuppressed individuals
Adenovirus	Often pneumonia, more common in children and individuals with hypoglobulinemia, serotypes 1, 6, 7, 12, 32 most commonly affect CNS
Herpes simplex virus type 2	Mainly occurs in neonates in first few weeks after vaginal delivery
West Nile virus	Common in Africa and parts of Europe. In the United States recently has occurred in the east coast area. Follows bite of a mosquito and has clinical picture similar to St. Louis encephalitis but has more flaccid paralysis
Least common causes	
Human herpes virus 6	Occasionally follows roseola infantum in children
Epstein-Barr virus	Infectious mononucleosis, adenopathy, pharyngitis
Powassan virus	Geographically restricted to upper midwest states, occurs in spring and summer, follows bite of infected *Ixodes cookei* or *marxi* tick
Cytomegalovirus	Occurs mainly in congenital infected newborns (congenital inclusion body disease) and immunosuppressed individuals, esp. AIDS
Rubeola virus	Occasionally follows measles in immunosuppressed individuals, more commonly causes acute disseminated encephalomyelitis
Reovirus	Rare cause of encephalitis that may follow enteritis in children
Nipah virus	Newly recognized virus in Indonesia that is associated with pigs and causes a severe encephalitis
Lymphocytic choriomeningitis virus	Follows exposure to infected pet hamsters and wild mice
Rabies virus	Follows bite of rabid animal (dog, skunk, raccoon, fox, bat, mongoose), pain and paresthesias of bitten limb may be first clinical sign

Notes:
Estimates on the frequency of the above infectious agents are based on the following clinical series (7,51–55) and the author's personal experience.

The geographical restriction implies the part of the world where the infectious agent is located in nature. If the patient has recently visited that area, that infectious agent should be included in the differential diagnosis.

Table 102.8. Mortality rate and frequency of neurologic sequelae in viral encephalitis

Virus	Approximate mortality rate (%)	Approximate rate of neurological sequelae (%)
Herpes simplex virus	70 untreated, 20–30 treated	90 untreated 50 treated
Arboviruses		
Eastern equine	20–40	30–50
Japanese B		
Russian spring summer		
Murray Valley		
Western equine	<20	5–20
St. Louis		
West Nile		
La Crosse		
Colorado tick fever		
Powassan		
Venezuelan		
Enteroviruses	<3	<10
Mumps virus	<1	<5
Varicella-zoster virus	50–80	>75
Rabies virus	99+	100

Notes:
Many of these figures are the author's estimates based on reviews of case reports since large clinical series of the less common types of infectious encephalitis are not available.

Laboratory Findings

The blood leukocyte count is often elevated. Blood urea nitrogen, creatine kinase, and transaminase levels may be elevated, particularly in arbovirus infections. A lumbar puncture shows a normal or elevated opening pressure. The CSF contains 5 to 300 WBC/mm^3, 50 to 200 mg/dl of protein, and normal glucose. Gram stain of CSF sediment is negative and bacterial cultures are sterile. The EEG is always abnormal and typically shows diffuse background slowing with occasional epileptiform or electrographic seizure activity (Gibbs et al., 1964). Early in the illness, MRI studies often show areas of increased signal intensity on T_2-weighted images. The CT scan may appear normal early in the clinical course with subsequent demonstration of areas of cerebral edema, necrosis or hemorrhage.

Differential diagnosis

The diagnosis of encephalitis must be distinguished from the more common encephalopathy (a general term implying diffuse dysfunction of the brain without inflammation) and acute disseminated encephalomyelitis (ADEM). Encephalopathies that may mimic encephalitis include metabolic (anoxia, hypoglycemia, hypatic, uremic, hyponatremia, endocrine), systemic infections (cerebral malaria, typhoid fever, Sydenham's chorea, Reye's syndrome, bacterial endocarditis, and critical illness (sepsis) encephalopathy), toxic substances (Wernicke's encephalopathy, sedating drug and aspirin overdoses, and arsenic intoxication), closed head trauma, hypertensive encephalopathy, paraneoplastic encephalomyelitis, central nervous system lupus erythematosus, and neuroleptic malignant syndrome (Davis, 2000). Acute disseminated encephalomyelitis or postinfectious encephalomyelitis will be discussed later in the chapter.

Diagnosis

The clinical diagnosis of infectious encephalitis is made on the following characteristics: (i) acute onset of fever and progressive mental status deterioration that may also include focal neurological signs and seizures (generalized or focal), (ii) CSF containing lymphocytic pleocytosis, normal glucose and elevated protein, (ii) abnormal MRI,

and (iv) abnormal EEG. Table 102.7 lists some characteristic features of the common viruses.

The specific etiology of the viral encephalitis is often made by (i) PCR assay of CSF, (ii) CSF IgM antibodies to some but not all viruses, (iii) virus isolation from throat or stool for some but not all viruses, (iv) acute and convalescent serum antibody titre rise, or (v) brain biopsy with virus culture. Virus is seldom isolated from CSF. Table 102.3 lists the recommended method of diagnosis for each virus. Unfortunately, most clinical series report up to 50% of cases of encephalitis in which no etiology was established (Koskiniemi et al., 1991; Studahl et al., 1998; Sivertsen & Christensen, 1996).

Management

Patients with encephalitis may rapidly deteriorate and become comatose. Therefore, patients should be hospitalized and placed in an area where they can receive intense nursing care. Patients should have a cardiac monitor as cardiac arrhythmias can develop. A determination should be made as to whether the patient requires isolation and, if so, what type of isolation. Patients with herpes simplex or arbovirus encephalitis do not require isolation. In both, virus is not present in body secretions and in arboviral infections, the viremia is too low a magnitude to transmit virus to a biting mosquito. However, patients suspected of rabies should be in isolation with saliva precautions. If a rash is present, isolation should be considered until a definite diagnosis can guide recommendation.

Treatment of symptoms for all patients includes control of seizures and elevated intracranial pressure (ICP). Seizures occur in 30–60% of patients and may be generalized or focal, single or multiple. If seizures develop, they should be treated promptly as seizures transiently elevate ICP, which could adversely affect the patient's cerebral blood flow. Lorazepam or diazepam can be given if seizures are multiple. Fosphenytoin or phenytoin can be administered I.V. in a loading dose to prevent further seizures.

Increased ICP usually develops a few days into the clinical course and may be elevated enough to impede cerebral blood flow or cause brain herniation. Treatment is difficult. Intubation and mechanical hyperventilation to keep the arterial Pco_2 between 25 and 30 torr and mannitol administration are the most commonly used methods (Chapter 125). Corticosteroids are controversial as they may inhibit the host immune response necessary to eradicate the infection. Patients may have excessive hypothalamic release of antidiuretic hormone leading to the syndrome of inappropriate antidiuretic hormone secretion with retention of free water, hyponatremia, and increase in cerebral edema (Brinker & Monath, 1980).

The acute clinical course usually lasts 1–2 weeks. During convalescence, patients often require physical therapy and speech therapy to regain their motor and verbal skills.

Prognosis

The mortality and morbidity rates vary greatly depending on the encephalitic virus as shown in Table 102.8.

Specific viral encephalitis syndromes

Herpes simplex encephalitis

Herpes simplex encephalitis (HSE) is important to diagnose rapidly as early administration of acyclovir definitely improves outcome. Herpes simplex virus (HSV), type 1, accounts for over 90% of HSE in children and adults. Herpes simplex virus, type 2, is the cause of most neonatal HSE.

In the United States, HSE is the most common sporadic encephalitis (Whitley, 1995) with an incidence of about 2 cases per 1 million individuals per year (Skoldenberg et al., 1984). HSE occurs in both sexes, at all ages, and at any time of the year.

The pathogenesis of HSE remains incomplete. The primary infection occurs in children and usually is a stomatitis and pharyngitis that resembles a 'strep' throat. Virus ascends sensory fibres from the mouth to reach the trigeminal ganglia where it becomes latent (Baringer & Swoveland, 1973). Spontaneous exacerbations occur frequently producing the typical 'fever blister' around the mouth.

HSE appears to develop by at least two routes. In newborn and young children who lack antibody to herpes simplex virus, a primary HSV infection in the oral pharynx rarely may reach the brain, possibly by infection of olfactory nerves in the nose (Ojeda, 1980). However, older children and adults usually have existing HSV antibody on admission suggesting that the encephalitis resulted from exacerbation of a latent viral infection. Davis and Johnson (1979) have hypothesized that latently infected ganglia in the second division of the trigeminal ganglia occasionally activate sending viral particles to one temporal lobe base via sensory fibres to that region.

Within the brain, HSV infects both glial cells and neurons often producing Cowdry type A intranuclear inclusion bodies. The virus spreads directly from cell to cell meaning that specific cellular immunity, not humoral

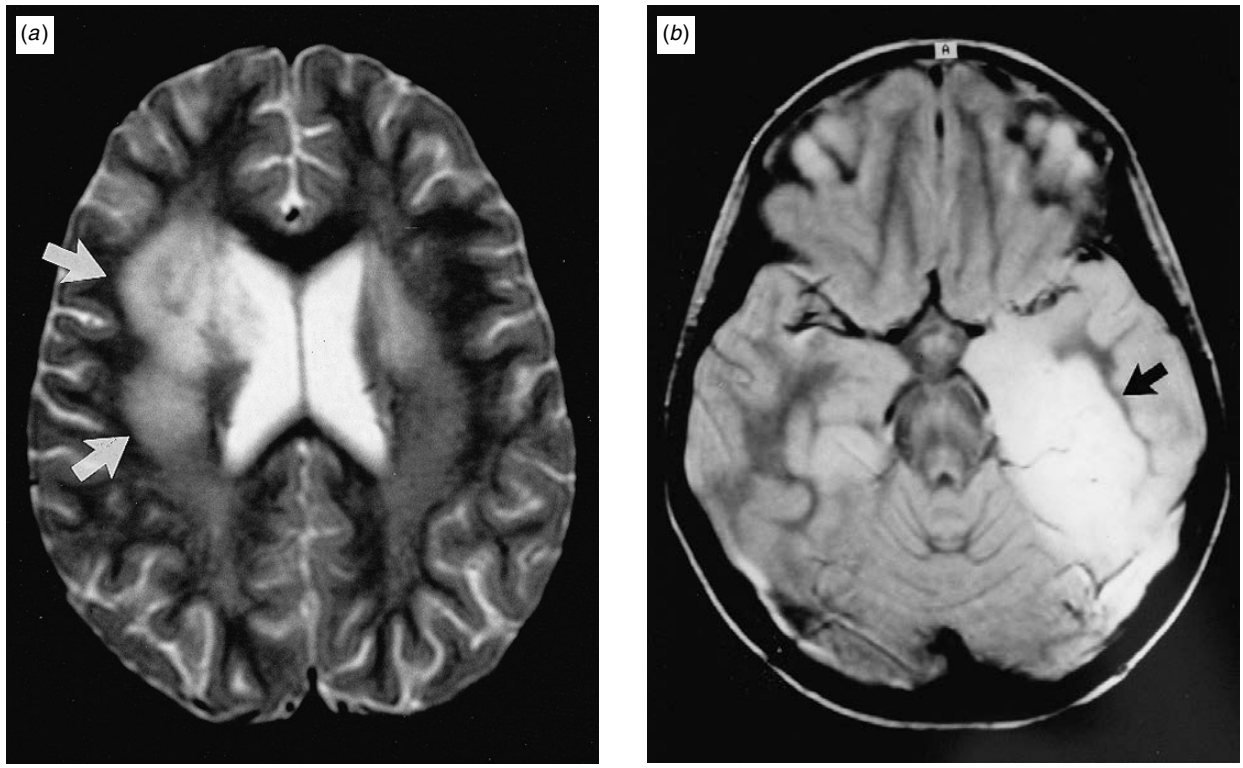

Fig. 102.1. (*a*) Acute disseminated encephalomyelitis in a 13-year-old child: T_2-weighted magnetic resonance image demonstrates multiple hyper intense lesions in cerebral white matter. (*b*) Herpes simplex encephalitis in a 40-year-old man: T_2-weighted magnetic resonance image demonstrates hyperintense lesion in the mesial temporal lobe. (From Davis, 2000.)

immunity, is essential to eradicate the infection. The infected brain regions show marked inflammation, necrosis and areas of focal hemorrhage.

There appears to be no set of symptoms or signs that clearly distinguishes HSE from other types of viral encephalitis. In two studies, cases of suspected HSE were confirmed by brain biopsy in only 50% (Whitley et al., 1986; Whitley & Lakeman, 1995). A history of 'fever blister' is of no diagnostic value because the majority of all adults occasionally experience 'cold sores'. Likewise, the presence of a 'fever blister' on admission or isolation of HSV from the mouth may occur in any type of encephalitis.

The onset is usually abrupt, with the clinical course rapidly progressing over 1 to 2 days. Table 102.6 lists the most common signs and symptoms. Although the encephalitis begins in the temporal lobe, acute memory loss occurs in only 20%.

With the advent of a PCR essay to establish the diagnosis of HSE, it is now recognized that a few patients with confirmed HSE have atypical clinical features. These patients have had a milder clinical course (with or without acyclovir), lack focal neurological signs, and progress at a slower rate than the classical disease (Fodor et al., 1998; Domingues et al., 1997).

Several laboratory values are abnormal but not specific for HSE. The peripheral white blood count may be elevated with a shift to the left but the total WBC is rarely above 20 000/mm^3. Liver and renal tests are usually normal. The CSF is similar to other infectious encephalitis but the CSF of occasional patients has red blood cells (10–500 cells/mm^3) or a mild hypoglycorrhachia (30–40 mg/dl). Only 5% of patients have a normal CSF (Whitley et al., 1989). HSV is rarely isolated from CSF (Nahmias et al., 1982).

Later in the clinical course, patients may develop a characteristic EEG pattern of high-voltage, periodic, lateralizing epileptiform discharges (PLEDS) at a rate of 2–3 Hz originating from the temporal lobe (Ch'ien et al., 1977). While PLEDS are suggestive of HSE, they are not diagnostic.

Magnetic resonance imaging (MRI) is often abnormal early in the clinical course and may suggest HSE. The MRI often demonstrates damage to the blood–brain barrier with accumulation of edema and necrosis in the medial aspect of a temporal lobe (Tien et al., 1993) (Fig. 102.1(*b*)).

In one clinical series, patients with HSE had 89% of their MRIs showing hyperintensity in the temporal lobe on T_2-weighted images compared to only 10% of other forms of encephalitis (Domingues et al., 1997). HSE lesions may also be seen in the orbital surfaces of frontal lobes, insular cortex, cerebral convexity, and cingulate gyrus. Lesions are seldom seen in the basal ganglia, brainstem or cerebellum. The CT scan is less sensitive and may be normal during the first few days of HSE. It then becomes abnormal with focal regions of hypointensity similar to the MRI and foci of hyperintensity due to small brain hemorrhages.

HSE should be clinically suspected if the (i) encephalitis occurs in winter or early spring, (ii) encephalitis occurs as an isolated case, (iii) MRI shows focal medial temporal lobe abnormality and (iv) EEG shows PLEDS. The diagnosis of HSE is confirmed by detection of fragments of herpes simplex viral DNA in CSF by PCR assay, or brain biopsy showing (i) diffuse inflammation with intranuclear inclusion bodies, (ii) identification of HSV particles by electron microscopy, (iii) viral antigen identification by immunohistochemistry, (iv) herpes simplex DNA fragments detected by PCR or (v) isolation of HSV from the tissue. The diagnosis of HSE is faster and easier with the development of widely available PCR assays for HSV. Current PCR tests detect HSV DNA in CSF in more than 95% of patients with HSE during the first week of the encephalitis (Lakeman et al., 1995). PCR assays are sensitive (more sensitive than viral isolation methods), rapid (assay usually completed within one day), and less expensive than other methods of diagnosis. While PCR assays are accurate, they require meticulous technique to avoid false positive or negative tests that can occur when hemoglobin or inhibitors, such as heparin, are present in the CSF.

Treatment with the antiviral drug acyclovir (acycloguanosine) has dramatically improved both the number of patients who survive and the quality of their survival. Acyclovir is relatively non-toxic to normal cells. The drug is effective because in the presence of thymidine kinase from HSV, acyclovir is monophosphorylated. Host cell thymidine kinases then phosphorylate the drug to its active triphosphate state, which inhibits DNA synthesis of the virus (Balfour, 1999). Development of resistance to acyclovir in the treatment of HSE has not been recognized.

The drug is most beneficial when given early in the clinical course and before the patient becomes comatose (Whitley et al., 1986). The standard dose of acyclovir is 30 mg/kg per day divided into 3 doses and given i.v. for 14 days. In immunosuppressed patients, the duration is often extended to 21 days to mimimize the risk of relapse. Drug complications are few and include thrombophlebitis at the needle site, elevation in serum transaminase levels, and transient renal failure from too rapid i.v. administration. When there is clinical suspicion of HSE, it is prudent to administer acyclovir immediately while awaiting PCR confirmation of the diagnosis.

When classical HSE is untreated, up to 70% of patients die and fewer than 3% resume a normal life (Whitley, 1995; Whitley et al., 1977). Early treatment with acyclovir can reduce the mortality rate to 20% to 30% (Skoldenberg et al., 1984; Whitley et al., 1986). Of survivors, 45% have a good to excellent outcome.

Arboviral encephalitis

There are more than 200 strains of arthropod-borne viruses (arboviruses) in the world. Arboviruses comprise alphaviruses, flaviviruses, and bunyaviruses and are responsible for miningitis, encephalitis, hemorrhagic fever, hepatitis and rashes. The majority of arbovirus strains occur in troptical regions. The normal life cycle of many arboviruses is between birds and mosquitoes. Man becomes an accidental host when bitten by an infected mosquito or tick. The same type of mosquito does not transmit all strains of arboviruses. Hence, there is a regional distribution of arboviral infections that depends on the location of the specific vector required for viral transmission. In other circumstances, such as West Nile virus, cases of encephalitis are developing in the USA east coast region because this arbovirus appears to have been recently introduced into the region (Asnis et al., 2000).

Killed virus vaccines are available to prevent Japanese B and Russian spring summer encephalitis viruses but human vaccines are not available for US strains.

Arbovirus encephalitis occurs only in the summer and autumn when the vector is present in the community. Over 95% of primary arbovirus infections result in an asymptomatic infection or a mild fever and myalgias (Monath, 1980). The encephalitis occurs in both sexes and at all ages. Some strains of arbovirus, such as St. Louis encephalitis virus, cause a more severe illness in the elderly (Southern et al., 1969) while Western equine encephalitis virus causes a more severe illness in infants and the elderly (Earnest et al., 1971). Geographical distribution and frequency of encephalitis of the North American arboviruses is listed in Table 102.7.

In the United States, an infected mosquito is the most common vector. During the bite, virus is inoculated into the subcutaneous tissue and blood vessels beneath the skin. Primary viral replication occurs in lymph nodes, spleen and endothelial cells resulting in a persistent viremia. In brain capillaries, some strains of arboviruses disrupt the blood–brain barrier by replicating within cerebral endothelial

cells. Hence, the resulting encephalitis begins in multiple areas throughout the brain. The incubation period for most arbovirus infections is from 4 to 21 days.

Within the brain, arboviruses cause a widespread infection of neurons and glia of the cerebral cortex, basal ganglia, brainstem, cerebellum and spinal cord. There is neuronal necrosis, perineuronal and perivascular edema inflammation (Adams & Weinstein, 1948). In severe cases, widespread necrosis and hemorrhage occur.

The viremia is terminated when the host produces antibodies (often around the first day of encephalitis). Eradication of virus from the brain usually requires both humoral and cellular immune reactions. Gliosis of damaged brain develops during recovery.

Some patients develop a prodromal illness of fever, nausea, malaise, and headache for several days before the encephalitis begins. Less than 10% of infected individuals develop encephalitis or meningitis. Table 102.8 lists the clinical signs of the acute encephalitis. Patients with West Nile viral encephalitis tend to be older (over 60 years) and usually develop the typical signs of encephalitis. However, about one-fourth of patients develop limb weakness from spinal cord infection (Nash et al., 2001). The encephalitis progresses rapidly over a few days and lasts 1 to 2 weeks (Brinker & Monath, 1980). The severity of the encephalitis depends on the strain of arbovirus (Table 102.7). Convalescence may take months, with patients often complaining of headache and fatigue.

Most patients have a moderate blood leukocytosis. The CSF shows typical changes for viral encephalitis. Virus is rarely isolated from CSF. The MRI usually shows multiple areas throughout the brain of hypointense signal demonstrating foci of edema and necrosis. The CT scan may be normal early in the illness and later can demonstrate areas of hypointensity (edema and necrosis) and hyperintensity (hemorrhages) in severe cases.

Clinical suspicion of arboviral encephalitis should be raised in an individual with encephalitis who develops the illness in summer or fall when the vector is present or is part of a cluster or epidemic of similar encephalitides. The diagnosis is established by: (i) detection of specific arbovirus IgM antibody in serum by IgM antibody capture immuno-assay (available for many US arboviruses), (ii) a fourfold or greater antibody titre rise to the arbovirus between the acute and convalescent serum samples, or (iii) isolation of virus from a brain biopsy. The diagnosis of arboviral encephalitis by PCR assay of CSF is currently experimental but may become more widely available.

There presently is no effective antiviral therapy available. Patients should be symptomatically managed as given above in the general encephalitis section.

The mortality and morbidity of arboviral encephalitis varies with the strain of virus (Table 102.8).

Rabies

Although rare in developed countries, rabies encephalitis kills up to 50 000 individuals per year mainly in Asia (Hemachudha & Mitrabhakdi, 2000). In the United States, infected bats are the major route of human transmission with some cases due to bites of infected raccoons, foxes, coyotes, skunks and dogs. In developing countries, infected dogs are the primary carriers along with mongooses and wolves. Following a bite of an infected animal, rabies virus replicates locally in muscle fibres to reach nerves in the muscle. The virus then infects the nerve endings and spreads retrograde in axons to reach the spinal cord and dorsal root ganglia. Once within the spinal cord or brainstem (via cranial nerves), the virus spreads widely throughout the brain by infecting neurons (Murphy et al., 1973). Virus then travels down nerves to reach salivary glands, where local replication also occurs producing infected saliva. The incubation period of rabies varies from a few weeks to over 1 year. It is unclear where the virus is located during the prolonged incubation period.

In contrast to most cases of virus encephalitis, the brain demonstrates little inflammation. As a consequence, the CT scan may appear normal. However, MRI often shows hyperintense signals in the brainstem, thalamus, hypothalamus, and spinal cord. The CSF usually has a minimal lymphocytic pleocytosis, mildly elevated protein level and normal glucose level.

The clinical features of rabies are of two types: furious and paralytic (dumb) rabies. In both, some patients may experience a prodrome of fever, burning, numbness, paresthesias or local myalgias around the wound that progresses to involve the entire limb. About 80% of patients develop furious rabies, which is characterized by periods of agitation, confusion, excessive motor movements, muscle spasms, vocal cord paralysis, seizures, focal limb paralysis, and coma. Hydrophobia (violent, jerky contracting of diaphragm and accessory muscles of inspiration triggered by attempts to swallow liquids) occurs in about half the patients. Abnormalities of the autonomic nervous system are common. Paralytic or dumb rabies presents with an ascending paralysis that resembles the Guillain–Barré syndrome.

The diagnosis should be suspected in an individual who has been bitten or scratched by a suspected rabid animal and develops signs consistent with furious or paralytic rabies. The risk of developing rabies in an individual who is bitten by a rabid animal but never receives rabies immu-

nization is about 50%. The diagnosis is established by (i) identification of the virus (isolation from brain or saliva, PCR assay of salivia, (ii) detection of viral antigen by immunohistochemical staining of nuchal skin biopsy or corneal impression smear or (iii) identification of rabies virus antibody in serum of an unimmunized individual (Hemachudha & Mitrabhakdi, 2000). Unfortunately, rabies antibody may not be present early in the hospital course.

There are no antiviral drugs presently available and virtually all patients who develop neurological symptoms die. As such, prophylaxis is the only mechanism to prevent rabies. The criteria from the Advisory Committee on Immunization Practices for unvaccinated individuals with single or multiple bites from a suspected or confirmed domestic or wild animal or animal unavailable for observation, state that one should immediately administer rabies immunoglobulin (preferably of human origin) locally at the site of the wound and then vaccinate with rabies vaccine (preferably a live attenuated tissue culture vaccine) (see ACIP, 1999 for details and other postexposure treatment recommendations).

Postviral encephalomyelitis or acute disseminated encephalomyelitis

Acute disseminated encephalomyelitis (ADEM), a monophasic syndrome that predominately affects CNS white matter, usually follows a systemic, often viral, illness or a vaccination by 1–3 weeks (Tyler, 1951; Siriam & Steinman, 1984; Miller et al., 1956). Although some patients experience diverse clinical signs from multiple widespread white matter lesions, others develop signs referable only to one part of the nervous system, such as cerebellar ataxia, optic neuritis, or transverse myelitis. ADEM is thought to account for about 20% of all encephalitis cases. The majority of cases occur in children. Childhood infections such as measles, mumps, chickenpox, and rubella and vaccines are associated with most cases (Table 102.9). Worldwide, rubeola (measles) infections have the highest incidence and are thought to produce ADEM in 1 per 1000 measles cases (Johnson, 1998).

The pathogenesis of ADEM is currently thought to be immune mediated rather than conventional viral replication in brain cells. Details are covered in Chapter 98. The brain pathology is characterized by perivenular inflammation (perivascular cuffing) and adjacent demyelination that is all of the same age.

The clinical onset is abrupt and usually occurs towards the end of the predisposing illness or 1–4 weeks after vaccination. Patients develop a monophasic illness characterized by depression of mental status, seizures, headaches, and focal neurologic signs that include hemiparesis, visual loss, ataxia, etc. Less common signs include choreoathetosis, myoclonus, and cranial nerve palsies. Table 102.10 lists some differences between ADEM and infectious encephalitis that may be helpful.

The MRI in over 50% of patients demonstrates lesions in the subcortical white matter, corona radiata, and centrum semiovale (Murphy et al., 1999). Multiple areas of hyperin-

Table 102.10. Comparison of acute disseminated encephalomyelitis and infectious encephalitis

	Acute disseminated encephalomyelitis	Infectious encephalitis
Clinical features		
Most common age	Children	Any age
Recent vaccination	Common	Uncommon
Prodromal illness	Usually	Occasionally
Fever	May occur	Common
Visual loss (one or both eyes)	May occur	Uncommon
Spinal cord signs	May occur	Uncommon
Laboratory findings		
Blood	Leukocytosis occasionally occurs	Leukocytosis common
MRI (T_2-weighted)	Multiple focal areas of hyperintensity that are the same age and involve white matter of both hemispheres, basal ganglia, brainstem, cerebellum and spinal cord	Areas of hyperintensity involving grey matter of both cerebral cortices and its underlying white matter. To a lesser extent, basal ganglia, brainstem and cerebellum.
Culture of virus from brain	Rare	Common
Brain pathology	Perivenular inflammation, adjacent demyelination and edema	Perivascular inflammation, brain inflammation, neuronal and glial cell necrosis, edema, and inclusion bodies in some infections.

tensity on T_2-weighted and FLAIR images are seen that range from less than 1 to 4 cm in diameter, are the same age and involve white matter of both cerebral hemispheres (Fig. 102.1(*a*)). Up to 50% of patients also will have lesions in the thalamus, caudate, putamen (often bilateral), and in cerebellar white matter. Less than 10% develop lesions in the spinal cord. T_1-weighted lesions are hypointense and occasionally enhance with administration of gadolinium. Individuals with only cerebellar ataxia are the least likely to have abnormal neuroimaging (Connolly et al., 1994; Murphy et al., 1999). The CSF usually shows a lymphocytic pleocytosis, elevated protein and normal glucose but can be normal in up to one-third of patients.

General management of a patient with ADEM is similar to a patient with infectious encephalitis. Although there is no proven specific treatment for ADEM, many clinicians attempt to reduce or suppress the immune reaction through administration of corticosteroids (Straub et al., 1997), plasmapheresis (Kanter et al., 1995), or immunoglobulins (Nishikawa et al., 1999). Presently, many patients are treated with high dose intravenous mythylprednisolone in doses similar to those used to treat acute attacks of multiple sclerosis. Support of this treatment consists of case reports (Hauley, 1998). However, small series of ADEM patients treated with oral corticosteroids have reported no benefit (Swanson, 1956).

Recovery from ADEM often takes weeks to months depending upon the maximum severity of signs. Children often require rehabilitation for problems of weakness, hemiparesis, ataxia, mental confusion and behavioural changes. The neuroimaging abnormalities resolve slowly over months and may remain abnormal for prolonged periods after the patient has completely recovered. Mortality rates range from 5% to 25% and neurological sequelae are reported in 5% to 35% of survivors (Tyler, 1951; Siriam & Steinman, 1984; Miller et al., 1956).

Rare patients develop a more fulminant disease called acute hemorrhagic leukoencephalitis (AHLE) (Adams et al., 1949). This disease is clinically more severe than ADEM with coma, seizures and focal neurologic signs developing. Treatment of AHLE generally has been similar to that of ADEM (Byers, 1975). However, the mortality rate is about 50% and survivors are often left with seizures, mental retardation and focal neurological signs.

Optic neuritis

Optic neuritis has been associated with several viruses including measles, mumps, Epstein–Barr, and varicella-zoster (Bradley, 1967). Visual symptoms usually begin at the termination of the viral infection. Patients develop a rapidly progressive loss of central vision with falling visual

acuity. The visual loss is unilateral in three-fourths of patients. There is often drabness or desaturation of coloured objects (especially red). A light shown in the affected eye is perceived as less bright and triggers a weaker direct and consensual pupillary constriction than the same light in the good eye (Marcus Gunn phenomenon). The retina and disk are often edematous with blurred disk margins. Flame-shaped hemorrhages may be seen in the retina. The CT is usually normal but T_2-weighted MRI images may demonstrate a focus of hyperintensity (edema) in the optic nerve. The CSF is usually normal.

Acute treatment with IV methylprednisolone (250 mg every 6 hours) for 3 days followed by oral prednisone (1 mg/kg for 11 days) has proven superior to treatment with oral prednisone alone (Beck et al., 1992). Most patients make a good recovery of 20/40 or better visual acuity, but some are left with a relative central visual deficit and some with colour desaturation. Some adult patients may have repeated attacks of optic neuritis or develop multiple sclerosis (Optic Neuritis Study Group, 1997). If the MRI demonstrates discrete lesions in subcortical white matter, the risk of subsequent development of multiple sclerosis is increased to about 50%.

Subacute and chronic viral infections

Although most CNS viral infections either kill the patient or are eradicated by the host's immune system within 2 weeks, some viruses can produce a persistent or chronic infection of the brain. The resulting infection often produces severe, often fatal, progressive CNS damage (e.g. rubeola virus in subacute sclerosing panencephalitis or J C papovavirus in progressive multifocal leukoencephalopathy), but occasionally the virus can persist producing limited brain damage (e.g. HIV virus). Immunosuppression of the host predisposes to a chronic viral infection but rubeola virus (measles) can persist in the brain of immunocompetent individuals. Below are several forms of chronic viral infections.

Subacute sclerosing panencephalitis (SSPE)

This childhood disease follows a typical measles infection with rubeola virus with a latency of months to years. Early in the clinical course, children develop personality changes becoming more irritable and having difficulty in concentrating (Dyken, 1985). There is no fever or nuchal rigidity. The illness progresses over months with the child developing dysarthria, myoclonic jerks, hyperkinesia and ataxia. School performance deteriorates. By 6–12 months, the child becomes demented, blind and spastic. The EEG often demonstrates a characteristic pattern of slow and sharp waves occurring at 3 to 10 second intervals. The CSF has a mild lymphocytic pleocytosis, normal glucose, elevated total protein, elevated gammoglobulin, and the presence of oligoclonal bands.

The diagnosis is usually made by identification of very high rubeola virus antibody titres in CSF. Rubeola virus has been difficult to isolate from CSF or brain but cultivation of brain with permissive tissue culture cells can result in a rubeola virus isolate that is highly cell associated and has mutations resulting in failure to produce M, H and F viral proteins (Cattaneo et al., 1988). The pathogenesis of how wild rubeola virus mutates to cause SSPE is unclear. No antiviral drugs have yet to prove effective. SSPE is usually fatal within 12 months but occasional cases with arrest in the disease progression have been reported. In countries where the measles vaccine is administered to children, SSPE has practically disappeared.

Progressive multifocal leukoencephalopathy

The JC virus, a human polyomavirus of the family papovaviridae, is the cause of progressive multifocal leukoencephalopathy (PML). About 75% of normal adults have antibodies to this virus from a prior asymptomatic infection. The virus appears to become latent in the kidney and other unknown sites. In the presence of immunosuppression from AIDS, chronic leukemia, Hodgkin's disease, lymphomas, systemic lupus erythematosus, or immunosuppressive drugs, the virus appears to reactivate and infect oligodendroglia producing intranuclear inclusion bodies and resulting in poor or absent myelin production with multiple foci of demyelination and infects astrocytes giving them a bizarre appearance (Demeter, 2000).

Patients develop a progressive neurologic illness that is insidious and lacks signs of systemic illness, fever, headache or elevated white blood cell count. Neurological signs and symptoms usually indicate multifocal lesions involving both hemispheres, brainstem, and cerebellum (Berger et al., 1987; Brooks & Walker, 1984; Krupp et al., 1985). Common signs include a progressive hemiparesis, visual field deficits, ataxia, aphasia, cranial nerve palsies and cognitive impairment. The CSF is usually normal. MRI scan is usually abnormal with the presence of one or more hyperintense areas in the white matter on T_2-weighted images (Mark & Atlas, 1989).

The diagnosis is established by brain biopsy with characteristic histopathology. In the presence of an appropriate clinical setting with MRI or CT brain lesions, the presence of JC virus genome fragments detected in CSF by PCR assay

is highly suggestive (McGuire et al., 1995; Demeter, 2000). However, a negative PCR assay does not rule out PML and a positive PCR assay in CSF occasionally can occur in immunosuppressive patients without clinical disease. No antiviral drug has proven efficacy but cidofovir is currently being studied in an open label trial (Demeter, 2000). Most patients die within 6 months of diagnosis, but occasional patients have spontaneous disease fluctations for up to 3 years.

Varicella-zoster encephalitis

The most common CNS complication of varicella-zoster virus (chickenpox) is cerebellar ataxia that develops about 1 week after the chickenpox rash onset in immunocompetent children (Connolly et al., 1994). Neuroimaging is usually normal. The ataxia usually clears within weeks.

In immunosuppressed individuals, more serious encephalitis can develop days to months after an episode of shingles. The main pathology is a vasculitis involving medium and small blood vessels of the CNS resulting in multiple brain infarctions mainly in subcortical white matter (Amlie-Lefond et al., 1995). Varicella-zoster virus also infects adjacent oligodendroglia producing intranuclear inclusions.

Patients develop an insidious progressive illness characterized by headache, fever, cognitive impairment, seizures, and focal neurological deficits relative to the brain infarctions (Gilden et al., 2000a,b). Other patients may develop acute stroke symptoms from large artery granulomatous arteritis following shingles most often in the trigeminal distribution (Gilden et al., 2000a,b).

The diagnosis is usually made by detection of varicella-zoster DNA in CSF by PCR assay (Gilden et al., 2000a,b) or by intrathecal synthesis of varicella-zoster virus antibody, especially of the IgM class (Gilden et al., 1998). The diagnosis can also be made from brain biopsy with characteristic histopathologic changes, identification of varicella-zoster antigen within blood vessel walls or oligondendroglia, or detection of viral DNA in tissue by PCR assay.

Patients should be treated with acyclovir (1500 mg/m^2 per day divided into 3 doses i.v., which is usually 30 mg/kg per day in adults) for 14–21 days (Gilden et al., 2000a).

Viral infections of the spinal cord

Viral infections of the CNS not infrequently include the spinal cord. The resulting infection can result in a diffuse spinal cord infection (myelitis or poliomyelitis) or an infection or immune reaction localized to one part of the spinal cord (transverse myelitis).

Paralytic poliomyelitis

Paralytic poliomyelitis is the classic infection of the spinal cord. The majority of cases are from infection with polioviruses, serotypes 1, 2, and 3 although occasional cases are associated with other enteroviruses and arboviruses (Figueroa et al., 1989). In particular, the cases of West Nile encephalitis in the USA east coast region commonly have a flaccid paralysis (Asnis et al., 2000).

Until recently, polioviruses were found worldwide. With the success of poliovirus vaccination programs, cases of paralytic poliovirus are now confined mainly to Asia and Africa. Like other enteroviruses, poliovirus spreads through contaminated water. In temperate climates, epidemics have occurred mainly in the summer. Cases of paralysis mainly occur in children.

Following ingestion of poliovirus by a non-immune individual, the virus replicates initially in the oral pharynx and intestine. Secondary replication occurs in tonsils, Peyer's patches and lymph nodes producing a viremia. Over 95% of primary infections are asymptomatic or result in mild gastroenteritis. Only 1% of infected patients develop spinal cord infection with paralysis and 1–2% develop viral meningitis. The virus reaches the spinal cord most likely from the viremia but in experimental animals poliovirus can reach the spinal cord via retrograde axoplasmic flow in peripheral nerves. In the spinal cord, necrosis and loss of neurons occurs mainly in the anterior horn accompanied by inflammation and perivascular cuffing with lymphocytes. Occasionally, virus spreads to the brainstem tegmentum, precentral cortex, and hypothalamus.

After an incubation period of 9–12 days, the illness begins with fever, headache, malaise, nausea and back stiffness (Price & Plum, 1978; Melnick, 1996). Weakness with myalgia begins 1–2 days later. The pattern of weakness is asymmetrical with more involvement of legs than arms and proximal muscles more than distal muscles. Muscle tone is flaccid and reflexes are hypoactive. Muscle atrophy begins about a week after the onset of weakness and continues for several weeks. About 5–20% of patients develop involvement of cranial nerves X, IX, and VII resulting in pharyngeal, laryngeal and facial muscular weakness. In some patients with involvement of thoracic and bulbar muscles, breathing is impaired to the point of requiring mechanical ventilation.

The blood may be normal or show a mild leukocytosis. CSF typically contains 20–200 WBC/mm^3 with a mildly elevated protein level and normal glucose level. The MRI

demonstrates areas of hyperintensity within the spinal cord, particularly in the lumbar region.

The diagnosis should be suspected in an individual who develops acutes progressive asymmetrical limb paralysis with a CSF pleocytosis. Virus can easily be isolated from the throat or stool but only occasionally from CSF. The virus isolate should be sent to reference laboratories, such as the Centers for Disease Control and Prevention, to determine whether the isolate is wild type or vaccine-like. In the United States, use of the live oral poliovirus vaccine was associated with 1–5 cases of paralysis each year. Currently, most advisory committees are recommending use of the killed vaccine that could eliminate vaccine-associated cases. Poliomyelitis also causes a diagnostic four-fold or greater rise in neutralizing or complement fixing antibodies between acute and convalescent serum specimens (Melnick, 1996).

Acute treatment requires hospitalization with careful monitoring for respiratory failure and the necessity of mechanical ventilation. Good hydration is required to prevent kidney stones. Rehabilitation is clearly beneficial.

Death occurs in about 8% of patients from bulbar involvement. In most patients, recovery begins in several weeks. By 6 months, 80% of patients make a good to excellent recovery. Paralytic poliomyelitis can be prevented by vaccination before wild virus exposure with either killed or live attenuated poliovirus (Melnick, 1996).

A postpolio syndrome develops in about one-quarter of recovered paralysed patients 20 or more years later. These patients develop progressive weakness in their involved limbs and fatigue. New muscle weakness, fasciculations, cramps, and dysarthria may be seen. Patients may also develop arthritis, tendinitis, and ligament strain from chronic incorrect posture and misuse of joints. Some patients develop increasing scoliosis, and occasionally swallowing difficulties (Dalakas et al., 1986). To date, a persistent poliovirus infection has not been demonstrated but there is histologic evidence of new active denervation and resulting muscle atrophy (Dalakas et al., 1984). It appears that during recovery from poliomyelitis, surviving motor units enlarge by sprouting terminals to reach the denervated muscle fibres. These enlarged motor units then become unstable years later (Johnson, 1965). Rehabilitation programs using mild to moderate exercise to strengthen weakened muscles do not seem to accelerate disease progression.

Transverse myelitis

Transverse myelitis may be due to an infectious agent or postinfectious immune-mediated process. The criteria for diagnosis is (i) acutely developing paraparesis, affecting motor and sensory systems as well as sphincters, (ii) spinal segmental levels of sensory disturbances, (iii) stable, nonprogressive clinical course after the acute phase, (iv) no evidence of spinal cord compression, and (v) absence of other known neurological diseases that affect the spinal cord such as syphilis, severe back trauma, multiple sclerosis, encephalitis, or malignant disease with spinal metastases (Berman et al., 1981).

Varicella-zoster virus following an episode of shingles by 1–2 weeks can produce an infectious paraparesis with a sensory level and sphincter impairment (Gilden et al., 2000a). The spinal cord viral infection occurs more commonly in immunosuppressed individuals. The CSF may be normal or show a lymphocytic pleocytosis and elevated protein level. MRI shows gadolinium enhanced areas within the spinal cord. While the diagnosis is often made solely on clinical grounds, varicella-zoster viral DNA has been detected by PCR in CSF. Varicella-zoster virus is rarely isolated from CSF. Treatment with acyclovir 15–30 mg/kg per day for 10–14 days appears beneficial but patients are often left with a mild to moderate paraparesis or quadriparesis.

Immune-mediated transverse myelitis has been associated with several viruses that include rubeola, mumps, influenza, Epstein–Barr, dengue, rubella and hepatitis. The rabies and smallpox vaccines have also been implicated (Hemachudha & Mitrabhakdi, 2000). With the older killed rabies (Semple) vaccine prepared from infected mouse or rabbit spinal cords, cases of transverse myelitis could occur as often as 1 per 600 to 6000 vaccinations. In fatal cases the spinal cord demonstrated perivenous demyelination and perivascular cuffing.

Patients should be hospitalized and placed in the intense care unit. Catheterization of the bladder is often necessary. High dose i.v. corticosteroids or immunoglobulins (polyclonal IgG) are often given but the evidence for benefit is anecdotal. About one-third of patients made a good recovery; one-third make a fair recovery; and one third make a limited recovery and are left with varying degrees of paralysis.

Viral infections of peripheral nerves

While viruses, such as herpes simplex and rabies, can infect peripheral nerves and travel within the axon, they do not produce significant damage to the nerve. Shingles, from varicella-zoster virus does damage peripheral nerves. In immunosuppressed individuals, such as AIDS, cytomegalovirus can cause an acute lumbosacral polyradiculitis

(So & Olney, 1994). Many viruses have been associated with immune-mediated Guillain–Barré syndrome.

Shingles or Herpes Zoster

The hallmark of shingles is a vesicular skin eruption that follows a unilateral dermatomal pattern. About half the eruptions appear in thoracic dermatomes and 25% develop over the face (Hope-Simpson, 1965). The skin eruption begins as a localized reddening of skin, followed by a maculopapular lesion that develops into a blister or vesicle about 2–3 mm in diameter (Burgoon et al., 1957). The vesicle then ruptures and becomes a pustule that crusts over and heals in 1–3 weeks. The number of vesicles can vary from few to hundreds. Pain, the second characteristic, follows the dermatomal distribution. The pain may be burning, lancinating (electric-like and brief), and allodynic (dysesthetic sensations triggered by light mechanical stimulation of the involved dermatome) (Watson et al., 1988). The pain usually subsides within 2–6 weeks as the lesions heal. Rarely, one may experience dermatomal pain without the skin eruptions (zoster sine herpete) (Lewis, 1958).

During the chickenpox skin infection, virus ascends the sensory nerves and becomes latent within dorsal root or trigeminal ganglia neurons. Years later, shingles results when the dormant virus reactivates, replicates in the ganglion, and travels down sensory root nerves in a dermatomal pattern (Gilden et al., 2000a,b). The incidence increases in individuals over age 60 and with illnesses that depress cellular immunity, such as Hodgkin's disease, leukemia and AIDS.

The diagnosis of shingles is usually clinically made in a patient with typical unilateral, painful vesicular rash that follows a dermatome. The diagnosis is confirmed by isolation of virus cells at the base of vesicles, by detection of viral DNA by PCR of vesicle fluid, by immunohistochemical identification of viral antigen in vesicle cells, or by identification of multinucleated giant cells by Giemsa staining of vesicle cells (Tzanck smear).

Treatment of acute shingles depends on the severity and location of the dermatomal rash and immunocompetence of the individual. Individuals with a mild rash may require only symptomatic treatment with non-narcotic analgesics. When shingles is severe or develops in the presence of immunosuppression, antiviral treatment is recommended with famciclovir (500 mg orally three times daily for 7 days) or valaciclovir (1 gm orally three times daily for 7 days). Both drugs are well tolerated with few side effects. In severe cases or where the virus has disseminated, acyclovir (5–10 mg/kg i.v. every 8 hours for 5–7 days) can be given (Gilden et al., 2000a,b). When these antiviral drugs are started within the first few days of rash onset, the drugs shorten the period of viral shedding from the vesicles and shorten the time to rash healing. The drugs may lessen the severity and duration of dermatomal pain, but it is unclear whether the drugs prevent postherpetic neuralgia. Treatment of the dermatomal pain is a challenge and may require ibuprofen, acetaminophen, or opiates depending on the severity. Carbamazepine (200 mg p.o. three to four times a day) may reduce lancinating pain (Killian & Fromm, 1968) and amitriptyline (25–50 mg P.O. twice or three times a day) or gabapentin (900–1800 mg/day divided into three daily doses) may reduce burning and allodynia pain (Max, 1994). Isolation is seldom required but vesicle fluid should be considered infectious. Shingles patients cannot give shingles to others but can spread chickenpox to children who have not had chickenpox or received the attenuated varicella-zoster virus vaccine.

Acute complications of shingles occasionally occur. Herpes zoster ophthalmicus develops in some patients with shingles involving the upper face. Ocular involvement cases severe eye pain with loss of vision. These patients should be seen by an ophthalmologist and given i.v. acyclovir and acyclovir eye drops as the inflammation may lead to monocular blindness, cicatricial lid retraction, ptosis, conjunctivitis, scleritis, uveitis, and chorioretinitis. Herpes zoster oticus occurs when varicella-zoster virus in the geniculate ganglia reactivates. Vesicles develop on the ear pinna and external auditory canal walls (Adour, 1994; Aleksic et al., 1973). Patients develop peripheral facial palsy resembling Bell's palsy. The facial nerve inflammation may spread to involve auditory and vestibular nerves. About 20% of patients develop tinnitus or hearing loss and 10% experience vertigo. Antiviral treatment is usually given. Recovery of facial muscles is usually good but may not be excellent. Recovery of balance and hearing usually occurs. Peripheral motor neuropathy develops in 3% of shingles patients most likely from virus spreading from the involved ganglion to involve the neighbouring mixed nerve. Slow recovery of the myotome muscle weakness usually occurs but 25% are left with residual weakness (Thomas & Howard, 1972).

A dreaded complication is postherpetic neuralgia. In this syndrome, pain in the affected dermatomal distribution persists, often for years. The pain is often severe and has marked allodynia characteristics such that the patients try to prevent clothing from touching the involved skin area. The pathogenesis of postherpetic neuralgia is unknown. The incidence is unusual following shingles in individuals under age 60 years but increases with advancing age. Treatment is difficult and often requires a combination of

opiates, carbamazepine, amitriptyline and gabapentin in doses described above. Use of capsaicin or lidocaine creams over the involved skin is occasionally beneficial.

Guillain-Barré syndrome

Idiopathic polyneuritis or Guillain-Barré syndrome (GBS) commonly follows a viral infection (Ropper, 1992). About 50% of patients experience an upper respiratory tract or gastrointestinal infection 1 to 3 weeks before the onset of weakness. Numerous viruses have been associated with GBS that include Epstein–Barr, hepatitis A, enteroviruses, hepatitis B, cytomegalovirus, herpes simplex, mumps, measles, rubella, HIV, and vaccinations with influenza A/New Jersey, mumps/rubella, and smallpox vaccines. Patients usually develop an ascending symmetrical progressive flaccid weakness beginning in the legs that progresses up to 2 weeks (Ropper, 1992). Some patients develop marked autonomic dysfunction or respiratory weakness sufficient to require mechanical ventilation. CSF is acellular but may contain elevated protein levels. Please see Chapter 67 for details of the clinical course, pathology and treatment.

Sudden deafness and acute vertigo

Mumps, measles, varicella-zoster, rubella, influenza, and herpes simplex viral infections have been associated in children and adults with the sudden development of deafness, unilateral hearing loss or acute vertigo (Okamoto et al., 1994; Adour, 1994; Davis & Johnsson, 1983). Syphilis may also cause the vertigo and deafness. Patients may complain of tinnitus, nausea or vomiting. Otitic pain is uncommon. High frequency hearing loss and/or hypoactive caloric response on the involved side is seen on objective testing. Treatment with the antiviral drug, acyclovir, has not shown benefit (Stokross et al., 1998). The vertigo usually resolves in weeks but the hearing loss is often permanent. Congenital viral infections with cytomegalovirus or rubella may produce severe bilateral hearing loss in newborn infants (Davis et al., 1981; Menser & Forrest, 1974). In occasional children with congenital cytomegalic inclusion disease, the hearing loss may suddenly worsen 5 to 20 years later (Stagno et al., 1977).

Neurological manifestations of HIV infection

Justin C. McArthur

Departments of Neurology and Epidemiology, Johns Hopkins University, Baltimore, MD, USA

Since the initial descriptions in 1981 of cases of a rare disease, *Pneumocystis carinii* pneumonia, among homosexual men in Los Angeles, AIDS has expanded to become a global pandemic. In the past two decades, millions of people worldwide have died of AIDS, and one in every 200 Americans is infected with HIV-1 (UNAIDS, 2000). Our concept of the biology of HIV infection has changed radically to a model of continuous active HIV replication throughout HIV infection (Ho et al., 1995). The introduction of highly active antiretroviral therapy (HAART) regimens in the mid-1990s has resulted in a 50% decline in AIDS death rate, decreased maternal–infant transmission rates, reductions in incidence rates of opportunistic infections (Fig. 103.1), and a 40–50% decrease in the incidence of HIV-associated dementia (Brodt et al., 1997). Nonetheless, AIDS-associated neurological diseases continue to be major causes of morbidity and mortality, and because the blood–brain barrier may prevent the CNS penetration of antiretroviral agents, the brain may serve as a sanctuary for HIV, with persistent HIV replication within macrophages and microglia, the principal target cells in the CNS.

Epidemiology of HIV infection and AIDS

The World Health Organization (WHO) estimates that worldwide there have been 13.9 million deaths from AIDS and the number of infected people reached 54 million in 2000 (UNAIDS Joint United Nations Programme on HIV/AIDS, 1998) with 16000 new infections occurring each day. In the USA, through June 1999, surveillance has identified 711344 cases of AIDS and 420201 AIDS deaths (Centers for Disease Control and Prevention, 1999) and 431924 Americans are estimated to be living with HIV/AIDS. The proportion of AIDS cases among women has increased from 8 to 23% with proportional decreases among homosexual men. Though the disease was first recognized in the USA among homosexual men and injection drug users, heterosexual contact now constitutes the most frequent risk factor worldwide. In developed countries, in utero transmission from mother to infant has been significantly reduced through the use of antiretrovirals during pregnancy (Connor et al., 1994). Blood products are now an infrequent source of HIV infection in the USA, with the risk of HIV infection estimated at 1 in 493000 units of blood (Schreiber et al., 1996). In 1995, AIDS surpassed cancer as the predominant cause of death in young Americans (25–44 years) in the USA (Centers for Disease Control and Prevention, 1995) but a 60% fall in death rates was seen in the US from 1996 to 1998, attributable to the use of combination antiretrovials (Palella et al., 1998). The results of clinical trials of combination antiretroviral therapy, and the subsequent widespread introduction of highly active antiretroviral therapy (HAART) have produced a new era of optimism for HIV-infected people, and their providers (Shapiro et al., 1999). For the majority of HIV-infected persons worldwide these expensive treatments are simply out of reach. Only financial support from developed countries will enable millions to receive antiretroviral treatment. The most frequent disease manifestations of AIDS include *Pneumocystis carinii* pneumonia, *Candida esophagitis* and HIV wasting syndrome (Table 103.1).

Biology of HIV infection

The virus

The retrovirus family, *retroviridae*, is composed of three major subfamilies: lentivirus, to which HIV

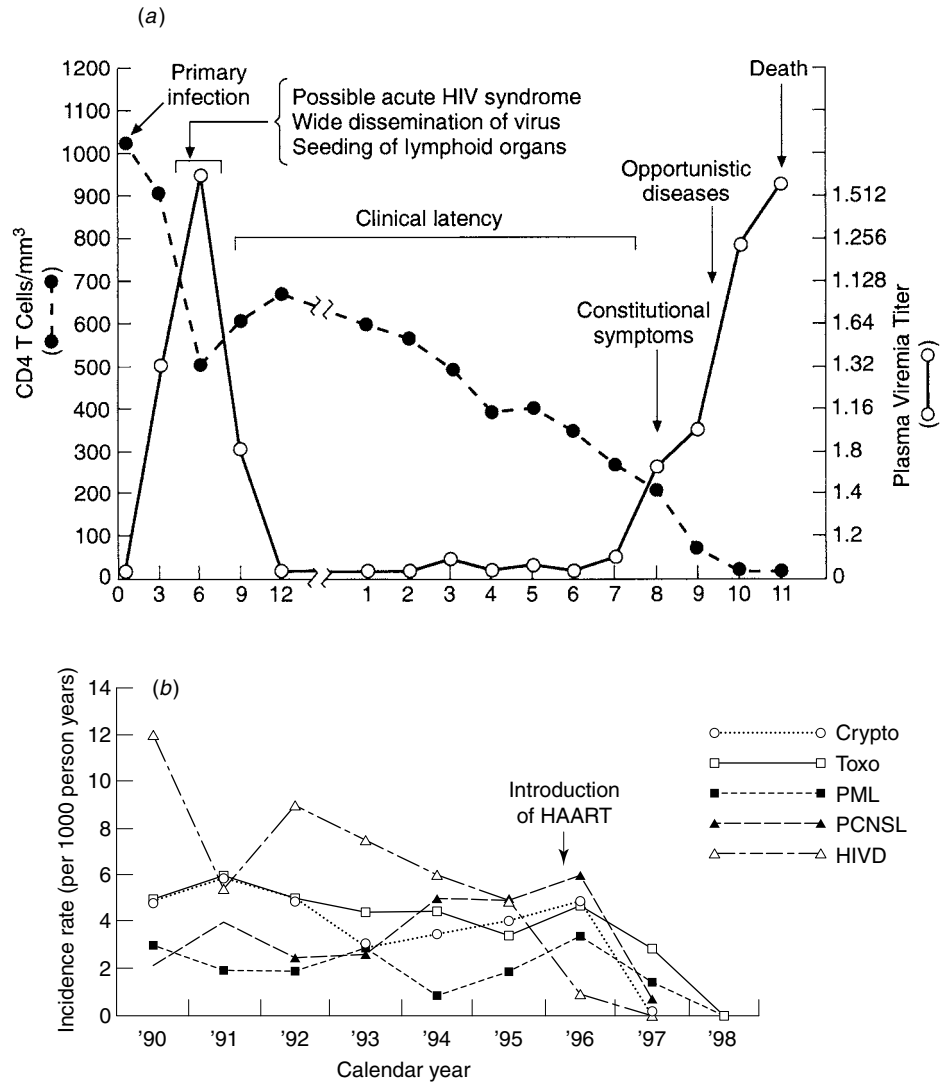

Fig. 103.1.(*a*) Relationship between neurologic disease and systemic disease stage. (*b*) Declining incidence of neurological diseases associated with HIV/AIDS (from Sacktor et al., 2000a).

belongs (lenti:slow); oncovirus, to which HTLV-1 belongs (onco:tumour); and spumavirus (spuma:foam). Of these three subfamilies, only members of the lentivirus and oncoviruses have been linked to neurological disease in humans. The retroviruses share genomic and morphological similarities and may have originally derived from an ancestral virus. The retroviruses include a number of RNA viruses which replicate in a unique manner; their other distinguishing characteristics are listed in Table 103.2. The lentiviruses or 'slow viruses,' of which HIV-1 is a member, share certain pathogenic similarities, and there are important parallels between human and animal lentivirus infections, because all lentiviruses cause an encephalitis (Johnson et al., 1988). All lentiviruses have evolved mechanisms by which they evade host defences and immune clearance and cause persistent infection. They share morphological and genomic characteristics, have long incubation periods, and are typically associated with chronic diseases. The lentiviruses comprise: visna virus, caprine arthritis encephalitis virus; equine infectious anemia virus; bovine immunodeficiency virus; and feline immunodeficiency virus. Human infection with HIV-2, murine immunodeficiency virus, and simian disease with SIV-1, which produces an AIDS-like syndrome after experimental inoculation in macaques, complete the currently recognized list. HIV-2 is a retrovirus distinct from HIV-1,

Disorder	HIV dementia	CMV encephalitis	PML
Features	memory, mental slowing, gait	delirium, seizures, brainstem signs	focal neuro signs
Course	several months	days–weeks	weeks–months
Typical CD4 range	<500	<100	<100
MRI	diffuse atrophy/ diffuse hyperintensity in deep WM	normal or periventriculitis	subcortical WM lesions T_1 hypotense
CSF	non-specific: immune activation	PCR+90%	PCR+60%

which is prevalent in part of Western Africa, and is remarkably similar to SIV-1, which is endemic among sooty mangabeys (De-The et al., 1989). Evidence from phylogenetic analyses, prevalence data, and the geographic incidence of HIV-1 strains suggests that the AIDS pandemic most likely originated in Western Equatorial African during the early part of the twentieth century (Hahn et al., 2000). The most likely introduction of AIDS to humans occurred from the transmission of SIV viruses derived from chimpanzees and sooty mangabeys, probably from direct contact during the hunting and slaughtering of these primates. The theory that oral polio virus trials conducted in the Belgian Congo during the late 1950s may have used infected chimpanzee kidney cells has been discounted.

HIV is a non-transforming retrovirus that produces a cytopathic or lytic effect on T-cells, although the precise mechanisms for T-cell depletion are uncertain. The CD4 receptor is the principal target site for HIV; however, specific chemokine receptors appear to serve as important secondary cellular receptors for HIV (He et al., 1997; Premack & Schall, 1996). Additionally, specific lectins on dendritic cells may serve to stabilize HIV for later presentation to susceptible T-lymphocytes or monocytes (Steinman, 2000). HIV-1 strains have been divided into T-tropic (preferring to replicate in T-lymphocytes) and M-tropic (preferring macrophages) on the basis of in vitro experiments. In vivo, the M-tropic (or R5) strains predominate in early infection, while the T-tropic (R4) strains evolve later, usually with advanced disease. Chemokine receptor usage is different for each, with T-tropic viruses making use of CD4 and CXCR4 (or fusin, the receptor for SDF-1), and M-tropic viruses using CCR5 (the receptor for RANTES) (Fig. 103.2).

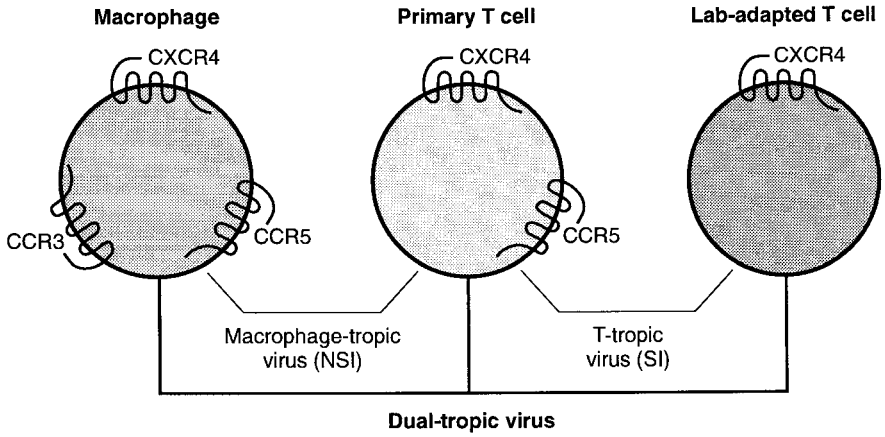

Fig. 103.2. Patterns of chemokine receptor usage for HIV-1 (from McArthur, 2000).

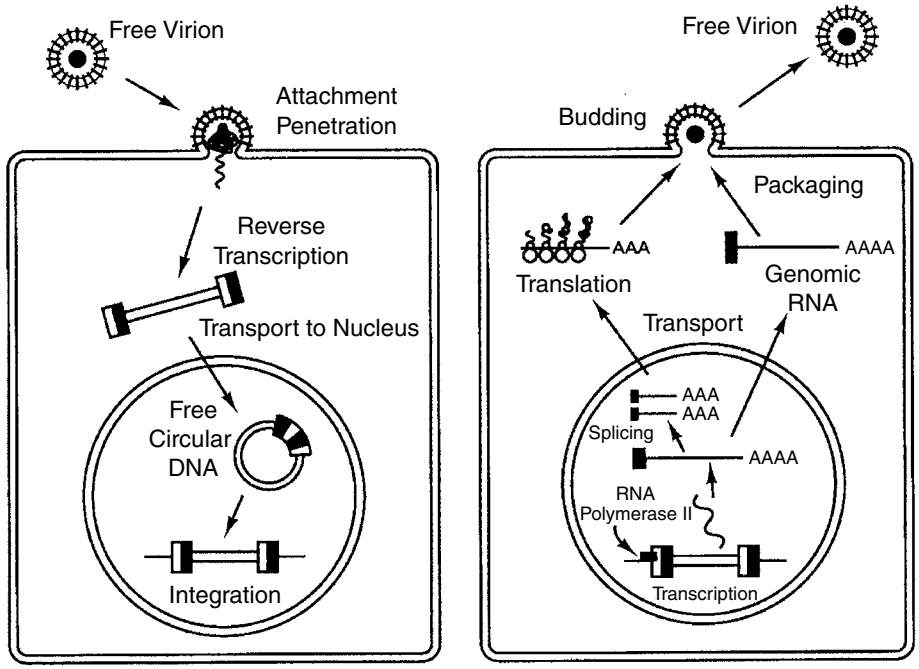

Fig. 103.3. HIV-1 life cycle: stages of HIV-1 replication (from Harrrison & McArthur, 1995).

A genetic variant of CCR5, Delta32, has been found to be protective against HIV infection in homozygotes and to delay disease progression in heterozygotes (Kostrikis et al., 1998; Barroga et al., 2000).

HIV structure and life cycle

HIV and other retroviruses can be distinguished from other viruses because they carry a unique pair of enzymes; first, an RNA-dependent DNA polymerase (reverse transcriptase), which uses RNA as a template to make a complementary DNA strand, and a second enzyme (a ribonuclease) which breaks down the original RNA strand, thus allowing a complementary DNA strand to be synthesized on the remaining DNA strand. After the double-stranded DNA has been synthesized, it is incorporated by the enzyme integrase into the host cell DNA and replicates with it (Fig. 103.3). Once integrated into the host cell genome, it is termed a provirus, and may remain latent for months or years, without affecting cellular function. With

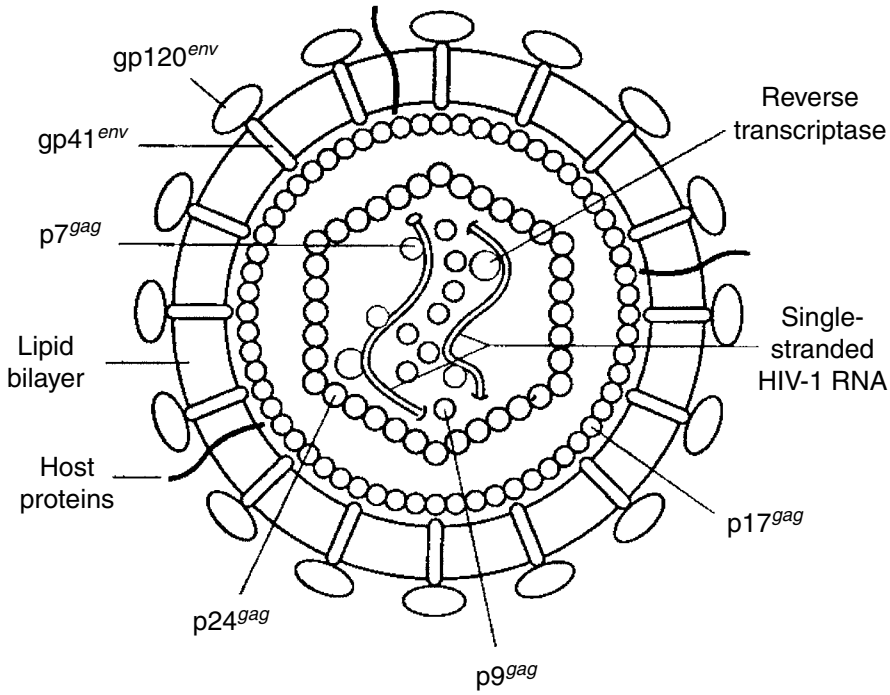

Fig. 103.4. HIV structure. Structure of the HIV virion (from Harrison and McArthur, 1995, after Greene, 1991).

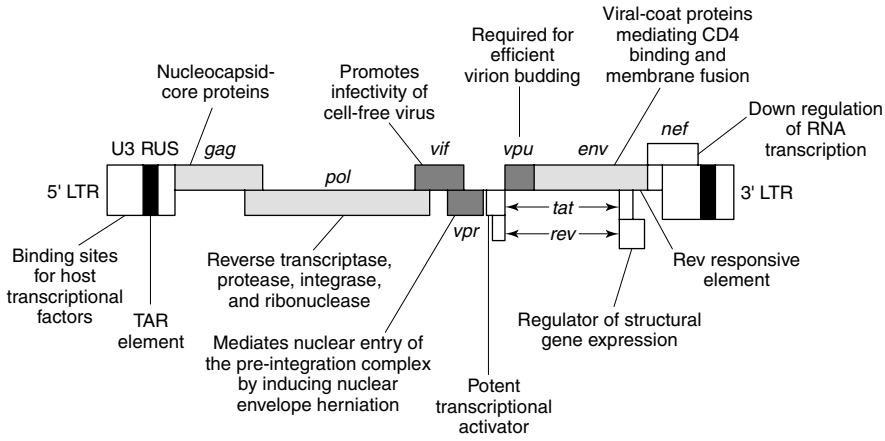

Fig. 103.5. Genome of HIV-1 (revised from Harrison & McArthur, 1995, after Greene, 1991). The proposed functions of the regulatory genes are indicated.

cell activation, the provirus may separate from the host cell DNA to produce retrovirus mRNA, which directs viral protein synthesis. Macrophages are apparently able to sustain a productive infection without cellular activation, and may therefore serve as an important reservoir of virus, both in the body and particularly in the brain.

The HIV virion is a relatively large, icosahedral structure with numerous external spikes (Fig. 103.4). The envelope spikes are composed of gp120 with a transmembrane component, gp41. The lipid bilayer is derived from host cell proteins during viral budding. The core is formed from four nucleic capside proteins: p24 (the major component), p17, p9 and p7. Genomic structure of HIV includes genes that code for structural proteins and several genes that code for regulatory proteins (Fig. 103.5). The three groups of structural proteins are coded for by the *gag*, *pol*, and *env*

regions of the HIV gene. The *env* gene encodes for the two major envelope proteins, gp120 and gp41; gp120 is a large glycoprotein that forms the surface spikes of the virion, while gp41 is a transmembrane glycoprotein. The two envelope proteins are critical for viral binding and cell fusion. The *pol* region codes for reverse transcriptase, a protease and an endonuclease. Endonuclease is critical for the integration of DNA into the host denome and the protease cleaves the polyproteins encoded for by gag and pol into their active forms. The gag region encodes for the core proteins, including p24, the nucleoid shell and several smaller proteins. Additional information is available in two reviews (Levy, 1989; Greene, 1991). At least five genes (*tat*, *rev*, *nef*, *vif*, and *vpr*) are involved in the regulation of HIV-1 replication (Fig. 103.5). After reverse transcription, the 'preintegration complex' appears to travel to the host cell nucleus along the host cell's microtubules, and crosses the nuclear envelope. The mechanisms for this critical step are unclear, but it has been hypothesized that the viral matrix protein serves as a 'nuclear address label', i.e. a nuclear localization signal recognized by cellular proteins that permits transport into the nucleus. It is likely that the viral matrix protein is not the only mediator of HIV nuclear importation. Vpr may also assist with binding to the nuclear pores, or may disrupt the nuclear membrane by inducing blebbing and rupturing, with the subsequent ingress of cytoplasmic soluble components (Henklein et al., 2000).

Initially it was thought that, after infection and integration of HIV DNA into the host cell genome, there followed a longer period of of virological and clinical latency. Recent work has shown that, even during this period of clinical latency, there is very active viral replication and release of active virions (Michael et al., 1992; Ho et al., 1995). There appears to be a very rapid turnover of CD4 lymphocytes (approximately 2 billion daily), with release of approximately 10 billion new virions daily (Coffin, 1996; Saag, 1997). With millions of replicative cycles daily, and a relatively high error rate in RNA transcription, resistant mutants can arise readily unless HIV replication is suppressed. This rapid replication leads to the establishment of a swarm of related HIV quasispecies within an individual. Quiescent memory CD4+ T-lymphocytes, and macrophages may serve as a long-lived reservoirs for latent HIV infection (Saag, 1997; Finzi et al., 1997). The resting memory T-lymphocyte has been shown to be a particularly important reservoir which prevents eradication because HIV remains either latent, or maintains a low level of replication for years (Finzi et al., 1997). In addition, the concern exists that the brain may serve as a sanctuary for unchecked HIV replication, both because the blood–brain barrier may prevent CNS penetration of antiretrovirals, and also because macrophages, the principal target cells within the CNS, may be long-lived sequestered sites for HIV (Finzi et al., 1997; Wong et al., 1997).

After acute infection with HIV, the immune system is stimulated to control the virus and a lower level of HIV viremia is established after the initial peak viremia. The level of this viral 'set-point' appears to be an important predictor of subsequent disease progression. HIV-specific immune responses, both antibodies and cellular (cytotoxic T-cells) develop to a variable degree. Some individuals appear to be able to control HIV replication even without antiretrovirals, and have no or a very slow progression of disease. These 'long-term non-progressors' constitute about 10–15% of chronically infected individuals. HIV enters the nervous system early after infection, but productive infection is rarely established before immunosuppression has developed. It is more likely that CNS reseeding, with the establishment of productive CNS infection only occurs later in HIV disease, after the development of immunosuppression. The major direct effect of HIV infection on the immune system is the profound and progressive loss of CD4 lymphocytes. This, of course, leads to the impaired cellular immunity, and the development of reactivated latent infections or infections with organisms which are normally not pathogenic ('opportunistic'). In addition, the loss of the regulatory CD4 subset appears to lead to a dysregulation of macrophages, with the overproduction of a variety of proinflammatory cytokines and chemokines. The activation of circulating monocytes is probably a critical step which permits their ingress into the brain (Gartner, 2000). This macrophage activation within the CNS and PNS may be particularly important for the development of HIV dementia and sensory neuropathy, as is discussed below (Tyor et al., 1995; Gartner, 2000).

Advances in antiretroviral therapy

In the past few years several important advances have led to concrete improvements in the care and prognosis of HIV-infected individuals. The first is an understanding of the direct relationship between viral replication and immunological and clinical progression, which reinforces the need to suppress viral replication to control the infection. The second is the wider availability of multiple, potent antiretroviral regimens that can provide effective suppression of HIV (Table 103.3a.) The third major change is the ability to monitor the response to therapy through regular measurement of plasma HIV RNA levels which, with CD4 counts, has become a routine part of clinical

Table 103.3(a). Anti-HIV drugs: CSF: plasma concentration ratios

	Date approved	CSF: plasma
Nucleoside RT inhibitors		
Retrovir (zidovudine, AZT)	3/87	0.3–1.35

care. In addition, resistance to antiretrovirals can now be relatively easily measured with genotypic or phenotypic assays. Incomplete adherence, underdosing, and pharmacokinetic interactions with other medications can result in the development of drug resistant strains of HIV-1 (Condra & Emini, 1997). Of the 15 antiretroviral agents available in the USA, these act either to inhibit reverse transcriptase, or are protease inhibitors. Further details can be found in a recent review (Sepkowitz, 2001). New agents in development may block fusion steps or the integration of HIV-1. Guidelines for the use of antiretroviral (ART) therapy have been developed by expert panels, and include the broad recommendation that all symptomatic patients, and asymptomatic patients with immunodeficiency (CD4 $<350/\mu l$) or plasma HIV RNA levels >55 000 copies/ml be treated with combination ART regimens (Table 103.3) (http://www.hivatis.org). These regimens might include either three nucleoside RT inhibitors (NRTIs), or two NRTIs + one non-nucleoside RTI, or two NRTIs + a protease inhibitor (Table 103.3b). Potent antiretroviral treatments have resulted in significant improvements in survival, for example, the mortality among people with CD4 counts $<100/mm^3$ has dropped from 35:100 person–years (PY) in 1993 to 10:100 PY in 1997 (Palella et al., 1998). Structured treatment interruption has been proposed as a strategy to reduce the cumulative toxicities of HAART, and to allow for stimulation of HIV-specific immune responses. However, a recent study of HAART interruption showed prompt rise in plasma HIV RNA levels, with falls in CD4 counts, and increases in viral replicative capacity (Deeks et al., 2001). It is beyond the scope of this chapter to discuss the long-term effects of potent antiretroviral regimens; however, it is now clear that these combinations can produce significant metabolic effects, including hypertriglyceridemia, fat remodelling or lipodystrophy, pancreatitis, lactic acidosis, and mitochondrial toxicity. Peripheral neuropathy has become one of the common treatment-limiting effects.

As CD4 counts decline with advancing HIV infection the range of cellular responses, or 'repertoire', constricts. With HAART, dramatic reductions in plasma HIV levels can be seen within weeks, producing a sustained (or 'durable') virological suppression. Immunological response occurs over a few months, and can be dramatic, with normalization of CD4 counts. Initially, the rise in CD4 counts is from a redistribution or expansion of existing T-lymphocytes from the lymphoid tissue. These are mainly memory cells, and will only respond to specific antigens, so that the overall immune response remains constricted with a 'limited

repertoire'. A reduction of T-cell activation and improved CD4+ reactivity to recall antigens is then seen (Autran et al., 1997). Even later, naive T-cells (CD45RA+/CD27+) are produced from the bone marrow and thymus and the repertoire of T-cell responses can potentially increase (Roederer, 1998; Powderly et al., 1998). Prolonged therapy may produce continuing immune improvement, with the restoration of specific immune responses to pathogens (Autran et al., 1997). Prophylactic therapies can be safely discontinued in individuals whose CD4 count has been restored by HAART to above 200/mm^3 (Furrer et al., 1999). With reconstitution of the immune system a variety of inflammatory responses have been reported to opportunistic infections leading to apparent 'flares' in the activity of opportunistic infections, and probably representing a heightened immune response (Race et al., 1998). Whether this will be important for neurological diseases remains uncertain.

Several attempts have been made to augment the immune system in patients with HIV infection, including structured treatment interruptions, interleukin-2 therapy to stimulate T-cells, and IL-12 therapy to stimulate y-IFN and promote TH1 immunity. Interleukin-2 therapy is probably the most widely tested at this point, although it it expensive and has associated side effects. IL-2 stimulates the production of CD4 cells, and theoretically might also activate latent HIV producing a transient increase in circulating HIV levels.

Neurological manifestations of HIV infection (Table 103.4)

Most neurologic illnesses are confined to the later stages of HIV disease, after cellular immunodeficiency has developed (Johnson et al., 1988) (Fig. 103.1a). HIV may affect the nervous system in two ways: directly, producing distinct neurological syndromes, or indirectly, by causing immunodeficiency with a resultant susceptibility to opportunistic infections and neoplasia. CNS infection with HIV-1 can produce a wide spectrum of clinical manifestations, ranging from asymptomatic infection to severe, life-threatening opportunistic infections. For example, within 6 weeks of infection, an acute seroconversion illness can occur with meningoencephalitis, or inflammatory demyelinating neuropathies. The common reactivated or opportunistic processes include cerebral toxoplasmosis, cryptococcal meningitis, progressive multifocal leukoencephalopathy (PML), tuberculous meningitis, and primary CNS lymphoma. The incidence rates of most have fallen since the introduction of HAART, because of immune restoration in HAART-treated patients (Brodt et al., 1997; Sacktor et al., 2001). Effective treatments have been developed for several of these processes, and primary prophylaxis is particularly useful for toxoplasmosis (Johnson et al., 1988).

HIV-associated dementia, myelopathy and sensory neuropathy (Table 103.5)

The HIV-associated syndromes, dementia, myelopathy and sensory neuropathy, are novel, debilitating conditions which generally do not develop until advanced HIV infection. Typically, patients will have had other AIDS-defining illnesses before the onset of these neurological syndromes.

HIV-1 associated dementia (HIV-encephalopathy/ AIDS dementia complex

HIV-1 infected individuals are susceptible to developing a progressive and frequently fatal dementia. This syndrome was added as an AIDS indicator illnesses in 1987, and termed HIV-1 encephalopathy (or HIV-associated dementia (HIV-D)). Occasionally HIV-D develops before profound immunosuppression, but in general, it is rare among

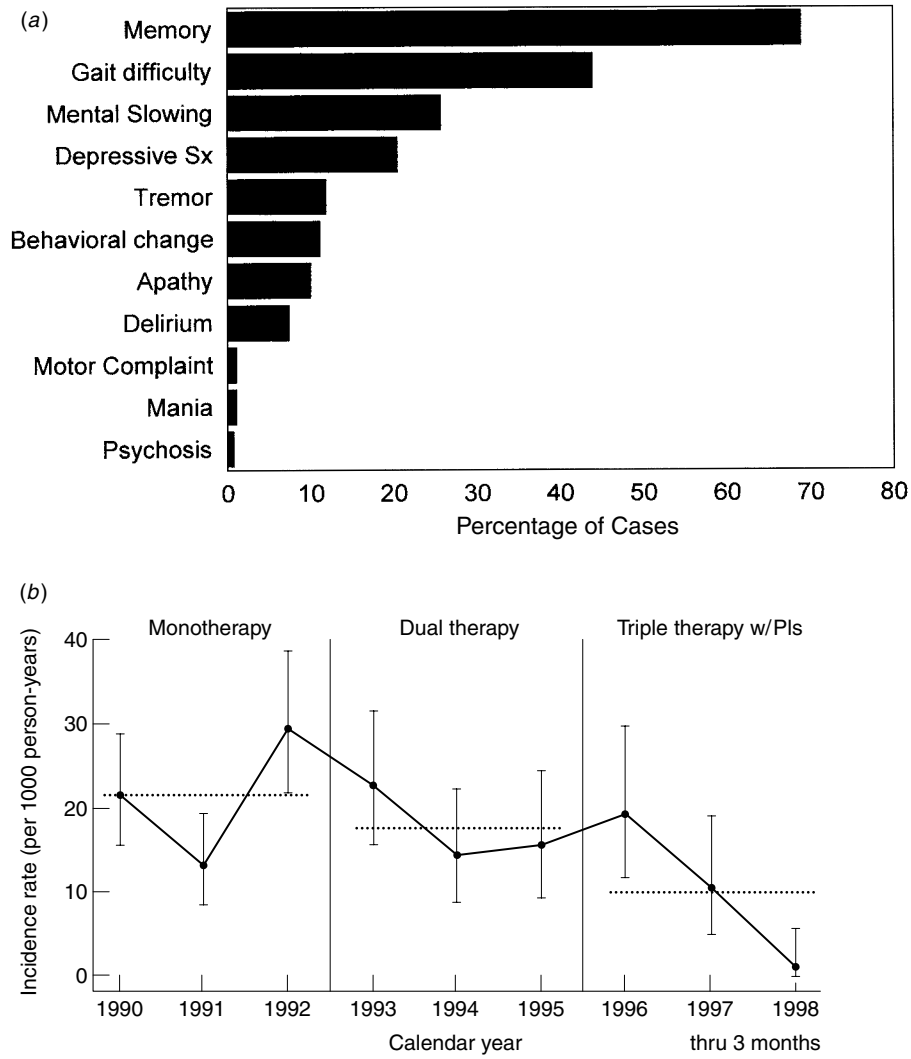

Fig. 103.6.(*a*) Frequency of neurological symptoms in HIV-D. (From McArthur, 2000.) (*b*) Declining incidence of HIV-associated dementia with successive improvements in antiretroviral therapy. (After Sacktor et al., 2000a).

healthy HIV-1 infected persons. The cumulative prevalence of HIV-D during the lifetime of an HIV+ person is estimated at 15%, and risk factors include high plasma HIV RNA levels, low CD4+ counts (Childs et al., 1999) anemia, low body mass index, older age, more constitutional symptoms before AIDS (McArthur et al., 1993), injection drug use (Janssen et al., 1992), and female sex (Chiesi et al., 1996). More subtle forms of cognitive impairment termed minor cognitive/motor disorder (MC/MD) exist in 20% of symptomatic HIV-seropositive adults (Janssen et al., 1989). Children can also be affected by a progressive encephalopathy, with an estimated prevalence of 30% (Belman et al., 1988) and a typical survival of 6 to 24 months (Epstein et al., 1985; Mintz et al., 1989). The incidence of HIV-D has declined by about 50% since the introduction of HAART (Fig. 103.6a).

HIV-D occurs in all groups at risk for HIV-1 infection, including children. Clinical features in pediatric cases include microcephaly, developmental delay, then loss of developmental milestones, leading to death unless treated with antiretrovirals. In adults, the clinical manifestations of HIV-D are often stereotypic, developing over a few months; however, occasionally the course is more fulminant. A typical presentation includes cognitive, behavioural, and motor dysfunction, and has been characterized as a subcortical dementia. The initial symptoms may be subtle,

and therefore overlooked, and can be misdiagnosed as depression. In the early stages, memory loss, mental slowing, reading and comprehension difficulties, and apathy are frequent complaints. Table 103.2(b) illustrates some of the salient features which differentiate HIV-D from CMV encephalitis and PML. Other conditions which may mimic HIV-D include cryptococcal meningitis, primary CNS lymphoma and depression (Table 103.6). Gait disturbance, with non-specific complaints of stumbling and tripping, is frequent, and tremor may develop, with impairment of fine manual dexterity. Examination findings include impaired rapid movements of eyes and limbs, diffuse hyperreflexia, and release signs. New onset mania develops in 5% of patients. Neuropsychological abnormalities include a preferential impairment of psychomotor speed and memory. As the dementia advances, more widespread deficits develop, including a global dementia, often accompanied by myelopathy and neuropathy. The course of HIV-D is variable, and some individuals remain stable for prolonged periods of time, particularly with HAART. In addition, a less severe form, termed HIV-associated minor cognitive–motor disorder, has been defined, which frequently heralds the later development of HIV-D.

Cerebrospinal fluid abnormalities are common, with elevated CSF levels of HIV RNA and immune activation markers occurring in most demented individuals. CSF levels of HIV RNA correlate with the severity of neurological deficits (McArthur et al., 1997; Brew et al., 1997). Decline in CSF HIV RNA with HAART correlates with the successful reversal of neurological deficits (Marra et al., 1999; Ellis et al., 2000). Various CSF markers of immune activation such as neopterin (Brew et al., 1990), $\beta 2$ microglobulin (Brew et al., 1989), and quinolinic acid (Heyes et al., 1991) also correlate with the severity of HIV-D, and also decline with treatment. Magnetic resonance imaging demonstrates both cortical and central atrophy (Table 103.6), and characteristic confluent signal abnormalities within the deep white matter (see Fig. 103.7). These represent increased water content, and can be reversible with HAART. Magnetic resonance spectroscopy has shown increases in myoinositol and choline levels, reflecting chronic inflammation and astrocytosis, and reductions in *N*-acetyl aspartate, indicating neuronal injury (Fig. 103.8). Brain metabolite levels correlate strongly with various clinical and biochemical indices of neurological progression in HIV+ individuals such as severity of HIV-D, overall functional level, CD4 cell count, plasma viral load, and CSF viral load (Chang et al., 1999). Cerebral metabolite levels can normalize after 9 months of treatment with HAART, although the changes appear to lag behind improvements in CD4 count and CSF HIV RNA levels (Chang et al., 2001).

HIV probably gain access to the CNS from the blood stream by the ingress of infected or activated monocytes (Gartner, 2000). Productive HIV-1 infection occurs principally in perivascular macrophages and multi-nucleated giant cells (Fig. 103.9, Fig. 103.10, see colour plate section), and rarely in astrocytes, endothelial cells or neurons (Takahasi et al., 1996). The pathological features include multinucleated giant cells, which represent the fusion of HIV-infected macrophages, and a marked activation of macrophages and astrocytes. Immunocytochemical studies show a preponderance of productive HIV infection within the basal ganglia, brainstem, and deep white matter (Kure et al., 1991; Brew et al., 1995). In situ PCR studies have confirmed that most productive infection is contained with macrophages and microglia, with a non-productive infection of astrocytes (Takahashi et al., 1996). These observations suggest that initial infection occurs in the deep brain regions, probably from infection of perivascular macrophages by trafficking monocytes.

Diffuse rarefaction of white matter occurs commonly, with breakdown of the blood-brain-barrier (Thompson et al., 2001) with astrocyte apoptosis and eventually, dendritic simplification and neuronal loss. Morphometric studies have shown an approximate 40% reduction in

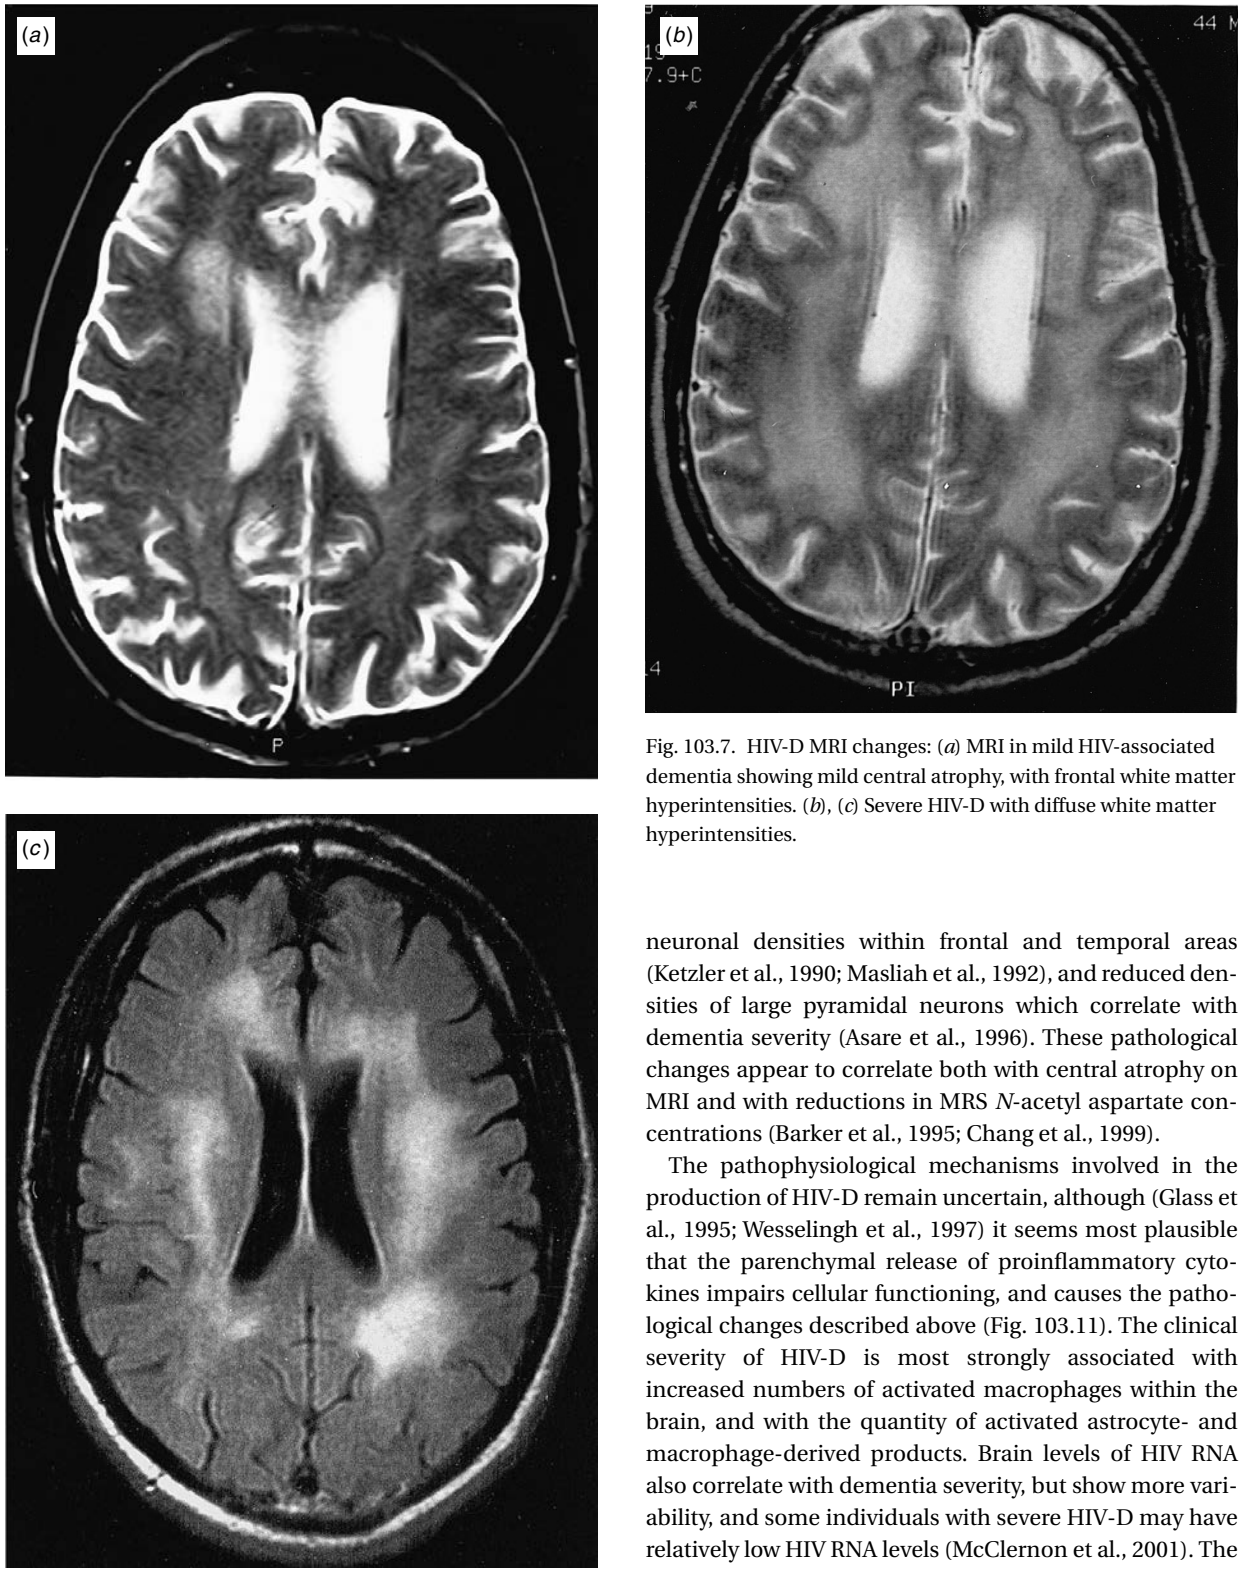

Fig. 103.7. HIV-D MRI changes: (*a*) MRI in mild HIV-associated dementia showing mild central atrophy, with frontal white matter hyperintensities. (*b*), (*c*) Severe HIV-D with diffuse white matter hyperintensities.

neuronal densities within frontal and temporal areas (Ketzler et al., 1990; Masliah et al., 1992), and reduced densities of large pyramidal neurons which correlate with dementia severity (Asare et al., 1996). These pathological changes appear to correlate both with central atrophy on MRI and with reductions in MRS *N*-acetyl aspartate concentrations (Barker et al., 1995; Chang et al., 1999).

The pathophysiological mechanisms involved in the production of HIV-D remain uncertain, although (Glass et al., 1995; Wesselingh et al., 1997) it seems most plausible that the parenchymal release of proinflammatory cytokines impairs cellular functioning, and causes the pathological changes described above (Fig. 103.11). The clinical severity of HIV-D is most strongly associated with increased numbers of activated macrophages within the brain, and with the quantity of activated astrocyte- and macrophage-derived products. Brain levels of HIV RNA also correlate with dementia severity, but show more variability, and some individuals with severe HIV-D may have relatively low HIV RNA levels (McClernon et al., 2001). The density of apoptotic astrocytes correlates with the rapidity of progress of HIV-D (Thompson et al., 2001). Using in situ

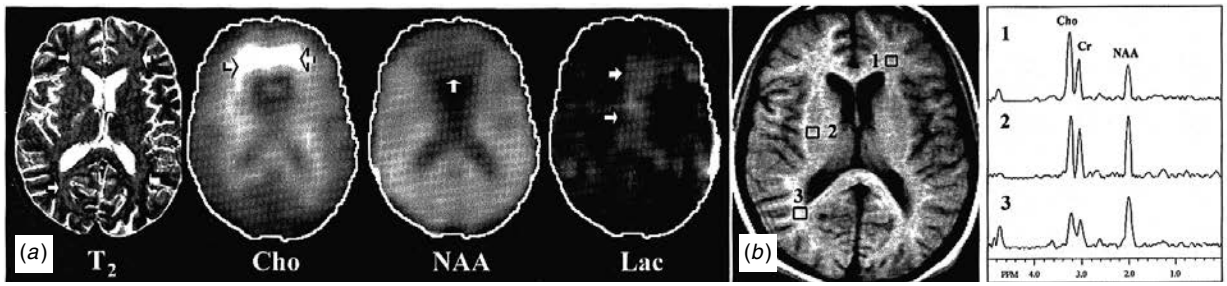

Fig. 103.8. (*a*) MRS: Magnetic resonance spectroscopic imaging in patient with mild to moderate HIV-associated dementia: Spectra are strikingly abnormal, particularly in the frontal lobe white matter. MRI shows minimal atrophy and some hyperintensity in the T_2 images in the periventricular white matter. Spectroscopically, a markedly decreased NAA is apparent throughout much of the brain, especially in the frontal lobe (white arrow). Choline is also elevated throughout the white matter (arrows), with the highest levels in the frontal lobe. A small lactate signal can also be observed in the ventricles (arrows). (*b*) Single voxel MRS indicating three separate voxels with spectra for Cho, Cr, and NAA. NAA peak is reduced in frontal area (1).

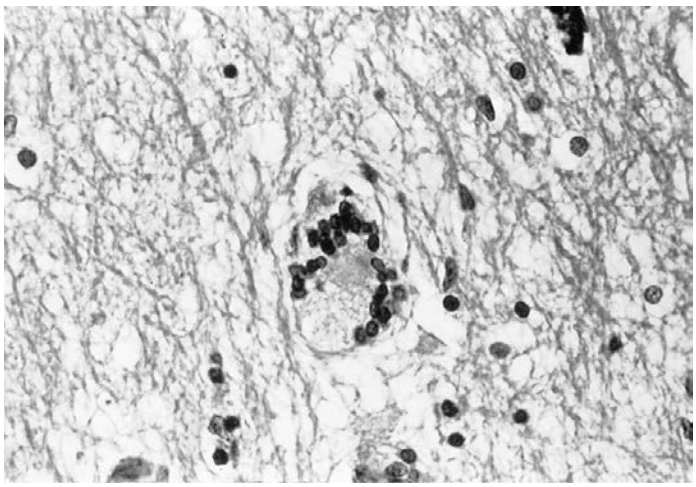

Fig. 103.9. HIV-D: multinucleated giant cell in focus of HIV encephalitis.

PCR, a greater number of astrocytes contained HIV DNA in the rapid progressor group. This suggests that there is both an increased rate of astrocyte apoptosis in rapidly progressive dementia and increased rates of astrocyte infection.

A very wide range of inflammatory mediators has been implicated in the pathogenesis of HIV-D, and it is unlikely that any one 'factor' is directly causative. These products include proinflammatory cytokines, eicosanoids, nitric oxide, and extracellular matrix-degrading proteases (Griffin, 1997; Adamson et al., 1999; Wesselingh et al., 1997). Platelet activating factor, nitric oxide, and matrix metalloproteases can be neurotoxic (Epstein & Gendelman, 1993) and may also have important effects on synaptic structure and function (Yong et al., 1998; Vos et al., 2000; Patton et al., 1998). Monocytes may contribute to the development of HIV dementia through multiple mechanisms. Activated and/or HIV-infected monocytes release a number of potent toxins, including viral gene products such as tat and gp120, as well as cellular gene products such as TNFα, nitric oxide, and platelet activating factor (Lipton & Gendelman, 1995). The precise role of viral proteins in pathogenesis is uncertain, and is reviewed in detail (Nath & Geiger, 1998). Tat is a non-structural viral protein, which acts as a trans-acting nuclear regulatory protein, and is essential for viral replication. It may be released into the extracellular space (Ensoli et al., 1993), and both in vitro and in vivo may be neurotoxic for selected neuronal populations (Hayman et al., 1993). Tat also stimulates the release of proinflammatory cytokines in the brain (Chen et al., 1997), and induces the migration of monocytes in a blood–brain barrier model (Nath, 1999; Nath et al., 2000; Magnuson et al., 1995). The envelope glocoprotein, gp120, is also a potent neurotoxin, in vitro, and it has been proposed that the neurotoxicity is mediated indirectly through actions on glial cells.

The products of activated monocytes can activate astrocytes, leading to the release of astrocyte-derived cytokines and chemokines, as well as to altered neurotransmitter uptake (Fig. 103.11). These products may also sensitize astrocytes and neurons to the effects of glutamate (Conant et al., 1998). Astrocytes participate in the inactivation of neurotoxins, particularly excess excitatory amino acids, such as glutamate and aspartate, and their loss may perturb the regulation of extracellular glutamate leading to neuronal injury. In situ studies have shown that monocyte–macrophages are the dominant source of toxins including TNF-α, and that apoptotic neurons are generally detected in close proximity to activated macrophages (Gelbard et al., 1995). Both monocytes/microglia and astrocytes are also capable of producing MMPs, which may

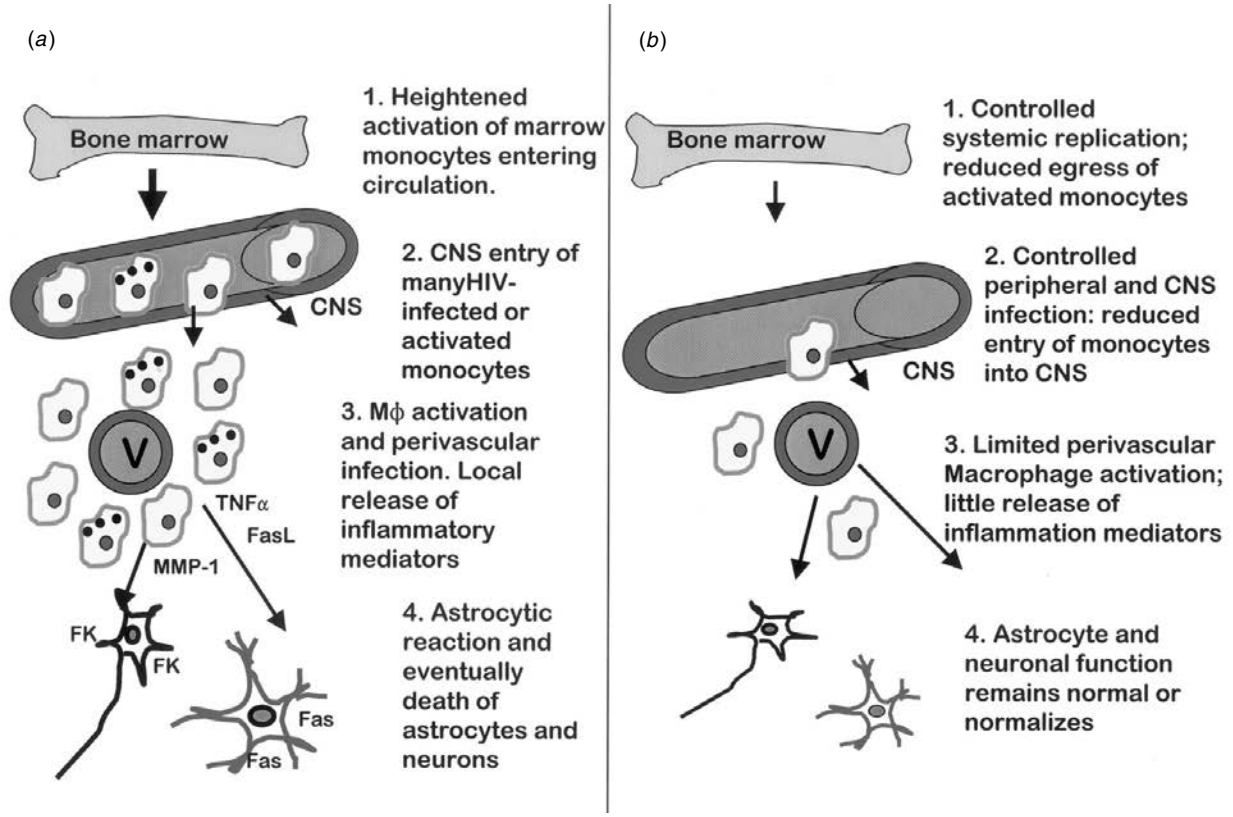

Fig. 103.11. Cartoon of pathogenesis of HIV-D: illustrates hypothetical reversible and irreversible phase of neuropathology. (*a*) No antiretroviral treatment: activation of monocytes in marrow and blood results in enhanced monocyte ingress to CNS. This produces perivascular inflammation and foci of productive infection. End result: neuronal/astrocytic death leading to progressive irreversible dementia. (*b*) Successful antiretroviral treatment: with virological suppression there is reduced ingress of activated/infected monocytes. CNS inflammation is reduced and productive HIV infection in CNS is limited with less injury of neurons and astrocytes and reversible dementia.

lead to breakdown of the BBB, and exposure of the brain to circulating substances. Locally produced chemokines may stimulate the ingress of additional activated monocytes. Importantly, this inflammatory cascade may become 'self-sustaining' so that even if HIV replication is suppressed, there may be continuing macrophage-mediated damage (Fig. 103.11).

Treatment of HIV-associated dementia

Neuropsychological testing has traditionally been used to measure progression in HIV-D, with particular emphasis on timed tasks. While specific neuropsychological instruments that measure psychomotor speed may indeed be sensitive to HIV-D, the relationship of changes in neuropsychological performance to improvements in function has not yet been demonstrated. Increasingly, surrogate markers of improvement are being introduced into clinical practice, including CSF HIV RNA levels, CSF markers of immune activation, and MRS. The primary principle of antiretroviral therapy in HIV-D is to produce complete virological suppression both in plasma, and the CNS. While it is still debated whether particular combinations might be more effective at penetrating the blood–brain barrier and therefore for use in HIV-D (Clifford, 2000), recent data have not demonstrated a difference in CNS efficacy between different HAART regimens (Sacktor, 2001).

Initial open-label studies with zidovudine (AZT) monotherapy in HIV-D showed promising improvements in clinical function, and neuropsychological performance (Fischl et al., 1987). The initial multicentre licensing trial (Fischl et al., 1987) suggested that AZT improved neuropsychological function in the short term, but no clear predictors of response were identified. There is very limited information about the therapeutic effect in HIV-D of the other nucleoside reverse transcriptase inhibitors, didanosine (ddl) or

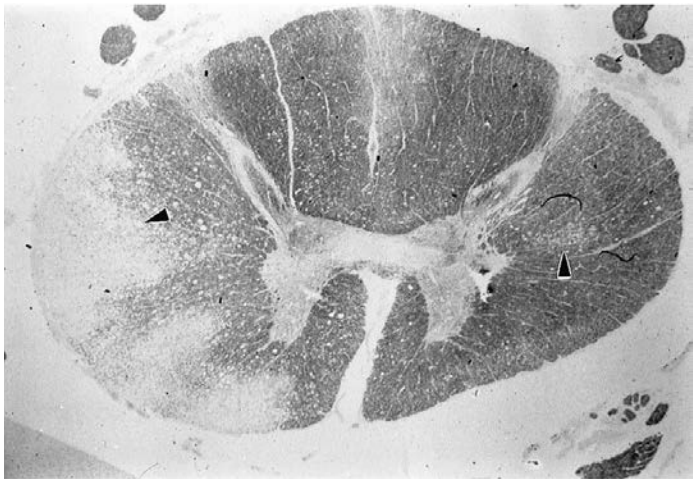

Fig. 103.12. Photomicrograph of spinal cord in vacuolar myelopathy. Innumerable vacuoles are identifiable, particularly in corticospinal tracts (arrowheads).

dideoxycytidine (ddC). The only placebo-controlled trial of AZT in HIV dementia suggested that improvement is seen with doses of AZT around 2000 mg daily (Sidtis, 1993), a dose that is rarely tolerated. Few of these studies have examined why some demented patients respond, and others fail to, and there has been little study of the kinetics and durability of treatment response. For example, Tartaglione et al. (1991) noted neurological improvement in most patients with mild HIV-D, but no relationship between treatment response and CSF AZT concentrations, cumulative AZT dose, or HIV isolation from CSF. There is no longer any role for monotherapy in the treatment of HIV-D. The effect of more potent antiretroviral regimens was examined in a multicentre trial of 1313 adult HIV+ subjects with CD4 counts $<$50 cells/mm^3. Four combinations consisting of AZT, alternating monthly with ddI; or AZT + ddC; AZT + ddI; or AZT + ddI + nevirapine were tested. A four-item quantitative neurological performance battery score was administered. Triple therapy and the AZT/ddI combination preserved or improved neurological performance compared with the alternating dual therapy ZDV/ddI and ZDV/ddC regimens ($P<0.001$, paralleling their impact on survival (Price et al., 1999). Other studies have also confirmed the effects of HAART in reversing the neurocognitive deficits of HIV-D (Sacktor et al., 2000a,b; Fernando et al., 1998).

Given that aberrant immune activation is likely to play a pivotal role in sustaining or magnifying the CNS damage induced by HIV-1, attention has focused on adjunctive therapies targeted at attenuating the CNS effects of inflammatory products. These have included the NMDA-antagonist memantine, the calcium channel blocker nifidepine, the platelet-activating factor antagonist lexipafant, the TNF-α antagonists pentoxifylline and CPI1189, and an experimental antioxidant, thioctic acid. The result of most trials have been disappointing, with either no or only modest effects on neuropsychological function. One agent, the MAOB inhibitor selegiline, has been shown to improve memory in two separate placebo-controlled studies (Sacktor et al., 2000a; Schiffito et al., 2001). Although its mechanism of action is speculative, a larger Phase II trial is under way in the USA.

Further information about the symptomatic management of HIV-D is beyond the scope of this chapter and the reader is referred to Gendelman et al. (1998).

HIV-1 associated vacuolar myelopathy

The most common myelopathy associated with HIV-1 is a slowly progressive myelopathy characterized by prominent vacuolar changes in the ascending and descending tracts. It affects 5–10% of patients with AIDS, but has been identified pathologically in almost 50% at autopsy (Dal Pan et al., 1994). It manifests as a progressive spastic paraparesis, with sensory ataxia, and is often associated with HIV-D. Typically, there is no back pain, or sensory level, and spine MRIs are usually normal. Occasionally, the myelopathy develops before, or without, dementia but usually the two progress in parallel. The differential diagnosis includes HTLV-1 associated myelopathy (see Chapter 104), CMV myeloradiculitis and HIV-myelitis, which is accompanied by HIV replication within the cord, and may be associated with contrast-enhancing foci.

The major pathological finding is vacuolation in the spinal white matter, particularly in the lateral and posterior columns of the thoracic spinal cord (Fig. 103.12). Productive infection, as indicated by multinucleated giant cells, is rare, however, there is marked macrophage activation and cytokine release within the spinal cord (Wesselingh et al., 1997). Because of some similarities to the myelopathy induced by vitamin B12 deficiency, this has been implicated in AIDS, however the role remains unclear. As with HIV-D, the role of local macrophage activation is probably critical (Tyor et al., 1995; Lipton & Gendelman, 1995). Antiretrovirals have not been convincingly proven effective for VM, however, a trial of methionine suggested some benefit (Dorfman et al., 1997).

Peripheral nerve disorders associated with HIV-1

Although the CNS complications of HIV-1 infection constitute the most significant neurologic disorders with respect

to morbidity and mortality, the peripheral nervous system may become involved in diverse ways. Not only do novel and distinct clinical syndromes exist, but the timing of onset varies, suggesting that diverse pathogenic mechanisms may produce the different peripheral neuropathies.

A number of possible immune-mediated phenomena have been described in association with HIV-1 infection, including polymyositis, inflammatory demyelinating polyneuropathies (IDPs) and thrombocytopenia. The IDPs typically occur in a relatively early stage of HIV-1 infection before profound immunodeficiency, and typically present with the acute onset of profound motor weakness and Guillain–Barré syndrome. In contrast to GBS occurring in HIV-seronegative individuals, CSF pleocytosis commonly occurs with GBS in the setting of HIV infection. The IDPs are often self-limited or respond to immunomodulatory therapy. Since IDPs resemble autoimmune diseases and occur early in infection, they probably result from an autoimmune phenomenon directed against peripheral nerve antigens, and triggered by HIV-1 (Sheikh et al., 1998). Further details of these disorders are discussed elsewhere (Cornblath et al., 1987).

Up to 30% of patients with AIDS will develop sensory neuropathies, characterized by painful sensory symptoms usually in the feet. In contrast to the IDP's discussed above, HIV-associated sensory neuropathies (HIV-SN) usually occur late in HIV-1 infection, in association with multiple opportunistic infections and profound immunodeficiency. Some of the dideoxynucleoside antiretrovirals produce neurotoxicity, and induce peripheral neurotoxicity (antiretroviral toxic neuropathy, ATN) which is indistinguishable from the neuropathy associated with HIV, distal sensory polyneuropathy (DSP) (Table 103.4). DSP is characterized by a length-dependent axonal degeneration of sensory fibres, with minimal evidence of nerve fibre regeneration. (Fig. 103.13, see colour plate section) Both large myelinated fibres and unmyelinated nerve fibres are lost, so DSP can therefore approximately be classified with conditions like diabetes and amyloidosis that have prominent small sensory fibre involvement. DSP conforms to the concept of a 'dying back' neuropathy (Cavanagh, 1964), with degeneration of the rostral gracile tract (Rance et al., 1998), the CNS counterpart of the peripheral degeneration. The degree of pain and 'positive' neuropathic symptoms are frequently out of proportion to the neuropathic signs, and to the degree of nerve fibre loss in the epidermis (Polydefkis et al., 2001) (Fig. 103.14, see colour plate section). This suggests that the neuropathic pain associated with HIV-SN and ATN derives from the spontaneous activity of uninjured C fibres after injury in neighbouring nerve fibres, an observation that has been made in rodent models of neuropathic pain (Wu et al., 2001). The overt neuropathological changes in DSP include inflammatory infiltrates of lymphocytes and activated macrophages, decreased numbers of DRG neurons and increased frequency of nodules of Nageotte (Nagano et al., 1996; Rizzuto et al., 1995; Shapshak et al., 1995; Pardo et al., 2001) (Fig. 103.15, see colour plate section). Although HIV infection of DRG neurons has been suggested using PCR in situ hybridization (Brannagan et al., 1997), it seems more likely that the virus is predominantly localized in perivascular inflammatory cells and the nodules of Nageotte (Yoshioka et al., 1994; Nagano et al., 1996). The most consistent pathology in the DRG, however, appears to be the activation of inflammatory mechanisms that indirectly leads to damage to DRG neurons (Kolson & Gonzalez-Scarano, 2001). The presence of proinflammatory cytokines including TNF-α, IFN-γ, IL-6, and other mediators including nitric oxide, have consistently been demonstrated in DRGs in AIDS. This aberrant inflammatory response probably plays a critical role in damaging or sensitizing DRG neurons, and axons, and subsequently affecting the inputs to central pain pathways. This aberrant inflammatory response might lead to the up-regulation of sodium channels within the dorsal root ganglia leading to neuronal hyperexcitability, as has been seen in animal models (Waxman, 1999). The loss of unmyelinated input into lamina II of the substantia gelatinosa might lead to ingrowth of Aβ fibres, and the aberrant processing of sensory inputs (Baba et al., 1999).

Very little is known about the pathology of ATN, although sural nerve biopsies obtained from patients with ATN have shown severe axonal destruction, prominent in unmyelinated fibres (Dalakas & Cupler, 1996; Lewis & Dalakas, 1995). Prominent mitochondrial abnormalities have been demonstrated in association with NRTIs (Chen et al., 1991). Other complications of NRTI therapy include ATN (with all dideoxynucleosides), pancreatitis (DDI, D4T), myositis (zidovudine) and macrocytosis, as well as metabolic abnormalities, and lipodystrophy. Some of these clinical manifestations resemble genetic mitochondrial diseases (Lewis & Dalakas, 1995) suggesting that the pathogenesis of many specific NRTI side effects may be related to drug-induced mitochondrial dysfunction. This theory is further supported by evidence of increased serum lactate level (Brew et al., 2001) and reduced serum levels of acetylcarnitine (Famularo et al., 1997) in patients with ATN. Further support for the potential role of mitochondrial dysfunction is derived from in vitro observations of a graded inhibition of gamma DNA polymerase by the different nucleoside reverse transcriptase inhibitors (Martin et al., 1994). Dideoxynucleosides are the most potent inhibitors of the enzyme in vitro; and zidovudine, lamivudine, and abacavir have only minimal effects. The effect of

NRTIs on mitochondria is manifest in vitro as a reduction in the copy numbers of mtDNA (Chen & Cheng, 1989; Chen et al., 1991) resulting in NRTI-associated metabolic abnormalities (Brinkman et al., 1998, 1999). The mechanism of dideoxynucleoside toxicity leading to sensory neuropathy has been hypothesized to involve a selective inhibition of mitochondrial gamma DNA polymerase. In vitro studies of neuron-like cultures have shown that the dideoxynucleosides inhibit neurite outgrowth in a dose-dependent manner (Cui et al., 1997).

Unfortunately, animal models of dideoxynucleoside toxicity have been disappointing, so that, for example, rats exposed to ddC at very high concentrations, even in doses up to 100 mg/kg intraperitoneally for several months, have not shown any evidence of epidermal nerve fibre degeneration (J.C. McArthur, unpublished data). This might be explained by differences in absorption, bioavailability, or species differences in the selectivity of gamma DNA polymerase to ddX agents. In human studies, assays are being refined to measure mitochondrial DNA levels in various tissues, including peripheral blood leukocytes, and subcutaneous fat (Gahan et al., 2001) to help understand the mechanisms of lipodystrophy and peripheral neuropathy.

In summary, the pathogenesis of the neuropathic pain in HIV-SN may be multifactorial. First, because of nutritional deficiencies, alcohol exposure, substance abuse or other nonspecific factors, a mild degree of distal axonal degeneration develops, resulting in the loss of axons in the distal sensory nerves. This damage may be magnified by cumulative exposure to NRTIs, and hepatitis C. As in other types of Wallerian-like degeneration, macrophages would then be recruited into the affected nerves. These macrophage responses to axonal degeneration are 'hyperactive' in HIV infection compared to other axonal neuropathies. Multifocal inflammation in the nerve and DRG leads to further loss of both large myelinated and unmyelinated fibres. The macrophage-dominated pathology of the PNS has obvious parallels to the microglia/macrophage activation characteristic of HIV-associated dementia (Wesselingh et al., 1993). The development of spontaneous activity in uninjured nociceptive fibres, changes in the patterns of expression of ion channels, and remodelling within the dorsal horn leads to persistent neuropathic pain.

Treatment of HIV-associated sensory neuropathies

At this stage, while the pathogenic mechanisms of HIV-SN are being explored, no specific therapy can be offered. For ATN, it is reasonable to discontinue the offending HAART regimen, provided that there is an alternative regimen to offer. Failing this, a patient may need to remain on the regimen with pain-modifying agents added. After discontinuation of a toxic dideoxynucleoside, symptomatic improvement can be expected in 3 months (Blum et al., 1996). A variety of pain-modifying agents have been used for HIV-SN, as for diabetic polyneuropathy, including tricyclic antidepressants, anticonvulsants, and narcotics. The results of placebo-controlled trials have demonstrated a modest benefit on neuropathic pain for amitriptyline (Kieburtz et al., 1998), and a larger effect for lamotrigine in two separate studies (Simpson et al., 2001). In severe neuropathies narcotic analgesics may be required. Transdermal fentanyl, long-acting morphine or oxycodone preparations, or methadone are particularly useful. Specific prescribing guidelines should be followed, particularly if there is a history of substance abuse. Further management details are provided in Pardo et al. (2001).

Regenerative strategies have been attempted by HIV-SN, utilizing recombinant human nerve growth factor, which has also been tested for diabetic polyneuropathy. The rationale is that nerve growth factor is trophic for small sensory neurons, and in both in vitro and in vivo models stimulates the regeneration of damaged nerve fibres (Apfel et al., 1998). In a study of 270 patients with HIV-SN, a modest effect on neuropathic pain and pin sensibility was demonstrated (McArthur et al., 2000). Unfortunately, the clinical development of nerve growth factor has been halted, and interest has now moved to the prosaposin and neurophilin classes of compounds.

HIV-associated polymyositis

Polymyositis is an uncommon complication of HIV-1 infection that is probably another autoimmune phenomenon. In the early years of the AIDS epidemic, when zidovudine was the only available antiretroviral agent, and it was used in higher doses than today, myotoxicity would develop frequently. Clinically, polymyositis presents with proximal weakness, elevated levels of serum CPK, and irritative changes on EMG. The pathology of HIV-associated polymyositis includes myofiber necrosis and inflammatory infiltrates, and is indistinguishable from polymyositis with HIV (Dalakas et al., 1990). Polymyositis sometimes responds to immunomodulatory agents such as corticosteroids or intravenous IgG.

CNS opportunistic infections in HIV/AIDS

Introduction

Infections in immunocompromised patients are generally with 'opportunistic' infections or 'reactivated' infections.

Opportunistic infections generally result from exposure to ubiquitous organisms which are normally of low pathogenicity, but cause an infection in immunocompromised hosts. Reactivated infections include organisms which may have caused a remote primary infection with few or no symptoms, which become reactivated in the setting of immune deficiency. Opportunistic infections and neoplasms of the CNS develop frequently in association with HIV infection, but usually do not develop until the CD4+ count is below 200, reflecting the underlying immunodeficiency. The immune restoration associated with HAART has produced significant reductions in the incidence rates of opportunistic infections (Brodt et al., 1997). Although highly active antiretroviral therapy often produces dramatic increases in CD4 counts, the circulating memory CD4 lymphocytes may still have only a limited repertoire of cellular responses.

There are some general differences between CNS OIs in AIDS and those occurring with other immunodeficiency states. First, HIV-infected patients may have multiple concurrent opportunistic processes, or opportunistic processes may coexist with HIV-related neurological disorders. Thus, the assessment of an immunosuppressed HIV+ may be more complex. Secondly, the immunodeficiency associated with HIV infection is usually progressive without antiretrovirals, with an annual loss of 50–100 CD4 cells/mm^3. Thus, after developing an OI an AIDS patient is usually at lifelong risk for developing other OIs or a recurrence. Lifelong maintenance therapy for secondary prophylaxis will generally be required, although with improvements in immune function with antiretrovival therapy this is now being debated. Thirdly, the OIs associated with HIV infection are somewhat predictable, and primary prophylactic regimens have been developed for many of the systemic and CNS OIs and are usually initiated when CD4 counts drop to 200/mm^3 or below. The success of these prophylactic regimens hinges on complete adherence with medications, and improving adherence has become a major focus of most HIV programs. Finally, the incidence of CNS OIs in AIDS has changed in recent years because of the introduction of potent antiretroviral regimens.

The most common CNS opportunistic processes are presented in Table 103.1. These and other common neurological opportunistic processes are discussed briefly below. The diagnosis of several of these processes has been facilitated in recent years with the introduction of sensitive PCR assays which can be performed on CSF. Brain biopsy may occasionally be necessary to differentiate lesions, but increasingly non-invasive techniques are used for diagnosis. Management strategies are beyond the scope of this article and readers are referred to other sources (Marra, 1999).

Cerebral toxoplasmosis

T. gondii is an obligate intracellular protozoan pathogen of humans and animals, which causes necrotic and inflammatory brain abscesses. Cerebral toxoplasmosis occurs in 5–10% of patients with AIDS, but the incidence has been declining because of the widespread use of timethoprim-sulfamethoxazole as prophylaxis against *P. carinii*. This agent is also an effective prophylactic for *T. gondii* (Brodt et al., 1997). Cerebral CNS toxoplasmosis is the result of reactivation of a latent infection, rather than a primary infection. In some areas, for example France, central or south America, or Florida, the prevalence of toxoplasmosis is significantly higher. This is because seroprevalence rates are much higher in these areas, around 70–80%, than in the UK (22%) or the north-eastern USA (25%). This wide variation in the prevalence of latent infection among different populations reflects differences in dietary and other sociocultural factors. Grant et al. (1990) estimated that the 3-year probability of developing CNS toxoplasmosis is 28% for HIV-infected patients also seropositive for antibodies to *Toxoplasma gondii*; thus primary prophylaxis is mandated for those with positive toxoplasma antibodies and CD4 $<$ 200. Contact with the oocyst or egg form generally occurs in childhood from exposure to the definitive host the cat in feces. Eating undercooked meat which contains the encysted forms can also transmit infection. After ingestion, sporozoites are released into the small intestine, penetrate the gut wall and are spread hematogenously. Tissue cysts, or bradyzoites form within the muscles, eyes and brain (see Fig. 103.16(*b*), see colour plate section), and can become activated if cellular immunity wanes, releasing the active form, the tachyzoite (Fig. 103.16(*c*), see colour plate section). The mechanisms by which the encysted forms of *T. gondii* are normally controlled are uncertain, but presumably depend principally on cellular rather than humoral immunity.

Reactivation within the brain produces multifocal abscesses, scattered throughout the cerebral hemispheres (Fig. 103.16(*a*), see colour plate section). Pathologically the encephalitis is a focal, necrotizing process with tissue cysts rupturing, releasing tachyzoites, and inducing inflammation. A typical clinical presentation is with development of fever, altered mentation, seizures, and focal neurological signs evolving over a few days. Imaging studies demonstrate multiple 'ring-enhancing' mass lesions (see Fig. 103.17); however, this radiological appearance is not specific for toxoplasmosis and can be mimicked by primary CNS lym-

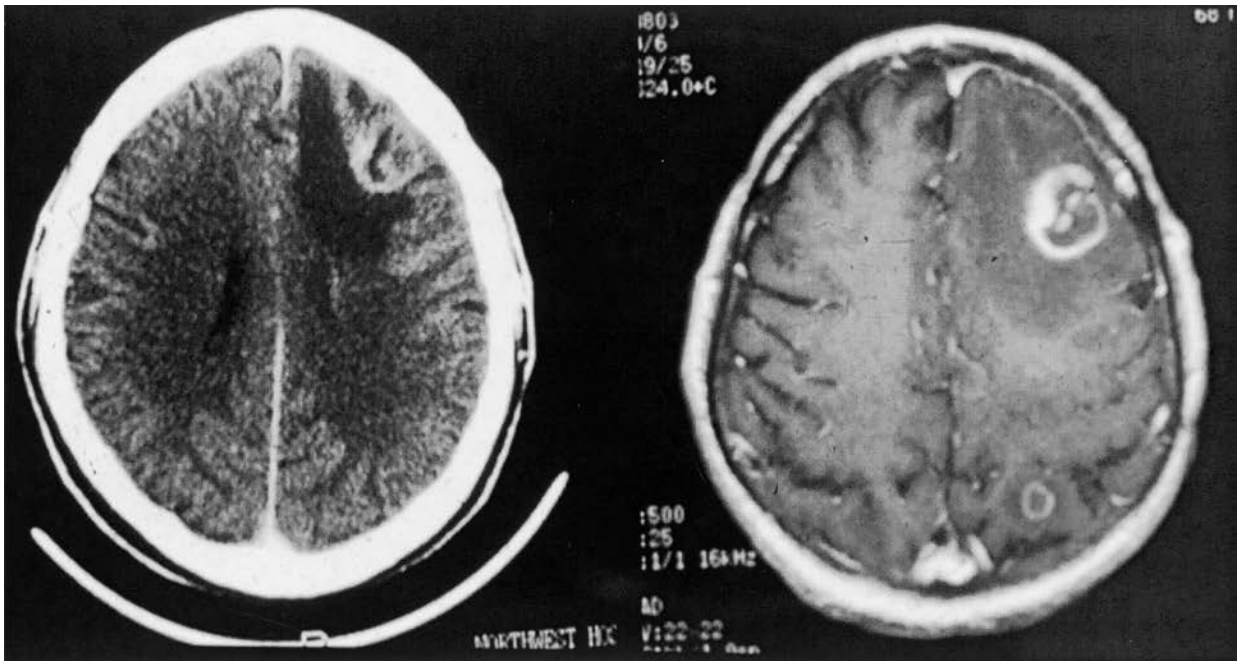

Fig. 103.17. CT scan (left panel) showing a single contrast-enhancing lesion in toxoplasmosis. Right panel: MRI from same patient showing multiple contrast-enhancing 'ring' abscesses, with surrounding edema.

phoma, or other causes of abscess, including tuberculomas or polymicrobial bacterial brain abscesses in injection drug users. Because this is a reactivated infection, most individuals will already be seropositive for *T. gondii* at the time of presentation; however, serological testing is not particularly helpful because of a high false-negative rate of 15% (Navia et al., 1986; Harrison & McArthur, 1995).

The prompt initiation of antimicrobial therapy with the combination of the dihydrofolate reductase inhibitor pyrimethamine, and sufadiazine, a dihydrofolate synthetase inhibitor leads to clinical and radiologic improvement in 90% of patients within 10 days (Porter & Sande, 1992; Katlama et al., 1996). Folinic acid is usually given to counteract the hematological toxicity of this combination. Treatment must be used for at least 6 weeks, and then doses reduced to provide secondary prophylaxis. In sulfa-allergic patients clindamycin can be substituted for sulfadiazine. Recrudescence occurs in 30%, usually because of incomplete adherence with secondary prophylaxis.

CNS tuberculosis

Mycobacterium tuberculosis is a non-motile bacillus, an obligate aerobic parasite, and humans serve as the only natural reservoir. *M. tuberculosis* is one of the most common opportunistic infections worldwide, with high rates of HIV and TB coinfection (De Cock et al., 1992). This frequent state of coinfection has led to a reversal in the previously declining rates of TB in the USA (Anon, 1988a). The degree of immunosuppression for CNS TB need not be as severe as for some of the other CNS OIs. For example, in one series (Dube et al., 1992), CD4 counts varied from 7 to 251/mm^3. The pathophysiology of CNS tuberculosis in HIV/AIDS is similar to that described before the AIDS epidemic. CNS infection begins with the inhalation of airborne infectious particles, usually from exposure to an active case of pulmonary TB. There is initially widespread hematogenous dissemination with trapping of organisms in the brain and meninges (Rich, 1946). It is usually a reactivation of latent disease (as discussed in Chapter 110), and tuberculosis of the meninges results from the rupture of small subependymal foci. A thick tuberculous exudate fills the subarachnoid space, and may impede CSF flow resulting in hydrocephalus or cranial nerve deficits. Parenchymal tuberculomas or, less commonly, tuberculous abscesses may develop. In the spine, a diffuse inflammatory arachnoiditis can develop with a similar pathology to the intracranial disease. Intramedullary tuberculomas can develop, but tuberculous osteomyelitis is more common, with epidural masses causing root and cord compression (see Chapter 110, Fig. 110.4). In contrast to bacterial spinal epidural abscess, tuberculous osteomyelitis usually results in

epidural masses anterior to the cord, producing localized or radicular pain, followed by weakness, bowel or bladder dysfunction, and eventually paralysis. With TB meningitis in HIV/AIDS, the clinical presentation of headache, altered mentation and fever does not differ from that seen in non-AIDS patients (Berenquer et al., 1992). In the late stages, seizures, coma and severe neurological deficits occur. Up to 66% of those with CNS TB will have pulmonary or extrapulmonary TB (Barnes et al., 1991). The diagnosis is usually made from positive skin tests, characteristic chest X-ray findings, and sputum smears. Cutaneous anergy is common in HIV/AIDS, so skin tests are less reliable. The typical CSF profile in TB meningitis is a high protein, and depressed glucose. A moderate pleocytosis is typical, with a mononuclear differential and up to 300 WBC/mm^3. Elevated adenosine deaminase or depressed chloride are not specific findings. CSF cultures may take several weeks to become positive, and the sensitivity of PCR is still unproven, with reported sensitivities of 83% (Kaneko et al., 1990). Treatment is with quadruple antituberculous therapy: isoniazid, pyrazinamide, ethambutol or rifampin for 2 months, followed by 4 months with two drugs (Anon, 1988b). Multidrug resistant TB has become a concern in many areas (Fischl et al., 1992), largely as a result of incomplete medication adherence.

Cryptococcosis

Cryptococcus neoformans, a ubiquitous encapsulated yeast, is the only encapsulated fungus. The thick polysaccharide capsule is composed of α-kinked D-mannopyranoside residues, and in the CNS may prevent an effective inflammatory reaction against the yeast. *C. neoformans* has been subdivided into various serotypes, and *C. neoformans* var. *neoformans* is most commonly the cause of cryptococcosis in HIV/AIDS. The organism is widely distributed in the environment and has been found in pigeon and other bird droppings and fruit. After inhalation, *C. neoformans* is ingested by alveolar macrophages, but the capsulate may render the fungus resistant to killing. With disturbance of cellular immunity, as in HIV/AIDS, the organism escapes from the lungs, spreads hematogenously, and can seed the prostate, skin and particularly the meninges. *C. neoformans* causes meningitis in about 5–10% of AIDS patients (Larsen et al., 1990), and in a significant proportion is the first recognized opportunistic infection. Incidence rates have dropped in the USA, both as a result of the widespread use of antifungals for treatment of oropharyngeal candidiasis and because of immune reconstitution following the introduction of HAART. Coincident antifungal use may decrease the hematogenous seeding of the meninges by *C. neoformans*. The most common presentation is with headache (82%), fever (75%), nausea and vomiting (46%), and altered mentation (24%) (Graybill, 1998). Papilledema, cranial nerve deficits and seizures are frequent. Meningismus occurs only in a minority of cases, presumably because the polysaccharide capsule does not elicit much inflammation. For the same reason, the cerebrospinal fluid (CSF) may have normal cellular and protein constituents in up to half (Dismukes, 1988). In severe cases, massive collections of cryptococcal yeast forms (termed cryptococcomas) accumulate within the basal ganglia, having spread centripetally along the Virchow–Robin spaces (see Fig. 103.18). Intracranial hypertension occurs frequently, and can lead to headache, visual blurring, sixth nerve palsies, other cranial nerve deficits and herniation (Denning et al., 1991). The development of intracranial hypertension suggests a very poor prognosis (Graybill et al., 2000), and other prognostic factors include very high titres of cryptococcal antigen, presence of altered mentation, CSF WBC <20/mm^3, and hyponatremia (Chuck & Sande, 1989). This constellation of symptoms can mimic bacterial meningitis, cerebral toxoplasmosis or occasionally, if protracted, HIV-D, however, fungal cultures are uniformly positive with detectable cryptococcal antigen in $>95\%$ (Kovacs et al., 1985). Antifungal therapy (with amphotericin B) is only of moderate efficacy in AIDS-associated cryptococcal meningitis, and is poorly tolerated because of side effects. While antifungals may suppress the infection initially and lead to clinical improvement, complete clearance rarely occurs. At best, current regimens achieve rates of CSF sterilization of about 60% after 2 weeks. Current recommendations are to treat with a combination of amphotericin B and 5-flucytosine for 2 weeks, followed by fluconazole 400 mg/day for 8 weeks, then 200 mg/day for life (Larsen et al., 1990; van der Horst et al., 1997). Lipsomal forms of amphotericin are now available, and although more expensive, can reduce nephrotoxicity (Leenders et al., 1997). Relapses are frequent even with lifelong suppressive treatment with fluconazole, and frequently follow poor adherence with secondary prophylaxis.

Cytomegalovirus encephalitis/retinitis

In the 1980s and early 1990s the DNA virus cytomegalovirus (CMV, a member of the Herpes family) was a common pathogen during the advanced stages of AIDS. CMV produces retinitis, encephalitis or infection of nerve roots (polyradiculitis) typically when the CD4+ count is <100 cells/mm^3. CMV-induced disease represents reactivation of latent cytomegalovirus infection, which is almost ubiquitous among homosexual men. The introduction of

potent antiretrovirals has reduced the incidence of CMV disease significantly in the USA. CMV frequently causes an opportunistic infection of the retina, producing painless visual loss in patients with profound immunodeficiency (Kupperman et al., 1993). Less commonly, CMV leads to an encephalitis, which usually presents more acutely than HIV-D, with acute encephalopathy, seizures, and detectable CMV DNA in CSF using PCR (Cinque et al., 1992; Holland et al., 1994). The third neurological complication is an infection of the lumbosacral nerve roots which presents as a subacute cauda equina syndrome (Miller et al., 1990; Eidelberg et al., 1986). In other immunodeficiency states, for example, after bone marrow transplantation, retinitis and polyradiculitis are very rare. Several antivirals are available to treat CMV neurological complications: ganciclovir, Foscarnet, cidofovir, and the recently introduced agent, valganciclovir, which is the only oral anti-CMV agent.

Progressive multifocal leukoencephalopathy (PML)

PML will develop as a complication in 2–4% of AIDS cases, and is a demyelinating CNS disorder caused by infection of oligodendrocytes and astrocytes following reactivation of JC virus, a member of the papovaviridae, which has at least four different genotypes (Agostini et al., 1997). Primary infection with this DNA virus, although usually clinically silent, is common in childhood and early adulthood, with 80–90% of the general population infected by middle adulthood (Elliot et al., 1997; Albrecht et al., 1997). Papoviridae remain latent within the bone marrow, kidney and circulating B lymphocytes, but not within the brain (Houff et al., 1988; Major et al., 1992; Berger et al., 1987). The reactivated papovavirus enters the brain, and infects glial cells, damaging the hemispheric white matter, and producing patchy foci of demyelination, which may become confluent (Fig. 103.19(*a*), see colour plate section). Giant atypical astrocytes and oligodendroglia with markedly enlarged nuclei are seen and inflammatory infiltrates may appear (Fig. 103.19(*b*), see colour plate section). Electron microscopy may reveal intranuclear papovavirions. PML appears to be more common with JCV type 2 (usually considered to be of African/Asian origin) (Elliot et al., 1997; Albrecht et al., 1997). Prior to the description of AIDS, PML was seen most frequently in patients with lymphoma, leukemia, or receiving immunosuppressive drugs for treatment of rheumatoid arthritis, sarcoidosis, or following organ transplantation. PML typically presents with the progressive, slow accumulation of focal or multifocal neurological deficits: aphasia, hemiparesis, or ataxia. Dementia, altered mentation and seizures are very unusual. Prior to the introduction of HAART, the median survival was 16 weeks. Diagnosis is usually made by recognition of a typical clinical course with characteristic imaging studies (see Fig. 103.19(*c*), see colour plate section), and a + PCR test in CSF for JCV PCR. The MRI appearance is characteristic, with discrete subcortical hyperintensities, usually non-enhancing. In contrast to HIV-D, PML lesions are usually hypodense on T_1-weighted images. Potent antiretroviral regimens may improve, or even reverse the course of PML, probably by improving immune function (Clifford et al., 1999). Other antivirals, including cytosine arabinoside, cidofovir, and alpha-interferon have been tried without any convincing effect on disease progression (Clifford, 2001; Geschwind et al., 2001).

Other opportunistic infections

It is beyond the scope of this chapter to cover the other opportunistic infections in depth. The reader is referred to sources such as Gendelman et al. (1998). Some of the other infections and neoplasms will be briefly discussed.

Syphilis

The spirochete *T. pallidum* can cause various neurological diseases during the lifetime of the untreated HIV-positive patient. In the USA, the rates of syphilis have begun to increase again since 1986, after five years of steady decline. Some US cities (including Baltimore) are in the midst of epidemics fuelled by the 'crack-for-sex' phenomenon. While not strictly an opportunistic infection, the course of syphilis may be accelerated by the disturbance in cellular immunity accompanying HIV-1 infection (Hook, 1989), and the time course from primary to tertiary syphilis shortened (Johns et al., 1987; Passo & Rosenblum, 1988). Common presentations in HIV-infected persons include syphilitic meningitis, ocular complications and meningovascular syphilis. In general, the interpretation of serological tests for syphilis is not affected by HIV infection, and treatment recommendations are similar to those for HIV-negative patients. However, the rate of recurrence or treatment failure in HIV-positive patients is around 30% even after intravenous regimens of ceftriaxone or penicillin (Marra et al., 1996, 2000).

Bacillary angiomatosis

This is an unusual vascular lesion, which may involve skin, bone, and even brain. The related angioproliferative lesion affecting the liver and spleen is termed bacillary peliosis. Both are associated with infection with a fastidious gram-negative bacilli caused by two species, *Bartonella henselae* or *B. Quintana*. Macrolide antibiotics are usually preventive and MAC prophylactic regimens which include a

macrolide may also provide simultaneous prophylaxis against Bartonella infection. Bacillary angiomatosis and Kaposi's sarcoma can be difficult to differentiate clinically and may require tissue biopsy. *B. henselae* infection usually causes peliosis hepatis and lymph node involvement, whereas *B. quintana* results in subcutaneous infection and lytic bone lesions. Cat scratch disease is associated only with *B. henselae* and over 40 000 cases are reported annually in the US.

Human herpes virus-8 (HHV-8)

Several investigators have shown that a herpesvirus-like agent (KSHV/HHV-8) has an etiologic role in the development of Kaposi's sarcoma and potentially in lymphomas, both in people with and without HIV infection (Chang & Moore, 1994, 1996; Moore & Chang, 1995). HHV-8 may produce malignancy by encoding for a gene with homology to the cytokine IL-6 which enhances B-cell survival and proliferation. After seeding of endothelial sites, HHV-8-infected monocytes may stimulate the local upregulation of cytokines. Interestingly, the anti-CMV agent ganciclovir may have a prophylactic effect against HHV-8. In a study comparing ganciclovir intraocular implants to systemic ganciclovir for patients with CMV retinitis, there was a 75% (for oral ganciclovir) – 93% (for intravenous) reduction in KS rates (Martin et al., 1999).

Primary CNS lymphoma (PCNSL)

Up to 3% of AIDS patients develop PCNSL, making AIDS the most common disease associated with this malignancy. It remains controversial whether the incidence of PCNSL is changing in the era of HAART. For example, the EUROSIDA study suggested a three-fold increase in the proportion of AIDS defining illnesses represented by non-Hodgkin's lymphoma (including both systemic and PCNSL) from 1994 to 1998, irrespective of CD4 count. This does not, however, necessarily mean that the absolute number of PCNSL cases has increased. By contrast, in the US Multicenter AIDS Cohort Study, the incidence rates of PCNSL were stable when adjusted for progressive immunosuppression within the cohort (Bacellar et al., 1994). In the last 3 years in observing 800 HIV-positive individuals, only four cases of PCNSL have been reported (L. Jacobson, personal observation).

In AIDS, PCNSL is almost always associated with EBV infection, however the mechanisms leading to the induction of the malignancy are unknown (MacMahon et al., 1991). The latent membrane protein 1 of EBV is now thought to play an important role in the malignant transformation of B-lymphocytes in immunosuppressed states including AIDS by mimicking members of the family of TNF-α receptors, and transmitting growth signals to the nucleus (Liebowitz, 1998). HHV-8 has been linked to some cases, however, this requires further study (Corboy et al., 1998). PCNSL is usually a high or intermediate grade malignancy, and either large cell immunoblastic or small cell non-cleaved B-cell type. Although clinically the tumour may present with a single large lesion, on pathological study it is almost always multicentric, with a perivascular location. About one-half of these B-cell-derived tumours are clinically silent and detected only at autopsy (Rosenblum et al., 1988). The tumours are of similar histological appearance to those observed in immunosuppressed renal allograft recipients. The majority of PCNSL cases occur when the CD4+ count is less than 50 cells/mm^3 (Levine et al., 1991), and a typical presentation is with slowly progressive neurological deterioration with headaches, focal neurological deficits, and mentation changes, leading to death within 1–2 months. Imaging studies in PCNSL show large contrast-enhancing mass lesions, however, these radiological features can overlap cerebral toxoplasmosis since the radiological appearance of both may be multicentric with edema surrounding contrast enhancing lesions. In general, toxoplasmosis lesions tend to be smaller and more numerous, with a simple 'ring-enhancing pattern' in contradistinction to a more complex heterogeneously enhancing PCNSL lesion (Dina, 1991). PNCSL can be differentiated from cerebral toxoplasmosis or bacterial brain abscesses by their uptake of the radioisotope thallium on SPECT scans (Fig. 103.20, see colour plate section). Both false-positive and false-negative scans can occur, depending on radiological expertise, size of the lesion, and particularly if the lesions are close to the base of the brain where the scalp and soft tissues can produce interference. Trypanosomiasis is a differential in S. America. CSF cytology is positive in $<$10% of cases, but assay of CSF EBV PCR has a sensitivity of about 60% (Cinque et al., 1993). The diagnosis may be made by stereotactic biopsy, or empirically on the basis of a failed toxoplasmosis therapy trial, and positive thallium scan and CSF EBV PCR. A patient with contrast-enhancing mass lesions, who has failed to respond to empiric antitoxoplasmosis therapy for 10 days, and who has positive CSF EBV DNA PCR and positive uptake on a thallium SPECT scan is highly likely to have PCNSL (Report of the Quality Standards Subcommittee of the American Academy of Neurology (1998)). In some centres, including our own, consideration of empirical radiation therapy without biopsy would be given, because of the high probability of PCNSL in this situation, and the relatively high morbidity of brain biopsy (7%) (Skolasky et al., 1999) in this population. The only proven treatment is cranial radiotherapy,

which can prolong survival and prevent further neurological progression. Whole brain radiation remains the standard therapy despite encouraging reports in small series of intrathecal chemotherapy (Chamberlain & Kormanik, 1999). Systemic chemotherapy prior to radiation therapy does not appear to improve survival based on a small pilot study of single cycle CHOP given prior to cranial radiation (Ambinder et al., 2001). In the era of HAART, patients with PCNSL can now survive for years after radiation, provided that they have an immunological response to antiretrovirals.

Metastatic systemic lymphoma

Most lymphomas are extranodal, diffuse high-grade malignant lymphomas of B-cell origin. Central nervous system involvement occurs in over 50% of patients with systemic lymphoma, and complications include cranial neuropathies, meningeal involvement, cerebral metastasis, and spinal cord compression.

Neurological manifestations of HTLV-I infection

Mitsuhiro Osame

Third Department of Internal Medicine, Kagoshima University Faculty of Medicine, Kagoshima, Japan

Human T-cell lymphotropic virus type I (HTLV-I) is the causative agent for adult T-cell leukemia (ATL). ATL was first proposed as a clinical entity in Japan (Takatsuki et al., 1976; Uchiyama et al., 1977). The association of this disease to a new human retrovirus, HTLV-I, was discovered by independent research groups in USA (Poiesz et al., 1980) and Japan (Miyoshi et al., 1980; Hinuma et al., 1981; Yoshida et al., 1982). This same virus was found to be related to another human disease, a progressive spastic paraparesis, independently in two areas of the world, the Caribbean basin and Japan. In Martinique, 59% of patients with tropical spastic paraparesis (TSP) had antibodies to HTLV-I (Gessain et al., 1985). In Japan, a high prevalence of primary lateral sclerosis or spinal spastic paraparesis was found in South Kyushu (Osame et al., 1975). A follow-up study of this disorder established the existence of a new disease associated with HTLV-I which was named as HTLV-I associated myelopathy (HAM) (Osame et al., 1986, 1987; Osame & Igata, 1989). The disease is now known under the acronym, HAM/TSP (World Health Organization, 1989; Osame et al., 1990a).

HTLV-I virus

HTLV-I is a type C retrovirus, subfamily Oncoviridae. In contrast to the human immunodeficiency virus (HIV), HTLV-I causes disease in only about 5% of infected people. HTLV-I is estimated to infect approximately ten million people worldwide. There are large endemic areas in southern Japan, Central and West Africa, the Caribbean and South America, and smaller foci in the aboriginal populations of Australia, Papua New Guinea and northern Japan. In Europe and North America the virus is found chiefly in immigrants from these endemic areas and in some communities of IV drug users. Within the endemic areas, the seroprevalence varies between 1% and 20%. The number of the patients with ATL and HAM/TSP is estimated to be more than 3000 and 5000, respectively.

There are three important modes of transmission: parental and neonatal infection from a seropositive mother, in which breastfeeding is a significant factor; sexual transmission, particularly from males to females; and transmission by infected blood, either by transfusion or by sharing of needles among drug users. Transmission of the virus depends on transfer of cells from infected people. Blood for transfusion is now routinely screened for HTLV-I in several countries, including Japan (Osame et al., 1990b), the USA and Brazil.

HTLV-I is known as a complex retrovirus: in addition to the three genes present in other typical replication-competent exogenous retroviruses (*gag*, *pol* and *env*), it encodes at least two further proteins: Tax, which stimulates transcription of the proviral genome, and Rex, which controls the splicing of HTLV-I mRNA.

Although it can infect a wide variety of cell types in vitro, HTLV-I appears to replicate efficiently only in CD4+ (helper) T-cells; these are the cells that are transformed in ATL. Antibodies against the Gag protein are the first to appear after infection, and they predominate in the first 2 months. Thereafter, anti-Envelope antibodies predominate, and about half of infected individuals subsequently produce antibodies to the Tax protein. Diagnosis of HTLV-I infection depends on the detection of specific antibodies by particle agglutination or ELISA assays, and confirmation by PCR or western blot assay.

Adult T-cell leukemia lymphoma

A person infected with HTLV-I has about a 5% lifetime risk of developing ATL.

The main features of ATL consist of: (i) age of onset from about 20 to 70 years, the mean age at onset of ATL being about 60 years in Japan, and 40 years in the Caribbean and Brazil: the reason for this difference being not known; (ii) lymphadenopathy and hepatosplenomegaly; (iii) skin lesions similar to mycosis fungoides, or Sezary syndrome; (iv) presence of proliferated T-cell lymphocytes with flower-like nuclei; (v) hypercalcemia; and (vi) poor prognosis with a mean survival of 10 months (Uchiyama et al., 1977). ATL clinically presents in four different ways: (i) acute ATL whose clinical manifestations are those listed above; (ii) chronic ATL; (iii) smouldering ATL; and (iv) lymphoma type ATL (Takatsuki et al., 1985).

Southern blot analysis indicates the presence of oligoclonal or monoclonal proliferation of CD4+ cells that carry the HTLV-I provirus in the cellular DNA.

The mean survival times (untreated) for acute, lymphomatous and chronic (smouldering) ATL in Japan are 6.2, 10.2 and 24.3 months, respectively. The disease often responds initially to standard chemotherapeutic regimes, but early relapse is common, and the disease typically becomes refractory to further chemotherapy after 2–6 months. Recently, significant progress has been made with the discovery that a combination of extensive chemotherapeutic regimes and bone marrow transplantation can lead some patients to complete remission.

More than half of ATL cases will have neurological complications during the course. These manifestations mainly consist of the following: (i) altered consciousness derived mainly from hypercalcemia; (ii) dementia; (iii) seizures; (iv) hemiparesis and pyramidal tract signs; (v) cranial nerve deficits; (vi) meningeal irritation; and (vii) polyneuropathy. Except for altered consciousness, these complications have been associated with direct tumour cell invasion in most of the cases (Tara et al., 1989).

HTLV-I associated myelopathy (HAM/TSP) and other inflammatory diseases associated with HTLV-I

HTLV-I has shown to be associated not only with HTLV-I associated myelopathy (HAM/TSP) but also with uveitis (Sasaki et al., 1989; Nakao & Ohba, 1993; Nakagawa et al., 1995; Mochizuki et al., 1996), T-lymphocyte alveolitis (Sugimoto et al., 1987; Vernant et al., 1988; Nakagawa et al., 1995), polymyositis (Higuchi et la., 1995, 1996), arthritis (Kitajima et al., 1989; Nishioka et al., 1989), and sicca syndrome (Vernant et al., 1988). There are also less certain associations with chronic infective dermatitis (LeGrande et al., 1990), Behçet disease (Kanazawa et al., 1993; Igakura et al., 1993), pseudohypoparathyroidism (Yoshida et al., 1993) and systemic lupus erythematosus (Takayanagui et al., 1997).

The prevalence of HAM/TSP is between 0.1 and 2% of HTLV-I-infected individuals. The lifetime risk of developing this disease among carriers is estimated to be 0.23% in Japan (Kaplan et al., 1990). About two-thirds of patients are female (Nakagawa et al., 1995). Other known risk factors for HAM/TSP include a high proviral load of HTLV-I (Nagai et al., 1998) and a certain HTLV-I subgroup (Furukawa et al., 2000). Most people infected with HTLV-I mount a strong cytotoxic T-lymphocyte (CTL) response to the virus (Jacobson et al., 1990; Bangham, 2000). This strong CTL response protects against the development of HAM/TSP by reducing the proviral load (Jeffery et al., 1999). However when the proviral load exceeds a threshold level, HTLV-I-specific CTL could contribute to inflammation (Nagai et al., 1998; Jeffery et al., 1999). The immunological response to HTLV-I is now beginning to be clarified (Bangham, 2000).

Clinical features of HAM/TSP

HAM/TSP is characterized by a spastic paraparesis that is slowly progressive, or in some cases static after initial progression, and anti-HTLV-I antibody positivity in serum and cerebrospinal fluid (Osame et al., 1986, 1987). Almost all patients show spasticity and/or hyperreflexia of the lower extremities, initially presenting as gait and urinary disturbances. Many patients manifest with low back pain, weakness of the lower extremities and a poorly defined (mild) sensory involvement. Rarely, the disease presents as cerebellar ataxia. Patients with younger age of onset (<15 years old) tend to have short stature and slow progression of the disease, while patients with older age of onset (>61 years old) show faster progression regardless of the mode of transmission (Nakagawa et al., 1995).

The clinical and laboratory guidelines for the diagnosis of HAM/TSP are summarized in Table 104.1, based on the recommendation of the WHO meeting (World Health Organization, 1989; Osame, 1990).

Patients with HAM/TSP have high antibody titres to HTLV-I both in serum and CSF (Osame et al., 1990). The presence of antibodies can be detected by ELISA or particle agglutination method and confirmed by Western blot (Osame et al., 1987) or PCR. Aside from HTLV-I antibody positivity, other characteristic laboratory findings include lymphocytic pleocytosis in the CSF and increased CSF neopterin levels (Nomoto et al., 1991, Nakagawa et al., 1995). In MRI, hyperintensities T_2-weighted are observed

Table 104.1. Diagnostic Guidelines for HAM/TSP

I Criteria

The florid picture of chronic spastic paraparesis is not always seen when the patient first presents. A single symptom or physical sign may be the only evidence of early HAM/TSP.

A *Age and sex incidence*

Mostly sporadic and adult but sometimes familial, occasionally seen in childhood; females predominant.

B *Onset*

This is usually insidious, but may be sudden.

C *Main neurological manifestations*

1 Chronic spastic paraparesis which usually progresses slowly, sometimes remains static after initial progression.
2 Weakness of the lower limbs, more marked proximally.
3 Bladder disturbance usually an early feature, and constipation usually occurs later, and impotence or decreased libido is common.
4 Sensory symptoms such as tingling, pins and needles, burning, etc. are more prominent than objective physical signs.
5 Low lumbar pain with radiation to the legs is common.
6 Vibration sense is frequently impaired, proprioception less often affected.
7 Hypeneflexia of the lower limbs, often with clonus and Babinski's sign.
8 Hyper-reflexia of upper limbs, and positive Hoffmann's and Tromner signs frequent. Weakness may be absent.
9 Exaggerated jaw jerk in some patients.

D *Less frequent neurological findings*

Cerebellar signs; optic atrophy; deafness, nystagmus, other cranial nerve deficits; hand tremor; absent or depressed ankle jerk. Convulsions, cognitive impairment, dementia or impaired consciousness are rare.

E *Other neurological manifestations which may be associated with HAM/TSP*

Muscular atrophy; fasciculations (rare); polymyositis; peripheral neuropathy; polyradiculopathy; cranial neuropathy; meningitis; encephalopathy.

F *Systemic non-neurological manifestations which may be associated with HAM/TSP*

Pulmonary alveolitis; uveitis; Sjögren's syndrome; arthropathy; vasculitis; ichthyosis; cryoglobulinemia; monoclonal gammopathy; adult T-cell leukemia/lymphoma.

II Laboratory diagnosis

A Presence of HTLV-I antibodies or antigens in blood and cerebrospinal fluid (CSF).
B CSF may show mild lymphocyte pleocytosis.
C Lobulated lymphocyte may be present in blood and/or CSF.
D Mild to moderate increase of protein may be present in CSF.
E Viral isolation possible from blood and/or CSF.

in the white matter similar to those found in multiple sclerosis (Newton et al., 1987; Kira et al., 1998; Furukawa et al., 1989). Swelling or atrophy of the spinal cord has been reported in few cases of HAM/TSP (Tashiro et al., 1989).

Histopathologic features of HAM/TSP

Autopsied cases mostly reveal severe involvement of the thoracic spinal cord. Histopathologic features include mononuclear cell infiltration, marked myelin and axonal destruction and astrocytic gliosis. Lesion distribution suggests that a chronic inflammatory process starts in the mid to low thoracic cord levels and extends both rostrally and caudally. Meningeal thickening involving the arachnoid has been seen with some cell infiltration. A non-random distribution of affected regions was suggested by an autopsy study which showed that the mainly affected regions are the so-called 'watershed' zones of the thoracic spinal cord in patients with HAM/TSP (Izumo et al., 1992). Inflammatory changes are inversely correlated with the duration of the disease, and significant cellular inflammation with expression of inflammatory cytokines and major histocompatibility complexes (MHC) (class I and II) is observed in cases of short duration (Umehara et al., 1993, 1994a). In presumably early lesions, the axons are relatively preserved. A predominance of CD8+ cells has been observed in cases of longer disease duration (Umehara et al., 1993). Both HTLV-I proviral DNA and HTLV-I tax gene expression were observed only in the CD4+ infiltrating

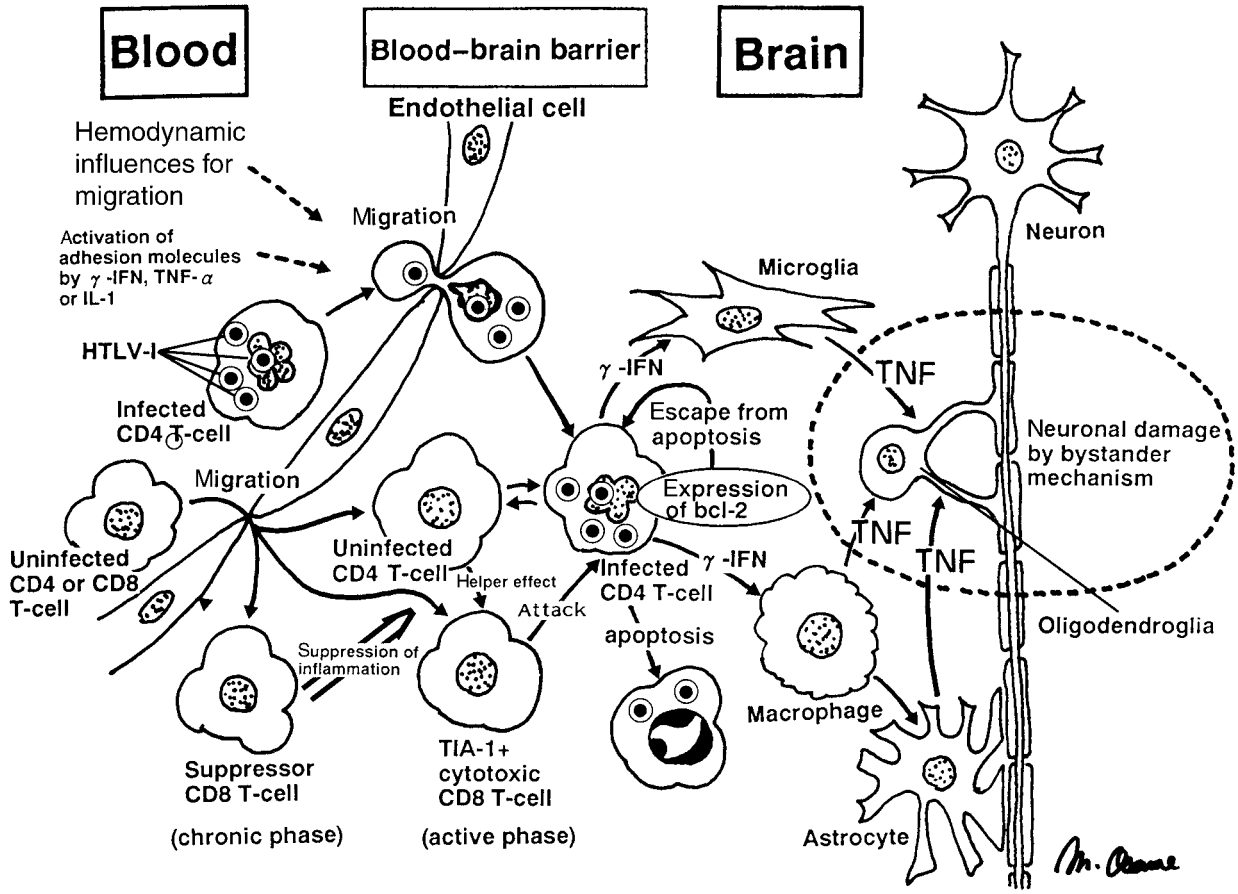

Fig. 104.1. Proposed pathogenesis of HAM/TSP based on currently available information.

mononuclear cells and not in other tissue cells in the spinal cord lesions (Moritoyo et al., 1996; Matsuoka et al., 1998). Activity of inflammation corresponded well with the amount of HTLV-I proviral DNA in situ, and responded with the presence of apoptosis of CD4+ T cells (Umehara et al., 1994b). The spinal cord lesions had greater expression of the adhesion marker, VCAM-1 on the endothelium compared with those of controls (Umehara et al., 1996). In the brain, perivascular mononuclear cell infiltration was also seen, but parenchymal infiltration was very sparse and was not associated with tissue destruction (Aye et al., 2000). The proposed pathomechanism of HAM/TSP is shown in Fig. 104.1.

Treatment of HAM/TSP

There is no definitive treatment yet established for HAM/TSP. Several clinical trials have shown transient beneficial effects of the following: corticosteroids, alpha-interferon, azathioprine, high-dose vitamin C, pentoxifylline, danazol, and plasmapheresis (Nakagawa et al., 1996). A double blind, multi-centre study on the therapeutic effect of treatment with natural interferon-α showed a significant treatment effect (Izumo et al., 1996). There is recent evidence that treatment with the nucleoside analogue lamivudine can reduce the provirus load of HTLV-I (Taylor et al., 1999), but the clinical impact of such treatment is not yet known.

Clinical features of human prion diseases

Robert G. Will

National CJD Surveillance Unit, Western General Hospital, Edinburgh, UK

Introduction

Human prion diseases are rare disorders affecting the central nervous system, characterized by protracted incubation periods, progressive and eventually fatal neurological deficits and the deposition in the brain of prion protein (PrP) (Prusiner, 1994). Scientific interest in this group of diseases has been stimulated by the accumulating evidence in support of the prion hypothesis, which proposes that the transmissible causal agent is a post-translationally modified 'infectious' form of a normal host-encoded protein, PrP (Prusiner, 1982) (Chapter 6). There has also been an extraordinary level of public interest in prion diseases following the occurrence of bovine spongiform encephalopathy (BSE) and the proposition that this cattle disease has been transmitted to humans to cause a novel human prion disease, variant Creutzfeldt–Jakob disease (vCJD) (Will et al., 1996).

Although human prion diseases are rare, concern about the possibility of such a diagnosis is not uncommon, particularly after the extensive media coverage of the potential risks of BSE to public health. This chapter describes the clinical features and diagnosis of human prion diseases.

Classification of human prion diseases

Table 105.1 lists the different forms of human prion disease, which are classified according to etiology and distribution. Genetic forms of human prion diseases are associated with mutations of the prion protein gene (*PRNP*) which is located on chromosome 20 in humans (Gambetti et al., 1999). Codon 129 of *PRNP* is a polymorphic region, expressing either methionine or valine, and variations in genotype can influence susceptibility to disease and/or clinicopathological phenotype in all human prion diseases (Table 105.2).

Kuru

Kuru was transmitted from person to person through the consumption of infected tissues during cannibalistic rituals (Gajdusek, 1981). Women and children were most often affected, because they consumed the tissues such as brain, which contained the highest levels of infectivity (Alpers, 1979). The incidence of kuru has declined since the cessation of cannibalism in the late 1950s, but cases are still occurring with incubation periods exceeding 40 years (Klitzman et al., 1984).

In kuru homozygosity at codon 129 of *PRNP* is associated with an earlier age at onset and possibly a shorter incubation period than heterozygotes (Cervenakova et al., 1998). The codon 129 genotype does not have a major influence on the clinical features, but can influence the pathology with plaque deposition being more frequent with a methionine allele.

Sporadic CJD

This is the most common form of human prion diseases, accounting for about 90% of cases, and occurs worldwide with an incidence of approximately one case per million per annum (Will et al., 1998). Studies of the geographical distribution of cases within individual countries suggest a random distribution with no good evidence of clustering to suggest a point source of infection (Cousens et al., 1997). Case control studies have not identified any common environmental or medical risk factor for the development of disease (Wientjens et al., 1996) and the cause of sporadic CJD is unknown. It may be due to the spontaneous development of the disease-associated form of PrP within the brain with subsequent self-replication and eventual disease.

Over 70% of cases of sporadic CJD are methionine homozygous at codon 129 of *PRNP* in comparison to about 40% of the general population with this genotype

Table 105.1. Human prion diseases

Disease	Distribution	Etiology
Creutzfeldt–Jakob disease	Worldwide	Sporadic
Familial Creutzfeldt–Jakob disease	Many countries	Genetic
Gerstmann–Straussler–Scheinker syndrome	Many countries	
Fatal familial insomnia	Many countries	
Kuru	Papua New Guinea	Transmitted
Iatrogenic Creutzfeldt–Jakob disease	Many countries	
Variant Creutzfeldt–Jakob disease	UK (112 cases)	
	France (4 cases)	
	Republic of Ireland (1 case)	

Table 105.2. The codon 129 *PRNP* genotype distribution in the normal population and in human prion diseases (percentages)

	MM	MV	VW
Normal white population	39	50	11
Sporadic CJD	71	13	16
Kuru	30	45	25
Iatrogenic CJD			
central route	74	20	6
peripheral route	47	21	32
Variant CJD	100	0	0

(Alperovitch et al., 1999). Overall, in sporadic CJD the duration of illness is shorter and the age at death younger in methionine homozygotes, but the influence of *PRNP* codon 129 genotype on disease phenotype is complex (see below).

Familial prion disease

Familial forms of human prion disease account for about 10% of all cases and all are associated with mutations of PRNP (Gambetti et al., 1999). The majority are classified as familial CJD and are linked to point or insertional mutations in the open reading frame of *PRNP*. Gerstmann–Straussler–Scheinker syndrome (GSS) was originally associated with a point mutation at codon 102 of *PRNP* (Hsiao et al., 1989), but other mutations result in a similar phenotype. Fatal familial insomnia (FFI) is associated with a mutation at codon 178 of *PRNP* (Medori et al., 1992) and the importance of codon 129 in modulating expression of disease is underlined by the phenotypic variability with mutations at this locus. Cases expressing methionine in association with the 178 mutation develop FFI, while those expressing valine have a phenotype similar to sporadic CJD (Goldfarb et al., 1992).

Iatrogenic CJD

CJD has been transmitted accidentally from person to person in the course of a range of medical or surgical treatments (Brown et al., 2000) (Table 105.3). All these iatrogenic transmissions have involved potential transfer from patient to patient of the high levels of infectivity found in the central nervous system in prion diseases. Human growth hormone (HgH) and gonadotrophin were extracted from cadaveric human pituitary glands and the eye is known to contain significant levels of infectivity in prion diseases. Accidental transmission of CJD through blood or blood products has not been documented (Wilson et al., 2000) and guidelines have been introduced to minimize the risks of iatrogenic transmission, for example the recommendation that all neurosurgical or ophthalmological instruments should be destroyed after use in patients with CJD.

The incubation period in sporadic CJD is unknown, but in iatrogenic CJD the incubation periods can be estimated. With a central route of infection into or adjacent to the brain the incubation period is 1.5 to 6 years, while with the peripheral route, as in HgH injections, the incubation period mean is about 12 years with a range of 4.5 to over 30 years.

Homozygosity at codon 129 of *PRNP* predisposes to iatrogenic CJD, with an excess of methionine homozygotes in dura mater related cases and an excess of valine homozygotes in HgH recipients with CJD (Brown et al., 2000). There is little evidence that codon 129 genotype influences disease expression in iatrogenic CJD, but heterozygosity

Table 105.3. Summary of iatrogenic cases of CJD from all causes

Mode of infection	Number of patients	Agent of entry into brain	Medical incubation period (range)[a]	Clinical signs on presentation[b]
Corneal transplant[b]	3	Optic nerve	16, 18, 320 mos	Dementia/cerebellar
Stereotactic EEG	2	Intra-cerebral	16, 20 mos	Dementia/cerebellar
Neurosurgery	5	Intra-cerebral	17 mos (12–28)	Visual/dementia/cerebellar
Dura mater graft	114	Cerebral surface[c]	6 yrs (1.5–18)	Cerebellar (visual/dementia)
Growth hormone	139	Hematogenous (?)	12 yrs (5–30)	Cerebellar
Gonadotrophin	4	Hematogenous (?)	13 yrs (12–16)	Cerebellar

Notes:

[a] Calculated from the mid-point of treatment to the onset of disease.

[b] One definite, one probable, and one possible case.

[c] In two cases, dura was used to embolize vessels of non-CNS tissues, rather than as intracranial grafts.

may prolong the incubation period in HgH-related CJD (Deslys et al., 1996).

Variant CJD

This novel form of human prion disease was identified in the UK in 1996 (Will et al., 1996) and it was proposed that this human disease might be caused by BSE. Since 1996 there have been 112 cases of vCJD in the UK, 4 in France and 1 in Ireland, consistent with the relative sizes of the BSE epidemics in these countries. The clinical and pathological features of vCJD have not been identified in any historical case of CJD, and laboratory transmission studies have demonstrated that the characteristics of the transmissable agent in vCJD are very similar to the BSE agent (Bruce et al., 1997; Hill et al., 1997a; Scott et al., 1999). There is now compelling evidence that BSE is the cause of vCJD, and it is thought that the most likely mechanism of transmission was through human consumption of bovine CNS tissues containing high levels of infectivity (Will, 1999). The future number of vCJD cases cannot be predicted.

All tested cases of vCJD have been methionine homozygous at codon 129 of *PRNP*. However, cases of human BSE infection in association with other codon 129 genotypes could occur in the future, perhaps with a different clinical or pathological phenotype.

Clinical features of human prion diseases

Kuru

There is a prodrome of headache and limb pains followed by a progressive cerebellar syndrome involving midline trunkal ataxia, tremor and titubation (Alpers, 1987). Dysarthria and gait ataxia develop as the illness progresses and, although terminally there is severe neurological disability, myoclonus does not occur and dementia is conspicuous by its absence. Even in the terminal moribund, akinetic and mute state, most patients can attempt to carry out simple commands. In juveniles the overall clinical picture is similar to adults, although brain stem signs are common, including nystagmus, strabismus, facial weakness and ptosis.

The total duration of illness ranges from 12–18 months in adults and 3–12 months in children.

Sporadic CJD

The characteristic clinical features of sporadic CJD are rapidly progressive dementia, myoclonus and death within a few months (Will & Matthews, 1984). These features are associated with a range of focal cortical deficits, which accumulate rapidly and lead to severe neurological disability. The mean duration of illness in sporadic CJD is only about 4 months, although there is a wide range with about 10% of cases surviving for over a year and 5% over 2 years (Fig. 105.1). Sporadic CJD is mainly a disease of late middle age with a mean age at death of about 65 years (Fig. 105.2).

The presenting symptoms (Table 105.4) of sporadic CJD vary with dementia, ataxia and behavioural disturbance occurring most frequently. Rare presentations include a pure cerebellar syndrome (The Brownell–Oppenheimer variant), cortical blindness with visual hallucinations (the Heidenhain variant) and a stroke-like onset (McNaughton & Will, 1997). One striking feature of sporadic CJD is the relentless multifocal progression in

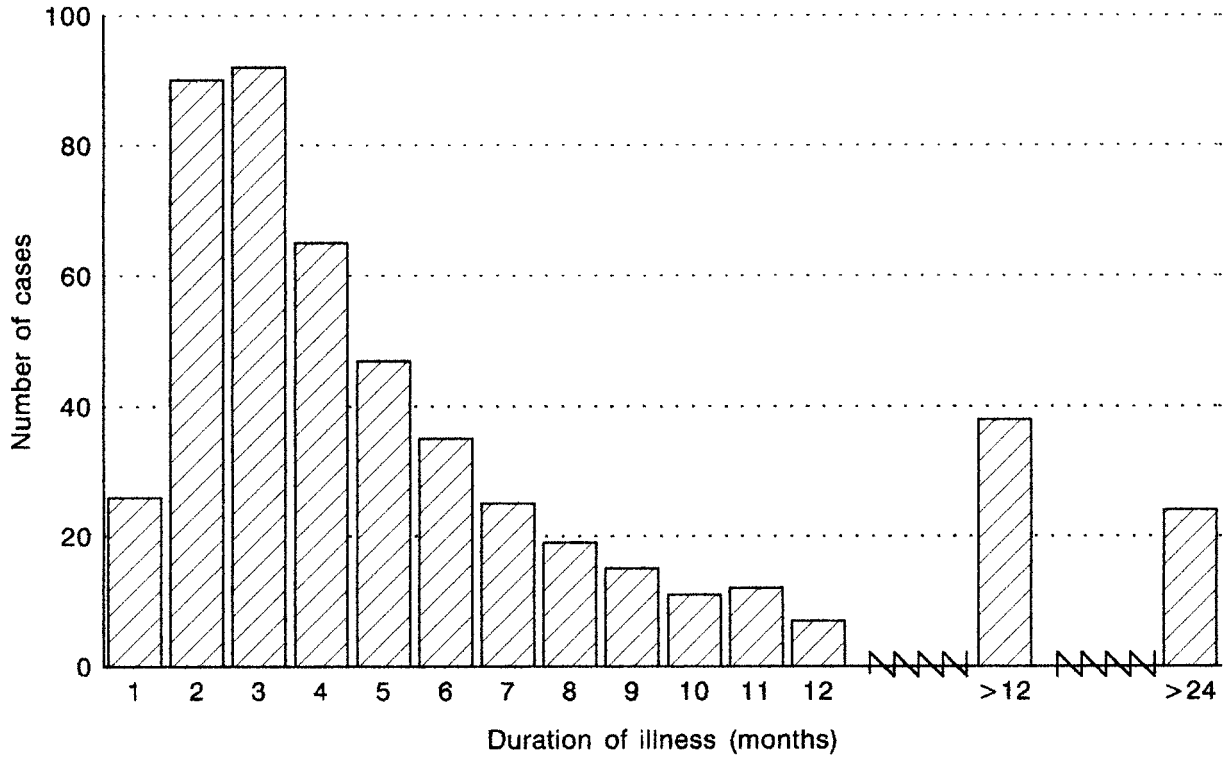

Fig. 105.1. Sporadic Creutzfeld–Jacob disease UK Study 1 May 1990–November 2001 ($n = 506$). Duration of illness (months).

neurological deficits. Patients with initial ataxia may develop dementia, myoclonus and rigidity, while patients with initial dementia may develop ataxia, cortical blindness and dysphasia. There may be great variation in the symptoms during the illness, but the rapid evolution of deficits involving multiple cortical areas is typical of sporadic CJD.

The signs in sporadic CJD (Table 105.4) parallel the variation in clinical symptomatology. The most frequent initial signs are cognitive impairment or ataxia, but as the illness evolves a range of neurological signs may develop, including myoclonic involuntary movements of the limbs and/or trunk in about 80% of cases (Brown et al., 1994). All patients develop dementia and the majority ataxia and paratonic rigidity of the limbs. Other signs include dysphasia, cortical blindness and primitive reflexes. Lower motor neuron signs are rare. Terminally most patients develop akinetic mutism and death is often due to intercurrent infection such as pneumonia.

The clinical presentation in sporadic CJD is relatively stereotyped, but there are atypical cases with a long duration of illness (Brown et al., 1984) or with a relatively young age at onset of symptoms. Western blot analysis has led to the identification of two types of PrP that can be deposited in the brain in sporadic CJD (Parchi et al., 1996) and this, combined with the codon 129 genotype, has led to the identification of 6 subgroups of sporadic CJD with largely different phenotypes (Parchi et al., 1999) (Table 105.5). The majority of cases are MM or MV type 1 and have a phenotype typical of sporadic CJD. The other subtypes represent the atypical forms of sporadic CJD, for example VV type 1 cases which have a prolonged clinical illness and a young age at death.

Familial prion disease

The clinical features in familial forms of human prion disease vary overall according to the underlying mutation of *PRNP* (Table 105.6), but there are inconsistencies in phenotype both between and within families (Gambetti et al., 1999). As a group the mean age at death is about 10 years less in hereditary cases compared to sporadic cases and the clinical illness is often more protracted and can extend to many years.

Worldwide, the codon 200 mutation is the most frequently identified and is associated with a clinical picture

Table 105.4. Symptoms at presentation and signs during clinical course in sporadic CJD (percentage of cases)

Symptom	Percentage	Sign	Percentage
Unsteadiness	30	Dementia	100
Forgetfulness	29	Myoclonus	82
Behavioural change	23	Cerebellar	64
Visual	14	Pyramidal	62
Dizziness	11	Dysphasia	60
Headache	8	Akinetic mutism	57
Speech disturbance	5	Primitive reflexes	44
Sensory	4	Cortical blindness	32
Involuntary movements	3	Lower motor neuron	11

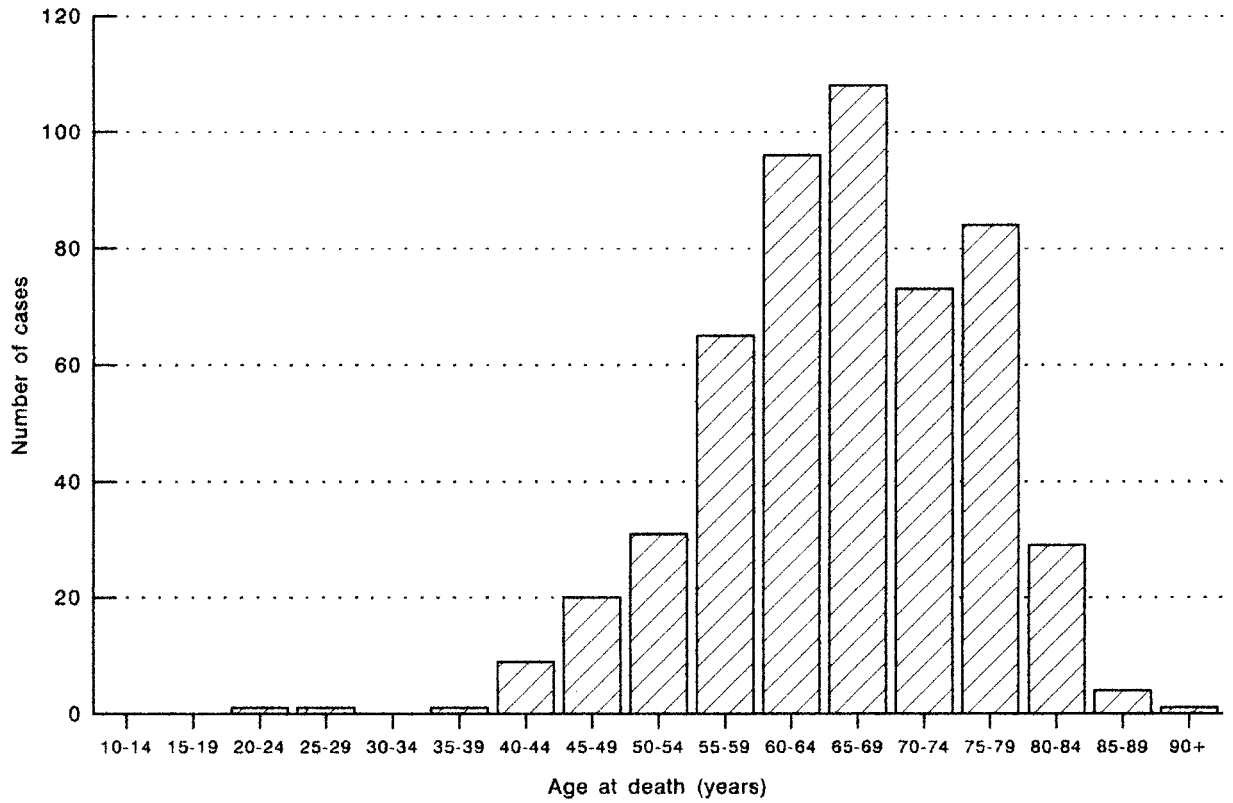

Fig. 105.2. Age at death in sporadic CJD UK Study 1 May 1990–November 2001 ($n = 523$).

that is very similar to sporadic CJD (Brown et al., 1991a). Other mutations with a similar phenotype to sporadic CJD are listed in Table 105.6 and include the codon 178 mutation in association with valine at codon 129 of *PRNP*. GSS is characterized clinically by slowly progressive ataxia with pyramidal signs and cognitive impairment later in the clinical course (Brown et al., 1991b). The clinical features in insert mutations are variable with some cases similar to sporadic CJD and others to GSS. The codon 178 mutation associated with methionine at codon 129 of *PRNP* causes the FFI phenotype with early insomnia and dysautonomia followed only later by cognitive impairment and sometimes other features reminiscent of sporadic CJD (Gambetti et al., 1993).

Table 105.5. Variants of sporadic CJD classified by codon 129 genotype and prion protein isotype[a]

Sporadic CJD Variant	Percentage of cases	Clinical features	Neuropathological features
MM1 or MV1	70	Rapidly progressive dementia Myoclonus Typical EEG	Classic sporadic CJD pathology
VV2	16	Ataxia at onset Late dementia EEG often not typical	Subcortical involvement including brain stem PrP staining shows plaque-like focal deposits
MV2	9	Ataxia and progressive dementia EEG not typical Long duration	Similar to VV2 but with amyloid-kuru plaques in the cerebellum
MM2 – thalamic	2	Insomnia, ataxia and cognitive impairment EEG not typical	Prominent atrophy of the thalamus and inferior olive Little spongiosis PrP detected in lower amount than in other subtypes
MM2 – cortical	2	Progressive dementia EEG not typical Long duration	Large confluent vacuoles with perivacuolar PrP staining Cerebellum relatively spared
VV1	1	Young age at onset (mean 40 yrs) Progressive dementia EEG not typical Long duration	Severe pathology in the cerebral cortex and striatum Sparing of brain stem and cerebellum

Notes:
[a] adapted from Parchi et al. (1999).

Table 105.6. Mutations of the prion protein gene

Mutation	Description	Typical clinical features
178M	Fatal familial insomnia	Insomnia, dysautonomia, late dementia
102	GSS	Slowly progressive cerebellar syndrome, late dementia
105	GSS	Spastic paraparesis, late dementia
117	GSS	Dementia, Parkinsonism
198	GSS	like GSS with 102 mutation
212	GSS	like GSS with 102 mutation
217	GSS	like GSS with 102 mutation
178V	Familial CJD	Like sporadic CJD
145	Familial CJD	Slowly progressive dementia
180	Familial CJD	Like sporadic CJD
200	Familial CJD	Like sporadic CJD
208	Familial CJD	Like sporadic CJD
210	Familial CJD	Like sporadic CJD
232	Familial CJD	Like sporadic CJD
Insert	Familial CJD	Mixed – usually like sporadic CJD but can be similar to GSS

Iatrogenic CJD

In iatrogenic CJD the clinical phenotype is determined by the route of infection (Brown et al., 1992). With introduction of infection in, or adjacent to, the central nervous system, the clinical picture is similar to sporadic CJD. With infection by a peripheral route, as in HgH recipients, there is a progressive cerebellar syndrome, without myoclonus, and cognitive impairment does not develop until late in the clinical course, if at all. The mean duration of illness also varies, with survival of approximately 2–12 months with central infection and 8–18 months following infection by a peripheral route.

Variant CJD

The clinical features of vCJD are remarkably consistent in comparison to the variation seen in other human prion diseases and are also relatively distinct (Zeidler et al., 1997). The mean duration of illness in vCJD of about 14 months is significantly more prolonged than sporadic CJD (Fig. 105.3), and vCJD affects a younger age group with a mean age at death of 29 years (Fig. 105.4).

In vCJD there is an initial phase, lasting for months, in which there are psychiatric symptoms including

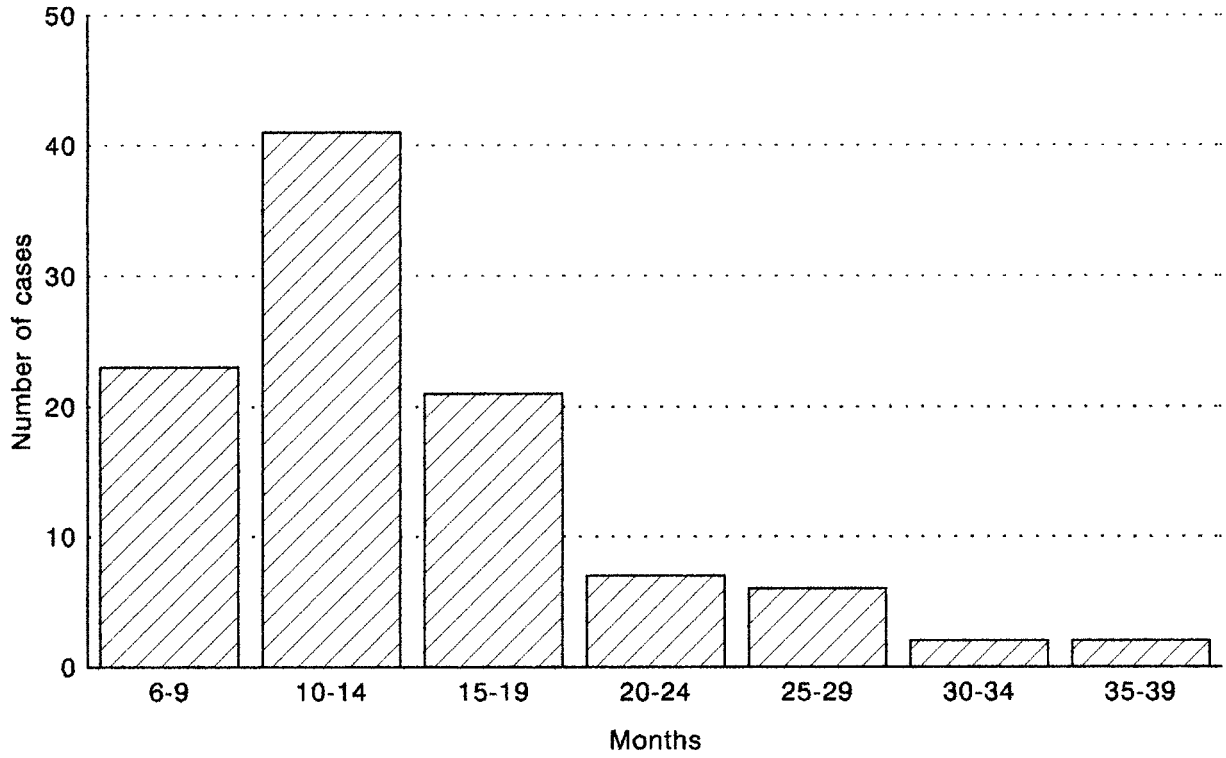

Fig. 105.3. Definite or probable vCJD UK Study 1995–November 2001 ($n = 102$). Duration of illness (months).

depression, anxiety and withdrawal, which may be impossible to differentiate from conventional psychiatric illness (Will et al., 1999). During this period some patients develop painful sensory disturbance in the limbs, trunk or face and some describe unsteadiness of gait or forgetfulness. After about 6 months, ataxia of gait develops, sometimes with associated dysarthria, and there is progressive cognitive impairment. Involuntary movements develop and may include chorea and dystonia as well as myoclonus (Will et al., 2000). Terminally the illness is similar to sporadic CJD, with a proportion of cases developing akinetic mutism. Death often follows intercurrent infection such as pneumonia.

Diagnosis of human prion diseases

In the absence of any serological test for infection, the diagnosis of all forms of human prion disease depends on recognition of the clinical features and applying a range of investigations to provide support for the diagnosis and to exclude other conditions. A definite diagnosis requires neuropathological validation, usually after postmortem. Diagnostic criteria for sporadic, iatrogenic, familial and variant CJD have been proposed and partially validated (Tables 105.7 and 105.8). Cases fulfilling criteria for 'probable' sporadic or vCJD are very likely to be suffering from the disease.

- The diagnosis of sporadic CJD is usually suspected because of the suggestive combination of rapidly progressive dementia, focal neurological deficits and myoclonus. The electroencephalogram (EEG) and the cerebrospinal fluid (CSF) 14-3-3 immunoassay are the most helpful investigations.
- Familial forms of human prion disease may be suspected because of a family history of a similar disorder. However, a positive family history of CJD is found in only about a third of mutation-related cases and about a further third have a family history of other neurodegenerative disease. *PRNP* gene analysis is necessary to confirm the presence of a mutation.
- The possibility of iatrogenic CJD may be raised by the development of a progressive neurological disorder in an individual with a recognized risk factor.
- The diagnosis of vCJD depends on the recognition of suggestive neurological features such as depression,

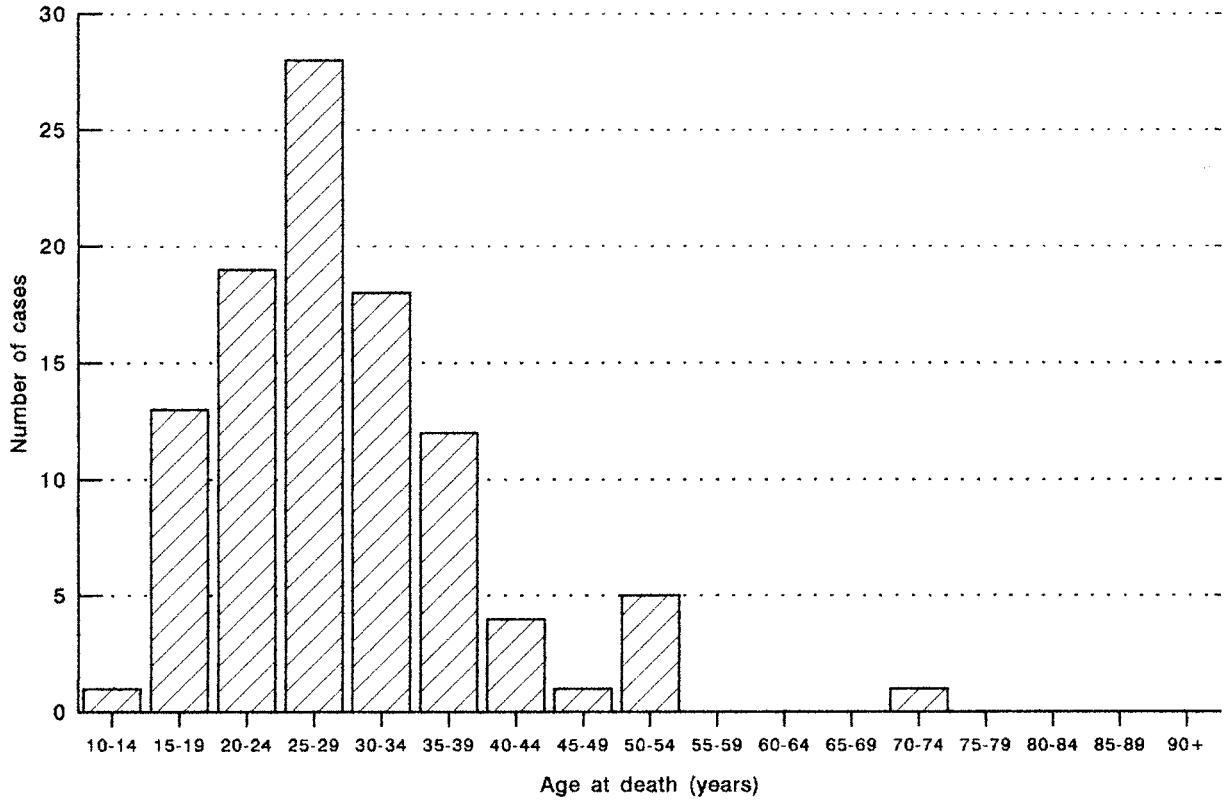

Fig. 105.4. Age at death in variant CJD UK Study 1995–November 2001 ($n = 102$).

ataxia and chorea in a patient of relatively young age. The MRI brain scan is the most helpful investigation.

Investigations in human disease

Routine hematological and biochemical tests are usually normal in human prion diseases, although a minority of cases of sporadic or vCJD may have minor abnormalities in liver function tests. The CSF is acellular, but may show an elevated protein content. The CSF 14-3-3 protein is a marker of neuronal damage and is elevated in over 90% of cases of sporadic CJD (Zerr et al., 2000), in a proportion of cases with familial or iatrogenic CJD and in about 50% of cases of vCJD (Green et al., 2001). In the appropriate clinical context a positive 14-3-3 CSF immunoassay has a high sensitivity and specificity for the diagnosis of sporadic CJD, but is less useful in the diagnosis of other forms of human prion disease.

The EEG is the most important investigation in sporadic CJD, showing generalized periodic complexes (Fig. 105.5) in about 70% of cases (Bortone et al., 1994). These changes are relatively specific for sporadic CJD, although they can be seen in some metabolic and toxic disorders. In vCJD the EEG is either normal or shows non-specific slow wave changes.

CT brain scan does not show any specific findings in CJD, but is important in the exclusion of other conditions, some of which may be treatable. Although cerebral atrophy may occur, particularly in cases with long survival, many patients have a normal scan as this investigation is often carried out relatively early in the clinical course as part of the diagnostic work-up. MRI brain scan is a more useful investigation, as high signal in the basal ganglia or thalamus supports the diagnosis of CJD. In sporadic CJD observational studies have suggested that a significant proportion of cases have symmetrical high signal changes on T_2-weighted images in the caudate and putamen regions (Finkenstaedt et al., 1996) (Fig. 105.6). However, the MRI findings have not yet been included in the diagnostic criteria for sporadic CJD as the sensitivity and specificity of the MRI abnormalities are uncertain. In vCJD the MRI scan shows symmetrical high signal changes in the pulvinar region of the posterior thalamus on T_2-weighted images in at least 75% of cases (Zeidler et al., 2000) (Fig. 105.7) and these abnormalities can be more apparent on FLAIR or diffusion-weighted images. These MRI scan

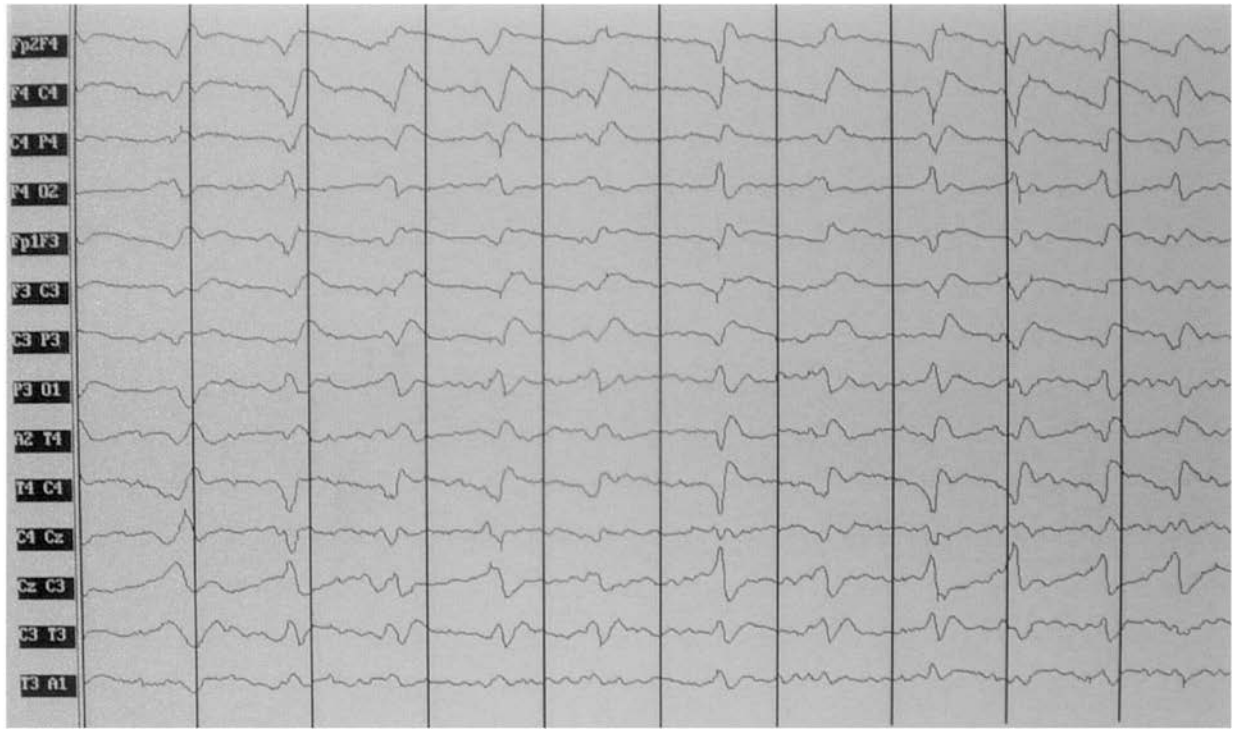

Fig. 105.5. EEG in sporadic CJD showing periodic complexes.

Fig. 105.6. Sporadic CJD: FLAIR axial image. High signal is seen in the putamen and caudate head laterally.

Fig. 105.7. Variant CJD: FLAIR axial image. Symmetrical high signal is seen in the pulvinar of the thalamus. This is known as the 'pulvinar sign of vCJD'.

Table 105.7. Diagnostic criteria for sporadic, iatrogenic and familial CJD

1	*Sporadic*		
	I		Rapidly progressive dementia
	II	A	Myoclonus
		B	Visual or cerebellar problems
		C	Pyramidal or extrapyramidal features
		D	Akinetic mutism
	III		Typical EEG
1.1	Definite:		Neuropathologically/ immunocytochemically confirmed
1.2	Probable:		I + 2 of II + III or Possible + positive 14-3-3
1.3	Possible:		I + 2 of II + duration <2 years
2	*Accidentally transmitted CJD*		
2.1	Definite		
	Definite CJD with a recognized risk.		
2.2	Probable		
2.2.1			Progressive cerebellar syndrome in human pituitary hormone recipients.
2.2.2			Probable CJD with recognized risk.
3	*Familial TSEs*[a]		
3.1	Definite		
	Definite TSE plus definite or probable TSE in a first-degree relative.		
3.2	Probable		
3.2.1			Probable TSE plus definite or probable TSE in a first degree relative.
3.2.2			Progressive neuropsychiatric disorder plus disease-specific mutation.

Notes:
[a] Including GSS and FFI.

Table 105.8. Diagnostic criteria for variant CJD

I	A	Progressive neuropsychiatric disorder
	B	Duration of illness >6 months
	C	Routine investigations do not suggest an alternative diagnosis
	D	No history of potential iatrogenic exposure
	E	No evidence of a familial form of TSE
II	A	Early psychiatric symptoms[a]
	B	Persistent painful sensory symptoms[b]
	C	Ataxia
	D	Myoclonus or chorea or dystonia
	E	Dementia
III	A	EEG does not show the typical appearance of sporadic CJD[c] (or no EEG performed)
	B	Bilateral pulvinar high signal on MRI scan
IV	A	Positive tonsil biopsy[d]

DEFINITE:	I A and neuropathological confirmation of vCJD[e]
PROBABLE:	I and 4/5 of II and III A and III B OR I and IV A[d]
POSSIBLE:	I and 4/5 of II and III A

Notes:
[a] depression, anxiety, apathy, withdrawal, delusions.
[b] this includes both frank pain and/or dysesthesia.
[c] generalized triphasic periodic complexes at approximately one per second.
[d] tonsil biopsy is not recommended routinely, nor in cases with EEG appearances typical of sporadic CJD, but may be useful in suspect cases in which the clinical features are compatible with vCJD and MRI does not show bilateral pulvinar high signal.
[e] spongiform change and extensive PrP deposition with florid plaques, throughout the cerebrum and cerebellum.

abnormalities have a high sensitivity and specificity for the diagnosis of vCJD and are included in the diagnostic criteria.

Invasive diagnostic procedures such as brain biopsy remain controversial. In many countries brain biopsy is discouraged because the diagnosis of CJD can usually be made with some confidence on clinical grounds, the procedure does not alter patient management and it has risks. In other countries brain biopsy is carried out to allow confirmation of the diagnosis in life and to exclude potentially treatable disorders, for example cerebral vasculitis. Tonsil biopsy has been advocated as a diagnostic procedure in vCJD (Hill et al., 1997b) because, in contrast to sporadic and iatrogenic CJD, immunostaining for PrP is positive in lymphoreticular tissues, including tonsil. Although tonsil biopsy may allow more confidence in the diagnosis in life, the procedure has risks and is of no direct benefit to the patient.

Conclusion

Human prion diseases are rare, but these are devastating disorders for the patient and their family. Early diagnosis is an important objective as it is difficult for the doctor and the family to see a previously fit person deteriorate so rapidly without a diagnosis. In sporadic CJD the affected patient often loses awareness and insight fairly quickly, but a frank explanation of the nature of the illness and prognosis can be helpful to the relatives. Managing patients with CJD can be difficult because of the rapid development of

cumulative neurological deficits. Symptomatic treatment of distress and involuntary movements can be effective, but there is no treatment available for the underlying disease process. In view of the possibility that a large number of people may have been exposed to the BSE agent in the UK and in other countries an important scientific objective is the discovery of an effective prophylactic treatment for human prion diseases.

Bacterial infections

Dakshin Gullapalli[1] and Thomas P. Bleck[2]

[1]Department of Neurology, University of Virginia School of Medicine, Charlottesville, VA, USA
[2]Neuroscience Intensive Care Unit, University of Virginia School of Medicine, Charlottesville, VA, USA

Infections of the central nervous system (CNS) are notable for rapid progression resulting in death or permanent damage in a very short time (Baraff et al., 1993; Grimwood et al., 1995). CNS infections share many distinct characteristics, which distinguish them from systemic infections. The CNS is confined anatomically within a bony casement which allows little room for expansion following inflammatory responses; the resulting increase in intracranial pressure may cause severe damage to the structures within. The CNS also lacks a well-developed conventional immune system to defend against offending pathogens, and thus infections are more difficult to eradicate than in the periphery. Because of the presence of the blood–brain barrier (BBB), delivery of antimicrobial agents in adequate concentrations is difficult. As vital tissues are involved, CNS infections can cause devastating sequelae, and in some cases may result in both neurological and medical emergencies. Understanding their pathophysiological mechanisms, neuroanatomical principles, clinical manifestations and neuroaradiological features is essential to providing effective treatment.

Infections can primarily occur either within the brain parenchyma or in the spaces between the different layers of the brain called meninges. Between the dura mater and the arachnoid lies the subdural space, through which the veins course from the brain surface to the venous sinuses. The dura mater is tightly bound to the inner table of skull, and hence intracranially the epidural space is a potential space; along the spinal column, the dura is separated from bone by fat and other structures. The subarachnoid space refers to the space between the pia mater and the arachnoid membrane which contains CSF and the medium-sized arteries supplying blood to the brain. CSF in the ventricles is in continuity with the CSF in the subarachnoid space through the foramina of Luschka and Magendie. The CSF is finally absorbed by the arachnoid granulations to drain into the venous sinuses.

Bacterial meningitis

Bacterial meningitis is an inflammatory response to infection of the pia-arachnoid and the CSF of the subarachnoid space. Since the subarachnoid space is continuous throughout the neuraxis, this inflammation extends throughout the subarachnoid space as well as ventricles. When there is accompanying obvious brain involvement, it is more appropriately called meningoencephalitis. Histologically, most meningitides include some parenchymal involvement, but when clinical signs of meningeal inflammation predominate one traditionally refers to the condition as meningitis. Knowledge of the anatomic details and CSF flow pathways is important to understand the pathophysiologic manifestations.

Historical background

Meningitis was first described in detail by Gaspard Vieusseux as malignant purpuric fever in 1805 following an outbreak in Switzerland. Following the introduction of lumbar puncture in 1891 by Quinke, the CSF changes associated with meningitis were recognized, and attempts made at treatment with CSF drainage and irrigation with a variety of fluids. Survival from bacterial meningitis improved following the development of horse antimeningococcal antiserum and its intrathecal and systemic administration by Simon Flexner during the first world war. However, a much more substantial impact on outcome followed the advent of antimicrobial therapy. Although sulfonamides were discovered in 1908, their antibiotic potential was not appreciated until 1932 with the discovery of sulfachrysoidine (Prontosil). The subsequent isolation of penicillin by Howard Florey in 1941 further improved survival from bacterial meningitis. Though the techniques of its administration and dosage

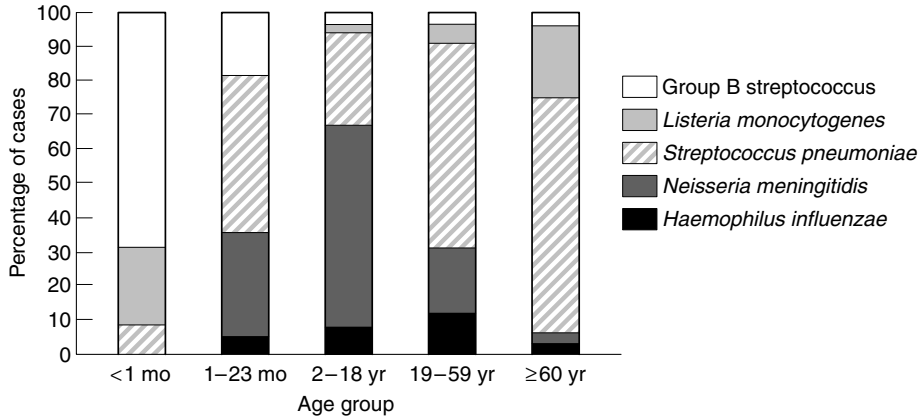

Fig. 106.1. Pathogenic agents for bacterial meningitis according to age group. (From Schuchat, 1997.)

have changed, and newer antibiotics have been developed, penicillin remained one of the most important drugs in the treatment of bacterial meningitis until the worldwide emergence of penicillin-resistant pneumococci in the 1990s. Further successes occurred in the last few decades with the synthesis of the third- and fourth-generation cephalosporins, and breakthroughs in immunizations against *Neisseria meningitidis* and *Hemophilus influenzae* type B.

Epidemiology

Bacterial meningitis is a fairly common problem, with an incidence varying between 4.6 and 10 per 100 000 people per year in US; it is much more common in developing countries. Until recently, the extremes of age were primarily involved, with the majority of cases occurring in children below 5 years. In a prospective laboratory-based surveillance project during 1986, covering a population of 34 million (thus representing 14% of US population), the overall incidences of the three most common organisms responsible for about 80% of cases of bacterial meningitis were 2.9, 1.35 and 1.0 per 100 000 population for *H. influenzae, N. meningitidis,* and *Streptococcus pneumoniae* (Wenger et al., 1990).

However, the most dramatic recent change in the epidemiology of bacterial meningitis has been a virtual disappearance of *H. influenzae* meningitis in populations immunized against this organism. Since the introduction of the *H. influenzae* type B conjugate vaccine, the common etiological agents are *S. pneumoniae* (47%), *N. meningitidis* (25%), *S. agalactiae* (group B streptococcus, 12%), *Listeria monocytogenes* (8%) and *H. influenzae* (7%) (Schuchat et al., 1997).

In addition, there was an overall decrease in the total number of cases of bacterial meningitis from 12 920 cases from these five common pathogens in 1986 to 5755 cases in 1995 (Schuchat et al. 1997). Apart from a 94% decrease in *H. influenzae* meningitis, there was also decrease in the number of cases secondary to *N. meningitidis* and group B streptococcus by 33% and 25% respectively. The median age of bacterial meningitis also changed from 15 months in 1986 to 25 years in 1995.

The organisms responsible for bacterial meningitis thus depend on the age of the patient (Fig. 106.1) and a number of other host factors. The relative frequency of each organism varies with geographic location (Sung et al., 1997) and race (Schuchat et al., 1997; McIntyre, 1998). Socioeconomic conditions also have a major impact on epidemiology of meningitis (Jones et al., 1997).

Pneumococcal meningitis is more common in adults over 30 years of age. A partial list of predisposing conditions include asplenic states (either physical or functional), multiple myeloma, immunoglobulin deficiency states, alcoholism, cirrhosis, and the Wiscott–Aldrich syndrome. It is also the most common organism responsible for recurrent meningitis in patients with history of prior head injury and residual CSF leak. There are 84 serotypes, of which about 14 cause disease in humans.

Meningococcal meningitis is most often encountered in children and young adults, and may occur in epidemics. Until 1946, meningococcal meningitis occurred in epidemics in the United States, but since then has been seen there only in local outbreaks, while still occurring in frequent epidemics in the developing countries, especially sub-Saharan Africa. However, clusters of meningococcal disease have been increasingly reported recently among adolescents and young adults in the US. Most of these clusters have

been associated with secondary schools and serogroup C strains (Gold, 1999). The use of serogroup C meningococcal vaccine can terminate such clusters (Gold, 1992), and guidelines to control such outbreaks are available (ACIP, 1997). Hot and dry climate, respiratory infections damaging the host defences, shifting antigenicity of the group A meningococcus, and blocking IgA antibodies induced by cross-reacting gram-negative enteric bacilli are some of the factors responsible for epidemics. There are 13 major serogroups, of which A, B, C, W, and Y most commonly cause meningitis. Serogroups A and C are commonly isolated in epidemics, and groups B, W, and Y occur in endemic or sporadic cases. Recently, serogroup C has been reported to be replacing serogroup B strains in certain endemic areas (Ashton et al., 1991). Serogroup B also is seen with sporadic cases, and serogroup Y is in addition associated with pneumonia. Nasopharyngeal carriage provides the usual reservoir of the organism, and such colonization serves as the portal of entry for the organism. Infection is more common with individuals having deficiencies in the terminal complement components (C5 to C8) and properdin. Antibodies to surface antigens of the bacteria are the major determinants of natural immunity (Griffiths et al., 1987; Jones et al., 1998).

Group B streptococci are an important cause of neonatal meningitis, accounting for approximately 70% of cases. They cause meningitis less frequently in adults, accounting for an overall incidence of 13% of bacterial meningitis of all age groups (Schuchat et al., 1997) (see Fig. 106.1). In early-onset cases (<7 days after birth), the organism is acquired from the mother's genital tract during delivery, whereas the source of the late onset is unclear (Spach & Jackson, 1999).

H. influenzae was the commonest organism responsible for meningitis in children between six months and six years of age until the introduction of the vaccine; more than 90% of cases were due to the capsular type B strains. Non-typable strains (NTHi) are responsible for recurrent meningitis and infections in non-immunized children. Nasopharyngeal colonization is a common preceding event prior to systemic invasion. It is not an typical isolate in patients older than 6 years, unless there is a predisposing condition increasing the risk of infection with encapsulated organisms.

L. monocytogenes infection is more likely in neonates, the elderly, alcoholic patients, and other immunocompromised adults (Khayr et al., 1992). However, there may not be an obvious predisposing condition in up to 30% of patients.

Gram-negative bacilli constitute the other major group of organisms producing meningitis in the neonatal period. Aerobic gram-negative bacillary meningitis is uncommon except at the extremes of age, but appears to be increasing in incidence. In one study, these organisms were responsible for about 33% of cases of nosocomial meningitis, but only 3% of the community-acquired episodes (Durand et al., 1993). The most common gram-negative bacilli isolated are *Escherichia coli, Klebsiella pneumoniae* and *Pseudomonas* species. *Pseudomonas*, *Serratia marcesens*, and *Flavobacterium* are common in patients on mechanical ventilation, presumably related to their tendency to first colonize the upper airway.

Staphylococcus epidermidis meningitis is found in patients with CSF shunts, indwelling catheters, endocarditis, following head trauma, and after neurosurgical procedures.

Anaerobic bacteria are rarely associated with meningitis, and their isolation from CSF should suggest intraventricular rupture of a brain abscess or meningitis occurring in the context of a subdural empyema.

Myobacterium tuberculosis, *Treponema pallidum*, *Nocardia* species, *Actinomyces* species, and cysticercosis usually produce chronic meningitides, but on occasion may present as an acute meningitis.

Unlike brain abscess, polymicrobial bacterial meningitis is unusual, accounting for less than 1% of cases.

Crowding, as seen commonly in military barracks, households in developing countries, and daycare or chronic care facilities, was independently associated with a higher risk of bacterial meningitis in a population-based case-control study of *H. influenzae* (Fraser et al., 1974). Breastfeeding was protective in preventing bacterial meningitis in young infants. Close contacts of patients with *H. influenzae* and meningococcal meningitis have a 500-fold increased risk of developing the disease for the first 30 days after contact.

Cigarette smoking was recently demonstrated to increase the risk of bacterial meningitis in general, and meningococcal carriage and disease in particular (Bredfeldt et al., 1995; Caugant et al., 1994; Dagan et al., 1992; Davies et al., 1996; Kremastinou et al., 1994; Stanwell-Smith et al., 1994). It is not clear whether smoking increases risk by increasing transmission between contacts or by damaging mucosa.

Pathogenesis

In recent years, our understanding of the pathogenesis of bacterial meningitis has increased dramatically, especially with the identification of some of the inflammatory and neurotoxic mediators involved in the processes leading to neuronal injury (Tauber et al., 1997; Tunkel & Scheld,

1993). These developments suggest widening the traditional therapeutic approaches from eradication of the bacterial pathogen with antibiotics and prevention with vaccines to attenuation of the detrimental effects of the host defences.

Bacteria reach CNS in three ways: via the blood, via contiguous sites, or by direct implantation (traumatic or iatrogenic). Most cases of bacterial meningitis occur as a result of hematogenous spread.

The pathogenesis of bacterial meningitis involves four phases: (i) invasion of the host by the bacteria (Fig. 106.2, see colour plate section) with subsequent infection of CNS; (ii) replication and induction of inflammation by bacteria within the CSF; (iii) progression of inflammation with associated pathophysiologic alterations; and (iv) production of tissue damage.

Bacterial invasion and CNS infection

Four sequential steps are involved in the process of bacterial pathogens reaching the CSF (Quagliarello et al., 1992; Tunkel et al., 1990):

Nasopharyngeal colonization

Most bacterial pathogens initially colonize the nasopharyngeal mucosa before they invade the host. They are usually acquired either from an asymptomatic carrier or from a patient through infected airborne droplets. The host's defence mechanisms responsible for preventing this colonization of bacteria include: local presence of IgA, ciliary clearance mechanisms, and the integrity of the mucosal membranes. The majority of isolates of the three classically common organisms secrete IgA proteases that cleave IgA in the hinge region (Wani et al., 1996), thus facilitating bacterial adhesion to the epithelium. *H. influenzae* and *N. meningitidis* also cause injury to the ciliated epithelial cells, resulting in ciliostasis and selective adherence to non-ciliated epithelial cells in nasopharyngeal organ cultures. Pili on meningococci and *H. influenzae* help them to adhere to mucosal surfaces and are responsible for their binding (Quagliarello et al., 1992). Although the nasopharynx is the usual portal of entry of the common organisms causing meningitis, any source of infection that results in bacteremia can potentially infect the meninges.

Nasopharyngeal epithelial cell invasion and entry into blood

Meningococci enter non-ciliated epithelial cells by an endocytic process and move to the abluminal side (basolateral side) by a transcellular route within membrane-bound vacuoles. *H. influenzae,* in contrast, break the apical tight junctions of the columnar epithelial cells and traverse through an intercellular route (Stephens & Farley, 1991). The mechanism of further transport from subepithelial layers into the bloodstream is unknown. Sequential switching of phase-variable surface components may be a prerequisite for the microorganism to adapt to the changes of environment between the mucosal surface, intra- or intercellular spaces, and the blood stream (de Vries et al., 1996).

Survival in the blood

Opsonized phagocytosis, specific antibodies, and complement activation are the principal mechanisms by which reticuloendothelial system normally clears bacterial pathogens from the blood. The role of antibody is exemplified by the protection afforded by the breastfeeding and peak age-specific incidence of meningitis which occurs at age 6–8 months, when the antibodies are at their lowest level, as passively acquired maternal IgG antibodies disappear (Wenger et al., 1990). The importance of antibody is further highlighted by the recent observation of more than 95% reduction in incidence of *H. influenzae* type b meningitis after the introduction of conjugate vaccine, which induces anticapsular antibody titres. If there has been prior infection or exposure to an organism, the classical complement pathway is primarily involved in eliminating the organism by opsono-phagocytosis mediated by the specific antibodies. In the absence of such prior exposure, bacteria must evade the alternative complement pathway to allow their intravascular survival; this is primarily achieved by the capsular polysaccharide, which also protects bacteria from circulating antibodies and neutrophil phagocytosis (Kim et al., 1992). The importance of the complement system is underscored by the predisposition to pneumococcal infections in patients with absent functional spleens, as in sickle cell disease or following splenectomy; and the predisposition to meningococcal infections in patients with defective terminal complement components (Quagliarello, 1992; Virji, 1996). The characteristics of the polysaccharide capsule of meningeal pathogens that reduce activation of the alternate complement system include presence of sialic acid, which is also present in human cells. Hence, the capsules resemble host cell surfaces, and thus evade complement activation.

Capsules also impede C3 convertase-mediated activation of the alternate complement cascade via a low binding affinity for serum protein B, which contributes to C3 convertase activity, or via a high binding affinity for serum protein H, which promotes decay of C3b complexes (Tunkel & Scheld, 1993). Bacteria also survive if there is a defect in the host defence system. These may include T-cell

deficiency, B-cell deficiency, terminal complement deficiency, and alternate complement pathway deficiency.

Transport across BBB and entry into CSF

The CNS is relatively protected from systemic influences by the BBB, which maintains homeostasis of the CNS microenvironment through selective restriction of the entry of macromolecules, cells, and pathogens. The BBB is formed by tight junctions between capillary endothelial cells, a pericyte-derived basal membrane, and the astrocytic foot processes investing the capillaries. However, many essential substances are transported across the barrier through non-specific diffusion, specific facilitated diffusion, and energy-dependent carrier-mediated transport. Early studies on an infant rat model suggested that dural venous sinuses were the major route of CNS invasion. Recent studies suggest that a non-specific sterile focal inflammation above the cribriform plate facilitates CNS invasion at this site. Experimental studies demonstrate the choroid plexus as the portal of entry due to its high blood flow (200 ml/g/min) and fenestrated capillaries. A high-grade bacteremia could also alter the capillary tight junctions. Three factors may be responsible for the organisms' neurotropism and CSF entry: (i) bacteremia of sustained duration and magnitude; (ii) adhesion to critical BBB components (mediating CNS invasion); and (iii) transfer within macrophages or other phagocytic cells (entering CNS by normal cellular trafficking pathways). Recent work suggests a complex interplay between endothelial cells and microbial gene products to orchestrate the traversal of bacteria across the BBB (Ring & Tuomanen, 1997). The initial step in this process is attachment of the pathogen to receptors located on endothelial cells. Following attachment, bacteria adopt one of the several strategies to cross the BBB, which include (i) paracellular passage by disruption of the intercellular endothelial connections or endothelial injury (Patrick et al., 1992; Arditi et al., 1995); (ii) transcellular transport by active or passive trancytosis; and (iii) invasion within white cells during diapedesis. Pneumococci appear to invade both through transcellular and paracellular pathways (Ring et al., 1998).

As mentioned earlier, infections may reach CNS by extension from contiguous sites like the paranasal sinuses, middle ear, or mastoid processes through compromised integrity of barriers around the brain. Finally, organisms may spread to CNS by direct implantation via a CSF communication that occurs following head trauma (either accidentally or iatrogenically through neurosurgical procedures), through congenital causes like myelomeningocele, congenital dermal sinus and by neoplastic destruction of skull bone.

Bacterial replication and induction of inflammation

Survival and replication within CSF is enhanced because typical host defence mechanisms are virtually absent in CSF, as neutrophils, plasma cells, complement components and immunoglobulins are significantly excluded by the BBB. In one study, CSF opsonic activity was undetectable in 50% of patients with bacterial meningitis (Simberkoff et al., 1980); this impedes phagocytosis by leptomeningeal macrophages and recruited peripheral granulocytes (Richardson, 1996). Bacteria can efficiently multiply within the CSF (Small et al., 1986). Induction of inflammation within the subarachnoid space occurs following invasion and replication of the bacterial pathogen in the CSF, which is primarily responsible for pathophysiological consequences that result in the clinical syndrome.

The cell wall of gram-positive organisms and the endotoxins (lipopolysaccharides) of gram-negative organisms are primarily responsible for stimulating subarachnoid inflammation; teichoic acid and peptidoglycan, the major cell-wall components, have a key role (Tuomanen et al., 1985). Intracisternal inoculation of either *H. influenzae* type B polysaccharide or *H. influenzae* outer membrane induces meningeal inflammation in animal experiments (Mustafa et al., 1989; Wispelwey et al., 1989). Release of various inflammatory mediators like interleukin 1 (IL-1) and tumour necrosis factor α (TNFα), and possibly prostaglandins, appear to be responsible for the initiation of inflammatory responses. Direct inoculation of IL-1 and TNFα into CSF of rats or rabbits induces meningeal inflammation (Quagliarello et al., 1992; Ramilo et al., 1990; Tunkel et al., 1990). Cytokines are released from meningeal macrophages, glial cells, ependymal cells, recruited inflammatory cells, and brain microvascular endothelial cells. Increased CSF concentrations of TNFα, IL-1, IL-6, IL-8, and IL-10 are characteristic of bacterial meningitis. These cytokines are proinflammatory, except for IL-10, which down-regulates the production of TNFα and other proinflammatory cytokines (Arvin et al., 1996; Tunkel et al., 1990). TNFα is a relatively specific marker for bacterial meningitis, as it is not released in viral meningitis. It is a glycoprotein produced by lymphocytes, NK cells, astrocytes and microglial cells. Experimental administration of TNFα into the CSF as well as intracerebrally results in pathophysiologic changes characteristic of bacterial meningitis (Tureen, 1995; Rosenberg et al., 1995; Glabinski, 1998). Antibiotic therapy causes additional rapid lysis of pathogens resulting in higher TNFα concentrations with initiation of antimicrobial treatment. IL-1 released in the CNS by

mononuclear phagocytes, glial cells and endothelial cells, has proinflammatory actions independent of but synergistic with TNFα (Quagliarello et al., 1992). Both IL-1 and TNFα induce other secondary cytokines like IL-6, IL-8, and IL-10 (Waage et al., 1998). Though there is evidence that IL-6 and IL-8 levels are increased in bacterial meningitis, and that they have proinflammatory effects, their presence is not strongly correlated with other indices of meningeal inflammation or with severity of the disease (Rusconi et al., 1991). IL-1 and TNFα cause secretion of adhesion molecules on endothelial cells and neutrophils, which helps migration of neutrophils into CSF.

Progression of inflammation

A CSF neutrophilic pleocytosis is a hallmark of acute subarachnoid inflammation. However, neutrophil movement into the CSF is complicated, yet a crucial step in the pathogenesis of bacterial meningitis. The initial step in this process is margination and adhesion of neutrophils to vascular endothelial cells, followed by transmigration through the vessel wall. Three families of adhesion molecules may mediate these interactions, including the immunoglobulin superfamily (e.g. ICAM-1 and ICAM-2), the integrin family, and the selectin family. A three-phase model was proposed by Quagliarello and Scheld in 1992 to explain neutrophil migration into the CSF. The first phase, lasting 1–2 hours, involves release of IL-1 and TNFα into the CSF in response to bacterial pathogen replication or lysis. The cytokines then interact with the surface membranes of endothelial cells, generating local production of thrombin and leading to expression of selectin molecules (ELAM-1 and CD62), which in turn enhance neutrophil endothelial cell binding. Subsequently, IL-8 is released by prolonged cytokine stimulation, which replaces the initial selectin-mediated neutrophil binding with an integrin-mediated neutrophil binding to endothelial intercellular adhesion molecules (ICAMs), and finally leading to neutrophil diapedesis through vessel walls along a chemotactic gradient into the CSF. In the final phase, cytokine activation of neutrophils results in their degranulation and release of leukotrienes, platelet-activating factor, prostaglandins, and and toxic oxygen metabolites, which damage the BBB by opening tight junctions.

Support for the role of these adhesion molecules is found in experimental models of meningitis, where systemic administration of monoclonal antibody (IB4) against the CD11/CD18 family of receptors results in absence of CSF pleocytosis and this is more effective when dexamethasone is administered along with the antibody. Corticosteroids reduce the release of cytokines into CSF, and reduce release of vasoactive substances from neutrophils directly into the CSF.

Recent work also has shown a correlation of high levels of IL-1 and IL-6 with high cerebral blood flow velocities (Fassbender et al., 1996). Nitric oxide also appears to have a significant role in pathogenesis of bacterial meningitis. Increased concentration of NO in CSF is shown to cause cerebral edema (Destache et al., 1998; Pfister & Scheld, 1997). Animal studies suggest that induction of NO synthase occurs within meningeal vessels and within cells of CSF; the production of NO appears to reduce cerebral ischemia (Leib et al., 1998a).

Reactive oxygen species play an important role in the pathophysiology of bacterial meningitis. Increased formation of ROS occur during inflammatory processes stimulated by bacterial products, phagocytosis, and TNFα. Inhibition of the effects of ROS by free radical scavengers prevented BBB breakdown, providing neuronal protection (Koedel & Pfister, 1997; Leib et al., 1998b). Vascular endothelial cell activation, cerebral inflammation, ischemia/reperfusion injury, neuronal apoptosis, and excitotoxic neuronal injury are the processes linked to the generation of ROS most likely to be important in meningitis. The harmful effects of NO are mediated through its role in generating a CSF pleocytosis, altering BBB permeability, inducing intracranial hypertension, producing brain edema, and influencing cerebral metabolism (Buster et al., 1995; Koedel et al., 1995; Leib et al., 1998b; Tureen, 1995). Despite these observations, there is evidence that use of NO inhibitors in meningitis may have deleterious effects (Leib et al., 1998a). This may reflect varying effects on the constitutive and inducible forms of NO synthase, or the need for NO-induced vasodilation as a protective mechanism against meningitis-induced vasculopathy.

Matrix metalloproteinases belong to a family of zinc-dependent endopeptidases; their release is induced by TNFα, and they appear to be involved in the pathogenesis of bacterial meningitis through BBB breakdown, extravasation of inflammatory cells into the CNS and glial and neuronal death (Paul et al., 1997; Sporer et al., 1998).

By the end of the first week of infection, neutrophils are replaced by macrophages, derived from meningeal histiocytes. Further infiltration of subependymal tissues and perivascular spaces by PMNs and lymphocytes occurs. Interference with normal CSF flow, and its resorption at the arachnoid granulations, by the inflammatory exudate may result in the blockage of pathways of flow and drainage. Cerebral edema and failure of CSF resorption result in dangerously elevated ICP. Cranial and spinal nerve deficits, focal neurological deficits, seizures, encephalopathy, and

subdural effusions are commonly recognized complications of meningitis.

Development of neuronal damage

The main abnormal processes involved in neuronal injury are: (i) alteration of the BBB; (ii) raised intracranial pressure; (iii) alterations in cerebral blood flow; and (iv) direct neurotoxicity. Increased permeability of the BBB results in vasogenic edema, as well as entry of potentially harmful molecules from the blood stream which may have a direct harmful effects on brain parenchyma or alter the brain's microenvironment. Dynamic changes in CBF are marked in meningitis, with early increased blood flow followed by its reduction in the late phases (Koedel et al., 1995; Leib et al., 1998a,b). Inadequate cerebral blood flow results from increased metabolism, seizures, and reduced cerebral blood flow secondary to disturbed autoregulation (Tureen et al., 1990) and systemic hypotension. Direct neurotoxicity is likely secondary to TNFα, ROS, NO, cerebral ischemia, and EAAs (Tauber et al., 1997; Leib et al., 1996), rather than by the direct spread of bacteria into the brain. In an infant rat model of neonatal meningitis, kynurenic acid, a nonselective inhibitor of EAAs attenuated brain injury, strengthening the role of EAAs (Leib et al., 1998a,b). In addition, neutrophils, by tracking along Virchow–Robin spaces, damage small vessels, infiltrate and damage cortex.

Peroxynitrate, which is a highly cytotoxic product of the reaction of superoxide and NO, appears to interfere with mitochondrial function (Beckman & Koppenol, 1996). Its inhibition appears to have a neuroprotective effect (Tureen et al., 1998).

One of the major pathophysiologic changes of bacterial meningitis is brain edema (and the consequent increase in ICP). The types of edema produced include (i) vasogenic edema, which occurs as a result of separation of intercellular tight junctions; this is correlated by penetration of marker protein across BBB; (ii) cytotoxic edema, due to alteration of cell membranes secondary to hypoxia and toxins released by bacteria and neutrophils, leading to increased intracellular water content; (iii) increased CSF volume secondary to increased CSF outflow resistance both within the CSF pathways and at the arachnoid granulations by the exudate (Quagliarello et al., 1992; Scheld et al., 1980); (iv) hypotonicity of extracellular fluid in the presence of increased permeability of BBB, reflecting either the syndrome of inappropriate antidiuretic hormone effect (Kaplan & Feigin, 1978) or cerebral salt wasting; (v) interstitial edema either secondary to increased CSF production or its outflow resistance; and (vi) increased blood volume in the brain from hyperemia or venous congestion (Tureen et al., 1996).

Pathology

Neurological sequelae from bacterial meningitis fall into three categories; (i) cranial nerve deficits, primarily sensorineural deafness; (ii) obstructive hydrocephalus; and (iii) parenchymal brain damage leading to focal neurological deficits in the form of deafness, blindness, seizures, and mental retardation in children. The main pathological features of bacterial meningitis involve inflammation of the subarachnoid space, disorders of the cerebral vasculature, and parenchymal brain damage.

The hallmark of meningitis is subarachnoid space exudate, most abundant in the cisterns at the base of the brain and over the convexities in the Rolandic and Sylvian fissures (See Fig. 106.2, see colour plate section). Initially, inflammatory cells are confined to the exudate, but during the subsequent 2 to 3 days they are also seen within the walls of the small and medium vessels (Cairns & Russell, 1946). The presence of subintimal inflammatory cells is unique to meningeal infections. Meningeal veins become distended and develop mural infection, which may be complicated by focal necrosis of the vessel wall, mural thrombus formation in the lumen, or involvement of the dural sinuses. Hemorrhagic cortical infarction may result from cortical venous and dural sinus thrombosis. Toxic effects of the inflammatory mediators and bacterial pathogen on the hair cells of the inner ear are likely responsible for deafness associated with bacterial meningitis (Blank et al., 1994).

Treatment

Management of bacterial meningitis involves rapid diagnosis, quick institution of antibiotic therapy, and monitoring for and treatment of associated systemic and neurological complications. Though many physicians believe in the importance of avoiding any delay in instituting antimicrobial therapy in bacterial meningitis, an analysis of prior studies did not reveal a good correlation between the duration of symptoms and the clinical outcome in at least half of these studies (Radetsky, 1992). However, the study of Aronin and colleagues (1998) provides strong evidence that treatment delay adversely affects outcome. Therefore, time must not be wasted before starting antibiotic therapy. Though experimental evidence showed explosive inflammatory enhancement following antibiotic therapy due to bacteriolysis, recent animal studies revealed lesser amounts of bacterial endotoxin compared to bacteria not exposed to antibiotics

(Friedland, 1993). Furthermore, delaying antibiotic treatment would facilitate bacterial spread to brain parenchyma and other sites. If a delay in obtaining the CSF sample is expected, as when imaging is requested prior to the lumbar puncture, empiric antibiotic therapy should be initiated immediately. As knowledge about a specific causative pathogen and its susceptibility is not available at the initial evaluation, one must choose appropriate antibiotic empirically based on the information from the initial evaluation. Age, patient risk factors, and regional antibiotic resistances help in the empiric choice of antibiotics. In view of the increase in penicillin-resistant *S. pneumoniae*, empiric antibiotic regimens usually include vancomycin when this pathogen is suspected. The antibiotic regimen can be modified after a specific organism and its susceptibilities are identified. For many years penicillin, chloramphenicol, and ampicillin were the traditional drugs against most of the pathogens. However, several events in the last decade or so necessitated modification of initial empiric antibiotic therapy.

A few general guidelines are important in the treatment of bacterial meningitis. (i) Antibiotic treatment in CNS infections is unique in that high doses of antimicrobials are usually needed to cross the BBB and achieve therapeutic levels in the CSF and brain. This is also important because effective drug concentrations in vivo are substantially higher than the minimal bactericidal concentrations in vitro (Tauber, 1984; Tunkel et al. 1990). Possible reasons for these observations are enhanced degree of protein binding (Sande, 1978), reduced antibiotic efficacy in the acidic environment of purulent CSF (Strausbaugh & Sande, 1978), and a reduced bacterial growth rate in the milieu of the CSF (Ernst, 1983). Fortunately, the increased permeability of the BBB that contributes to pathophysiology of meningitis also increases permeability for some antibiotics. Lipid solubility, protein binding, molecular size, degree of inflammation and capillary and choroid plexus efflux pumps are some of the determinants of drug penetration into the CSF (Andes, 1999). (ii) Antibiotic therapy should be initiated very early in the disease course, as permanent neurologic damage and even death can rapidly occur in patients with meningitis. Hence the importance of a rapid diagnosis, or of empiric treatment if a lumbar puncture must be delayed, cannot be overemphasized. (iii) Antibiotic regimens should include agents which are bactericidal in the CSF (Scheld & Sande, 1983). Suggested regimens for community-acquired meningitis in an immunocompetent host: third-generation cephalosporin and vascomysin. If immunodeficiency is suspected (diabetes, renal impairment or alcoholism), then ampicillin should be added (Schuchat et al., 1997). (iv) The duration of antibiotic treatment is generally empirical, but depends on the specific bacterial pathogen and should be individualized based on clinical and laboratory responses. In some cases, acute phase reactants like ESR and CRP are suggested as indices to guide the duration of treatment (Saez-Llorens, 1993). (v) Knowledge of the pharmacodynamics of the drugs is also important. Aminoglycosides and quinolones have a prolonged postantibiotic effect and concentration-dependent activity in serum that allows for once or twice-daily dosing (Craig, 1998). In contrast, β-lactam antibiotics and vancomycin show concentration-independent activity and no postantibiotic effect in serum, explaining the reason for these drugs to be given at more frequent intervals (Craig, 1995).

Since 1988, significant interest has been focused in the use of corticosteroids in bacterial meningitis (Lebel, 1988). However, the issue remains controversial. A meta-analysis of randomized, controlled trials of use of dexamethasone in childhood meningitis published between 1988 and 1996 did not show a definite benefit from the use of dexamethasone in preventing neurological deficits other than hearing loss (McIntyre et al., 1997). However, there were no uniform criteria for evaluating neurologic deficits (other than hearing loss) in this analysis. Also, in most of these studies, *H. influenzae* was the commonest organism, which now is very uncommon; and most studies were performed prior to penicillin resistant *S. pneumoniae* (Spach & Jackson, 1999). There are few data regarding the use of dexamethasone in meningitis in adults. There is also some concern from experimental studies regarding the potential for dexamethasone to interfere with the penetration and bactericidal activity of some antibiotics (Paris, 1994; Bonadio, 1996). However, some still favour the use of dexamethasone, especially in children above two months of age and in adults where gram positive organisms and increased intracranial pressure are present (Quagliarello & Scheld, 1997).

Chemoprophylaxis of household and close contacts of bacterial meningitis patients is warranted in infections secondary to *N. meningitidis* and *H. influenzae*.

Future directions

With the encouragement from the success of Hib vaccine, future efforts would likely focus on the development of vaccines for other pathogens. This is especially important for *S. pneumoniae*, as it is the most common organism for bacterial meningitis currently and also for the growing concern over spreading drug resistant strains. The preliminary data on the use of new conjugated *S. pneumoniae* vaccine is encouraging (Black et al., 1998).

Brain abscess

Brain abscess is a focal intracerebral suppuration with an historically high morbidity and mortality. Until the late nineteenth century, it was a uniformly fatal condition. Major breakthroughs in neuroimaging, stereotactic brain biopsy, and newer antibiotics have led to improved care and outcomes of this once devastating condition (Gonzalez-Garcia, 1999).

Pathophysiology

The brain is protected from blood-borne pathogens by the BBB and its abundant blood supply. Underlying brain pathologies like intracerebral hematoma, infarction, and tumour sometimes predispose development of brain abscess. Common pathogens reach brain by spread from contiguous sites like the paranasal sinuses, middle ear, mastoid air cells and teeth, presumably through invasion via valveless emissary veins draining these regions, draining into venous system of the brain. Surprisingly, brain abscess formation is not common following penetrating brain injuries (Saba, 1995), but hematogenous spread of pathogens from distant sources may occur. In about 20–30%, no identifiable source can be found, and these are termed *cryptogenic* brain abscesses.

Based on information from experimental models of brain abscess, supplemented by CT scanning, four stages of brain abscess can be identified; an early cerebritis stage (1–3 days), characterized by focal area of inflammation and edema, visualized as a hypodense lesion on the CT; a late cerebritis stage (4–9 days), with expansion of cerebritis and development of central necrosis; an early capsular stage (10–14 days), where peripheral gliosis and fibrosis is beginning to form a capsule seen as a ring-enhancing lesion with peripheral edema on CT scan; and a late capsular stage (beyond 14 days), with the formation of a discrete abscess with a well-formed capsule surrounded by edema.

Diagnosis

The clinical manifestation of a brain abscess depends upon the size, location, offending pathogen, and the underlying predispositions. Headache is the most common symptom, which has no distinguishing features. It is poorly localized and of acute to subacute onset; an abrupt onset is much less common. However, abrupt worsening of headache suggests rupture of the abscess into the ventricular system, which is commonly associated with signs of meningeal irritation and a fatal course (Zeidman et al., 1995). With increasing size of the abscess and the associated surrounding edema, symptoms of raised intracranial pressure develop in the form of nausea, vomiting, increasing headache, and worsening level of consciousness. Papilledema, if present, suggests significantly raised ICP.

Contrary to general expectation, fever is a presenting symptom in less than half of patients (Mathisen, 1984; Chun et al., 1986). In more than one-third of patients there are focal neurological signs based on the location of the abscess. Fluctuating mental status suggests a poor prognosis (Seydoux & Francioli, 1992). Presence of infection in contiguous sites not only serves as a clue to the diagnosis but also to the location of the brain abscess.

The diagnosis of brain abscess can be very difficult, in view of the fact that in addition to the non-specific clinical presentation, routine laboratory data (peripheral leukocyte count, sedimentation rate, blood cultures) are frequently normal. Lumbar puncture is contraindicated in view of potential brain herniation, the CSF analysis is often normal, and a microbiological diagnosis can rarely be made from the CSF. The diagnosis depends on clinical suspicion and cerebral imaging. CT and MRI techniques help not only in the diagnosis of cerebral abscess but also in its staging. Contrast-enhanced CT or, preferably, MRI is mandatory. Ring-enhancing lesions evolve with progression of the abscess formation, with surrounding edema (Fig. 106.3, see colour plate section). Though ring enhancement usually suggests formation of capsule, this appearance can also be seen in the cerebritis stage. To differentiate this, a delayed scan about 30–60 min later, showing filling in of the central hypodense area by the contrast suggests the cerebritis stage with no central necrosis (Enzmann et al., 1979). Once ring enhancement is seen, the differential diagnosis includes all the conditions that produce ring-enhancing lesions. However, there is no radiographical sign which can reliably distinguish an abscess from a rapidly growing tumour, underscoring the need for histologic and microbiologic diagnoses. MRI achieves better resolution than CT scan (Haimes et al., 1989). T_1-weighted images with contrast show hypointense centre with ring enhancement. On T_2-weighted sequences, abscess appears as hyperintense with hypointense periphery formed by capsule, and surrounding edema as hyperintense area mainly involving the white matter.

Microbiology and therapy

With the advent of modern imaging techniques aiding in early diagnosis, and with newer antibiotics and improved surgical techniques, the morbidity and mortality of the brain abscess has improved significantly in recent years.

Management of brain abscess is both medical and surgical (Fig. 106.4, see colour plate section). Most often brain abscesses are caused by multiple pathogens. The common organisms include viridans streptococci, anaerobic bacteria, *Staphylococcus aureus*, and sometimes facultatively anaerobic gram-negative bacteria. Empirical antibiotic treatment should be started for suspected pathogens based on infection in contiguous sites or a distant focus. Brain abscesses formed secondary to sinus infections are usually caused by viridans streptococci and anaerobic bacteria. The empiric antibiotic regimen should hence include a third generation cephalosporin or cefepime (if *Pseudomonas aeruginosa* is a concern) and metronidazole. In case of otitic source, coverage for *P. aeruginosa* and *Enterobacteriaceae* should be included in the antibiotic regimen. Penetrating brain injury, as in the case of trauma or surgery, is usually associated with *Staphylococcus* species, and hence an antistaphylococcal penicillin or vancomycin may be indicated. In addition, these patients benefit from prophylactic antibiotics (Patir et al., 1995). In contaminated wounds, *Clostridium* species and facultative gram-negative organisms are usually associated with the other pathogens.

Similar rules as to those for bacterial meningitis apply to brain abscess in antibiotic dosing, based on the drug's ability to penetrate the BBB and its bactericidal potency. In addition, antibiotics need to penetrate into the abscess cavity; however, limited information in this regard is currently available. Although penicillin seems to penetrate into the abscess, it may be inactivated in pus (Gortvai et al., 1996). Conversely, although CSF levels of vancomycin reach only 10% of the serum levels, it appears to have a high penetration into the brain abscess (Levy et al., 1986). Metronidazole, cefotaxime, its active metabolite desacetylcefotaxime, and ceftazidime, have favourable pharmacokinetic features with good penetration both into CSF and brain abscess (Ingham & Selkon, 1982; Sjolin et al., 1991; Yamamoto et al., 1993; Green et al., 1989). The other third-generation cephalosporins (e.g. ceftriaxone and ceftizoxime), meropenem, and some quinolones also appear to be effective antibiotic agents in brain abscess.

The duration of the antibiotic treatment is generally 6–8 weeks, though the size of the abscess, microbial features, surgical drainage, and both clinical and radiological responses may aid in individualizing the duration of therapy. A small area of enhancement is not surprising even after adequate treatment (Whelan & Hilal, 1980).

Operative treatment

The brain may on occasion constitute one of the exceptions to the general rule that abscesses should always be drained. This may be true in some cases where brain abscesses are small (<2 cm) and difficult to safely reach in clinically stable patients who are poor candidates for surgery. Disadvantages with this conservative approach include prolonged antibiotic treatment, risk of clinical deterioration, and the risk intraventricular rupture. Some authors believe that late epilepsy is more common in patients who do not have at least an aspiration of a suspected abscess.

A major change in the trends of operative management of brain abscess has been a shift from an open craniotomy and drainage to a closed drainage, commonly through stereotactic technique (Mampalam & Rosenblum, 1988; Lunsford, 1987; Skrap et al., 1996). However, the stereotactic drainage has a disadvantage in that it requires time for planning and hence may not be feasible in emergency situations. This technique is more useful in abscesses involving deeper structures, where precision is very important. The alternative freehand procedure, which also requires CT guidance and use of scalp markers, can be done in the emergency setting with an accuracy of 4–5 mm. The role of open drainage is now limited to multiloculated abscesses in which closed drainage procedures have failed, and in cases of abscesses secondary to resistant organisms. Intracavitary administration of antibiotics may be helpful in some situations with large, poorly responding abscesses (Broggi et al., 1985; Gentile et al., 1988), but this remains controversial. Management of intraventricular rupture of brain abscess involves open craniotomy with an external drainage procedure and is associated with significant mortality (>80%). The role of corticosteroids as adjunctive treatment is controversial, but in general, these agents have not been shown to be effective in altering morbidity (Yang, 1981; Chun et al., 1986; Seydoux & Francoli, 1992). Adjunctive treatment includes treatment of brain edema (for which steroids may be useful) and anticonvulsant drugs for seizures. Poor prognosticators include severe neurological deficits and shorter duration of symptoms (Seydoux & Francoli, 1992). Stereotactic needle aspiration might help as a diagnostic aid to obtain material for gram stain and culture as well as therapeutic drainage in selected cases. Not uncommonly, serial imaging is indicated to decide the timing for surgical drainage as well as for monitoring the response to medical therapy.

Epidural abscess

The epidural space is between the dura mater and the overlying skull or the vertebral column. As the dura forms the inner periosteal layer of the skull, infection within this

potential space in the cranium is almost always associated with osteomyelitis. Unlike that in the cranium, the spinal dura mater is separated from the vertebral column by an epidural space filled with fat, vascular and loose areolar tissue. Due to anatomical reasons, infection within this space, first described by Morgagni in the eighteenth century (Gellin, 1997), can spread longitudinally along the vertebral column and thus cause cord compression.

Intracranial epidural abscess is identical to intracranial subdural empyema in etiology, pathogenesis and microbiology (Silverberg & Di Nubile, 1985). Hence this discussion will be restricted to spinal epidural abscess.

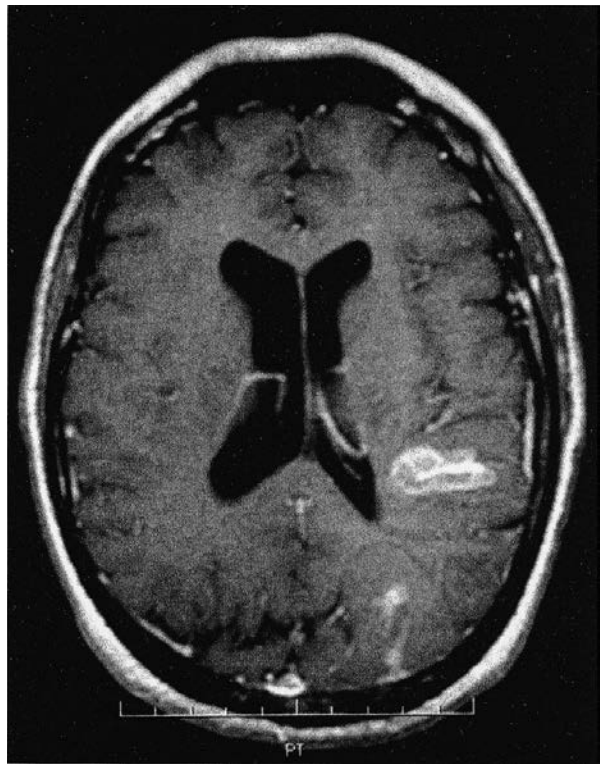

Fig. 106.5 (For (*a*), see colour plate section) (*b*) Contrast-enhanced MRI scan illustrates septic embolization in subacute bacterial endocarditis. (Figure courtesy of Dr Justin C. McArthur.)

Etiology and pathogenesis

Spinal epidural abscess can be acute or chronic and forms either by spread of infection from the vertebral column or by hematogenous spread from distant foci (Baker et al., 1975; Danner & Hartman, 1987). Chronic forms usually follow contiguous osteomyelitis of the vertebral column. Intravenous drug abuse is becoming a common etiological factor (Nussbaum et al., 1992). Though back surgery, lumbar puncture, and epidural anesthesia are recognized as possible precipitating events (Shintani et al., 1992), short-term epidural analgesia is not considered a major risk (Burstal et al., 1998), unlike chronic epidural analgesia (Smitt et al., 1998).

Microbiology

S. aureus is responsible for 60–90% of all cases of epidural abscess (Nussbaum et al., 1992); the remainder are caused by streptococci and gram-negative bacteria. A polymicrobial etiology is seen in only 10% of cases (Nussbaum et al., 1992; Danner & Hartman 1987).

Pathology

The majority (50–80%) of abscesses occur near the thoracic cord, followed by lumbar and cervical regions (Brock & Bleck, 1992; Baker et al., 1975), although in children the lumbar and cervical regions are more frequently involved. An abscess can occur on any side in relation to the spinal cord. Associated discitis or vertebral osteomyelitis, detectable by MRI, occurs in almost all cases. Granulation tissue containing loculated pus is the pathologic feature of an acute abscess, whereas, prominent fibrotic component is seen mainly with chronic cases. An abscess extends along the length of the cord, usually for about four or more segments (Baker et al., 1975) and may result in cord necrosis secondary to both direct pressure and vascular compression (Baker et al., 1975). Occasionally infection can spread into the subarachnoid space (Darouiche et al., 1992).

Clinical features

A spinal epidural abscess may present acutely or insidiously. Initially there is focal vertebral pain, followed by radicular pain along the involved nerve roots, and finally signs of spinal cord compression (Darouiche et al., 1992). Chronic epidural abscess may mimic epidural tumour in its presentation and lacks fever that usually accompanies the acute infections.

Diagnosis

Diagnosis of epidural abscess should be suspected in any patient with localized back pain, with or without radicular pain, occurring in a setting of infection (local or elsewhere). Nuchal rigidity and focal tenderness to percussion

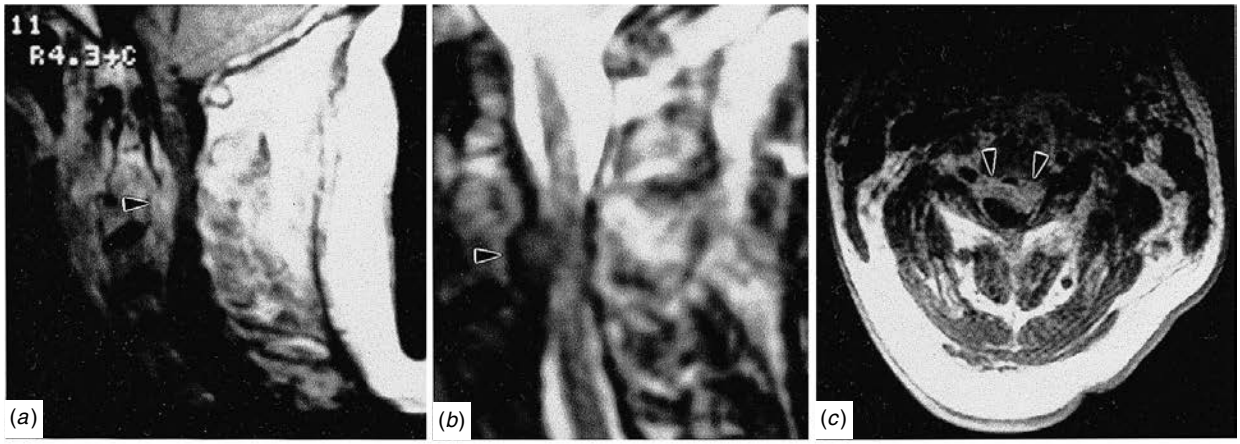

Fig. 106.6. Spinal epidural abscess: composite MRI scans showing (*a*) sagittal T_1-weighted contrast study with enhancing abscess (arrowhead) anterior to the spinal cord at C2; (*b*) T_2-weighted images showing cord compression from large anterior collection (arrowhead); (*c*) contrast-enhanced axial image showing enhancing abscess (arrowheads) deforming spinal cord. (Figure courtesy of Dr Justin C. McArthur.)

almost always follow the above signs, especially in an acute abscess. MRI is the first procedure of choice, and delay should be avoided in attempting to initially obtain plain films (Bleck, 1995) (See Figs. 106.5, for (*a*), see colour plate section, 106.6). Lumbar puncture is contraindicated for the risk of spreading of the infection into subarachnoid space.

Therapy

Epidural abscess is a surgical emergency. Delay in diagnosis or treatment results in permanent cord damage. Immediate surgical decompression and drainage is mandatory. Endoscopic surgical techniques are possible alternatives to open drainage in the future (Roselli et al., 1998). Patients with local pain alone and a small lesion might be managed with percutaneous CT-guided aspiration for a microbiologic diagnosis if close observation is assured. Antibiotic coverage should begin prior to surgery, either with nafcillin or vancomycin, and with the addition of a third generation cephalosporin in diabetic patients or those with a history of recent gram-negative infection elsewhere. In contrast to the other CNS infections, choice of antibiotics need not depend on the BBB permeability. Occasionally, antibiotic treatment alone might successfully treat the infection in cases of early abscess with minimal signs (Nordberg & Mark, 1998), but this should not be considered a standard treatment. Antibiotic coverage is indicated for about 3–4 weeks or 8–10 weeks in case of associated local osteomyelitis (Bleck & Greenlee, 2000c). A short course of corticosteroids may help with evidence of acute cord compression. Spinal stabilization procedures may be required in case of bony destruction. Good prognosis is seen in early institution of treatment prior to the onset of radicular treatment in addition to younger age (Khanna et al., 1996), with about overall neurological recovery in about 50% (Baker et al., 1975; Danner & Hartman, 1987).

Subdural empyema

The cranial subdural space is a potential space between the two outer layers of the meninges, the dura mater and the arachnoid. It is divided into multiple anatomical compartments by the falx cerebri, the tentorium, the base of the brain, and the foramen magnum, which confine infection within the space to these compartments. Although subdural empyema was first described by Sir Richard Bright in 1836 (Bleck, 1992), detailed clinicopathologic descriptions were only reported in the 1940s (Kubic & Adams, 1943; Courville, 1944). They account for 13–23% of intracranial bacterial infections (Harris et al., 1987; Mauser & Tulleken, 1984; Gallagher et al., 1998). Spinal subdural empyema is rare and usually metastatic.

Etiology and pathogenesis

Subdural infection, like brain abscess, usually develops in extension from contiguous sites via emissary veins or by extension from osteomyelitis of the skull (Brock & Bleck, 1992). In a majority of these latter cases, sinus infection is

the primary source (Dolan & Chowdhury, 1995). Rarely, it occurs through hematogenous spread from distant focus; in infants, it can be a complication of bacterial meningitis. The most frequently isolated organisms are aerobic streptococci or staphylococci; in a minority of cases, *S. pneumoniae, H. influenzae*, or other gram-negative bacteria are responsible. Unusual organisms such as *Salmonella* may be involved in immunocompromised patients (Aliaga et al., 1997; Parkers et al., 1995).

Pathology

Infection may involve any of the compartments of the subdural space, based on the source of the infection. Extension of the infection into the subarachnoid space is not common, but a focal inflammatory reaction is frequently present. However, focal osteomyelitis or epidural abscess is seen in about 50% of cases. Infection can also spread through septic thrombosis of veins into either the venous sinuses or to the cortical veins, resulting in hemorrhagic infarction and superficial brain abscess formation. Subdural empyema and the associated cerebral edema may result in rapid increases in ICP, unless the empyema is immediately surgically drained.

Clinical

Most cases present with fever, signs of raised ICP, and signs of meningeal irritation over a background of associated sinus or ear infection. Focal neurological deficits, alteration of consciousness, and seizures occur early in the course, with rapid worsening leading to signs of brain herniation and death, unless treated promptly. Rarely, the presentation may be more insidious, especially following craniotomy or with prior use of antibiotics. Fever, meningeal signs and focal neurological deficits should make one suspect this diagnosis. MRI with gadolinium contrast is superior to contrast CT scanning in the diagnosis of subdural empyema (Campbell & Zimmerman, 1994; Conlon et al., 1996). As with brain abscess, lumbar puncture is contraindicated in subdural empyema secondary to risk of herniation and in addition, CSF changes are non-specific.

Therapy

Surgery is the mainstay of the treatment of subdural empyema. Early subdural empyemas, deemed by some too small to be surgically drained, are occasionally managed with antibiotics, but in our experience this is rarely successful. The clinical state of the patient should direct the choice of therapy, as imaging techniques can sometimes underestimate the actual volume of the empyema. Open craniotomy is the preferred approach for drainage. In early cases however, some authors believe that burr hole drainage may be sufficient (Ak et al., 1996). The collected purulent material should be processed to identify the organism. Treatment of the infection in contiguous sites is important. Antibiotic therapy should be given at least for 3 weeks.

Prognosis

Permanent neurological sequelae rapidly result with any delay in the treatment, and often occur no matter how rapidly the diagnosis is made and treatment commenced. Mortality also depends on the clinical state at the time of presentation, the age of the patient, and coexistent immunosuppression.

Neurocysticercosis

Life cycle of *Taenia solium*

The infection caused by the complex Taeniasis/cysticercosis in humans represents a rather peculiar phylogenetic encounter between *Taenia solium*, the most evolved cestode parasite (order cyclophyllidea, family taeniidae) (Willms, 1992) and human, the most evolved mammal (order primates, family hominidae). Both protagonists are endowed for survival with sophisticated biological mechanisms. In fact, rather than being another infection, cysticercosis is the transplant of the embryo of *Taenia solium*, into the tissues of the intermediate host (pork and humans) where it hatches in the intestine and is transported, by the blood stream, to tissues to become a larva. For the cycle to be completed a human must ingest, undisturbed and intact, a cysticercus whose size is between 0.5 and 1 cm diameter. The unique source of this larva is undercooked pork meat; it is truly amazing to observe that the cyst survives not only the cooking process but also the powerful masticatory movements and the fast intestinal passage. Once within the digestive tract, the metacestode (larva), measuring between 1 and 2 mm evaginates from the cyst and strongly attaches itself to the intestinal wall with the aid of its four suckers and a double chain of hooks. Two months later, a cestode measuring 2–4 metres long has developed; thereafter, every day, a few mature progglotides spontaneously detach, each containing several thousand fertilized eggs, which in turn will pollute areas with deficient sanitary installations and inadequate disposal of human feces. When contaminated food is ingested either by pigs or humans, cysticercosis develops in these new hosts. In a strict sense, only cysticercosis in pigs and taeniasis in humans are favourable for the perpetuation of the parasite; cysticercosis in humans is a failed attempt, since cannibalism would be the only possibility for a cysticercus in human muscle or brain to develop to the cestode stage in the intestine of another human. Nonetheless, neurocysticercosis (NCC) is the most frequent and severe parasitic disease of the nervous system of humans.

The presence of a whole cyst larva within the brain provokes a far more complicated immune response of rejection or tolerance than would be the case for other less complex infectious agents (Del Bruto et al., 1998). A cysticercus is an intermediate stage of the organism, with its own nervous system (Fig. 107.1, see colour plate section), capable of active mechanisms of immune-evasion. The host, in dealing with this parasite may also produce an unpredictable immune response, which varies in immunocompetent individuals, from a hyperimmune response with fast elimination of the parasite to a remarkable tolerance in which the cysticercus survives in the brain for several years, with membranes that may grow to a very large size of 10–15 cm diameter.

Clinical characteristics of neurocysticercosis

Most cysticerci (around 80%) lodge in the brain parenchyma; the second location is meninges (around 18%); far less frequent are the ventricles, eye, and spinal cord (around 2% of all cases). As would be expected, clinical symptomatology may include a wide variety of syndromes dependent on the location and number of lesions (Castillo et al., 1996; Salgado et al., 1997), in fact, almost any neurological sign can be caused by NCC (Pitella, 1997). In this regard, its clinical expression is similar to that of multiple sclerosis where severity and clinical manifestations depend on number and location of lesions. Clinical signs of NCC are so varied that in neurological wards of endemic countries the diagnosis of NCC is entertained as a possibility at initial consultation in one-third of all neurological patients, regardless of their specific symptomatology (Del Brutto et al., 1998).

Some syndromes are associated with the two most frequent locations of parasites. In parenchymal cysticercosis epilepsy is conspicuous (Del Brutto et al., 1994); while in meningeal cysticercosis hydrocephalus is common (Estañol et al., 1986). These disorders are so closely related with NCC that in endemic areas the main causes of late-onset epilepsy and of hydrocephalus in adults are parenchymal and meningeal cysticercosis, respectively (Medina et al., 1990). As the main age for presenting symptoms of NCC is between 20 and 40 years, in any adult who presents a seizure or has hydrocephalus the diagnosis of NCC must be strongly suspected. Brain cysticercosis is far more frequent in adults than in children with an approximate ratio of 8/1. Thus, these two disorders, epilepsy and hydrocephalus, whose etiology in children might be due to several causes, in adults are usually related to NCC (Medina et al., 1990; Monteiro et al., 1991). In addition, a wide variety of neurological signs can also be present, the more frequent being motor and sensory disturbances, cranial nerve dysfunction due to basal arachnoiditis, persistent vascular headache due to cysticercotic vasculitis (Rodríguez-Carbajal et al., 1989); tumour-like syndromes due to giant cysts or clumps of cysts (Ramina & Hunhevicz, 1986); psychiatric syndromes due to scattered cysts in brain parenchyma; small and large brain infarctions due to vasculitis; and encephalitis due to diffuse brain edema.

Table 107.1. Cysticercosis classification

I	Brain parenchyma
	1 Cysts
	2 Colloid cysts
	3 Granulomas
	4 Calcifications
	A Single
	B Multiple
	C Racemose
	D Edema
	E Infarction
	F Inflammation
II	Subarachnoid space
	1 Cysts in cortical sulci
	2 Cysts in basal cisterns
	3 Arachnoiditis
	A Inflammation
	B. Hydrocephalus
	C Fibrosis
III	Ventricular system
	1 Lateral ventricles
	2 3rd and 4th ventricles
	A Hydrocephalus
	B Ependymitis
IV	Spinal canal
	1 Intramedullary
	2 Subarachnoid
	A Single
	B Multiple
	C Inflammation
	D Fibrosis
V	Ocular cysticercosis
	1 Vitreous cavity
	2 Subretinal
VI	Extraneural cysticercosis
	1 Muscular
	2 Systemic

Diagnosis of NCC

The clinical possibility of NCC might be suspected in a large number of patients, however, the only way to confirm the diagnosis is with the aid of neuroimaging studies, computed tomography (CT) and magnetic resonance (MR); as well as with the analysis of cerebrospinal fluid (CSF), including immunodiagnostic assays (either immunoblot, ELISA or complement fixation) (Table 107.1; Salgado et al., 1997; Téllez-Girón et al., 1987). Each of these diagnostic studies has advantages and limitations in the complex picture of NCC (Spina-Franca et al., 1993).

The main advantage of CT is the reliable localization of cysts, granulomas and calcifications (Chandy et al., 1989), the last two are the most frequent remnant lesions left by parenchymal cysticercosis (Chayasirisobhon et al., 1999); its relatively low cost makes it the study of choice for screening of NCC cases. Limitations of CT include low definition for visualization of cysticerci located at the base of the skull, fourth ventricle, eye and spinal cord. Besides, it has a lower image resolution than that achieved by MR for the analysis of perilesional histological abnormalities such as inflammation, edema and fibrosis (Salgado et al., 1997).

The main advantages of MR are the detection of NCC lesions (see Fig. 107.2, see colour plate section) in the areas mentioned above where CT has limitations, also the high resolution of MR allows a precise characterization of cyst viability according to the characteristics of fluid contents (viable cysts susceptible to cysticidal therapy are those whose fluid has image intensity similar to that of ventricular CSF, it changes to hyperintense soon after successful cysticidal therapy) (Martinez et al., 1989; Salgado et al., 1997). MR also provides detailed information on tissular abnormalities around cysticerci. The main disadvantages of MR are its higher cost and the difficulty in detecting granulomas and calcifications (Salgado et al., 1997).

The main advantages of CSF analysis are: the quantifica-

tion sof the inflammatory response in the subarachnoid space (increased cell and protein contents); the search for common, although non-specific findings (eosinophils and pleocytosis of mononuclear cells) and the accessibility for performing immunodiagnosis of NCC, which is particularly valuable in cases of hydrocephalus, vasculitis or chronic arachnoiditis that are not accompanied by specific features of NCC on imaging studies (such as cysts or granulomas). The main limitations of CSF analysis are the obvious difficulties posed by the need to carry out lumbar puncture, and those cases of parenchymal brain cysticercosis without inflammatory reaction in the subarachnoid space in which the immunodiagnostic tests might be negative even in the presence of active forms of NCC demonstrated by imaging studies. This feature makes the sensitivity of immunodiagnostic tests in CSF highly dependent on the presence of inflammation signs (increased cells and proteins) in CSF. Thus, in cases of NCC with inflammatory signs in CSF the sensitivity of ELISA and immuno-blot is high, around 95%; but decreases to about 50% when the CSF has no signs of inflammation. Nevertheless, specificity in both instances is good (around 98%). Therefore, immunodiagnostic tests in CSF are of great help when the interpretation of results is made within the context of the cytochemical results and imaging studies (Chang et al., 1988). In contrast with CSF, immunodiagnostic tests practiced in serum are unreliable for NCC diagnosis (Ramos-Kuri et al., 1992); there is a high frequency of false-positives (30%) in healthy individuals from endemic areas who have been in contact with the parasite but have not developed the disease or who have cross-reacting antibodies due to other parasitic diseases or who have muscle cysticercosis (Larralde et al., 1989). Also, false-negative results in tests on serum from NCC patients are frequent (20%) in cases of a single cysticercus in brain parenchyma with little or no evidence by imaging studies of inflammatory reaction around the parasite. More important, immunodiagnostic studies are usually negative in patients with epilepsy secondary to granulomas and calcifications without active forms of the disease (Rajshekhar, 1991); this is a very frequent presentation of NCC (over 30% of all cases).

Comprehensive treatment of NCC

Different pathological processes may participate in the clinical picture of NCC, each must be treated accordingly (Del Brutto et al., 1998). Some are due directly to the presence and growth of the parasite, some to the intensity of the inflammatory reaction developed by the host, some to the neurological disturbances induced by the tissue lesion, while others are due to the mechanical obstruction of the CSF transit and absorption. Therefore, treatment must be individualized, the independent therapeutic approaches are: (i) treatment with cysticidal drugs, (ii) anti-inflammatory treatment, (iii) symptomatic treatment and (iv) surgical treatment.

Treatment with cysticidals

Albendazole (ALB) and Praziquantel (PZQ) are highly effective cysticidal drugs; both are remarkably atoxic and have a good pharmacological profile (Cruz et al., 1991; Kim, 1999; Sotelo et al., 1990; Takayanagui & Jardin, 1992). Fast destruction of parenchymal cysticerci after a single course is obtained in 75–85% with ALB and in 65–75% with PZQ. In cases of cysts resistant to an initial course with either drug, the use of the alternative drug increases its effectiveness. In this way; destruction of more than 95% of viable parasites can be achieved, as shown by imaging studies, with the sequential use of ALB and if necessary with PZQ, or vice versa. The drug scheme of ALB that has been validated in most studies is 15 mg/kg/day during 1 week (Cruz et al., 1995; Sotelo & Jung, 1998); the drug is administered every 12 hours. ALB is effective against cysticerci located almost anywhere; brain parenchyma, muscle, subarachnoid space, ventricles and even within the eye (Lozano-Elizondo & Barbosa-Horta, 1990; Puri & Grover, 1998). In the latter, when the cyst is located in the vitreous body ALB kills the parasite, which has to be excised by surgery, in contrast, when the cyst is subretinal the parasite is destroyed and the debris are removed by the endogenous immune mechanisms which prevent the damage induced by surgical extraction.

Pharmacological studies have delineated two schemes of PZQ therapy, the 'traditional' lasts 2 weeks at doses of 50 mg/kg/day administered every 8 hours (Leblanc et al., 1986; Robles et al., 1987; Wadia et al., 1988): alternatively, a brief scheme of a single day has recently been designed (Corona et al., 1996); PZQ is given at a total dose of 75 mg/kg divided in three doses of 25 mg administering one every 2 hours (e.g. at 7, 9 and 11 am) on the same day. The pharmacodynamic foundation for this design is that the drug is promptly absorbed in the gastrointestinal tract; it reaches its maximum peak of plasma levels with cysticidal efficacy within two hours, decreasing soon afterwards. With the traditional scheme, high plasma and CSF contents of PZQ are achieved only for brief and sporadic moments during treatment (Overbosch et al., 1987); with the new scheme, high plasma contents of PZQ are obtained 2 hours after the first dose, and an additional dose maintains this level and a third one 2 hours later keeps the drug level higher, so that a lasting plateau of about 5–6 hours of high plasma and CSF contents of PZQ is obtained. This scheme has shown in initial clinical

studies to be as effective as the two week scheme (Del Brutto et al., 1999; Rajshekhar, 1991), with the additional advantage of being 10 times less expensive, 10 times lower total dose and 15 times shorter duration. Also, patients are treated at the outpatient clinic and the adherence to treatment can be supervised. Moreover, it has been recently demonstrated that plasma levels of PZQ are greatly increased when it is administered jointly with cimetidine (Jung et al., 1997) and with a high carbohydrate diet (Castro et al., 2000), these circumstances could further improve its therapeutic efficacy. The only drawback of PZQ is that it is less efficacious than ALB in the treatment of parenchymal and subarachnoid cysticercosis and it is not effective in ventricular and ocular cysticercosis.

Some early studies challenged cysticidal therapy arguing that in some cases the presence of the parasites in the brain causes discrete symptomatology (usually epilepsy) that can be managed with symptomatic therapy and that cysticidal treatment may prompt unwanted symptoms (Moodley & Moosa, 1989). In our experience cysticidal treatment should be given to all patients with active forms of the disease for the following reasons (Sotelo & Jung, 1998): (i) the drug treatment is highly effective, atoxic, brief and inexpensive; being so convenient there is no reason to leave to its natural course the presence of live parasites within the brain. Even in cases when they look clinically 'harmless', chronic fibrosis and astrogliosis develop in the surrounding area, becoming the principal source of long-term refractory epilepsy (Del Brutto et al., 1992; Gupta et al., 1999). Furthermore, cysticerci left untreated leave, as seen by prospective imaging studies, a remnant granuloma (Nash & Patronas, 1999; Sheth et al., 1998), whereas most cysticerci successfully eliminated by cysticidals disappear without the development of remnant granulomas (Ramos-Kuri et al., 1992); (ii) Secondary reactions are prevented by adequate steroid therapy; (iii) although at any given moment the symptomatology caused by the parasite might be mild, the natural course will follow two possible ways, either the cysticercus will grow over the years to reach a giant size of 15–20 cm long or it will spontaneously die, eliciting an acute immune reaction that is supposedly avoided by withholding the drug treatment (Caparros-Lefebvre et al., 1997); (iv) recent studies have suggested that the chronic presence of NCC may induce hematological or neurological malignancies in humans (Herrera et al., 1999).

Anti-inflammatory treatment

Inflammation, with various degrees of intensity is the conspicuous accompaniment of cysticercosis. In many cases it is responsible for neurological damage, rather than the parasite itself (Joubert, 1990). The inflammatory reaction may last years in the subarachnoid space or brain parenchyma causing pachymeningitis and calcified granulomas. Inflammation is the cause of vasculitis that may induce brain infarctions and obstruction of CSF absorption by the arachnoid villi (Del Brutto, 1992), with development of hydrocephalus. Acute exacerbation of inflammation is also the result of the parasite death, which may occur spontaneously or be mediated by the immune reaction, or by cysticidal treatment. Two schemes of anti-inflammatory therapy are used either for acute or for chronic inflammation. Treatment is based mostly on steroids, usually dexamethasone, aided in severe cases by immunosupressants suds as azathioprine or methotrexate. No studies have been reported with the use of selective immunosupressants such as cyclosporin.

Acute anti-inflammatory treatment is used mostly in two instances; as adjuvant of cysticidal treatment and as treatment of brain edema in cases of cysticercotic encephalitis. Cysticidal treatment may be accompanied by a brief period of exacerbation of neurological symptomatology such as headache, nausea, vomiting and occasionally seizures; this picture is caused by the acute destruction of parasites, it usually starts on the second day of treatment and spontaneously disappears two or three days later. These reactions may even be taken as a reliable predictor of successful treatment. Nevertheless, nowadays with the new pharmacological schemes these disturbances are prevented and in a great majority of cases the cysticidal treatment is uneventful, minimizing the anxiety by the practicing physician of clinical disturbances elicited by the cysticidal treatment. As dexamethasone increases the plasma levels of ALB by 50%, its addition favours the pharmacodynamics of treatment (Jung et al., 1990). Administration of 20 mg of oral dexamethasone once a day during the first 4 days of ALB therapy prevents secondary reactions in most patients, the other four days ALB is administered alone. In cases of retinal or ventricular cysticercosis treated with ALB longer courses of dexamethasone and retroocular steroids are used.

Dexamethasone interferes with the metabolism of PZQ, lowering its plasma levels by 50%. Therefore, in the traditional scheme of two weeks PZQ therapy the use of dexamethasone may be reserved as immediate therapy for those cases that present headache or secondary reactions. It can be assumed that when physical complaints develop, the parasites have already been affected, so, at this time 20 mg of IM dexamethasone are given. With this measure the symptoms abate a few minutes after the injection of dexamethasone. With the new scheme of a single day PZQ therapy the rationale for steroid administration is differ-

ent: subsequent to the three consecutive administrations of PZQ, the cysticidal effect lasts about 5 hours during the morning and disappears by the afternoon, when the plasma levels of PZQ drop. At this time, the parasites have already been targeted and it is the proper time for anti-inflammatory therapy, 20 mg of oral dexamethasone early in the afternoon and the next two days will prevent acute inflammatory reactions and clinical disturbances.

In many NCC patients chronic anti-inflammatory treatment is necessary, this is particularly important in arachnoiditis where activated immune cells and cell-mediators are distributed throughout the CNS by the CSF circulation producing widespread damage which can persist for several years. This has been called the 'malignant' form of NCC with a mortality rate of 50% within 2 years of diagnosis (Estañol et al., 1986). In these cases, sustained anti-inflammatory treatment is particularly important. Good results have been obtained with 50 mg of prednisone in a single oral dose administered three times a week (e.g. Monday, Wednesday and Friday). This schedule can be maintained for years minimizing the effects secondary to the chronic therapy with steroids (Suastegui-Roman et al., 1996). Follow-up should be made with periodic CSF analysis aiming to lessen the inflammatory signs.

Symptomatic treatment

Seizures secondary to cysticercosis must be managed according to the standard guidelines for treatment of epileptic disorders (Del Brutto et al., 1998). Some features of epilepsy are common in NCC patients: partial seizures with or without secondary generalization are more frequent than generalized seizures. In endemic areas it is common to find previously asymptomatic young adults, who have late-onset epilepsy secondary to a single calcified granuloma in brain parenchyma. This feature indicates that a cysticercus may lodge in the brain remaining alive for an undetermined period; afterwards, it dies either spontaneously or secondary to the endogenous immune response and a granulomatous scar develops which, in turn, becomes calcified over the years. All these events may be clinically silent; later, at any given time epilepsy develops without any evidence of active NCC. In many such cases, seizures are difficult to control with antiepileptic drugs (Del Brutto et al., 1998; Pradhan et al., 2000), in contrast with seizures secondary to live cysts that usually respond well to treatment (Vazquez & Sotelo, 1992). Therefore, every attempt should be made to prevent the development of granuloma as sequelae to the death of the parasite (Pradhan et al., 2000), cysticidal therapy must be administered soon after the diagnosis of NCC.

Symptomatic treatment should be individually designed according to each of the many clinical manifestations of NCC such as vascular headache, vertigo, psychiatric disturbances etc. Also, rehabilitation programs for neurological sequelae must be designed for diplopia, paresis, etc. (Del Brutto et al., 1998).

Surgical treatment

Nowadays, surgery has been limited mostly to the few cases of cysts refractory to cysticidal treatment: to ventricular shunting for treatment of hydrocephalus, and to ocular cysticercosis (Del Brutto et al., 1998).

Cerebral malaria

Cerebral malaria (CM) is the most severe complication of *Plasmodium falciparum* infections, the only species of plasmodia with CNS involvement (Hamer & Wyler, 1993). Severe *P. falciparum* malaria is one of the most lethal parasitic infections. It is responsible for more than a million deaths yearly in African children (Newton & Krishna, 1998). It is estimated that the syndrome causes death in 20–50% of all cases, infected children and adolescents being at high risk in endemic areas (Roman & Senanayake, 1992).

The pathogenesis of CM is caused by the sequestration of parasitized red blood cells in the cerebral microvasculature. Knobs, which appear on the membrane of infected erythrocytes, adhere to the vascular endothelium causing obstruction of small blood vessels (Aikawa et al., 1990; Turner, 1997). It is still unclear, however, how entrapment and clogging of small blood vessels result in the clinical expressions of cerebral dysfunction. A major line of inquiry has been the study of inflammatory cytokines such as tumour necrosis factor (TNF) which are overproduced in sepsis and infectious diseases, and which in turn induce widespread endothelial cell activation as well as focal endothelial cell damage and necrosis. It has been suggested that the local production of TNF by cerebral endothelial cells activated by infected erythrocytes, triggers the production of nitric oxide, which leads to cerebrovascular dilatation, increased cerebrospinal fluid pressure and defective neurotransmission (Clark et al., 1992, 1997).

Clinical manifestations of CM include altered cognitive functions, behavioural changes and hallucinations; major motor seizures and occasionally hemiparesis, Babinski sign, tremors, myoclonus and choreiform movements. Hypoglycemia is a frequent finding in severe cases and may aggravate manifestations of CM. In children, the febrile convulsions may be difficult to distinguish from

CM. Neurological sequelae have been described in patients recovered from the disease, but have not been widely documented, they appear to be more frequent in children than in adults (Nguyen et al., 1996).

Diagnosis of malaria is established by identification of parasitized erythrocytes on Giemsa stained blood smears. These should be prepared only fresh from finger or earlobe pricks and examined by trained personnel. In all cases of suspected falciparum malaria, it is recommended that a number of slides be prepared during the day until infected red blood cells are identified. In highly endemic areas, efforts should be made to quantify the parasitemia in order to administer the best possible supportive treatment.

P. falciparum malaria is a medical emergency! Treatment should be instituted immediately in order to avoid complications such as CM. Specific antimalarial treatment should consider the geographic area where the patient acquired the infection, since chloroquine and fansidar resistant strains are widespread in all regions. Chloroquine resistance has not been reported in: Dominican Republic, Haiti, Central America west of the Panama Canal and the Middle East. Fansidar resistant strains have been documented in Brazil, Panama, Vietnam, Kampuchea, Myanmar, Thailand, East Africa, Papua New Guinea, Vanuatu and Irian Java.

Updated information on the risk for malaria by country as well as appropriate preventive measures are available through the Centers for Disease Control in the US (Tel. 404 639 1610) 24 hours a day.

Laboratory results in acute malaria include: anemia (normocytic normochromic), thrombocytopenia, decreased lymphocyte and neutrophil counts, and hypoglycemia (Perrin et al., 1982).

Prognosis of CM continues to be poor. Current treatment includes injectable quinine in doses that vary from 10 to 20 mg/kg every 8 h (van der Torn et al., 1998); in distant areas with difficulties for medical implementation oral mefloquine in a single dose of 25 mg/kg through a nasogastric tube seems a good alternative (Di Perri et al., 1999). Addition of allopurinol (4 mg/kg every 8 h during 5 days) enhances the therapeutic effect of quinine (Sarma et al., 1998). There is evidence that activated microglia plays an important role on the pathogenesis of CM; acute adjuvant immunosuppressive and anti-inflammatory treatment similar to that used for other parasitic diseases, such as NCC should be evaluated.

African trypanosomiasis or sleeping sickness

Two species of trypanosomes cause sleeping sickness: *Trypanosoma brucei gambiense* and *Trypanosoma brucei rhodesiense*. Transmission of the infection occurs in focal areas of sub-Saharan Africa by the tse-tse fly (*Glossina*), which inhabits riverbanks and highly humid areas (Kurzoe, 1993). CNS involvement usually manifests itself several months after the mosquito bite, which produces a trypanosomal chancre at the site of the mosquito bite. The organism spreads slowly from the site of infection and eventually to bloodstream, lymphatics and other interstitial spaces, where the parasites continue to multiply. Hallmark of the infection are the recurring waves of parasitemia, which last for months or years, and are the result of antigenic variation encoded in the genome of these parasites. Each episode of parasitemia increases until enough serum antibodies area are produced to cause a sharp drop in the number of parasites. Parasites that have different surface antigens variants (Borst & Rudenko, 1994) escape destruction by the first wave of antibodies, duplicate and produce a new parasitemia wave. The CNS becomes infected after months or years, however, the pathogenesis of cerebral trypanosomiasis is not well understood. Signs and symptoms are pleomorphic and may include: personality changes, loss of concentration, persistent headaches, seizures, motor deficits (tremors, choreoathetosis, ataxia) and eventually coma. A rather unique feature of the disease is the daytime somnolence, due to disruption of normal circadian sleep and wakefulness patterns (Buguet et al., 1993).

Definitive diagnosis of the disease is made by observation of trypanosomes in blood, CSF or lymphatic fluid. The morphological characteristics can be established on Giemsa or Wright stained slides. Since neurological disease caused by African trypanosomes is almost always fatal, it is recommended that the CSF be examined in all patients.

Treatment should be administered as early as possible, before the CNS becomes infected. The recommended drugs are: pentamidine isothionate, Suramin, Melarsoprol and Effornithine. All of them are toxic and expert assistance should be sought before prescribing treatment, and can be obtained from the Centers for Disease Control and Prevention in Atlanta, GA.

Other protozoan infections with CNS involvement

Toxoplasma gondii

Congenital toxoplasmosis is a consequence of maternal infection with oocysts during the first and second trimester of pregnancy. Oocysts are transmitted in households from infected cats, which harbour the sexual stages in the intestine (contaminated litter boxes) and infected raw meat (beef, lamb and pork).

Naegleria fowleri

N. fowleri is a free-living ameba, and when the trophozoite is aspired into the nasal cavity can penetrate the nasal mucosa, enter the submucosal nerve plexus and gain access to the CNS, a pathway that has been demonstrated experimentally in mice (Jarolim et al., 2000) *Naegleria* is found worldwide in fresh water bodies and soil.

In the CNS the amebas cause acute meningo-encephalitis (AME), with fulminating necrosis of the meninges and brain; most documented cases have been fatal (Carter, 1968; John, 1982). The disease is rare and difficult to diagnose because of the short period between onset and the clinical picture of meningo-encephalitis, a time lapse of 72 h. The course of AME is dramatic at onset with intense headache, fever of 39–40 °C and anorexia. Later symptoms include nausea, vomiting and signs of meningeal irritation. Patients are confused and irritable and may present convulsions before falling into coma. The disease is typically seen in children and adolescents who have been swimming in freshwater lakes, pools, streams, ponds and hot spring waters in which the temperature is high.

No satisfactory treatment has been found for *Naegleria*. High doses of amphotericin B (1–15 mg/kg for 6 days) have been reported to cure a few cases.

Helminth parasites with CNS involvement

All helminthic infections with tissue migrating larval stages are potentially capable of inducing CNS disease. In practice, only a few need be taken into account when considering differential diagnosis. Eosinophilic meningitis is a frequent finding in gnathostomosis and angiostrongilodosis, both acquired by ingesting raw seafood.

Gnathostoma spinigerum is a disease contracted in countries where raw freshwater fish is routinely consumed (Japan, Thailand, China, Philippines, Korea, Malaysia, India, Vietnam, Taiwan, Bangladesh and Myanmar). In America cases have been documented in Mexico, Ecuador and Colombia. The larval stage in infected fish can traverse the intestinal wall of humans and migrate to various tissues, more often inducing the clinical entity of cutaneous larva migrans. In Thailand, a number of cases of eosinophilic meningo-encephalitis have been reported (Puri & Grover, 1998). Diagnosis can be established in suspected cases by ELISA using adult worm antigen (Diaz Camacho et al., 1998). Eosinophilia is also frequent in these nematode infections. The antihelminthic albendazole has been used for treatment of cutaneous gnthostomosis, although results have not always been satisfactory.

Other helminthic infections associated with eosinophilic meningitis are *Angiostrongylus cantonensis*, a rat lungworm that is acquired by ingestion of raw fish, snails and molluscs. It is endemic in the Far East, Pacific Islands and Hawaii.

Schistosoma, *Paragonimus westermanni* and *Strongyloides* infections should also be considered in patients with persistent meningeal signs in the absence of eosinophilia, particularly when they have a history of travel to endemic areas and present specific manifestations of helminth infections outside the CNS.

Lyme disease

Patricia K. Coyle

Professor of Neurology, School of Medicine, State University of New York at Stony Brook, Stony Brook, NY, USA

In the mid-1970s several dozen patients living near Lyme Connecticut developed an illness, initially misdiagnosed as juvenile rheumatoid arthritis, and subsequently called Lyme arthritis (Steere et al., 1977). It was renamed Lyme disease when its systemic nature was appreciated. In retrospect, skin and neurological manifestations of Lyme disease had been described in Europe for decades, and had even been recognized as antibiotic responsive (Coyle, 2000). Lyme disease is a multisystem infection due to the spirochete *Borrelia burgdorferi*. This spirochete, named after its discoverer Willy Burgdorfer, is present in hard body ticks of the *Ixodes ricinus* family (Burgdorfer, 1984). *Ixodes* ticks feed on a variety of hosts, including humans. Virtually all transmissions occur through tick bite, although there have been rare congenital cases. To date, there have been no documented blood transfusion cases (McQuiston et al., 2000). Lyme disease is one of the major emerging pathogen infections. It has generated significant publicity and controversy, and has become a focus of interest for both lay action groups and the popular press.

Spirochetal infection

B. burgdorferi is a spirochete. Spirochetes are gram negative bacteria that belong to a distinct eubacterial phylum (Benach & Coleman, 1993; Reik, 1987). They are flexible cells with a helical configuration, excessive length to diameter ratios of up to 100 to one, and flagella that lie between inner and outer cell membranes. These endoflagella convey motility properties. Of the four recognized human spirochetal infections which cause neurological disease, all show frequent central nervous system (CNS) seeding during the spirochetemic stage (Table 108.1). CNS infection may be inapparent, or associated with clinical disease. Spirochetes can also persist silently within the CNS, only to cause late neurologic problems months to years after initial infection. These spirochetal disorders have a number of features in common (Table 108.2). The shared features provide guidelines to think about Lyme disease.

Organism

Borrelia spirochetes have coils which are spaced irregularly 2 to 4 micrometres (μm) apart (Benach & Coleman, 1993). *B. burgdorferi* is easy to culture from ticks, but difficult to culture from patients. The spirochete is 11 to 39 mcm long. It consists of a central protoplasmic cylinder, with seven to 12 attached periplasmic flagella, surrounded by an outer cellular membrane and covered by a carbohydrate-containing slime layer (Rosa, 1997). The *B. burgdorferi* genome has been completely sequenced, including its 12 linear and nine circular plasmids (Casjens et al., 2000; Fraser et al., 1997). *B. burgdorferi* shows significant genetic diversity (Mathiesen et al., 1997). Although there are at least ten genospecies in the *B. burgdorferi sensu lato* complex, only three are well documented to cause Lyme disease (Table 108.3). *B. burgdorferi* gene expression varies depending on whether the spirochete is in the tick vector, the host, or the test tube. Organisms can clearly adapt rapidly. Environmental triggers, such as ambient temperature or exposure to a blood meal, change gene expression. The fact that genes can change, with differential antigen expression, probably influences pathogenicity. Recent studies support strain differences in organotropism and virulence, and there are likely to be neurotropic and neurovirulent strains. *B. burgdorferi* is quite heterogeneous, with differences in protein expression, plasmids, and DNA between organisms. Variable major protein-like (Vmp) sequences have recently been described in *B. burgdorferi*, which could be involved in antigenic variation similar to that described in relapsing fever.

Table 108.1. Human spirochetal infections which cause neurological disease

Genus	Spirochete	Disease	Transmission	CNS seeding	Culture
Treponema	*T. pallidum*	Syphilis	Sexual contact	Up to 40%	Not possible
Leptospira	*L. interrogans*	Leptospirosis	Animal exposure	Up to 90%	High yield
Borrelia	*Borrelia* species (multiple)	Relapsing fever	Tick (endemic), or louse (epidemic) bite	Up to 50%	Low yield (but easily visualized)
Borrelia	*B. burgdorferi*	Lyme disease	Tick bite	Up to 40%	Low yield (not easily visualized)

Table 108.2. Shared properties of spirochetal infections

Skin or mucous membrane entry portal
Neurotropic and neurovirulent spirochete strains
Frequent CNS invasion during spirochetemia
Clinical disease stages, separated by quiescent periods
Broad clinical spectrum
Causes chronic persistent infection
Produces vasculopathy
Jarisch Herxheimer reaction may occur with initiation of antibiotics

Table 108.3. *B. burgdorferi sensu lato complex*

	Associated with Lyme disease
Genospecies	*Comment*
B. burgdorferi sensu stricto	North America; less so Eurasia Less genetic diversity Neurologic, dermatologic, rheumatologic disease
B. afzelii	Eurasia More genetic diversity Dermatological disease
B. garinii	Eurasia More genetic diversity Neurologic disease
	Not associated with Lyme disease
	B. andersonii *B. bissetti* *B. japonica* *B. lusitaniae* *B. tanukii* *B. turdae* *B. valaisana*

B. burgdorferi is a very tissue-tropic organism. Spirochetes do not tend to float free within body fluids, which probably explains the low culture and polymerase chain reaction (PCR) yield from cerebrospinal fluid (CSF). They will bind to endothelium, to platelets via integrins, and to most mammalian cells via glycosaminoglycans. In the host *B. burgdorferi* is often associated with extracellular matrix collagen fibres. This may involve the spirochete-specific decorin binding proteins A and B. In vivo, *B. burgdorferi* is always extracellular. Intracellular localization has only been described in vitro, and is therefore of uncertain significance.

Epidemiology

Lyme disease represents 96% of the vector-borne infection in the United States. It is also the most common vector-borne infection in Europe (Githeko et al., 2000). *B. burgdorferi* is the most common CNS bacterial pathogen in Sweden, and is an important pathogen in Germany, Austria, and Switzerland. A central feature of Lyme disease is that it is a highly focal disorder, geographically restricted to areas where the tick vector is found. In the United States *Ixodes scapularis* (Northeast, mid-Atlantic, and upper Midwest) and *I. pacificus* (upper Pacific coastal region) are the main vectors. *I. ricinus* is the major vector in Europe, and *I. persulcatus* in eastern Europe/Asia. *Ixodes* ticks have a two year, three stage (larva, nymph, adult) life cycle, and only feed a total of three times. These ticks are very small and easy to miss, and their bite is painless (Shapiro & Gerber, 2000). They will feed to repletion, and can remain attached for days. Infected ticks probably need to feed for 24 hours or longer to passage spirochetes (Sood et al., 1997). Within endemic areas, in the Northeast and Midwest, 30% or more of ticks may be infected. Even within these areas, small geographic differences may be associated with extreme variations in the number of infected ticks. The infection rate is much lower ($\leq$5%) for

Table 108.4. Lyme disease stages

Stage	Syndromes	Comments
Early local infection	Erythema migrans (EM) Flu-like illness with seroconversion	Occurs within 1 month of infection EM is the major Lyme disease syndrome, and the only pathognomonic clinical marker Flu-like syndrome may reflect dissemination
Early disseminated infection	Multifocal EM, lymphocytoma cutis (LC) Arthralgias, myalgias, brief arthritis/myositis Conduction block, myopericarditis, pancarditis Conjunctivitis Meningitis/meningoencephalitis, cranial neuropathy, acute painful radiculoneuritis	Occurs within 3 months of infection LC occurs outside North America Cardiac involvement has become rare Ocular involvement is uncommon
Late stage infection	Acrodermatitis chronica atrophicans (ACA) Oligoarticular arthritis, chronic arthritis Uveitis, keratitis Encephalopathy, chronic polyradiculoneuropathy, encephalomyelitis	Occurs 3 months or longer after infection ACA occurs outside North America Arthritis is more common in North America Ocular involvement is very uncommon

I. pacificus in the West, with a consequent lower number of Lyme disease cases from this region. Although ticks have a limited number of preferred hosts, they can feed on over 100 different species. Humans are accidental hosts, and in temperate climates are most likely to be bitten by questing nymphs during late spring and early summer.

Lyme disease occurs in over 50 countries worldwide (Shapiro & Gerber, 2000). In the United States cases have been reported from 49 states and the District of Columbia (Orloski et al., 2000). However, most are confined to 100 counties in 10 states. Over 90% of cases come from ten states: New York, Connecticut, Pennsylvania, New Jersey, Wisconsin, Rhode Island, Maryland, Massachusetts, Minnesota and Delaware. Although more than 160 000 cases have been reported to the Centers for Disease Control and Prevention (CDC), this is probably a significant underestimate. The incidence approximates 5 cases per 100 000 population; in endemic areas 1 to 3% of the population area are affected each year. Lyme disease-like cases have been reported in the South (Barbour, 1996; Kirkland et al., 1997). Although the tick vector is present, *B. burgdorferi* has not been documented within resident ticks. A different tick, *Amblyomma americanum* (the Lone Star tick), carries a presumptive new species, *B. lonestarii* sp. nov. It is possible that this slightly different spirochete is a cause of mimicking disease.

Lyme disease affects both genders and all ages, with peaks in children (ages 5 to 9) and middle-aged adults (ages 45 to 54). The major epidemiologic risk factor is time spent out of doors, either on a recreational or vocational basis. In temperate climates most cases cluster from June to August, but infection can occur all year round.

Clinical presentation

Infection with *B. burgdorferi* does not necessarily lead to disease. Asymptomatic infection occurs in perhaps 20 to 30% of cases. Subclinical disease may reflect non-pathogenic strains, ineffective inoculum, or efficient host immunity. Clinical illness occurs in stages, with suggestive organ-specific syndromes (Table 108.4). Target organs in Lyme disease are the skin, joint, heart, eye, and nervous system (Steere, 1989).

The only pathognomonic clinical syndrome is erythema migrans (EM). This early local infection marker occurs in up to 90% of patients, and is the major Lyme disease syndrome. It occurs one to 30 (typically 7 to 10 days) after tick bite. Spirochetes are present in the skin, particularly at the leading edge, so that punch biopsies of skin have a high yield on culture, stain and PCR studies. Important features to look for are expansion of the rash over days, large size (typically inches), and common accompanying symptoms (arthralgias, myalgias, headache, stiff neck, palpitations, malaise, fever, chills) (Nadelman & Wormser, 1998). A rash which occurs within 24 hours of a tick bite, or which clears spontaneously within 48 hours, is not EM. Flu-like illness has been associated with seroconversion, and probably represent early dissemination. A helpful diagnostic clue is that respira-

tory and gastrointestinal symptoms occur in less than 10% of these patients.

B. burgdorferi disseminates within days to weeks in blood, and possibly skin and lymphatics. Early dissemination is associated with multiple EM lesions, as well as characteristic musculoskeletal, cardiac, ocular, and neurologic syndromes. Migratory joint and muscle pains are more common than frank joint swelling at this stage. Involvement of the temporomandibular joint is a suggestive feature. High-degree heart block, the characteristic cardiac finding, is becoming very unusual. This may reflect more effective early antibiotic regimens.

Late stage infection occurs after months to years. Migratory oligoarticular or monoarticular large joint arthritis (tenosynovitis with swelling) is a particularly suggestive feature, especially when accompanied by Baker's cysts, while small joint involvement is seen in less than 10% of patients (Nadelman & Wormser, 1998; Steere, 1997). Approximately 10% of patients develop chronic Lyme arthritis unresponsive to antibiotics. This relates to genetic susceptibility, and is likely an immune-mediated phenomenon (see pathophysiology section below). Two skin manifestations, lymphocytoma cutis (LC), which consists of a collection of plasma cells within the earlobe, nipple or scrotum, and acrodermatitis chronica atrophicans (ACA), a sclerotic skin lesion particularly common in elderly women, are virtually confined to European cases. This probably reflects genospecies and strain differences between North America and Europe.

Congenital infection

Congenital infection is rare, and there is no identifiable congenital Lyme disease syndrome (Silver, 1997). Individual reports suggest perinatal transmission can lead to preterm delivery, fetal death, and fetal malformations, but epidemiologic studies indicate a very low risk. In one study of 19 maternal infections, in whom only 13 received antibiotics, the transmission rate was zero (Markowitz, 1986). In a European study of EM during pregnancy, patients were treated with ceftriaxone or penicillin, and no adverse fetal outcome was found (Maraspin, 1996). In population surveys, there is no difference in fetal outcomes between seropositive and seronegative mothers.

Neurological manifestations

Neurological involvement can occur at all stages of Lyme disease and can involve any part of the neuraxis (Table 108.5). (Belman et al., 1993, 1997; Coyle, 2000; Garcia-Monco & Benach, 1997; Haass, 1998; Halperin et al., 1987, 1990; Logigian, 1990; Logigian & Steere, 1992; Luft et al., 1992; Pachman & Steere, 1985). Spirochetes can invade the CNS quickly; a proportion of EM patients have CNS seeding. Since many EM patients experience some headache and stiff neck, this is probably most consistent with a pre-meningitis phase. Early dissemination is associated with three characteristic syndromes. Meningitis/meningoencephalitis appears to be the most common early neurologic syndrome in North America. It is an aseptic meningitis, and can occur along with EM. Aseptic meningitis with facial nerve or radicular involvement should suggest Lyme meningitis. CSF shows mononuclear pleocytosis (typically 100 to 200 WBC/mm^3, range 5 to 4000 WBC/mm^3) with elevated protein, normal glucose, and intrathecal organism-specific antibody production in up to 60% of North American meningitis cases and essentially all European cases. Lyme-related cranial neuropathy involves the facial nerve in most cases. About one-third of patients have bilateral involvement. Most Lyme-related facial nerve palsies, unlike idiopathic Bell's palsy, occur during summer time and are accompanied by a multisymptom complex (fatigue, arthralgias, myalgias, headache, stiff neck, cognitive difficulties). Most patients have abnormal CSF consistent with CNS involvement. Other cranial nerves (such as the optic and oculomotor nerves) are occasionally involved. Acute painful radiculoneuritis (lymphocytic meningoradiculitis, or Bannworths' syndrome) is the most common European neurologic manifestation. Patients frequently begin with intrascapular pain, radiating down the spine or into extremities. Patients develop asymmetric dermatomal and myotomal abnormalities. Meningeal features are subtle, yet these patients show the most inflammatory CSF changes.

The most common late stage neurologic syndrome in North America is Lyme encephalopathy. This involves rather subtle cognitive deficits in memory, concentration, and processing speed. CSF changes are not marked, and parameters may be normal. Neuroimaging shows cerebral blood flow disturbances on brain SPECT. Lyme encephalopathy is most consistent with CNS infection. Chronic polyradiculoneuropathy is an axonal process. Patients may experience subtle paresthesias, occasional shooting pains, numbness, and restless legs. CSF is normal, unless there is associated encephalopathy. Examination suggests mild polyneuropathy or radiculoneuropathy. In Europe, late stage ACA is often accompanied by a distal sensory polyneuropathy (Kindstrand et al., 1997). Chronic progressive encephalomyelitis has been reported mainly in Europe. There is parenchymal brain or spinal cord involvement,

Table 108.5. Neurologic manifestations of Lyme disease

Stage	Characteristic syndromes	Comments
Early local infection	Asymptomatic Non-specific symptoms	CNS invasion can occur with normal CSF (premeningitis phase)
Early disseminated infection	Meningitis, meningoencephalitis	Clinical features may be subtle Can see associated facial nerve, radicular involvement Spontaneous resolution, occasional chronic meningitis
	Cranial neuropathy	Over 80% involve facial nerve, one-third bilateral, accompanied by multisymptom complex Spontaneous resolution
	Acute painful radiculoneuritis	Most common neurological syndrome in Europe Very inflammatory CSF Spontaneous resolution
Late stage infection	Encephalopathy	Subtle memory, attention, processing abnormalities Abnormalities may include low grade CSF changes, cerebral blood flow disturbances Does not spontaneously resolve
	Polyradiculoneuropathy	Axonal process Subtle clinical and laboratory abnormalities CSF generally normal Does not spontaneously resolve
	Encephalomyelitis	Abnormal CSF Does not spontaneously resolve
Stage	Unusual syndromes	Comments
Late stage infection	Cerebrovascular disease	Includes vasculitis, transient ischemic attacks and hemorrhagic strokes Abnormal CSF
	Intracranial hypertension	Age restricted (children, adolescents) Abnormal CSF
	Psychiatric disease	Reflects encephalomyelitis Abnormal CSF
	Myositis, myopathy	Muscle infection Unifocal or multifocal

with a variety of clinical syndromes that can mimic multiple sclerosis, brain tumour, myelopathy, or degenerative syndromes. This is the most uncommon of the well-defined neurologic syndromes.

A number of unusual syndromes have been related to *B. burgdorferi* infection. They include psychiatric syndromes, cerebrovascular disease, or age-related intracranial hypertension syndrome, and myositis/myopathy (Coyle, 2000). Rare cases of dementia, normal pressure hydrocephalus, and motor neuron disease have been attributed to Lyme disease. Important clues are that these syndromes are associated with inflammatory CSF, and they improve after antibiotic therapy.

Diagnosis

Diagnosis of neurologic Lyme disease is complicated by the lack of a readily available active infection assay. Culture is not helpful. Although Lyme disease is ultimately a clinical diagnosis, it should be supported by laboratory data. The single exception is EM. With typical features, and endemic area exposure, no confirmatory laboratory testing is needed (Nichol et al., 1998; Tugwell et al., 1997). The American Academy of Neurology has provided a Practice Parameter Guideline to diagnose neurologic Lyme disease (Table 108.6) (American Academy of Neurology Quality Standards Subcommittee, 1996; Halperin et al.,

Table 108.6. American Academy of Neurology Practice Guidelines for diagnosis of neurological Lyme disease[a,b]

Exposure to appropriate ticks in area where Lyme disease occurs
One or more of the following:
– Skin manifestation (EM, or histopathologically proven LC or ACA)
– Immunologic evidence of *B. burgdorferi* exposure
– Detectable *B. burgdorferi* (by culture, histology, or PCR)
One or more specified disorders, no other etiology, possible additional testing (such as CSF evaluation for suspected CNS infection)
– Causally related disease
Lymphocytic meningitis +/− cranial neuropathy, painful radiculoneuritis, or both
Encephalomyelitis
Peripheral neuropathy
– Causally related syndrome
Encephalopathy

Table 108.7. Diagnosis of neurological Lyme disease

History
Endemic area exposure
– Outdoor activities
– Tick exposure (strain, geographic origin, attachment, blood engorgement)
History of EM-like rash or flu-like illness prior to neurological syndrome
Extraneural involvement
– Target organ involvement (skin, musculoskeletal, cardiac, ocular)
– Systemic symptoms (fatigue, myalgias, arthralgias, palpitations)
Characteristic neurological syndrome
Laboratory
Blood studies
– Specific (anti-*B. burgdorferi* antibodies)
– Nonspecific (↑ acute phase reactants and liver enzymes early, anticardiolipin IgM antibodies)
CSF
– specific (intrathecal anti-*B. burgdorferi* antibodies, culture, PCR)
– Non-specific (cell count, protein, glucose, cytology, VDRL, oligoclonal bands, IgG index)
Neuroimaging
– MRI (yield ≤25%; variable pattern)
– Brain SPECT
Electrophysiologic
– Nerve conduction tests, electromyography
Neurocognitive testing

1996). Both clinical and laboratory features can be used to support a diagnosis of neurologic Lyme disease (Table 108.7).

The single most used laboratory test is serology. Positive serology, if accurate, documents prior exposure to *B. burgdorferi* but not active infection. Following an antibody titre is not helpful in Lyme disease, since high titres may remain for years in treated and recovered individuals. Intrathecal antibody production can also persist for months to years. A proportion of recovered Lyme disease patients will even show persistent IgM reactivity, but the significance of this finding remains unknown.

Current CDC recommendations involve a two tier test system to evaluate antibodies. Screening serology (typically ELISA, using sonicated spirochetes as the antigen target) is used first. If positive or borderline, a second more specific immunoblot test is performed. Lyme serology is only standardized to the extent that positive IgM and IgG immunoblots need to show two of three (p23, 39, 41) and five of nine (p18, 21, 28, 30, 39, 41, 58, 66, 93) possible bands, respectively. First tier tests are not standardized, antigen targets are not standardized, and use of monoclonal antibodies and recombinant proteins are not required. Because spirochetes contain a number of immunodominant non-unique antigens, under optimal conditions the screening ELISA has a false-positive rate of at least 5%. There is great variability between laboratories with regard to sensitivity and specificity of Lyme serology tests. Second generation antibody tests have been developed, which do use recombinant and chimeric proteins. Chimeric proteins consist of epitopes of selected recombinant proteins, which have been joined together to provide multiple reaction sites. A recently approved office-based rapid detection assay (PreVue *B. burgdorferi* antibody detection assay, Wampole Laboratories, NJ) measures reaction to a chimeric protein; positive samples produce an immunostripe stain within a few minutes. Alternative antibody tests based on detection of neoantigens (spirochetal proteins only expressed in the host) are also under development. It is likely that both ELISA and immunoblot assays to detect anti-*B. burgdorferi* antibodies will be improved in the next few years, using recombinant/chimeric technology and automated readout.

CSF is abnormal in most neurologic Lyme patients. Intrathecal organism-specific antibody production can be

considered diagnostic for CNS infection. PCR assays have been somewhat disappointing, since the positivity rate in obvious neurological cases is no more than 40% (Luft et al., 1992; Nocton et al., 1996). This probably reflects the paucity of spirochetes in CSF. Abnormalities such as mononuclear pleocytosis, increased protein, monoclonal or oligoclonal bands, or intrathecal IgG production are helpful to document CNS involvement, but are not diagnostic. In fact, oligoclonal bands and intrathecal IgG antibody production are seen in a minority of neurologic Lyme disease patients in North America, in contrast to European patients. Electrophysiological tests, which suggest a multifocal axonal radiculoneuropathy are also helpful to support a diagnosis of neurologic Lyme disease, but are not diagnostic.

Neurocognitive function tests (to document objective deficits) and brain SPECT (to document multifocal cerebral blood flow disturbances) are suggestive of late Lyme encephalopathy. These abnormalities, along with any CSF disturbances, should improve following antibiotic treatment (Logigian et al., 1999).

There are certain experimental tests for diagnosis, that include special ways to culture spirochetes or to detect antigens in urine (the Lyme urine antigen tests or LUAT). These are not widely accepted, and there have been issues with regard to reproducibility of results. The LUAT test in particular uses no parameter to assure specificity, and becomes positive with concurrent urinary tract infection. Such tests should never be used in isolation to support a diagnosis of Lyme disease.

Treatment

Early local infection (EM) is treated with doxycycline (100 mg po BID), amoxicillin (500 mg po TID), or cefuroxime axetil (500 mg po BID) for at least two weeks (Nadelman & Wormser, 1998). Doxycycline is preferred because it also treats ehrlichia, a potential tick copathogen. This antibiotic cannot be used in young children under age 8 however, because of dental discolouration and bone problems. Side effects include gastrointestinal upset and photosensitivity.

Most extraneural disseminated Lyme disease syndromes also respond to doxycycline given for several weeks (Dattwyler et al., 1997). Although definitive randomized controlled trial data is lacking to specify the optimal treatment of neurological Lyme disease, expert consensus panels recommend the third generation cephalosporin ceftriaxone, at 2g QD for 2 to 4 weeks (Wormser et al., 2000). This is frequently used on an outpatient basis, since it is given intravenously once a day over 30 to 60 minutes. Anecdotal reports indicate it can be delivered over as short a time frame as ten minutes. The drug is basically well tolerated. Pseudomembraneous colitis is unusual; to avoid this problem patients are often placed on acidophilus (*Lactobacillus* species) from health food stores or from yogurt. One to 10 billion viable organisms need to be consumed, divided over a TID or QID schedule. Gall bladder disease, due to drug sludge, is another very unusual complication. Biliary pseudolithiasis is more likely in young women and children. Alternative regimens to ceftriaxone include intravenous cefotaxime (2 g TID), penicillin (at 18 to 24 million units) or doxycycline (200 mg BID or twice the usual dose to give higher CSF levels). Most patients respond to appropriate treatment. Late stage infection patients may continue to note improvement months after treatment has stopped.

With regard to the pregnant patient, both oral amoxicillin or ceftriaxone can be used safely. With a term pregnancy, cefotaxime is usually substituted for ceftriaxone. It does not involve biliary excretion, and does not carry a risk for jaundice in the newborn.

In certain cases patients continue to complain of symptoms (such as fatigue, arthralgias, myalgias, headache) after treatment for Lyme disease (Asch et al., 1994; Bujak & Weinstein, 1996; Gaudino et al., 1997; Seltzer, 2000; Shadick et al., 1994). They are sometimes diagnosed as 'chronic Lyme disease', and treated with extended combination antibiotics. There are no accepted criteria for this diagnosis. It is likely that a number of etiologies might explain persistent post-treatment problems (persistent *B. burgdorferi* infection, infection with another tick agent, postinfectious immune/inflammatory process, slow recovery, alternative diagnosis, reinfection, fixed damage, hypochondriasis). Several prospective studies have attempted to evaluate these patients, to address whether or not they have an antibiotic-responsive syndrome. The National Institute of Allergy and Infectious Disease (NIAID) funded a 5-year contract to analyse antibiotic responsiveness in seropositive and seronegative patients with persistent symptoms following a well documented history of treated Lyme disease. Patients received 30 days of intravenous ceftriaxone, followed by 60 days of oral doxycycline. At a recent preplanned interim analysis, after 131 patients had been entered, the independent Data Safety and Monitoring Board recommended termination of the treatment component. They recommended no further patient entry, since no significant benefit of antibiotic treatment had been found. In another recently completed NIAID-funded study of chronic Lyme disease patients with persistent fatigue, four weeks of ceftriaxone compared to placebo treatment

was associated with a significant improvement in fatigue at six months. However, there were no CSF or other biologic markers of treatment response, and no evidence for true persistent infection.

Prevention

Because Lyme disease involves exposure to an environmental source, preventive strategies such as daily body checks, protective clothing, and use of tick repellants have been tried. Although prophylactic antibiotics are often used following tick bite (Fix et al., 1998), prospective randomized double blind trials have failed to document a benefit over watchful waiting (Agger & Case, 1997; Costello et al., 1989; Shapiro et al., 1992). In a recent meta-analysis involving over 600 patients with tick bite, antibiotic prophylaxis was not found to be of benefit (Warshafsky et al., 1996). One study did suggest that with a high risk of Lyme disease after tick bite (>0.036), prophylactic doxycycline therapy should be considered (Magid et al., 1992).

A prophylactic monovalent vaccine (LYMErix, SmithKline Beecham), which uses recombinant lipidated outer surface protein A (OspA), is now available (Steere et al., 1998; Steigbigel & Benach, 1998). It is given at 0, 1, and 12 months, with 50% protection after the second dose and 80% protection after the third dose. There are several areas of concern about the current vaccine. Protection depends on generation of specific anti-OspA antibodies, which kill spirochetes within the feeding tick. Protective antibodies do not persist, so that frequent booster shots will be necessary. These may involve annual booster shots (Thanassi & Schoen, 2000). Patients become seropositive on current antibody tests, and can even show multiple bands on immunoblot. There is also a concern that the vaccine may result in an immune-mediated arthritis in genetically susceptible individuals (see below). Second generation multivalent vaccines are currently being evaluated.

Prognosis

For the most part, neurological Lyme disease has an excellent prognosis. Early disseminated syndromes get better on their own, and improve within 3 to 5 days of starting antibiotics. Radicular pain can improve within hours. Overall 85% of Lyme-related facial nerve palsies improve, while 70% show complete recovery (Smouha et al., 1997). A minority of patients (about 7%) may show development of new abnormalities (such as facial nerve palsy) during treatment, but this does not appear to reflect therapeutic failure since they ultimately do well. Late stage neurological syndromes do not resolve spontaneously. Treatment prevents worsening, and generally results in clinical and laboratory improvement over months. Patients may be left with residual problems, however.

Pathophysiology

Lyme disease produces a wide array of neurological problems in the setting of a limited number of organisms and pathological damage. Lyme disease neuropathology is not marked. There is low grade meningeal and perivascular mononuclear inflammation, but little tissue destruction. Late infection can produce obliterative vasculopathy, and rare patients show prominent demyelination or granulomatous tissue changes (Coyle, 2000; Oksi et al., 1996). The occasional visualized spirochete is always extracellular. These have never been visualized in peripheral nerve, although a recent study reported PCR reactivity in a sural nerve biopsy (Maimone et al., 1997). Peripheral nerve biopsies show axonal damage, with perivascular inflammation (Vallat et al., 1987). The pathology suggests that indirect mechanisms are likely to be important in the pathogenesis of neurological disease.

B. burgdorferi produces a number of immune and inflammatory abnormalities in the host (Coyle, 2000; Garcia-Monco & Benach, 1997; Hu & Klempner, 1997; Sigal, 1997). Spirochete outer surface (Osp) proteins induce inflammatory responses. Organisms bind to endothelial cells, up-regulate adhesion molecules, and induce local chemokine production. They cross endothelium through intercellular openings, or by transcytotic mechanisms, to penetrate multiple organs. They also bind to platelets, red blood cells, plasminogen, and glycosphingolipids on the surface of neurons, astrocytes, oligodendrocytes, and Schwann cells. In culture, *B. burgdorferi* injures both astrocytes and oligodendrocytes. Several different *B. burgdorferi* strains are neurotropic, and can invade the CNS (Wilske et al., 1996).

Chronic Lyme arthritis is now believed to be an immune-mediated syndrome (Gross et al., 1998a). It occurs in approximately 10% of Lyme arthritis patients. They are HLA-DR4 (DRB1*0401) positive, have an antibiotic unresponsive arthritis, and have PCR negative synovial fluid (Gross et al., 1998b). Patients show a strong cellular and humoral immune response to OspA. OspA reactive CD4+T helper 1 (TH1) cells within the joint release damaging proinflammatory cytokines, and inflammatory arthritis parallels the TH1: TH2 ratio within synovial fluid. OspA shows molecular mimicry with

human lymphocyte functional antigen-type 1 (LFA-1), an integrin receptor and adhesion molecule found primarily on T-cells. It binds to intercellular adhesion molecule-type 1 (ICAM-1). Both LFA-1 and ICAM-1 are overexpressed in inflammatory tissue.

B. burgdorferi can cause a vasculopathy similar to endarteritis obliterans. It produces cytokine changes. Proinflammatory cytokines such as interleukin-1 (IL-1), IL-6, and tumour necrosis factor-α (TNF-α), are elevated in the joints of arthritis patients (Yin et al., 1997). Cloned T-cell lines from synovial fluid and blood of Lyme arthritis patients secrete interferon-γ (IFN-γ) when exposed to *B. burgdorferi*. Mononuclear cells from neurologic Lyme disease patients also preferentially secrete IFN-γ when exposed to *B. burgdorferi* Osp proteins (Ekerfelt et al., 1997), particularly CSF cells. The antagonistic anti-inflammatory/regulatory cytokine, IL-4, is down-regulated. Neurological patients show increased levels of IL-1 and TNF-α in CSF. Soluble IL-2 receptors are increased in both CSF and blood, and decrease after treatment (Nilsson et al., 1994). IL-12 production is increased in monocytes collected from patients with longstanding Lyme disease, which favours TH1 cell production (Pohl-Koppe et al., 1998). In a recent study *B.burgdorferi* induced TH1 cells which produce IL-17, another potent inflammatory cytokine (Infante-Duarte et al., 2000). Overall, the cytokine data suggests an imbalance of the TH1:TH2 CD4+T cell ratio in Lyme disease, with TH1 cells predominant in late infection. This would favour cell-mediated immunity and inflammatory cytokine production, and is consistent with the concept that humoral immunity is protective in *B. burgdorferi* infection.

There are a number of potential pathogenetic factors in addition to cytokines. *B. burgdorferi* induces neurotoxins such as nitric oxide and quinolinic acid, an NMDA receptor antagonist and excitotoxin which is elevated in the CSF of neurological patients. Antibodies and immune complexes also appear to have some role. *B. burgdorferi* is B-cell mitogenic. Infection can result in autoreactive antibodies to cardiolipin and acidic gangliosides (GM1, asialo-GM1), anticardiolipin IgM, antiaxonal IgM, antibodies to myelin and myelin components, antineuronal antibodies, antibodies to heat shock protein, and antibodies to a 46kD protein which crossreacts with myosin (Coyle, 2000; Sigal, 1997; Yu et al., 1997). *B. burgdorferi* specific immune complexes have been reported in both serum and CSF, and may correlate with disease activity (Coyle et al., 1990; Schutzer et al., 1990). CSF T-cells from neurological patients react to cardiolipin as well as a variety of neural antigens, including myelin and galactocerebroside (Wang et al., 1996). In summary, a number of these indirect mechanisms could contribute to neurologic manifestations of infection.

There are many animal models of Lyme disease, but none truly mimic human disease. In some animals infection causes no obvious disease, while in others selected organs are involved. In some models infection spontaneously clears, in others infection clears with antibiotics, while in still others antibiotics contain but never clear infection (Foley et al., 1995; Goodman et al., 1991; Straubinger et al., 1997). The best animal model for neurological Lyme disease is in rhesus monkey primates (England et al., 1997a,b; Pachner et al., 1995a,b; Philipp et al., 1997; Roberts et al., 1995). They can be infected by tick bite, and go on to develop neurologic involvement. CSF pleocytosis occurs within 5 weeks of inoculation, and CSF is PCR positive. CSF pleocytosis and PCR positivity may wax and wane. Within three months of infection there is peripheral nerve involvement which persists at least 2 years. Infected monkeys show chronic meningeal inflammation. For unclear reasons, CNS and PNS tissues remain culture negative. This model remains under investigation.

Dual infections

Ixodid ticks carry other bacterial, parasitic, and viral pathogens. Patients can be coinfected with *B. burgdorferi*, and one or more other agents through a tick bite (Mitchell et al., 1996; Nadelman et al., 1997; Persing, 1997; Walker et al., 1996). Coinfection has been associated with more prolonged spirochetemia, more severe clinical illness, and a poorer therapeutic response. It is estimated that 4 to 30% of Lyme disease patients are dually infected with a parasite or a rickettsia-like bacterium. *Babesia microti* is a parasitic infection which can cause a malaria-like illness. It can also cause chronic infection, with fatigue, episodic fever, and chills (Krause et al., 1998). Patients who are coinfected with *B. burgdorferi* and babesia are more likely to experience fatigue, headache, sweats, chills, anorexia, emotional lability, nausea, conjunctivitis, and splenomegaly (Krause et al., 1996). They are 13 times more likely to be symptomatic for months, and three times more likely to be PCR positive in blood for circulating *B. burgdorferi* DNA. The antibiotic treatment for babesia is entirely different than that for *B. burgdorferi*. However, in a retrospective cohort study of Lyme disease patients with subclinical babesia infection, long-term outcome was not adversely affected (Wang et al., 2000). A recent study found that treatment over 1 week with atovaquone (750 mg BID) plus azithromycin (500 mg, followed by 250 mg QD) for babesiosis was not only as effective as conventional therapy (clindamycin plus

quinine), but was much better tolerated (Krause et al., 2000).

Ehrlichiae are obligate intracellular gram-negative like bacteria, which resemble rickettesiae. They show a marked tropism for leukocytes and platelets. Originally recognized to cause veterinary diseases, they are capable of producing chronic infection. The agent of human granulocyctic ehrlichiosis (HGE), an *E. equi-E. phagocyctophila*-like agent, infects Ixodid ticks (Dumler, 1997; Wallace et al., 1998). It responds well to tetracycline agents such as doxycycline. Patients infected with Lyme disease and HGE also appear to have worse clinical syndromes.

Coinfection may contribute to persistent post-treatment symptoms. A patient treated for Lyme disease could have persistent problems due to an unrecognized and untreated babesia or ehrlichia infection. In addition, there are likely to be other as yet unrecognized tick-borne pathogens. Although a tick borne flavivirus has been reported in North American Ixodid ticks, no clinical syndrome has been recognized to date. In Europe tick borne encephalitis virus causes a severe infection; fortunately, an effective vaccine is available.

There are some helpful clues to suspect an alternative tick pathogen. Both babesiosis and HGE increase alanine aminotransferase, and produce thrombocytopenia. These are unusual in Lyme disease, and should suggest the possibility of dual infection. Both of these alternate infections appear to be immunosuppressive, which could explain a more severe clinical illness. In endemic areas tick copathogen exposure should be considered when evaluating for Lyme disease. The simplest way to screen for exposure is to look for an antibody response, although PCR, culture, and peripheral smears and stains are available as well.

Neurosyphilis

Louis Reik, Jr

Department of Neurology, UCONN Health Center, Farmington, CT, USA

Venereal syphilis is a chronic systemic infection caused by the spirochete *Treponema pallidum* and distinguished clinically by three stages: (i) a local primary lesion with regional lymphadenopathy; (ii) a secondary bacteremic stage with disseminated mucocutaneous lesions; and (iii) a tertiary stage of skin, bone, and visceral involvement that develops after a latent period lasting years.

Epidemiology

Treponema pallidum is an obligate human parasite with no animal or environmental reservoir that is nearly always transmitted sexually through contact with infectious mucocutaneous lesions. Transmission can occur also via non-sexual personal contact, accidental direct inoculation, blood transfusion, needle sharing, or transplacentally (Stamm, 1999).

The disease was first identified in Europe when an epidemic of severe infection overran the continent at the end of the fifteenth century, coinciding with the return of Columbus from the West Indies. Because of this, syphilis was believed to be a New World illness communicated to Europe by Columbus's returning sailors. But the infection likely was already present in the Old World, unrecognized and mistaken for leprosy (Hackett, 1963; Hollander, 1981; Sparling, 1999).

In the next five centuries, syphilis spread worldwide, becoming so common that its prevalence reached 5 to 10% in general autopsy series by the first half of the twentieth century (Sparling, 1999). Following the introduction of penicillin and the initiation of public health programmes in the late 1940s, however, the number of new cases fell by over 90% throughout the developed world. In the USA, for example, the incidence peaked in 1947 at 76 primary and secondary cases per 100 000 population and declined to a nadir of 2.6 per 100 000 in 1998 (Aral & Holmes, 1999; Centers for Disease Control and Prevention, 1999). In the developing world, however, syphilis remains common, and there is now an explosive outbreak in Eastern Europe and parts of the former USSR (Aral & Holmes, 1999).

Etiology

Treponema pallidum is a small (below the limit of resolution of the light microscope), motile, flagellated, spiral bacterium 6–20 μm long and 0.1–0.2 μm wide. It stains poorly with aniline dyes but can be stained by silver impregnation or visualized by either dark field or phase contrast microscopy. It lacks a capsule. Like gram-negative bacteria, it has an outer membrane, inner membrane, and a thin cell wall composed of peptidoglycan. Unlike gram-negative bacteria, the outer membrane lacks lipopolysaccharide and contains only rare integral membrane proteins, few of which are surface exposed ($<$100 particles/μm^2 compared to 6000–10 000/μm^2 in *Escherichia coli*) (Norris, 1993; Stamm, 1999).

T. pallidum is a fastidious organism that cannot be grown in culture. Capable of DNA, RNA, and protein synthesis, the spirochete can use both glucose and pyruvate as energy sources. But it lacks a complete Krebs cycle and depends on its host for at least some of its nutritional requirements (Stamm, 1999). Both the fastidious nature of the organism and its host dependence probably relate to its small genome: *T. pallidum*'s single circular chromosome of about 1000 kilobase pairs is one of the smallest prokaryotic genomes known (Norris, 1993).

Pathogenesis and pathophysiology

T. pallidum rapidly penetrates intact mucous membranes or abraded skin, attaches to host cells, and then prolife-

rates. Within hours, the proliferating treponemes migrate to local lymph nodes, enter the blood stream, and disseminate. Days to weeks later, a primary lesion or chancre develops at the site of inoculation. Spirochetes are present in the chancre in and between epithelial, endothelial, and phagocytic cells and fibroblasts; and there is accompanying perivasculitis, capillary endothelial proliferation, and obliterative endarteritis of the small vessels. The chancre heals spontaneously in weeks as cell mediated immunity develops: the treponemes are cleared via phagocytosis by activated macrophages facilitated by opsonizing antibodies (Stamm, 1999).

Not all of the organisms are cleared, however, and some survive to cause chronic infection. How they do so is still a matter of debate. Candidate mechanisms include localization inside cells or in immunoprotective niches like the CNS, the presence of a subpopulation resistant to phagocytosis, premature down-regulation of the local immune response, or an antigenically inert surface secondary to either a coat of host serum proteins or the paucity of treponemal outer membrane proteins. Evidence at present favours the last (Stamm, 1999).

Whatever the mechanism, proliferation and dissemination of the surviving organisms results in secondary syphilis. The onset is usually about 6 weeks after the chancre heals. Constitutional symptoms, generalized lymphadenopathy, and disseminated skin lesions are typical. Treponemes are present in the skin lesions, again accompanied by small vessel perivasculitis and endarteritis obliterans. Other abnormalities include the presence of spirochetes in the CSF and aqueous humor, granulomatous iritis, immune-complex glomerulonephritis, and infiltration of the liver by lymphocytes and neutrophils (Stamm, 1999).

These secondary lesions subside in turn, without treatment and within weeks, as the treponemes are eliminated via immune mechanisms. Latent syphilis follows. Then infection is detected only by serologic tests. The organisms are still present, however, especially in the spleen and lymph nodes; and they can still seed the blood stream and cause mucocutaneous relapse. Among untreated patients, 25% have one or more such relapses, 90% of them during the first year after infection (early latent syphilis). Late latency (>1 year after infection) brings relative immunity to relapse and increasing resistance to reinfection. Even then, intermittent spirochetemia still occurs. So transplacental transmission is possible while venereal transmission is not (Stamm, 1999).

Late latent syphilis probably never is cured spontaneously. Untreated, it has only two possible outcomes: lifelong inapparent infection or progression to late (tertiary) syphilis. Before penicillin, tertiary syphilis developed in about a third of those infected, most often years after latency began: cardiovascular syphilis in 10%, neurosyphilis in 6.5%, and gumma in 16% (Clark & Danbolt, 1964). Now rare, likely due to its sensitivity to low doses of penicillin or other antibiotics, gumma is a granulomatous lesion that results from a hypersensitivity response to *T. pallidum* antigens. Obliterative endarteritis of CNS vessels and the vasa vasorum of the ascending aorta and direct invasion of the CNS parenchyma underlie the other late manifestations.

Clinical manifestations

General clinical features

Early localized (primary) syphilis (Fig. 109.1)

The typical chancre begins as a painless papule that ulcerates to form a 1–2 cm clear-based sore with an indurated margin, then heals spontaneously within 3–6 weeks. Chancres are located most commonly on the penis of heterosexual men; on the labia, fourchette, or cervix of women; and on the penis or in the mouth, anus, or rectum of homosexual men. Accompanying regional adenopathy is common, usually developing about a week after the chancre. Multiple lesions are frequent (Musher, 1999).

Early disseminated (secondary) syphilis

The skin lesions of secondary syphilis develop 4–10 weeks after the appearance of the chancre. An evanescent macular rash occurs first, followed within days by a symmetric papular eruption. The red or red–brown papules, 0.5–2 cm in diameter, are present on the trunk, face, scalp, and limbs, including the palms and soles. In warm, moist, intertriginous areas where skin breakdown occurs, the lesions enlarge to become raised grey–white or pink infectious condyloma lata. Involvement of the mucous membranes results in greyish areas of superficial erosion with surrounding erythema (mucous patches). When the hair follicles are affected, alopecia results (Musher, 1999).

Generalized, non-tender lymphadenopathy frequently accompanies the rash as do systemic symptoms. These include malaise, sore throat, anorexia, weight loss, fever, myalgias, pruritis, headache, and meningismus. Abnormal liver function tests are also frequent (20% of cases), but symptomatic hepatitis is rare. Other, less common features are arthritis, gastritis, iridocyclitis, the nephrotic syndrome, periostitis, and proctitis (Musher, 1999).

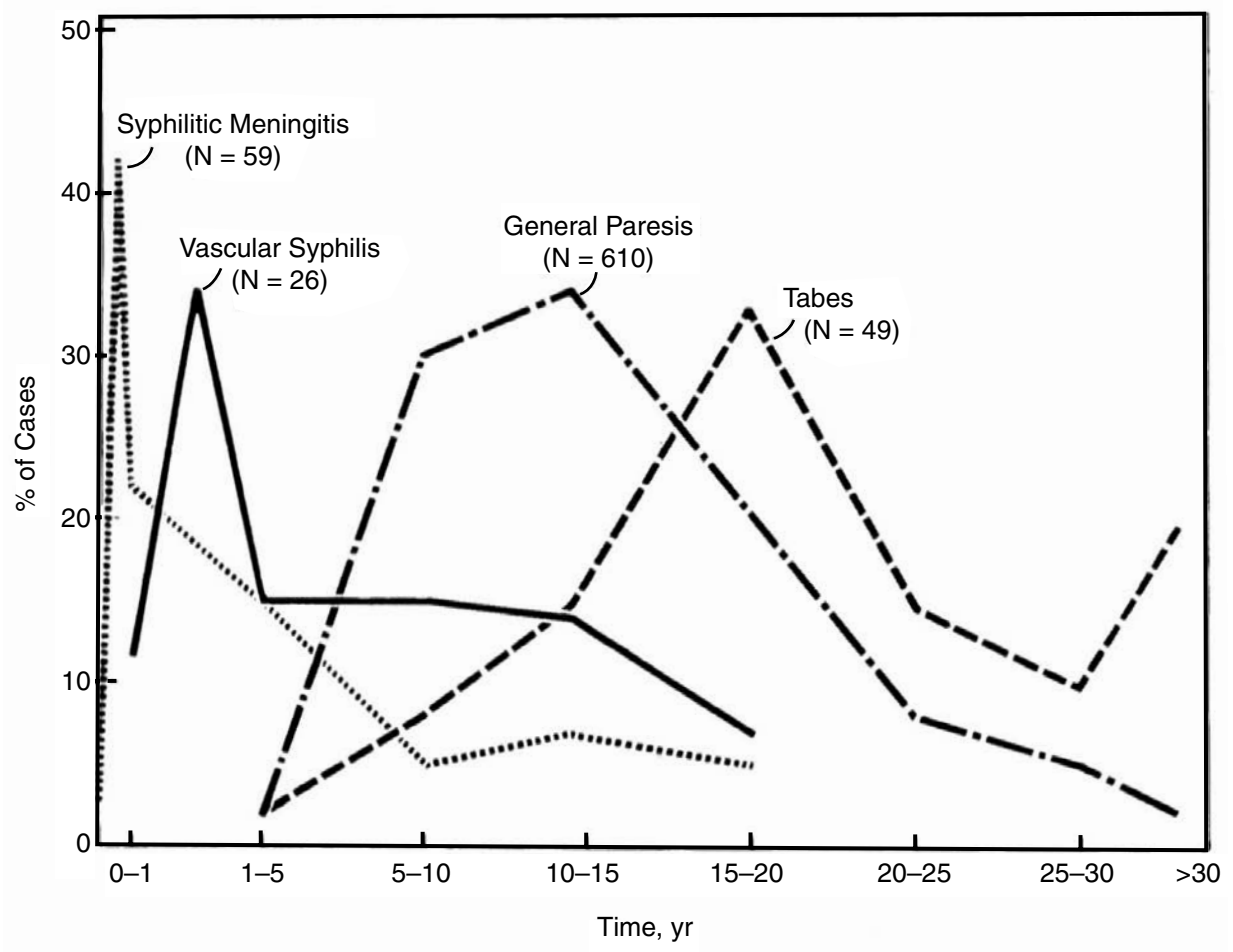

Fig. 109.1. Timing of neurological complications of syphilis.

Latent syphilis

The signs and symptoms of untreated secondary syphilis resolve spontaneously after 3–12 weeks. Then latency begins. The patient is asymptomatic and the physical examination normal (Musher, 1999).

Late (tertiary) syphilis

The disease is only relatively quiescent during latency, however. Ongoing and slowly progressive inflammation that begins then is followed years later by aortitis, gummata, and neurosyphilis (Table 109.1).

The consequences of aortitis are valvular insufficiency, aneurysm, and coronary ostial narrowing, their symptoms beginning 15–30 years after infection (Swartz et al., 1999). The symptoms of gumma/gummata, single or multiple destructive angiocentric granulomas with central necrosis and surrounding perivasculitis, usually start earlier, within 15 years of infection (range, 1–46 years). Remissions and recurrences (up to 7) are common (25–33% of patients). Gummata most commonly involve the skin (70%), mucosa (10%), and bone (10%). But any organ can be involved, including the liver, stomach, and CNS (Aral & Holmes, 1999; Swartz et al., 1999). However, most tertiary CNS abnormalities, meningovascular syphilis, general paresis, and tabes dorsalis, are the result of chronic syphilitic meningitis.

Neurosyphilis

Early syphilis

Treponemal invasion of the CNS probably occurs in the majority of patients with syphilis, usually within the first year after infection and almost always within the first two. Among patients with primary or secondary syphilis, up to 43% and 58% respectively have CSF abnormalities (Hook, 1997; Jaffe & Kabins, 1982; Mills, 1927; Moore & Faupel, 1928; Swartz et al., 1999 Zenker & Rolfs, 1990). Considering

Table 109.1. Time to development of symptomatic neurosyphilis

	Time of onset (latency)	
Type of neurosyphilis	Usual	Range
Acute syphilitic meningitis	<2 yr	2 mos–20 years
Meningovascular syphilis	5–10 yrs	mos to 12 yrs
Gummatous neurosyphilis	<15 yrs	1–46 yrs
General paresis	15–20 yrs	1–40 yrs
Tabes dorsalis	20–25 yrs	3–47 yrs

also that *T. pallidum* has been isolated from otherwise completely normal CSF (Chesney & Kemp, 1924; Lukehart et al., 1988), the frequency of CNS invasion in early syphilis is likely even higher. Among the CSF abnormalities described, pleocytosis (usually <100 lymphocytes/mm^3) is most common, increased protein or globulins less so, and positive serology the least (Hahn & Clark, 1946).

Acute syphilitic meningitis

No CNS signs or symptoms aside from a mild headache accompany these early CSF changes in most cases, but in 1–2%, symptomatic meningitis develops, usually within 2 years of infection. The onset is subacute, and the most common symptoms are headache, nausea, and vomiting (91%). Meningismus is slightly less routine (59%), and fever is present in less than half. Cranial nerve palsies are also frequent (45%) and often multiple. The vestibulocochlear, facial and oculomotor nerves are involved most often (in that order), and papilledema and optic perineuritis are common as well (Figs. 109.2, 109.3, see colour plate section). Hydrocephalus is present in about a third of cases, resulting either from meningeal adhesions in the posterior fossa or the basal cisterns. Seizures, hemiparesis, aphasia, other focal signs, and mental changes are less typical but do occur occasionally (Hook, 1997; Merritt, 1940; Merritt et al., 1946; Merritt & Moore, 1935; Swartz et al., 1999).

The CSF cell count is always increased (up to 2000 cells/mm^3, mainly lymphocytes). Other CSF changes include abnormal colloidal gold curves in 96%, increased protein (up to 380 mg/dl) in 90%, positive serology in 86%, increased pressure (up to 520 mm CSF) in 65%, and hypoglycorrhachia (as low as 18 mg/dl) in 45% (Merritt, 1940; Merritt et al., 1946; Swartz et al., 1999). Increased globulins and oligoclonal bands of IgG may be present (Bayne et al., 1986). CT and MR imaging with contrast may show meningeal enhancement (Katz et al., 1993).

Even untreated, the outcome is often favourable and spontaneous recovery likely. But cranial nerve palsies can be permanent, and progressive CNS disease can follow. Penicillin therapy is curative: the meningeal symptoms clear within days (Bayne et al., 1986).

Asymptomatic neurosyphilis

The prevalence of CSF abnormalities in untreated syphilis peaks 8–10 months after infection begins, then falls gradually (Hahn & Clark, 1946). After 2 years, 20–30% of patients still have abnormal spinal fluids, and further spontaneous reversion is rare. The CSF abnormalities that remain reflect chronic CNS infections that is not advanced enough to show symptoms (asymptomatic neurosyphilis). But these persisting changes are harbingers of symptomatic neurosyphilis, the risk of its development proportional to the initial degree of CSF abnormality (Hahn & Clark, 1946; Hook, 1997; Jaffe & Kabins, 1992). A normal CSF after 2 years on the other hand, virtually guarantees that neurosyphilis will not develop (Lukehart et al., 1988; Merritt, 1940; Moore & Hopkins, 1930).

Those affected show no definite signs of neurosyphilis, but they are not always asymptomatic. As many as 22% of them complain of headache, insomnia, giddiness, nervousness, rheumatic pains, or weakness. Minor neurologic abnormalities are also frequent: up to 28% have abnormal pupils, sluggish light reflexes, or slight deep tendon reflex abnormalities; and 8% have aortitis (Merritt et al., 1946; Moore & Hopkins, 1930).

The CSF is always abnormal. The abnormalities include pleocytosis in 40% (usually <100 cells/mm^3), increased protein in 41% (up to 100 mg/dl), increased globulins in 82%, and positive serology in 84% (Merritt et al., 1946).

Among untreated patients, the number with asymptomatic neurosyphilis declines over time as CNS infection progresses and symptomatic neurosyphilis develops. Symptomatic CNS disease is probably inevitable whenever patients with asymptomatic neurosyphilis live long enough. For example, in one study of asymptomatic neurosyphilitics, all already infected for 10–20 years when their CSF was first examined, 26 of 30 developed clinical neurosyphilis during the next 5–10 years (Hahn & Clark, 1946).

Meningovascular syphilis

Meningovascular syphilis typically develops 5–10 years after infection (range, months to 12 years; average, 7 years). Overall, it comprises about 15% of cases of symptomatic neurosyphilis (Holmes et al., 1984; Hook, 1997; Merritt et al., 1946).

A combination of meningitis and arteritis distinguishes

its pathology. Lymphocytic and plasmacytic infiltration of the leptomeninges and perivascular spaces and diffuse meningeal thickening, opacification, and fibrosis are typical and most marked over the convexities and in the basal cisterns. When the fibrosis is severe, cranial nerves can be compressed and CSF flow obstructed. Accompanying arteritis results in thrombosis and parenchymal ischemia and infarction. The walls of large and medium-sized arteries are infiltrated by inflammatory cells, their muscularis and elastica destroyed, and their intima thickened by fibroblastic proliferation (Heubner's arteritis). In small arteries, proliferation of endothelial and adventitial cells similarly causes narrowing or obliteration of the lumen (Nissl–Alzheimer arteritis) but their walls are not infiltrated. The arteries most often involved are the cortical branches of the middle cerebral and those at the base of the brain, especially the lenticulostriates. Similar pathological changes, either generalized or patchy, and usually more marked posteriorly, can affect the spinal dura, leptomeninges, and arteries. The clinical consequences are cord compression, meningomyelitis, radiculitis, and cord infarction (Holmes et al., 1984; Hook, 1997; Merritt et al., 1946).

The illness begins insidiously with diffuse cerebral and meningeal symptoms. Headache, dizziness, insomnia, irritability, difficulty concentrating, impaired memory, apathy, and emotional lability are most common. Dementia, psychosis, convulsions, optic atrophy, reflex iridoplegia, and cranial nerve palsies (most often nerves VII, VIII, V, IX, and X, in that order) are possible also. Weeks to months later, progressive arteritis results in cerebral infarction. The onset can be apoplectic (75%) or subacute (25%) and is sometimes preceded by premonitory transient focal symptoms. Typically (90% of cases), a single vessel is involved clinically, usually a branch of the middle cerebral (60%) or the basilar (12%). Hemiplegia or hemiparesis is the most frequent sign (83%), followed by aphasia (31%), hemianesthesia (14%), cerebellar ataxia (10%), and hemianopia (7%). As many as 14% may have convulsions in addition (Holmes et al., 1984; Hook, 1997; Johns et al., 1987b; Merritt et al., 1946).

Meningomyelitis, usually thoracic, begins with leg weakness or paresthesias and progresses to paraparesis, incontinence, girdle and leg pains, and impaired position and vibratory sense in the legs. If spinal artery thrombosis supervenes, spinal cord infarction is the outcome. Radiculitis causes segmental deficits: focal amyotrophy, fasciculation, and reflex loss with anterior, and dermatomal pain and sensory loss with posterior root involvement (syphilitic meningopolyradiculitis), asymmetric, areflexic leg weakness and sensory loss ensue when multiple roots are involved (Lanska et al., 1988; Feraru et al., 1990). Inflammation and thickening of the cervical dura (pachymeningitis cervicalis hypertrophica) result first in radicular pain, followed by segmental amyotrophy and then progressive paraparesis and sensory loss (Merritt et al., 1946).

The CSF is probably always abnormal in meningovascular syphilis. Typical changes are lymphocytic pleocytosis (usually 11–100 cells/mm^3), increased protein (usually 45–260 mg/dl, but higher in cases with spinal subarachnoid block), increased globulins, and positive serology (81%). The CSF pressure is routinely normal. Both CT and MR images generally show areas of abnormality consistent with infarction, and may show meningeal enhancement if contrast is given; but the changes are not specific (Berry et al., 1987; Gordon et al., 1994; Harris et al., 1997; Holmes et al., 1984; Johns et al., 1987a; Kaplan et al., 1981). Changes on cerebral angiograms, similarly non-specific, indicate vasculitis. These include local areas of concentric constriction, beading, and spasm of arteries (Harris et al., 1997; Simon, 1985). In one case of meningomyelitis, an area of increased signal intensity was present on T_2-weighted MR images of the mid-thoracic cord (Strom & Schnek, 1991).

The response to penicillin is usually good: treatment halts progression, meningeal symptoms resolve, and focal deficits may improve. But residual disability is common, and mental changes may be permanent (Holmes et al., 1984; Kaplan et al., 1981; Kase, 1988; Perdrup et al., 1981).

Gummatous neurosyphilis

Nervous system gummata arise from the meninges in areas of especially intense local inflammation. They are characterized histologically by an area of central necrosis surrounded by histiocytes, epithelioid cells, lymphocytes, and plasma cells plus a few foreign body giant cells (Kaplan et al., 1981; Merritt et al., 1946). Treponemes can be demonstrated within them by silver stains or immunofluorescence (Horowitz et al., 1994). Over time, the inflammation subsides spontaneously and is replaced by proliferating connective tissue. Non-specific scarring is the result.

Small gummata are frequent in meningovascular syphilis but generally cause no symptoms. Larger symptomatic ones, though rare, can arise any time during the illness. Usually durally based and up to several centimetres in size, they compress and invade the underlying brain or spinal cord. Cerebral gummata are located routinely over the brain convexity or at its base (where they occur as small tumours along arteries and cranial nerves). Their signs and symptoms are non-specific and reflect only lesion size and location (Eltomey et al., 1984; Kaplan et al., 1981). Spinal cord gummata are most often cervical. They mimic rapidly

growing tumours and cause root pains, paresthesias, spastic paraparesis, incontinence, and sensory loss below the level of the lesion (Merritt et al., 1946).

The frequency of CSF anomalies in gummatous neurosyphilis is not known; but pleocytosis, increased protein (especially when spinal cord gummata cause subarachnoid block), and positive serology are typical (Hook, 1997; Merritt et al., 1946). Neuroimaging abnormalities are not specific. Reported CT findings include both high- and low-density mass lesions, with or without surrounding edema, that are usually durally based and extra-axial. Following contrast infusion, both diffuse and ring-like enhancement are possible (Eltomey et al., 1984; Horowitz et al., 1994; Harris et al., 1997; Madsen et al., 1987). The MR appearance similarly is not diagnostic. Gummata are either hypo- or iso-intense on T_1 images and hyperintense on T_2 images. They enhance with gadolinium (Harris et al., 1997). Angiography normally shows an avascular mass with a contiguous zone of arteritis (Eltomey et al., 1984; Harris et al., 1997; Kaplan et al., 1981; Tonelli et al., 1989).

Because gummatous neurosyphilis is rare and its radiologic appearance non-specific, diagnosis usually requires biopsy: positive serology can only provide a clue. If gumma is diagnosed and penicillin prescribed, the lesion generally regresses (Kaplan et al., 1981).

General paresis

General paresis develops in about 40% of patients with symptomatic neurosyphilis, usually beginning 15–20 years (range, 1–40) after infection. Men are affected 4–7 times more often than women (Hook, 1997; Merritt et al., 1946; Swartz et al., 1999).

Chronic spirochetal meningoencephalitis is the cause. In the usual case, both frontal and temporal lobes are atrophied. Less often, there is striking focal cerebral atrophy, frequently unilateral (Lissauer's form). The meninges are cloudy and thickened, especially those overlying the areas of atrophy. The ventricles are dilated and their surface is covered by fine granulations (granular ependymitis). Underlying microscopic changes include round cell infiltration of the leptomeninges and perivascular spaces, Heubner's and Nissl-Alzheimer arteritis, loss of neurons, proliferation of astrocytes and microglia, the appearance of rod cells, deposition of iron pigment in blood vessel and rod cells, and demyelination of cortical and subcortical fibres. Spirochetes are present in the walls of blood vessels and inside microglia and astrocytes in the cerebral grey matter, basal ganglia, cerebellum, brain stem, and spinal cord (Merritt et al., 1946).

The illness begins insidiously with subtle changes in cognition and personality. Impaired concentration, forgetfulness, faulty judgement, poor hygiene, and changes in mood are common. Without treatment, the mental symptoms progress. Ultimately, they can mimic almost any psychiatric syndrome. Simple dementia is most frequent; but grandiose, manic, depressed and agitated, and paranoid types are all recognized. With further progression, dementia is inevitable in every case, regardless of the initiating symptoms. Neurologic signs develop later than mental symptoms. Seizures; tremors of the tongue, face, and fingers; pupillary abnormalities, especially Argyll Robertson pupils; and dysarthria are routine. Focal signs are less typical. They occur regularly only in Lissauer's form where they often appear suddenly (apoplectiform attacks). Then, hemiplegia and aphasia are most common. Clonus and Babinski signs appear later still. Eventually the patient becomes bedridden and incontinent and dies within 4–5 years of symptom onset (average, 2.5) (Hook, 1997; Merritt et al., 1946; Swartz et al., 1999).

The CSF is abnormal in 100% of untreated cases. Typical changes include lymphocytic pleocytosis of 10–100 cells/mm^3, increased protein (usually, 45–100 mg/dl), increased globulins, and strongly positive serology (Dewhurst, 1969; Hook, 1997). Reported CT abnormalities include frontal and temporal atrophy and bilateral symmetrical areas of white matter hypodensity (Kulla et al., 1984; Zifko et al., 1996). Similar areas of atrophy are depicted by MRI and can be accompanied by increased signal intensity in the hippocampi and frontal lobes on T_2-weighted images (subcortical gliosis) or signal loss in the basal ganglia (from iron deposition) (Zifko et al., 1996). Lissauer's form appears on CT as a low-density mass lesion with either diffuse or gyral enhancement. On MRI, the lesion's intensity is low on T_1-weighted and high on T_2-weighted images (Ito et al., 1990; Kulla et al., 1984; Nitrini et al., 1988).

Penicillin therapy reliably normalizes the CSF and arrests the disease, but complete cure is possible only when symptoms are of recent onset (months). The deficits of patients with disease of longer duration improve only partially or not at all (Perdrup et al., 1981).

Tabes dorsalis

Tabes dorsalis also develops in about 40% of patients with symptomatic neurosyphilis, its symptoms beginning from 3 to 47 years after infection (average latency, 21 years) (Fischer et al., 1976; Hook, 1997; Swartz et al., 1999). Clinical features of other forms of neurosyphilis may be present simultaneously, especially general paresis (taboparesis). Men are affected 4–6 times as often as women (Merritt et al., 1946).

Degeneration of the posterior roots and columns of the

spinal cord defines the gross pathology. The posterior columns are shrunken, primarily the fasciculus gracilis, the overlying arachnoid is opaque and thickened, and the lumbar and lower thoracic dorsal roots are atrophied. In early cases, inflammatory cell infiltration of the leptomeninges and dorsal roots and accompanying destruction of myelinated nerve fibres are the underlying microscopic changes. In older, 'burnt-out' cases, inflammation is either less conspicuous or entirely absent. Ultimately, few intact fibres remain in the lumbar posterior roots, the dorsal root entry zone and tract of Lissauer atrophy, and the central processes of the dorsal root ganglion cells degenerate. Secondary shrinkage and gliosis of the posterior columns follow. Sensory ganglia are not affected. The cranial nerves, on the other hand, often are, especially nerves II, III, V, and VIII. The microscopic changes are similar: arachnoidal inflammation and adhesions and nerve fibre loss are characteristic (Hook, 1997; Merritt et al., 1946).

The onset is insidious and the course progressive. Pains, paresthesias, sensory loss, and ataxia dominate the picture. The pains and paresthesias generally come first. Sudden, severe, stabbing, paroxysmal pains that last mere seconds (lightning pains) are most common (present in 75% of cases). These affect mainly the legs, less often the back, arms and face. Repeated salvos, lasting minutes to days, separated by pain-free intervals are typical. The individual pains either recur in the same spot or migrate. Paresthesias, also waxing and waning, are present in 25%. These include numbness, tingling, tightness, coldness, hypersensitivity to touch, and aching of the legs and trunk; deadness of the soles of the feet; and girdle sensations on the trunk (Hook, 1997; Merrick et al., 1946; Swartz et al., 1999).

Less often (10–15% of cases), probably when posterior root inflammation irritates visceral afferent fibres, reflex spasm of visceral smooth muscles causes paroxysms of pain that can last for days (tabetic or visceral crises). Gastric crises with epigastric pain and vomiting are most common. Less frequent are rectal crises with tenesmus; intestinal with colic and intermittent diarrhea and constipation; laryngeal with throat pain, hoarseness, stridor, and dyspnea; and vesical with pain and strangury (Hook, 1997; Merritt et al., 1946; Swartz et al., 1999).

Sensory loss develops later. Early on, sensitivity to pain and touch is lost from the nose and cheeks, the ulnar surface of the forearms, around the nipples, and the peroneal surface of the legs (Hitzig's zones). Later, first vibratory and then position sense and deep pain sensibility are impaired in the legs and then in the arms. Next, Romberg's test becomes positive and locomotor ataxia develops. The gait is wide based and foot slapping, the steps are uneven and uncertain, and the head and eyes are positioned to watch the feet. When the cervical roots are affected, clumsiness and pseudoathetosis of the arms, hands, and fingers result (Hook, 1997; Merritt et al., 1946; Swartz et al., 1999).

Deafferentation also leads to muscular hypotonia and loss of the knee and ankle jerks. The hypotonia in turn causes hyperextensibility and injury of anesthetic joints. With repeated injury, painless degenerative arthropathy (Charcot's joints) develops (7% of patients), usually in the knee, ankle, hip, shoulder, elbow, wrist, or spine in that order. Similarly, painless perforating ulcers (mal perforans) may form at pressure points on the sole of the foot when the anesthetic tissue is injured during walking. Also caused by deafferentation are impotence, anesthesia of the genitalia, bladder hypotonia, urinary retention and dribbling incontinence, and constipation (Hook, 1997; Merritt et al., 1946; Swartz et al., 1999).

Common results of cranial nerve involvement include optic atrophy (20% of patients), oculomotor palsies (20–25%, usually of nerve III), hearing loss, sometimes sudden (28%), and zones of facial hypalgesia. Pupillary abnormalities are nearly universal (94%), especially Argyll Robertson pupils (present in about 50%) (Merritt et al., 1946).

CSF abnormalities tend to decrease with increased duration of the disease: the fluid can be normal in 'burnt-out' cases. Overall, 47% of patients have pleocytosis (usually <100 cells/mm^3, mostly lymphocytes), 53% increased protein (up to 250 mg/dl, usually <100), 75% abnormal globulins, and 72% reactive serology (Hook, 1997; Merritt et al., 1946; Swartz et al., 1999). Electrodiagnostic testing yields normal sensory and motor nerve conduction velocities and F waves, but H reflexes are absent and somatosensory evoked potentials abnormal (Donofrio & Walker, 1987).

Penicillin clears the CSF and arrests the course in about 50% of cases when treatment is begun early. In advanced cases, symptoms may worsen in spite of treatment, probably because of continuing fibroblastic proliferation around posterior roots (Kofman, 1956; Perdrup et al., 1981; Swartz et al., 1999). Sensory loss and hypotonia generally do not improve, hence Charcot joints and mal perforans can still develop after treatment. Lightning pains and visceral crises often continue. Carbamazepine may relieve the lightning pains (Ekbom, 1972) and atropine and phenothiazines the visceral crises. Charcot joints are treated by bracing or fusion.

Changes in neurosyphilis in the antibiotic era

Cases of late syphilis have declined steadily in the USA in the last five decades in spite of relatively constant rates of

primary and secondary disease during most of this period (Sparling, 1999). Almost certainly, antibiotic therapy has been responsible for the decline.

As regards neurosyphilis in particular, some observers believe that antibiotics have modified more than its frequency. They maintain that partially effective and often incidental (prescribed for other infections) antibiotic treatment has altered its clinical features as well (Hook, 1997). Kofman (1956) suggested this possibility first. In a study of 177 neurosyphilitics, he described many monosymptomatic cases and formes frustes; a result, he felt, of arrested illness progression and fixation of neurologic deficit at an early stage following penicillin therapy. Hooshmand et al. (1972) reached similar conclusions: their patients with neurosyphilis seldom suffered from classical paresis, tabes, or meningovascular syphilis. Instead, their disease was more often monosymptomatic or atypical or its diagnosis incidental; and the accompanying CSF abnormalities were less striking than those described earlier (as others: Burke & Schaberg, 1985; Dewhurst, 1969, have noted also). But because Hooshmand et al. (1972) relied heavily on non-standard tests (CSF-FTA) for diagnosis, their conclusions likely are not valid. Indeed, in several more recent series of patients with neurosyphilis, the presenting clinical features were no different than those reported in the pre-antibiotic era (Fischer et al., 1976; Luxon et al., 1979; Perdrup et al., 1981).

Neurosyphilis and HIV infection

More recently still, the HIV epidemic has altered the epidemiology and natural history of syphilis further. HIV infection increases the risk for syphilis (and vice versa); and coinfection with the virus can modify the clinical manifestations of syphilis, its serologic reactions, its response to treatment, and the appearance of its complications (Hook, 1997). In the USA, the nature of neurosyphilis has been affected in particular as nearly 50% of neurosyphilitics are now coinfected with HIV-1 (Katz & Berger, 1989; Musher et al., 1990; Berger, 1991).

The principal change in neurosyphilis related to coinfection is an increase in the relative frequencies of meningitis and meningovascular disease (Burke & Schaberg, 1985; Johns et al., 1987a; Katz et al., 1993; Musher, 1999; Stamm, 1999), possibly because most coinfected patients die of AIDS before they can develop tabes or paresis. But the latencies of syphilitic meningitis and meningovascular syphilis are shorter in addition, especially in those HIV patients who relapse with neurosyphilis following conventional benzathine penicillin G therapy for early disease (Johns et al., 1987a; Musher, 1999; Musher et al., 1990). In the pre-antibiotic era, patients treated for early syphilis relapsed neurologically in the same manner if their arsenical treatment was either inadequate or interrupted (Merritt et al., 1946; Musher & Baughn, 1984; Nichols & Hough, 1913). While penicillin therapy of syphilis is more effective than was arsenical, it is not always curative: natural immune mechanisms work with the antibiotic in arresting the disease (Musher et al., 1990; Musher & Baughn, 1984; Tramont, 1987). Hence both inadequate treatment and host immunocompromise can have the same outcome, early meningitis and meningovascular syphilis.

HIV-infected patients are living longer now because of newer antiretroviral therapies. Whether the number of cases of tabes and general paresis among them will increase as a result remains to be seen, they still may not survive long enough. It is worth noting though that, in the past, inadequate arsenical treatment shortened the latency of tabes (Merritt et al., 1946) just as it did that of meningovascular syphilis.

Diagnosis

Laboratory diagnosis

Because *Treponema pallidum* cannot be cultured routinely, the laboratory diagnosis of syphilis depends on serologic tests. Two types of antibodies are measured ordinarily: non-specific, non-treponemal antibodies (reagins) that react with lipoidal antigens, either of *T. pallidum* itself or formed through its interaction with the host, and treponemal antibodies that react with specific *T. pallidum* antigens (Musher, 1999; Simon, 1985).

Reagins usually are measured by flocculation tests: a precipitate forms when antibody-containing syphilitic serum is added to a suspension of cardiolipin–lecithin antigen. A number of such tests are available. Laboratories in the USA commonly use either the rapid plasma reagin (RPR) test or the Venereal Disease Reference Laboratory (VDRL) test. The RPR can be automated to screen large numbers of samples, but it cannot be quantified. While the VDRL can be (the titres reflect disease activity and the response to treatment), it takes longer to perform. Regardless of the exact non-treponemal test used, however, as many as 20–40% of all positive results are falsely positive. The tests are also insensitive: they are non-reactive in up to 25% of cases of late neurosyphilis (Fishman, 1992; Simon, 1985).

The tests for treponemal antibodies are more sensitive and more specific. Several are available. Among these, the fluorescent treponemal antibody-absorption (FTA-Abs) test is performed most often (in the USA). The test almost invariably is reactive in late syphilis and seldom falsely positive

(<2%, and then usually only borderline). But it cannot be quantified, and it remains positive for life despite successful treatment, so its results do not reflect disease activity. Consequently the FTA-Abs test is used most often to confirm the specificity of a positive non-treponemal test or to evaluate seronegative patients with suspected tertiary syphilis. If the serum FTA-Abs is negative, neurosyphilis is ruled out (Fishman, 1992; Simon, 1985).

Among the others, the *T. pallidum* microhemagglutination (MHA-TP) assay is easier to perform than the FTA-Abs as it requires no fluorescence microscopy and is automated. Like the FTA-Abs (which it eventually could replace), the MHA-TP is more sensitive and specific than the VDRL. Unfortunately, its reactivity similarly persists after treatment (Musher, 1999; Simon, 1985).

These serological tests have been applied to spinal fluid as well. The non-treponemal tests are most useful. A positive CSF VDRL test is definite evidence of neurosyphilis (Fishman, 1992), unless the fluid is visibly contaminated by blood, at serum VDRL titres of 1:256 or less, contamination sufficient to make the CSF tests reactive always results in a perceptibly bloody mixture (Izzat et al., 1971). But CSF reagin tests are negative in up to 30% of patients with neurosyphilis (Fishman, 1992; Merritt et al., 1946). Tests for CSF antitreponemal antibodies are more sensitive, yet the antibodies detected are usually derived from serum, and their presence represents only a dilute serum sample (Jaffe et al., 1978). Consequently, there is no basis for applying these tests to CSF in clinical practice (Davis & Schmitt, 1989; Hook, 1997; Lukehart et al., 1988).

Clinical diagnosis

The diagnosis is straightforward in typical cases with reactive serum and CSF reagin tests and compatible CSF abnormalities. But both serum and CSF non-treponemal tests can be negative in neurosyphilis (Jaffe et al., 1978). Hence, all patients whose neurologic abnormalities suggest neurosyphilis should be tested by serum FTA-Abs or MHA-TP and then CSF examination if the serum test is positive. The diagnosis is established and treatment should be prescribed if a reactive CSF (pleocytosis, increased protein or IgG, or reactive VDRL test) is present (Burke & Schaberg, 1985).

CSF reactivity is the best measure of disease activity in neurosyphilis, and patients with fixed deficits due to inactive disease do not improve with antibiotic therapy (Simon, 1985). Therefore, patients with consonant neurological abnormalities, reactive serum treponemal tests, and normal CSF should be considered for treatment only if their deficits are progressive and no cause other than syphilis can be identified.

Table 109.2. Antibiotic therapy of neurosyphilis[a]

IV penicillin G, $18\times10^6-24\times10^6$ units/day ($3\times10^6-4\times10^6$ units every 4 hours), for 10–14 days[b]
or
IM procaine penicillin, 2.4×10^6 units/day, plus oral probenecid, 500 mg 4 times/day, each for 10–14 days[b]

Notes:

[a] from Centers for Disease Control and Prevention (1998).

[b] benzathine penicillin, 2.4×10^6 units IM, may be given at the end of either regimen to achieve a total of 3 weeks of therapy.

Treatment

Penicillin is the treatment of choice for all stages of syphilis. For neurosyphilis, the Centers for Disease Control and Prevention (CDC) (1998) recommend 10–14 days of therapy with either IV aqueous crystalline penicillin G or IM procaine penicillin plus oral probenecid (Table 109.2). For other forms of late syphilis, the recommended treatment is longer, 3 weekly injections of benzathine penicillin G (BPG). Because the duration may be as important as the intensity of antibiotic therapy, some experts in the field prescribe BPG at the end of these regimens for neurosyphilis to achieve a comparable total treatment span. Alternatives to penicillin have not been evaluated in large scale clinical trials, and published data supporting their use are minimal. Hence, the CDC recommend desensitizing penicillin-allergic neurosyphilis patients and treating them with penicillin. Some experts give IV ceftriaxone, 1 gm daily for 3 weeks instead (Swartz et al., 1999).

Changes in the CSF best reflect the efficacy of treatment, so the fluid should be examined weekly during treatment and every 3–6 months thereafter for 2 years (Simon, 1985). The cell count should fall during treatment. By 6 months, the count should be normal and the protein level falling. The VDRL titre usually falls too, but the test may remain reactive at low titre. Persistent or recurrent pleocytosis warrants retreatment (with more intensive therapy if possible). A normal CSF at 1 year indicates cure, and relapse is rare after 2 years (Dattner et al., 1951). Once the CSF is normal, no further clinical response to antibiotics should be expected. Fixed neurological deficits will remain and may even progress, especially the deficits in tabes and optic atrophy (Hook, 1997; Kofman, 1956).

A Jarisch–Herxheimer reaction, caused by the release of cytokines during phagocytosis of dead spirochetes, can complicate the first 24 hours of penicillin therapy (2% of

cases) (Zenker & Rolfs, 1990). Usually mild the symptoms (fever, headache, myalgia, and other systemic complaints) are easily managed with bedrest and antipyretics, but neither antipyretics nor corticosteroids prevent the reaction (Zenker & Rolfs, 1989). More severe reactions leading to irreversible progression of neurological deficit occur rarely (<1%).

HIV-infected patients with neurosyphilis may be at increased risk for treatment failure (Feraru et al., 1990; Gordon et al., 1994; Katz et al., 1993), though the increase is probably small. A recent trial comparing i.v. penicillin regimens with ceftriaxone showed a high rate of treatment failure (Marra et al., 2000). But no systematic studies provide a scientific basis for routinely treating coinfected patients differently than those who are HIV negative. Hence, the CDC (1998) recommend the same penicillin regimens for both. Follow-up must be meticulous, however, with regular CSF examination. If the CSF fails to clear, more prolonged treatment is indicated.

Tuberculosis

Yukari C. Manabe and Richard E. Chaisson

Johns Hopkins University School of Medicine, Baltimore, MD, USA

Despite the availability of curative therapy and a widely used vaccine, tuberculosis is one of the greatest threats to human health and continues to cause enormous suffering, disability and death. Infections with *Mycobacterium tuberculosis* cause a wide array of clinical manifestations, ranging from asymptomatic latent infection to disseminated and fulminant disease. Tuberculosis is generally regarded as a respiratory infection, but early in *M. tuberculosis* infection the organism is hematogenously disseminated and takes up residence in a number of organs, including the central nervous system. Tuberculosis affects the central nervous system in three principal ways: tuberculous meningitis, tuberculomas of the brain and spinal cord, and vertebral tuberculosis, or Pott's disease, an infection of vertebrae and paraspinous areas that can lead to destabilization of the spinal cord with potentially devastating neurological consequences. The purpose of this chapter is to describe the neurologic manifestations of tuberculosis and discuss its diagnosis and management.

Epidemiology

Tuberculosis remains a global problem with 8 million new cases per year and approximately 2 million deaths. Twenty-two countries account for 80% of all tuberculosis cases, and the case rate in developing countries is approximately sevenfold higher than in industrialized nations. Globally, increasing rates of HIV-related tuberculosis have been noted in areas where tuberculosis infection is endemic and HIV is epidemic. Tuberculosis is the most common opportunistic infection in people with HIV, and more HIV-infected individuals die from tuberculosis than any other cause. In many countries where HIV is not prevalent, tuberculosis remains a common cause of disability and death, primarily affecting young adults.

M. tuberculosis epidemiology can be divided into two components based on the natural history of the organism in humans: latent infection with *M. tuberculosis*, which is acquired from infectious cases of tuberculosis, and tuberculosis disease, which results from either primary or remote progression of a latent infection to clinical illness. Risk factors for acquiring tuberculosis infection include close contact with an infectious case, often in the same household or workplace, or exposure to air shared by infectious tuberculosis patients, such as in health care facilities or in public places in high prevalence communities. Socioeconomic factors associated with tuberculosis infection generally reflect an increased likelihood of exposure to others with active disease. Risk factors for developing active tuberculosis disease include recent infection, large inoculum, and impaired cellular immunity, such as with HIV infection or pharmacological immunosuppression. Cases of tuberculosis, not surprisingly, share epidemiological characteristics with tuberculosis infection, as the latter is required before the former can occur.

Most tuberculosis involves the lung, but between 15 and 50% can involve extrapulmonary sites, depending on the clinical setting. Tuberculous meningitis (TM) is the most common central nervous system manifestation of tuberculosis. The Centers for Disease Control and Prevention report that the proportion of extrapulmonary tuberculosis cases due to TM remained relatively stable between 1969 (4.7% of cases) and 1997 (5.2% of cases) (Farer et al., 1979; Rieder et al., 1990). TM is five times more likely to occur in children under the age of 15 than in adults, and substantially more common in HIV-infected patients than in immunocompetent adults (Rieder et al., 1990). Although TM accounts for only a small fraction of all cases of tuberculosis, it is a devastating form of the disease and is uniformly fatal if left untreated.

In developed countries, extrapulmonary tuberculosis has a disproportionately high incidence in non-whites as compared to whites (Ogawa et al., 1987). This is particularly important as non-whites make up an increasing proportion of urban populations. Further, in the United States, blacks and other racial and ethnic minorities have a case rate of extrapulmonary tuberculosis that is 5 times that for whites. In one study of population from in the Southwestern United States, the Native American population was overrepresented with 32% of all cases of extrapulmonary tuberculosis but only 8% of the population at large (Davis et al., 1993). HIV-infected persons with tuberculosis are more likely to have at least one extrapulmonary site of disease than HIV-uninfected patients (Chaisson et al., 1987). In a study of 2205 tuberculosis patients in Spain, 10% of the HIV-infected patients had *M. tuberculosis* isolated from their cerebrospinal fluid, compared to only 2% of the non-HIV-infected patients with culture-proven tuberculosis (Berenguer et al., 1992).

Pathogenesis

M. tuberculosis is transmitted via respiratory secretions with the acid-fast bacilli trapped in droplet nuclei that are the ideal vehicle for deposition into the alveoli. Those organisms that are not cleared by ciliary action in the bronchial tree are deposited in the alveoli. There, alveolar macrophages engulf the invading bacilli through a process of phagocytosis and the organisms are transported into intracellular holding spaces, or phagosomes. Ordinarily, an invading organism would be killed in the phagosome, as toxic chemicals, enzymes and cellular mechanisms to decrease the intraphagosomal pH would be introduced. *M. tuberculosis* is able to effectively prevent these processes and multiply intracellularly in macrophages. Some infected macrophages are then transported to the regional lymph nodes of the lung. In both the site of primary infection and the lymph node, the macrophages recruit and activate helper T-cells. Activated T-cells release cytokines such as IL-2 and IFN-α that, in turn, activate macrophages, cytotoxic T-cells and natural killer cells. Recruited T-cells and activated macrophages form a ring of inflammatory defenses around the central zone of infected macrophages, tubercle bacilli, and cellular debris. Some macrophages also die as a result of infection with *M. tuberculosis* and release bacteria and bacterial products that attract other lymphocytes to the site. A delayed type hypersensitivity inflammatory response is induced and eventually produces an inflammatory lesion called a granuloma. Histologically, granulomas consist of a central area of 'cheesy' necrosis, where the acid-fast bacilli can be seen, surrounded by macrophages, giant cells, hyaline and a ring of lymphocytes that have been recruited to the area (Fig. 110.1, see colour plate section). Therefore, containment of the mycobacteria in granulomas is contingent upon functioning cell-mediated immunity in the host. For this reason, patients infected with HIV and who have defective cell-mediated immunity are poorly equipped to handle tuberculosis.

At the time of the primary infection, there is also bloodborne spread of the organism to remote sites in the body including bone, joints, vertebral bodies, kidneys and the central nervous system. The majority of patients will control the infection both in the lung and at extrapulmonary sites through the formation of granulomas and will not develop disease. Patients who effectively wall off bacilli in granulomas are said to have latent disease that may lie dormant for many decades before reactivating. Despite the effective immune response, small numbers of viable bacilli remain. Immunosuppression with steroids, chemotherapy, or HIV infection as well as senescence can also precipitate reactivation as the immune mechanisms that keep the infection in check are disrupted and weakened.

In the 1930s, it was thought that TM was the direct and immediate result of miliary tuberculosis, a disseminated form of disease (Auerbach, 1951). The famous tuberculosis pathologist, Arnold Rich, first presented evidence of 'Rich foci', older lesions in the meninges that predated the miliary disease and that could cause diffuse infection of the meninges (Rich & McCordock, 1933). Further evidence that these CNS foci likely implanted at the time of primary bacillemia, was presented by MacGregor and Green in 1935 (MacGregor & Green, 1937). These caseous foci were found in 78 of 88 cases of TM. These tuberculous foci were found within the meninges, brain, and rarely in the adjacent bone or spinal cord. These lesions presumably rupture into the subarachnoid space, setting up the inflammatory response leading to TM. Therefore, meningitis usually develops as the result of reactivation of a latent focus in the CNS. TM can also occur in conjunction with miliary disease especially in children who are particularly susceptible to hematogenous spread of tuberculosis after primary infection. Likewise, adults can acquire meningeal disease during bacillemia of miliary disease, but this is not the usual pathogenesis of meningeal infection. Rarely, invasion into the spinal canal from a paraspinous or vertebral focus can also be the source. Rare cases of skull fracture leading to disruption of the blood–brain barrier can also lead to TM.

As inflammation progresses in the meninges and leptomeninges, hydrocephalus almost invariably occurs as a result of tuberculous exudates acutely, and later as a result

of an adhesive leptomeningitis. In most patients, the hydrocephalus is communicating and secondary to blockage of the basal cisterns. In the minority of patients, the hydrocephalus is non-communicating as the blockage occurs at the level of the foramina of the IVth ventricle. Gross pathological studies of TM patients have shown that narrowing and block of the aqueduct occurs as a result of brainstem meningeal exudates exerting circumferential pressure (Dastur et al., 1970). In general, the degree of hydrocephalus correlates with the duration of illness (Lorber, 1951; Foltz & Sheehy, 1956; Bharucha et al., 1969; Tandon et al., 1975). Children are more likely than adults to develop hydrocephalus (Dastur et al., 1970; Tandon et al., 1975). This may be due to the ability of the larger ventricular system in adults to accommodate the increased CSF, and the fully myelinated adult brain to resist stretch (Bhargava et al., 1982).

Hydrocephalus alone cannot account for the high mortality associated with this disease, however. Studies on the MRI appearance of infected patients' brains correlated with pathologic studies and reveal ischemic lesions in the basal ganglia and diencephalons (Dastur & Lalitha, 1973). Vasculitis develops in vessels traversing through the basal exudates with subsequent inflammation, spasm, constriction, and thrombosis. The 'tuberculous zone' was defined in one study of cerebral infarctions as the zone fed by the medial striate, thalamotuberal and the thalamoperforating arteries (Hsieh et al., 1992). In one MRI study of 27 patients, 20 patients had supratentorial lesions, 10 of whom also had brainstem ischemic lesions. All patients had evidence of ventricular dilatation (Schoeman et al., 1988). Arteritis of the subarachnoid space vessels and occlusion of the penetrating arteries extraparenchymally result in cerebral infarction or vascular lesions in 17–53% of patients examined by CT (Bhargava et al., 1982; Bullock & Welchman, 1982; Bonafe et al., 1985; Kingsley et al., 1987; Teoh et al., 1989).

Clinical presentation

The clinical spectrum of TM has historically been separated into three stages, defined by the Medical Research Council in 1948 (Medical Research Council, 1948). In Stage 1 disease, patients can have a long (>3 month) prodrome, although the most common length of time with symptoms is generally 3 weeks. Non-specific symptoms such as fever, malaise, and headache predominate. In this stage, patients are conscious and rational, but may have signs of meningismus. Focal neurologic signs are absent and there cannot be any signs of hydrocephalus in order to be classified Stage 1 disease. Some studies have found the general appearance of patients to be misleading, with only a minority presenting with significant weight loss, generalized lymphadenopathy, or hepatosplenomegaly (Barrett-Connor, 1967). Because of the non-specific clinical signs and symptoms of Stage 1, and the insidious neurological symptoms in the setting of tuberculous toxemia, diagnosis is often delayed (Kennedy & Fallon, 1979).

Stage 2 is notable for the development of single cranial nerve impairment (ptosis or facial paralysis) due to progressive basilar disease, paresis, and focal seizures. Kernig and Brudzinski signs have been noted as well as hyperactive deep tendon reflexes (Lincoln & Kirmse, 1950). Unusual focal neurologic signs such as internuclear ophthalmoplegia have been reported (Sandyk & Brennan, 1984). Prominent signs include alterations in mentation, behavioural change, impaired cognitive ability, and often increasing stupor. Worsening chronic headache, and persistent fever may also be features of this stage of disease.

In Stage 3, patients are comatose (Glasgow coma scale $\leq$8) or stuporous and often have multiple cranial nerve palsies, complete hemiplegia, or paraplegia. Seizures have also been described both in this stage and in Stage 2. By this stage, hydrocephalus is common and chronic inflammation in the enclosed space of the skull may result in significant intracranial hypertension.

Fever, headache, changes in mentation, and meningismus are present in the majority of patients in most large studies, although no one single sign or symptom has any reliable degree of sensitivity or specificity (Ogawa et al., 1987; Davis et al., 1993; Kent et al., 1993; Watson et al., 1993; Verdon et al., 1996). Children can be especially difficult to diagnose as symptoms such as fever, vomiting, drowsiness, or irritablity are commonly seen in many minor viral illnesses (Lincoln & Kirmse, 1950). Several atypical presentations of disease have been described in the literature. Behavioural abnormalities including social withdrawal, personality change, cognitive change, and memory decline can make the diagnosis difficult to differentiate from other causes of dementia or psychiatric disease. By the same token, a clinical picture indistinguishable from acute pyogenic meningitis has also been described. Although signs and symptoms of meningeal irritation are seen in the majority of cases, they can be predated or superseded by focal neurologic signs, signs of hydrocephalus, or obtundation (Udani & Dastur, 1970; Leonard & Des Prez, 1990).

A syndrome of transient, spontaneously remitting TM or 'serous meningitis' has also been described. In 1922, Cramer and Bickel published 48 cases of TM spontaneously cured in the era before anti-tuberculous therapy

Table 110.1. Diagnostic contribution of chest X-ray, tuberculin skin test, and clinical evidence of miliary disease in patients with tuberculous meningitis

Years of study	CXR evidence of TB	Tuberculin	Evidence of miliary disease	Reference
1958–1966	12/21(57%)	7/16(44%)	7/21(33%)	Barrett-Connor (1967)

1983–1994	21/31(68%)	8/13(62%)	4/31(13%)	Yechoor et al. (1996)
1966–1967		13/23(57%)		O'Toole et al. (1969)

(Cramer & Bickel, 1922). Presumably, small foci in the meninges brought there by transient bacillemia are contained by the immune system after a mild inflammatory response in the spinal fluid. Even in this early report, the authors note that such contained disease can often be a harbinger for future fatal tuberculosis with several patients in their series later admitted with pulmonary tuberculosis. In 1937, MacGregor and Green sectioned 112 brains showing old tuberculomas in the CNS, 20 with no evidence of meningitis in the face of florid pulmonary disease (MacGregor & Green, 1937). Subsequently, other sporadic case reports have appeared in the literature suggesting that some cases of 'aseptic meningitis' could be due to tuberculosis that is subsequently contained (Edmond & McKendrick, 1973; Zinneman & Hall, 1976).

Diagnosis

The diagnosis of TM (Table 110.1) rests on a constellation of findings that, together, are highly suggestive of the diagnosis. Because of the high morbidity and mortality associated with this disease despite treatment, the diagnosis of TM should be entertained in any patient with subacute meningitis. A history of recent exposure to an active case of tuberculosis can be helpful, although only a minority of patients in most large series could establish an epidemiologic link with an infectious case. Also, patients who are members of high risk groups such as HIV-infected, injection drug users, alcoholics, and some racial groups (Native American, African American) may be more likely to have TM. The tuberculin skin test is only positive in 31–64% of patients with TM, illustrating the limited sensitivity of this test. The tuberculin test is most helpful in children who develop TM in the course of primary disease. In one study of pediatric TM patients, 85% of the children were reported to be tuberculin positive (Lincoln & Kirmse, 1950). Up to one-third of patients had evidence of miliary disease either by CXR, biopsy of a remote site, or autopsy evidence. Chest X-ray, however, may be more helpful and should be performed on any patient suspected of having TM, as 30–74% of patients showed evidence of tuberculosis on a chest film. Finally, funduscopic evidence of choroidal tubercles may also be present and may be helpful in the enigmatic case.

Other more routine laboratory tests again are nonspecific and may show evidence of an elevated peripheral white blood cell count, anemia, elevated sedimentation rate; all consistent with subacute or chronic infection. None of these parameters have enough sensitivity or specificity to recommend them as definitive diagnostic tests. Hyponatremia, postulated to be secondary to the syndrome of inappropriate secretion of antidiuretic hormone, has been noted in a few studies. Davis et al., describe 79% of their cohort of 54 patients in the Southwestern United States with serum sodium $<$135 mEq/l in the first week of hospitalization, 68% with $<$130 mEq/l, and 45% with $<$125 mEq/L (Davis et al., 1993). In another urban study in the

US, 11 of 45 patients (24%) were noted to be hyponatremic during their hospital course (Ogawa et al., 1987). In an Australian study, 50% of patients were noted to have a serum sodium <130 mEq/l (Kent et al., 1993).

Examination of the cerebrospinal fluid is mandatory although elevated opening pressures and the possibility of a non-communicating hydrocephalus should be borne in mind. In one study, a 65% mortality rate was attributable in large part to 35% of patients who herniated after undergoing lumbar puncture (O'Toole et al., 1969). The CSF is clear early in disease and often becomes cloudy or turbid with chronicity. If the CSF if allowed to stand, a pellicle may form at the surface that can often be smear positive. Pleocytosis is generally present with a large range from none to over one thousand white blood cells. Greater than 50% of the cells are usually lymphocytes in 48–93% of the cohorts reviewed. Early in disease polymorphonuclear cell predominance has been reported, but usually changes to lymphocyte pleocytosis in a repeat tap several days later. Elevated protein is reported in the majority of patients in the range of 100–500 mg/dl. Nevertheless, more than a quarter of patients can have proteins less than 100 mg/dl (Iseman, 2000). Very high proteins >1000 mg/dl are rare and occur in patients with non-communicating hydrocephalus or long-standing disease with inflammation. Low CSF glucose <45 mg/dl is seen in 43–88% of patients. In some studies, a declining CSF glucose was used as evidence for a probable diagnosis of TM (Lincoln & Kirmse, 1950; Davis et al., 1993). In a paper by Kumar et al., they found five independent predictors of TM in a study with 110 cases of TM, 94 non-tuberculous meningitis patients, and 28 indeterminate patients: prodromal state >7 days, optic atrophy on fundal examination, focal deficit, abnormal movements, and CSF pleocytosis with <50% polymorphs. If three or more of these criteria were present, specificity was 98.3% (Kumar et al., 1999). The differential diagnosis of a lymphocytic pleocytosis, elevated protein, low glucose CSF profile includes the other causes of a granulomatous basilar meningitis including fungal infection, syphilis, and neurobrucellosis, as well as brain abscess.

A positive acid-fast stain of the cerebrospinal fluid combined with a positive CSF culture is the best way to diagnose TM. Because of the relative paucity of organisms in the CSF and the length of time required to grow *M. tuberculosis*, repeated CSF examinations of large volumes (10–15 ml) may be necessary to secure a diagnosis. The wide variability (4–87%) in the percentage of patients in different cohorts reported to have positive CSF smears is the result of variable technique and tenacity. Kennedy et al., report 87% of all patients had at least one CSF smear with acid fast bacilli. In this study, patients had up to 4 CSF samples sent to the laboratory with 37% of patients positive on sample 1, 25% positive on sample 2, 19% positive on sample 3 and 6% positive on sample 4. In addition, samples were concentrated by centrifugation with 0.02 ml of centrifuged deposit of CSF allowed to dry on an area not to exceed 1 cm in diameter, and with 500 high power fields examined with a 50x oil-immersion objective. The CSF culture positivity rate was also high (83%) with cultures held a minimum of 8 weeks (Kennedy & Fallon, 1979).

Alternative tests for the diagnosis of TM lack in sensitivity and specificity in a disease where diagnosis and treatment delay have profound consequences for subsequent morbidity and mortality. Polymerase chain reaction (PCR) amplifying the IS6110 insertion sequence has an overall sensitivity of <65% with slightly higher sensitivities among probable cases. False positivity rates are as high as 9%. ELISA, immune complex, and antibody immunoassays have similarly low sensitivity and specificity. Adenosine deaminase has been touted to have high sensitivity (100%), high specificity (99%), in addition to good discriminating power for TM and neurobrucellosis with levels >10 IU/L (Ribera et al., 1987; Lopez-Cortes et al., 1995). Subsequent reports showing unacceptable overlap between TM and other pyogenic causes of meningitis have shed doubt on the initial encouraging studies (Donald et al., 1987; Chawla et al., 1991).

The newer radiographical modalities such as CT and MRI have enabled clinicians to see more of the pathologic changes associated with TM. CT and MRI abnormalities are present in the majority of patients, although there are no pathognomonic changes. As described above, the finding of hydrocephalus and ventricular dilatation alone are relatively good prognostic signs. In a study by Bhargava et al. Of 60 cases of TM, only 3 patients had a normal CT scan, with 87% of pediatric patients showing evidence of hydrocephalus and only 12% of adults. The degree of basilar enhancement or evidence of inflammatory exudates is a harbinger for the formation of arteritis and ultimately ischemic injury (Bhargava et al., 1982). Therefore the presence of both meningeal and parenchymal disease with basilar enhancement is associated with the worst prognosis (Jinkins, 1991). Arteriography of patients who have evidence of basilar enhancement by CT often reveals vascular irregularity of the medium and large vessels of the basal subarachnoid cisterns. In one study of MR on 27 children with TM, MR was found to be superior in identifying both supratentorial (basal ganglia and diencephalic) lesions as well as brainstem parenchymal signal abnormalities, an area poorly examined by CT. In terms of prognostic staging, however, these authors concluded that no radiologic finding was a more superior prognostic indica-

Table 110.2. Overall mortality in tuberculous meningitis series

Years of study	Country	Stage 1	Stage 2	Stage 3	Mortality	Reference
1958–1966	Miami, USA	5(24%)	12(57%)	4(19%)	33%	Barrett-Connor (1967)

1967–1970	Cali, Columbia			25(25%)	52%	Eschobar et al. (1975)

tor than the clinical stage of disease on admission in patients with TM (Schoeman et al., 1988). The differential diagnosis of the radiologic appearance of TM can include brain abscess, neurocyticercosis, tumour and the other causes of basilar meningitis listed above.

Prognostic factors

Table 110.2 illustrates that the proportion of patients in worse stages of disease at the time of admission predicts subsequent overall mortality in most studies (Haas et al., 1977; Delage & Dusseault, 1979; Ogawa et al., 1987; Humphries et al., 1990; Kent et al., 1993). Age >40 (or >60 (Kent et al., 1993), >50 (Delage & Dusseault, 1979)) is significantly associated with increased mortality (Haas et al., 1977; Delage & Dusseault, 1979; Ogawa et al., 1987). Likewise, the other extreme of age (<3) is also associated with a worse prognosis (Medical Research Council, 1948; Freiman & Geefhuysen, 1970). In developed countries as the incidence of pulmonary tuberculosis in young persons decreases, it is the elderly who carry latent disease and have a higher than average risk for reactivation. In one study by Ogawa et al., 16% of the cases were in persons older than 65. The mortality in this group was 57% as compared with 31% overall. Delaying treatment more than 1 week after admission also often correlated with a longer duration of symptoms and generally portended a worse prognosis (Haas et al., 1977; Kennedy & Fallon, 1979; Verdon et al., 1996). These risk factors for increased mortality are listed in Table 110.3.

Table 110.3. Risk factors associated with mortality in tuberculous meningitis

Risk factor
Age >50, <3
Stage 3 Disease/coma
Delaying treatment
Very high CSF protein
Multiple cranial nerve deficits

Presentation and outcome in HIV-infected persons

Patients with HIV infection are more likely to reactivate latent disease, more likely to contract primary tuberculosis, and also more at risk for developing extrapulmonary disease. In data from San Francisco, 60% of the AIDS group had at least one extrapulmonary site of involvement, as compared to only 28% of the non-AIDS patients (Chaisson et al., 1987). Other studies have shown an increased predilection to the development of TM in particular (Bishburg et al., 1986; Fertel & Pitchenik, 1989). In the largest series comparing HIV-infected to non-infected from Spain, HIV-seropositive patients were five times more likely to have central nervous system involvement. In their series, it was the most frequently identified meningeal pathogen and was the AIDS-defining oppor-

tunistic infection in the majority of the seropositive patients (Berenguer et al., 1992). In general, the clinical presentation of patients with HIV does not differ markedly from those who are seronegative. Some have noted a trend towards more patients presenting with normal CSF protein, perhaps due to less inflammatory response in those with immune compromise (Berenguer et al., 1992). In a study by Yechoor et al., with 20 HIV-infected patients, a higher percentage of patients with Stage 2 and 3 disease was noted (87%) with an overall mortality of 65% (Yechoor et al., 1996). Prognostic factors for the HIV-infected include stage of disease on admission, delay in diagnosis and the institution of therapy, and lower CD4 counts (Berenguer et al., 1992; Dube et al., 1992; Yechoor et al., 1996). One small study from Los Angeles showed that intracerebral mass lesions were more common in the HIV-infected group (60% vs. 14%), although the presence of such lesions did not correlate with mortality or focal neurological findings (Dube et al., 1992). Another cohort of ten AIDS patients, nine of whom were intravenous drug users, found eight cases of TM with intracranial mass lesions (tuberculomas, see below) (Bishburg et al., 1986).

Tuberculomas

In neuropathological studies, tubercles in the brain deposited during hematogenous dissemination of disease result in intraparenchymal caseous foci. They are often multiple and have been reported to be more common in patients under 30 years of age (Loizou & Anderson, 1982). These foci do not cause frank meningitis unless they erode into the subarachnoid space (Fig. 110.2), and if small, may be silent clinically. The vigour of the immune response to such lesions determines whether there will be inflammation (cerebritis) or areas of abscess (Rich & McCordock, 1933). CT scanning has greatly enhanced the clinician's ability to diagnose such intraparenchymal lesions. Tuberculomas typically are rounded or lobulated in appearance and following contrast enhancement can show either a solid or radiolucent centre with irregular wall thickness (Fig. 110.3). Moderate surrounding edema is usually noted with contrast enhancement (Jinkins, 1991). By MR, lesions greater than 2 cm generally show a T_2 hypointense wall with T_2 hyperintensity of the surrounding area consistent with edema. The contents of the granulomatous mass is generally inhomogenous as would be expected with

Fig. 110.4. Sagittal spine MRI scan showing large area of intramedullary tuberculous involvement at T10–12. (Courtesy of Dr J.C. McArthur.)

caseous necrosis. Smaller lesions in an early stage of evolution are less likely to be encapsulated and are usually T_2 hypointense, with hyperintense spots (Schoeman et al., 1988). Older lesions that often have microscopic or macroscopic calcification can appear as a high-attenuation area with little enhancement (Loizou & Anderson, 1982). The differential diagnosis of the CT tuberculoma lesion includes gliomas, metastases, meningiomas, abscesses, cysticercosis, coccidioidomycosis and tuberous sclerosis (Rodriguez et al., 1978; Witham et al., 1979). Intramedullary tuberculomas are uncommon, estimated to occur 50 times less frequently than intracranial tuberculomas (Fig. 110.4).

Tuberculomas are seen more often in the developing world where there are more cases of extrapulmonary disease overall (Lalitha & Dastur, 1980; Loizou & Anderson, 1982; Dastur, 1983). As noted above, the increasing prevalence of HIV in the developed world and in the developing world may result in an increase in the numbers of TM as well as of tuberculomas. Diagnosis in the HIV-infected and in areas where tuberculoma is unusual epidemiologically may necessitate needle biopsy for definitive diagnosis. Cerebral angiograms can be helpful in differentiating tumour masses from tuberculomas as tuberculosis rarely causes tumour blush secondary to an absence of increased vascularity. Tuberculomas respond well to medical treatment with antituberculous antibiotics so that surgery is rarely necessary (Harder et al., 1983). Surgical intervention is best reserved for cases with obstructive hydrocephalus (often with very large lesions), or brainstem compression as it may be complicated by severe, fatal meningitis (Tandon & Bhargava, 1985).

With treatment, tuberculomas can paradoxically worsen before they recede, or appear in cases where no lesions were seen by CT or MR (Lees et al., 1980; Loizou & Anderson, 1982; Chambers et al., 1984; Chang et al., 1986; Shepard et al., 1986; Teoh et al., 1987; Watson et al., 1993) There are numerous reports in the literature of paradoxical worsening. In general, these cases should be medically managed and in cases where surrounding edema is severe and symptomatic, systemic corticosteroids may be useful (Harder et al., 1983; Leonard & Des Prez, 1990; Watson et al., 1993)

Vertebral tuberculosis

Bone and joint tuberculosis may affect a number of areas, but vertebral tuberculosis (Pott's disease) is the most common form, accounting for almost one-half of cases. Hematogenous seeding of the anterior portion of vertebral bone during initial infection sets the stage for later development of Pott's disease. Infection grows initially within the anterior vertebral body, then may spread to the disk space and to paraspinous tissues. Destruction of the vertebral body causes wedging and eventual collapse. Patients usually complain of back pain, with constitutional symptoms less prominent. Neurologic impairment is a late complication, but delays in diagnosis are common and many patients experience neurological sequelae. Imaging studies of the spine reveal anterior wedging, collapse of vertebrae and paraspinous abscesses most often. The diagnosis is established with bone biopsy or curettage, or by culture of the drainage from a paraspinous abscess.

Treatment

Treatment of tuberculosis requires the use of multiple agents active against the infecting strain; when only one active drug is given, selection of innately drug-resistant clones can occur, resulting in the emergence of drug-resistant disease. The current standard regimen to treat pulmonary tuberculosis is isoniazid and rifampin given for 6 months, with pyrazinamide and ethambutol or streptomycin given during the first 2 months. Standard dosages of

Table 110.4(*b*). Chemotherapy in tuberculous meningitis

Antibiotic	Recommended dose	CSF penetration (no inflam.)	CSF penetration with TM	Clinical efficacy
Isoniazid	5 mg/ kg, usual maximum 300 mg daily; doses of 10 mg/kg/d–20 mg/ kg/d sometimes used in CNS disease	++	(Elmendorf et al., 1952; Barclay et al., 1953; Fletcher, 1953; Lanier et al., 1958; Donald et al., 1992)	Documented (Clark et al., 1952)
Pyrazinamide	20–30 mg/kg/d	++	(Ellard et al., 1987; Donald & Seifart, 1988)	No proven efficacy, but important sterilizing drug in pulmonary TB
Ethionamide	10–15mg/kg/d	++		Only 5x the MIC at peak concentration with rapid elimination
Ethambutol	25 mg/kg/d	+	(Place et al., 1969; Bobrowitz, 1972)	Static drug at non-toxic doses with no proven efficacy in TM
Streptomycin	22 mg/kg TIW 15 mg/kg/d 1 gm qd (adults)	±	(McDermott et al., 1947; Bunn, 1948; Lincoln & Kirmse, 1950; Illingsworth & Lorber, 1951; Perry, 1952)	Some limited efficacy in early studies even when used as monoRx. 8th nerve toxicity
Rifampin	10 mg/kg/d, maximum dose 600 mg daily, some experts recommend up to 750 mg daily for CNS disease	±	(D'Oliveira, 1972; Sippel et al., 1974)	Important sterilizing drug in pulmonary TB, 5–25% of serum levels only, ?additional benefit with increased doses

the first line antituberculous agents are given in Table 110.4(*a*). When treating pulmonary and some extrapulmonary forms of tuberculosis, intermittent therapy with higher doses of most agents is frequently employed, usually after an initial 2–8 weeks of daily therapy. Treatment of neurological forms of tuberculosis is usually given daily throughout treatment because the drug levels achieved in cerebrospinal fluid may be marginally adequate. Moreover, treatment of neurological tuberculosis generally requires more prolonged therapy, usually 12 months, as described below. Drug-resistant tuberculosis may require prolonged therapy, as well, depending on the drugs to which the isolate is resistant. All patients being treated for tuberculosis should have cultures taken to confirm the

diagnosis, and susceptibility testing of the initial isolate should be performed to rule out drug-resistance.

Since the advent of chemotherapy for TM, the mortality has changed remarkably little. Streptomycin was the first antituberculous drug produce, and it brought about remarkable remissions of tuberculous meningitis. Many patients experienced relapses with streptomycin-resistant organisms, however, dampening the initial enthusiasm for antibiotic therapy. Subsequently, landmark studies by the British Medical Research Council and the US Public Health Service verified the efficacy of combination therapy against tuberculosis, and multidrug treatment became the rule. Isoniazid became the mainstay of therapy in the early 1950s, and later ethambutol, pyrazinamide (PZA) and rifampin were added to the repertoire of antituberculosis agents. Although the development of these latter drugs was critically important for the therapy of most forms of tuberculosis, their availability did not change mortality in TM compared to streptomycin or isoniazid.

Treatment of central nervous system tuberculosis is complicated by the difficulty of delivering adequate concentrations of antimicrobial agents to the site of infection. Penetration through the blood–brain barrier with uninflamed meninges depends on the molecular weight, ionization, protein binding, and, to a lesser extent, to the lipid solubility of the antimicrobial compound. Isoniazid, PZA, and ethionamide have the best CSF levels among the antituberculosis arsenal. In contrast, rifampin, streptomycin, and ethambutol have poor CSF penetration unless there is meningeal inflammation, and even in that setting, rifampin achieves only 5–25% of the serum levels (Holdiness, 1985; Ellard et al., 1993).

The treatment of TM, therefore, should begin with at least four drugs, usually isoniazid, rifampin, PZA and ethambutol. Drug dosages used in TM are shown in Table 110.4(*b*). Isoniazid is the cornerstone of any regimen unless there is known or suspected resistance, because its good CSF penetration results in drug exposures (area under the curve) in CSF similar to that in serum. The dose of isoniazid for tuberculosis is generally 5 mg/kg/day, with a maximum daily dosage of 300 mg. In central nervous system tuberculosis, however, some authorities recommend increasing the dosage to 10 mg/kg per day to assure adequate drug levels in cerebrospinal fluid. At this dosage, the isoniazid concentration in the CSF 12–14 hours after a dose still exceeds the MIC for *M. tuberculosis*. In areas where there is a high prevalence of multidrug resistant tuberculosis a dosage of 20 mg/kg may allow for coverage of moderately resistant *M. tuberculosis* strains by achieving slightly higher CSF concentrations, even in patients who are rapid acetylators of this agent (Donald et al., 1992). Although the number of tubercle bacilli in the CSF in TM is several orders of magnitude lower than that in a pulmonary cavity, at least two other active drugs should be added to the regimen to prevent the selection of drug resistance. Isoniazid (INH) eliminates only actively dividing bacilli, and drugs with known activity against dormant and semidormant organisms are also required. PZA and rifampin probably contribute to sterilization of the meninges in TM, though firm evidence of this is lacking (Fox & Mitchison, 1975; Jindani et al., 1980). PZA is a small molecule that is uncharged, not protein bound and lipophilic and consequently has good CSF penetration (Ellard et al., 1987). Data from studies of pulmonary tuberculosis show a better tuberculocidal effect with the addition of this agent to isoniazid and rifampin, and this drug should be included in the first 2 months of treatment for TM. Some experts continue PZA throughout the course of treatment for TM, especially in severely ill patients. Increased doses of rifampin should be considered given the poor CSF penetration of this agent, but liver function tests should be monitored closely. In a study by Ramachandran et al., the incidence of jaundice was related to high dosages of both INH and rifampin; at INH doses of 20 mg/kg with rifampin doses of 12 mg/kg, 39% of patients developed jaundice, while at a dosage of INH 12 mg/kg jaundice occurred in 16% of patients. Moreover, when rifampin was given only twice weekly only 5% of patients developed jaundice (Ramachandran et al., 1986).

Several alternatives exist for the fourth drug in combination with INH, rifampin and PZA. Streptomycin showed initial efficacy when used as monotherapy in the 1940s and 1950s and may be a reasonable alternative. In the extensive experience at National Jewish Center in Denver, a thrice weekly regimen of streptomycin is given with daily isoniazid, rifampin and PZA in order to minimize eighth cranial nerve toxicity (Iseman, 2000). Ethambutol may be a reasonable alternative as it showed some efficacy in combination with INH in a small trial of patients with TM, although it does not have good CSF penetration (Bobrowitz, 1972). Alternatively, ethionamide may be an attractive alternative, especially for the pediatric patient, as it has better CSF penetration, no ocular toxicity, and may be better tolerated from a gastrointestinal standpoint (Ellard et al., 1993; Iseman, 2000). Twelve months of therapy is likely required for TM, although 9 months may be adequate in patients with a rapid initial improvement with therapy. Overall, those who present with Stage 3 disease are least likely to benefit from chemotherapy, as the mortality in the moribund patient at presentation is high and has not changed since the advent of antituberculous drugs.

Table 110.5. Studies examining adjunctive corticosteroid (CS) therapy in TM[a]

Year	# Pts (#CS)	Antibiotic regimen	Steroid regimen	Comments	Ref
1955	12(6)	INH/S	Cortisone 100mg/day, ACTH during taper	Faster recovery 2–3 days vs. 7–10 days, less neuro sequelae 0/6 vs. 4/6 controls	Ashby & Grant (1955)
1952–8	33(16)	INH/S/PAS	IM cortisone, then PO prednisone (34 day mean)	3/16 steroid Rx'ed died vs 9/17 controls	Voljavec & Corpe (1960)
	37(19)	INH/S/PAS	Hydrocortisone, 300mg/d× 14 d, ACTH (days11–14)	No difference in CSF parameters, death or neuro sequelae	Lepper & Spies (1963)
1966–7	23(11)	INH/S	Dexamethasone 9 mg/d, 4 wk taper	Faster drop in CSF pressure with fewer herniations in steroid Rx'ed, CSF gluc, prot, WBS count all improved faster with steroids	O'Toole et al. (1969)
1967–70	99(52)	INH/S/PAS	Prednisone 1 or 10 mg/kg/ day, 30 day taper	22/52 steroid Rx'ed died vs. 23/47 controls died, no difference in sequelae	Escobar et al. (1975)
1979–82	136(66)	INH/S/Eth	Dexamethasone 8–12 mg/day×21 d	No significant difference in survival or ocular complications, less optic atrophy in steroid Rx'ed	Girgis et al. (1983)
1982–7	160(75)	INH/S/Eth	Dexamethasone 12 mg/day, taper over 6 wks	Faster improvement in CSF parameters in steroid Rx'ed, significantly decreased mortality 43% vs. 59%, and neuro sequelae (4/10 steroid Rx'ed vs. 6/13)	Girgis et al. (1991)
1955–77	445(339)	INH/S/PAS (345) Kan/INH (80) Kan/INH/PAS(20)	Prednisone 30–40 mg/day, after one month, 2 month taper	Reduction in mortality in steroid Rx'ed in Stage 2 and 3 disease	Shaw et al. (1984)
1991–2	47(24)	RIF/INH/PZA	Dexamethasone 16 mg/day, p.o. dexamethasone 8 mg/day ×21 days, 14 day taper	Trend towards better outcome with mild sequelae, no survival difference	Kumarvelu et al. (1994)

Note:

[a] Adapted from table in Dooley et al. (1997).

Steroid therapy in TM

There are eight published studies in the literature examining the impact of steroids in TM (Ashby & Grant, 1955; Kumar et al., 1994; Shaw et al., 1984; Voljavec & Corpe, 1960; Lepper & Spies, 1963; O'Toole et al., 1969; Escobar et al., 1975; Girgis et al., 1983, 1991). They are summarized in Table 110.5. There are methodologic flaws in all, but taken together, there is likely some benefit to the administration of corticosteroids (Dooley et al., 1997). Patients with intermediate disease are most likely to benefit based on the two trials that stratified patients by stage of disease at presentation. Interestingly, drowsy rather than comatose patients were more likely to benefit, those with single cranial nerve paresis, or hemiparesis were also found to have better outcomes (Voljavec & Corpe, 1960; Girgis et al., 1991). Studies testing steroid regimens longer than 4 weeks were more likely to demonstrate significant benefit (Ashby & Grant, 1955; Voljavec & Corpe, 1960; Escobar et al., 1975; Girgis et al., 1991). The mechanisms of action resulting in lower mortality seems to be in the alleviation of cerebral edema, decrease in arachnoiditis with concomitant relief of hydrocephalus, increased intracranial pressure, and cranial nerve palsies. Relief of spinal cord blockage or non-communicating hydrocephalus secondary to inflammation could also occur. One potential concern with the initiation of steroids is an unfavourable decrease in the CSF penetration of antituberculous drugs. In one study, however, steroid therapy did not significantly alter the CSF pharmacokinetics of chemotherapy (Kaojarern et al., 1991).

The treatment of CNS tuberculomas requires prolonged courses of antituberculous drugs. Surgery is usually only indicated for establishing the diagnosis or managing impending neurologic catastrophes such as herniation. Penetration of drugs into tuberculomas is limited, and the time to a clinical response may be prolonged. During the course of treatment for tuberculomas, masses are frequently noted to increase in size and generally follow an erratic course. The majority of lesions are improved after 6 months of therapy, and most have resolved after 12–15 months.

Pott's disease is usually diagnosed by biopsy of a vertebra or paraspinous abscess, and debridement is often required. Surgical intervention to stabilize the spine is needed in a minority of cases. The optimal surgical management of Pott's disease is controversial, but one study found that patients given early surgical treatment had fewer long-term deformities and neurologic sequelae than those treated conservatively. Antimicrobial therapy for Pott's disease is the same as for pulmonary tuberculosis, but the duration of treatment is extended to 9–12 months. Previously, most patients with Pott's disease were treated for 18 months, but a controlled trial of 9 vs. 18 months of therapy found no differences in outcomes with the longer course.

Head trauma

M. Sean Grady and Tracy K. McIntosh

Department of Neurosurgery, University of Pennsylvania, Philadelphia, PA, USA

Traumatic brain injury (TBI) is one of the leading causes of morbidity and mortality in children and young adults throughout the world. Substantial progress has been made in reducing death and improving outcome for this little recognized epidemic since the 1980s. Nonetheless, over 50 000 US citizens die annually as a consequence of TBI and 80 000–90 000 survivors experience substantial long-term disability. In this chapter, we will discuss recent epidemiologic studies, diagnosis and management of TBI and describe ongoing efforts in bench and translational research.

Trends in TBI (Thurman et al., 1999)

The Centers for Disease Control and Prevention (CDC) began the development of a multi-state surveillance system for TBI in 1989 in response to a Federal Interagency Head Injury Task Force report that identified a need for better information on TBI. Prior to this, data was derived from hospital-based clinical case series in geographically restricted epidemiological studies. Consequently, the ability to broadly generalize findings from these early efforts was limited. Prior to 1990, estimates of hospital admissions for TBI in the US were about 500 000 per year, with an incidence ranging from 132 to 367 per 100 000, depending on the region studied. With the onset of the CDC study, a much broader and more representative analysis began which now includes 15 states (Thurman et al., 1999). These include states with rural populations (Alaska, Arkansas, Minnesota and Nebraska), major cities (New York, California) and broad racial representation. Guidelines were established to define TBI: craniocerebral trauma due to blunt or penetrating trauma to the head resulting in decreased level of consciousness, amnesia, other neurologic or neuropsychologic abnormalities, skull fracture, diagnosed intracranial lesions or death. As a result of these efforts, a more accurate representation of TBI in the US may now be described (see Figs. 11.1, 11.2).

Recent data show that 230 000 people are hospitalized and survive TBI with over 80 000 of these individuals sustaining long-term disability. The hospital admission number is substantially reduced from prior decades when over 500 000 patients per year were hospitalized. This is probably a consequence of improved and readily available technology (CT scan) which can screen for intracranial pathology as well as changing criteria for hospital admission. About 50 000 die from TBI, which is 30% of all traumatic deaths. Adolescents, young adults and the elderly are most at risk, with a male:female rate of 2:1. The age and gender profile is unchanged from prior studies but the death rate has decreased, from 24.7 per 100 000 to 19.8 per 100 000. There has been a substantial shift in the cause of death from transportation to firearms due to improvement in vehicle safety, more stringent drinking and driving laws, increased seat belt use and other safety measures (helmets, child seats). Firearms became the leading cause of TBI-related death in 1990, with two-thirds of these firearm-induced deaths due to suicide. Given the restriction on firearms, transportation accidents remain outside the US the leading cause of death due to TBI.

Estimates of TBI-induced long-term disability are based on hospital discharge data combined with an estimate of severity using the Abbreviated Injury Scale included as part of the discharge data. Using this information, a prevalence of 5.3 million US citizens (2% of the population) live with TBI-related disability. The incidence of TBI-related disability is estimated at 80 000 individuals. Less information is available on the age, gender or ethnicity of this population. Economic analysis of the annual cost of TBI-related disability ranges from $4.5 billion in direct expenditure (medical care and services) to $20.6 billion in injury-related work loss and disability. Thus, while much progress

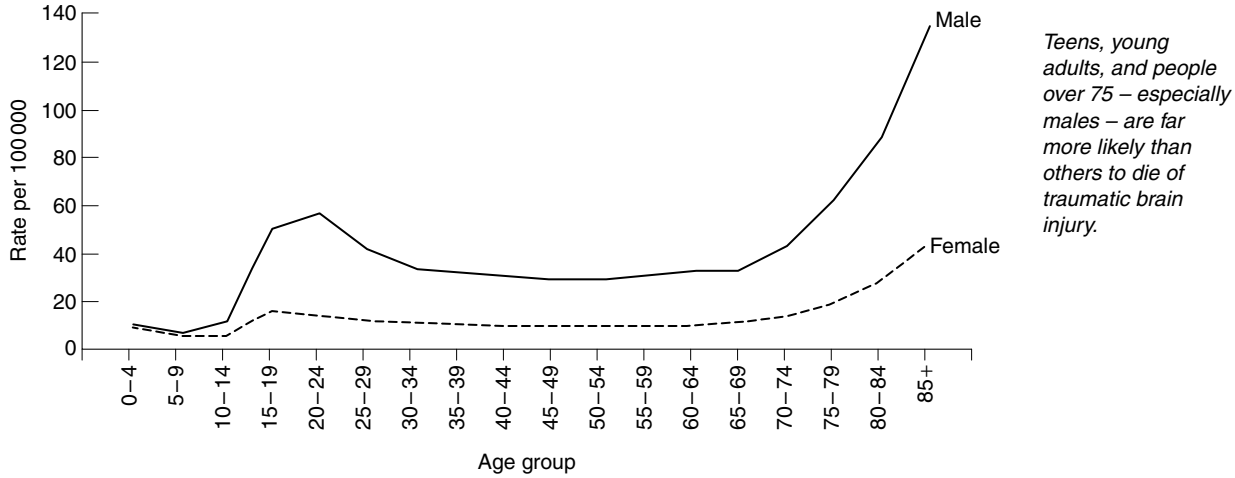

Fig. 111.1. TBI death rates by age and gender (permission: Traumatic Brain Injury in the United States: A Report to Congress, Division of Acute Care, Rehabilitation Research, and Disability, Prevention, National Center for Injury Prevention and Control, Centers for Disease Control and Prevention, US Department of Health and Human Services, December 1999).

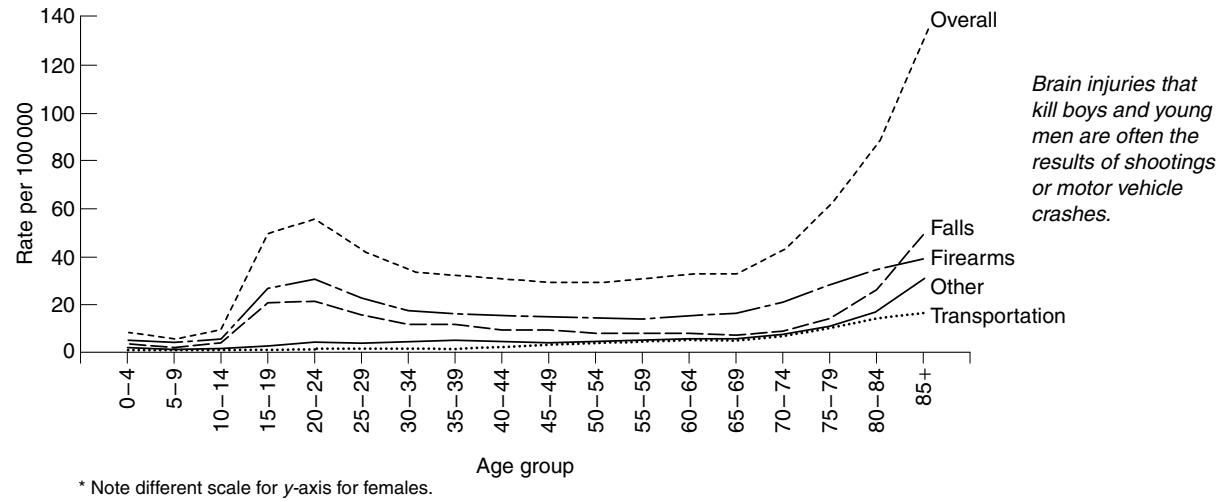

Fig. 111.2. TBI related deaths by cause (permission: Traumatic Brain Injury in the United States: a Report to Congress, Division of Acute Care, Rehabilitation Research, and Disability, Prevention, National Center for Injury Prevention and Control, Centers for Disease Control and Prevention, US Department of Health and Human Services, December 1999).

has been made in reducing death and disability from TBI, much more remains to be accomplished.

Medical and surgical management of TBI (Bullock et al., 1996)

A system of classification of TBI into three grades: minor, moderate and severe was established by Teasdale and Jennett in 1974. This schema, known as the Glasgow Coma Scale, has demonstrated persistence because of its ease of administration, high interobserver reliability and utility for grading severity and predicting outcome (see Fig. 111.3).

The summation of these individual scores ranges from 3–15, with severe TBI classified as less than or equal to 8, moderate 9–12 and minor as 13–15.

Motor Score:	
Obey verbal commands	6
Localize to painful stimuli	5
Withdrawal to painful stimuli	4
Flexion (decorticate) posturing to painful stimuli	3
Extension (decerebrate) posturing to painful stimuli	2
No motor response	1
Verbal Score:	
Oriented and conversing	5
Conversing but disoriented	4
Inappropriate words	3
Incomprehensible sounds	2
No verbal response	1
Intubated	T
Eye Score:	
Open spontaneously	4
Open to verbal stimuli	3
Open to painful stimuli	2
No eye opening	1
Total Score:	**3-15**

Fig. 111.3. Glasgow Coma Scale.

In the field

Treatment of TBI begins with resuscitation in the field by trained paramedics or emergency medical technicians. Following the initial insult, the brain is susceptible to a variety of secondary insults that will compromise neurological outcome. These insults can occur within minutes of injury and may include expanding hematomas or brain edema causing raised intracranial pressure, hypoxia due to ventilatory compromise or hypotension due to hemorrhagic shock. These events must be recognized and reversed to optimize long-term recovery potential.

Traditionally, ambulance services attempted to transfer the trauma patient as rapidly as possible from the injury scene to the emergency room. However, a significant number of patients with severe TBI experience at least one episode of hypotension (systolic blood pressure $<$90 mm Hg) or hypoxia ($PaO_2 < 60$ mm Hg), according to data from the Traumatic Coma Data Bank (Marshall et al., 1991). Mortality increased 150% in those patients with an episode of hypotension, compared to patients without hypotension. Pathological studies of brains of humans dying from TBI but with no recorded episodes of hypotension identified ischemic lesions in 40% of these patients (Adams et al., 1982). Therefore, even minor ischemia may have adverse consequences on a traumatically injured brain. Consequently, there has been an emphasis on resuscitation in the field including intubation for airway control and intravenous fluids for maintaining adequate volume. The notion of keeping the brain-injured patient in a relative state of dehydration to avoid brain edema is no longer supported by the literature or in practice (Bullock, 1996).

There are several studies demonstrating the importance of an organized trauma system to improving outcome from

TBI. In a prospective study, Colohan et al. (1989) compared outcome after severe TBI in two very different environments, Charlottesville, Virginia and Delhi, India. The mortality rates of the most severely injured patients, those with GCS 3 or 4 were similar at both centres. However, the mortality of patients with GCS 5 was 12.5% in Delhi as opposed to 4% in Charlottesville. The difference was attributed to prehospital systems, with <3% of patients in Delhi receiving prehospital care by trained professionals compared to >85% of patients in Charlottesville receiving field resuscitation by paramedics. Further, transport time to definitive care was substantially different, with only 7% of patients in Delhi being admitted to a hospital within 1 hour compared to 50% in Charlottesville. Further, air transport where possible has reduced anticipated mortality by as much as 52% (Baxt & Moody, 1983).

In the emergency room

After transport to a facility capable of managing trauma, patients undergo an overall evaluation to determine the basics of life support and to identify and prioritize treatment of all injuries. For example, 10% of patient with severe TBI have a concomitant spine fracture (O'Malley & Ross, 1988). Further chest, abdominal, pelvis or extremity injuries may result in hemorrhagic shock that must be corrected. The American College of Surgeons has developed the Advanced Trauma Life Support (ATLS) course curriculum for physicians to provide a rational and standardized trauma care. Standards have been developed by the ACS Committee on Trauma that specify how trauma systems should be organized and these have been adapted by many states. Patients are evaluated according to a simple mnemonic in the primary survey: airway, breathing, circulation, disability and exposure/environment control. The first three efforts are directed at preventing or correcting hypotension and hypoxia, the fourth effort categorizes the neurological disability and the fifth concentrates on exposing for a complete examination and avoiding or correcting hypothermia. The GCS is performed as part of the Disability exam, along with pupillary examination for dilated or asymmetric pupils. Even when there has been pharmacological paralysis as a measure for intubation, the pupillary exam is reliable. The severity of the TBI is graded as previously described, and appropriate measures undertaken.

For moderate (GCS 9–12) and severe (GCS 3–8) TBI an emergency computed tomographic (CT) scan is mandatory after hemodynamic stabilization. The use of CT has revolutionized management of TBI, giving physicians the ability to rapidly and accurately diagnose hematomas, cerebral edema, infarction or hydrocephalus. Skull radiographs play virtually no role in assessment of patients with blunt trauma demonstrating a moderate or severe TBI. In cases of penetrating injury, skull radiographs may help in localizing metal or bone fragments. Use of skull films in minor TBI (GCS 13–15) has been evaluated. The presence of a skull fracture significantly increases the risk of an important intracranial hemorrhage. However, with the widespread availability of CT scanners, the cost efficacy of skull films is difficult to rationalize. In a prospective study at an inner city level 1 trauma centre, the presence of one or more of seven simple clinical findings (headache, vomiting, age >60 years, drug or alcohol intoxication, deficits in short term memory, physical evidence of trauma above the clavicles, and seizure) was 100% sensitive in predicting a positive finding on CT scan in patients with minor TBI (Haydel et al., 2000). The completion of the CT scan now provides the physician with definitive treatment of the brain injury.

In the hospital: minor TBI (Stein & Ross, 1990)

This category comprises the majority of patients, as many as 350 000 annually in the United States. At a minimum, all of these patients will have had a loss of consciousness, but many may not require hospitalization. For those patients with a GCS of 15 in the emergency room and a normal CT scan, discharge from the emergency room to a reasonable home environment is safe. There is controversy as to indications for CT scan in patients who have had transient loss of consciousness only, but Stein has shown in 1538 patients with mild TBI, 209 (13.5%) had an abnormal scan (Stein & Ross, 1990). As comparison, Duus reported a series of 1876 patients with mild TBI in whom 27 (1.4%) underwent CT scan due to clinical deterioration (Duus et al., 1993). Of those patients scanned, 9 had an intracranial hematoma. With the cost of CT scan being lower than that of hospital admission for a single day observation, a strong argument may be made for more frequent utilization of CT scan. Consideration must be made for those patients with signs of alcohol or drug intoxication, as these will impair an accurate neurological examination. A low threshold for obtaining a CT scan must be maintained for this population who are also likely to be frequent patients in the emergency soom.

In the hospital: moderate/severe TBI (Bullock et al., 1996)

Literature based guidelines for treatment of severe TBI have been published and represent the most recent

Fig. 111.4. Acute subdural hematoma: CT scan shows blood extending over the convexity of the brain causing compression of the ipsilateral ventricle and shift (herniation) of the brain.

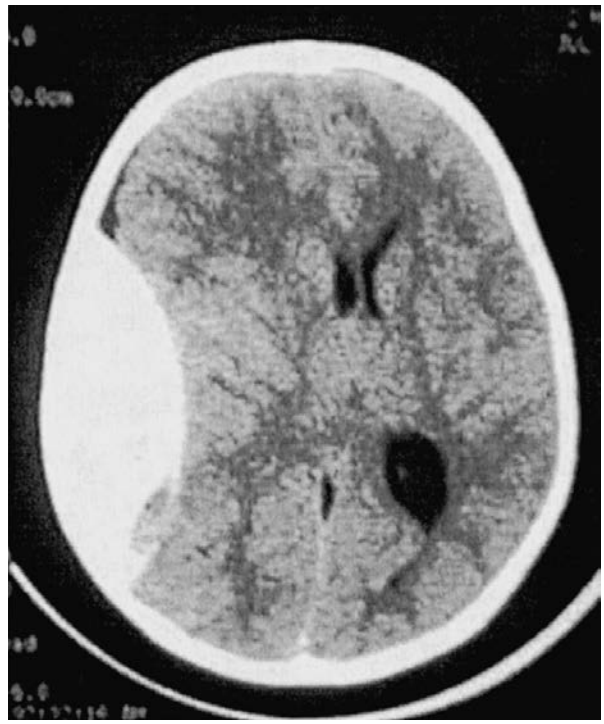

Fig. 111.5. Acute epidural hematoma: In this entity blood between the skull and the dura expands to cause brain shift, creating a secondary injury due to herniation.

attempt at standardizing the care of these patients (Bullock et al., 1996). Patients with these injuries are admitted to a nursing unit with the capacity to perform frequent neurological examinations in addition to invasive monitoring, ventilatory and blood pressure support. Alternatively, if the patient has a significant subdural or extradural hematoma detected by the initial CT scan, the patient will be taken to the operating room for evacuation of the clot. Acute subdural hematoma (Fig. 111.4) is often associated with underlying brain injury, as may be anticipated with a force strong enough to tear veins over the surface of the brain. Consequently, outcome after severe TBI with acute subdural hematoma is worse than with extradural hematoma. In extradural hematomas (Fig. 111.5) a blood clot forms between the calvarium and the dura, often due to a torn meningeal artery. Patients with this entity are often initially alert but deteriorate into coma as a consequence of mass effect causing a herniation syndrome. Drainage of the clot frequently has dramatic positive results on neurologic outcome.

In the intensive care unit, patients are monitored for adequate blood pressure and oxygenation. Patients with a severe TBI should undergo placement of an intracranial pressure (ICP) monitor to determine and treat raised intracranial pressure. The efficacy of this modality has not been prospectively tested, but is commonly accepted. There are several modalities for decreasing intracranial pressure, including drainage of cerebrospinal fluid, dehydration using intravenous mannitol or decreasing intracranial blood volume using hyperventilation. To understand the importance of lowering the intracranial pressure in a patient with severe TBI, one must understand intracranial compliance and consequences of raised ICP.

The brain rests within a closed vault, with the components being brain, CSF and blood. When a blood clot accumulates or cerebral edema occurs, the brain accommodates by shifting CSF out of the intracranial compartment into the spinal subarachnoid space. Since the total CSF volume of the adult head is about 75 cm^3, a blood clot of this size could theoretically be accommodated without substantial pressure on the brain. At this point the brain has no more compliance for the clot volume and the ICP begins to rise. The effect of this is twofold. First, the blood pressure must rise to maintain cerebral circulation. This reflex is known as the Cushing reflex and is associated with bradycardia. Secondly, the brain shifts by moving underneath the

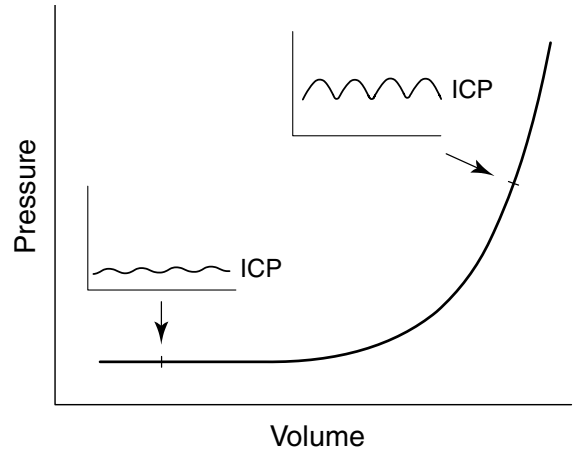

Fig. 111.6. Pressure–volume curve that reflects the ability of the brain to accommodate an expanding intracranial lesion. As the volume increases, the brain loses its compliance and intracranial pressure may rise abruptly.

falx, or through the tentorium or foramen magnum. These shifts, known as herniation, compress blood vessels and brain tissue leading to infarction and, if untreated, death or severe disability. While small increases in volume may cause substantial rises in ICP, conversely small decreases in volume may have substantial effect on lowering ICP (Fig. 111.6).

Drainage of CSF through a catheter placed into a ventricle may be a very effective way of both lowering ICP as well as being useful as a pressure monitoring device. Risks include a 1% risk of intracerebral hemorrhage as a consequence of catheter placement and a risk of infection ranging from 3–7% (Narayan et al., 1982). Otherwise, a fibreoptic monitor can be placed into the subarachnoid space or into the brain parenchyma. The osmotic diuretic mannitol rapidly lowers ICP when given intravenously. While it does lower water content within the brain, it is more probable that its effects are caused by acutely raising cerebral blood flow through volume expansion which decreases blood viscosity permitting cerebral vasoconstriction and lowering ICP (Mendelow et al., 1985; Muizelaar et al., 1984). Its effectiveness is lost as serum osmolarity rises beyond 320 mOsm. Bolus doses of 0.5 to 1 mg/kg may be given, a Foley catheter must be in place due to the diuretic effect, and fluids must be replaced to avoid hypotension due to hypovolemia. Hyperventilation decreases raised ICP through cerebral vasoconstriction. For each 1mm Hg decrease in pCO_2, the cerebral blood flow drops 2.5%. Consequently, hyperventilation must be used with caution. Aggressive hyperventilation (pCO_2 >25 mm Hg) clearly results in cerebral ischemia in the traumatically injured brain and is associated with poor outcome (Muizelaar et al., 1991). The guidelines for treatment of severe brain injury indicate that a pCO_2 between 30–35 mm Hg is optimal for ICP control without the adverse consequences of lowered cerebral blood flow.

Other medical strategies include the short-term use of dilantin for seizure prophylaxis. Several prospective, double-blind, placebo-controlled randomized studies have shown that use of an anticonvulsant longer than 1 week after TBI is not able to prevent seizures and may have some detrimental psychomotor effects (Temkin et al., 1990). Seizure control in the initial period after injury is important to prevent raised ICP as a consequence of airway compromise or increased cerebral blood flow. Barbiturates have been used to lower ICP by decreasing CBF (through reducing cerebral metabolism). However, barbiturates may also cause hypotension and consequently their use is recommended only in hemodynamically stable patients in whom other measures have failed. The use of glucocorticoids remains controversial. Several prospective randomized studies failed to find efficacy but a meta-analysis by Alderson and Roberts concluded that while there was not significant beneficial effect, there was a modest positive trend towards better outcome (Alderson & Roberts, 1997; Newell et al., 1998). A large multicentre European trial is under way to re-evaluate the efficacy of glucocorticoids.

Research in traumatic brain injury

The biomechanics of experimental TBI (Melvin, 1994) Numerous studies have evaluated the response of the skull and the underlying brain tissue to direct impact loading (Melvin, 1994). In response to relatively large impact forces, the skull deforms only slightly before fracturing due to its inherent mechanical properties. For forces distributed over very small areas, the fracture tolerance decreases and its nature changes from a linear to a penetrating or comminuted depressed fracture. The local depression, or inbending, of the skull from dynamic contact forces causes stress waves to propagate through the skull in all directions from the point of impact. These waves travel and meet at points on the skull remote from impact and they consequently cause skull fracture remote from the impact site (Got et al., 1993).

The local distortion of the skull without fracture can also transiently deform the underlying brain tissue and create pressure gradients throughout the neuraxis. Work with experimental biomechanical models has indicated that the rate and amount of local skull displacement are important predictors of the magnitude of pressure underneath,

and distant to, the impact site (Lee & Advani, 1975; Liu et al., 1975). Due to the apparent association between skull displacement and intracranial pressure, several studies have utilized mechanical impedance methods to reveal that the characteristic driving force frequency is an important parameter in assessing the magnitude of intracranial pressures caused solely by bending of the skull (Gurdjian, 1975). Short duration impact forces (<2 ms) generated pressure disturbances only if the skull was allowed to accelerate.

Despite the observations that the contact effects from impact forces can produce skull bending and intracranial pressure changes, the resulting brain injuries caused by these mechanical events appear to be restricted to focal lesions such as surface cerebral contusions, intracerebral hematomas, subdural hematomas, and epidural hematomas. Negative intracranial pressure changes have also been hypothesized to be significant factors in producing cerebral contusions at the sites of impact (Ommaya et al., 1994). An intracerebral hematoma may be viewed as a more extensive form of cerebral contusions related to negative pressures larger in magnitude than those required to cause cerebral contusions. A subdural hematoma due to local contact may occur when a skull fracture compromises the vascular network beneath the fracture site. Similarly, an epidural hematoma is not associated at all with intracranial pressure increases in 85% of cases, but is thought to occur when underlying dural vessels are torn as a result of skull fracture. In the remaining 15% of cases, fracture is not observed.

Impact or impulsive loading creates different mechanical effects (e.g. acceleration) on brain tissue. Brain lesions produced by inertial forces can be quite different, therefore, from those injuries due to contact. Two forms of acceleration, translational and rotational, form the basis for most biomechanical studies aimed at defining mechanisms and biomechanics of brain injury. Translational acceleration produces an intracranial pressure gradient and movement of the brain relative to the inner surface of the skull, the magnitude of which depends directly on the level of translational acceleration (Hayashi, 1969). In comparison, rotational acceleration produces widespread and significant tissue strains throughout the brain. The amount of shear strain is related not only to the amount of rotational acceleration, but also to the presence of intracranial dural compartments (e.g. falx, tentorium cerebri) and direction of motion.

In all, the intracranial pressure changes and brain motions due to translational accelerations have been linked most extensively to lesions such as coup and contrecoup contusions, intracerebral hematomas, subdural hematoma, and histological lesions in the brainstem region. Other lesions, however, such as diffuse axonal injury and gliding contusions, cannot be explained by the effects of translational acceleration.

Evidence for the importance of rotational acceleration in brain injury first appeared in experimental studies, and was soon followed with several theoretical or computational studies. Indeed, with the exception of epidural hematoma and injuries associated with skull fracture, rotational acceleration can produce every major form of brain injury. Using photoelastic gelatin skulls subjected to rapid rotation without impact, Holbourn (1943) reported that areas of high maximum shear stress coincided with brain lesions identifiable at autopsy. In contrast to the translational acceleration motions and pressures, these areas of high strain were throughout the brain and depended more on the geometric characteristics of the skull. Additional mathematical studies, complemented with experimental studies, have shown significant intracranial motions can occur for a range of rotational accelerations, and these motions are relatively unaffected by adding translational accelerations to these loading conditions (Meaney et al., 1993). Moreover, physical modelling studies indicate that regions of the brain experiencing large strains during rotational accelerations may differ depending upon the direction and orientation of acceleration (Margulies et al., 1990; Meaney et al., 1993). Currently, sophisticated finite element models of the brain (Willinger et al., 1992) are being used to understand the response of the brain to impact loading, and will assist in further delineating the effects of rotational acceleration on several forms of brain injury.

Experimental models of TBI play an important role in evaluating and understanding the complex physiologic, behavioural and histopathologic changes associated with TBI. Many of the preclinical models of TBI have been designed to mimic closely the clinical sequelae of human TBI. However, since human TBI is very much a heterogeneous disease, no single animal model of TBI can mimic the whole spectrum of clinical TBI. Rather, the concurrent use of a number of distinct yet complementary models is necessary to reliably reproduce the whole range of injury severity and characteristic features observed upon clinical and postmortem examination of TBI patients (Gennarelli, 1994; McIntosh et al., 1998a). Intensive experimental research over the past decades employing these preclinical models has contributed to our knowledge of these sequelae after TBI (Teasdale et al., 1999). The new understanding of these processes prompted the development of several novel diagnostic and treatment strategies, which are either now part of clinical standard practice or are under intense

preclinical and clinical investigation (McIntosh et al., 1998b).

Current concepts on the pathobiology of TBI

Brain trauma and neurodegenerative disease

(Graham et al., 1995)

Convincing epidemiological studies have implicated head injury as a risk factor for Alzheimer's disease (Mortimer et al., 1991; Gualtieri & Cox, 1991; Clinton et al., 1991). Brain damage associated with dementia pugilistica (punch-drunk syndrome) and associated memory loss and Parkinson-like symptoms include diffuse beta-amyloid (Aβ) deposits and neurofibrillary tangles (Roberts et al., 1991; Geddes et al., 1996), pathological hallmarks of Alzheimer's disease that have also been identified and associated with brain trauma. In experimental animal models, up-regulation of β-amyloid precursor protein (β-APP) has been reported to occur within hours following experimental TBI and is associated with axonal damage. This increased expression of β-APP has been observed following weight-drop brain injury (Lewen et al., 1995) and lateral FP brain injury in rats (Pierce et al., 1996, 1998). Laboratory studies of brain injury in rodents, however, have been unable to find evidence for diffuse or senile neuritic β-AP plaque deposits. Using transgenic mice which overexpress human β-APP twofold, recent studies have failed to note any evidence of Aβ plaques or worsened behavioural outcome after CCI brain injury (Murai et al., 1998). However, a subsequent study employing a strain of transgenic mice that overexpressed mutant human β-APP ten-fold showed evidence of exacerbated neuronal cell loss in vulnerable hippocampal regions, significantly impaired cognitive scores and increased regional concentrations of Aβ 1–42 with no evidence of amyloid plaque formation (Smith et al., 1998).

Diffuse Aβ plaques have also been reported in head-injured patients who died 6–18 days following brain trauma (Roberts et al., 1991). Subsequent studies employing larger series of patients showed that in 152 head injured patients, with survival times between 4 hours and 2.5 years, 30% of cases showed Aβ deposits. No correlation was observed between Aβ deposits and cerebral contusions, intracranial hematoma, ischemic brain damage, brain swelling or the pathology of raised intracranial pressure, suggesting that the deposition of this peptide may represent a consequence of the acute phase response of neurons to stress in susceptible individuals (Roberts et al., 1994; Graham et al., 1995). Conversely, other studies have been unable to detect any significant increase in Aβ deposits following human head injury (Adle-Biassette et al., 1996). Still other clinical studies have associated immunohistochemical detection of β-APP expression with the topography of axonal injury in head-injured patients (Gentleman et al., 1993).

Cytoskeleton-related neurodegenerative pathology

(Yaghmai & Povlischock, 1992; Smith et al., 1999)

In addition to amyloid plaques, Alzheimer's disease is characterized by neurofibrillary tangles, composed of hyperphosphorylation tau protein, which is believed to contribute to reduced binding to microtubules, with subsequent microtubule destabilization and disruption of axonal transport (Trojanowski et al., 1993). Neurofibrillary tangles in brains from ex-boxers also immunolabel for tau, suggesting tau pathology may be a feature of dementia pugilistica-associated neurodegeneration as well (Tokuda et al., 1991). In brain-injured humans, cleaved forms of tau proteins are markedly elevated in the CSF (Zemlan et al., 1999). Although little is known about alterations in tau in the traumatically injured brain, there is some indication that phosphorylated tau may accumulate in injured axons and cell bodies following experimental TBI (Kanayama et al., 1996; Smith et al., 1999). In addition, increased tau immunoreactivity has been observed in oligodendrocytes in the acute posttraumatic period following TBI in humans (Irving et al., 1996).

Many aspects of the neurofilament (NF) alterations, which accompany neurodegenerative diseases, are also present in the pathology of TBI. Increased NF immunoreactivity in axonal swellings, indicative of NF protein accumulation, is a well-established consequence of traumatic axonal injury (Yaghmai & Povlishock, 1992; Grady et al., 1993). This disruption of the neurofilamentous cytoskeleton and loss of NF proteins occurs in regions of grey and white matter following TBI (Posmantur et al., 1996; Saatman et al., 1998), although a transient increase in neurofilament immunoreactivity in injured neurons has been reported after brain injury of moderate severity in rats. Abnormal phosphorylation of NF proteins in neuronal cell bodies (Kanayama et al., 1996) and dephosphorylation of NF proteins in axons (Yaghmai & Povlishock, 1992) has been reported to occur after experimental TBI, paralleling changes in NF phosphorylation observed after axotomy and nerve crush (Rosenfeld et al., 1987). While it is not well appreciated how the neurofilament cytoskeleton contributes to the morbidity or mortality of TBI, transgenic mice expressing a NF fusion protein and exhibiting perikaryal NF accumulation subjected to experimental lateral fluid percussion brain injury had greater initial neuromotor dysfunction, slower recovery of function, and larger cortical lesions than their wild-type littermates after

TBI (Nakamura et al., 1999). Together, these data suggest that the study of neurodegenerative disease may provide great insight into the mechanisms and treatment of cytoskeletal pathology-associated TBI.

Calcium-mediated cytoskeleton proteolysis (McIntosh et al., 1998b; Doppenberg & Bullock, 1997)

Alterations in brain Ca^{2+} homeostasis (Maxwell et al., 1995; McIntosh et al., 1997) and receptors/channels associated with Ca^{2+} entry (voltage sensitive channels or ionophore-associated glutamate receptors such as *N*-methyl-D-aspartate-NMDA receptors) have been associated with regional cerebral edema, vasospasm, and delayed cell death. Traumatic, ischemic, or anoxic injury to neurons is associated with widespread neuronal depolarization (including the induction of cortical spreading depression) and releases excitatory amino acid neurotransmitters such as glutamate, leading to the opening of NMDA receptor-associated ion channels and influx of Ca^{2+} (Faden et al., 1989; Katayama et al., 1990). Marked post-traumatic increases in Ca^{2+} have been documented using ^{45}Ca-autoradiography and indirectly via cytochemical evidence for redistribution of membrane pump calcium-ATPase and ecto- Ca^{2+}-ATPase activity, and Ca^{2+} influx in myelinated nerve fibres of the guinea-pig optic nerve after stretch (Maxwell et al., 1995) and the analysis of calcium-mediated gene expression (McIntosh et al., 1997). Ca^{2+} channel blockers and competitive and non-competitive NMDA receptor antagonists have been shown to be efficacious in the treatment of experimental TBI (see McIntosh et al., 1998b for review), but to date have been disappointing in human studies (Doppenberg & Bullock, 1997).

Pathological elevations in intracellular Ca^{2+} after TBI can precipitate an attack on the lipid bilayer cell membrane via the activation of calcium-dependent phospholipases and generation of reactive oxygen species (ROS) (McIntosh et al., 1998b). These ROS cause direct peroxidative destruction of the cell membrane, oxidize cellular proteins and nucleic acids, and destroy the cerebral vasculature. Calcium can also activate non-lysosomal cysteine protease calpain, which can degrade a wide range of cytoskeletal protein substrates, including spectrin, microtubulin, microtubule-associated proteins MAP-1B, MAP-2, and the neurofilament protein family. The activation of calpain can be determined by direct detection of autolyzed calpain or indirectly via detection of calpain-specific proteolytic fragments. Several recent studies have documented both acute calpain activation and regional calpain-induced cytoskeletal proteolysis following experimental TBI (Saatman et al., 1996). Both the neuronal and axonal cytoskeletons appear to be vulnerable to calpain-induced proteolysis (Saatman et al., 1996) in laboratory models of brain injury and in human TBI (McCracken et al., 1999), and therapeutic strategies to block or antagonize the proteolytic effects of calpain on the cytoarchitecture of the cell have proven effective by attenuating both posttraumatic motor and cognitive deficits (Posmantur et al., 1996; Saatman et al., 1996).

Inflammation and cytokines: is TBI an inflammatory disease?

A great deal of recent attention has been paid to the potentially deleterious (and paradoxically beneficial) role of postinjury inflammation in mediating delayed neuronal damage following brain trauma. Alterations in blood-borne immunocompetent cells have been found in head-injured patients (Quattrocchi et al., 1992a,b), and since the blood–brain barrier is remarkably leaky in the acute post-traumatic period, entry into the brain of circulating immunocompetent cells may influence on neuronal survival and death. Infiltration and accumulation of polymorphonuclear leukocytes (PMNLs) into brain parenchyma has been associated with the development of posttraumatic edema (Schoettle et al., 1990), while pharmacological depletion of PMNL has been shown to improve outcome following experimental brain injury in rats. More recently, the infiltration of PMNLs into brain parenchyma has been documented in the acute (first 3 days) post-traumatic period following human head injury.

Head injury and programmed cell death pathways (Smith et al., 2000)

While necrotic cell death has been extensively documented after both clinical and experimental TBI, brain injury also appears to activate other pathological cell death cascades, including programmed cell death (PCD). Unlike necrosis, PCD involves the initiation and active expression of transcription and translation-dependent pathways in which apoptosis is regarded as the primary hallmark. Although necrosis and apoptosis have been more traditionally considered as distinct mechanisms, it may be possible to consider them to be part of the same continuum of cell death, particularly within the context of traumatic CNS injury. Using a combination of terminal deoxynucleotidyl transferase (TdT)-mediated biotinylated deoxyuridine trisphosphate (dUTP) nick end labelling (TUNEL) histochemistry with electron microscopy and DNA gel electrophoresis, it has been possible to identify apoptotic cells

after experimental lateral fluid percussion brain injury in the rat (Rink et al., 1995). These observations have been extended by demonstrating regional and temporal differences in apoptotic cell death cascades in astrocytes, oligodendrocytes and neurons some months after experimental traumatic brain injury in a number of TBI models (Yakovlev et al., 1997; Conti et al., 1998), and by the presence of apoptotic, TUNEL-positive neurons and oligodendrocytes in the tissue of surface contusions of human head-injured patients (Smith et al., 2000).

Toxic chemicals and natural products in the environment contribute to the burden of neurological disease. For this reason, research on environmental neurotoxins can increase our ability to identify and control preventable causes of these often incurable diseases. Several reviews have catalogued lists of chemicals and agents associated with human neurotoxicity, including solvents, metals, pesticides, and natural toxins of marine origin (OTA, 1990; NRC, 1992; IOM, 1991; Morris, 1999). Many toxic chemicals in the workplace, especially solvents and narcotizing agents, are regulated on the basis of their neurotoxic effects (OTA, 1990). Many biocides, including insecticides, fungicides, and rodenticides were deliberately designed to be neurotoxic to pest organisms (OTA, 1990). However, target sites in the nervous system are largely conserved across species, and desirable lethal effects in pests may engender undesirable neurotoxicity in humans.

The effects of both acute and chronic exposures to many neurotoxins have been well studied. However, there is at present considerable uncertainty about the role of neurotoxins in the long latency neurodegenerative diseases, such as Parkinsonism, dementia or progressive neuropathies. Recent epidemiological studies strongly suggest associations between certain pesticides and increased risks of Parkinsonism, and between chronic exposures to certain solvents and dementias of the non-Alzheimer type (Feldman, 1999). Detecting chemical etiologies of these neurological diseases is difficult, for two reasons: epidemiological resources and data on patterns of neurological disease incidence and prevalence are very limited, and there are few animal models of acquired neurological disease.

In this chapter, we discuss examples of neurotoxic agents associated with human disease and neurological impairments. We have selected examples that illustrate the importance of understanding differences in the effects of high dose acute exposures from the effects of low dose chronic exposures. In addition, for many neurotoxins the route of exposure and the age or developmental stage of the exposed individual determines the type of neurotoxic insult. In some cases, toxic agents by themselves damage the nervous system, while in other cases, these agents probably interact with host susceptibility factors, including genetics, to induce disease or to hasten the onset or increase the severity of disease.

Lead

The heavy metal lead may be the single most significant cause of neurotoxicity in human populations worldwide. Because of its long history of human use, especially its relatively recent use in automotive fuels, lead levels in human populations are significantly elevated, by orders of magnitude, over 'natural' levels in preindustrial or remote societies (Silbergeld & Nash, 2000). Residues from past uses continue to provide exposure sources, such as lead in soils from gasoline fallout, lead in paint in old housing, and lead in plumbing in some older water systems (Silbergeld, 1997).

The neurotoxicity of lead was well understood by early medical writers, including its effects on the central and peripheral nervous system (Hamilton, 1925; Lin-fu, 1985). In the eighteenth and nineteenth centuries, Ramazzini, Tanquerel des Planches, and Oliver all described neuropsychiatric problems in lead workers, along with weakened neuromuscular function (lead palsy). These writers

* Neuropathic disorders due to environmental or industrial use agents with neurotoxic properties (acrylamide, arsenic, hexacarbons, organophosphates and others) may be found in the text and tables of Chapter 66.

noted that lead neurotoxicity was associated with both acute, high dose exposures, and also, insidiously, with low dose chronic exposures. When the manufacture of tetraethyllead began in the 1920s to supply antiknock additives to gasoline, florid neuropsychiatric symptoms, and deaths, were encountered by workers at DuPont's Deepwater facility in New Jersey (Rosner & Markowitz, 1985).

In the late nineteenth century, physicians noted that children were also, and possibly especially, at risk of lead neurotoxicity. Lockhart Gibson, in 1897, first described painted surfaces as a hazard to young children (Gibson, 1904); Oliver in 1914 referred to lead as a 'race poison' because of its abortifacient effects, fetotoxicity, and adverse effects on mental development of young children (Oliver, 1914). The often fatal effects of lead 'encephalitis' were frequently reported from large cities in the US throughout the 1920s and 1930s (Silbergeld, 1997). In 1943, Byers and Lord first reported that mental retardation and behavioural problems persisted in young children exposed to levels below those causing frank or acute encephalopathy (Byers & Lord, 1943; Silbergeld, 1997).

Starting in the 1970s, with new emphasis on environmental health in the USA through the creation of the Environmental Protection Agency, clinicians and researchers began to focus on understanding the nature of lead neurotoxicity in children. Some of the first indications that early lead exposure, at what were considered 'subclinincal' exposures, was associated with persistent and significant neurotoxic effects in children came from prospective studies of children's development in which some subjects became lead exposed during the study (Silbergeld, 1997). Over the next 20 years, a body of epidemiological and toxicological research produced an extraordinarily convergent literature on the nature of chronic, low dose lead neurotoxicity in young children (Rice & Silbergeld, 1996). The functional manifestations of chronic, low level lead toxicity in young children involve decrements in cognitive function, problems in sustained attention, and behavioural problems involving aggression and social behaviours. A meta-analysis of the effects of lead on cognitive performance was conducted by Needleman and coworkers, as shown in Table 112.1.

Many of the neurotoxic effects of lead appear to persist and may possibly be amplified years after lead exposure ceases (Needleman et al., 1990). Lead toxicity may recur as internal lead stores change over aging, as reported for postmenopausal women (Nash et al., 1998).

Mechanistic research has provided information on how lead affects the peripheral nervous system, the development of the CNS, and the functional manifestations of cognitive impairments, inattention, and aggressiveness (Rice & Silbergeld, 1996). The consensus of this research can be summarized as follows: lead interferes with neuronal signaling, at the level of transmitter release and receptor transduction, largely related to those processes requiring calcium (such as voltage-dependent transmitter release, calmodulin-regulated signal transduction, and synaptic strengthening). In the developing brain this interference

with intercellular signalling affects the neuromorphology of development, since firing supports wiring at this stage. A recent study found that relatively low dose lead exposure induces significant alterations in specific cortical nuclei within the somatosensory areas of the rat brain (Wilson et al., 2000). Cory Slechta and colleagues have reported persistent changes in NMDA and dopaminergic pathways in the midbrain and cortex of lead-exposed rodents (Cory-Slechta et al., 1996a,b, 1997, 1998; Cory-Slechta, 1997).

Lead is also neurotoxic for adults. Several reviews and meta-analyses of lead neurotoxicity in adults demonstrate consistent impairments in certain performance tasks requiring attention and appropriate motor function.

Because of the ubiquity of lead exposures in the biosphere and its continued uses in many countries, lead will continue to be a major neurotoxin of public health significance. Excess exposures are reported in many developing countries, especially in India and other regions where lead is still used in gasoline, in workers and families involved in or living near cottage industries (Jamaica; Manila), in persons using lead compounds as traditional medicines and in low-fired pottery glazes (Silbergeld, 1995). Vigilance is especially necessary to identify lead exposures, by means of blood lead screening, prior to the induction of characteristic symptoms. This is because such symptoms usually appear at exposures associated with severe and persistent neurological damage and because as with many neurotoxins these symptoms are not unique to lead.

Manganese

Manganese (Mn) neurotoxicity poses a major challenge since, contrary to many other toxic substances such as lead and mercury, which are not required by normal biological processes, Mn is an essential element, particularly for nervous system development. Both deficiency and overload can result in neurological disorders.

The normal daily requirement for Mn is obtained through food intake. Approximately 3–5% of dietary intake is absorbed, and subjected to homeostatic control through the hepatic portal system. The principal route of excretion is in feces. Most absorbed Mn is transported in plasma bound to a gamma globulin, probably transferrin. The biological half-life of Mn in the body is about 37 days, but in brain, which Mn readily accesses, the half-life is two to three times longer.

Recent studies have shown that, when hepatic control mechanisms are damaged through liver dysfunction or bypassed during parenteral nutrition, blood manganese levels (MnB) increase (Andersen et al., 1999). Magnetic resonance imaging (MRI) of patients with these conditions indicates subsequent dose-related build-up of Mn in the basal ganglia, particularly in the pallidum; some patients, but not all, display neurological symptomatology (Krieger et al., 1995; Hauser et al., 1996; Pomier-Layrargues et al., 1995; Bertinet et al., 2000).

The risk for overexposure to Mn through inhalation of airborne Mn was first demonstrated in workplace studies. Airborne Mn enters the lungs and the small, 'respirable' particles are absorbed through the alveoli, thereby bypassing the hepatic control mechanisms. Animal studies suggest that there may be a further mechanism of Mn uptake in the brain through the olfactory epithelium (Tjalve et al., 1996; Tjalve & Henriksson, 1999; Gianutsos et al., 1997; Vitarella et al., 2000).

Occupational exposures include manganese ore mining, manganese alloy production, welding (particularly soft-steel), dry alkaline battery manufacture, and manganese oxide and salt production, as well as work with agrochemicals containing manganese such as the fungicides maneb and mancozeb. These fungicides serve as seed protectants and foliar fungicides on a wide variety of small fruits and vegetables as well as banana plantations. Registered uses for these fungicides have been reduced in North America, but they are still used extensively in developing countries,

Neurologic damage in Mn exposed workers was first documented in 1837 by Couper, who described a condition resembling Parkinsonism in five pyrolusite mill workers who inhaled manganese oxide (Couper, 1837). Since that time, hundreds of cases of manganism, characterized by exytrapyramidal dysfunction and neuropsychiatric symptomatology, have been reported among industrial workers and miners throughout the world (Cook et al., 1974; Mena et al., 1967; Wang et al., 1989; Cotzias, 1958; WHO, 1981). Although manganism bears many similarities to Parkinsonism, it differs in clinical presentation and neuropathology (Calne et al., 1994; Pal et al., 1999). Within several months symptoms can progress to include posture and gait dysfunction, a characteristic dazed facial expression (masque manganigue), spasmodic laughing, and generally slow and clumsy movements. In the final stages of disease, disorders of walking become more severe; the inability to walk backwards due to severe retropulsion is a diagnostic feature (Huang et al., 1989). The characteristic neuropathology of manganism is degeneration of the basal ganglia, principally the medial segment of the globus pallidus and the substantia nigra pars compacta, although other areas of the brain may be affected (Larsen et al., 1979; Yamada et al., 1986; Newland et al., 1989). Manganism is a progressive disorder and neurodegeneration can continue even after

the cessation of exposure (Huang et al., 1998; Meco et al., 1994; Nelson et al., 1993). Active workers, without clinical disease, can display preclinical signs and symptoms of manganism (Tanaka & Lieben, 1969; Ferraz et al., 1988; Schuler et al., 1957). Recent studies have shown a consistent profile of nervous system deficits among Mn-exposed workers, involving poorer hand–eye coordination, motor slowing, increased tremor, reduced response speed, olfactory enhancement, mood changes, diminished libido, and some memory and intellectual deficits (Iregren, 1994, 1999; Mergler & Baldwin, 1997). In workers with long-term exposure to Mn, prolactin levels are increased (Smargiassi & Mutti, 1999) and MRI results shown Mn accumulation in the palladium (Lucchini et al., 1999).

Concern about environmental exposure to Mn has increased over the past years with the use of an organo-manganese gasoline additive, methylcyclopentadienyl manganese tricarbonyl (MMT). Introduced in Canada in 1976, MMT utilization in that country increased substantially until it completely replaced tetraethyl lead by 1990. Canadian studies show that atmospheric concentrations of Mn increase with traffic density, and in areas with high traffic density they can surpass the US EPA reference concentration (RfC) of 0.05 $\mu g/m^3$ for respirable Mn (Zayed et al., 1999). MMT is now approved for use in Argentina, Australia, Bulgaria, Russia, the United States, France and conditionally in New Zealand. Nevertheless, because of the lack of adequate information on its toxicological properties and possible health effects, gasoline manufacturers in some countries have been hesitant to use MMT.

There have been few studies on the effects of environmental exposures to Mn. In Japan, an episode of 16 cases of Mn poisoning resulted in four deaths, due to high levels of Mn in drinking water (20–30 mg Mn/l) from contaminated wells around which 300 dry cells had been buried (Kawamura et al., 1940). Two community studies have been carried out in areas with high levels of Mn in well water. The first, performed in Greece (Kondakis et al., 1989) among men and women aged 50 years and over, showed a progressively increasing prevalance of subclinical Parkinsonian symptoms with increasing Mn concentrations in drinking water, ranging from 0.004–0.015 mg/l in the lowest group to 1.80–2.39 mg Mn/l in the highest group. Older people appeared to be more susceptible to the effects of manganese. However, a second study compared two cohorts from rural Northern Germany, exposed to well water with high (mean of 0.300 mgMn/l, range of 0.300 to 2.106) or low manganese content (less than 0.050 mgMn/l) for up to 40 years. These authors found no neurological deficits associated with Mn exposure, and conclude that Mn in drinking water is not a risk factor (Vieregge et al., 1995).

Two reports from China describe a study of 92 children aged 11–13 years who lived in an area with moderately high Mn levels in drinking water (0.24–0.35 mg/l) due to extensive field irrigation with sewage products (He et al., 1994; Zhang et al., 1995). Neurobehavioural performance of the exposed children was significantly lower, and negative correlations between Mn in hair and most endpoints were reported. These results are consistent with an earlier reports of higher hair Mn levels in learning disabled than in normal children (Collipp et al., 1983).

A recent community based study, carried out in Canada, examined the neurotoxic effects of manganese from various environmental sources (Mergler et al., 1999; Bowler et al., 1999; Hudnell, 1999; Baldwin et al., 1999; Beuter et al., 1999). The highest levels of airborne Mn were observed downwind of the site of a former Mn alloy production plant and in the region of highest traffic density. Although blood Mn concentrations were lower than those observed among Mn exposed workers, it was significantly higher in the region with higher airborne Mn. Blood Mn (MnB) was higher among women than men, increased with consumption of cereals and leafy vegetables and paralleled airborne MnB levels in areas with higher airborne Mn (Baldwin et al., 1999). Higher MnB levels were associated with poorer performance on tasks involving coordinated movements of the upper limbs and changes in tremor parameters; among men, increasing MnB was significantly correlated to poorer postural stability, slower learning and recall and depressed near visual contrast sensitivity (Hudnell, 1999; Mergler et al., 1999; Beuter et al., 1999). An age-Mn interaction was observed, with poorest performance among those >50 years in the higher MnB category (>7.5 $\mu g/l$) (Mergler et al., 1999; Beuter et al., 1999). Mood states likewise showed an age–Mn interaction for men (Bowler et al., 1999).

Overall, the results of the studies on Mn neurotoxicity suggest that, depending on the intensity and duration of exposure, nervous system deterioration is on a continuum of dysfunction. Mn metabolism is complex and appears to be sex related. Manganese may accelerate the aging process, which would have important consequences for the onset of neurodegenerative disorders and the well-being of the elderly.

Aquatic neurotoxins (Table 112.2)

Potent neurotoxins can be secreted by harmful algal blooms (HABs), the devastating result of toxic-producing bacteria, algae, or dinoflagellates. All are single-celled eukaryotic organisms which flourish in marine and estua-

Table 112.2. Marine neurotoxins – source, exposures and toxicity

Toxin	Source (organism)	Exposures	Toxicity
CTX	*Gambierdiscus toxicus*	Via consumption of fish, especially carnivorous	GI; paresthesias; motor dysfunction; low mortality
STX	*Gonyaulax Alexandrinum* spp.	Via shellfish (red tide)	GI; paresthesias; motor flaccidity; apnea; neuropathy; moderate mortality
TTX	Unknown	Via fish, amphibians, shellfish	GI; paresthesias, bulbar and motor sign; apnea; high mortality
Brevetoxins	*Gymnodinium breve*	Via shellfish	GI; paresthesia; rhinorrhea; bronchospasm; low mortality
Domoic acid	*Nitzschia pungens*	Via shellfish and crabs	GI; paresthesia; neuropathy; seizure; soma; amnesia; low mortality
Okadaic acid	*Diophysis* spp.	Via shellfish	GI; diarrhea; nausea; chills; no mortality
Pfiesteria toxin	*Pfiesteria piscicida* (?)	Contact with water	Paresthesias; amnesia; psychological disturbances; impaired psychometric function; no mortality

Source: Taken from Silbergeld et al. (2000).

rine environments. Increasing awareness of HABs as a major health threat has spurred research on these harmful aquatic micro-organisms, and increased regulation of the seafood industry (Morris, 1999). HABs have been responsible for massive fish kills, alterations in marine habitats, and severe human illness through ingestion of affected fish and shellfish (Silbergeld et al., 2000). The production of toxins, both water and lipid soluble, has been demonstrated for approximately 60 of the over 2000 known dinoflagellate species. Toxic blooms along the coastal United States afflict hundreds of Americans annually; in countries with poor surveillance and response measures incidence rates are much higher (Morris, 1999). These events can constitute serious public health problems, in addition to deleterious effects on the environment. The occurrence of HABs is poorly predicted, either temporally or geographically, with existing methods. Thus, prevention of harmful effects depends on strict surveillance of marine environments, routine screening of seafood, and rapid response when an outbreak occurs.

Paralytic shellfish poisoning (PSP)

Paralytic shellfish poisoning results from the consumption of shellfish that bioaccumulate saxitoxins, fast-acting sodium channel blockers, produced by dinoflagellates such as *Alexandrium tamarensis* and *Alexandrium catenella*. Effects are primarily neurological, including paresthesias, ataxia, dysarthria, and confusion within an hour of ingesting contaminated shellfish. Death, due to respiratory paralysis, can occur in severe exposures. In Alaska between 1973 and 1992, PSP was responsible for 117 illnesses and one death (Gessner & Middaugh, 1995). The estimated cost of a single outbreak of paralytic shellfish poisoning in Maine was estimated to be $6 million in medical costs and lost productivity (Shumway et al., 1988).

Neurotoxic shellfish poisoning (NSP)

The brevetoxins, produced by the dinoflagellate *Karenia brevis* (formerly *Gymnodinium breve*) are the cause of neurotoxic shellfish poisoning, characterized by gastrointestinal symptoms, cramping, nausea, diarrhea, and vomiting (Hughes & Merson, 1976). Aerosolization of the brevetoxins can cause illness following inhalation, including respiratory stress and eye irritation. In 1987–1988 a bloom in North Carolina lasting several months affected 48 persons with symptoms severe enough to seek medical attention, and cost the coastal community an estimated $25 million in lost seafood and tourist revenue (Tester & Fowler, 1990). On the southwest coast of Florida, where blooms occur annually, this NSP was responsible for the deaths of 150 manatees in 1996.

Ciguatera poisoning

Ciguatera poisoning results from the consumption of predatory coral fish which accumulate toxins produced by the coral-associated dinoflagellate *Gambierdiscus toxicus*. These toxins are heat stable, and thus not inactivated by cooking fish. They bioaccumulate through the food chain, so that the larger predatory fish are the most toxic. Affected

individuals suffer gastrointestinal pains, including nausea, cramping, vomiting, and diarrhea, as well as neurological symptoms that include paresthesis, pain and weakness of the limbs, paradoxical temperature dysesthesia (cold feels hot), and 'aching teeth' (Morris, 1999). Acute toxicity may result in coma and, in severe cases, death. In Miami between 1972–1976, 129 cases of ciguatera poisoning were reported to local Health Departments (annual incidence of 5 cases/100 000 population/year) (Lawrence et al., 1980). In the South Pacific 219 cases/100 000 population were reported in 1987; the high incidence makes development of a seafood industry impossible, although the local population still eats local catch ((Glaziou & Legrand, 1994).

Amnesic shellfish poisoning (ASP)

In 1987 a dramatic new shellfish poisoning was first described in Prince Edward Island (Perl et al., 1990a,b). Following consumption of mussels, patients suffered acute gastrointestinal pain, nausea, diarrhea, and headache. But most disturbing of all, severely afflicted patients suffered permanent memory disturbances, profound loss of anterograde memory, neuronal degeneration in the hippocampus and amygdala, seizures, and, in several cases, death. The toxin responsible, domoic acid, is produced by the diatom *Pseudonitzschia*, and has been shown to act as an excitatory neurotoxin, irreversibly binding to glutamate receptors (specifically the MK801 and NMDA receptors), inducing excitotoxic neuronal death. In the spring of 1998, domoic acid was demonstrated to be the cause of severe neurologic symptoms and deaths in Californian sea lions following ingestion of contaminated anchovies (Lefebvre et al., 1999) confirming an ongoing need for monitoring of diatom and algal blooms, regular screening of fish and shellfish for toxicity, physician awareness, and public health surveillance systems.

Pfiesteria piscicida

The recent recognition of *Pfiesteria piscicida* as a neurotoxic dinoflagellate with severe human health effects provides an example where astute clinicians working closely with public health officials were able to limit toxic exposure and prevent further injury (Silbergeld et al., 2000). Although estimated to be at least several thousand years old, current thinking is that *P. piscicida* is usually present as a non-toxic predator, feeding on bacteria or algae. It was first introduced to researchers as an unknown contaminant of aquacultures in North Carolina in 1988 (Smith & Music, 1998; Glasgow et al., 1995). In 1991 it was associated with a fish kill event involving over 1 million Atlantic Menhaden in the Pamlico River, North Carolina (Smith & Music, 1998). Subsequently, other estuaries and outdoor aquaculture facilities in North Carolina suffered *P. piscicida*-associated fish kill events (1991–1993); in the summer of 1996 the organism was detected in the Chesapeake Bay (Morris, 1998). It was identified as the causative agent of both fish kill events and a novel human health syndrome in Maryland's Chesapeake Bay in 1997 (Silbergeld et al., 2000; Glasgow et al., 1995; Levin et al., 1999; Matuszak et al., 1997). *Pfiesteria* is ubiquitous in estuarine waters along the Eastern coast of the USA, from Florida to Delaware, mainly in its non-toxic forms, and research efforts are currently under way to better define/predict the environmental conditions (temperature, salinity, nutrient-load, pH, etc.) which 'trigger' production of toxins.

From an environmental and human health perspective, *Pfiesteria* came on like a lion, effecting swift and dramatic damage, both in terms of fish kills, and in terms of wreaking severe, long-lasting neurological damage. Lab researchers, watermen, and recreationists were affected, making it a hazard of great concern to the general public (Faith & Miller, 2000; Silbergeld et al., 2000; Burkholder, 1999; Fleming et al., 1999). Lab researchers exposed to toxic *Pfiesteria* culture by skin contact and inhalation of aerosolized toxin experienced neurocognitive impairments and emotional disturbances, in addition to gastrointestinal pain, respiratory stress, eye irritation, and localized dermatitis (Glasgow et al., 1995). Although the severely affected underwent clinical tests, which included electroencephalogram, MRI, and PET analysis, no site of organic damage could be determined. Neuropsychological examinations of Maryland watermen who reported to physicians during and immediately following a large fish kill event in 1997 revealed common symptoms of fatigue, confusion, headaches, and some respiratory irritation. Skin rashes were spotted in areas coinciding with water contact. All reports coincided with fish-kill events. Epidemiological studies following the investigation of the 1997 oubreak in Maryland resulted in a defined symptomatology correlated with a dose-dependent exposure to *Pfiesteria piscicida*. Of the people exposed at high doses many suffered neurological symptoms (confusion, disorientation, difficulty concentrating on a task, forgetfulness), headache, muscle/leg cramps, and skin lesions. These watermen showed dose-dependent deficits in performance on neuropsychological examination, particularly in tasks requiring divided attention, new learning, and memory (Grattan, 1998; Grattan et al., 1998a,b). Interestingly, tests for possible respiratory, immunogenic, or other physiological dysfunction proved negative.

The isolation and characterization of the precise toxin, or toxins, produced by *P. piscicida* has been difficult.

Evidence suggests that the fish kill event signals the final outcome of toxicity, at which time the toxic agent may no longer be present. Several reporter gene assays have recently been developed with the hope that screening water for presence of toxic organisms may be a rapid, routine procedure (Fairey et al., 1999). In addition, gene-screen assays have been developed to detect the organism based on a species-specific sequence of the small-subunit (18S) rRNA (Oldach et al., 1998). A reliable screen for the presence of toxin in biological samples (urine or sera) is needed for diagnostic certainty. Mounting evidence of the dramatic neurotoxicity of *P. piscicida* is based on observation of neurobehavioural changes and death in exposed fish, and impaired learning and memory formation in rats following ingestion and injection of toxic culture (Levin et al., 1999). Cytotoxicity has been demonstrated in vitro, in both piscine- and mammalian-derived cell lines. Media from toxic aquaculture samples can induce alterations in the transcription of regulatory proteins (Fairey et al., 1999). Recent studies suggest that *pfiesteria* toxins may act as antagonists at the *N*-methyl-D-aspartate (NMDA) receptor (El-Nabawi et al., 2000) which is known to be involved in learning and memory formation.

Role of clinicians in identifying an outbreak

The role of clinicians in the identification of toxic exposures cannot be overstated. Clinical practitioners are relied upon to identify alterations in the normal patterns of diseases. Increases in the number or severity of cases and/or clustering of cases by occupation or geographic location may suggest an environmental etiology. Recognizing changes in the patterns of disease is made difficult by the paucity of information available on the background incidence and prevalence of many major neurological diseases. Characterization of neurological effects of an environmental exposure is made more difficult by the range of individual reactions to an exposure, complicated by gender, age, dose, and confounding factors like smoking, diet, and general health. If disease progression is slow, onset of clinical symptoms may be months or even years after exposure. All these complications point to the need for careful and complete documentation of clinical observations, and data collection through formal surveillance systems. The documentation of an exposure and occupational history, including possible exposure sources such as hobbies, self-medication, eating habits, and recent travel history, is critical. The sharing of information between physicians other health professionals, existing disease surveillance systems, and public health departments facilitates the rapid formation of a case definition and development of a case series. The public health response is crucial in limiting or preventing a disease outbreak.

Alcohol neurotoxicity

Ivan F. Diamond[1,2] and Steven L. McIntire[1,2]

[1] Ernest Gallo Clinic and Research Center, Emeryville, CA, USA
[2] Department of Neurology, University of California San Francisco, CA, USA

Alcoholism and alcohol abuse

Alcoholism is a chronic disease characterized by addiction to ethanol; the alcoholic craves and consumes alcoholic beverages without apparent satiation. Alcoholics are remarkably tolerant to the intoxicating effects of ethanol. When drinking is discontinued, however, they exhibit the neurological symptoms and signs of alcohol withdrawal; this is considered to be evidence of physical dependence on ethanol. Addiction to ethanol also occurs as a secondary complication in patients with specific neuropsychiatric disorders, but the vast majority of alcoholics do not have an antecedent history of major psychiatric disease; they are considered to have primary alcoholism. Alcohol abuse is characterized by prodigious drinking without evidence of physical dependence upon withdrawal. Such individuals continue to drink excessively, sometimes as binge drinkers for several days at a time, despite considerable personal socioeconomic hardship and serious medical complications.

Epidemiology

Almost two-thirds of Americans older than 14 years of age drink alcoholic beverages. The per capita ethanol consumption in this group is the equivalent of nearly 90 gallons of beer, 31 gallons of wine, or 10 gallons of whisky per year (*Seventh Special Report to the US Congress on Alcohol and Health, 1990*). However, only 7% of Americans are heavy drinkers. This small group accounts for approximately 50% of the alcohol consumed in the USA and probably most of the socioeconomic and medical complications of alcoholism and alcohol abuse. These alcohol-related complications are not trivial; in 1990, the annual cost to US society is estimated to have been $136 billion (*Seventh Special Report to the US Congress on Alcohol and Health, 1990*). The prevalence of alcoholic disorders among hospitalized patients is about 25%.

Clinical pharmacology of ethanol

Ethanol is rapidly and completely absorbed from the gastrointestinal tract into the circulation within minutes after drinking (Goldstein, 1983). It is then widely distributed to all organs and fluid compartments in the body, readily equilibrates into total body water, and intercalates into biologic membranes. Ninety to 98% of ethanol is removed by metabolism in the liver, and the remainder is excreted by the kidneys, lungs and skin. An important rate-limiting step in ethanol metabolism is oxidation to acetaldehyde by alcohol dehydrogenase in the liver. Acetaldehyde is then converted to acetate by aldehyde dehydrogenase, a metabolic step with significant clinical ramifications.

Ethanol intoxication

Clinical features

Because of the solubility properties of ethanol, it readily crosses the blood–brain barrier and its uptake into the brain is limited primarily by cerebral blood flow and capillary perfusion. Therefore, within a short time after drinking, the concentration of ethanol in the brain is nearly identical to the level of ethanol in the blood. In non-alcoholics, rising blood alcohol levels of 50–150 mg/dl are associated with symptoms of intoxication. Symptoms vary directly with the rate of drinking and are more severe when the blood alcohol concentration is rising than when it is falling (Goldstein, 1983).

Table 113.1. Acute ethanol intoxication

Blood ethanol levels (mg/dl)	Symptoms and signs	
	Sporadic drinkers	Chronic drinkers
50–100	Euphoria Gregariousness Incoordination	Minimal or no effect
100–200	Slurred speech Truncal ataxia Labile mood Drowsiness Nausea Impaired cognition	Sobriety or incoordination Euphoria
200–300	Lethargy Combativeness Stupor Incoherent speech Vomiting	Mild emotional and motor changes
300–400	Coma	Drowsiness
>500	Respiratory depression Death	Lethargy Stupor Coma

Many of the effects of acute ethanol intoxication are indicated in Table 113.1. Most individuals feel euphoric, lose social inhibition, and manifest expansive, sometimes garrulous behaviour; others may become gloomy, belligerent, or even explosively combative. Some people do not experience euphoria but instead become sleepy after moderate drinking; they rarely abuse alcohol. With continued drinking, cerebellar and vestibular function deteriorates and at higher blood ethanol levels the findings of central nervous system (CNS) depression predominate. Progressive lethargy leads to hyporeflexia, hypotension, depression of the brainstem respiratory centre, and coma without focal signs. In non-alcoholics, fatalities may occur at 500 mg/dl, usually because of respiratory depression with ventilatory acidosis and hypotension. Alcoholics are more resistant to ethanol than non-alcoholics (Johnson et al., 1982; Lindblad & Olsson, 1976; Urso et al., 1981; Watanabe et al., 1985).

Acute tolerance

A slow rise in blood ethanol levels produces less intoxication than a more rapid rise to the same concentrations. Moreover, intoxication may not always be present when blood ethanol concentrations are elevated (see Table 113.1). Tolerance to ethanol may develop during a single bout of drinking (Goldstein, 1983; Victor & Adams, 1953) and is characterized by a reduced intoxicating response to ethanol. Indeed, subjects can become sober at blood ethanol levels higher than those at which intoxication first developed (Mirsky et al., 1941). This phenomenon is known as acute tolerance and appears to be due primarily to adaptive CNS changes.

Chronic tolerance

The magnitude of increased tolerance to ethanol in chronic alcoholics is not often appreciated. Chronic alcoholics have increased resistance to the intoxicating effects of ethanol and can appear to be sober or merely drowsy at blood alcohol levels of 400–500 mg/dl (Urso et al., 1981), concentrations that are severely intoxicating or even fatal in naïve individuals (see Table 113.1). This is known as chronic tolerance. A serum ethanol level of 1510 mg/dl was documented in an ambulatory chronic alcoholic, who had stopped drinking 3 days earlier (Lindblad & Olsson, 1976). Despite legal definitions of intoxication at blood alcohol levels above 80–100 mg/dl, a single blood ethanol determination may not accurately measure the extent of drunkenness (Urso et al., 1981).

Alcoholic blackouts

Alcoholic blackouts sometimes complicate acute alcohol intoxication during excessive drinking. These episodes can occur in alcoholics or sporadic drinkers and are characterized by hours of amnesia without impaired consciousness. The patient reports an inability to remember new events, but has no difficulty with long-term memory or immediate recall. These symptoms resemble the syndrome of transient global amnesia.

Evaluation and management of acute ethanol intoxication

Severe acute alcohol intoxication can be fatal and is a medical emergency. The airway must be evaluated immediately if the patient is stuporous and unable to walk. Masked hypoventilation, accumulating secretions, and coma are all indications for endotracheal intubation and assisted ventilation. If the blood alcohol level is too low to account for the patient's obtundation or if improvement does not occur as expected, it is necessary to search for other causes, such as hypoglycemia, meningitis, subdural hematoma, and hepatic encephalopathy. Evidence of head trauma or focal or lateralizing neurologic signs suggests an

urgent intracranial pathologic condition. Gastric lavage may be performed if obtundation is due to recent and substantial alcohol ingestion but only after endotracheal intubation. Thiamine (100 mg) should be given parenterally to each patient to prevent or treat Wernicke's encephalopathy (see later), followed by daily thiamine and multivitamins.

Intoxicated patients without serious medical problems, who have adequate vital signs and acceptable mental status can be observed until they become sober. However, it is important to search for commonly associated complications, such as hypoglycemia, ketoacidosis, hypokalemia, hypophosphatemia, hypomagnesemia and anemia.

Alcohol withdrawal syndrome

Ethanol is a CNS depressant. The nervous system appears to adapt to chronic ethanol exposure through neural mechanisms that counteract alcohol's depressant effects. When drinking is abruptly reduced or discontinued, these adaptive changes appear to persist unopposed by ethanol and a hyperexcitable *ethanol withdrawal* syndrome develops (Porter et al., 1990). It is considered to be evidence of physical dependence on ethanol. The clinical features of the ethanol withdrawal syndrome consist of several characteristic abnormalities that vary in severity (Victor & Adams, 1953). These include tremulousness, disordered perceptions, convulsions, and delirium tremens (Table 113.2). The same general medical evaluation and treatment of the ethanol withdrawal syndrome should be followed as for acute ethanol intoxication (described earlier).

Table 113.2. Alcohol withdrawal syndrome

Time	Clinical features
8 h	Onset of tremors, anxiety, irritability, nausea, vomiting
24 h	Increasing tremors, hyperexcitability, insomnia
12–48 h	Hallucinations, grand mal seizures
2–5 d	Delirium tremens
	Profound confusion
	Delusions
	Vivid hallucinations
	Agitation
	Autonomic nervous system hyperactivity

Tremulousness and disordered perceptions

Tremor, the earliest, most common, and most apparent symptom, begins about 6–8 hours after the last drink, usually the morning after an overnight abstinence (morning shakes). The tremor is diffuse, rapid and coarse in amplitude and resembles other accentuated physiological tremors. It is often accompanied by irritability, nausea and vomiting. The patient usually senses an inner tremulousness even when tremor is not severe. Self-treatment is commonly a morning drink to 'quiet the nerves', and the drinking is continued for the rest of the day. If drinking is not resumed, tremor becomes much more intense by 24–36 hours later and is exacerbated by motor activity or stress. It can be so severe as to interfere with walking, eating or speech. Accompanying symptoms and signs of sympathetic hyperactivity are also apparent.

The patient is increasingly anxious, easily startled by minor stimuli, and complains of insomnia and anorexia. Increased sweating, facial flushing, mydrasis, tachycardia, mild hypertension and hyperreflexia occur. Although most abnormalities subside in a few days, increased arousal and anxiety may persist for 2 weeks. Elevated levels of norepinephrine and its metabolites have been measured in the blood and cerebrospinal fluid of patients during the withdrawal syndrome (Hawley et al., 1981).

Disordered perceptions may parallel the development of tremor and sympathetic hyperactivity. They become most pronounced at 24–36 hours and clear in a few days. Ordinary visual, auditory and tactile experiences become distorted and are misinterpreted. Vivid nightmares interfere with sleep.

Alcoholics undergoing withdrawal can develop isolated and more prolonged auditory hallucinations (alcoholic hallucinosis) despite being alert, oriented, and without memory deficits. Because auditory hallucinations can persist for weeks after other manifestations of ethanol withdrawal improve, these symptoms may be confused with acute schizophrenia. However, alcoholic hallucinosis is easily distinguished by its close association with ethanol withdrawal; symptoms usually subside in weeks to months.

Management of ethanol withdrawal tremors and disordered perceptions

Benzodiazepines are quite effective in the management of ethanol withdrawal tremors and disordered perceptions. The goal of treatment is to suppress symptoms and produce mild sedation; drug dosage is adjusted to the severity of the withdrawal syndrome. Patients with mild tremulousness and few associated symptoms usually respond to 5–20 mg diazepam orally every 4–6 hours. Dosage is then reduced on successive days or increased if symptoms of ethanol withdrawal return. If symptoms are

severe, diazepam is used intravenously; some patients may require extraordinarily high doses to achieve mild sedation. When the symptoms of ethanol withdrawal have been suppressed, it is necessary to avoid oversedation and the danger of respiratory depression by carefully titrating the dose of diazepam to just keep the patient calm.

Ethanol withdrawal convulsions

A small percentage of alcoholics (approximately 12% of hospitalized patients) develop generalized tonic–clonic convulsions, most often within 6–24 hours after they reduce or discontinue ethanol consumption (Victor & Adams, 1953). Ethanol withdrawal convulsions are usually associated with a history of chronic daily consumption, but binge drinking can also be followed by withdrawal seizures. Normally, generalized tonic–clonic seizures are observed. Focal seizures are rare and should always suggest a focal lesion and an additional diagnosis. Alcoholics who have seizures during one episode of ethanol withdrawal are likely to have convulsions again when alcohol withdrawal is repeated. Status epilepticus occurs in only about 3% of cases; although, ethanol withdrawal accounts for about 15% of all patients who present with status epilepticus (Aminoff & Simon, 1980).

Evaluation and management of ethanol withdrawal convulsions

Ethanol withdrawal seizures usually are brief and self-limited. A complete evaluation for a convulsive disorder is indicated if there is a clinical suspicion of trauma or other CNS disorder, if there are focal seizures, or if the seizure disorder or postictal state is prolonged. Typical ethanol withdrawal convulsions do not require specific anticonvulsant therapy. Benzodiazepines (diazepam, loraxepam and chlordiazepoxide) are effective in patients with repeated seizures. Controlled studies indicate that phenylhydantoin does not prevent recurrent seizures in these patients (Alldredge et al., 1989). Phenobarbitol may also be effective although controlled trials have not compared this drug to benzodiazepines. It also poses a greater risk of respiratory depression due to the long half life and possible additivity if combined with ethanol. Status epilepticus from any cause is a medical emergency and requires immediate treatment in the same way as status from other causes. Alcoholics are at particular risk for multiple other causes of status (hyponatremia, hypoglycemia, meningitis, other drug ingestions, history of head trauma, or occult head trauma). Approximately one third of alcoholics experiencing withdrawal seizures go on to have delirium tremens.

Delirium tremens

Delirium tremens is the most alarming manifestation of the ethanol withdrawal syndrome. It is characterized by agitated arousal, global confusion and disorientation, insomnia, and vivid, often threatening hallucinations and delusions. Signs of sympathetic hyperactivity include tremor, mydriasis, tachycardia, fever, and intense diaphoresis. In contrast to the early appearance of tremulousness and disordered perceptions, and seizures, delirium tremens develops abruptly within 2–5 days of abstinence. This is often a surprising development in unrecognized alcoholics who have been admitted to the hospital for other reasons. These patients are terrified by their hallucinations and can be combative, destructive, and dangerous. Episodes of delirium tremens last 1–3 days and may end as abruptly as they begin.

Evaluation and management of delirium tremens

Delirium tremens requires hospitalization and vigorous emergency treatment. It may be difficult to distinguish delirium tremens from an acute psychosis when there are no signs of sympathetic hyperactivity. However, the diagnosis is usually suggested by the evolution of symptoms in a chronic alcoholic who is undergoing withdrawal. The differential diagnosis includes alcoholic hypoglycemia; overdose with anticholingergic agents; intoxication with amphetamines, cocaine, or phencyclidine piperdine; encephalitis; meningitis; thyrotoxicosis; and withdrawal from other sedating drugs. Seizures are unusual in delirium tremens and should be evaluated promptly because of the possibility of meningitis or other diagnoses. The major threat to life derives from associated illness or injuries, hyperthermia, and dehydration with circulatory collapse.

The goal of treatment is to control behaviour and suppress symptoms without excessive sedation and danger to the patient. A variety of sedatives, neuroleptics, and sympatholytic drugs have been given to patients with delirium tremens, usually in uncontrolled trials. Benzodiazepines are the mainstay of therapy, and 5–10 mg diazepam is given intravenously every 10–15 minutes until the patient is calm, followed by 5–10 mg every 1–4 hours as needed. Doses of 200 mg are not usual during the first few hours, and some patients may need up to 1200 mg in the first 3–4 days of treatment to maintain calm. Special care must be taken to support fluid and electrolyte balance and hypoglycemia; volume depletion accompanying delirium tremens may cause circulatory collapse, and fluid losses can require replacement of 4–10 l in the first day. Hypomagnesemia is frequent and can be treated with 1 g i.v. every 6 hours for the first 24 hours in patients with normal renal function.

Cellular pathophysiology of ethanol intoxication, tolerance, and physical dependence

Unlike most drugs of abuse, ethanol does not appear to act through a single major molecular target in the brain. Historically, it was thought that ethanol (and other agents capable of inducing anesthesia) acted through a disruption of membrane fluidity. More recent studies have demonstrated clearly that specific proteins mediate effects of ethanol on neural excitability (Diamond & Gordon, 1997; Chandler et al., 1998). Targets of ethanol include major ligand-gated channels such as the $GABA_A$ and NMDA receptors, voltage-gated Ca^{2+} and K^+ channels, neuropeptides and second messenger systems. The determination of the mechanisms of action of ethanol on a molecular level has provided the basis for a directed approach to the development of therapeutics to treat alcoholism and alcoholic neurological disorders.

NMDA receptors

In multiple electrophysiological preparations, ethanol antagonizes NMDA receptors at physiological doses (Lovinger et al., 1989; Hoffman et al., 1989). This is consistent with the neurodepressant behavioural effects of ethanol. Ethanol sensitivity of NMDA receptors varies with subunit composition. This is supported by brain regional differences in ethanol sensitivity and by recombinant expression systems showing variability with different expressed subunit combinations. Acute tolerance to the inhibitory effect of ethanol on NMDA receptor function is observed at the cellular level. There is gradual recovery of the initial induced depression in NMDA-mediated EPSPs in the hippocampal CA1 region. The tolerance may be mediated through a non-receptor tyrosine kinase, Fyn (Miyakawa et al., 1997). Fyn deficient mice (fyn-/fyn-) are defective in acute tolerance to ethanol and are hypersensitive to the intoxicating effects of the drug. The observed ethanol-induced increase in tyrosine phosphorylation of the NR2B subunit of the NMDA receptor is not observed in fyn-/fyn- mice.

$GABA_A$ receptors

In addition to antagonizing excitatory glutamatergic neurotransmission, ethanol also enhances inhibitory GABAergic neurotransmission (Suzdak et al., 1986; Allan & Harris, 1987; Mehta & Ticku, 1988). Potentiating effects of ethanol are well demonstrated in vitro and are again dependent on subunit composition. A proposed 'hydrophobic binding pocket' of ethanol has been defined in the $GABA_A$ receptor by chimeric receptor studies (Mihic et al., 1997). A specific role for the γ subunit of the $GABA_A$ receptor has been proposed from studies of clonal cell lines. One form of the γ subunit (γ21) has a phosphorylation site for PKC and phosphorylation of this site in vitro modulates ethanol sensitivity of the receptor. Mutant mice lacking the PKC-γ are relatively resistant to the effects of ethanol on behaviour and on $GABA_A$ receptors.

Clinically, ethanol shows cross tolerance with other compounds acting on the $GABA_A$ receptor such as benzodiazepines and barbituates. Benzodiazepine receptor inverse agonists interfere with ethanol intoxication but are not clinicaly useful as they act as convulsants. The use of benzodiazepines to treat alcohol withdrawal is descibed above.

Calcium channels

Acutely ethanol has been shown to inhibit N, T and L-type Ca^{2+} channels (Twombly et al., 1990; Wang et al., 1991). With more prolonged ethanol exposure there is a secondary increase in apparent channel number as measured with labelled antagonists (Dolin & Little, 1989). Such increases have also been demonstrated in alcohol-dependent animals (Little, 1991). The increase in Ca^{2+} channel number has been shown to reflect ethanol-induced increases in PKC isoenzymes and PKC-mediated phosphorylation (Messing et al., 1990, 1991). These findings of elevated channel number are consistent with the observed increases in depolarization induced Ca^{2+} influx in cells chronically exposed to ethanol. Up-regulation of Ca^{2+} channels persists for approximately 16 hours after cessation of ethanol exposure (Diamond & Gordon, 1997). This correlates with the time period for withdrawal seizure risk in alcoholics stopping ethanol consumption. Enhanced Ca^{2+} channel activity would stimulate neurotransmitter release and NMDA receptor activation, plausible mechanisms for hyperexcitability and seizure induction. Furthermore, Ca^{2+} channel blockers have been shown to reduce withdrawal seizures as well as withdrawal tremors and mortality in human alcoholics.

Potassium channels

Ethanol interactions with K^+ channels may also contribute to the observed physiological effects of the drug (Weight, 1992; Anantharam et al., 1992). An activating effect of ethanol at physiological doses on the BK class of voltage and Ca^{2+} activated K^+ channels has been demonstrated in vitro (Dopico et al., 1998, 1999). The potentiation persists

when the channel is reconstituted in lipid bilayers, suggesting a possible direct effect of ethanol on the channel (Chu et al., 1998). Potentiation of K^+ channels would depress neural activity, consistent with the depressant behavioural effects of ethanol. Ethanol activation of the G-protein-activated, inwardly rectifying K^+ (GIRK) channel has also been demonstrated in vitro (Lewohl et al., 1999). The effect appears independent of G proteins or second messangers. *Weaver* (*wv*) mutant mice, have a mutation in the GIRK2 channel and are hyposensitive to ethanol-induced analgesia.

Neuropeptide Y

Recent studies have demonstrated an important role of the peptidergic neurotransmitter, neuropeptide Y (NPY), in drinking behaviour and mammalian responses to alcohol. NPY is a widely expressed neuropeptide with particularly high levels in cerebral cortex, basal ganglia, hypothalamus and amygdala. NPY acts through multiple G protein-coupled receptors. NPY knockout mice show substantially increased ethanol consumption, a preference for ethanol over water, and less sensitivity to the sedative effects of ethanol (Thiele et al., 1998). Conversely, mice overexpressing NPY show increased sensitivity to ethanol and drink less than controls. Furthermore, P rats which were bred for elevated ethanol preference have a QTL with a substantial effect on alcohol behaviour that was mapped to a region containing the precursor of NPY (Carr et al., 1998). Therapeutics related to human drinking behaviour may emerge from further pharmacological characterizations of NPY receptors.

Adenosine

Adenosine is a global inhibitory neuromodulator in the nervous system, acting through A1, A2 and other receptor subtypes. Adenosine acts presynaptically to inhibit the release of excitatory neurotransmitters and postsynaptically to diminish the response of dopamine and acetylcholine receptors. The extracellular concentration of adenosine increases with neural activity and inhibitors of adenosine uptake potentiate cellular responses to adenosine, suggesting that physiologic effects are terminated, in part by reuptake into the cell.

Adenosine appears to mediate acute ethanol-induced ataxia in rodents; adenosine receptor agonists increase ethanol-induced intoxication and antagonists diminish this response. Sensitivity to adenosine agonists correlates with acute sensitivity to alcohol in mice bred selectively for differential responses to ethanol. There is also cross-tolerance between ethanol and adenosine agonists. In cell culture systems ethanol inhibits adenosine reuptake via a specific nucleoside transporter (ENT-1) thereby increasing extracellular adenosine that activates adenosine A2 receptors. This increases cAMP levels, resulting in activation and translocation of cAMP-dependent protein kinase (PKA) into the nucleus, increasing cAMP-dependent gene expression. This suggests that adenosine plays a role in acute responses to ethanol and, perhaps, the development of chronic alcohol-related behaviours such as craving, tolerance and dependence (Diamond & Gordon, 1997). It is possible that specific adenosinergic agents can be developed to modify acute and chronic alcohol-related behaviours and neurological complications.

Protein kinase signalling

PKA and protein kinase C (PKC) play major roles in regulating and mediating neural responses to ethanol (Diamond & Gordon, 1997). Ethanol increases cAMP levels in many biological preparations, resulting in activation of PKA. This can involve adenosinergic mechanisms, as described above. In cultured cells ethanol causes PKA to translocate into the nucleus where it remains as long as ethanol is present (Dohrman et al., 1996). This results in phosphorylation of the cAMP response element-binding protein (CREB) and sustained increases in cAMP dependent gene expression. These kinds of molecular events are known to regulate neuronal function and may contribute to such long-term alcoholic neuroadaptive behaviours as craving, tolerance and dependence. It is of interest, therefore, that mice genetically engineered with diminished PKA activity in the striatum have reduced sensitivity to ethanol intoxication and exhibit excessive drinking behaviour (Thiele et al., 2000). Taken together, these findings suggest that ethanol-induced activation of cAMP and PKA signalling appears to modulate many of the short-term and prolonged effects of ethanol in the nervous system.

Ethanol also increases the activity and translocation of a few PKC isozymes. In PC-12 cells an ethanol-dependent increase in epsilon PKC is required for ethanol-induced neurite outgrowth, a process associated with neuronal plasticity. Mice lacking PKC epsilon are more sensitive to ethanol intoxication and drink 75% less alcohol than wild-type littermates (Hodge et al., 1999). This suggests that, in contrast to PKA, normally functioning PKC epsilon in the brain might enable excessive alcohol consumption. Most important, the discovery that mice lacking PKC epsilon drink less raises the possibility that drugs designed to inhibit PKC epsilon might be effective in reversing excessive drinking.

Clinical observations in young adults with a genetic risk for alcoholism (see below) suggest that individuals with a diminished intoxicating response to alcohol more often develop alcoholism in the future (Schuckit, 1994). This is consistent with observations made in genetically engineered mice who drink excessively; often they are less sensitive to acute intoxication (Schuckit, 2000). By contrast, animals with increased sensitivity to alcohol intoxication are often less likely to drink excessively. Current concepts suggest that phosphorylation regulates alcohol sensitivity of many membrane proteins that are selective targets for ethanol in the brain. Experimental findings in animal models suggest that PKA and PKC epsilon may function as homeostatic mechanisms to regulate sensitivity to ethanol intoxication and the development of excessive drinking afterwards. It is possible, therefore, that drugs designed to selectively modify protein kinase activities, including PKA and PKC signalling, may become novel and effective therapies for alcoholism and alcohol-related behaviours.

Genetics of alcoholism

There is evidence that genetic factors play a role in alcoholism. A genetically transmitted susceptibility for alcoholism has been demonstrated in family, twin and adoption studies (Ball & Murray, 1994; Begleiter & Kissin, 1995). Genes that influence the risk for alcoholism have not yet been identified. As with many complex behavioural traits, the identification is complicated by the probable multigenic nature of the disorder and the difficulties in defining and distinguishing between the different phenotypic forms of alcohol dependence and alcohol abuse.

Many biochemical and physiological measurements have been evaluated as possible relevant phenotypic markers. One that has emerged as likely to be significant is the 'low level of response to alcohol'. The level of response (LR) is an objective and subjective measure of the response to the intoxicating effects of alcohol as determined at specific blood alcohol concentrations. Objective measurements include electrophysiological and hormonal measures. Individuals with a low LR have an increased risk of alcoholism (Schuckit, 1994). Low LRs have been observed at an elevated frequency in studies of 700 children of alcoholics. A longitudinal study of 435 sons of alcoholics demonstrated that a low LR is a significant predictor of later alcohol abuse or dependence (Schuckit & Smith, 1996). Groups identified as having a relatively higher risk for alcoholism, such as Native Americans, tend to show low LRs, while other groups identified as having relatively lower risks of alcoholism (Jews and certain Asian groups) have higher LRs.

The LR to alcohol appears to be genetically influenced. In humans, the LR is more similar in first degree relatives than unrelated individuals. The LR is also more similar in identical twin pairs than fraternal twin pairs. Studies in animals have identified a QTL associated with the LR.

Another potentially useful marker of increased risk of alcoholism is the lower amplitude P3 on the event-related potential paradigm. Approximately one-third of offspring of alcoholics have a low amplitude P3. Small P3 amplitudes are observed in alcoholics after extended abstinence. There is controversy however as to whether or not a low amplitude P3 more directly reflects Anti Social Personality Disorder (see below) or related disorders found in a subset of alcoholics.

Alcoholism emerges with greatly increased frequency in patients with certain specific neuropsychiatric disorders. Nearly two out of three patients with the antisocial personality disorder are alcoholic. Twenty percent of all alcoholics meet the criteria for this disorder. Antisocial personality disorder and alcoholism appear to coexist in many families and are often inherited together.

Particular alleles of genes encoding alcohol metabolizing enzymes also affect the risk of alcoholism. Alcohol is metabolized to acetaldehyde by alcohol dehydrogenase (ADH). Acetaldehyde is metabolized by ALDH. Asian individuals who are homozygous for the ALDH 2-2, 2-2 allele lack the low Km form of ALDH and produce high levels of acetaldehyde. These individuals are at extremely low risk of alcoholism. Such individuals experience an alcoholic flush reaction from the very high levels of acetaldehyde. Shortly after drinking, there is vasodilation, facial flushing, hot sensations, tachycardia and hypotension. Heterozygotes for the 2-2 allele also have a lower risk for alcoholism. In the case of ADH, certain alleles (ADH 2-2, 2-3, 3-1) are associated with more rapid production of acetaldehyde and deceased risk of alcoholism. In these later cases, however, it is not clear that the reduced risk relates to an obvious aversive reaction as in the ALDH homozygotes.

Treatment of alcoholism

Medications have recently emerged from clinical trials as effective in the treatment of alcoholism. The opiate antagonist, naltrexone, has been approved by the Food and Drug Administration for the treatment of alcohol dependence. In several studies, recently abstinent alcoholics who were treated for 12 weeks with naltrexone (50 mg/day) showed reduced relapse rates and greater periods of maintenance

of abstinence. The effect of naltrexone on relapse was however small to moderate (20–25% difference between medication and placebo groups) and not all studies have demonstrated significant effects. Larger multisite trials with naltrexone are ongoing.

European studies have demonstrated effectiveness of the drug, acamprosate, in the treatment of alcoholism. Three thousand alcoholics were treated in seven multicentre trials in Europe. Effects were significant but again small to moderate changes were observed. Acamprosate is thought to act through modulation of NMDA receptor function. Acamprosate is in use for the treatment of alcoholism in Europe but awaits FDA approval in the US. Additional acamprosate studies are ongoing in the US.

Alcoholic neurologic disorders

The alcoholic neurologic disorders complicate alcoholism and alcohol abuse (Table 113.3). These major syndromes do not develop in all alcoholics, however, and it is not understood why some patients manifest one or several of the disorders and other patients are relatively spared. Many clinicians consider malnutrition to be of primary importance in the pathogenesis of many of these syndromes (Victor & Adams, 1961).

Alcoholics often obtain as much as 50% of their calories from ethanol, and some develop serious nutritional deficiencies, particularly for protein, thiamine, folate, and pyridoxine. However, evidence suggests that genetic factors also contribute to the diverse toxicity of ethanol (Devor et al., 1988).

The transition between reversible metabolic effects of ethanol and the development of alcoholic organ damage in the brain or elsewhere is not understood. Studies of alcoholics with skeletal myopathy and cardiomyopathy suggest that a lifetime ethanol consumption threshold is exceeded before significant damage develops (Diamond, 1989; Urvano-Marquez et al., 1989). Evidence suggests several possibilities to account for the potential neurotoxicity of ethanol. Ethanol can be an exogenous substrate for specific enzymes, thus leading to the accumulation of potentially toxic abnormal products. These include phosphatidylethanol (Alling et al., 1984; Kobayashi & Kanfer, 1987; Mueller et al., 1988), a product of phospholipase D activity, and fatty acid ethyl esters (Bora et al., 1989; Laposata et al., 1987), products of synthase activity.

Acetaldehyde, a product of alcohol dehydrogenase, is another potential toxin. Acetaldehyde can react with diverse proteins to form acetaldehyde–protein adducts (Behrens et al., 1988; Lin & Lumeng, 1989).

Prolonged ethanol-induced changes in receptor-stimulated second-messenger production and ion channel function could also be cytotoxic (Diamond, 1989), particularly for ordinarily non-proliferating organs, such as brain, muscle and liver.

Wernicke's encephalopathy

Wernicke's encephalopathy develops most commonly in chronic alcoholics but also occurs in other conditions (Table 113.4). A clinical triad of ataxia, ophthalmoplegia, and global confusion is characteristic (Victor et al., 1989), although Wernicke's encephalophathy should be suspected in any poorly nourished patient with a confusional state of recent onset. The major clinical manifestations are summarized in Table 113.5. Patients first complain of diplopia or difficulty with balance. Horizontal nystagmus on lateral

Abrupt onset
Encephalopathy, opthalmoplegia, gait ataxia
Confusion, apathy, sleepiness
Horizontal and vertical nystagmus
Lateral rectus palsies
Conjugate gaze defects
Reactive pupils

gaze is almost always demonstrable, vertical nystagmus is less frequent, and rotary nystagmus is rare. Bilateral, usually asymmetric lateral rectus palsies may develop rapidly, and defects in conjugate gaze are common. Ptosis and internuclear ophthalmoplegia occur rarely. There may be decreased pupillary reactions to light, but failure to respond to light should suggest an alternative or additional diagnosis. Mild-to-severe cerebellar truncal ataxia occurs in nearly all patients, tremor and limb ataxia are found less often, and speech is rarely affected.

An acute confusional state with inattention, disorientation, and sleepiness is common in patients with Wernicke's encephalopathy. Patients may sometimes be agitated, but most patients exhibit apathy and indifference. Amnesia and an inability to form new memories is observed. Pathologic studies have indicated that obtundation and coma can be important features in clinically unrecognized cases of Wernicke's encephalopathy (Harper, 1983; Harper et al., 1986; Torvik et al., 1982). Therefore, it is necessary to consider this diagnosis in all patients with unexplained stupor or coma. Fever should prompt a search for concomitant infection.

A peripheral neuropathy often coexists with Wernicke's encephalopathy. Hypothermia and hypotension may also be observed.

Pathophysiology

Wernicke's encephalopathy is the only alcohol-related neurological disorder that can be corrected by a specific vitamin – thiamine. Thiamine (vitamin B1) is absorbed in the small intestine and is transported into brain by a saturable energy-dependent transport system. A series of phosphorylation reactions produces thiamine pyrophosphate, a required cofactor in carbohydrate and amino acid metabolism. Four principal thiamine-dependent enzymes are pyruvate dehydrogenase, α-ketoglutaric dehydrogenase, transketolase, and branched chain α-keto acid dehydrogenase. Evidence suggests that functional thiamine deficiency in alcoholics may result from combination of inadequate diet, impaired intestinal absorption, and, perhaps, a genetically determined abnormality of transketolase (Blass & Gibson, 1977; Mukherjee et al., 1986, 1987). Such individuals would be at greater risk to develop functional thiamine deficiency when thiamine levels in the diet are compromised. However, the precise role of thiamine deficiency in the pathogenesis of the characteristic brain lesions in Wernicke's encephalopathy is poorly understood.

Evaluation and management

The diagnosis of Wernicke's encephalopathy is usually suggested by the clinical triad of ataxia, ophthalmoplegia, and confusion in an alcoholic as well as by the response to thiamine treatment. Although there are no antemortem laboratory tests that unequivocally establish the diagnosis, evidence suggests that magnetic resonance imaging (MRI) may be valuable in mild or unusual cases.

Management of Wernicke's encephalopathy requires hospitalization (mortality rate 10–20%) and prompt treatment with thiamine. 100 mg of thiamine is given parenterally because intestinal absorption is impaired in malnourished alcoholics. Thiamine treatment should be started before beginning intravenous glucose or oral feeding; carbohydrates administered before thiamine can precipitate or worsen the encephalopathy. Recovery begins promptly. Oral treatment with thiamine (50 mg) should be started after several days of IV thiamine. Ophthalmoplegia and gaze palsies begin to resolve during the first day. Nystagmus, gait ataxia, and confusion may improve within days to weeks. However, residual nystagmus and cerebellar truncal ataxia may persist after the patient recovers from the acute episode. Nearly all patients with Wernicke's encephalopathy recover from the global confusional state, but many are left with a residual disorder of memory, Korsakoff's amnestic syndrome.

Korsakoff's amnestic syndrome

A characteristic defect in forming new memories (anterograde amnesia) and in recalling established memories (retrograde amnesia) occurs with Korsakoff's amnestic syndrome. Recent memories tend to be most severely affected, and patients are usually disoriented for place and time. Patients often have well preserved distant memories. Immediate recall is intact, but patients are unable to remember the same information several minutes later. Imaging studies are consistent with pathologic findings, which suggest that lesions in the dorsal medial nucleus of the thalamus are probably responsible for the memory

deficits (Shimamura et al., 1988). Korsakoff's patients often show a lack of appreciation of their deficit. The patients may exhibit confabulation or make-up stories to compensate for their impaired recall. Other aspects of cognitive function, including arousal, language, praxis and judgement, are unaffected.

All patients should be given thiamine to treat coexistent Wernicke's encephalophy or to prevent further memory loss. About 20% of patients with Korsakoff's syndrome recover completely, but more than one-half show little or no change. Recovery may be delayed for 1–3 months. The transition between the reversible metabolic disorder of Wernicke's encephalopathy and the development of permanent neurological deficits in Korsakoff's syndrome is not well understood. However, calorie-containing ethanol appears to be an important contributing factor. Calorie-deprived prisoners of war who developed Wernicke's encephalopathy rarely exhibited the irreversible amnestic syndrome. Alcohol may be required with malnutrition to produce the syndrome.

Alcoholic dementia

Most alcoholics have cognitive deficits on psychometric evaluation. Alcoholics also tend to develop cerebral atrophy that increases with age and that can be visualized on CT scans and MRI of the brain. Symmetric enlargement of the lateral ventricles and an increase in the size of the cerebral sulci and the width of interhemispheric and sylvian fissures have been described. These structural changes may improve if drinking is discontinued (Carlen et al., 1986; Schroth et al., 1988). The structural abnormalities, however, correlate poorly with specific cognitive deficencies (Carlen et al., 1981). The specific mechanisms underlying alcoholic dementia are not known. Experimental studies have demonstrated that ethanol exposure leads to altered dendritic morphology in the hippocampus and neuronal loss (Durand et al., 1989; Ferrer et al., 1989).

Marchiafava–Bignami disease

This rare condition affects mainly individuals who have a long history of alcoholism. The clinical features are quite variable. Patients may present with seizures and coma or may follow a subacute progressive course with agitation or apathy, hallucinations, and emotional disorders until stupor and coma supervene. Clinical signs are non-specific but often suggest bilateral frontal lobe involvement with later spasticity and rigidity. Recovery is rare. Patients may not progress with abstinence and nutritional supplementation, but remain demented. Symmetric demyelination of the corpus callosum and anterior commissure can be seen on MRI and CT scans (Kawamura et al., 1985). Adjacent white matter regions are less frequently involved. The etiology is unknown, and there is no specific treatment.

Alcoholic cerebellar degeneration

Cerebellar degeneration occurs frequently in chronic alcoholics. Pathologically, the cerebellar findings are highly similar to those observed in Wernicke's encephalopathy. The disorder may reflect a history of Wernicke's encephalopathy. The patients are usually long-standing alcoholics. Affected patients usually complain of progressive unsteadiness and difficulty in walking. Abnormalities of gait and station are the most common findings, and truncal ataxia may be mild or severe. Limb ataxia, particularly of the lower extremities, may also be observed. Dysarthria and nystagmus are less common. Often, the cerebellar syndrome develops rapidly over a period of several weeks or months and then remains stable. The disorder sometimes develops more slowly, but exacerbation occurs during binge drinking or intercurrent illness. CT scans and MRI studies may confirm cerebellar vermis atrophy. Affected patients should discontinue drinking and be treated with thiamine and multivitamins.

Central pontine myelinolysis

Central pontine myelinolysis (CPM) is a rare disorder encountered in alcoholics and in other settings such as patients with electrolyte disorders, liver disease, malnutrition, anorexia, burns, cancer, Addison's disease, sepsis, and Wilson's disease. CPM results from rapid correction of hyponatremia rather than from a toxic effect of ethanol.

Alcoholic neuropathy

Polyneuropathy is quite common among alcoholic patients (Mills et al., 1986). Complaints include parasthesias, dysasthesias, weakness and ataxia. Symptoms usually begin insidiously in the distal lower extremities and progress proximally. On examination, decreased vibration sense is typically observed. Light touch, pain and temperature sensation may also be impaired. Absent or diminished reflexes are common. Distal weakness is also frequently seen. Rarely are there autonomic or cranial nerve findings. Alcoholic polyneuropathy is characterized primarily by axonal degeneration. Segmental demyelination is, however, also described. NCS can be used to demonstrate a primarily axonal process. Treatment includes

abstinence and nutritional supplementation (including thiamine). Improvement sometimes occurs. Dysesthesias are treated with agents used for other forms of neuropathic pain (including tricyclics and anticonvulsants).

An unusual form of alcoholic neuropathy has been described that evolves within several days and results in severe weakness, hyporeflexia and sensory loss (Wohrle et al., 1998). It may be confused with Guillian–Barré syndrome. Unlike GBS, however, there is not respiratory muscle involvement or bulbar signs. CSF protein is also normal or only mildly elevated. Electrophysiological and pathological studies reveal primarily an axonal process. Recovery typically occurs over several months.

Alcoholic myopathy

Acute alcoholic myopathy

Acute alcoholic myopathy is a dramatic and life-threatening disorder that occurs in alcoholics, often after several days of heavy binge drinking (Haller & Knochel, 1984). Symptoms begin abruptly with pain, cramps, tenderness, proximal weakness, and swelling of the muscles. Muscle involvement can be generalized or asymmetric. Weakness is typically proximal. There may be arrhythmias because of cardiac involvement and electrolyte abnormalities. CHF may occur. Creatine kinase activity in blood is elevated, and muscle biopsy shows necrotic changes in muscle fibres. Myoglobinuria is a frequent complication and may lead to hyperkalemia, renal failure and death. Arrhythmias may be observed on the electrocardiogram. The electromyogram usually shows evidence of mypopathic changes. Recovery generally occurs within weeks of abstinence but may be incomplete with a residual proximal muscle weakness and cardiac conduction abnormalities.

Chronic alcoholic myopathy

A chronic, typically painless, syndrome of proximal muscle weakness and atrophy may evolve gradually in alcoholics. The myopathy can be mild or severe and affects legs more often than arms. Muscle biopsy reveals Type II fibre involvement. Improvement usually occurs between 2 and 3 months after drinking is discontinued.

Fetal alcohol syndrome

Alcoholic mothers who drink heavily throughout pregnancy can give birth to infants with intrauterine growth retardation, dysmorphic features, microcephaly, and neurological abnormalities (Rosett & Weiner, 1984). The dysmorphic features include short palpebral fissures, midfacial hypoplasia, thinned upper lip vermilion, diminished or absent philtrum, and a low nasal bridge. The disorder is known as fetal alcohol syndrome, but some investigators consider these features to be ungrouped congenital anomalies (Kalter & Warkany, 1983). Moreover, malnutrition, tobacco, and concomitant drug abuse frequently complicate maternal alcoholism and can also adversely affect the developing fetus. Infants with fetal alcohol syndrome may show hypotonia, poor sucking, tremulousness, irritability, and seizures. Older children exhibit mental retardation, hyperactivity and learning disabilities. The incidence of this syndrome in the offspring of alcoholic mothers ranges from 2.5–40% and is about 0.25% of all live births (Rosett & Weiner, 1984).

Neurological consequences of drug abuse

John C.M. Brust

Department of Neurology, Harlem Hospital Centers and Columbia University College of Physicians and Surgeons, USA

There are two kinds of drug dependence. 'Psychic dependence' is compulsive recreational use of a substance to produce pleasure or to avoid discomfort. 'Physical dependence' is an adaptive state in which cessation of drug use (or administration of an antagonist) causes intense physical discomfort. 'Tolerance' is the need for ever larger doses of a drug to achieve the desired effect or to avoid withdrawal symptoms. 'Sensitization' ('reverse tolerance') is a lowered threshold for certain drug effects following repeated use. The term 'addiction' refers to psychic dependence. The term 'drug abuse' refers to the perception that recreational use of a substance, licit or illicit, is harmful (Brust, 1993).

Pathophysiological aspects of drug addiction, including intended effects, are discussed in Chapter 30. This chapter addresses, first, clinical features of overdose and withdrawal and, second, other neurological complications encountered in recreational substance users. Alcohol is discussed in Chapter 113.

Drugs of dependence

Opiates

Of the many opiates available in the United States (Table 114.1), heroin (diacetylmorphine) is the most popular urban street drug. Before the 1980s it was usually taken parenterally, but ready availability of cheap potent heroin, plus fear of AIDS, have more recently favoured snorting or smoking. The drug is highly addicting, and tolerance in daily users leads to the need for huge doses. Many users, however, take heroin only occasionally, and erratic use combined with variably potent street mixtures carries considerable risk for overdose (Brust, 1993).

Acting at different types of receptors in many areas of the central and peripheral nervous systems, opiates produce

Table 114.1. Opiates

Agonist
Powdered opium
Tincture of opium (laudanum)
Camphorated tincture of opium (paregoric)
Morphine
Heroin (legally available only for investigational use)
Methadone (Dolophine, etc.)
Fentanyl (Sublimaze)
Oxymorphone (Numorphan)
Hydromorphone (Dilaudid)
Codeine
Oxycodone (in mixtures, e.g. Percodan, Percocet)
Levorphanol (Levodromoran)
Meperidine (pethidine, Demerol, etc.)
Diphenoxylate (in Lomotil)
Loperamide (Imodium)
Dextromethorphan (Robitussin)
Propoxyphene (Darvon)
Apomorphine
Tramadol (Ultram)
Mixed agonist–antagonist/partial agonist
Levallorphan (Lorfan)
Nalorphine (Naline)
Pentazocine (Talwin)
Butorphanol (Stadol)
Nalbuphine (Nubain)
Buprenorphine (Buprenex)
Cyclazocine (for investigational use only)
Antagonist
Nalmefene (Revex)
Naloxone (Narcan)
Naltrexone (Trexan)

diverse effects. In intended dosage heroin causes analgesia, drowsiness, and euphoria; injected or smoked heroin produces an ecstatic 'rush' followed by either a dreamlike 'nodding' or increased psychomotor activity ('drive'). Other effects include nausea and vomiting, miosis, dryness of the mouth, pruritis, sweating, suppression of the cough reflex, constipation, hypothermia, respiratory depression, and postural hypotension.

Overdose causes coma, pinpoint pupils, and respiratory depression. Miosis may be so marked that the light reflex, which opiates do not interrupt, may be difficult to discern. On the other hand, anoxia–ischemia or hypothermia can produce large and unreactive pupils. Further confusing the picture are the effects of concomitantly administered drugs. Heroin is frequently taken with cocaine or amphetamine ('speedball'), and heroin addicts often abuse ethanol. Signs of overdose from one agent may therefore coexist with signs of overdose or withdrawal from another agent. For example, seizures in a heroin user may be the combined result of cocaine toxicity, ethanol withdrawal, anoxia, and the opiate's own ability to lower seizure threshold.

Treatment of overdose begins with attention to apnea or shock (Nelson, 1998). Opiates depress brainstem carbon dioxide sensitivity, and so oxygen is administered cautiously. Hypotension usually responds to correction of hypoxia and administration of fluids; vasopressors or plasma expanders are rarely needed. In some patients heroin causes pulmonary edema, which vigorous fluid administration can aggravate.

Patients with respiratory depression are given naloxone, 2 mg intravenously (or, if veins are unavailable, intramuscularly or subcutaneously). If signs persist, boluses of 2 to 4 mg are repeated up to a total of 20 mg. Higher doses may be required for propoxyphene, pentazocine, nalbuphine, butorphanol, buprenorphine or diphenoxylate, but failure to respond to 20 mg suggests the presence of additional drugs, anoxic–ischemic brain damage, or an alternative diagnosis.

Patients with depressed sensorium but normal respirations receive smaller doses of naloxone to avoid precipitating withdrawal signs: 0.4 to 0.8 mg are given, and if there is no response, 2-mg doses are repeated every 2 to 3 minutes.

Maximal effects occur 2 to 3 minutes after intravenous naloxone but only about 15 minutes after intramuscular or subcutaneous naloxone. Because of vomiting, some emergency medicine physicians perform endotracheal intubation before giving naloxone. Too much naloxone can precipitate opiate withdrawal. On the other hand, naloxone is shorter acting than most opiate agonists, and patients who seem to have fully recovered can slip back into coma and apnea. Hospitalization and close observation are required for at least 24 hours with heroin and 72 hours with methadone, during which time it may be necessary to give naloxone in repeated doses or as a continuous infusion.

Physical dependence develops rapidly in daily heroin users, and symptoms and signs develop within hours of withdrawal (Khanzian & McKenna, 1979). Unlike withdrawal from ethanol or sedatives, the opiate abstinence syndrome does not include seizures, hallucinosis, or delirium and in adults is rarely life threatening. Rather, there are irritability, weakness, lacrimation, rhinorrhea, sweating alternating with chills and piloerection, myalgia, nausea, vomiting, diarrhea, abdominal cramps, hot flashes, fever, rhonchi, rales, tachypnea, tachycardia, and hypertension. Symptoms can resemble a severe case of 'the flu', with drug craving disproportionate to other symptoms. With heroin, symptoms peak at 24 to 72 hours and last a week or two. With methadone, symptoms peak at about a week and last up to 3 months. Opiate withdrawal symptoms are promptly relieved by oral methadone 20 mg once or twice daily, with subsequent dosage titrated to symptoms.

By contrast, opiate abstinence in newborns exposed in utero is often severe or even fatal. Tremor, jitteriness, muscle hypertonia, screaming, lacrimation, tachypnea, tachycardia, vomiting, and diarrhea can progress to myoclonus or convulsions (although seizures can be difficult to tell from jitteriness and if present might be secondary to barbiturate or ethanol withdrawal). Mortality is as high as 90% without treatment, which includes either methadone or another opiate such as paregoric (Kandall et al., 1983). Symptoms resemble those associated with neonatal hypoglycemia, sepsis, meningitis, hypocalcemia, or intracranial hemorrhage, any of which might coexist.

Overdose of other opiates has special features. Meperidine, through its metabolite normeperidine, causes tremor, myoclonus, and seizures (Hershey, 1983). Fentanyl and its many 'designer drug' analogs produce acute muscular rigidity, which further impairs ventilation (Henderson, 1988). Propoxyphene causes naloxone-resistant cardiotoxicity and seizures (Young, 1983). Pentazocine, sometimes taken parenterally with antihistamine or methylphenidate, causes psychosis (Sandoval & Wand, 1969).

Psychostimulants

Psychostimulant drugs include amphetamine and related agents, as well as cocaine (Table 114.2). Their major CNS effects are the result of indirect dopamine agonism, causing psychic symptoms through actions within the

Table 114.2. Amphetamines and related agents

Amphetamine (Adderall, Biphetamine)
Dextroamphetamine (Dexedrine)
Methamphetamine (methedrine, Desoxyn, Fetamin, 'speed', 'ice')
Ephedrine
Pseudoephedrine
Phenmetrazine (Preludin)
Methylphenidate (Ritalin)
Pemoline (Cylert)
Diethylpropion (Tenuate, Tepanil)

Chlorphentermine (Pre-Sate)
Phendimetrazine (Plegine, Bontril, Phenzine, Prelu-Z)
Phentermine (Ionamin, Wilpo, Adipex, Fastin)
Phenylpropanolamine (Propadrine, and in decongestants, e.g. Ornade, Comtrex, and in diet pills, e.g. Dex-a-Diet, Dexatrim, Maxi-Slim, Vita-Slim)
Propylhexedrine (Benzedrex)
Tuaminoheptane (Tuamine)
Naphazoline (Privine)
Tetrahydrozoline (Tyzine)
Oxymetazoline (Afrin)
Phenylephrine
Xylometazoline (Otrivin)
Cyclopentamine (Clopane)
Fenfluramine (Pondimin) (withdrawn)
Dexfenfluramine (Redux) (withdrawn)
Methylenedimethoxymethamphetamine ('ecstasy', 'Adam')
Methylenedimethoxyethamphetamine ('Eve')

limbic 'reward system' (see Chapter 30) and abnormal movements through actions within nigrostriatal circuits of the basal ganglia. Amphetamine-like agents release dopamine at synaptic endings through a dopamine transporter; cocaine blocks dopamine re-uptake through the same transporter (Hyman, 1996). Peripherally, similar actions affect norepinephrine nerve endings. Amphetamine-like drugs and cocaine therefore produce similar syndromes of overdose and withdrawal, although the symptoms and signs of cocaine overdose tend to be shorter lived.

Dextroamphetamine and methamphetamine are taken orally or parenterally, and crystalline methamphetamine ('ice') is smoked. Cocaine hydrochloride is either snorted or injected; its alkaloidal form ('free-base' or 'crack') is smoked (Cho, 1990). Less often used recreationally are decongestants such as phenylpropanolamine, ephedrine and propylhexadrine, some of which are sold as 'legal stimulants' (Lake & Quirk, 1984). The 'designer amphetamine' methylenedioxymethamphetamine ('ecstasy'), popular among college students, has both psychostimulant and LSD-like hallucinogenic properties (Bost, 1988). Increased international travel has led to the appearance in Europe and North America of lesser known psychostimulants such as khat, a shrub widely used in East Africa and the Arabian peninsula (Kalix, 1990).

Injectors or smokers of methamphetamine or cocaine often take the drug daily in huge doses, for psychic dependence and tolerance to euphoria are rapidly acquired. During the course of repeated administration, users may be continuously awake and gradually undergo mood changes, which progress to paranoia or frank psychosis with auditory and visual hallucinations. Violent behaviour can result in suicide or homicide. Abnormal movements progress from stereotypic activity, bruxism, and tremor to dystonia and choreoathetosis. The appearance of psychosis and abnormal movements with repeated use is an example of sensitization ('reverse tolerance').

More acute overdose causes excitement, confusion, headache, chest pain, tachycardia, hypertension, sweating, mydriasis, and then delirium, cardiac arrhythmia (including ventricular tachycardia and ventricular fibrillation), fever (sometimes over 109 °F), myoclonus, seizures, coma, shock, and death. There may be myoglobinuria, disseminated intravascular coagulation, or intracranial hemorrhage. Especially with cocaine, peripheral vasoconstriction causes myocardial infarction, aortic dissection, and gastrointestinal infarction or perforation (Derlet & Albertson, 1989; Ruttenber et al., 1997).

Treatment of psychostimulant overdose includes temperature control, fluid replacement, sedation and oxygen. Benzodiazepines are preferable to neuroleptics, which lower seizure threshold and cause hypotension, hypothermia, cardiac arrhythmia, and acute dystonia. Very high doses of a benzodiazepine may be necessary, e.g. diazepam 100 mg in the first 30 minutes. If seizures do not respond to benzodiazepine administration, barbiturates are preferred to phenytoin. Hypertension usually responds to sedation, but if sustained or dangerous is treated with an alpha-blocker (e.g. nitroprusside). (Beta-blockers may result in unopposed alpha-agonism and paradoxical worsening of hypertension.) Conversely, hypotension requires blood pressure support, and close ventilatory and cardiac monitoring are essential. Metabolic acidosis can be severe, requiring large doses of bicarbonate; although urinary acidification increases cocaine and amphetamine excretion, it is contraindicated in such a setting. Recovery from cocaine intoxication usually occurs within a few hours and is complete unless there has been anoxic-ischemic brain damage. Signs of amphetamine poisoning tend to be more prolonged, and in some cases hemodialysis may be appropriate (Goldfrank & Hoffman, 1991; Chiang, 1998).

Psychostimulant withdrawal causes fatigue, hunger, depression, and drug craving. There is little in the way of objective signs, but suicidal ideation may require hospitalization.

Barbiturates and other sedatives

Sedative drugs include barbiturates, benzodiazepines, and a variety of other agents (Table 114.3). Although they differ in many of their properties, most resemble ethanol in their sedative affects and withdrawal symptoms. They are partially cross-tolerant with ethanol and with each other.

Barbiturate overdose is most often the result of a suicide attempt or accidental ingestion by children. Recreational use usually involves short-acting agents such as secobarbital, taken orally or parenterally. Tolerance develops rapidly to euphoria and sedation but less so to respiratory depression, and so small increments in dosage can be dangerous. Ethanol, moreover, can aggravate the effects of barbiturates.

Overdose causes coma and respiratory depression progressing to apnea (Gary & Tresznewsky, 1983). Hypotension is more often secondary to hypoxia than to direct medullary depression. Treatment begins with respiratory support and oxygen. If only a few hours have elapsed since ingestion, induced emesis or gastric lavage is performed. Activated charcoal and a cathartic are administered, and if hypotension does not respond to artificial ventilation, it may be necessary to use volume expansion or pressors, and metabolic acidosis may require correction. Urinary alkalization hastens the excretion of long-acting barbiturates such as phenobarbital. Hemodialysis is also more effective with long-acting agents. CNS stimulant drugs are contraindicated.

As noted in Chapter 30, barbiturates and ethanol cause similar withdrawal syndromes, including tremor, hallucinations, seizures, and delirium tremens (Wikler, 1968). Symptoms can last weeks, and cardiovascular collapse can be fatal. Mild barbiturate withdrawal symptoms can be treated with titrated doses of a short-acting barbiturate. Seizures are appropriately treated with phenobarbital. Hallucinations are also treated with a barbiturate, for neuroleptics lower seizure threshold. Delirium tremens is a medical emergency requiring sedation (appropriately with a barbiturate, although, as with alcohol delirium tremens and in contrast to opiate withdrawal, administration of the offending agent does not reverse symptoms once full-blown delirium tremens is present). Cooling, correction of fluid and electrolyte imbalance, and close cardiac monitoring are best performed in an intensive care unit.

Table 114.3. Sedatives

Barbiturates
Amobarbital (Amytal)
Aprobarbital (Alurate)
Barbital (in Plexonal)
Butalbital (Sandoptal, and in mixtures, e.g. Amaphen, Fiorinal, Plexonal, Repan)
Hexobarbital (Sombulex)
Mephobarbital (Mebaral)
Methohexital (Brevital)
Pentobarbital (Nembutal)
Phenobarbital (Luminal, etc. and in mixtures, e.g. Donnatal)
Primidone (Mysoline)
Secobarbital (Seconal)
Talbutal (Lotusate)
Thiamylal (Surital)
Thiopental (Pentothal)

Benzodiazepines
Alprozolam (Xanax)
Bromazepan (Lectopam)
Chlorazepate (Tranxene)
Chlordiazepoxide (Librium)
Diazepam (Valium)
Flunitriazepam (Rohypnol) (illegal in the US)
Flurazepam (Dalmane)
Halazepam (Paxipam)
Lorazepam (Ativan)
Nitrazepam (Mogadon)
Oxazepam (Serax)
Oxazolam (Serenal)
Prazepam (Verstran, Centrax)
Temazepam (Cerepax, Levanxol)
Triazolam (Halcion)

Others
Bromide
Buspirone (Buspar)
Chloral hydrate (Noctec)
Chlormezanone (Trancopal)
Ethchlorvynol (Placidyl)
Glutethimide (Doriden)
Hydroxyzine (Atarax, Vistaril)
Meprobamate (Miltown, Equanil)
Methaqualone (Qualude, Sopor) (withdrawn)
Methyprylon (Noludar)
Paraldehyde (withdrawn)
Zolpidem (Ambien)

The abuse potential of benzodiazepines is less than that of barbiturates, but illicit use does occur (probably more often to treat pre-existing symptoms than to obtain a 'high'). Benzodiazepine overdose is much less likely than barbiturate overdose to depress respiration. Flumazenil reverses the sedative effects of benzodiazepines (and of zolpidem), but symptoms tend to return within 30 to 60 minutes, and withdrawal symptoms can be precipitated (Geller et al., 1991).

Benzodiazepine abstinence symptoms, usually limited to anxiety and tremor, are often difficult to tell from those symptoms for which the drug was being taken in the first place. Seizures, hallucinations, and delirium can follow abrupt withdrawal from short-acting agents (du Bard, 1979).

Non-barbiturate, non-benzodiazepine sedatives also cause coma and respiratory depression in overdose and tremor, seizures, or delirium in withdrawal. Some also have characteristic features of their own. Overdose with methaqualone (no longer marketed in the United States) causes delirium, hallucinations, myoclonus, seizures, papilledema, and congestive heart failure (Wetli, 1983). Glutethimide and methyprylon can cause severe circulatory failure, and with its anticholinergic properties glutethimide causes dilated unreactive pupils, ileus, and atonic bladder. As a street drug glutethimide is often injected parenterally combined with codeine ('hits', 'loads') (Bender et al., 1988). Ethchlorvynol causes hypotension, pulmonary edema, and prolonged coma; exchange transfusion and hemoperfusion with Amberlite resin can be used to treat ethchlorvynol poisoning (Lynn et al., 1979). Bromide salts (no longer present in over-the-counter sleeping pills) cause a skin rash; treatment of overdose includes sodium chloride and diuresis.

Increasingly popular during the 1990s, gamma-hydroxybutyrate (GHB) is readily synthesized from the industrial solvent gamma-hydroxybutyrolactone (Chin et al., 1992). Taken for its sedative and euphoric properties, GHB (and the illegal benzodiazepine flunitrazepam) are particularly implicated as 'date rape' drugs. GHB overdose causes coma and respiratory depression, which tend to be short lived, requiring supportive treatment, but fatalities have occurred. Withdrawal symptoms consist of tremor, anxiety and insomnia.

Marijuana

The most widely used illicit drug in the United States, marijuana consists of leaves and tops of the hemp plant *cannabis sativa*, which contains numerous cannabinoid compounds. Delta-9-tetrahydrocannabinol (Δ-9-THC), the principal psychoactive ingredient, causes euphoria and drowsiness. Hashish, derived from the plant resin, has high concentrations of Δ-9-THC. Cannabinoid compounds act at specific receptors in the central and peripheral nervous systems, and endogenous ligands for these receptors have been identified, yet the mechanisms of cannabinoid compounds' multiple actions – convulsant, anticonvulsant, hyperthermic, hypothermic, analgesic, bronchodilating – are uncertain (Brust, 1999).

Marijuana and hashish are usually smoked but can be eaten. Acute adverse effects are infrequent, and fatal overdose has never been convincingly described. (Marijuana users are, however, over-represented in traffic and other accidents.) Often accompanying the intended dreamy euphoria are jocularity, disinhibition, depersonalization, subjective time slowing, conjunctival injection, tachycardia, and postural hypotension (Heishman et al., 1990). High doses cause auditory or visual hallucinations, confusion, anxiety, and psychotic depression or excitement, and conventional doses can cause paranoia, delusions, depression, or panic ('freaking out') (Weil, 1970). 'Flashbacks' consist of the spontaneous reappearance, weeks or months after using marijuana, of hallucinations or other symptoms associated with earlier use. Adverse reactions usually last a few hours and require no more than calm reassurance; benzodiazepine therapy can be used for severe cases, which should raise suspicion of concomitant use of another drug such as phencyclidine.

Tolerance develops to marijuana's cardiovascular and perhaps to its depressant behavioural effects, but there may be 'reverse tolerance' for excitement or psychosis. Addiction occurs, but symptoms of physical dependence – jitteriness, anorexia, and headache – tend to be mild.

Hallucinogens

Hallucinogenic plants are used ritualistically or recreationally around the world; most often encountered in North America are mushrooms containing psilocin and psilocybin, peyote cactus containing mescaline, and the synthetic ergot d-lysergic acid diethylamide (LSD), which during the 1990s became increasingly popular among American adolescents (Table 114.4). Taken orally, these substances produce similar effects and are cross-tolerant with one another (Jacobs, 1987; Schwartz & Smith 1988).

Acute effects of hallucinogens are perceptual (distortions and hallucinations, usually visual and elaborately formed), somatic (dizziness, tremor, paresthesias, hyperthermia, piloerection, mydriasis with preserved light reflex, tachycardia, hypertension), and psychological (depersonalization, altered mood, derealization, autism,

Table 114.4. Hallucinogens abused in the United States

Mescaline (peyote cactus)
Psilocybin and psilocin (*Psilocybe*, *Penaelous*, and *Conocybe* mushrooms)
D-lysergic acid diethylamide (LSD)
Dimethyltryptamine (DMT)
Diethyltryptamine (DET)
Dimethoxymethylamphetamine (DOM, 'STP')
Dimethoxyethylamphetamine (DOET)
Methylenedioxyamphetamine
D-lyseric acid amide (morning glory seeds)
Myristicin (nutmeg)
Nepetalactone (catnip)

mystical elation), and it is the latter that pose potential danger (Hollister, 1984). 'Bad trips', with panic or marked paranoia, can lead to accidents, self-mutilation, suicide, or homicide. Such symptoms can spontaneously recur as flashbacks weeks or months after original use (Hatrick & Dewhurst, 1970). Adverse reactions usually clear within 24 hours and can be managed with talking down or benzodiazepine therapy. (Neuroleptics can paradoxically exacerbate symptoms.) Death directly attributable to LSD has not been described, but severe hypertension may require treatment with an alpha blocker or direct vasodilator, and hyperthermia, which in the presence of agitation can cause myoglobinuria, may require cooling.

Tolerance develops to LSD's effects, but physical dependence does not seem to occur.

Inhalants

Inhalation of volatile substances to achieve euphoria is popular among American children and adolescents, who sniff a wide variety of products with many constituents (Table 114.5). Substances are usually sniffed from a saturated rag, a plastic bag, directly from the container, or from a heated frying pan, sometimes for hours at a time daily over years. Nitrous oxide is obtained from whipped cream canisters, and butyl or amyl nitrite from 'room odorizers'.

Acute effects, including toxicity, are remarkably similar among different agents (Morton, 1987). Moderate doses produce euphoria and ataxia resembling ethanol intoxication, with similar propensity to accidents or violence. Higher doses cause psychosis with delusions and hallucinations, as well as cyanosis, seizures, and coma (Ramsey et al., 1989). Aspiration of vomitus and asphyxiation by plastic bags can be fatal; unexplained sudden death is probably due to cardiac arrhythmia, and respiratory depression can occur. Acute lead encephalopathy has followed gasoline sniffing, and nitrous oxide sniffers have died from brain anoxia. Nitrite sniffing causes methemoglobinemia, but syncope tends to prevent inhalation of a life-threatening amount (Brust, 1993).

Table 114.5. Substances commonly abused as inhalants

Aerosols (refrigerants, frying pan sprays, antitussives, bronchodilators, deodorants, hair sprays, shampoos, antiseptics)
Lacquers, paints, enamels, and lacquer and paint thinners
Lighter fluids
Fingernail polish removers
Cleaning fluids (spots, shoes, wigs)
Airplane model cements
Furniture polishes
Household cements
Plastic (polystyrene) cements
Rubber, tyre-patching, or tube repair cements
Gasoline
Anesthetics (ether, nitrous oxide, halothane, trichlorethylene)
'Room fresheners' (nitrites)

Acute symptoms tend to clear within a few hours, and treatment includes respiratory and cardiac monitoring. Tolerance develops, but there is no predictable abstinence syndrome other than craving.

Phencyclidine

Developed as an anesthetic and withdrawn because it causes psychosis, phencyclidine ('PCP', 'angel dust') blocks *N*-methyl-D-aspartate receptor excitatory neurotransmission. The drug can be eaten, snorted, or injected but is most often smoked, sprinkled on tobacco or marijuana (Thombs, 1989). A number of PCP congeners sold as street drugs, including the anesthetic ketamine, may give negative results on toxicological testing for PCP.

Low doses of PCP cause euphoria or dysphoria, emotional liability, a sense of numbness, and sensory distortions. Higher doses produce agitation, confusion, bizarre behaviour, synesthesias, and analgesia and then psychosis with both negative and positive features of schizophrenia, including paranoia with auditory hallucinations and stuporous catatonia (McCarron et al., 1981a,b). Somatic signs include burst-like horizontal and vertical nystagmus, miosis, ataxia, myoclonus, fever, sweating, tachycardia and hypertension. Anesthetic doses produce seizures, coma

with extensor posturing, respiratory depression and hypotension. Myoglobinuria occurs, and malignant hyperthermia may cause liver necrosis. Death can be the result of direct overdose, accidents, violence or suicide. Recovery can take days, during which time even mild stimuli may provoke agitated or violent behaviour.

Very little active drug is excreted through the kidney, and so diuresis is ineffectual; although acidification increases PCP excretion, myoglobinuria contraindicates such treatment. Gastroenteric recirculation favours intermittent gastric lavage, and a cathartic and activated charcoal prevent absorption. Severe hypertension, which can appear days after drug intake, may require alpha-blockade or direct vasodilatation. Seizures are treated with a benzodiazepine or phenytoin.

Agitation or psychosis (which can emerge as the patient comes out of stupor or coma) does not respond to 'talking down'. Although benzodiazepines prolong PCP's half-life and can aggravate its depressant actions, they are preferable to neuroleptics, which lower seizure threshold, are hypotensive, and cause a malignant neuroleptic syndrome with myoglobinuria, and, through anticholinergic actions, aggravate delirium. Symptoms of overdose last hours to days, and sometimes psychosis outlasts other symptoms and signs; in such a situation, a trial of neuroleptic therapy is appropriate.

Tolerance develops to PCP's effects, but physical dependence and withdrawal symptoms, other than craving, are not encountered.

Anticholinergics

The recreational use of anticholinergic agents includes ingestion of the plant *Datura stramonium*, popular among American adolescents, as well as the use of antiparkinsonian drugs, antiasthmatic inhalers, and tricyclic antidepressants (especially amitriptyline). Symptoms and signs include euphoria, excitement, delirium, hallucinations, dilated unreactive pupils, dysphagia, urinary retention, dry flushed skin, high fever, hypertension, tachypnea, and tachycardia (Mikolich et al., 1975). Severe poisoning causes myoclonus, seizures, extensor posturing, coma, respiratory failure, shock and death. Delusions and hallucinations can be prominent during recovery.

Symptoms last hours to days. Treatment includes physostigmine 1 to 3 mg intravenously at 30 minute to 2 hour intervals (unless intraventricular conduction delay is suspected), plus gastric lavage (the drug delays gastric emptying), cooling, bladder catheterization, respiratory and cardiac monitoring, and, if necessary, anticonvulsants, Neuroleptics, which have anticholinergic actions, are contraindicated; benzodiazepines can be used cautiously for agitation.

A withdrawal syndrome is not described.

Neurological complications

Trauma

Acute intoxication from any of the above drugs, as well as ethanol, can result in accidents or violent behaviour, including suicide. Overprescribing of sedatives is a common cause of falls in the elderly. Cerebral or spinal cord injury must always be considered in intoxicated subjects, who may be difficult to examine or to image. Trauma among illicit drug users, however, is more often related to the drug's illegal status, i.e. either involving crimes committed to obtain the drug or reflecting the business practices of drug traffickers (Goldstein, 1985). Prior to the AIDS epidemic violence accounted for nearly half of all fatalities among New York city heroin addicts, and a surge of violent crime in American cities accompanied the 'crack' cocaine epidemic of the 1980s and 1990s.

Infection

An array of local and systemic infections affect parenteral users of any drug. Frequently encountered are local abscesses, pyomyositis, cellulitis, pneumonia, sepsis, endophthalmitis, chorioretinitis, episcleritis, fasciitis, osteomyelitis, and pyogenic arthritis (Richter, 1993). Infections frequently affect the central or peripheral nervous systems. Endocarditis, bacterial or fungal, leads to meningitis, cerebral infarction, diffuse vasculitis, abscess (brain, subdural, or epidural, including the spinal cord), or subarachnoid hemorrhage from rupture of a septic ('mycotic') aneurysm (Gattell et al., 1984). Mycotic aneurysms in parenteral drug users have occurred on the carotid, subclavian and pulmonary arteries.

Infectious hepatitis can cause encephalopathy or, because of deranged clotting, hemorrhagic stroke. Vertebral osteomyelitis or disc infection can cause radiculopathy or myelopathy. Tetanus, seen especially in subcutaneous injectors of heroin, tends to be severe (Brust & Richter, 1974). Botulism occurs at injection sites or, among cocaine snorters, in the nasal sinuses (Kudrow et al., 1988). Malaria has affected heroin users in endemic areas (Gonzalez-Garcia et al., 1986).

As of 2000, in the United States non-homosexual parenteral drug abusers accounted for 26% of adult and

adolescent cases of acquired immunodeficiency syndrome (AIDS) reported to the Centers for Disease Control and Prevention (and nearly half of reported women with AIDS). Male homosexual drug abusers represented another 6%, and heterosexual contact with a parenteral drug abuser another 4%. Over half of the 8000 American children less than 13 years of age with AIDS have had a mother who either abused drugs or who had sex with a drug abuser (HIV/AIDS Surveillance Report, 2000). Nearly two-thirds of patients receiving methadone maintenance therapy in New York City are seropositive for human immunodeficiency virus (HIV) (DesJarlais et al., 1989).

Parenteral drug abusers develop the same neurological complications of AIDS as do those with other risk factors (Malouf et al., 1990). They are particularly susceptible to tuberculosis (including drug-resistant strains) and syphilis (Friedman et al., 1996). Because of promiscuity and associated sexually transmitted diseases, non-parenteral cocaine users are also at increased risk for HIV infection. Heroin and cocaine are themselves immunosuppressant, yet HIV-seropositive users do not seem to be more susceptible to the development of AIDS.

Parenteral drug abusers are also subject to infection with human T-cell lymphotrophic retrovirus (HTLV) type I or type II, and a number of cases of associated myelopathy have been reported (Jacobson et al., 1993).

Seizures

As noted, seizures can be a feature of drug toxicity (e.g. psychostimulants) or drug withdrawal (e.g. sedatives) (Earnest, 1993; Alldredge et al., 1989). With amphetamine-like agents, seizures are usually accompanied by other signs of overdose. With cocaine, however, seizures can occur without other symptoms and signs (Pascual-Leone et al., 1990). Animal studies demonstrate a 'kindling' pattern at initially subconvulsant doses; the difference between amphetamine and cocaine epileptogenicity might be related to cocaine's local anesthetic properties (Karler et al., 1989). Seizures have also occurred following ingestion of phenylpropanolamine in recommended dosage for weight reduction (Mueller & Solow, 1982).

In animals, opiates can be proconvulsant or anticonvulsant depending on receptor specificity and seizure model (Ng et al., 1990). Opiate agonists lower seizure threshold in humans, but seizures are an uncommon feature of heroin overdose, and an alternative cause should always be sought. Meperidine, however, readily causes myoclonus and seizures through the proconvulsant properties of its metabolite normeperidine (Hershey, 1983). Seizures are also frequently seen in injectors of the mixed agonist-antagonist pentazocine combined with the antihistamine tripelennamine ('Ts and blues'); both drugs are proconvulsant (Caplan et al., 1982).

As with ethanol, seizures associated with barbiturate or benzodiazepine withdrawal tend to be single or clustered, but status epilepticus can occur. Seizures as a toxic effect are described with methaqualone (which is sometimes combined with an antihistamine) and with glutethimide (which has anticholinergic properties) (Hoaken, 1975).

As a blocker at NMDA receptors, phencyclidine would be expected to have anticonvulsant properties, yet seizures and myoclonus are often encountered at high doses (McCarron et al., 1981a,b).

A case-control study found that marijuana was protective against the development of new onset seizures. In animals, the non-psychoactive cannabinoid, cannabidiol, is anticonvulsant, and limited studies suggest it can reduce seizure frequency in human epileptics (Ng et al., 1990).

Stroke

Many illicit drug users also abuse tobacco and ethanol, increasing their risk for ischemic and hemorrhagic stroke. (Low-to-moderate doses of ethanol protect against both myocardial infarction and ischemic stroke, but heavy doses increase risk, and even low doses of ethanol increase risk of hemorrhagic stroke.) Systemic complications of parenteral drug abuse, for example, hepatitis, endocarditis, or AIDS, also predispose to stroke. Heroin nephropathy causes uremia, bleeding, and hemorrhagic stroke (Brust, 1998).

Heroin has caused ischemic stroke without such intermediary conditions or other evident risk factors (Brust & Richter, 1976). In some reported cases, angiographic changes were consistent with cerebral vasculitis, and laboratory abnormalities, e.g. blood eosinophilia, hypergammaglobulinemia, positive Coombs test, suggested hypersensitivity. Other possible mechanisms are systemic hypotension following overdose and embolization of injected foreign material. Stroke in injectors of pentazocine and tripelennamine ('Ts and blues') has resulted from embolization of particulate material passing through secondary pulmonary arteriovenous shunts (Caplan et al., 1982). Possibly vascular in origin is heroin myelopathy, in which acute paraparesis, sensory loss, and urinary retention follow injection, sometimes after a period of abstinence (Goodhart et al., 1982).

Intracerebral hemorrhage, often associated with fever and acute hypertension, affects users of amphetamine-like drugs. Ischemic stroke in amphetamine or methampheta-

mine users has reportedly been a feature of systemic and central nervous system vasculitis resembling polyarteritis nodosa (Citron et al., 1970). Small vessel vasculitis more typical of hypersensitivity angiitis has also caused ischemic stroke. Although reported cases are often based on non-specific angiographic 'beading', cerebral vasculitis has been demonstrated in animals receiving repeated doses of methamphetamine over weeks or months (Brust, 1997).

Stroke in cocaine users can be secondary to drug-induced cardiac arrhythmia, myocardial infarction, or cardiomyopathy. In many cases, however, neither cardiac disease, infection, nor other risk factor is apparent (Sloan et al., 1998). Of the more than 400 cocaine-related strokes reported to date, about half were ischemic and half hemorrhagic. Strokes have occurred with both cocaine hydrochloride and alkaloidal 'crack' (Levine et al., 1990). Ischemic strokes include transient ischemic attacks and infarction of the cerebrum, thalamus, brainstem, spinal cord, and retina. Of those patients with hemorrhagic stroke who underwent cerebral angiography, about half harboured saccular aneurysms or vascular malformations. A plausible mechanism for hemorrhagic stroke is surges of systemic hypertension. Some ischemic strokes might be the result of direct cerebral vasoconstriction induced by the drug. Most autopsies have failed to show cerebral vasculitis, and when present, it was mild (round cell infiltration without vessel wall necrosis). Contributory might be cocaine effects on platelets and clotting factors and the ability of the drug to accelerate atherosclerosis (Brust, 1998).

LSD and phencyclidine are vasoconstrictive, and occlusive and hemorrhagic stroke have followed their use (Lieberman et al., 1974). In the case of phencyclidine acute elevation of blood pressure and intracerebral hemorrhage have occurred a few days after using the drug (Eastman & Cohen, 1975).

Altered mentation

Illicit drug users are at risk for altered mentation, including dementia, by indirect mechanisms such as concomitant ethanol abuse, malnutrition, head trauma, and infection, especially HIV. Less clear is whether the drugs themselves cause lasting cognitive or behavioural change. Predrug mental status is nearly always uncertain, and many drug users are self-medicating pre-existing psychiatric conditions, for example, cocaine for depression. The weight of evidence is against chronic mental abnormality secondary to opiates, marijuana, or hallucinogens (Weinrieb & O'Brien, 1993).

Controversial is whether repeated use of psychostimulants predisposes to lasting depression, a proposed mechanism for which would be perturbation of dopaminergic circuits in the mesolimbic 'reward circuit'. Cerebral atrophy and irregularly decreased cerebral blood flow are described in chronic cocaine users, and studies using controls have shown abnormalities on psychometric testing; a proposed mechanism is repeated widespread cerebral vasoconstriction and ischemia (Pascual-Leone et al., 1991; Holman et al., 1991). In a careful prospective analysis, however, chronic exposure to cocaine was associated with neuropsychological impairment, yet there was no correlation with brain volume loss when subjects with additional substance abuse were excluded (Langendorf et al., 2000).

Chronic barbiturate abuse is associated with psychological and social deterioration, including paranoia and suicide, but in contrast to ethanol abuse, CT results do not differ from controls (Allgulander et al., 1984).

Behavioural changes and EEG abnormalities are described in sniffers of halogenated hydrocarbons, but causality is unproven (Chadwick & Anderson, 1989). More convincing is persistent encephalopathy following chronic toluene exposure; autopsies on such patients reveal widespread loss of CNS myelin (Filley et al., 1990).

Memory disturbance, word-finding difficulty, loss of impulse control, and symptoms suggesting schizophrenia are common among users of phencyclidine, but as with other drugs, cause versus effect is uncertain (Fauman et al., 1976).

Fetal effects

The effects of illicit drugs on intrauterine development are similarly confounded by ethanol and tobacco use, malnutrition, inadequate prenatal care, and incompetent parenting (Chiriboga, 1993). Infants exposed in utero to heroin (or methadone) are reportedly small for gestational age, at risk for respiratory distress, and cognitively impaired later in life; other studies, however, have failed to identify long-term developmental or cognitive sequelae when correcting for other risk factors (Strauss & Reynolds, 1983). Low birth weight and later cognitive impairment do follow intrauterine opiate exposure in animals (Kirby, 1979).

In utero marijuana exposure is associated with decreased birth weight and length (Zuckerman et al., 1989; Frank et al., 1990). Whether such exposure causes cognitive or behavioural abnormalities in either humans or animals is controversial.

Cocaine exposure has reportedly caused absuptio placentae, decreased birthweight, a variety of congenital

anomalies, microcephaly, perinatal stroke, and developmental delay. A prospective study found diffuse or axial hypertonia in cocaine-exposed neonates compared to controls, and this 'spastic tetraparesis' cleared by 24 months of age, with no differences between groups in mental or motor development (Chiriboga et al., 1999). Animal studies, however, offer evidence that cocaine damages fetuses, perhaps by decreasing placental blood flow; in one study impaired learning occurred in the absence of evident brain malformation (Church et al., 1988).

Miscellaneous effects

Guillain–Barré polyneuropathy and brachial and lumbosacral plexopathy, probably immunologic in origin, are described in heroin users (Shafer, 1993). (Brachial plexopathy has also resulted from compression by a subclavian infected aneurysm.)

Sniffers of glues containing n-hexane are at risk for severe sensorimotor polyneuropathy, which can result in quadriplegia over a few weeks, with incomplete improvement upon removal of the toxin (Procop et al., 1974). Nerve biopsy reveals distention of axons by masses of neurofilaments and secondary demyelination.

Myeloneuropathy clinically and pathologically indistinguishable from combined systems disease of cobalamin deficiency affects sniffers of nitrous oxide, which oxidizes cobalamin. Anemia is usually absent, and serum cobalamin levels are usually normal (Heyer et al., 1986).

Severe irreversible parkinsonism developed in Californians exposed to a meperidine analog contaminated with 1-methyl-4-phenyl-1,2,3,6 tetrahydropyridine, a metabolite of which is toxic to neurons in the substantia nigra. Levodopa relieved symptoms, which in some cases were of life-threatening severity, but treatment had to be continued indefinitely, and levodopa-induced dyskinesias were common (Langston, 1985). Moreover, delayed parkinsonism has developed in previously asymptomatic subjects exposed to small doses of the drug.

Smoking the vapour of heroin heated on metal foil ('chasing the dragon') resulted in cerebral and cerebellar spongiform leukoencephalopathy in European and North American users. Dementia, ataxia, quadriparesis and blindness progressed to death in several cases; in others there was incomplete improvement. The mechanism of damage is unclear; elevated lactate in white matter suggests mitochondrial dysfunction (Kriegstein et al., 1999).

A man who took large parenteral doses of heroin containing quinine developed blindness. His vision improved when he resumed using heroin without quinine (Brust & Richter, 1971).

Dystonia and chorea lasting days or weeks occur in chronic cocaine users, and cocaine can precipitate symptoms in patients with Tourette's syndrome (Factor et al., 1988). Opsoclonus is also reported in cocaine users.

Marijuana inhibits luteinizing and follicle-stimulating hormone, causing erectile dysfunction and sterility in men and menstrual irregularity in women. Symptoms are reversible with abstinence (Powell & Fuller, 1983).

In addition to cerebral leukoencephalopathy, toluene sniffers develop cerebellar white matter degeneration and ataxia (Kelly, 1975).

Part XVI

Degenerative disorders

115

Genetically engineered models of neurodegenerative disorders

Philip C. Wong, Huaibin Cai, David R. Borchelt and Donald L. Price[1]

Departments of Pathology, [1] Neurology and [1] Neuroscience, and the Division of Neuropathology,
The Johns Hopkins University School of Medicine, Baltimore, MD, USA

The neurodegenerative diseases (Table 115.1) represent some of the greatest challenges for basic science and clinical medicine because of their prevalence, cost, complex biochemistries and pathologies, lack of mechanism-based treatments, and impacts on individuals, caregivers, and society at large (Price et al., 1998a,b; Wong et al., 1998; Hardy & Gwinn-Hardy, 1998; Dunnett & Bjorklund, 1999; Lee & Trojanowski, 1999; Lin et al., 1999; Yamamoto et al., 2000). This heterogeneous group of age-associated, chronic, illnesses, including Alzheimer's disease (AD), Parkinson's Disease (PD), motor neuron diseases (MND), the trinucleotide repeat diseases, and the prion disorders, are usually characterized by: genetic risk factors; onset within certain age ranges; progressive courses; well-defined clinical syndromes; evidence of dysfunction/death of specific populations of neurons; specific pathological and biochemical abnormalities; and presence, in many instances, of intra- or extracellular protein aggregates (Burright et al., 1995; Mangiarini et al., 1996; Robitaille et al., 1997; Davies et al., 1997; Becher et al., 1998; Price et al., 1998a,b; Wong et al., 1998; Hardy & Gwinn-Hardy, 1998; Goedert et al., 1998; Schilling et al., 1999; Selkoe, 1999; Cleveland, 1999; Lin et al., 1999; Lansbury, 1999; Zoghbi & Orr, 1999). At present, only symptomatic treatments are available and there are no mechanism-based therapies. The vast majority of patients with these various disorders become severely disabled and die of intercurrent illnesses. However, recent research, particularly in animal models, has begun to provide new insights into the mechanisms of these disorders and has identified new targets for therapy (*see also* Chapter 15).

Over the past few years, genetic studies have provided major clues as to pathogeneses of these illnesses. For some of these diseases, the cause is always due to genetic abnormalities (Table 115.2). For example, the trinucleotide repeat diseases (i.e. the autosomal dominant spinocerebellar ataxias, SCA and Huntington's disease, HD) are always associated with expanded CAG repeats in specific genes and all cases of autosomal recessive infantile and childhood spinal muscular atrophy (SMA) are caused by mutations/deletions of both alleles of the gene encoding survival motor neuron (SMN). In other instances, the illness can be familial or putatively sporadic. The majority of cases of AD, ALS, and PD are considered to be sporadic because most affected individuals do not exhibit obvious Mendelian patterns of inheritance. However, perhaps 5–10% of cases of AD, PD, and amyotrophic lateral sclerosis (ALS) have positive family histories, distinct patterns of inheritance, and mutations of specific genes (Price et al., 1998a,b; Wong et al., 1998; Hardy & Gwinn-Hardy, 1998) (Table 115.2). For example, familial ALS (FALS), AD (FAD), and PD (FPD) as well as frontotemporal dementia with Parkinsonism (FTD-P) show autosomal dominant inheritance: some cases of FALS are linked to mutations in the superoxide dismutase 1 (*SOD1*) gene (Wong et al., 1998; Andersen et al., 2000); subsets of cases of FAD are caused

Table 115.1. Neurodegenerative diseases

Chronic, progressive neurological disorders
Sporadic and/or familial
Autosomal dominant, recessive, X-linked, allele-associated
Clinical manifestations reflect involvement of subsets of cells (selective vulnerability)
Often associated with intra- or extracellular aggregates, degeneration of synapses and axons, and evidence of cell dysfunction/death
Significant causes of morbidity and mortality
With rare exceptions, no effective therapies
Associated with enormous costs to society
New opportunities for mechanism-based therapies

Table 115.2. Autosomal dominant neurodegenerative diseases and transgenic models

Disease	Mutant gene	Intracellular or extracellular aggregates	Aggregate component	Transgene in models
FAD	APP PS1 PS2	Extracellular amyloid	Aβ	Mutant APP and PS1
FALS	SOD1	Cytoplasmic inclusions	SOD1	Mutant SOD1
FTDP-17	Tau	Tangle-like structures	tau	Mutant tau
PD	α-syn	Lewy bodies Lewy neurites	α-syn	wt (or mutant)α-syn
Prion	PrP	Amyloid-like material	PrP^{SC}	mutant PrP
HD	huntingtin	Intranuclear inclusions	huntingtin	huntingtin (expanded repeat)
SCA-1	ataxin-1	Intranuclear inclusions	ataxin-1	ataxin-1 (expanded repeat)
SCA-3	ataxin-3	Intranuclear inclusions	ataxin-3	ataxin-3(expanded repeat)
DRPLA	atrophin-1	Intranuclear inclusions	atrophin-1	atrophin-1 (expanded repeat)

by mutant genes encoding the amyloid precursor protein (APP), presenilins 1 (PS1) or presenilin 2 (PS2) (Price et al., 1998a,b; St. George-Hyslop, 1999) (Fig. 115.1); some individuals with FPD are linked to missense mutations in α-synuclein (*α-syn*); and cases of FTD-P linked to chromosome 17 are associated with either intronic or exonic mutations in *tau*. Some individuals with autosomal recessive parkinsonism have mutations/deletions in *parkin*. Often, patients within each of these familial illnesses exhibit clinical and pathological features that are difficult to distinguish from those manifestations occurring in cases of sporadic disease.

The identification of mutations in specific genes causing each of these neurodegenerative diseases has provided new opportunities to investigate the molecular participants in disease processes and to explore pathogenic mechanisms in model systems. To investigate the biochemical pathways whereby mutant gene products impact, directly or indirectly, on the functions of neural cells, investigators have increasingly used transfection, transgenic, and gene targeting methods to introduce mutant genes or ablate genes in both in vitro and in vivo model systems (Table 115.2). Genetically engineered animal models allow investigations of the in vivo consequences of mutations or deletion of genes and determination of the biochemical pathways/mechanisms leading to dysfunction/death of affected populations of neural cells. Transgenic mice overexpressing mutant genes are of great value in the autosomal dominant genetic neurodegenerative disorders in which the mutant proteins do not exhibit reductions in their normal functions, but instead often acquire toxic properties or participate indirectly in the formation of toxic products (Price et al., 1998a,b; Wong et al., 1998; Hardy & Gwinn-Hardy, 1998; Goedert et al., 1998; Schilling et al., 1999; Selkoe, 1999; Cleveland, 1999; Zoghbi & Orr, 1999). The autosomal recessive diseases, which are associated with absence of the encoded protein (loss of function), can often be modelled by gene targeting strategies. In models of both groups of disorders, knocking out or overexpressing some of the genes that influence the pathways leading to disease have proved to be extremely valuable strategies (Fig. 115.1). In concert, these approaches have begun to provide information critical for the identification of new targets for mechanism-based treatments, which, if successful in model systems, can be rapidly introduced into clinical trials for these once intractable and mysterious diseases of the central nervous system (CNS).

In this review we focus on the familial forms of two of these diseases, AD and MND, to illustrate the ways new approaches are providing insights into these illnesses. For these two prototypes of the inherited neurodegenerative disorders, we discuss: the nature of clinical syndromes/neuropathology; the genetics and biochemistry of specific gene products; the value of genetically engineered models; issues critical to the understanding of the selective vulnerability of neurons and the pathogenesis of cell dysfunction/death in one of these diseases (AD); and experimental therapeutics. Our ultimate goal is to indicate how the information from different approaches is leading to new understanding of the susceptibilities of neurons to disease and the mechanisms leading to cell pathology, to identification of new therapeutic targets, and to

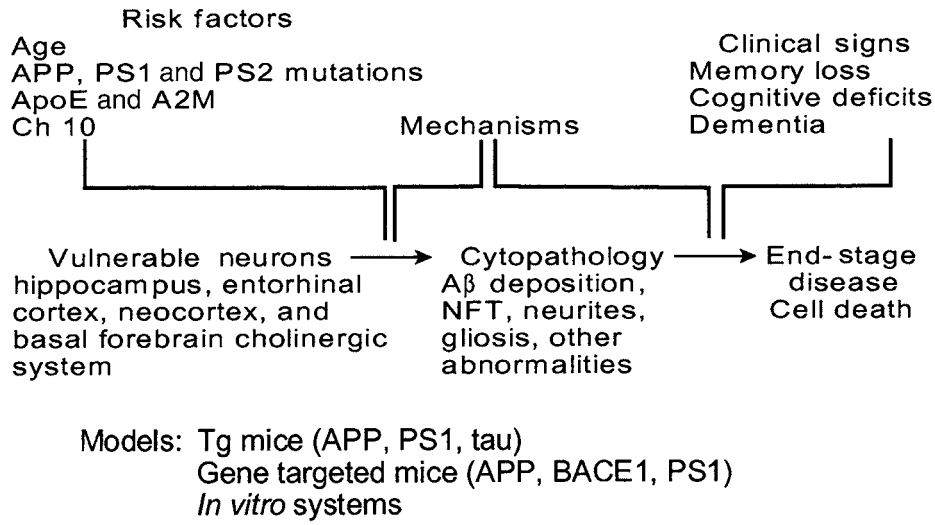

Fig. 115.1. Interactions of various risk or susceptibility factors with vulnerable populations of neurons that are responsible for memory and higher cognitive functions. The brains of individuals with Alzheimer's disease develop Aβ deposits, tangles, neurites, etc. These pathologies involving critical neuronal circuits lead to the clinical signs. In transgenic models, mutant genes linked to FAD are introduced and reproduced in the amyloid pathology seen in human subjects. Gene-targeted mice are valuable for understanding the functions of specific gene products and for defining, in the case of the secretases, the participation of specific proteins in pathogenic processes. For example, BACE1, is a key secretase in amyloidogenesis and an excellent therapeutic target.

design/testing of novel treatments for these tragic human illnesses.

Clinical signs/neuropathology

In this section, we define briefly some of clinical-pathological features of AD and MNDs that reflect the selective dysfunction/death of specific subsets of nerve cells.

Alzheimer's disease (AD)

In 1907, Alois Alzheimer described a middle-aged woman whose first complaints were increased suspicion of her husband's behaviour, followed by impairments in memory, orientation and cognition. Approximately 5 years after the onset of illness, an autopsy disclosed the now-recognized classical pathology of AD: neurofibrillary tangles and senile plaques in the neocortex and hippocampus.

In the majority of individuals with AD, the initial manifestations appear during the seventh decade, but the condition may develop in mid-life; in these instances, there may be a family history. In both the sporadic and familial forms of AD, patients have difficulties with memory, problem solving, language, calculation, visual–spatial perceptions, judgment, and behaviour; some patients develop psychotic symptoms, such as hallucinations and delusions. Mental functions and activities of daily living become progressively impaired. The accuracy of clinical diagnoses of specific causes of dementia, particularly AD, has greatly improved during the past two decades. Early diagnosis will be particularly important as mechanism based treatments become available.

Five million people in the United States now suffer from dementia. Because of increased life expectancy and post-World War II baby boom, the elderly, the population at risk for AD, is the fastest growing segment of our society. During the next 25 years, the number of people with AD in the United States will triple, as will the cost. Thus, AD is one of society's major public health problems.

As occurs in many other neurodegenerative diseases, AD involves the brain (and not other organs) and certain populations of neurons are selectively vulnerable (Table 115.1, Fig. 115.1). Thus, the clinical signs of AD are the consequence of the selective degeneration of nerve cells in those brain regions/neural circuits critical for memory, cognitive performance, and personality (Albert, 1996; Price & Sisodia, 1998; Mesulam, 1999). Dysfunction/death of neurons in the cortex, hippocampus, amygdala, basal forebrain cholinergic system, and brainstem monoaminergic nuclei leads to reduced numbers of generic and transmitter specific synaptic markers in target fields (Whitehouse et al., 1982; Francis et al., 1994; Sze et al., 1997; Price & Sisodia, 1998; Masliah, 1998); the disruption of synaptic communication in affected regions/circuits leads to memory/cognitive impairments and, finally, severe dementia (Morrison & Hof, 1997; Price & Sisodia, 1998).

Another feature of AD, shared with other neurodegenerative diseases (Tables 115.1–115.2), is the presence of characteristic protein aggregates, which in AD can be intracellular or extracellular. Within many affected neurons, aberrant tau immunoreactivity exists in: neurofibrillary tangles (NFTs), inclusions located within cell bodies and proximal dendrites; neuropil threads, which are usually within dendrites; and dystrophic neurites, filamentous swellings of distal axons/terminals (usually seen in proximity to Aβ deposits) (Price & Sisodia, 1998; Goedert et al., 1998; Delacourte et al., 1998; Price & Morris, 1999). Each of these cytoskeletal abnormalities reflects the intracellular accumulation of poorly soluble paired helical filaments (PHF), which are composed principally of hyperphosphorylated isoforms of tau, a low molecular weight microtubule-binding protein (Goedert et al., 1998; Delacourte et al., 1998). It is hypothesized that perturbations related to hyperphosphorylated tau are associated with disturbances in intracellular transport. Since nerve cells have complex geometries, they rely on transport systems to deliver critical constituents to the proper parts of the cell. Impairments of these transport processes compromises the functions and viability of neurons.

The extracellular aggregates in AD are abnormal accumulations of an amyloid peptide, termed Aβ, a 4kD α-pleated sheet amyloid peptide, derived by α- and γ-secretase cleavages of the amyloid precursor protein (APP) (Fig. 115.2, see colour plate section). Levels of Aβ are elevated in brain and Aβ monomers form oligomers and multimers which assemble into protofilaments and then fibrils (Price & Sisodia, 1998; Selkoe, 1999; Lansbury, 1999). Eventually, Aβ fibrils are deposited as the amyloid cores of neuritic or senile plaques, which are complex structures also containing dystrophic neurites, astrocytes, and microglia. Plaques are preferentially localized to cortex, hippocampus, and amygdala. As outlined below, the levels and distributions of APP and its cleavage enzymes in neurons are principal determinants leading to the selective appearance of Aβ in brain. Significantly, Aβ42 is thought to be particularly toxic to nerve cells and their processes. It is hypothesized that, at least in cases of FAD linked to mutant genes implicated in promoting amyloidogenesis, toxic Aβ peptides accumulate near synapses, and, in ways not yet clear, impair transsynaptic communication, and, ultimately, synaptic connections between neurons and their targets (other nerve cells). In parallel, subtle, possibly age-related, independent changes occur in the neuronal cytoskeleton whereby damaged nerve cells, responding to Aβ-mediated injury to its terminal fields, starts to hyperphosphorylate tau. Eventually, microtubule stability becomes compromised and intracellular transport processes are impaired; cell geometry is altered, particularly synapses and dendrites, and the cell is incapable of performing its normal functions for a significant interval before a death program kills the cell.

Motor neuron diseases

Amyotrophic lateral sclerosis (ALS)

The most common adult-onset motor neuron disease, ALS manifests as weakness/muscle atrophy and spastic paralysis, which are the result of the selective involvement of lower and upper motor neurons, respectively (Rowland, 1994; Wong et al., 1998). In ALS, the pathology of lower motor neurons evolves through a progression of stages: chromatolysis or loss of Nissl substance; alterations of the cytoskeleton, particularly neurofilaments; atrophy of dendrites and cell body; and, finally, apoptosis (Martin, 1999). Chromatolytic neurons often accumulate phosphorylated neurofilament and ubiquitin immunoreactivities in cell bodies; similarly, in FALS, caused by the presence of mutant SOD1, neurons exhibit SOD1 and ubiquitin immunoreactive cytoplasmic aggregates. The roles of these inclusions are unclear, but the presence of ubiquitin immunoreactivity suggests that these inclusions contain specific proteins destined for degradation, presumably, in part, via the proteosomal pathway. It is not known whether components within these aggregates sequester essential molecules needed for the biology of motor neurons or whether the malfolded proteins can perform aberrant catalytic reactions. In the majority of cases of ALS, neurofilamentous swellings are identified in proximal axonal segments (Carpenter, 1968; Chou, 1992; Hirano, 1996; Wong et al., 1998; Martin, 1999; Ince, 2000). Motor axons become disconnected from the muscles and begin to undergo Wallerian degeneration. Over time, cell bodies shrink and dendrites are attenuated. In the late stages, there is evidence of cell death manifest by: TUNEL labelling of some neurons; internucleosomal DNA fragments (laddering); conversion of DFF 45 to DFF 40 (the latter is the active form of enzyme that cleaves DNA into fragments); activation of caspase 1 and 3; and alterations in the distributions of Bax and Bcl_2, pro- and anti-apoptotic proteins, respectively, in the soluble and membranous (mitochondrial) compartments (Wyss-Coray et al., 1995; Martin, 1999).

This series of observations on motor neurons in ALS has been interpreted to signify that early biochemical changes impact on cell size/metabolism, the cytoskeleton, and attempts to degrade proteins via the ubiquitin–proteosomal pathway. Subsequently, cell shape is altered: proximal axons are enlarged (with accumulated neurofilaments); and dendritic arbors shrink (perhaps with attendant alter-

ations in synaptic inputs). Both the axonal and dendritic lesions could have functional consequences (impairments in conduction by axons and in integration of inputs by dendrites, respectively). Axons begin to 'die back' in peripheral motor nerves and corticospinal tracts and there is denervation of target fields (muscle and motor neurons, respectively). At this stage, trophic support from muscle and, possibly, from other cells is compromised. The neurons die utilizing the same molecular pathways that are associated with apoptosis in other cells. Ultimately, the numbers of motor neurons in brainstem nuclei and spinal cord are reduced and there is a loss of large pyramidal neurons in motor cortex; clinical signs are most closely linked to the disconnection of terminals from targets.

Spinal muscular atrophy (SMA) of infancy and childhood

Characterized by early-onset of muscle weakness and atrophy (Crawford & Pardo, 1996), this autosomal recessive disease, caused by homozygous deletion/conversion of SMN (Lefebvre et al., 1995, 1997; DiDonato et al., 1997; Pellizzoni et al., 1999; Monani et al., 1999), is classified as Type I, II, and III on the basis of age of onset and degree of functional disabilities. The incidence of Type I SMA (Werdnig–Hoffmann disease) is estimated at ~1:10 000 live births with a carrier rate frequency between 1:50 and 1:80. Infants with Type 1 SMA become weak prior to six months of age; ~30% of individuals show reduced fetal movements in utero, and these infants develop respiratory and bulbar difficulties and die before 2 years of age. Type-II SMA is usually recognized before the first birthday; these children are never able to walk independently. Type-III SMA begins in early childhood; affected individuals have milder degrees of disability.

The characteristic neuropathological features of SMA are: chromatolysis and accumulations of phosphorylated neurofilaments in cell bodies of motor neurons; degeneration of motor roots leading to denervation of skeletal muscle; evidence of apoptosis of large motor neurons in the spinal cord and brainstem; and reduced numbers of motor neurons. Relatively spared are cranial nerve nuclei III, IV, and VI as well as motor neurons of the phrenic nerve (which innervates the diaphragm) and Onuf's nucleus (which innervates the male genitalia and anal sphincters). Upper motor neurons do not appear to be affected. Because of the relative paucity of cases of SMA well studied by modern methods, it will probably be necessary to extrapolate, for the moment, from analyses of mouse models of SMA to understand the sequence and mechanisms of pathology.

Table 115.3. Treatment strategies

Inhibit formation of toxic Aβ (inhibitors of BACE1 and γ-secretase)
Promote clearance of Aβ (Aβ immunization)
Cholinomimetics (cholinesterase inhibition)
Suppress inflammation/oxidative injury (COX inhibition, Vitamin E)
Ameliorate synaptic/axonal degeneration (?)
Attenuate tau abnormalities (? target kinases)
Promote cell viability (trophic factors)
Prevent cell death (caspase inhibitors)
Replace neurons or other essential cells (stem cells)

Genetics and biochemistry

In this section, we review the genes and aspects of the biology of the gene products implicated in several of the familial forms of AD and MND inherited in a Mendelian fashion.

Mutant genes implicated in familial Alzheimer's disease (FAD)

In some individuals, particularly those with early-onset AD, the illness may be inherited as an autosomal dominant with mutations in three different genes: *APP*; *PS1*; and *PS2* (Price et al., 1998b; Hardy & Gwinn-Hardy, 1998; Selkoe, 1999) (Table 115.3).

APP

Encoded by a gene on chromosome 21, APP is expressed in many cells/tissues, but is particularly abundant in neurons. This type 1 transmembrane protein is cleaved endoproteolytically by an enzyme, β-site APP cleaving enzyme 1 (BACE1) (Sinha et al., 1999; Yan et al., 1999; Vassar et al., 1999; Hussain et al., 1999; Lin et al., 2000), and by an activity termed 'γ-secretase', which, in concert, generate the N- and C-termini of the Aβ peptide, respectively (Price et al., 1998b; Selkoe, 1999) (Fig. 115.2, see colour plate section). The levels and distributions of APP and the pro-amyloidogenic cleavage enzymes, particularly BACE1, in neurons are principal determinants leading to formation of Aβ in brain (see below). The formation of Aβ 1–40, 42 is precluded by the endoproteolytic cleavage of APP within the Aβ sequence by: 'γ-secretase', now thought to be either tumour necrosis factor (TNF) α converting enzyme (TACE) or a disintegrin and metalloproteinase 10 (ADAM 10), both members of the family of 'sheddases' (Sisodia, 1992); and by BACE2, a protease sharing features with BACE1, but

cleaving APP at different sites (i.e. within the Aβ domain). 'α-Secretase', cuts between residues 16 and 17 of Aβ, while BACE2 cleaves after residues 19 and 20 of Aβ. These different endoproteolytic cleavages generate various C-terminal peptides and can release the ectodomain of APP from the cell (Selkoe, 1999) (Fig. 115.3, see colour plate section).

A variety of APP mutations, including APPswe (a double mutation at the N-terminus of Aβ) and APP-717 (near the C-terminus of Aβ), have been reported in cases of FAD (Goate et al., 1991; Mullan et al., 1992) (Fig. 115.2, see colour plate section). These mutations, strikingly situated near several secretase cleavage sites, are pro-amyloidogenic and cells that express mutant APP show aberrant APP processing: the APPswe mutation, which enhances BACE1 cleavage, is associated with elevated levels of Aβ; the APP 717 mutations, which impact on γ-secretase activity, lead to a higher secreted fraction of longer Aβ peptides (Aβ42) relative to cells that express wild-type APP (Citron et al., 1992; Suzuki et al., 1994; Price et al., 1998b; Selkoe, 1999).

PS1 and *PS2*

Localized to chromosomes 14 (PS1) and 1 (PS2) respectively, these genes encode highly homologous 43- to 50-kD proteins with: multiple transmembrane (TM) domains (Sherrington et al., 1995); and, oriented towards cytoplasm, an hydrophilic acidic 'loop' region, an N-terminal domain, and a C-terminal domain (Doan et al., 1996). PS1 is synthesized as an ~42- to 43-kD polypeptide, but the preponderant PS1-related species that accumulate in vitro and in vivo are ~27- to 28-kD N-terminal and ~16- to 17-kD C-terminal derivatives (Thinakaran et al., 1996; Lee et al., 1996; Podlisny et al., 1997). These fragments accumulate/associate in a 1:1 stochiometry, and they are stable, tightly regulated, and saturable. *PS* genes are widely expressed at low abundance in the CNS. PS1 influences APP processing: cells from *PS1* mutants secrete increased levels of Aβ42; and cells from *PS1* knockouts secrete reduced levels of Aβ. It is not clear whether PS1 itself acts as an aspartyl protease (i.e. γ-secretase), functions as a co-factor critical for the activity of γ-secretase, or exerts its influence by playing a role in trafficking of APP to the proper compartment for γ-secretase cleavage (De Strooper et al., 1998; Naruse et al., 1998; Wolfe et al., 1999). Consistent with the concept that PS1 may act as an aspartyl protease or may be a critical co-factor essential for the activity of γ-secretase are several observations: cells in which the *PS1* gene has been targeted show decreased levels of secretion of Aβ (see below); PS1 is isolated with γ-secretase under specific detergent soluble conditions; substitutions of aspartate residues at D257 in transmembrane 6 (although now possibly controversial) and at D385 in transmembrane 7 reduce secretion of Aβ and final cleavage of Notch1 in vitro; and PS1 is selectively crosslinked or photoaffinity labelled by γ-secretase transition state inhibitors. Alternatively, PS1 may play a critical role trafficking APP, γ-secretase, and other elements of the catalytic complex into the proper compartments for ultimate Aβ42 cleavage.

The *PS1* gene has been reported to harbour >50 different FAD mutations in >80 families, whereas only a small number of mutations have been found in PS2-linked families (Hardy, 1997; Cruts et al., 1998). The vast majority of the abnormalities in *PS* genes are missense mutations that result in single amino acid substitutions; however, a mutation that deletes exon 9 from *PS1* has been identified in several different FAD families. In general, the various *PS* mutations appear to influence γ-secretase activity and increase the levels of the Aβ 42 peptide.

Motor neuron diseases

Familial amyotrophic lateral sclerosis (FALS)

Approximately 10% of cases of ALS are familial, and, in the majority of these cases, the disease is inherited in an autosomal dominant pattern (Brown, 1997; Andersen et al., 2000). Approximately 15–20% of patients with autosomal dominant FALS (i.e. ~2% of cases of ALS) have mutations in the gene that encodes cytosolic Cu/Zn superoxide dismutase (SOD1) (Table 115.2)(Rosen et al., 1993; Deng et al., 1993), a 153 residue enzyme that, as a homodimer, catalyzes the conversion of $\cdot O^-_2$ to O_2 and H_2O_2 (Fridovich, 1986; Stadtman, 1992). SOD1 is on the front line of free radical scavenging.

To date, ~90 different missense mutations and more than one frame shift mutation have been identified in the *SOD1* gene (Wong & Borchelt, 1995; Andersen et al., 2000); these mutations are scattered throughout the protein and are not preferentially localized near the active site or the dimer interface. The phenotypes associated with different mutations may show some clinical differences, but all mutations result in motor neuron disease (Cudkowicz et al., 1998).

A variety of in vivo and in vitro studies have demonstrated that the mutant enzyme causes selective neuronal degeneration through a gain of toxic property rather than a loss of SOD1 activity; these observations are consistent with the finding that SOD1-linked FALS is inherited as an autosomal dominant. While some FALS SOD1 mutants show reduced enzymatic activities, others retain nearly wild type levels and mutant SOD1 subunits do not appear to alter the metabolism/activity of wild type SOD1 in a dominant negative fashion. Moreover, as described below, transgenic mice expressing different FALS SOD1 mutants

exhibit progressive motor neuron disease resembling the illness occurring in cases of ALS. Mice deficient in SOD1 do not develop a motor neuron disease-like phenotype. Crossing SOD1 mutant mice to mice overexpressing wild-type SOD1 or to SOD -/- mice does not influence disease in the progeny (Bruijn et al., 1998). Taken together, these results are consistent with the view that mutant SOD1 causes disease through a gain of neurotoxic property.

Other chromosomal loci have been linked to FALS showing autosomal dominant, autosomal recessive, or X-linked inheritance patterns (Brown & Chan, 2000; Andersen et al., 2000), but space constraints do not permit their discussion here. Deletion/insertion mutations in the KSP repeat motif of the NF-H tail domain have been identified in 10 of 1047 patients with sporadic ALS and in 1 of 295 FALS patients. Although these genetic alterations may represent risk factors, there is little direct evidence that mutations of NF genes are a primary cause of ALS.

Spinal muscular atrophy

Genetic studies have mapped SMA Type I, II, and III to a single highly complex genetic locus on chromosome 5q11.2–q13.3 (Roy et al., 1995; Lefebvre et al., 1995). The genomic organization of this region is polymorphic and complex, with numerous repeated DNA elements that occur in different orientations on chromosomes from different individuals. In this region, investigators initially identified two SMA candidate genes: survival motor neuron (*SMN*) and neuronal apoptosis inhibitory protein (*NAIP*) (Roy et al., 1995; Lefebvre et al., 1995). *SMN1* is now recognized as the SMA-determining gene with *NAIP* possibly playing a role in modifying the severity of the disease. The *SMN1* gene, encoding a 294-amino acid polypeptide (32 kD), lies in the telomeric portion of chromosome 5q11.2–q13.3 and a homologous copy of *SMN1*, termed *SMN2*, is located in a more centromeric position. Whereas, the two ~20-kb genes encode identical proteins, they can be differentiated by single-strand conformational polymorphism analysis or by RT-PCR, because of differences in the transcripts at two nucleotides in exons 7 and 8. Transcripts encoded by the two genes are subjected to alternative modes of post-transcriptional processing; *SMN1* produces full-length RNA, whereas *SMN2* produces mainly transcripts lacking exon 7. Recently, it was demonstrated that exon 7 skipping is caused by a single nucleotide difference between the *SMN1* and *SMN2* gene (Monani et al., 1999). *SMN* is highly conserved between mice (one copy on chromosome 13) and humans (two copies), with 82% identity (Bergin et al., 1997; Pagliardini et al., 2000). *SMN* is expressed in large motor neurons, but it is also expressed in many other cells, with the highest levels seen in the hippocampus and cerebellum.

SMN, a member of a multiprotein complex is involved in small nuclear ribonucleoprotein (snRNP) biogenesis and pre-mRNA splicing (Liu et al., 1997). SMN is present in the nucleus associated with small intranuclear structures termed 'gem bodies' for Gemini of coiled bodies, which are closely associated with, but distinct from, coiled bodies (Liu & Dreyfuss, 1996). Because of the similarity between gems and coiled bodies, it is suggested that gems and SMN might play roles in the processing of small nuclear RNAs. In the cytoplasm, the SMN complex is associated with snRNP Sm core proteins and is involved in spliceosomal snRNP assembly (Fischer et al., 1997). ('Sm' refers to Smith, which, in turn, refers to an antigenic site common to all snRNPs (small nuclear ribonucleoproteins). Sm proteins are proteins exhibiting the Smith antigen, an autoantibody target in lupus erythematosus.) A variety of methods have shown that SMN forms a stable heteromeric complex with a novel 32 kD protein termed Gemin2 (for components of gems 2), formerly called SIP1 (SMN-interacting protein-1). Gemin2 and SMN are present in a large stable complex (~300 kD) together with spliceosomal snRNP proteins (B, D1–3, and E) in both the nuclear and cytoplasmic fractions. SMN is physically associated with Sm proteins and functional studies reveal that Gemin2 plays an important role in the assembly of snRNPs. SMN also participates in the cytoplasmic assembly of snRNPs and is required for recycling of snRNPs in pre-mRNA splicing (Pellizzoni et al., 1998). More recently, other components of the SMN complex termed Gemin3 (a DEAD box protein with putative RNA helicase activity) (Charroux et al., 1999) and Gemin 4 have been identified (Charroux et al., 2000). Gemin3 colocalizes and interacts directly with SMN in gems and this interaction has been shown to be decreased in some SMA cases in which there is deficiency in snRNP regeneration activity. Gemin4 is associated with the SMN protein complex through direct interaction with Gemin3 and it is thought that Gemin4 functions as a cofactor for Gemin3. It is also shown that Gemin4 physically interacts with several Sm core proteins and is colocalized with SMN in the cytoplasm and in gems. It is proposed that the complex comprised of SMN, Gemin2, Gemin3, and Gemin4 represents an active functional unit that serves to bind substrates such as Sm proteins.

Mutations are present in nearly 100% of affected individuals, and the levels of SMN1 are different in cases of SMA (Crawford & Pardo, 1996; DiDonato et al., 1997; Lefebvre et al., 1997). Individuals with Type I SMA have the least amount of SMN in spinal motor neurons. Partial or complete deletions are detected in *SMN1* in over 95% of cases with other disabling mutations found in many of the remaining cases. Homozygous deletion of *SMN1* has not

been found in controls. *SMN2* has not been shown to be deleted in any affected individual, although it is deleted in 4% of normal controls. This finding suggests that embryos with homozygous deletion of the centromeric and telomeric copies of *SMN* are not viable; that such a deletion results in an embryonic lethal event is confirmed by gene targeting (Hsieh-Li et al., 2000; Monani et al., 2000). Levels of full-length SMN proteins govern whether the individual has SMA Type I, II or III, and *SMN2* is predicted to be able to partially substitute for *SMN1*. It is not clear why motor neurons are specifically vulnerable to reductions of this gene product.

These studies demonstrate that SMN is linked to several fundamental biochemical pathways and that SMN mutants occurring in SMA patients are defective in binding to Sm proteins because mutant SMN is incapable of forming large oligomers that are essential for high-affinity binding to spliceosomal snRNP Sm proteins. These findings further support the view that abnormalities of spliceosomal snRNP biogenesis and metabolism are directly involved in the pathogenesis of SMA.

Transgenic and gene targeted models

Models relevant to AD (Fig. 115.4, see colour plate section)

Transgenic models of Aβ amyloidogenesis

To attempt to generate animal models of Aβ amyloidogenesis and associated abnormalities, many groups have used cDNA or genomic constructs, to produce transgenic mice that express wild type APP, APP fragments, Aβ, and FAD-linked mutant APP and PS1 (Kammesheidt et al., 1992; Neve et al., 1992; Lamb et al., 1993; Buxbaum et al., 1993; Higgins et al., 1994; Moran et al., 1995; Hsiao et al., 1995; Games et al., 1995; LaFerla et al., 1995; Masliah et al., 1996; Hsiao et al., 1996; Borchelt et al., 1997; Nalbantoglu et al., 1997; Lamb et al., 1997; Irizarry et al., 1997). Some of the various lines of mutant APP mice, although they do not reproduce the full phenotype of AD, represent excellent models of Aβ amyloidosis and are of great value for testing causal effects of mutant genes, analyses of pathogenic pathways, determination of the molecules participating in Aβ amyloidogenesis, and identification of therapeutic targets. These models will be essential for testing a variety of therapeutic strategies, including the introduction/ablation of specific genes, administration of pharmacological agents (BACE1 and/or γ-secretase inhibitors), variants of protocols of Aβ vaccination or passive transfer of Aβ antibody, blockade of toxicity of Aβ oligomers on neurons (particularly synapses/synaptic interactions/axons), anti-fibrillogenic agents, anti-apoptotic agents, etc. (Table 115.3).

Reviewed below are selected examples of lines of mice expressing autosomal dominent FAD-linked mutant transgenes. We have not reviewed mouse models in which Apo E alleles have been introduced or ablated, nor have we attempted to review models in which tau is the transgene.

Mutant APP mice

Several different promoters have been used to drive the expression of APP minigenes that encode the FAD-linked APP mutants (swe and 717) in strains of mice. The pathology is influenced by the level of transgene product and the specific mutation. The brains of these mice have elevated levels of Aβ40 and Aβ42 as well as both diffuse Aβ deposits and mature neuritic plaques (dystrophic neurites displayed around an Aβ core) in amygdala, hippocampus, and cortex (Sotelo & Palay, 1971; Games et al., 1995; Masliah et al., 1996; Hsiao et al., 1996; Calhoun et al., 1999; Phinney et al., 1999). Some neurites contain hyperphosphorylated tau immunoreactivity; the degree of tau phosphorylation in neurons may increase with age, but accumulations of tangle-like structures in cell bodies are not evident. Astrocytes and microglia are clustered in and around plaques. There is relatively little evidence of neuronal loss in hippocampus. Some mice show abnormalities of synaptic transmission in hippocampal circuits that precedes the deposition of Aβ (Hsia et al., 1999). In some lines, mice may exhibit deficits in object recognition memory (related to the number of amyloid deposits in specific regions) and in alternation-spatial reference and working memory (related to reductions in synaptic density and hippocampal atrophy) (Dodart et al., 2000).

APPswe/PS1 mutant Tg mice

Transgenic mice that coexpress A246E HuPS1 and Mouse/Human-APPswe have elevated levels of Aβ in brain and develop numerous amyloid deposits in hippocampus and cortex (Borchelt et al., 1996, 1997). Associated with many of the Aβ deposits are dystrophic neurites that contain APP, PS1, and BACE1 immunoreactivities; thus, the key participants involved in amyloidosis are present locally at some of the sites of formation of Aβ. Reactive cells, astrocytes, and to a lesser extent, microglial cells, surround the amyloid and neurites. The presence of the PS1 mutations in mice with APP mutations accelerates the deposition of Aβ (as compared with mutant APP alone); in this respect, ΔE9 PS1 is more malignant than A246E PS1 (Borchelt et al., 1997).

Gene targeted mice relevant to AD

APP and APLP2 null mice

Homozygous *APP*-/- mice are viable and fertile, but they appear to have subtle decreases in locomotor activity and forelimb grip strength (Zheng et al., 1995). The absence of substantial phenotypes in *APP*-/- mice may be related to functional redundancy provided by homologous amyloid precurors-like proteins (APLP1 and APLP2), molecules expressed at high levels with developmental and cellular distributions similar to APP (Wasco et al., 1992, 1993; Slunt et al., 1994). Consistent with this idea are observations that *APLP2*-/- mice appear normal (von Koch et al., 1997), but mice with either both *APP* and *APLP2* targeted alleles or both *APLP1* and *APLP2* null alleles show significant postnatal lethality (von Koch et al., 1997; Heber et al., 2000).

PS1 and PS2 null mice

To examine the roles of PS1 in development, several groups have produced *PS1*-/- mice (Wong et al., 1997; Shen et al., 1997; De Strooper et al., 1998). Homozygous mutant mice fail to survive beyond the early postnatal period and show severe perturbations in the development of the axial skeleton and ribs (defects in somatogenesis). PS1 homologues interact with Notch1, a receptor protein involved in critical cell-fate decisions during development (Levitan & Greenwald, 1995), and cells lacking PS1 show reductions in proteolytic release of the Notch1 intracellular domain (NICD), a cleavage that is thought to be critical for Notch1 signalling (Struhl & Greenwald, 1999; Ye et al., 1999; Huppert et al., 2000). Several γ-secretase inhibitors block the proteolytic release of NICD, and it has been hypothesized that similar protease activities are involved in the transmembrane domain cleavage of Notch1 and APP. Substitutions in intramembranous aspartate residues 257 and 385, which appear to be critical for PS1 functions (Wolfe et al., 1999), inhibit generation of NICD and Aβ (Capell et al., 2000). This result is consistent with the view that PS1 differentially facilitates the final proteolytic cleavage of Notch1 pathway involved in the formation of NICD and the γ-secretase-mediated endoproteolysis of APP to generate Aβ. *PS1*-/- embryos also exhibit intraparenchymal hemorrhages, thin ventricular zones, and bilateral cerebral cavitation caused by loss of neurons (Shen et al., 1997). Both wild type and mutant human *PS1* transgenes rescue the spectrum of developmental defects in *PS1* null mice (Davis et al., 1998; Qian et al., 1998; Davis & Goodman, 1998). Thus, the FAD-linked PS1 variants retain sufficient normal function to allow normal mammalian embryonic development. With regard to the role of PS proteins in Aβ biology, mutations in *PS* genes increase formation of Aβ42, and ablation of *PS1* reduces secretion of Aβ. Significantly, as first reported by DeStrooper et al., and later by our group, cells from PS1-/- mice show selective reductions in the levels of γ-secretase cleavage products and levels of Aβ. This observation is a principal line of evidence that PS1 is either γ-secretase or a critical influence on this activity (see below).

Gene targeting of *PS2* is associated with viable fertile mice that develop age-associated mild pulmonary fibrosis and hemorrhage. There was little detectable evidence of APP processing. *PS1*+/−; *PS2*-/- survive in relatively good health, but *PS1*-/-; *PS2*-/- mice die midway through gestation with full Notch-1 deficiency (Herreman et al., 1999).

BACE1-/- mice

Gene targeting approaches (Cai et al., 2001; Luo et al., 2001; Roberds et al., 2001) have produced *BACE1* null mice that are viable and healthy, have no obvious phenotype or pathology, and are capable of successful mating. Importantly, the secretion of Aβ peptides is abolished in BACE1-deficient cortical neurons and Aβ peptides are not produced in brains of *BACE1* null mice. These results establish that BACE1 is the principal β-secretase required to cleave APP to generate the N-termini of Aβ and indicate that BACE1 is an excellent therapeutic target for drug development for AD (see below).

Transgenic and gene targeted models relevant to motor neuron diseases

A variety of experimental models of motor neuron disease have been described (Price et al., 1994; Elliott, 1999), but of greatest interest in the context of this review are genetically engineered models.

Transgenic models mutant SOD1 mice

Mice expressing a variety of mutant SOD1 develop progressive weakness and muscle atrophy (Gurney et al., 1994; Dal Canto & Gurney, 1994; Wong et al., 1995; Ripps et al., 1995; Chiu et al., 1995; Morrison et al., 1996, 1998; Tu et al., 1996; Bruijn et al., 1997; Dal Canto & Gurney, 1997; Kong & Xu, 1997; Borchelt et al., 1998; Williamson et al., 1998; Gurney, 2000). SOD1/ubiquitin immunoreactive cytoplasmic aggregates appear within motor nerve cells; dendrites and motor axons (both of which show swollen mitochondria) are irregularly enlarged; abnormal patterns of neurofilament immunoreactivities are seen in cell bodies/axons of motor neurons; motor axons undergo Wallerian degeneration; and, finally, neurons die.

The G37R SOD1 transgenic mice, which are similar to several other mutant lines, provide an excellent illustration of this disease in mice. G37R SOD1 accumulates to 3–12x levels of endogenous SOD1 in the spinal cord; the mutant

SOD1 retains full specific activity. The levels and nature of the mutant transgene product influence the age of onset; in general, higher levels of a given mutant are associated with earlier onset of clinical signs. Toxic SOD1 is transported anterograde in axons (Borchelt et al., 1998), and early on, it accumulates in axons where it is associated with structural pathology (Borchelt et al., 1998). Approximately 2–3 months before the appearance of clinical signs, SOD1 accumulates in irregular swollen intraparenchymal portions of motor axons, and axonal transport is abnormal as is the axonal cytoskeleton. Vacuoles, thought to represent degenerating mitochondria (Kong & Xu, 1997), are present in enlarged axons and in dendritic swellings, the latter reminiscent of changes seen in excitotoxicity, which has been suggested to play a role in ALS (Leigh & Meldrum, 1996; Rothstein, 1996; Shaw, 2000; Jackson & Rothstein, 2000)). The cell bodies of some neurons show SOD1 and ubiquitin-immunoreactive inclusions and phosphorylated NF-H immunoreactivities. Axonal and dendritic abnormalities (Wong et al., 1995; Zhang et al., 1997; Williamson & Cleveland, 1999), as well as intracellular aggregates, occur in animals without clinical signs. However, once Wallerian degeneration is obvious, the mice are usually weak. Eventually, the number of motor neurons is reduced, and astrocytes are increased in ventral horns.

The molecular mechanisms whereby mutant SOD1 causes selective motor neuron death have not yet been defined. It has been hypothesized that the toxic property of mutant SOD1 may be related to mutation-induced conformational changes in SOD1 that facilitate the interactions of the catalytic Cu with small molecules such as peroxynitrite or hydrogen peroxide to generate toxic free radicals that damage a variety of cell constituents important for the maintenance and survival of motor neurons. In this scenario, cell dysfunction/death could be initiated by aberrant oxidative chemistries catalyzed by the copper atom bound in the active site of mutant SOD1, especially after loss of zinc binding to SOD1. Two prominent proposed oxidative chemistries are copper dependent: (i) peroxidation to generate hydroxyl radical (Wiedau-Pazos et al., 1996); or (ii) nitration of tyrosines using peroxynitrite generated from reaction of nitric oxide with superoxide (Beckman et al., 1993; Estévez et al., 1999). However, there is no documentation of increased levels of nitrated proteins in mutant SOD1 mice as compared to controls, nor is disease progression in mutant mice influenced by lack of either the neuronal or endothelial nitric oxide synthase genes (Facchinetti et al., 1999). These results do not support a critical role for peroxynitrate or neuronal-derived nitric oxide in disease pathogenesis. With regard to peroxidase-mediated mechanisms, mutant SOD1 mice fail to show increased levels of hydroxyl radicals (or obvious oxidative damage) when compared to controls. Furthermore, the onset and progression of disease in mutant mice is independent of the levels of wild type SOD1 activities, results interpreted as inconsistent with either the peroxynitrite or the peroxidase hypotheses (Bruijn et al., 1998). As mentioned, it has been reported that the loss of zinc from either mutant or wild type SOD1 in cultured motor neurons can induce apoptosis following trophic factor withdrawal; the toxic effect requires Cu bound to SOD1 and production of endogeneous nitric oxide (Estévez et al., 1999). These results were interpreted to indicate that zinc-deficient SOD1 might play a role in disease through a nitric oxide-mediated mechanism involving Cu bound to SOD1. However, these aberrant Cu chemistries have not been demonstrated to occur in vivo, and the gene targeting experiments involving copper chaperone for SOD1 (CCS), which are described below, provide no support for the idea that Cu bound to mutant SOD1 mediates directly motor neuron degeneration in SOD1-linked FALS.

Gene targeted mice relevant to MND

SOD1-/- mice

While these animals do not develop an overt motor neuron disease, *SOD1-/-* mice show a distinct motor axonopathy as they age (Shefner et al., 1999). In addition, facial motor neurons lacking SOD1 are more susceptible to axotomy (Reaume et al., 1996)and *SOD1* null mice are more sensitive to paraquat exposure as compared to littermate controls (Huang et al., 1997; Ho et al., 1998). While the homozygous *SOD1* knockout male mice are fertile, the female *SOD1-/-* mice show reduced fertility due to abnormal development of follicles in ovaries (Matzuk et al., 1998; Ho et al., 1998).

CCS-/- mice

In its free form, copper is toxic and there is virtually no free copper in cells (Rae et al., 1999). Normally, copper is imported into cells by a plasma membrane bound copper transporter (Zhou & Gitschier, 1997; Kuo et al., 2001) and then selectively shuttled to intracellular target proteins by a series of specific copper chaperones. The delivery of Cu to specific proteins is mediated through distinct intracellular pathways of copper trafficking (Valentine & Gralla, 1997; Culotta et al., 1999). A family of soluble Cu chaperones is required to deliver Cu to specific intracellular metalloproteins (Lin & Cizewski Culotta, 1995; Glerum et al., 1996a,b; Klomp et al., 1997; Pufahl et al., 1997). Recently, the yeast Cu chaperone, termed lys7, or its mammalian homologue (CCS) was shown to be necessary to deliver copper to SOD1 in yeast (Culotta et al., 1997). CCS

is able to rescue the *lys7* null mutant and is shown to interact physically with SOD1 (Casareno et al., 1998; Rae et al., 1999). Biochemical and structural analysis of yeast CCS indicated that the insertion of Cu into SOD1 requires the interactions amongst three distinct domains of the copper chaperone: an Atx1p-like amino-terminal domain responsible for Cu uptake, an SOD1-like central domain functions in SOD1 recognition, and a carboxyl-terminal domain which is unique to copper chaperones and which mediates Cu incorporation into SOD1 (Lamb et al., 1999; Schmidt et al., 1999; Schmidt et al., 1999a,b). Inactivation of the *CCS* gene in mice has demonstrated that CCS is required for efficient copper incorporation into SOD1 in mammals and the phenotypes of the CCS *null* mice resemble those of the *SOD1* null mice (Wong et al., 2000).

SMN gene targeted mice

Smn−/− embryos died with massive cell death during the peri-implantation stage corresponding to the initiation of embryonic RNA transcription, precluding analysis of any postnatal phenotype (Schrank et al., 1997). These results are consistent with the view that SMN functions in essential cellular pathways, including the biogenesis of spliceosomal snRNPs and pre-mRNA splicing.

To test whether *SMN2* can complement the embryonic lethality of *Smn*−/− embryos and to generate a mouse model for SMA, several groups generated transgenic mice expressing human *SMN2* and crossbred them to *Smn*+/− mice to produce *SMN2* transgenic mice lacking mouse endogenous SMN (Hsieh-Li et al., 2000; Monani et al., 2000). These *Smn*−/−; *SMN2* mice have abnormalities in the spinal cord and skeletal muscles similar to those seen in cases of SMA, and the severity of the pathology correlates with the level of SMN polypeptide that retains the amino acids encoded by exon 7. These results demonstrate that *SMN2* can partially compensate for the endogenous mouse SMN and the variable phenotypes observed in the *Smn*−/−; *SMN2* mice recapitulate those seen in SMA Type I, II or III. These *Smn*−/−; *SMN2* mice exhibit several patterns of clinical signs: Type 1 mice, the most severe pathological form, do not develop furry hair and die before postnatal day 10; Type 2 mice are inactive and die between 2 to 4 weeks of age; and Type 3 mice survive and breed normally, and have short and enlarged tails. Furthermore, the level of full-length SMN protein in these *Smn*−/−; *SMN2* mice correlates with the severity of the disease. These studies strongly support the view that the level of intact SMN is the determining factor for severity of phenotypes in SMA. Interestingly, analysis of *Smn*+/− heterozygous knockout mice (Jablonka et al., 2000) disclose a ~50% reduction of SMN protein in the spinal cord which results in a progressive loss of motor neurons between birth and 6 months of age and the phenotype of these mice resembles SMA type III. In addition, a conditional deletion of the mouse *SMN* exon 7 directed to neurons resulted in a phenotype resembling SMA, suggesting that motor neurons are the primary target of the gene defect (Frugier et al., 2000). Taken together, these studies support the view that SMA is caused by insufficient level of SMN and the severity of the disease is dependent on the level of SMN generated from the *SMN2* gene. These mouse models of SMA will be useful in understanding disease mechanisms and for testing therapeutic strategies.

Investigations of genetically engineered models can provide important new information about selective vulnerability of neurons in specific diseases and for experimental therapeutics

Among the most challenging mysteries of neurodegenerative diseases is the identification of factors that render neurons particularly susceptible in specific diseases (principle of selective vulnerability). Recent research has begun to provide exciting new clues concerning the biological basis for these vulnerabilities, and this information has direct relevance to developing novel therapies. AD serves as an illustration of these principles. We hypothesize that the basis for the vulnerabilities of brain to AD are the levels and distributions of APP and its cleavage enzymes in neurons versus other cells, and that these enzymes are attractive targets for drug therapy.

Why do we think neurons are the principal source of Aβ? APP is one of the most abundant proteins in neurons, particularly as compared to other cells in other tissues. In nerve cells, APP is transported within axons by the fast anterograde system (Koo et al., 1990; Sisodia et al., 1993). For example, in peripheral sensory neurons of rodents, APP-695 is the predominant isoform; full-length APP-695 and, to a lesser extent, APP-751/770 are rapidly transported anterogradely in axons toward distal terminals (Koo et al., 1990; Sisodia et al., 1993). APP processing can occur in distal axons/terminals. Radiolabelling studies in the entorhinal cortex have shown that newly synthesized APP, principally APP-695, is transported via axons of the perforant pathway to accumulate at presynaptic terminals in the hippocampal formation (Buxbaum et al., 1998b). In the terminal fields of this pathway, soluble C-terminally truncated APP and amyloidogenic C-terminal fragments have been identified (Buxbaum et al., 1998b). Moreover, in mutant APP transgenic mice, APP, BACE1, and PS1, the key identified proteins in formation of amyloid, have been visualized in swollen

neurites in proximity to amyloid deposits. These observations are consistent with the idea that neurons and their processes, particularly, but not exclusively, axon terminals, are one source of the APP that gives rise to peptide species. Also consistent with this hypothesis are results of studies of a cross between APP −/ – mice and APP V717I mice, in which the transgene is driven by a neuron-specific promoter. In these APPV717I mice lacking endogenous mouse APP, Aβ is produced from neurons in many regions of brain. Significantly, although the *APP* transgene is not expressed around cerebral vessels, amyloid is deposited in the CNS vasculature (Calhoun et al., 1999). Hence, in this setting, neurons (the only cells expressing APP) appear to be a source of mobile Aβ that can accumulate in both the brain parenchyma and around vessels. This observation undercuts the argument that the Aβ in vessels is coming from the serum. Consistent with the concept that neurons are the major source of APP giving rise to Aβ are observations made by several groups, including scientists in our group, in which transection of the perforant pathways of mutant APP transgenic mice reduces the Aβ burden in the terminal fields of this input to hippocampus.

However, the presence of APP in neurons, although necessary, is not sufficient to explain why the brain and not other organs, such as the pancreas, are particularly vulnerable to Aβ amyloidogenesis. In our view, the patterns of APP cleavage enzymes in different cell populations are of equal importance. We believe that the cellular distributions, relative levels, and APP cleavage patterns of two β-secretases (BACE1 and BACE2) are the principal determinants of such vulnerability. Although both BACE1 (Asp2 or Memapsin2) and BACE2 (Asp1 or Memapsin1) are expressed ubiquitously, BACE1 mRNA levels are particularly high in brain and pancreas, whereas the levels of BACE2 mRNA are relatively low in all tissues, except in brain where it is nearly undetectable (Vassar et al., 1999; Bennett, 2000). We hypothesize that the ratios of BACE1: BACE2 in different cells/tissues profoundly influence the susceptibility to Aβ amyloidogenesis. In simple terms, the combination of abundant BACE1 in neurons coupled with low levels of BACE2 in these cells predisposes to amyloidosis in the brain. As indicated above, Aβ is generated by biochemical pathways involving the endoproteolytic cleavages carried out by BACE1, a type I transmembrane aspartyl protease (Sinha et al., 1999; Yan et al., 1999; Vassar et al., 1999), and by an activity termed 'γ-secretase', which generate the N- and C-termini of the Aβ peptide, respectively (Fig. 115.2, see colour plate section). Most importantly, BACE1 is the principal β-secretase necessary to cleave APP at the +1 and +11 sites of Aβ in neurons (Cai et al., 2001). In contrast, BACE2 cleaves APP more efficiently at residues +19 and +20 of APP compared to the +1 site of Aβ (Farzan et al., 2000). Significantly, levels of Aβ1–19 and Aβ1–20 are undetectable in brain. APP can also be cleaved endoproteolytically before residue +17 within the Aβ sequence by putative 'α-secretases', TACE (Buxbaum et al., 1998a) and ADAM10 (Lammich et al., 1999); significantly, +17 C-terminal products are relatively low in brain. These three cleavages within the Aβ domain of APP preclude the formation of Aβ 1– 40, 42. As BACE1 is the principal β-secretase in neurons and BACE2 may serve to limit the secretion of Aβ peptides, we hypothesize that BACE1 is a pro-amyloidogenic enzyme while BACE2 is an anti-amyloidogenic protease, and the relative levels of BACE1 and BACE2 are major determinants of Aβ amyloidosis. In this model, the secretion of Aβ peptides would be expected to be the highest in neurons/brain as compared to other cell types/organs because the neurons express high levels of BACE1 coupled with low expression of BACE2. If the ratio of the level of BACE1 to BACE2 is a critical factor that selectively predisposes the brain to Aβ amyloidosis, AD would be predicted to involve selectively the brain rather than other organs. Seemingly inconsistent with this hypothesis is a study showing a high level of BACE1 mRNA expression in the pancreas. However, it now appears that some of the pancreatic BACE1 mRNAs are alternatively spliced to generate a BACE1 isoform that is incapable of cleaving APP. Taken together with the observations that pancreas possesses low levels of BACE1 as well as low amounts of BACE1 activity (Sinha et al., 1999), these results are consistent with the view that a high ratio of the level of BACE1 to BACE2 activity leads to selective vulnerability to Aβ amyloidosis.

Thus, in concert with low activities of γ-secretases (TACE and ADAM10) and BACE2 in brain, the abundance of APP substrate and the activity of the pro-amyloidogenic BACE1 in neurons predisposes the brain to this type of amyloidosis. Finally, γ-secretase, which may be PS1 (or has its activity influenced by PS), is present in a relatively low level in brain and does not form Aβ without BACE1 cleavages. To test this hypothesis at the level of specific cell populations, it will be important to define the levels and distributions of BACE1 and BACE2 in specific brain regions/circuits/neurons using specific BACE1 and 2 antisera and to attempt to correlate these measures with the regional vulnerabilities to Aβ amyloidosis seen in AD.

Experimental therapeutics

Treatments of models of Aβ amyloidogenesis

Again, we use work on AD and model systems to illustrate the value of studies of transgenic and gene targeted mice for experimental treatments (Table 115.3). Although they do not model the full phenotype of AD, these mutant mice

represent excellent models of Aβ amyloidogenesis and are highly suitable for analyses of pathogenic pathways, determination of the molecular participants in amyloidogenesis, and identification of therapeutic targets. Moreover, they are invaluable for examining the effects of: introduction/ablation of specific genes; administration of pharmacological agents (secretase inhibitors); Aβ vaccination or passive transfer of Aβ antibody; reagents that interfere with Aβ (? oligomers) toxicity on neurons and their synapses; anti-fibrillogenic agents, etc. Several of these strategies are described below.

Secretase inhibition

The Aβ amyloidogenesis model has begun to be tested by a variety of approaches, including the use of transgenic and gene targeted mouse models. While both β- and γ-secretase activities represent therapeutic targets for the development of novel protease inhibitors for AD, the demonstrations that BACE1 is the principal β-secretase in cultured neurons (Cai et al., 2001) and in brain in vivo (Luo et al., 2001) provide excellent rationale for focusing on the design of novel therapeutics to inhibit BACE1 activity in brain. In contrast to *PS1*$-/-$ mice, the *BACE1*$-/-$ mice appear to be normal (Luo et al., 2001; Roberds et al., 2001). Most significantly, when mutant APP transgenic mice are crossed with *BACE1* null mice, the levels of Aβ are negligible in progeny lacking BACE1. Thus, not only do BACE1 deficient neurons fail to secrete Aβ but, APPswe transgenic mice lacking BACE1 do not generate Aβ peptides in brain (H. Cai et al., personal communication; Luo et al., 2001). These several observations suggest that it may be possible to develop inhibitors that are brain penetrant (i.e. can cross the blood–brain barrier), bind to the active sites of BACE1 to ameliorate Aβ deposition, and lack mechanism-based toxicity. The publication of the crystal structure of the protease domain of BACE1 associated with an eight-residue peptide inhibitor (Hong et al., 2000) should be of value in development of specific drugs designed to inhibit BACE1 activity. Moreover, lead compounds with potent BACE1 inhibition identified through high throughput screens can be further modified for efficacy and bioavailability and minimized for toxicity. These compounds can be tested in mutant APP transgenic mice to determine whether they ameliorate deposition in vivo and, if efficacious and nontoxic, they can be brought to clinical trials.

Although γ-secretase, which cleaves at the C-terminal portion of Aβ, has not yet been cloned, it has been shown that the PS1, which when mutated cause FAD (Sherrington et al., 1995), participates in the intramembraneous proteolysis of several proteins, including APP (De Strooper et al., 1998; Naruse et al., 1998) and Notch1 (De Strooper & König, 1999), and thus may be the putative γ-secretase or a critical cofactor for these cleavages. The demonstrations that PS1 co-fractionates with γ-secretase activity (Li et al., 2000b), that transition-state analogue inhibitors of γ-secretase can covalently label PS1 (Esler et al., 2000; Li et al., 2000c), and that two transmembrane aspartates appear to be required for γ-secretase activity (Wolfe et al., 1999) provide support for the view that PS1/2 may possess γ-secretase activity or that the PS are co-factors intimately influencing γ-secretase cleavages. Alternatively, PS1/2 may play a role in trafficking of APP or other molecules into proper compartments for processing (Naruse et al., 1998). Consistent with the idea that γ -secretase activity involves a multi-subunit catalytic complex is the recent identification of the type 1 transmembrane protein, nicastrin, which interacts with PS that are known to modulate both γ-secretase activity and Notch1 functions (Yu et al., 2000).

Because PS are involved in the proteolytic processing of Notch1 (to liberate the Notch intracellular domain which enters the nucleus to influence transcription) and are critical for Notch1 functions (Huppert et al., 2000), it is not surprising that *PS1* null mice have a phenotype resembling, to a lesser degree, that observed in the *Notch1* null mice (Wong et al., 1997; Shen et al., 1997). Thus, the design of therapeutics that inhibit γ-secretase and thus influence, at some level, Notch1 processing could have, in the adult, impact on some cell populations (hematopoetic cells, especially lymphocytes) that utilize Notch1 signaling for cell fate decisions (Hadland et al., 2001). In this case, it may be necessary to try to develop highly selective inhibitors that act principally on γ-secretase activities that cleave APP and have less inhibitory potency on Notch1 cleavage (Petit et al., 2001). Significantly, a newly developed γ-secretase inhibitor appears to reduce the levels of Aβ in APP mutant mice, and the compound is now in Phase 1 clinical trials. In the event that neither a γ-secretase nor a β-secretase inhibitor alone proves efficacious, a cocktail of γ- and β-secretase inhibitors might be developed to act in concert to reduce the burden of Aβ in AD.

Immunotherapy

Both Aβ immunization (with Freund's adjuvant) and passive transfer of Aβ antibodies reduce levels of Aβ and plaque burden in mutant APP transgenic mice in both prevention and treatment trials (Schenk et al., 1999; Bard et al., 2000; DeMattos et al., 2001) (Table 115.3). The mechanisms of enhanced clearance are not certain, but it has been suggested that a small amount of Aβ antibody reaches the brain, binds to Aβ peptides, promotes the disassembly of fibrils, and the Fc antibody domain attracts activated microglia to remove Aβ. It is also possible that antibody-mediated processes interfere with the toxicity of Aβ 42. Another possibility, not mutually exclusive with the

aforementioned, is that serum antibodies serve as a sink to draw the amyloid peptide from brain to circulation, thus changing the equilibrium of Aβ in different compartments and promoting removal from brain. Immunization appears to attenuate learning/behavioural deficits in at least two small cohorts of mutant APP mice (Janus et al., 2000; Morgan et al., 2000). Human Phase 1 trials are under way with Aβ and a safer adjuvant; the levels of antibody titre will be critical since these levels are predictive of amyloid clearance in mutant transgenic mice.

Editor's note These trials are on hold due to encephalitis -like side effects.

Treatments of models relevant to MND

A variety of mechanisms, including copper toxicity, protein misfolding, aggregation of critical components, alterations in the biology of neurofilaments, oxidation/nitration-mediated damage, excitotoxicity, calcium-related injury, and apoptosis are among the processes that have been suggested to play roles in ALS and FALS. As described above, in vivo and in vitro studies have demonstrated that the mutant enzyme causes selective neuronal degeneration through a gain of toxic property rather than a loss of SOD1 activity, consistent with some FALS pedigrees displaying an autosomal dominant pattern of inheritance.

Lines of mutant SOD1 mice have been used for pharmacological and 'genetic' therapeutic trials (Friedlander et al., 1997; Couillard-Després et al., 1998; Pasinelli et al., 1998; Klivenyi et al., 1999; Cleveland, 1999; Julien, 1999, 2001). Vitamin E and selenium modestly delay both the onset/progression of disease without affecting survival. In contrast, riluzole and gabapentin do not influence the onset/progression, but they do increase survival slightly (Gurney et al., 1996). Oral administration of D-penicillamine, a copper chelator, delays the onset of disease modestly (Hottinger et al., 1997). At present, treatment with creatine appears to have the most robust pharmacological impact on disease (Klivenyi et al., 1999); oral administration of creatine to G93A SOD1 mice resulted in a dose-dependent improvement in motor tasks and extended survival.

The effect of increasing or reducing the levels of SOD1 has been tested by mating mutant SOD1 mice with transgenic mice overexpressing wild-type SOD1 or by mating with SOD1$-/-$ mice. Neither of these genetic manipulations appeared to have a significant effect on the phenotype of mutant *SOD1* mice in these experiments (Bruijn et al., 1998) (The clinical course and pathology, including the presence of aggregates, which contain SOD1 and other unidentified components, are no different from those of mutant SOD1 transgenic mice.

Overexpression of *BCL-2* in these transgenic mice extends survival, but the presence of the gene does not change the progression of the disease (Kostic et al., 1997), while with overexpression of a dominant negative inhibitor of interleukin-1B converting enzyme (ICE), a cell death gene, produces a modest slowing of progression of disease (Friedlander et al., 1997).

The role of neurofilaments in SOD1 mutant mice was tested by cross-breeding to: (i) transgenic mice that accumulate NF-H-β-galactosidase fusion protein (NF-H-lacZ), a multivalent protein that crosslinks neurofilaments in neuronal perikarya and limits their export to axons (Eyer & Peterson, 1994); and (ii) transgenic mice expressing human NF-H subunits (Côté et al., 1993). In mutant SOD1 mice expressing NF-H-lacZ, NF are withheld from the axonal compartment, but there is no influence on disease (Eyer et al., 1998), implying that neither initiation nor progression of pathology requires an axonal NF cytoskeleton and that alterations in NF biology observed in some forms of motor neuron disease may be secondary responses (Eyer et al., 1998). By contrast, the expression of wild type human *NF-H* transgenes in the SOD1 mutant mice increases the mean life-span of the mice (Couillard-Després et al., 1998) and is associated with sparing of motor neurons (Couillard-Després et al., 1998; Julien, 1999). Similarly, mutant S*OD1: NF-L* $-/-$ mice show later onset and a slower progression (Williamson et al., 1998; Julien, 1999). The common properties shared by these compound transgenic mice are the reduced content of assembled neurofilaments in the axonal compartment and an increase in neurofilament proteins in cell bodies. How the distribution of neurofilaments in mutant SOD1 mice influences phenotype is not known.

To test the hypothesis that Cu bound to mutant SOD1 plays a key role in generating the toxic property in SOD1-linked FALS, multiple lines of mutant SOD1 mice were crossed with *CCS*$-/-$ mice. Metabolic ^{64}Cu labelling studies in mutant SOD1 mice lacking the CCS reveal that copper incorporation into wild type and mutant SOD1 is significantly diminished in the absence of the CCS. Motor neurons in mice lacking the CCS have an increased rate of death after facial nerve axotomy, a response previously documented for mice deficient in SOD1. Thus, CCS is necessary for efficient copper incorporation into SOD1 in motor neurons. However, while the absence of the CCS results in a significant reduction in the level of copper-loaded mutant SOD1, the onset, progression and pathology of motor neuron disease is not modified in mutant SOD1 mice. These results demonstrate that the CCS-dependent copper-loaded mutant SOD1 plays no role in the pathogenesis of mutant SOD1-induced motor neuron disease.

Although the molecular mechanisms underlying mutant SOD1-linked familial ALS remain unclear, several pathogenic mechanisms other than the copper hypothesis (Martin, 1999; Pasinelli et al., 2000; Li et al., 2000a) have been proposed. Mutant SOD1-containing aggregates have been implicated to participate in the pathogenesis of SOD1-linked FALS (Bruijn et al., 1998; Johnston et al., 2000; Beaulieu et al., 2000). While the role of aggregates in disease pathogenesis remains to be clarified, the identification of mutant SOD1-containing complexes as an early event in mutant SOD1 mice supports the importance of aggregates in the pathogenesis of SOD1-linked FALS.

In conclusion, this review of FAD and two inherited MND is intended to provide lessons for understanding other neurodegenerative diseases. Recent investigations of pathology of AD, of the genetics of FAD, of the biochemistry of APP processing (particularly the secretases involved), and of gene targeted and transgenic models have provided extraordinary new insights into the reasons why AD is a brain amyloidosis, the mechanisms of amyloidogenesis, and targets for mechanism-based therapies for this very common, devastating disease of the elderly. Of particular note are the discoveries that indicate BACE1 plays a key role in rendering neurons vulnerable to amyloidogenesis and that inhibition of this enzyme is an attractive treatment strategy.

Over the past several years, similar approaches have led to substantial progress in understanding the pathological and molecular processes that underlie MND. It was hypothesized that aberrant Cu chemistries generated neurotoxic radicals that damaged motor neurons, and that inhibiting this potential pathogenic pathway might have beneficial effects in FALS. Unfortunately, when the copper hypothesis was tested by targeting the gene encoding CCS and by crossing these mice with a series of mutant SOD1 mice, the outcome failed to confirm the hypothesis. Mutant SOD1 mice lacking the CCS did not incorporate Cu into wild type and mutant SOD1 in the absence of the CCS. However, the absence of Cu in SOD1 failed to modify the onset, progression and pathology of motor neuron disease in mutant SOD1 mice. These results demonstrate that the CCS-dependent copper-loaded mutant SOD1 plays little role in the pathogenesis of mutant SOD1-induced motor neuron disease, and that therapeutic attempts to inhibit aberrant Cu chemistries are not an attractive approach. The mechanisms that account for 'selective' neuronal degeneration in ALS and SMA are still uncertain and to date we have not sufficient information to develop mechanism-based therapies.

However, more generally, the identification of specific genes/proteins that are mutated/deleted in the inherited forms of neurodegenerative diseases has allowed investigators to create in vivo and in vitro model systems relevant to a wide variety of human neurological disorders. Genetically engineered mice (or other species, like Drosophila) that recapitulate some of the features of human diseases can provide important new information about the neurobiology of these diseases. The availability of new models will allow investigators to examine the molecular mechanisms by which mutant proteins cause selective dysfunction/death of motor neurons. Moreover, pathogenic hypotheses can be tested by experimental manipulations and by breeding mice carrying mutant genes to mice that express other transgenes or to gene-targeted mice. The results of these approaches should provide us with a better understanding of the pathogenic mechanisms of these diseases. In turn, this new knowledge should lead to the design of novel therapeutic strategies that can be tested in these animal models. Finally, it is highly likely that the discovery of genes linked to psychiatric diseases (affective disorders, schizophrenia, etc.) will allow the application of similar strategies to these devastating illnesses.

Acknowledgments

The authors wish to thank the many colleagues who have worked at JHMI, particularly Drs. Sangram Sisodia, Michael Lee, Gopal Thinakaren, Ed Koo, Jamuna Subramaniam, Lee Martin, Vassilis Koliatsos, Ann Bergin, Lucie Brujin, Carlos Pardo, Bruce Rabin, Tom Crawford, Mark Becher, Paul Hoffman, Jack Griffin, Valeria Culotta, and Don Cleveland as well as those at other institutions (Jonathan Gitlin) for their contributions to some of the original work cited in this review and for their helpful discussions. Aspects of this work were supported by grants from the U.S. Public Health Service (AG05146, AG07914, AG 10480, AG10491, AG14248, NS07435, NS20471, NS37145, NS10580, NS37771, NS40014, NS38377, NS38065) as well as the Metropolitan Life Foundation, Adler Foundation, and Bristol-Myers Squibb Foundation.

Motor neuron disease

Pamela J. Shaw

Department of Neurology, University of Sheffield, UK

The World Federation of Neurology classification of motor neurone diseases is based on heredity and presumed causes (De Jong, 1991). A simplified clinical classification is shown in Table 116.1. Motor neuron disease (MND, also referred to as amyotrophic lateral sclerosis (ALS)) is one of the commonest adult-onset neurodegenerative disorders with a worldwide incidence of 1–2 per 100 000. This chapter will review the clinical and pathological features of MND, current pathogenetic hypotheses and symptomatic therapy, as well as prospects for neuroprotective therapies.

Table 116.1. Clinical classification of motor neuron diseases

1	Sporadic motor neuron disease
	A Amyotrophic lateral sclerosis (ALS)
	B Progressive bulbar palsy (PBP)
	C Progressive muscular atrophy (PMA)
	D Primary lateral sclerosis (PLS)
2	Familial motor neuron disease
	A SOD_1 (Cu/Zn superoxide dismutase) related (20%)
	B Juvenile onset – autosomal recessive or autosomal dominant (linked to chromosome 2q, 9q or 15q)
	C Genetic locus unknown (80%)
	D Familial MND with fronto-temporal dementia (linked to chromosome 9q)
3	Other inherited forms of motor neuron degeneration, e.g. Kennedy's disease; Brown Vialetto van Laere syndrome; Spinal muscular atrophy
4	Western Pacific amyotrophic lateral sclerosis/parkinsonism/dementia complex
5	Juvenile onset MND with intracytoplasmic inclusions
6	Motor neuron diseases with definable causes, e.g. Postpolio syndrome; Heavy metal intoxication; Hexosaminidase-A deficiency

Clinical features of motor neuron disease

MND is a progressive neurodegenerative disorder involving primarily the motor neurons of the cerebral cortex, brainstem and spinal cord. The onset of symptoms in MND is often insidious and patients may not present to a neurologist until several months have elapsed. The disease is sporadic in 90% and familial, usually with an autosomal dominant mode of inheritance, in approximately 10% of cases. Twenty per cent of familial cases or two per cent of the MND population as a whole have a mutation in the gene on chromosome 21 encoding Cu/Zn superoxide dismutase (SOD1) (Rosen et al., 1993). The genetic alterations underlying the remaining 80% of cases of familial MND remain unknown.

Clinical variants

There are several clinical and pathological variants of sporadic MND. Approximately two-thirds of patients present with the amyotrophic lateral sclerosis (ALS) variant; 25% present with progressive bulbar palsy (PBP); 8% with progressive muscular atrophy (PMA) and 2% with primary lateral sclerosis (PLS) (Caroscio et al., 1984). Criteria have been developed for MND to allow clinicians and researchers to classify patients according to the level of certainty of the diagnosis (World Federation of Neurology El Escorial Criteria) (Brooks, 1994).

In the commonest ALS variant, there are signs of impairment of both upper and lower motor neurons with eventual involvement of both somatic and bulbar muscles. In progressive bulbar palsy, the initial symptoms begin in

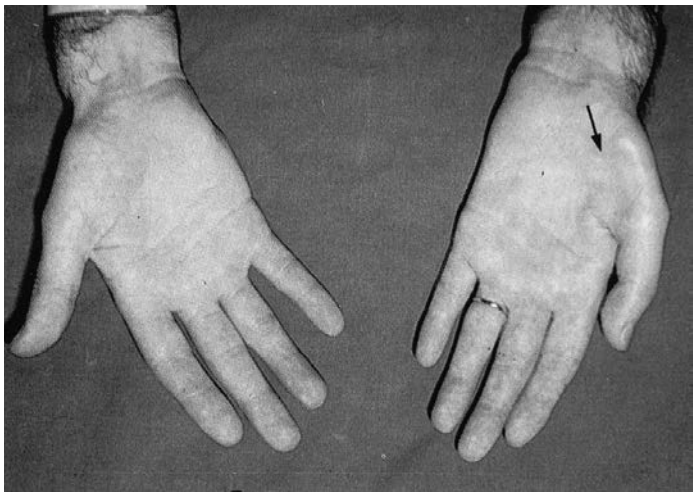

Fig. 116.1. Wasting of the thenar muscles (arrow) in a patient with ALS.

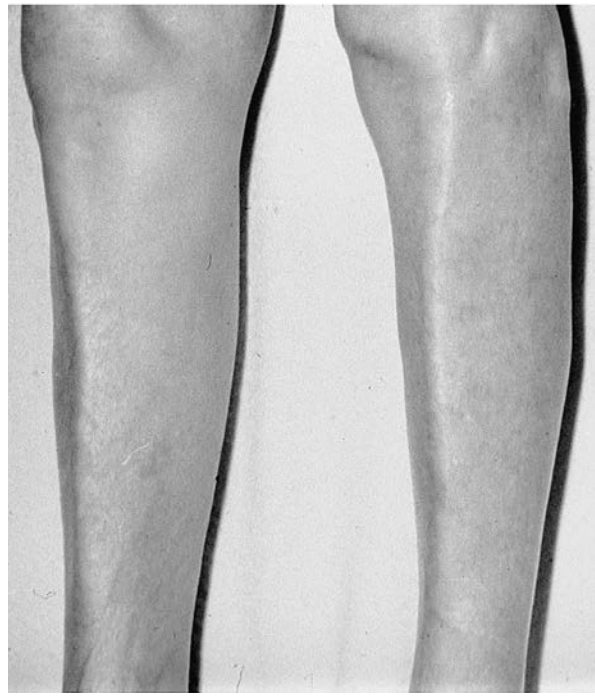

Fig. 116.2. Wasting of the anterior tibial compartment muscles in a patient with ALS.

muscles controlling speech and swallowing innervated by motor neuron groups in the pons and medulla. At presentation, there may be no clinical evidence of involvement outside the bulbar territory. In the progressive muscular atrophy variant, the initial symptoms are due to degeneration of lower motor neurons in the spinal cord, in the absence of clinical features indicating upper motor neuron or bulbar involvement. Primary lateral sclerosis is a relatively rare variant of MND. The patient presents with progressive upper motor dysfunction involving the limb and bulbar musculature, sometimes accompanied by alteration of sphincter function, in the absence of clinical or neurophysiological features of lower motor neuron pathology (Pringle et al., 1992). The PLS form of MND tends to progress more slowly than the other clinical variants. Lower motor neuron features may become apparent as long as 8 to 10 years after presentation.

Clinical features at diagnosis

Limb weakness

Upper limb symptoms are the presenting feature in 40–50% of patients, lower limb symptoms in approximately 25–40% and bulbar symptoms in 20–30% (Swash & Schwartz, 1995). Muscle weakness without sensory loss is the most frequent presenting feature, though occasionally the first complaint may be of muscle wasting, cramps or fasciculations. These early symptoms are usually asymmetrical and often involve only one limb. In patients with prominent upper motor neuron involvement presenting complaints may include stiffness, spasticity or ankle clonus.

Clinical examination of patients with MND will often reveal a rather characteristic pattern of limb involvement. Distally in the upper limb muscle weakness and wasting tends to be most severe in the thenar muscles, interossei and wrist and finger extensors, with relative sparing of the wrist and finger flexors (Fig. 116.1). A frequent early symptom is of difficulty in manipulating objects with the fingers of one hand. Proximally in the upper limb the biceps, deltoid and infraspinatus muscles tend to be affected first, with relative sparing of triceps. In the lower extremities weakness often initially involves hip flexion and ankle dorsiflexion. The calf and quadriceps muscles tend to be involved only later in the course of the disease. Common early lower limb symptoms include heaviness of one leg, unilateral foot drop or a tendency to trip (Fig. 116.2).

Tone and reflex abnormalities

Clinical evidence of upper motor neuron involvement is the rule in the commonest ALS variant of MND, though this may not be as functionally significant as the accompanying lower motor neuron features. The tendon reflexes are frequently brisk in the presence of significant wasting of

the limb musculature and extensor plantar reflexes may be present. Occasionally limb tone is severely increased and spasticity is an important cause of disability in some patients.

Fasciculation

Fasciculations are fine, rapid flickering movements of muscle due to spontaneous contractions of the fibres within a single motor unit. The cause of muscle fasciculation in MND is still debated. In general, the larger the muscle, the larger the size of the fasciculations, and they tend to be most readily observed in the bulky proximal limb muscles such as deltoid, biceps, triceps and quadriceps. Patients with MND will often be aware that their muscles are twitching, but do not usually find fasciculations painful or distressing.

Cramps

Muscle cramp is an sudden, involuntary and painful muscle contraction which is visible or palpable and which may be relieved by massage or stretching. In patients with MND muscle cramp is a frequent early complaint and is often observed during the clinical assessment of muscle power. Cramps may predate the onset of other symptoms in MND by several years (Fleet & Watson, 1986). Cramps are most commonly experienced in the lower limbs, but the hands, proximal upper limb muscles, neck, jaw, abdomen, chest and even the tongue may also be involved. The cause of cramp in MND is not well understood.

Fatigue

The neuromuscular junctions in muscles undergoing denervation and reinnervation are electrophysiologically unstable, which may cause fatigue following repeated muscle contraction. Fatiguability is a common symptom in MND and may occasionally be sufficiently pronounced so as to suggest a diagnosis of myasthenia gravis. The fatigue will often relate to specific activities, for example increasing dysarthria at the end of the day, or reduced ability to walk more than a certain distance without tiring. Fatigue may be demonstrated electrophysiologically in MND, using repetitive stimulation.

Bulbar dysfunction

The first evidence of bulbar involvement in MND is often an articulation problem due to weakness or spasticity of the tongue. Initial complaints include an inability to speak loudly or sing, a softening of the voice or slurring of speech. Hoarseness may result from paresis of vocal cord abduction. Weakness of palatal elevation may occur which imparts a nasal quality to the voice. Spasticity of the bulbar muscles leads to an effortful, tight quality to the speech and impairment of repetitive movements of the lips, tongue and pharynx. Progression to complete anarthria is common. Dysphagia is usually only noticed by the patient after the development of significant dysarthria. Particular problems include: weakness of lip closure allowing escape of oral contents; tongue weakness resulting in slowness and incoordination in the passage of the bolus from mouth to pharynx; weak palatal elevation causing nasal regurgitation of oral contents; pooling of material in the vallecula and pyriform recesses and impaired laryngeal elevation resulting in tracheal aspiration of swallowed material; spasticity of the cricopharyngeal sphincter hindering entry of the food bolus into the esophagus. Patients with bulbar MND frequently complain of drooling of saliva due to weakness of lip closure and dysphagia (Langton Hewer, 1995). Weakness of the facial and jaw muscles may also occur. Examination of the patient with bulbar dysfunction will frequently uncover a combination of upper and lower motor neuron signs. Facial weakness and reduced voluntary movement of the palate may be seen. The tongue often shows fasciculation, wasting and bilateral weakness, together with spasticity. The jaw jerk may be pathologically brisk.

Emotional problems

MND patients with upper motor neuron bulbar features may develop prominent emotional lability with inappropriate crying or laughter. Severe depression, however, appears to be surprisingly uncommon, occurring in 2.5% in one series of 40 patients (Houpt et al., 1977). While suicidal thoughts are common, particularly arising from the patient's fear of becoming a burden on the family, suicide attempts are uncommon (Ganzini et al., 1998).

Weight loss

Progressive muscle wasting and reduced caloric intake due to dysphagia or loss of appetite can cause progressive weight loss in patients with MND. Sometimes disproportionately severe weight loss occurs, a phenomenon which has been called MND cachexia and which is associated with a poor prognosis.

Neck weakness

Weakness of the neck extensor muscles may cause a tendency of the head to fall forwards. In more advanced disease, the head may adopt a completely flexed posture, resulting in limitation of the field of vision, interference with feeding and respiratory function and neck discomfort.

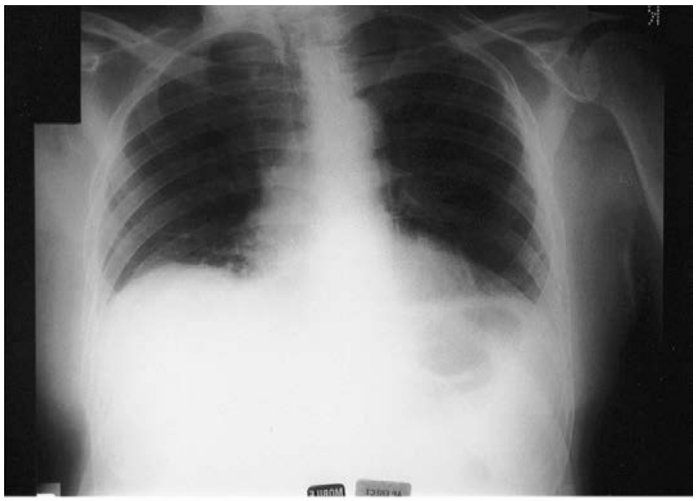

Fig. 116.3. Chest radiograph of a patient with ALS and respiratory failure showing raised hemidiaphragms bilaterally.

Respiratory symptoms

Up to 80% of patients with MND have a degree of impairment of respiratory function at the time of presentation, though this is seldom symptomatic (Schiffman & Belsh, 1993). In some patients diaphragmatic weakness is a relatively early feature, resulting in symptomatic breathlessness in the supine position (Fig. 116.3). A high frequency of sleep disordered breathing has also been reported in MND (Ferguson et al., 1996). On rare occasions, patients present with impending respiratory failure (Nightingale et al., 1982). As the initial manifestation of MND, this symptom is associated with a very grave prognosis. The symptoms of respiratory muscle weakness in MND include dyspnea on mild exertion or when lying flat; difficulty with coughing and talking; daytime somnolence; difficulty falling asleep, interrupted sleep, nightmares; morning headaches; nervousness, tremor, increased sweating, tachycardia and anorexia. When the vital capacity approaches 30–40% of the predicted value, there is a risk of sudden, life-threatening respiratory failure (Oppenheimer, 1993).

Sleep disturbance

Sleep disturbance is a common problem in patients with MND and may also have a significant impact on the well-being of the carer. Multiple factors may contribute to insomnia. Muscle weakness and the resultant impairment of mobility both reduces or prevents customary physical activities during the day and interferes with postural adjustments at night. Various types of pain may interfere with sleep including painful cramps, joint stiffness, and discomfort due to pressure effects or poor positioning. Anxiety and depression may also contribute to insomnia. Respiratory insufficiency with hypoxia and dyspnea may render the patient fearful of going to sleep.

Pain

Pain is not usually present in the early stages of MND, but is common in the later stages of the disease. One study of 42 patients reported that pain was a major feature in 64% (Newrick & Langton-Hewer, 1985). Saunders et al. (1981) evaluated 100 patients in a hospice setting and found that 45% had pain. The major identifiable problems were: stiffness of joints, muscle cramps, skin pressure, immobility requiring external help, severe spasticity and constipation.

Uncommon manifestations of MND

Dementia

Traditionally, it has been reported that patients with MND show preserved cognitive function. However, it has been estimated that dementia, typically of fronto-temporal lobe type, occurs in approximately 3% of patients and this may occasionally be the presenting feature of the disease (Hudson, 1981). MND patients with overt dementia frequently have a characteristic pattern of cognitive dysfunction, with prominent attentional deficits, particularly on tasks requiring sustained effort or the ability to shift from one thinking paradigm to another. Confrontation naming, verbal fluency, insight and judgement are also impaired. In contrast, verbal and non-verbal memory and spatial abilities are usually well preserved (Neary et al., 1990). Detailed neuro-psychological assessment in MND patients without overt dementia has shown that a mild degree of cognitive disturbance is more common than previously recognized, particularly in patients with prominent bulbar features (Rakowicz & Hodges, 1998).

Sensory impairment

Although sensory abnormalities are not usually considered a typical feature of the clinical spectrum of MND, patients may complain of sensory symptoms, particularly early in the disease. Objective signs of sensory impairment on examination, however, are virtually never found.

Autonomic function is generally preserved in MND. Normally, bowel and bladder control and ocular movements are preserved, unless the course of the disease is extended by respiratory support measures.

Disease progression and prognosis

In MND relentless progression of limb and bulbar weakness is the rule, ultimately producing severe disability.

Temporary stabilization sometimes occurs. Occasional cases have been described where the disease appears to remit (Tucker et al., 1991), but this is extremely rare. Limb weakness usually progresses to involve all four limbs. Early involvement of paravertebral muscles is unusual, but as the disease progresses weakness of trunk muscles and neck extensors is common. Significant diaphragmatic weakness usually occurs following the development of marked limb and/or bulbar weakness. Bulbar symptoms will eventually develop in approximately 80% of afflicted individuals. Speech difficulties may progress to anarthria. Dysphagia may also progress to a severe level, with the potential complications of dehydration, malnutrition and aspiration pneumonia.

Approximately 50% of patients with MND die within 3–4 years of the onset of symptoms, 20% live for 5 years, 10% live for 10 years and a few individuals live for as long as 20 years (Mulder, 1982). The cause of death in MND is usually respiratory failure, which may be accompanied by bronchpneumonia.

Investigation and differential diagnosis

The diagnosis of MND is essentially clinical, since there is no specific diagnostic test. The important features supporting the diagnosis are the presence of upper and lower motor neuron signs in a distribution extending beyond a discrete spinal level or peripheral nerve, usually with spontaneous fasciculation, and without sensory abnormalities. A number of specific investigations may be necessary to confidently exclude other diagnoses. Neurophysiological assessment is particularly useful. Evidence of denervation and reinnervation in muscles of at least two limbs, not corresponding to a single nerve root or peripheral nerve distribution, is strongly supportive of a diagnosis of MND. Motor conduction is normal or may be slightly slowed, with no evidence of conduction block, and with normal sensory conduction velocities. Neuroimaging may be advisable to exclude other intracranial or spinal disorders. Most biochemical investigations are normal. The blood creatine kinase level may be increased two–threefold in up to 50% of patients. The CSF protein is slightly elevated in a proportion of patients. Approximately 5% of MND patients have an IgG or IgM paraprotein band, though no causal association with motor neuron dysfunction has been demonstrated to date. Oligoclonal bands are also occasionally noted in the CSF of patients with MND (Younger et al., 1990).

The major conditions to be considered in the differential diagnosis of MND are listed in Table 116.2.

Table 116.2. Differential diagnosis of amyotrophic lateral sclerosis

Benign cramp/fasciculation syndrome
Degenerative spinal disease: radiculomyelopathy
Motor neuropathies, e.g. multifocal motor neuropathy with conduction block
Myasthenia gravis
Myopathies, e.g. inclusion body myopathy
Multifocal cerebrovascular disease
Postpoliomyelitis syndrome
Spinal muscular atrophy
Kennedy's disease (X-linked bulbospinal neuronopathy)
Syringomyelia/syringobulbia
Endocrine disease, e.g. hyperthyroidism, hyperparathyroidism
Heavy metal intoxication

Pathology of MND

The neurodegenerative process in MND is relatively selective for upper motor neurons, a proportion of which are represented by Betz cells in the fifth layer of the motor cortex, and for lower motor neurons in the ventral horn of the spinal cord and brainstem. Motor neurons innervating the extraocular muscles and those comprising Onuf's nucleus in the sacral spinal cord innervating the pelvic floor muscles, tend to remain unaffected, which correlates with the preservation of eye movements and control of bowel and bladder function in MND patients. However, the selective vulnerability of motor neurons to the disease process in MND is relative rather than absolute, and there is increasing evidence from pathological (Ince et al., 1998a,b) and clinical (Chari et al., 1996; Kew et al., 1993) studies that pathology outside the motor system can be found frequently and that MND is actually a multisystem disorder in which the motor system tends to be affected earliest and most severely. Experience from countries where clinical practice includes the use of respiratory support measures to prolong life to an advanced stage of disease has revealed very extensive multisystem pathological changes (Sasaki et al., 1992).

Gross pathological examination in MND may reveal atrophy of the precentral gyrus of the cerebrum, thin hypoglossal nerves and atrophied ventral roots emanating from the spinal cord. There may be shrinkage and sclerosis of the anterolateral tracts of the spinal cord. Microscopical examination reveals extensive loss of motor neurons with a degree of reactive gliosis in the ventral horns of the spinal cord and in the motor nuclei within the brainstem. There may be obvious depletion of Betz cells in layer V of the motor cortex.

Fig. 116.4. Hemisection of the spinal cord from a patient with ALS showing depletion of anterior horn cells and degenerative changes affecting the corticospinal tract. This patient also has a degree of myelin pallor in the ascending dorsal column sensory tract.

There is demyelination and axonal loss affecting the crossed and uncrossed corticospinal tracts of the spinal cord. The anterolateral pathways of the spinal cord often show reduction in staining for myelin, in contrast to the usually preserved posterior columns (Fig. 116.4). However, degenerative changes are seen in the posterior column sensory pathways and in the ascending spinocerebellar tracts in some cases.

The degenerating motor neurons in MND contain characteristic ubiquitinated inclusion bodies (Leigh et al., 1988; Lowe et al., 1988). The inclusions may be hyaline, Lewy body-like or skein-like (Fig. 116.5(*a*), (*b*), see colour plate section). The main protein constituent of the fibrils comprising these inclusions is unknown. In some cases of SOD1-related familial MND dramatic hyaline conglomerate inclusions have been observed which demonstrate intense immunoreactivity for both phosphorylated and non-phosphorylated neurofilament epitopes (Ince et al., 1998a,b, see colour plate section) (Fig. 116.5(*c*)).

Death of lower motor neurons denervates muscle fibres, which may, in time, be reinnervated by collateral sprouts from the axons of surviving motor neurons. In the earlier stages of the disease this reinnervation compensates for the progressive loss of motor neurons. Histological studies of muscle in MND show the features of fatty infiltration of muscle and denervation atrophy, with groups of angular atrophic muscle fibres. Enzyme histochemistry shows muscle fibre type grouping. Axonal sprouting from residual intramuscular nerve fibres, and increased segmentation and volume of the motor end-plate have been reported.

Pathogenesis of MND

The primary pathogenetic processes underlying MND are likely to be multifactorial and the precise mechanisms underlying selective cell death in the disease are at present unknown. Current understanding of the neurodegenerative process in MND suggests that there may be a complex interplay between genetic factors, oxidative stress, toxic activation of glutamate receptors and damage to critical target proteins and organelles (Brown, 1995). The relative importance of these factors may vary in different subgroups of patients.

Genetic factors

MND is sporadic in 90% of cases and familial in 5 to 10% of cases. Familial cases usually show autosomal dominant inheritance, though autosomal recessive and X-linked inheritance may be seen in some pedigrees. Multiple abnormal gene products can set the scene for motor neuron degeneration (Table 116.3). A very important research advance came from the finding that 20% of families with autosomal dominant MND showed mutations in the gene on chromosome 21 which encodes the free radical scavenging enzyme Cu/Zn superoxide dismutase (SOD1) (Rosen et al., 1993). More than 90 different mutations, largely point mutations, have been described. SOD1 is a cytosolic metalloenzyme, with copper and zinc binding sites, whose major role is to catalyse the conversion of intracellular superoxide radicals to hydrogen peroxide, which is then eliminated by the action of other free radical scavenging enzymes. SOD1 is ubiquitously expressed in cells throughout the body. The reasons why motor neurons are selectively vulnerable to injury in the presence of SOD1 mutations are not yet clear, though one factor may be the high level of expression of this anti-oxidant defence protein by motor neurons.

Table 116.3. Genetic factors in amyotrophic lateral sclerosis

Autosomal dominant		Gene locus
Mutations in Cu/Zn superoxide dismutase		Chromosome 21
Juvenile-onset ALS	linked to	Chromosome 9q34
ALS with fronto-temporal dementia	linked to	Chromosome 9q21–q22
Gene unknown in approximately 80% of pedigrees		
Autosomal recessive		
Tunisian juvenile-onset ALS	linked to	Chromosome 2q 33–q35
Scandinavian ALS with D90A SOD1 mutation		Chromosome 21
Juvenile-onset ALS	linked to	Chromosome 15q15–q21
X-linked		
X- linked dominant (single family)	linked to	Chromosome X centromere
Possible genetic risk factors for ALS (non-Mendelian inheritance)		
Deletions or insertions in KSP repeat region of neurofilament heavy subunit gene		Chromosome 22q12
Excitatory amino acid transporter gene (EAAT2)		Chromosome 11p13
Survival motor neuron (SMN) gene		Chromosome 5q13
Neuronal apoptosis inhibitory protein (NAIP)		Chromosome 5q13
Apolipoprotein E e4		Chromosome 19q13
Cytochrome c oxidase subunit 1		Mitochondrial
AP endonuclease		Chromosome 14q11–q12
Mn superoxide dismutase		Chromosome 6q25

The pathways leading to cell death of motor neurons in the presence of SOD1 mutations have not yet been fully elucidated, though there is a compelling body of evidence that the mutant SOD1 protein exerts its deleterious effects through a toxic gain of function rather than a loss of function. Several hypotheses have been formulated to explain this toxic gain of function (Brown, 1995; Cookson & Shaw, 1999). The most favoured suggestions include the possibility that the mutant SOD1 protein may cause alteration in the handling of intracellular free radicals resulting in oxidative stress or may cause the formation of toxic intracellular protein aggregates.

The genetic alterations underlying the remaining 80% of cases of autosomal dominant MND at present remain unknown. Linkage analysis has revealed that chromosomes 2q, 9q and 15q may harbour mutations associated with rare forms of juvenile-onset MND (Hentati et al., 1994; Chance et al., 1998; Anderson et al., 2000). Familial MND with frontotemporal dementia has recently been linked to chromosome 9q21–q22 (Hosler et al., 2000).

There have been isolated reports of rare genetic abnormalities found in sporadic cases of MND. Deletions or insertions in the KSP repeat region of the gene encoding the neurofilament heavy protein, which is a major component of the neuronal cytoskeleton have been described (Figlewicz et al., 1994; Tomkins et al., 1998). Isolated mutations have also been described in subunit 1 of the cytochrome c oxidase subunit, which is an important component of the mitochondrial respiratory chain (Comi et al., 1998) and in the AP endonuclease enzyme (Tomkins et al., 2000), which has a key role in the repair of oxidative damage to DNA. It has also been suggested that the apolipoprotein e4 genotype is a risk factor for the development of bulbar onset MND (Al Chalabi et al., 1996), though not all research groups have been able to confirm this finding. Other studies have indicated that mutations in the glutamate re-uptake transporter protein EAAT2, in the SMN (survival motor neuron) and NAIP (neuronal apoptosis inhibitory protein) genes may occasionally be found in patients with ALS or pure lower motor neuron syndromes. It has also been suggested that a polymorphism in the mitochondrial targeting sequence of Mn superoxide dismutase may be over-represented in cases of sporadic MND (for review see Andersen et al., 2000).

The possibility of hereditary factors protecting against the development of motor neuron degeneration has also been postulated. In Finland the D90A SOD1 mutation results in MND only when homozygously expressed, whereas in other parts of the world this mutation results in ALS in heterozygotes. This has led to the hypothesis that a

coinherited neuroprotective factor may be present in the Finnish patients (Anderson et al., 1996).

Glutamatergic toxicity

Glutamate is the major excitatory neurotransmitter in the human nervous system, with a widespread distribution. Motor neurons are activated by stimulation of cell surface glutamate receptors and the excitatory signal is terminated by active removal of glutamate from the synaptic cleft by transporter proteins which are largely located on perisynaptic glial cells. It is known that excessive stimulation of neuronal glutamate receptors (excitotoxicity) can injure neurones by mechanisms which include derangement of intracellular calcium homeostasis and excessive free radical production. A body of circumstantial evidence has implicated glutamate-mediated toxicity as a contributory factor to motor neuron injury (Shaw & Ince, 1997; Jackson & Rothstein, 2000). Antiglutamate therapy has some effect in prolonging survival in human patients (Lacomblez et al., 1996) and in a transgenic mouse model of familial MND (Gurney et al., 1996). The key findings are that the expression and function of the major glial glutamate re-uptake transporter protein EAAT2 (excitatory amino acid transporter 2) may be impaired in MND and that extracellular and CSF levels of glutamate may be abnormal in at least a proportion of MND patients (Rothstein et al., 1992, 1995; Shaw et al., 1995a). In addition, both PET (positron emission tomography) scanning studies and transcranial magnetic stimulation of the motor cortex in patients with MND have indicated that there is hyperexcitability of the motor system (Kew et al., 1993; Mills, 1995). Recently the presence of abnormally spliced RNA transcripts for the EAAT2 protein was reported in the motor system and CSF of patients with MND, and it was suggested that a specific defect of RNA processing may be important in disease pathogenesis (Lin et al., 1998). However, other groups have been unable to confirm that these alternatively spliced RNA transcripts are disease specific (Meyer et al., 1999).

Oxidative stress

The effects of oxidative stress within non-replicating cells such as neurones may be cumulative, and injury by free radical species is a major potential cause of the age-related deterioration in neuronal function occurring in neurodegenerative diseases. There is particular interest in the role of oxidative stress in MND given that mutations in the SOD1 gene, which encodes an enzyme crucial for cellular antioxidant defence, underlie some cases of familial MND as described above (Cookson & Shaw, 1999; Robberecht, 2000). Studies of human postmortem CNS tissue have demonstrated the presence of biochemical changes to proteins and DNA, which represent the effects of free radical damage and these changes are more pronounced in MND cases compared to controls (Shaw et al., 1995b; Ferrante et al., 1997). Other postmortem neurochemical changes, including altered expression of components of the intracellular antioxidant defence systems, have been interpreted to indicate an attempted compensatory response to the presence of oxidative stress during the course of MND (Sillevis-Smitt et al., 1994; Shaw et al., 1997). Fibroblasts cultured from the skin of patients with both familial and sporadic MND show increased sensitivity to oxidative insults compared to those from control cases (Aguirre et al., 1998). Recent studies of CSF from MND patients compared to controls have shown an increase in 4-hydroxynonenal (Smith et al., 1998) and 3-nitrotyrosine (Toghi et al., 1999), which may both reflect abnormal free radical metabolism.

Derangement of intracellular calcium homeostasis

Calcium plays a fundamental role in many normal cellular processes including neuronal excitability and regulation of intracellular second messenger systems. Intracellular calcium homeostasis is inextricably linked with other potential mechanisms underlying degeneration of motor neurons, including glutamatergic toxicity, oxidative stress and mitochondrial dysfunction. Activation of cell surface glutamate receptors is a major route for calcium entry into neurons. Both *N*-methyl-D-aspartate (NMDA) and AMPA receptors lacking the GluR2 subunit have calcium permeable ion channels. In addition, depolarization of a neuron by activation of glutamate receptors may lead to a secondary influx of calcium resulting from activation of voltage-gated calcium channels. Sustained elevation of intracellular calcium resulting from glutamate receptor activation can eventually lead to neuronal injury due to excessive activation of several enzyme cascades and the generation of free radicals (Siesjo, 1994). Mitochondria act as an important intracellular store for calcium. It has been suggested that the permeability transition pore in the mitochondrial membrane may act as a calcium release channel involved in calcium homeostasis in the cell (Bernardi & Petronilli, 1996).

The possibility that spinal motor neurons may be particularly vulnerable to calcium-mediated injury is suggested by the observations that this cell population appears to lack the expression of the Ca^{2+} buffering proteins parvalbumin and calbindin D28K (Ince et al., 1993), while expressing abundant calpain II, a calcium-activated prote-

olytic enzyme. Motor neuron groups such as the oculomotor neurons which are less vulnerable to pathology in MND do express parvalbumin. In addition, the expression of calcium-permeable AMPA receptors by human motor neurons (Williams et al., 1997) may be a further factor contributing to the vulnerability of this cell group to calcium-mediated toxic processes.

Siklos et al. reported in muscle biopsies from patients with MND, increased calcium, increased mitochondrial volume and increased numbers of synaptic vesicles in the motor axon terminals (Siklos et al., 1996). In a subsequent study the same group have demonstrated, using the oxalate–pyroantimonate technique and ultrastructural examination, that motor neurons of transgenic mice with a G93A SOD1 mutation exhibit alterations in intracellular calcium (Siklos et al., 1998). The cell bodies and proximal dendrites of spinal motor neurons showed small vacuoles filled with calcium, whereas these changes were not observed in oculomotor neurons. The authors concluded that the free radical-mediated stress induced by mutant SOD1 appeared to induce deleterious changes in intracellular calcium distribution in motor neuron populations lacking calbindin D28K and/or parvalbumin.

Cytoskeletal protein defects

Neurofilament proteins form a major component of the cytoskeleton of neurons and have significant roles in the maintenance of cell shape and axonal calibre as well as in axonal transport. Neurofilaments are the most abundant structural proteins in large cells with long axons, like motor neurons. Neurofilaments are composed of three subunit polypeptides: neurofilament light NF-L (MW 68 kDa); neurofilament medium NF-M (MW 150 kDa) and neurofilament heavy NF-H (MW 200 kDa), assembled in a 6:2:1 ratio to form macromolecular filaments. NF-L makes up the core of the neurofilament, while NF-M and NF-H are arranged around this core and contribute to the side arms radiating from the filament. Neurofilament subunits are assembled in the motor neuron perikaryon and are transported down the axon by slow axonal transport. Under normal circumstances there is progressive phosphorylation as the neurofilament proteins are transported down the axon.

Neurofilament proteins are of considerable interest in MND as potential cellular targets for injury. The abnormal assembly and accumulation of neurofilaments in the perikaryon and proximal axons of motor neurons is a characteristic feature of the pathology of MND (Hirano, 1991). Consensus agreement has not been reached as to whether phosphorylated neurofilaments are increased in cell bodies of surviving motor neurons in MND. Ubiquitinated inclusions with compact or Lewy body-like morphology in surviving motor neurons in MND may show immunoreactivity for neurofilament epitopes. In some cases of SOD1-related familial MND, large argyrophilic hyaline conglomerate inclusions expressing both phosphorylated and non-phosphorylated neurofilament epitopes, have been observed in the cell bodies and axons of motor neurons (Ince et al., 1998a,b). The importance of neurofilaments in the normal health of motor neurons is emphasized by the finding that occasional cases of sporadic MND have deletions or insertions in the KSP repeat region of the neurofilament heavy gene (Figlewicz et al., 1994; Tomkins et al., 1998). In addition, motor neuron pathological changes develop in transgenic mice overexpressing NF-L or NF-H subunits (Xu et al., 1993; Cote et al., 1993) or in mice expressing mutations in the NF-L gene (Lee et al., 1994). These in vivo models demonstrate that disruption of neurofilament assembly can selectively injure motor neurons.

Transgenic mice which carry mutations in the human SOD1 gene also show neuropathological changes affecting neurofilament organization. The G93A mutant transgenic mouse develops neurofilamentous spheroids within motor neurons (Tu et al., 1996) and reductions in axonal neurofilament content and in the rate of axonal transport have also been observed (Zhang et al., 1997).

Mitochondrial dysfunction

Important functions of mitochondria relevant to the pathogenesis of neurodegenerative diseases include the synthesis of ATP, buffering of intracellular calcium, generation of intracellular free radicals and initiation of apoptosis. Mitochondria have been shown to be particularly susceptible to free radical damage at both protein and DNA levels and free radicals are known to inhibit the activities of specific mitochondrial enzymes (Zhang et al., 1990). Changes in mitochondrial function have been suggested as an important factor contributing to age-related neurodegenerative diseases. A significant factor contibuting to the age-related decline in mitochondrial function is the effect of accumulating mutations in the mitochondrial genome (Linnane et al., 1989).

The evidence that mitochondrial dysfunction may contribute to motor neuron injury in MND (Beal, 2000; Menzies et al., 2000) can be summarized as follows.

Structural changes in mitochondria
