Demyelinating Disorders of the Central Nervous System

Istvan Pirko and John H. Noseworthy

HISTORY

MULTIPLE SCLEROSIS

ACUTE DISSEMINATED ENCEPHALOMYELITIS

ROLE OF MYELIN

NEUROMYELITIS OPTICA

HISTORY

Multiple sclerosis (MS) is now known to be a common malady even though it was first recognized as a distinct clinicopathological entity less than 150 years ago.¹ The lack of clear medical reports before the early 1800s is sometimes interpreted as evidence that MS is a relatively new disease. However, it is more likely that the evolution of medicine into science led to more precise observation and description of human diseases, including MS. Saint Lidwina of Schiedam (1380–1433) developed a relapsing neurological disorder at the age of 18 and may be the first case of clinically described MS.² Ollivier was the first to report a clinical case in the medical literature in 1824.¹ Shortly thereafter, Carswell illustrated a case of what is now clearly recognizable as MS in his atlas of anatomical pathology. Cruveilhier published gross pathological and clinical descriptions of MS. Vulpian first suggested the rubric of “sclerose en plaque” in 1866. Charcot was primarily responsible for establishing MS as a unique and recognizable syndrome.³ He also described the clinical spectrum and the histological appearance. Pierre Marie was the first to suggest an infectious cause of MS in 1884, a hypothesis that is still debated. Toxins were also considered to be responsible in the early 1900s. A major advance toward the understanding of demyelinating diseases was the discovery of experimental allergic encephalomyelitis (EAE) by Rivers in 1935.⁴ A variety of different demyelinating diseases have subsequently been described (Table 48-1).

ROLE OF MYELIN

Myelin provides insulation for axons and is necessary for saltatory conduction. It is composed of tightly wrapped lipid bilayers with specialized protein constituents. Peripheral nervous system (PNS) myelin is formed by the extension of Schwann cells, and central nervous system (CNS) myelin is produced by oligodendrocytes. The myelin coating is interrupted at regular intervals (nodes of Ranvier) where the axon membrane with its concentration of voltage-gated sodium channels is exposed to the extracellular environment (Fig. 48-1).⁵ The presence of myelin is essential to

maintain conduction velocity; its loss or damage can lead to significantly slower conduction or conduction block. Other factors affect conduction velocity including certain antibodies and chemicals like nitric oxide. In certain cases, blockade may be the initial event in the cascade of events leading to demyelination.

CNS and PNS myelin differ in a number of important ways. Schwann cells myelinate only one internodal segment from a single PNS axon, whereas oligodendrocytes myelinate multiple CNS axons. The proteins also differ. Proteolipid protein (PLP) accounts for approximately 50% of the CNS myelin proteins. Mutations in this highly conserved protein cause Pelizaeus-Merzbacher disease. Protein zero is the major PNS myelin protein and performs a function similar to PLP in compacting the intraperiod line. Myelin basic protein (MBP) makes up 30% of CNS and 10% of PNS myelin proteins. MBP is not an integral protein but binds to the cytoplasmic surface and is responsible for compaction at the major dense line. Myelin associate glycoprotein accounts for about 1% of both peripheral and central myelin. Myelin oligodendrocyte glycoprotein and cyclic nucleotide phosphodiesterase are minor constituents of CNS myelin and are not found in the PNS. Peripheral myelin protein 22 is a minor component of PNS myelin.

MULTIPLE SCLEROSIS

MS is an inflammatory relapsing or progressive disorder of CNS white matter and is a major cause of disability in young adults. Pathologically, it is characterized by multifocal areas of demyelination, loss of oligodendrocytes, and astrogliosis but with relative preservation of axons. While demyelination is the classic hallmark of MS, axonal and neuronal injury are important aspects of the disease and are gaining more recognition. Although certain clinical features are characteristic of MS, investigative studies are often needed to confirm the clinical suspicion and exclude other possibilities. Recently, there have been advances in understanding the etiology, mechanisms of myelin injury, and potential for repair, and several partially effective agents are now approved for use in relapsing-remitting and secondary progressive MS.

TABLE 48-1

Primary (Idiopathic) Inflammatory Demyelinating Disorders of the Central Nervous System

| |
|---|
| Acute disseminated encephalomyelitis |
| Monophasic |
| Multiphasic |
| Relapsing (controversial) |
| Monosymptomatic syndromes |
| Optic neuritis |
| Acute transverse myelitis (partial and complete) |
| Brain stem demyelination |
| Multiple sclerosis |
| Neuromyelitis optica |
| Marburg's disease |
| Schilder's myeloclastic diffuse sclerosis (controversial) |
| Balo's concentric sclerosis |

PATHOGENESIS AND PATHOPHYSIOLOGY (Fig. 48-2).

The pathogenesis and pathophysiology of MS remains incompletely understood. Several mechanisms may be important to MS plaque formation: autoimmunity, infection, bystander demyelination, and heredity. Although convincing proof is lacking, dietary factors and toxin exposure have been hypothesized to contribute as well. These mechanisms are not mutually exclusive, and the true pathophysiology is likely to depend on more than one of them.

Autoimmunity. During ontogenesis, autoreactive lymphocytes normally undergo clonal depletion, but some escape and are merely suppressed, becoming tolerant to their antigens. Low levels of autoreactive T and B cells persist even in normal individuals. Autoimmune disorders occur when the tolerance of these cells toward their antigen is broken. The decreased suppressor activity of circulating lymphocytes from patients with MS and other presumed autoimmune diseases may reflect loss of tolerance.⁶ One potential mechanism that may break tolerance is molecular mimicry between self and foreign antigens. Autoreactive T4 lymphocytes may become activated on exposure to structurally similar foreign antigens. Some evidence

Figure 48-2. Pathology of MS. **A**, Coronal brain slice showing several focal areas of sclerosis (arrows). **B**, Luxol fast blue stain of a coronal brain section showing numerous discrete areas of myelin loss. **C**, Hematoxylin and eosin stain of a chronic lesion showing perivascular mononuclear cells and prominent gliosis. **D**, Luxol fast blue/periodic acid-Schiff stain showing perivascular inflammation and loss of myelin.

suggests that molecular mimicry is relevant in MS. Not only do several viral and bacterial peptides share structural similarities with MBP, but it has also been demonstrated that these antigens may activate MBP-specific T-cell clones derived from MS patients.⁷ Blood-brain barrier leakage alone may break tolerance because it gives CNS-reactive lymphocytes easy access to otherwise inaccessible antigens. Alternatively, a primary event such as an infection or injury may release CNS antigens into the periphery, where they may activate corresponding autoreactive cells.⁸ The major support for autoimmunity in the pathogenesis and pathophysiology of MS is by analogy to EAE, the major animal model for MS. EAE is, however, an artificial situation and there is no spontaneous autoimmune animal model of MS. While EAE is the most commonly studied model of MS, several features of human MS can not be adequately captured by this model.^{9,10} Over a hundred different effective treatments have been described for EAE; however, almost all of them are ineffective and some are harmful in human MS. A recent editorial discusses the merits and important limitations of EAE as a model for MS.¹⁰ In EAE, just like in classic human autoimmune diseases such as systemic lupus erythematosus (SLE) or rheumatoid arthritis, the main target antigens are known. However, despite the discovery of several “weak” antigens in human MS, no dominant antigens have been identified to date. The only human demyelinating disease with an identified specific antigen is Devic's disease (neuromyelitis optica), which appears to be a novel autoimmune channelopathy with an antigen that is neither neuronal nor myelin related (see later discussion of Devic's syndrome under Neuromyelitis Optica).¹¹

Infection. The role of viral infections in the initiation and maintenance of MS has been debated for some time. Several viral infections are known to cause demyelination in animals, including visna virus of goats and sheep, canine distemper virus, and Theiler's murine encephalomyelitis virus. Viral infections in humans can also cause demyelination (progressive multifocal leukoencephalopathy [JC papillomavirus], subacute sclerosing panencephalitis

[measles virus], and human T-cell lymphotropic or leukemia virus type 1 [HTLV-1]-associated myelopathy). The epidemiology of MS suggests that environmental factors may promote the disease state, possibly due to one or more viruses. A virus may be involved in the pathogenesis of MS in several ways:

1. Transient or persistent infection outside the CNS may activate autoreactive T cells by means of molecular mimicry or by other nonspecific means (as superantigens do).
2. Transient CNS infection may initiate a cascade of events that fosters autoimmunity (breach the blood-brain barrier, release CNS antigens).
3. Recurrent CNS infections may precipitate repeated inflammation and demyelination.
4. Persistent CNS viral infection could either incite inflammatory reactions detrimental to oligodendrocytes or directly injure them.

Beyond speculation and epidemiological observations, there is insufficient evidence for a viral infection playing a causative role in MS. Early serological studies are difficult to interpret because of nonspecific immune activation and resulting elevation of titers to many different viruses. Many MS patients have elevated cerebrospinal fluid (CSF) titers to measles and herpes simplex (HSV) viruses, but this finding appears nonspecific. Virus has rarely been cultured from CSF of MS patients, but a new strain of HSV (the MS strain) and a new virus (Inoue-Melnick virus) were first isolated from the CSF of MS patients.^{12,13} Newer molecular techniques to search for a viral genome in CSF and brain have rejected the claim that HTLV-1 is associated with MS. The finding that human herpesvirus 6 (HHV6), although present in 70% of brains from both control subjects and MS patients, is localized to the oligodendrocyte nuclei near plaques of MS patients and to oligodendrocyte cytoplasm in control subjects indicates that persistent CNS viral infection is common.¹⁴ This raises the possibility that MS may depend on an aberrant host response to this normal condition or that a defective virus that lacks the ability to evade immune detection may be to blame.

More recently, measles and canine distemper virus antibodies were found elevated in blood and CSF samples of MS patients, although their relationship is not clear to the disease process. In a study from Denmark, patients with serological markers for late-stage Epstein-Barr virus (EBV) infection had a threefold increase in the likelihood of developing MS. A follow-up study from Sweden failed to reach this conclusion. In general, serum samples of MS patients may contain higher titers of antibodies to the following infectious organisms: adenovirus, canine distemper virus, HSV, HHV6, and influenza, measles, mumps, parainfluenza, rubella, vaccinia, and varicella zoster virus (VZV). Similarly, CSF samples from MS patients may show higher titers of adenovirus; *Chlamydia pneumoniae*; cytomegalovirus (CMV); EBV; HHV6; coronavirus; influenza viruses A and B; measles or mumps virus; *Mycoplasma pneumoniae*; parainfluenza viruses 1, 2, and 3; respiratory syncytial virus; rubella virus; vaccinia; and VZV. There has been an interest recently in a potential link between *C. pneumoniae* infection and the development of MS. No direct cause-and-effect relationship has been observed between any of these infections and MS.

“Bystander” Demyelination. Immune actions may mediate myelin injury in a nonspecific manner. Many soluble products of the immune response other than immunoglobulins are known or suspected to be toxic to myelin and oligodendrocytes. Activated complement is capable of lysing oligodendrocytes in an antibody-independent fashion.¹⁵

The proinflammatory cytokine tumor necrosis factor- α causes myelin disruption and oligodendrocyte apoptosis in vitro.¹⁶ Arachidonic acid metabolites may also participate in myelinolysis, and reactive oxygen species released by macrophages cause lipid peroxidation that can damage myelin. Other soluble substances that are potentially toxic to myelin include nitric oxide and vasoactive amines.

Histological Subtypes of MS Lesion Development.

Through the groundbreaking work of Lucchinetti and associates in the MS lesion project, it is postulated that the formation of MS lesions follows one of four patterns.¹⁷ Patterns I and II are related to immune-mediated damage to myelin sheaths. In pattern I, cellular mechanisms of injury seem to prevail (macrophages and T-lymphocytes) whereas in pattern II humoral mechanisms of injury predominate (e.g., antibody and complement-mediated mechanisms). Patterns III and IV are related to oligodendrocyte pathology: in pattern III, a distal oligodendroglialopathy and apoptosis have been reported, whereas in pattern IV, primary oligodendroglialopathy and degeneration of oligodendrocytes have been described. Currently these subtypes can be diagnosed only by biopsy; serum and magnetic resonance imaging (MRI) markers are not yet known, although lesional T2 hypointense rims and response to plasma exchange may correlate well with pattern II pathology. It is important to note that the patterns do not correlate with clinical subtypes of MS, with the exception of pattern IV, which has been identified only in primary progressive (PPMS) patients. Evidence to date suggests that the pattern of lesion formation remains the same within an individual patient; patients do not “switch” from one pattern to the other. Also, the patterns do not seem to represent different chronological stages of lesion formation.

Gray Matter Involvement. It has been known since the late 19th century that MS affects both gray and white matter structures. The importance of gray matter involvement has received little attention until recently, largely due to the development of advanced MRI techniques (see later) that indicate neuronal and axonal involvement even in the earliest stages of this disease. A classification system of gray matter plaques was proposed by Peterson and associates¹⁸ They described three patterns of cortical demyelination: type I lesions are contiguous with subcortical white matter lesions; type II lesions are confined to the cortex, and are often perivascular; type III lesions extend from the pial surface to cortical layer 3 or 4. Besides cortical gray matter involvement, there is also evidence for prominent basal ganglia involvement, which can be seen in the early stages of MS, and may correlate better with motor outcome and cognitive measures than measures of white matter involvement.

Lucchinetti and associates demonstrated that biopsy samples from newly diagnosed demyelinating cases contain numerous infiltrating immune cells, and can be destructive. The pathological classification of cortical lesions as described by Petersen can also be found in these early

MS biopsy samples. Approximately 20% of biopsy cases in which gray matter was also sampled had evidence of clear cortical demyelination.

In 2005, an extensive histological study by Kutzelnigg and associates investigated the role of cortical demyelination in all clinical subtypes of MS.¹⁹ In this study, 52 brains of MS patients (relapsing-remitting [RR], secondary progressive [SP], and PPMS) and 30 control subjects were studied using advanced quantitative morphological techniques. Cortical demyelination and diffuse axonal injury in the normal appearing white matter (NAWM) were reported as hallmarks of progressive forms of MS. Cortical demyelination was mainly seen in the subpial layer of cortex, and was associated with significant inflammatory infiltrates in the surrounding meninges. Diffuse inflammation was also found throughout the white matter of the progressive cases, associated with activation of microglia. No significant correlation was shown between focal white matter lesion load and cortical demyelination. This study defines three crucially important pathological hallmarks of MS—focal demyelinated white matter lesions, diffuse injury in the white matter, and cortical plaque formation—and concludes that white matter lesion formation predominates in active forms of MS, while cortical pathology and diffuse white matter injury characterizes the progressive forms. The authors of this landmark paper also established that these three processes are potentially independent of each other.

Hereditry. Epidemiological findings support a polygenic hereditary predisposition to MS. A number of candidate genes have been investigated, often with conflicting results. The only definitive genetic association in MS is with the serologically defined human leukocyte antigen (HLA) DR15, DQ6. This is one of the DR2 haplotypes, also known as Dw2 in cellular terminology and DRB1*1501, DQA1*0102, DQB1*0602 in molecular nomenclature. Though its link to MS is well established, the risk conferred by this haplotype is small (relative risk of 3 to 4), and it is neither necessary nor sufficient for the development of MS. Linkage to this locus has not been proved, indicating that it plays only a minor role in familial susceptibility. Other susceptibility genes likely contribute, possibly the T-cell receptor variable β region and the IgG heavy-chain variable region (especially the VH2–5 gene). But their specific roles have not been established. Other genes under study have been the MBP coding gene, the CTLA-4 gene on chromosome 2q33, and the interleukin-1ra associated gene, in concurrence with the HLA-DR15 haplotype. Mitochondrial mutations are also under investigation, and an LHON-associated mtDNA mutation may be an important cofactor in developing MS in some patients. The ApoE4 gene, as in Alzheimer's disease, has been associated with a higher incidence of MS. On the other hand, ApoE3 is considered to have neurotropic, immunomodulatory, and antioxidant properties. These findings are yet to be confirmed by larger studies.

Twenty percent of MS patients have at least one affected relative. Only about 4% of first-degree relatives of patients develop MS, but this represents a 20- to 40-fold increase in risk compared with the general population. Unaffected family members sometimes have abnormal findings on cranial MRI, implying that this risk is even higher. One study

of MS rates in adopted relatives of MS patients verified that the familial distribution is due to genetic factors rather than shared environment.²⁰ Twin studies lend support to both genetic and environmental influences on MS development. Genetically identical monozygotic twins are more often concordant for MS than dizygotic twins (26% and 2.4%, respectively), indicating a genetic component;²¹ however, even after following monozygotic twins past age 50 or using MRI data, less than 50% are concordant, suggesting a role for environmental factors.

EPIDEMIOLOGY AND RISK FACTORS. MS is not a rare disease. It affects millions worldwide and approximately 400,000 in the United States alone. Symptoms usually begin during young adulthood, with the peak onset at age 24. Approximately 0.3% of MS cases are diagnosed before age 15. Women are affected nearly twice as often as men. MS has a predilection for whites, especially those of northern European heritage. Other races and ethnic populations are resistant to a variable extent. MS is virtually unknown among black Africans but occurs in African-Americans at half the rate of whites, possibly due to racial admixture or environmental factors. MS is rare in tropical areas, and the prevalence increases proportionally to the distance from the equator, excluding polar regions. The prevalence is less than 5 cases per 100,000 in tropical areas; in high prevalence areas it can be higher than 30 per 100,000,²² reaching up to 100 per 100,000 in selected areas. Although usually interpreted as the effect of environmental factors, the prevalence gradient is at least partially due to racial susceptibility.²³

Perhaps the most incriminating evidence for the role of environmental factors in the development of MS is the changing risk with migration and the occurrence of MS clusters and epidemics. Immigrant populations tend to acquire the MS risk inherent to their new place of residence. Migration from high to low prevalence before the age of 15 lowers the MS risk, whereas migration after this age does not affect risk.¹⁸ Migration from low to high prevalence areas increases the risk of MS, but the effect of age is less clear. Many clusters of MS have been reported.^{24,25} The occurrences of MS epidemics in Iceland and the Faroe Islands have been proposed to be the result of exposure to a pathogen brought by British troops during their occupation in World War II. Other environmental factors associated with the development of MS include cigarette smoking (odds ratio of 1.81, CI: 1.1–2.9), animal fat intake, and deficiency of vitamin D.^{26,27}

Epidemiological data support the view that MS is caused or triggered by an environmental factor in persons who are genetically susceptible. The familial frequency and distribution implies that several genes contribute to susceptibility, and this is consistent with the low relative risk conferred by the genetic loci studied so far. Data from clusters, migration studies, and family studies reveal that there is a latent period of some 20 years between exposure to the environmental factor and the development of clinical symptoms and that the age at exposure is around 15, the putative age at acquisition.

The precise environmental events that lead to CNS demyelination are uncertain. Viral infection is the most plausible, but because of the nonspecific elevation of viral titers and long latent period, there is little direct evidence.

Minor respiratory infections precede 27% of relapses in patients with established MS. Measles infection was found to have occurred at a later age in MS patients than control subjects, although the incidence of MS has not been reduced by immunization against measles. Head injury and trauma have received attention as putative triggering events, but cohort studies have not verified any link. Pregnancy does not alter the risk of developing MS, but it does seem to influence disease activity. The annualized relapse rate drops from approximately 0.56 to 0.12 by the third trimester, but this is offset by an increase to 1.2 in the first 3 postpartum months. Most studies have found no long-term effects of pregnancy on the prognosis for progression or disability, although one did report a favorable effect.²⁸ A multitude of other environmental factors have been suspected to alter the risk for MS (cold climate, precipitation, amount of peat in the soil, exposure to dogs, and consumption of meat, processed meat, and dairy products), but none has been verified to be an independent risk factor.

CLINICAL FEATURES AND ASSOCIATED FINDINGS. MS can cause a wide variety of clinical features. Many signs and symptoms are characteristic, and a few are virtually pathognomonic for the disorder. Conversely, some symptoms are atypical and some are so rare as to suggest a different diagnosis (Table 48-2). The course of the illness is also variable, but it remains a critical consideration in the diagnosis of MS.

Sensory symptoms are the most common presenting manifestation in MS (21% to 55%) and ultimately develop in nearly all patients.²⁹ Loss of sensation (numbness), paresthesias (tingling), dysesthesias (burning), and hyperesthesias are common. These symptoms may occur in practically any distribution: one or more limbs, part of a limb, trunk, face, or combinations. The more distinctive sensory relapses of MS consist of the sensory cord syndrome and the sensory useless hand syndrome. A common scenario is that of numbness or tingling beginning in one foot, ascending first ipsilaterally and then contralaterally. The sensory symptoms may ascend to the trunk, producing a sensory level, or

may involve the upper extremities. Associated symptoms commonly include poor balance, weakness, urinary urgency, constipation, and Lhermitte’s sign (see later). Brown-Séquard syndrome may occur with sensory disassociation and hemiparesis. The sensory cord syndrome reflects an evolving demyelinating lesion that begins in the medial posterior column ipsilateral to the first symptoms. Sensory cord syndromes are common in MS and suggest the diagnosis when they occur in young persons and remit spontaneously or in response to corticosteroids. Patients with the sensory useless hand may note subjective numbness and lose discriminatory and proprioceptive function, resulting in difficulty writing, typing, buttoning clothes, and holding onto objects, especially when not looking at the hand. This problem can occur bilaterally even without lower extremity symptoms. The responsible lesion is in the lemniscal pathways either in the cervical spinal cord or in the brain stem. This syndrome usually remits over several months. The useless hand syndrome is a very specific symptom and is only rarely caused by other disorders.

A large portion of MS patients have persistent sensory loss, usually consisting of diminished vibratory and position sensation in distal extremities (Video 5, Sensory Ataxia). Itching may occur in a dermatomal distribution with relapse or in paroxysms. Pain is not a major manifestation of MS, but distressing lower extremity dysesthetic pain associated with spinal cord involvement, radicular pain from lesions at the root entry zone, paroxysms, and an uncomfortable sensation of pressure or tightness surrounding a leg or the trunk may be present.

Pyramidal tract dysfunction is common in MS and causes weakness, spasticity, loss of dexterity, and hyperreflexia (Video 80, Hyper-reflexia). Motor deficits can occur acutely or in a chronic progression with weakness of one or more limbs and facial weakness, leg stiffness that impairs gait and balance, or extensor and flexor spasms (Video 3, Spastic Gait). Exercise or heat frequently worsens subtle deficits. Muscle atrophy is usually due to disuse, but lesions of lower motor neuron fibers or of the anterior horn itself can cause a pseudoradiculopathy with segmental weakness, atrophy, and diminished reflexes. Motor symptoms are presenting manifestations of MS in 32% to 41% of all cases; their prevalence is higher than 60% in long-standing MS.

The initial symptom of MS is optic neuritis (ON) in 14% to 23% of patients, and more than 50% experience a clinical episode of ON during their lifetime. The most common manifestation is visual loss in one eye that evolves over a few days. Periocular pain, especially with eye movement, usually accompanies and may precede the visual symptoms. Bilateral simultaneous ON is uncommon in adults, but formal visual field testing reveals unexpected defects in the clinically normal eye in a substantial number of patients. Children and Asian patients are more likely to have bilateral simultaneous ON; it may also be seen in neuromyelitis optica (NMO) patients. Examination shows an afferent pupillary defect, diminished visual acuity, subdued color perception, and often a central scotoma (Video 200, Afferent Pupillary Defect). Funduscopic examination is usually normal but occasionally will reveal papillitis (more common in children) or venous sheathing. Most patients begin to recover within 2 weeks, and significant visual

TABLE 48-2

Diagnosis of Multiple Sclerosis

| CLINICAL FEATURES SUGGESTIVE OF MS | CLINICAL FEATURES NOT SUGGESTIVE OF MS* |
|---|---|
| Onset between ages 15 and 50 | Onset before age 10 or after 55 |
| Relapsing-remitting course | Continued progression from onset without relapses |
| Optic neuritis | Early dementia |
| Lhermitte’s sign | Seizures |
| Partial transverse myelitis | Aphasia |
| Internuclear ophthalmoplegia | Agnosia |
| Sensory useless hand | Apraxia |
| Acute urinary retention (especially in young men) | Homonymous or bitemporal hemianopia |
| Paroxysmal symptoms | Encephalopathy |
| Diurnal fatigue pattern | Extrapyramidal symptoms |
| Worsening symptoms with heat or exercise | Uveitis |
| | Peripheral neuropathy |

*Whereas features listed in the right column may be seen in MS, they are atypical and should prompt consideration of alternate explanations.

recovery is common. There may be persistent visual blurring, altered color perception, or Uhthoff's sign. MS patients without a clinical history of ON often have evidence of optic nerve involvement on fundusoscopic examination or visual evoked potentials. Recurrent optic neuritis can occasionally be seen without evidence for dissemination to other areas of the CNS. A retrospective study of 72 cases with recurrent ON concluded that the 5-year conversion rate to neuromyelitis optica was 12.5%; conversion rate to MS was 14.4%; while 73% did not convert to either condition. Patients with frequent and severe ON events in the first 2 years were more likely to convert to NMO; they also had a higher likelihood for significant persistent vision loss.³⁰

Cerebellar pathways are frequently involved during the course of MS, but a predominately cerebellar syndrome is uncommon at onset. The manifestations include dysmetria, dysdiadochokinesia (Video 12, Dysdiadochokinesia), action tremor with terminal accentuation, dysrhythmia, breakdown of complex motor movements, and loss of balance (Video 14, Tremor with Ataxia). Patients with long-standing MS may develop a "jiggling" gait and an ataxic dysarthria with imprecise articulation, scanning speech, or varying inflection, giving it an explosive character.

Urinary urgency, frequency, and urge incontinence (due to detrusor hyper-reflexia or detrusor-sphincter dyssynergia) result from spinal cord lesions and are frequently encountered in MS patients. The combined incidence of bowel and bladder dysfunction in MS is thought to be higher than 70%. Symptoms of bladder dysfunction may be transient and occur with an exacerbation but are commonly persistent. Impaired vesicular sensation causes a high capacity bladder and may lead to bladder atonia with thinning and disruption of the detrusor muscle. Incontinence results in constant dribbling of urine in this irreversible condition. Interruption of brain stem micturition center input sometimes leads to cocontracture of the urinary sphincter and detrusor muscles (detrusor-sphincter dyssynergia). The resulting high pressure may lead to hydronephrosis and chronic renal failure if untreated.

Constipation is a common problem, occurring in 39% to 53% of MS patients, especially with limited activity and spinal cord involvement. Fecal incontinence is a socially devastating symptom that is often associated with perineal sensory loss in MS patients.

Sexual dysfunction is seldom mentioned, even though it is a frequent problem in MS. Nearly two thirds of patients report diminished libido. One third of men have some degree of erectile dysfunction, and a similar percentage of women have deficient vaginal lubrication. Besides direct neurological impairment, sensory loss, physical limitations, depression, and fatigue additionally contribute to sexual difficulties in MS patients. In addition, the partner's attitude and psychological factors dealing with self-image, self-esteem, and fear of rejection may also lead to impotence or loss of libido.

Intense vertigo associated with nausea and emesis is an occasional manifestation of MS relapse. In the absence of a clear diagnosis of MS, these symptoms are often attributed to vestibular neuronitis. Patients may also develop a persistent but mild vertigo that is precipitated by movement, or this may be a residual finding after an acute relapse. Internuclear ophthalmoplegia, caused by a lesion in the

medial longitudinal fasciculus, is the most common cause of diplopia in MS patients (Video 200, Afferent Pupillary Defect). When symptomatic, it produces horizontal diplopia on lateral gaze that usually remits. Examination discloses incomplete or slow adduction of the eye ipsilateral to the lesion and nystagmus of the contralateral eye during abduction (see Chapter 9). Dissociated nystagmus may be the only finding of an old or subtle internuclear ophthalmoplegia (Video 19, Internuclear Ophthalmoplegia). Bilateral internuclear ophthalmoplegia is strongly suggestive of MS, although this rarely may occur with tumor, infarct, mitochondrial cytopathy, Wernicke's encephalitis, and Chiari malformation (Video 229, Wernicke's Encephalopathy). Vertical and diagonal diplopia usually results from skew deviation. Nystagmus, slow saccadic movements, broken ocular pursuits, and ocular dysmetria are other eye findings produced by lesions of cerebellar and vestibular pathways (see Chapters 9 and 12; Video 228, Saccadic Dysmetria). Abducens paresis occurs on occasion, but oculomotor and trochlear nerve impairment is rare.

Corticospinal, spinothalamic, lemniscal, vestibular, and cerebellar pathways can all be affected. Cranial nerve impairment may be seen with lesions that affect brain stem nuclei or exiting and entering fibers. Usually this occurs in association with other symptoms. Because of the long spinal tract and nucleus, the trigeminal nerve is frequently involved (Video 106, Trigeminal Neuralgia). Facial nerve paresis does occasionally occur, but MS is an extremely rare cause of Bell's palsy in patients without previous symptoms. Acute unilateral hearing loss is an uncommon manifestation. Dysphagia is often due to impairment of cranial nerves IX, X, and XII and generally appears late in the course of some patients.

Once thought uncommon, cognitive disorders are now known to be present in 40% to 70% of MS patients.³¹ Age, duration of MS, and physical disability do not completely predict the presence of cognitive dysfunction, but classic MRI measures like the total T2-weighted lesion load does not seem to correlate well with the degree of cognitive decline. Measures of cortical atrophy, ventricular enlargement, and neuronal integrity seem to correlate better with the cognitive aspects of MS. The problems are often subtle and may not be detected on standard mental status evaluation. The pattern of cognitive decline is typified by decrease of episodic memory, processing speed, verbal fluency, and difficulty with abstract concepts and complex reasoning. To a lesser extent, executive functioning and visual perception, semantic memory, and attention span may also be also decreased. General intelligence is not typically affected. As expected, cortical symptoms such as aphasia, apraxia, and agnosia are unusual. Homonymous hemianopia, which can be caused by cortical or subcortical lesions, is also uncommon. Despite prominent cerebral white matter involvement, many of the disconnection syndromes such as alexia without agraphia, conduction aphasia, and pure word deafness have not been reported in MS patients.

Affective disorders are more frequent in MS patients than in the general population. These include both anxiety and depression. In long-term studies, the incidence of depression in MS patients is close to 75%. Neither depression nor anxiety is related to physical or cognitive disability or

MRI lesion load. Patients sometimes experience uncontrollable weeping or less commonly laughter incongruent with their mood. Interruption of inhibitory corticobulbar fibers is responsible for these symptoms (pseudobulbar affect).

Fatigue is a pervasive symptom among MS patients that is not related to disability or depression. Over 75% of MS patients experience fatigue during their disease course. A diurnal pattern is characteristic and follows the normal circadian pattern of body temperature fluctuations, with the worse symptoms occurring in afternoon hours (peak core body temperature) often giving way to improvement in the late evening.

MS symptoms may fluctuate in a predictable fashion. Transient worsening of symptoms frequently follows exercise or elevation of body temperature. One example is Uhthoff's phenomenon, in which visual blurring occurs during strenuous activity or with passive exposure to heat. These episodes resolve when the body temperature cools to normal or after a period of rest. An intercurrent infection with fever can induce worsening of symptoms and may be confused with a relapse. Heat sensitivity is presumably related to conduction block, as demyelinated axons are more prone to failed conduction than normal, myelinated fibers.³²

Paroxysmal symptoms are characteristic of MS and are believed to be due to the lateral spread of excitation (ephaptic transmission) between denuded axons in areas of demyelination. Symptoms are typically brief (seconds to 2 minutes) and recur frequently, occasionally dozens of times per day. They may be precipitated by hyperventilation, certain sensory input, or particular postures. Tonic spasms (paroxysmal dystonia) most often affect the arm and leg on one side, but the face, one limb, or bilateral limbs are sometimes involved (Video 20, Tonic Spasms). These spasms may result from lesions anywhere along the corticospinal tract. They often begin during the recovery phase after an acute relapse and remit after a few months. Intense pain and ipsilateral or crossed sensory symptoms may accompany them. Paroxysmal weakness occurs, but it is uncommon. A wide variety of paroxysmal sensory symptoms may occur with MS, including tingling, prickling, burning, or itching, and sharp neuralgic pain is common. Trigeminal neuralgia may appear in patients with MS (Video 106, Trigeminal Neuralgia). The occurrence of trigeminal neuralgia in a person younger than age 40 is suggestive of MS. Lhermitte's sign (transient sensory symptoms usually precipitated by neck flexion) is usually described as an electrical or tingling sensation that travels down the spine or into the extremities. Although quite common in MS, Lhermitte's sign can also occur with a wide variety of other disorders, such as vitamin B₁₂ deficiency, spondylosis, Chiari malformation, and tumors, and after cisplatin chemotherapy. Several other paroxysmal symptoms are occasionally encountered, including paroxysmal dysarthria and ataxia, paroxysmal diplopia, and combinations of these symptoms. Facial myokymia and hemifacial spasm are additional transient (lasting months) phenomena sometimes due to brain stem demyelination (Video 110, Facial Myokymia; Video 224, Hemifacial Spasm). Trismus, kinesigenic dystonia, paroxysmal kinesigenic choreoathetosis, and segmental myoclonus have also been described in case reports of MS patients as rare and unusual examination findings.

Seizures occur in a larger proportion of MS cases compared to normal control subjects. A recently published review of 29 case series of MS patients with epileptic seizures yielded a prevalence of 2.3%.³³ This represents an approximately three- to sixfold increase compared to the general adult population. Cortical and juxtacortical lesions may be responsible for the increased incidence of seizures in MS patients. However, such plaques are common and seizures in MS are not, which suggests that other factors may also contribute to the relationship between epilepsy and MS. Focal motor seizures, possibly with secondary generalization, are the most frequent. The occurrence of seizures usually follows one of two patterns. On occasion, focal onset seizures begin early in the course of MS and later remit. The start of seizures late in the course of MS more often poses a chronic problem and may be difficult to control.

The eye is the only organ outside the nervous system that is sometimes involved in MS. Uveitis and retinal periphlebitis each occur in at least 10% of MS patients. In a recent study, most patients with MS-associated uveitis were white females between 20 and 50 years of age.³⁴ The diagnosis of MS preceded the onset of uveitis in 56%, followed it in 25%. In over 90% of the cases, the uveitis was bilateral. Pars planitis was found to be the most frequent form of uveitis (over 80%), and concomitant anterior chamber inflammation was also common. Usually MS-associated uveitis is benign from the standpoint of visual acuity. Uveitis can involve the posterior, intermediate (pars planitis), or rarely anterior portion and resembles that seen in other inflammatory (e.g., sarcoid, Reiter's syndrome, Behçet's syndrome, inflammatory bowel disease, systemic lupus erythematosus) and infectious (e.g., syphilis, tuberculosis, Lyme disease) conditions. Periphlebitis is seen as venous sheathing on fundoscopic examination and is histologically identical to the perivascular inflammation present in brain white matter. It is interesting that inflammation commonly occurs in the retina, which has a peripheral type of myelin produced by Schwann cells.

There are occasional reports of peripheral nerve or nerve root demyelination in MS patients as well as central demyelination in acute inflammatory demyelinating polyradiculoneuropathy and chronic inflammatory demyelinating polyradiculoneuropathy (see Chapter 49). Some of these cases may be due to the incidental occurrence of two unrelated disease processes. However, because the PNS and CNS share many antigens, including MBP, it is possible that an autoimmune reaction or a viral infection could involve both the CNS and PNS.

Persons with one autoimmune disorder generally have an increased risk of others. Even though there are several reports of systemic and organ-specific autoimmune diseases in MS patients, population-based studies have not confirmed any increase in prevalence of these disorders among MS patients.³⁵ In fact, there appears to be a negative association between MS and rheumatoid arthritis.

Multifocal CNS involvement and acute relapses, remissions, and slow progression of neurological deficits typify MS. A single episode of neurological dysfunction can be suggestive of MS if it follows the typical time course of a relapse: progression over less than 2 weeks (usually days), with or without a period of stabilization, and

improvement or resolution (often over months). Insidious progression of deficits localized to a single site in the CNS can also be due to MS, but other causes must be excluded. The temporal course of MS can be described by one of four categories: relapsing-remitting (RR), secondary progressive (SP), primary progressive (PP), and progressive relapsing (PR).³² Many physicians use the term *relapsing progressive*, which encompassed patients with SPMS, PRMS, and even those with RRMS who have stepwise relapse-related worsening disability. This term has recently been abandoned. Other terms that relate to the course of MS but have no consensus regarding their definition are sometimes encountered. *Benign MS* generally refers to patients who have had MS for a long time but have little or no disability. *Malignant MS* is sometimes used to describe patients with frequent relapses and incomplete recovery but is also used in reference to patients with acute fulminant demyelinating syndromes (see later). The term *clinically isolated syndrome* (CIS) refers to patients presenting with their first episode of region-restricted episodes of CNS inflammatory demyelination. This may remain an isolated syndrome (no recurrence), it may remain a *forme fruste* of acute disseminated encephalomyelitis (ADEM), or it may be the harbinger for one of the relapsing forms of MS. The probability of recurrent demyelinating episodes (e.g., clinically definite MS) has been the subject of several important investigations, and several clinical features and test results are of predictive value. Optic nerve, spinal cord, and brain stem are the most common sites of these recurrent monosymptomatic events, and the time profile follows that of MS relapses. The pathogenesis, pathophysiology, epidemiology, clinical features, associated disorders, differential diagnosis, evaluation, and management are the same as in MS.

The prognosis for visual recovery after each episode of ON is good, and most patients regain normal visual acuity. Profound visual loss, recurrent ON, and age older than 35 are associated with a higher risk for poor recovery. Investigators have concluded that recurrent multifocal demyelinating episodes, fulfilling the diagnostic requirements of clinically definite MS, develop in 50% or more of patients after isolated ON when follow-up is extended beyond 20 years.³⁶ Most of this risk is incurred within the first few years, although significant risk may continue into the fourth decade after the event. Children much more often develop simultaneous bilateral ON and have a lower risk for subsequent MS than adults. Factors that are associated with an increased risk of *developing* MS as a disseminated illness are the presence of venous sheathing, recurrent ON, family history of MS, white race, previous vague or non-specific neurological symptoms, and the presence of oligoclonal bands (OCBs), elevated IgG index, or IgG synthesis rate in CSF. The severity of acute transverse myelitis is inversely related to the risk of acquiring further symptomatic demyelinating lesions. Complete transverse myelitis with profound loss of motor, sensory, and sphincter function imparts a relatively low risk of 3 to 14 for the later diagnosis of MS. Partial transverse myelitis with preservation of significant motor function at peak is associated with a much higher incidence of MS. Although monosymptomatic brain stem demyelination is not as common as either ON or acute transverse myelitis, similar conclusions have

been reached. In the only study available, two thirds of these patients with cerebral white matter lesions detected on MRI developed MS within 5 years, compared with none of 5 patients with normal head MRI.^{37,38}

A recently published 10-year follow-up of the original Queen Square series continues to demonstrate the value of the baseline cranial MRI study in determining risk of recurrence (MS risk). In this cohort study of 81 CIS patients, approximately two thirds had at least one asymptomatic lesion (54 of 81, 67%) at baseline. After 5 years of follow-up, slightly more than half with one to three asymptomatic baseline cerebral lesions had developed MS (13 of 24) compared with the majority of cases presenting with at least four baseline lesions (28 of 33, 85%). After 10 years of follow-up, the majority of patients with any asymptomatic cerebral lesions had developed definite MS (45 of 54, 83%).³⁹ The recently published 14-year follow-up data on this group of patients reveals that 88% of the initially MRI positive patients developed MS versus 19% of the MRI negative subgroup.⁴⁰ This information is helpful for treating patients in the setting of CIS.

DIFFERENTIAL DIAGNOSIS. Only a few diseases cause neurological deficits that regress spontaneously and relapse in different areas of the CNS over the course of many years. However, because of the remarkable heterogeneity of MS, many disorders may resemble MS (Table 48-3), especially in the first years of active disease.

TABLE 48-3

Differential Diagnosis of Multiple Sclerosis

| | |
|--|---|
| Other inflammatory demyelinating CNS conditions | Cerebrovascular disorders |
| Acute disseminated encephalomyelitis | Multiple emboli |
| Neuromyelitis optica | Hypercoagulable states |
| Systemic or organ-specific inflammatory diseases | Sneddon's syndrome |
| Systemic lupus erythematosus | Neoplasms |
| Sjögren's syndrome | Metastasis |
| Behçet's disease | Lymphoma |
| Inflammatory bowel disease | Paraneoplastic syndromes |
| Vasculitis | Metabolic disorders |
| Periarteritis nodosa | Vitamin B ₁₂ deficiency |
| Primary CNS angiitis | Vitamin E deficiency |
| Susac's syndrome | Central (or extra) pontine myelinolysis |
| Eales' disease | Leukodystrophies (especially adrenomyeloneuropathy) |
| Granulomatous diseases | Leber's hereditary optic neuropathy |
| Sarcoidosis | Structural lesions |
| Wegener's granulomatosis | Spinal cord compression |
| Infectious disorders | Chiari malformation |
| Lyme neuroborreliosis | Syringomyelia/syringobulbia |
| Syphilis | Foramen magnum lesions |
| HTLV-1 associated myelopathy | Spinal arteriovenous malformation/dural fistula |
| Viral myelitis (HSV, VZV) | Degenerative diseases |
| Progressive multifocal leukoencephalitis | Hereditary spastic paraparesis |
| Subacute sclerosing panencephalitis | Spinocerebellar degeneration |
| | Olivopontocerebellar atrophy |
| | Psychiatric disorders |
| | Conversion reactions |
| | Malingering |

CNS, central nervous system; HSV, herpes simplex virus; HTLV-1, human T-cell lymphotropic virus type 1; VZV, varicella-zoster virus.

Other primary idiopathic inflammatory demyelinating CNS disorders may be mistaken for MS. ADEM usually causes monophasic CNS demyelination. Although it frequently involves multifocal areas of white matter simultaneously, ADEM cannot be reliably differentiated from the initial clinical episode of MS. Fulminant brain demyelination in persons without previous symptoms of MS is more likely due to ADEM or other conditions (Schilder's myelinoclastic diffuse sclerosis, Balo's concentric sclerosis, Marburg's variant of MS). Neuromyelitis optica differs from MS primarily in the topography and intensity of the lesions.

Several systemic or organ-specific inflammatory conditions can involve the CNS white matter. ON, myelitis, and other syndromes sometimes occur with systemic lupus erythematosus. Whether this autoimmune disease increases the risk of developing MS or causes similar syndromes by a different pathological process is unknown. Sarcoidosis can affect the nervous system in several ways, including multifocal, corticosteroid-responsive white matter lesions. Sjögren's syndrome sometimes occurs with MS, but this may only represent a chance association. Neuro-Behçet's disease has a predilection for the brain stem. Occasionally, isolated demyelinating syndromes are associated with inflammatory bowel disease.

A wide variety of vasculitic syndromes (e.g., primary angiitis of the CNS, periarteritis nodosa, Wegener's granulomatous angiitis, vasculitis associated with rheumatoid arthritis, Susac's syndrome, Eales' disease) may mimic MS. However, these syndromes can usually be distinguished by involvement of the cortex, seizures, early dementia, personality changes, psychosis, infarcts involving large vessel territories on MRI, and lack of improvement. Findings characteristic to the particular vasculitis (uveitis and vitreal hemorrhage in Eales' disease, retinal and cochlear involvement in Susac's syndrome, upper and lower respiratory tract involvement in Wegener's granulomatosis) also aid in the correct diagnosis.

A few infections must also be considered in the differential diagnosis of MS. Both Lyme disease and syphilis may cause multifocal white matter lesions. HTLV-1 causes a chronic progressive myelopathy (HTLV-1-associated myelopathy/tropical spastic paraparesis). Acute or recurrent myelitis can be caused by VZV. Progressive multifocal leukoencephalopathy and *Toxoplasma* abscesses should be considered in immunocompromised patients with progressive neurological decline. Bacterial endocarditis with brain abscess formation, subacute sclerosing panencephalitis, or chronic rubella encephalomyelitis may need to be considered in the appropriate circumstances.

Cerebrovascular disease is only rarely mistaken for MS. Occasionally, an MS relapse has an abrupt onset that may mimic an infarct, especially in those not previously diagnosed with MS. The usual circumstance is that of a hemisensory or hemimotor deficit imitating a lacunar infarct. Disorders with multiple cerebral infarcts (emboli, hypercoagulable states, Sneddon's syndrome, CADASIL, vasculitis) may produce an MRI appearance and course resembling MS. Vascular malformations may also produce symptoms similar to MS.

Additional neurological illnesses capable of producing multifocal lesions rarely mimic MS. Metastatic tumors

and multifocal gliomas are often cited examples, but rarely is this distinction difficult for an experienced clinician. Lymphoma more commonly masquerades as MS because the lesions may involve the white matter, may be multifocal, and are corticosteroid responsive. In addition, demyelination sometimes presents as one (or a few) mass lesion(s). In this situation, biopsy may be needed for diagnosis. Neoplasms can cause paraneoplastic syndromes that may be confused with MS. A high index of suspicion must be kept for older age at presentation, subacute ataxia, early dementia, and personality changes. A few metabolic disorders may resemble MS, such as vitamin B₁₂ deficiency, vitamin E deficiency (seen in Bassen-Kornzweig syndrome, hypobetalipoproteinemia, and Refsum's disease), and central pontine or extrapontine myelinolysis (Video 113, Pontine Myelinolysis). Leukodystrophies are usually not difficult to distinguish from MS. Krabbe's disease (galactocerebrosidase- β -galactosidase deficiency), metachromatic leukodystrophy (MLD; arylsulfatase A deficiency), and the usual adult form of adrenoleukodystrophy (ALD) and adrenomyeloneuropathy (AMN) exhibit both central and peripheral dysmyelination. Blood leukocyte or fibroblast culture enzyme activity levels will confirm the diagnosis of Krabbe's disease and MLD, and elevated levels of very long chain fatty acids occur in ALD/AMN. Mitochondrial disorders should also be given consideration because symptoms and MRI appearance may be similar to MS. A relapsing remitting disorder identical to MS is sometimes seen in patients with the mutations responsible for Leber's hereditary optic neuritis (LHON).⁴¹ This usually occurs in female patients, and there may not be a family history of visual loss. A number of rare biochemically defined illnesses and other genetic disorders may occasionally merit consideration (including cobalamin and folate dysmetabolism, adult polyglucosan body disease, hereditary spastic paraparesis, spinocerebellar degeneration, and hereditary cerebrotretinal vasculopathy).⁴²

Several additional disorders must be excluded before diagnosing primary progressive MS (PPMS). Spinal cord compression from spondylosis or tumor may produce chronic progressive myelopathy. Chiari malformations, syringomyelia, syringobulbia, other foramen magnum lesions, spinal arteriovenous malformations, and dural fistulas may also need consideration. Careful imaging readily identifies these structural abnormalities. Degenerative diseases such as olivopontocerebellar atrophy may mimic PPMS. MRI and CSF examination will help distinguish between the two.

Conversion reactions and somatization disorders are commonly encountered in a busy referral practice and must be accurately diagnosed to afford optimal patient management.

EVALUATION. The diagnosis of MS is based on the demonstration of white matter lesions disseminated in time and space in the absence of another identifiable explanation. MS remains a clinical diagnosis, although MRI, evoked potentials, and CSF examination can help clarify less certain cases. For research purposes, various categories of MS have been defined based on the certainty of the diagnosis.⁴³ At least two attacks and evidence of two separate CNS lesions (clinical or paraclinical) are required for the designation of *clinically definite MS* (CDMS). Two

attacks and evidence of one CNS lesion or one attack and evidence of two CNS lesions (clinical or paraclinical) is considered *clinically probable MS*. Cases that fulfill the criteria for clinically probable MS and have supportive CSF findings are labeled as *laboratory-supported definite MS*. Patients with a clear history of at least two attacks and supportive CSF but a normal neurological examination and no paraclinical evidence of CNS lesions are categorized as having *laboratory-supported probable MS*. Suspected cases that do not fit any of these criteria may be regarded as *possible MS*. Paraclinical evidence generally refers to abnormalities on evoked potential studies or imaging procedures.

As a result of increasing availability of refined paraclinical diagnostic modalities (especially MRI) and an overall better understanding of the disease process, new diagnostic criteria for MS were proposed by an international expert panel in 2001.⁴⁴ Three out of four of the following findings should be present on MRI: (1) one gadolinium enhancing lesion, or nine T2 hyperintense lesions; (2) at least one infratentorial lesion; (3) at least one juxtacortical lesion; and (4) at least three periventricular lesions.

According to the clinical diagnostic criteria, if a patient had two or more attacks with objective evidence on examination of two or more anatomical areas involved, no additional data is required to make the definite diagnosis. However, if such diagnostic studies were done and are not supportive of a diagnosis of MS, then the diagnosis should be reconsidered.

If a patient presents with a history of two or more attacks, but objective clinical evidence only suggests one lesion, the following additional data is needed to confirm the diagnosis: the disease process has to be disseminated in space as demonstrated by MRI; alternatively, two or more MRI-detected lesions consistent with MS plus positive CSF would suffice to meet the newly defined criteria. The clinician also may elect to await a further attack implicating a different anatomical site.

In case a patient had one attack, with objective clinical evidence of two or more lesions, dissemination in time as demonstrated by serial MRIs separated by at least 3 months or a second clinical attack would clarify the diagnosis. If a patient has a clinically isolated syndrome, or “monosymptomatic” presentation, the following criteria should be met: dissemination in space as demonstrated by MRI (again separated by at least 3 months), or two or more MRI-detected lesions consistent with MS plus positive CSF and dissemination in time on serial MRI scans, or a second clinical attack.

In case the patient presents with a progressive course, the presence of positive CSF is required, and dissemination in space should be present, as suggested by nine or more T2-weighted brain lesions, or two or more cord lesions, or four to eight brain lesions plus one cord lesion on MRI. Alternatively, abnormal visual evoked potentials (VEPs) with four to eight brain lesions, or fewer than four brain lesions plus one cord lesion, and dissemination in time on serial MRI scans, or continued progression for a year would meet the diagnostic criteria.

“Positive CSF” according to this set of criteria is defined by either the presence of oligoclonal bands detected by established methods (preferably isoelectric focusing on agarose gel followed by immunoblotting) different from

any such bands in serum, or by a raised IgG index. The presence of both enhancing and nonenhancing white matter lesions on a single MR image must not be used as evidence of dissemination in time as well as space, because these can also be seen in ADEM. Oligoclonal bands (OCBs) and an elevated IgG index provide supportive CSF findings.

Ancillary tests are frequently required to confirm the diagnosis of MS and to exclude other possibilities in uncertain cases. Laboratory tests on peripheral blood can help to exclude many of the infectious and other inflammatory disorders. A chest x-ray is generally needed to assess for sarcoid or paraneoplastic disorders if these are under consideration. An ophthalmological examination may be needed to search for alternative causes of visual loss. Imaging studies, CSF examination, and evoked potentials are often helpful because characteristic abnormalities are frequently present.

MRI of the head is the most sensitive imaging study for MS (Fig. 48-3). Focal areas of increased T2-weighted and decreased T1-weighted signal reflect the increased water content associated with demyelinated plaques. The MRI appearance of MS lesions, however, is not specific and similar abnormalities may be seen in normal aging, small penetrating vessel infarcts, Lyme disease, tropical spastic paraparesis/HTLV-1-associated myelopathy, sarcoid, systemic lupus erythematosus, Sjögren’s syndrome, mitochondrial cytopathies, vasculitis, and ADEM. The specificity for MS can be increased by consideration of lesion number, size, location, and shape.⁴⁵ This is especially important in persons older than age 50. MRI characteristics, other than the ones suggested by the international criteria outlined previously, are size larger than 6 mm, oval shape (often with the long axis directed perpendicular to lateral ventricles), and locations in the periventricular area, corpus callosum, and posterior fossa.

Longitudinal MRI studies have shown the evolution of MS lesions.⁴⁶ Gadolinium enhancement, indicating blood-brain barrier disruption, sometimes precedes the development of T2-weighted lesions and typically lasts for 4 weeks in the brain (occasionally longer, especially in larger hemispheric lesions), and perhaps somewhat longer in the spinal cord. FLAIR imaging is especially helpful for evaluating periventricular lesions that may go unnoticed on regular T2-weighted scans. The disadvantage of the technique is its relative insensitivity to posterior fossa lesions. Proton density weighted images are also part of the usual sets of images used in the MR diagnostics of MS. These images can be evaluated similarly to T2-weighted images. Technically, they are usually acquired together with the T2-weighted datasets, as a first echo in conventional fast spin echo sequences, where the subsequent echoes can be used for generating the T2-weighted images. New T2-weighted lesions have a fuzzy border and enlarge over a few weeks. After a period of stabilization, the T2-weighted lesion regresses and becomes more sharply delineated from the surrounding white matter as edema resolves. Most of the time, a residual abnormality with increased T2 weighting and decreased T1-weighted signal remains, reflecting demyelination and gliosis. The low attenuation T1 signal, or “T1 black hole,” is more often seen in secondary progressive MS and is thought to represent actual tissue loss.

Figure 48-3. Head MRI of patients with MS. **A**, T1-weighted sagittal image showing multiple hypointense periventricular lesions. **B**, Axial T2-weighted image showing confluent periventricular high-intensity lesions most prominent at the frontal and occipital horns. A focal lesion is also present in the posterior limb of the left internal capsule. **C** and **D**, Periventricular lesions suggestive of MS. **E**, A single large right cerebellar hemisphere lesion seen on T2-weighted MRI. **F**, Peripherally gadolinium-enhanced large right occipital white matter lesion. Enhancement can also be seen along the temporal horn of the lateral ventricles.

In several well-documented cases, hypointense lesions on T2-weighted scans were described in subcortical gray matter structures in MS patients. On a molecular level these areas are thought to represent iron deposition; their significance in MS is not fully understood. The MRI activity of disease, defined as either the number of new, recurrent, and enlarging lesions or the number of gadolinium-enhancing lesions, is usually higher than the clinical activity. This may be either because of the involvement of asymptomatic areas of the CNS or because of a pathophysiological difference between symptomatic and nonsymptomatic lesions based on the presence or absence of axonal dysfunction.

There is only poor correlation between disability and lesion load (volume of white matter abnormalities) determined by head MRI. Sometimes individuals have severe impairment and few MRI abnormalities, and the converse may occur. This disparity is partially explained by variable spinal cord involvement, but a pathophysiological difference may account for some of the discrepancy. Several MRI markers of gray matter involvement correlate better than measures of white matter pathology with clinical functional outcome measures in MS. In a recent study⁴⁷ EDSS showed the strongest correlation with gray matter volume loss and with T1 black hole volume increase ($p < 0.01$); both are considered to reflect neuronal and axonal pathology. Ambulatory function, assessed as the 25-foot timed walk, also correlated well with gray matter volume loss and T1 black hole volume. On normal appearing gray matter magnetization transfer ratio (MTR) histograms, normalized peak heights inversely correlated with EDSS in 18 RRMS patients ($r = -0.65, p = .01$).⁴⁸ In a study evaluating a number of MRI parameters (including brain T1-hypointense and FLAIR-hyperintense lesion volume, third ventricle width, brain parenchymal fraction and T2 hypointensities in the dentate nucleus), the best correlation with EDSS (and the only correlating parameter with 25-foot timed walk) was T2 hypointensity in the dentate nucleus.⁴⁹ In 41 MS patients, an MRI study concluded that gray matter atrophy correlated with clinical status (EDSS, 25-foot timed walking and disease duration).⁴⁷ A study of patients with PPMS and RRMS showed that neocortical volume as determined by MRI correlated with EDSS scores across all the patients, but the strength of the correlation was stronger ($p < 0.05$) in the PPMS ($r = -0.64, p < 0.0001$) than in the RRMS group ($r = -0.27, p = 0.04$).⁵⁰

MR spectroscopy is increasingly becoming an accepted diagnostic modality, where information can be obtained about the biochemical constituents of selected voxels of interest. With this technique, a cubic volume of interest is defined based on a regular MR image set. Simultaneous acquisition of multiple volume units is possible. With long echo time (TE) studies, NAA (*N*-acetylaspartate), choline, creatinine, and lactate peaks can be identified on the MR spectrum. With short TE studies, myoinositol, lipids, and some neurotransmitters may be identified. The resolution of the MR spectrum (the “number of lines” in the spectrum) is proportionate to the magnetic field strength used. NAA is the second most abundant amino acid constituent in the brain after glutamate. It is localized almost exclusively in neurons and axons. Creatinine is used as the “constant” peak in a MR spectrum, since it is the least likely to be altered by CNS-specific processes. Therefore, numeric

MRS data are usually presented as ratios related to creatinine. The NAA/creatinine ratio is decreased in areas of axonal or neuronal loss. It correlates well with disability. It can be decreased in normal appearing white matter, also in early stages of lesion formation, thus representing a challenge to the usual dogma of axonal loss being secondary to myelin damage. The decrease of the NAA/creatinine ratio may return to normal following the resolution of the acute phase. This process may be related either to reversibility of neuronal injury or to disappearance of edema in the involved areas. In general, more reduced NAA peaks are seen in progressive forms of MS with more profound tissue loss. If a relatively large hemispheric lesion shows decreased NAA content, similar findings may be seen in the other hemisphere in a “mirror” location. The lactate peak can be elevated in a variety of acute processes, and as such, carries relatively low specificity. The short TE spectrum is used less frequently; the “mobile lipid” peak (which is thought to represent macromolecular protein fragments) is increased in areas of acute demyelination.

Another newer MRI technique used in MS research is magnetization transfer imaging. The principle behind this imaging modality is relatively simple. In complex macromolecular systems, there is a baseline magnetization exchange in equilibrium between macromolecular protons and mobile protons. If the macromolecular protons are saturated before each excitation (and subsequent data acquisition) with a prolonged off-resonance broadband pulse, then the signal intensity of the image will be reduced owing to magnetization transfer exchange between the saturated (“bound”) and free (“mobile”) protons. By obtaining duplicate sets of images (with and without magnetization transfer pulse), a magnetization transfer ratio can be calculated. The ratio reflects the integrity of the macromolecular environment. It is reduced by approximately 3% to 5% in areas of edema, but it is more significantly reduced in areas of demyelination or axonal loss. If the ratio “normalizes” in a lesion, no subsequent tissue loss is usually seen on other imaging modalities. Despite these advantages, the magnetization transfer imaging is technically difficult because it produces variable findings depending on the technical environment and is not universally available. It has not become an accepted and standard technique for evaluation of MS patients. It may be very useful as a marker for remyelination and tissue repair in future neuroprotective or tissue restorative trials.

Diffusion-weighted imaging is well known from its widespread use in the diagnosis of ischemic stroke. This technique can show early stages of MS plaque formation. The increase in apparent diffusion coefficient correlates with acute plaques, and seems to best correspond with T1-enhancing lesions; this technique may show the lesions at an even earlier stage.

MRI has become an important component of clinical trials in MS. Because of the high sensitivity of MRI for disease activity, it is reasoned that periodic MRI may determine treatment efficacy more quickly than monitoring relapse rate or disability level. Many studies have used MRI as a secondary outcome, but clinical outcomes are still used as the primary outcome for definitive trials. Additional MRI techniques have also proved useful in the diagnosis of MS. MRI of the spinal cord shows discrete lesions in about

80% of CDMS patients. Several semiautomatic methods exist to determine lesion volume, ventricle volume, or hemispheric volume. These are generally applied for research purposes only, and are not part of the usual workup or diagnostic follow-up of MS.

CSF evaluation remains a valuable diagnostic tool for MS. A lymphocytic pleocytosis occurs during acute exacerbations in about one third of patients, but this seldom exceeds 50 cells. Eighty percent of the lymphocytes are CD3 positive. The ratio of CD4 to CD8 cells is 2:1. Less than 20% of the cells are B cells. CSF protein is normal in up to 60%; levels above 100 mg/dL are unusual and may suggest a different disorder. The proportion of γ globulin is high owing to the synthesis of immunoglobulins within the blood-brain barrier. The majority of CSF immunoglobulin is IgG, although IgM and IgA may also be elevated. Measures of intrathecal IgG production have been devised that are more useful than simple γ -globulin levels. The IgG index and synthesis rate are elevated in 70% to 90% of CDMS patients and occasionally in other disorders. Agarose gel electrophoresis, or the more sensitive isoelectric focusing of CSF proteins, often reveals discrete bands of immunoglobulin, each a monoclonal antibody. It is pertinent to compare serum and CSF banding patterns because peripheral monoclonal gammopathies may produce CSF bands. To reduce false-positive results, only unique CSF OCBs should be reported. Between 85% and 95% of clinically definite MS patients have OCBs; however, early in the course they are not as prevalent. Once present, OCBs persist and the pattern does not vary, although new bands occasionally appear. Unlike subacute sclerosing panencephalitis, in which the majority of OCBs are antibodies specific for measles virus, the antigenic specificity of OCBs in MS is unknown; they are unlikely to be pathogen specific or autoantigen directed; there is some evidence that they may be genetically determined germline antibodies. Five percent to 10% of noninflammatory CNS samples and 30% of inflammatory samples are also positive for OCBs.⁵¹ More detailed recommendations about the inclusion of CSF parameters to the diagnosis of MS were recently published⁵² suggesting that the cell count and differential should be completed within 2 hours. The new and recommended method for the detection of OCBs includes immunoelectrophoresis on agarose gel followed by immunoblotting. The reported sensitivity of this technique is above 95%, with a specificity of 86% to 87%. In other inflammatory or infectious illnesses, OCBs are often transient features. Their persistence is more suggestive of MS. The presence of myelin components, antimyelin antibodies, and kappa light chains in CSF has also been used in the diagnosis of MS. However, the sensitivity and specificity of these products is less than that of OCBs.

In late 2005, a new set of recommendations were published based on the first 5 years of using McDonald's criteria in diagnosing MS.⁵³ The original McDonald Criteria have been incorrectly interpreted by some as mainly relying on MRI for making a diagnosis of MS. In reality, the McDonald Criteria *cannot even be applied without careful clinical evaluation* of the patient. Neurological deficits must be evident to the examiner, and must be suggestive of MS. Scans that "look like" MS (and meet the criteria of Barkhof and Tintore) but have never been accompanied

by an obvious and documented neurological examination finding do not fulfill the McDonald Criteria. There was some sympathy among the International Panel members revising the McDonald Criteria to allow selected symptoms that are clearly and specifically enunciated by the patient (e.g., Lhermitte's symptom, trigeminal neuralgia, numbness ascending to the waist or higher) coupled with objective paraclinical (such as imaging and CSF) findings to be sufficient as an indicator of a prior or current attack needed for an MS diagnosis. However, the panel was *reluctant to endorse the diagnosis of MS in the absence of any objective clinical findings*, even if objective paraclinical findings are in place, at least until such a scheme is tested in prospective settings. Patients with imaging and CSF findings suggestive of MS but not showing any objective evidence for neurological deficits commonly seen in MS require careful clinical and radiological monitoring. Until objective evidence for neurological deficits are found, MS can not be diagnosed.

MS may be the correct diagnosis with less stringent imaging criteria than originally proposed; however, the panel was uncomfortable making changes that would allow MRI confirmation of dissemination in space based on lower stringency imaging criteria without appropriate prospective data. Most studies performed to date have been inadequately designed to address this issue. Advanced imaging technologies are constantly evolving and will likely one day be shown to aid in making the diagnosis of MS. Visualization of intracortical lesions, use of higher field strength magnets, and analysis of "normal appearing brain tissue," may be cornerstones of a future MRI criteria for MS. Preliminary evidence suggests that "occult" damage in normal-appearing white and gray matter seen with magnetization transfer, diffusion tensor imaging, or spectroscopy is an early feature of MS, whereas it likely does not occur in other demyelinating conditions such as acute disseminated encephalomyelitis and NMO.

Important changes have been made to the original definition of "dissemination in time" by MRI. In keeping with the definition that clinical relapses must be separated by at least 1 month, it was agreed that new T2 lesions on MRI should occur at least 30 days after disease onset. This means that any new T2 lesion occurring at any time point after a so-called reference scan performed at least 30 days after the onset of the initial clinical event is useful in meeting imaging diagnostic criteria for dissemination in time. It should be noted though that a new T2 lesion must be of sufficient size and location to exclude lesions that could have been missed previously for technical reasons of slice orientation, thickness or spacing, tissue contrast, patient motion, or other artifacts. This requires standardized scanning procedures with emphasis on careful repositioning, as well as input from *qualified evaluators experienced in MS imaging*. With the new revision, *there are two ways to show dissemination in time using imaging*: (1) detection of gadolinium enhancement at least 3 months after the onset of initial clinical event, if not at the site corresponding to the initial event; or (2) detection of a new T2 lesion if this appears at any time compared with a reference scan done at least 30 days after onset of the initial clinical event.

Spinal cord lesions can be important in differentiating MS from other white matter diseases; however, the original

McDonald Criteria did not provide sufficient guidelines for the use of cord imaging in MS. Spinal cord imaging that detects typical MS cord lesions (minimal or no swelling of the cord; clearly hyperintense on T2-weighted imaging; at least 3 mm in size, but less than two vertebral segments long; and occupying only part of the cord cross section) is particularly helpful if brain imaging does not detect dissemination in space in a patient suspected to have MS. For dissemination in space, a spinal cord lesion *is equivalent to, and can substitute for, a brain infratentorial lesion*, but not for a periventricular or juxtacortical lesion. An enhancing spinal cord lesion is equivalent to an enhancing brain lesion, and an enhancing spinal cord lesion *can "count" doubly in fulfilling the criteria* (e.g., a single enhancing spinal cord lesion can "count" for an enhancing lesion and an infratentorial lesion). Individual cord lesions can contribute together with individual brain lesions to reach the required nine T2 lesions to satisfy the Barkhof-Tintore criteria (the MRI criteria incorporated in the original McDonald's criteria). The panel recognized that diffuse cord changes may occur in MS, especially in the progressive forms; however, these changes are not sufficiently reliable to allow for their incorporation into the diagnostic criteria at this time. Repeat spinal cord imaging in patients without new symptoms of myelitis has a low yield in efforts to demonstrate dissemination of lesions in time. In other words, while it is common to see asymptomatic new brain lesions on repeated scans, new cord lesions generally do result in new neurological symptoms. Therefore, repeat cord imaging is recommended only to support an MS diagnosis *when there is a clinical reason to suspect a new cord lesion*.

Important changes have been proposed in diagnosing primary progressive MS. These Revised Criteria stress clinical and imaging (brain or spinal cord) evidence for diagnosis and place less emphasis on CSF findings. The new criteria for PPMS is as follows: (1) at least 1 year of disease progression (retrospectively or prospectively determined) (2) plus two of the following: (a) positive brain MRI (nine T2 lesions or four or more T2 lesions with positive VEP), (b) positive spinal cord MRI (two focal T2 lesions), (c) positive CSF (isoelectric focusing evidence of oligoclonal IgG bands or increased IgG index, or both).

Evoked potentials are summed cortical electrical responses to peripheral sensory stimulation that can be used to localize sites of disease and measure conduction velocity along sensory pathways. VEP and somatosensory evoked potentials (SSEPs) may detect subclinical sites of demyelination, thus providing evidence of multifocality. Brain stem auditory evoked potentials (BAEPs) are occasionally informative. More than 90% of persons with a history of ON have an abnormal VEP, and 85% of CDMS patients have abnormalities on VEPs even when the history of ON is absent. Slowed conduction is present on SSEP in nearly three fourths of patients with CDMS. BAEs are the least sensitive, with abnormalities in less than 50%. MRI has largely supplanted the use of evoked potentials in MS because of the greater sensitivity in the diagnosis and the detailed anatomical information it provides. In 2001, the American Academy of Neurology released practice parameters regarding the usefulness of evoked potential studies in MS. According to these recommendations, VEPs

are considered probably useful (class II evidence) to identify patients at increased risk for developing clinically definite MS. SSEPs are possibly useful, whereas the evidence for BAEPs supporting the diagnosis of CDMS is insufficient.

MANAGEMENT. There is no available prevention or cure for MS. Treatments focus on three areas: treating acute exacerbations and hastening their recovery; altering the natural history of MS; and providing symptomatic relief of current symptoms by enhancing physical abilities and preventing or treating complications. A fourth management topic concerns special treatment issues related to pregnancy.

Acute Exacerbations. Corticosteroids are the most commonly used treatment for MS, although there have been few studies to address their efficacy. Adrenocorticotropic hormone (ACTH) was shown to speed recovery from an exacerbation but had no effect on the ultimate degree of recovery. Because of the unpredictable cortisone response to ACTH, oral prednisone and later intravenous methylprednisolone became the preferred treatments. The Optic Neuritis Treatment Trial verified that intravenous methylprednisolone but not prednisone increased the recovery rate and unexpectedly increased the time to the next relapse, thus delaying the diagnosis of CDMS.⁵⁴ Moreover, the prednisone-treated group had twice as many recurrences. The finding was not replicated in a second study, but it has affected the practice of treating acute MS exacerbations. The current recommendation is to treat disabling attacks with 500 to 1000 mg of intravenous methylprednisolone per day for 3 to 5 days with or without a short tapering dose of oral corticosteroids. According to the practice parameters for steroid treatment of acute ON attacks released by the American Academy of Neurology in 2001, oral prednisone in doses of 1 mg/kg/day has no proven value. Higher dose of oral or parenteral methylprednisolone may result in quicker and more thorough recovery of visual function. There is no evidence of long-term benefit for visual function.

A study suggested that intravenous steroids may also have long-term effects on disease progression when given regularly.⁵⁵ In this study, RRMS patients randomized to receive regularly scheduled pulses of IV methylprednisolone (every 4 months for 3 years, then every 6 months for 2 years) demonstrated stability or improvement in disability measures, fewer "T1 black holes," and less brain atrophy than did control patients randomized to receive steroids only with relapses. These findings suggest a possible long-term benefit of pulsed IV methylprednisolone therapy on brain atrophy and disability. This as yet unconfirmed approach to long-term therapy might be considered a reasonable "control arm" in future phase III trials of experimental therapies.

Up to one third of patients do not have an adequate recovery after a relapse despite the use of corticosteroids. Plasma exchange (PLEX) alone was found beneficial in a substantial proportion of patients with severe inflammatory demyelinating episodes who had failed to improve following treatment with high-dose IV methylprednisolone.^{56,57} A randomized, sham-controlled, double-blind trial in 22 patients (seven exchanges over 14 days) without concomitant use of immunosuppressants in acute demyelinating events confirmed these findings.⁵⁸ Moderate or greater

clinical improvement was observed in over 42% of participants. A trial of seven PLEX treatments (alternate days) is a reasonable option for patients who fail to respond to conventional IV methylprednisolone therapy in acute, severe episodes of demyelinating diseases. The response to PLEX is stongly associated with the histological MS subtype.⁵⁹ Antibody and complement plays a crucial role in pattern II lesion formation. In a study of 19 biopsy-proven MS cases by Keegan and associates, 10 pattern II cases showed good response to PLEX, whereas 9 cases of pattern I or III did not respond at all to PLEX. Neuromyelitis optica, which is now considered an antibody-mediated condition with a known serological marker, also shows good response to PLEX: in a study by the Mayo group, 60% of NMO patients showed moderate or marked improvement to PLEX, and an additional 10% showed mild improvement.⁶⁰

Alteration of the Natural Course. The primary goal of drug treatment is to alter the natural course of the disease (e.g., reducing the frequency and severity of relapses, preventing the chronic progressive phase, and slowing the progression of disability). The disease activity seen on MRI is often used as a secondary outcome, although MRI measures currently correlate imperfectly with clinical outcome. Knowledge on altering the course of MS is largely restricted to three patient groups, those with clinically isolated syndromes, those with RRMS, and those with secondary progressive MS.

Before we discuss the known data in each of these demyelinating disease categories, it may be worth while to review the use of the most important evidence-based medicine (EBM) statistics that are applied to measure the magnitude of treatment effect. Relative risk reduction (RRR) is the metric most commonly cited in publications and promotional materials about clinical trials. The RRR is the degree that the treatment reduced the frequency of the outcome measure (experimental event rate, e.g., relapse, progression) compared with the control treatment (control event rate). The RRR is a ratio, not an absolute number, and is calculated as follows:

$$\text{RRR} = (\text{Control event rate} - \text{experimental event rate}) / \text{control event rate}$$

If the control event rate is low (making the denominator smaller), it will obviously inflate the RRR. An “impressive” 50% RRR may have a low biological significance if the outcome occurs infrequently. Therefore, the absolute risk reduction (ARR) should be calculated as this corrects for the frequency of the outcome.

$$\text{ARR} = \text{Control event rate} - \text{experimental event rate}$$

For most of the approved MS agents, the calculated ARR is considerably less than RRR. This metric is usually not cited in reports of clinical trials of disease-modifying agents. To calculate risk reduction, one must have access to the data citing comparisons of proportions (ratios), and this is not always immediately available in publications.

Another useful measure of treatment effect is the “number needed to treat” (NNT). It is calculated as the inverse of the ARR:

$$\text{NNT} = 1/\text{ARR}$$

Overall, the NNTs for the disease-modifying agents in MS are in the 7 to 14 range for treatment periods of 2 to

3 years. However, these NNTs are for outcomes that have limited predictive value for long-term outcomes (e.g., relapse behavior does not precisely predict long-term disability) and the agents are expensive, inconvenient to use, and not without risk. We must also remember that clinical trials typically enroll patients with very restricted eligibility criteria (often a history of considerable recent disease activity or progression), and considerable efforts are in place in trials to optimize compliance with the treatment plan. As such, the NNT experienced in a practice setting (effectiveness) may considerably exceed what was reported in the trial setting.

Altering the Course of a Clinically Isolated Syndrome.

When should treatment be initiated in patients with very early demyelinating disease? Two recently published multicenter studies have addressed this issue in persons at high risk of developing MS. In the CHAMPS study,⁶¹ 383 patients with their first episode of presumed demyelinating disease (“clinically isolated syndrome”) in the setting of an abnormal, asymptomatic baseline cranial MRI scan, were randomized to receive either weekly interferon- β 1a 30 μ g IM or placebo after an initial course of steroid therapy. This study was terminated early when the primary outcome measure of conversion to “clinically definite MS” (CDMS) status was reached in a greater number of placebo-treated patients. These findings were not unexpected given the known effect of interferons on reducing relapse rate but do provide some support for early treatment. The duration of follow-up in this study (71% 1 year, 34% 2 years, 16% 3 years) is insufficient to determine long-term benefit from early intervention, however. It is also clear that the treatment is only partially effective, as 50% of interferon (IFN)-treated patients in the CHAMPS trial had clinical or MRI evidence of recurrent disease within 18 months of starting treatment.⁶² The analysis of treatment effect related to the CHAMPS trial reveal a RRR of 38%, an ARR of 14.6%, and an NNT of 7 patients over 2 years to prevent one conversion to “clinically definite MS.”

In a second placebo-controlled study of 309 patients with either monosymptomatic (61%) or multifocal onset (39%) early demyelinating disease, early treatment with interferon- β 1a in an unusually low dose (22 μ g subcutaneously once weekly), reduced conversion to CDMS (34% versus 45%) at 2 years.⁶³ Again, there is no data on whether these treatments offer long-term benefit. The EBM calculations regarding this trial show a RRR of 24%, and ARR of 11%, and an NNT of 9 patients over 2 years in order to prevent one conversion to “clinically definite MS.” These two studies provide support for considering early treatment in patients presenting with first attack, in the presence of multiple asymptomatic MRI lesions, but further studies are needed to determine whether this approach will provide a prolonged benefit on disease course. It is important to note that these studies do not provide guidance about clinically isolated syndromes that present with a brain MRI that is not suggestive of MS (i.e., only one optic nerve lesion, or one brain stem or cord lesion explaining the CIS symptoms). We do not recommend that CIS patients with fewer than two asymptomatic MRI lesions receive treatment with interferons. Please see the discussions under “Summary of Recommendations for the Treatment of RRMS Patients” for further advice on patient counseling and decision making about the use of the disease-modifying medications.

Altering the Course of Relapsing-Remitting Multiple Sclerosis

β -Interferons. Interferons are a class of peptides that have antiviral and immunoregulatory functions. Both interferon- α and interferon- β are part of the anti-inflammatory T_H2 response. Interferon- β 1b (Betaseron) was the first drug approved by the U.S. Food and Drug Administration (FDA) specifically for the treatment of MS. A large clinical study in RRMS patients demonstrated a reduction in the frequency of relapses by about one third with subcutaneous injection every other day.⁶⁴ The severity of relapses was also lessened. Interferon- β 1b had a striking effect on MRI measures of disease activity. The placebo-control group continued to accumulate white matter lesions, whereas patients in the high-dose arm (8 million IU) had stabilization of their MRI lesion load. No difference was found in the disability levels, however. Side effects include injection site reactions, flu-like symptoms (low-grade fever, myalgias, headache; these lessen in frequency after treatment for a few months), mild liver enzyme elevation, and lymphopenia. Depression and attempted suicide were more common in the treated groups.

To illustrate the magnitude of treatment effect of the pivotal interferon- β 1b trial, the RRR was 18%, the ARR was 15%, and the NNT analysis showed that 7 patients are needed to be treated over 3 years to increase the number of those who were relapse free by one. One particularly disturbing result was the production of neutralizing autoantibodies (NAbs) in 38% of patients after 3 years of treatment. Not only do patients with these antibodies thereafter fail to respond to this drug, but there is also a concern that NAbs may cross-react with natural interferon- β and interfere with its function. All positive sera for NAbs seem to cross-react with both interferon- β 1a and 1b. Switching from one preparation to the other does not change the pattern of antibody response.⁶⁵ The long-term effects of NAbs are unknown. Recent studies seem to support that NAb formation reduces clinical and MRI effects although often NAb formation subsides with time. There are no firm guidelines for monitoring NAb formation. Most physicians do not measure NAbs but rather change therapies empirically when patients appear to be failing treatment. Low titer Nabs may be just transient phenomenon related to IFN treatment; persistent high titer NAbs on two consecutive tests at least 6 months apart is likely associated with poor treatment response to INF.

Interferon- β 1a (Avonex) has the same amino acid sequence as natural interferon- β and differs from interferon- β 1b by one amino acid as well as by the presence of carbohydrate moieties. Once-weekly intramuscular interferon- β 1a has been found to have effects similar to that of interferon- β 1b in reducing the frequency of MS relapses. In addition, a favorable effect on disability was also demonstrated and side effects were less common. In the original interferon- β 1-a intramuscular trial, the primary outcome measure was time to EDSS progression. The RRR was 37%, the ARR was 13%, and the NNT was 8 for 2 years to prevent one patient from developing EDSS progression. The calculations for "proportion relapse free" show an RRR of 16%, and ARR of 12%, and an NNT of 8 over 2 years (8 patients need to be treated for 2 years to increase the number of patients who were relapse free

by one). NAbs occurred half as often as with interferon- β 1b. Interferon- β 1a has been approved by the FDA for treatment of "relapsing MS."⁶⁶

The "correct" dose of interferon continues to be debated. In a recent placebo-controlled trial, patients randomized to a high dose of interferon- β 1a (44 μ g three times per week) did better than those receiving half this weekly dose. Both groups outperformed placebo and the high dose seemed to have more effect on relapse severity, hospitalizations, MRI activity, and lesion volume accumulation, and possibly on delaying disability in the most severely disabled patients. At the end of the 2 years of follow-up, placebo-treated patients were randomized to 22 or 44 μ g subcutaneously three times weekly; patients on active treatment were continued on their original dose.⁶⁷ The authors reported a benefit for the higher dose and for those treated for the full 4 years, again suggesting that early treatment and perhaps higher doses of interferons may be beneficial. The primary outcome, however, was relapse count per patient per 4 years and, as such, patients treated early had a significant advantage using this outcome measure. There were trends favoring the higher dose (relapse rate, MRI volumes; not for time to first confirmed progression, however). The authors did not make statistical adjustments for multiple comparisons and there were many dropouts in the high-dose groups, making it difficult to draw firm conclusions. Again, the answer to the question about the benefit of early treatment can best come from long-term (perhaps 8 to 10 years) studies using "hard outcomes" (e.g., time to progression, major milestones in disability). The EBM calculations based on the "proportion relapse free" data for the original interferon- β 1a (Rebif) study show an RRR of 19%, and ARR of 16%, and an NNT of 6 over 2 years to increase the number of relapse free by one. Relative treatment advantages of interferon- β 1a and 1b have not been clearly established but are under study.^{68,69} A pilot study in RRMS patients suggests that interferon- α may also have a therapeutic effect.⁷⁰ A study of interferon responders showed that younger patients with frequent relapses, and higher EDSS scores upon entry may be associated better response.⁷¹

Laboratory Monitoring of Interferon Products. It is important to note that even though the interferon products are generally safe to use, they can be associated with potentially harmful adverse reactions. We recommend that every newly starting patient should have a baseline complete blood count, liver function tests, and thyroid-stimulating hormone (TSH) test. The liver function tests and blood count studies should be repeated in 1 week, 1 month, and every 3 months thereafter; the TSH should be repeated every 6 to 12 months.

Glatiramer Acetate. Glatiramer acetate (GA) is a synthetic mixture of polypeptides produced by the random combinations of four amino acids that are frequent in MBP. After a preliminary study suggested efficacy,⁷² a phase III randomized, double-blind, placebo-controlled, multicenter trial showed a 29% reduction in relapse rate.⁷³ The FDA has approved this medication for use in RRMS. Even though this disease-modifying therapy requires daily subcutaneous administration, the side effects are relatively minor compared to the interferons, and patients do not need regular laboratory monitoring (Table 48-4). Glatiramer acetate reduces new lesion formation, the number of T2-enhancing

TABLE 48-4

Therapeutic Options in MS

| MS TYPE | AGENT | DOSAGE | PROVEN BENEFITS | ADVERSE EFFECTS | MONITORING |
|---------------------|--|---|--|---|---|
| Acute episodes | Methylprednisolone (Solu-Medrol) | 500–1000 mg IV for 3–7 days | Hastens recovery Effects on blood-brain barrier (transient restoration) Long-term effects (as of yet uncertain) | Usual steroid-related side effects | As usually with short-term steroid therapy |
| | Plasma exchange | 7 exchanges every other day | Promotes recovery in patients not responding to high-dose IV steroids | Problems with venous access site (hematoma, bleeding, pneumothorax); Anemia (usually asymptomatic); Risk of infection and sepsis Fatigue, thrombosis, hypotension Citrate toxicity (perioral numbness) Heparin-associated thrombocytopenia Flulike symptoms | CBC before therapy and at regular intervals |
| Relapsing-remitting | Interferon-β 1b (Betaseron, Betaferon) | 8 million IU subcutaneously every other day | Relapse rate reduction MRI benefits: reduces development of new lesions, delays increase in volume of lesions | Hepatotoxicity Leukopenia, anemia, thrombocytopenia Myalgias, depression, anorexia Menstrual disorders Hypocalcemia, injection site reaction, necrosis, neutralizing antibodies, pregnancy category C | CBC and LFT before therapy, every week in the first month, every month in the first 3 months, then every 3 months |
| | Interferon-β 1a (Avonex) | 30 µg IM once weekly | Relapse rate reduction May delay progression of disability MRI benefits: reduces development of new lesions, delays increase in volume of lesions | Flulike symptoms Hepatotoxicity Anemia, eosinophilia Syncope Depression Nausea, dyspepsia, anorexia Neutralizing antibodies Injection site reaction, necrosis Pregnancy category C | CBC and LFT before therapy, every week in the first month, every month in the first 3 months, then every 3 months |
| | Glatiramer acetate (Copaxone) | 20 µg SC daily | Relapse rate reduction Moderate, delayed MRI effects | Pain/edema at injection site Flushing Transient chest pain Transient dyspnea Transient eosinophilia Facial edema Palpitations Nausea, anorexia Anxiety Vasodilation Lymphadenopathy Pregnancy category B | None |
| | Interferon-β 1a (Rebif) | 22 µg or 44 µg SC every other day | Relapse rate reduction MRI benefits: reduces development of new lesions, delays increase in volume of lesions Possible dose-related benefit in patients with more severe disease | Flulike symptoms Hepatotoxicity Anemia, granulocytopenia, lymphopenia Blocking antibodies Injection site reaction Pregnancy category C | CBC and LFT before therapy, every week in the first month, every month in the first 3 months, then every 3 months |

Therapeutic Options in MS—cont'd

| MS TYPE | AGENT | DOSAGE | PROVEN BENEFITS | ADVERSE EFFECTS | MONITORING |
|----------------------------|--|---|---|---|---|
| Relapsing-remitting—cont'd | Intravenous immunoglobulin (IVIG) | 0.15–0.2 g/kg IV every 2 months for 2 years | Relapse rate reduction One phase III trial to date | Hyperviscosity syndrome Aseptic meningitis Headaches Neutropenia Anemia Pseudohyponatremia Renal failure | IgA level before therapy Renal function tests before therapy and at regular intervals |
| Secondary progressive | Interferon-β 1b (Betaseron, Betaferon) | 8 million IU subcutaneously every other day | Reduces disability regardless of relapse rate Relapse rate reduction MRI benefits | See above | See above |
| | Mitoxantrone (Novantrone) | 5 or 12 mg/m ² every 3 months Not to exceed 100–140 mg/m ² cumulative lifetime dose (cardiac toxicity) | Relapse rate reduction Delays progression of disability MRI benefits | Cardiomyopathy Menstrual disorders Leukopenia Nausea, vomiting Urticaria, skin rash Acute leukemia Pregnancy category D | Echocardiogram to determine EF before initiating therapy and every 6 months, more frequently if cumulative dose to exceed 100 mg/m ² ECG LFTs before each infusion CBC before each infusion |

CBC, complete blood count; ECG, electrocardiogram; LFT, linear function tests; MRI, magnetic resonance imaging.

lesions, lesion volumes, and the percentage of new lesions that will evolve into T1 “black holes,” although the MRI effect may be less pronounced compared to the interferon products, and is not apparent until the agent has been used for at least 6 months.⁷⁴⁻⁷⁶ The EBM calculations for GA using the “proportion relapse free” data show an RRR of 10%, ARR of 7%, and an NNT of 14 over 2 years to increase the number of relapse free by one.

Combined Azathioprine and Interferon- β 1b. A small trial at NIH showed significant reduction in the number of contrast-enhancing lesions when azathioprine in an average maintenance dose of 2 mg/kg/day was added to interferon- β 1b in a study of six RRMS patients followed for a median period of 15 months. The addition of azathioprine may be considered in “treatment failure” cases, but this study was hampered by the small number of patients, no control subjects, and no blinding.⁷⁷

Intravenous Immunoglobulin. Monthly treatment with low-dose (0.15 to 0.2 g/kg) intravenous immunoglobulin (IVIG) in RRMS patients resulted in fewer and less severe relapses in addition to slowing the accumulation of disability in a single randomized trial. The outcome was similar to that of injectable interferons.⁷⁸ This therapy is less accepted in the United States. More studies with larger number of patients and extended follow-up are needed to confirm these limited observations. Recent studies have failed to demonstrate that IVIG administration reverses long-standing deficits from MS and ON.⁷⁹⁻⁸¹ IVIG was also recently studied in acute ON and failed to demonstrate benefit on any of the outcome measures.⁸²

Natalizumab. In late 2004, natalizumab was approved for the treatment of RRMS.⁸³ Natalizumab is a humanized α -4 integrin antibody that inhibits the migration of all leukocytes (except for neutrophils) to target organs. A phase 2 study established⁸⁴ that a 300-mg monthly dose reduced the number of gadolinium-enhancing lesions by 90% and the clinical relapse rate by over 50% compared to placebo. This study was followed by the AFFIRM and SENTINEL phase III studies. The AFFIRM study enrolled over 900 patients with RRMS; none of them had been on other approved immunomodulators for longer than 6 months. The annualized relapse rate at 1 year was reduced from 0.74 in the placebo group to 0.25 in the treated group (66% relative reduction, $p < 0.0001$). The proportion of relapse-free patients was 76% in the treated group, 53% in the placebo group. The number of enhancing lesions was reduced by 92%, and the number of new or newly enlarging T2 lesions was reduced by 80%. The proportion of patients without clinical and MRI activity was 46% in the natalizumab group, and 14% in the placebo group. In the SENTINEL trial, the combination of intramuscular interferon- β 1a and natalizumab was studied against IM interferon- β 1a and placebo in patients who had demonstrated an incomplete response (relapse suppression) to interferon therapy. The EBM calculations of the AFFIRM data based on proportion with relapses suggests an RRR of 49%, an ARR of 23%, and an NNT of 4 over 1 year to increase the proportion of relapse free by one. The SENTINEL data shows an RRR of 31%, an ARR of 17%, and an NNT of 6 over 1 year to increase the proportion relapse free. The original pilot trial data shows a RRR of 50% and an ARR of 19%, with an NNT of 5 over 6 months to increase

the proportion relapse free. Based on these data, the FDA granted expedited approval of natalizumab on November 23, 2004.

On February 28, 2005, the medication was voluntarily withdrawn from the market by the sponsor (Biogen-Elan) after two cases of progressive multifocal leukoencephalopathy (PML) were reported in the SENTINEL study cohort.⁸⁵ Both patients were in the combined interferon and natalizumab arm. A third PML case was later identified from one of the phase III inflammatory bowel trials of this agent. At the time of writing this manuscript, natalizumab is still off the market. The natalizumab story has received significant media attention. Several consequences can be drawn from this failure. First, highly potent immunomodulators like natalizumab are best used by specialists in selected cases. A large number of prescriptions were written for natalizumab during its short 3 months on the market, including prescriptions by general practitioners. Widespread use of such medication in relatively stable cases of MS is not indicated. Second, the combination of potent immunomodulators may result in unpredictable adverse outcomes. Many MS experts anticipate that in the future MS therapies will need to be administered in combination to optimize therapeutic benefit. However, the exact effect of such combinations on the highly complex immune system is difficult if not impossible to predict. Furthermore, our inability to treat MS more effectively does not stem from the fact that we can not provide powerful immunosuppression, as evidenced by the autologous bone marrow transplantation studies. MS is a complex disease with a prominent inflammatory component; however, increasing evidence suggests that the neurodegenerative component of this illness may be independent of the inflammatory component, and is just as important, if not more important, from the standpoint of long-term disability. Third, in chronic diseases such as MS, a short 1-year trial, no matter how convincing the outcome may be, should not be considered sufficient to approve a medication, which will then be used in tens of thousands of patients on a “lifelong” basis. There clearly is a need for new and more effective medications for treating MS; however, clinical trials in chronic conditions are very difficult to sustain. To overcome this, many MS trials use primary MRI outcome measures, since inflammation and new lesion formation-related MRI markers respond more immediately to treatment; however, these markers do not correlate well with long term disability, as discussed earlier.

Summary of Recommendations for the Treatment of RRMS Patients. When making decisions about starting an MS patients on immunomodulators, several factors must be considered. One must realize that even though there are medications available for relapsing forms of MS, all the currently available therapies are only partially effective, the most reliable data is about short-term relapse rate reduction, and a relapse rate reduction does not necessarily translate into reduction of future disabilities. Natural history data clearly suggest that a subset of MS patients will do very well without treatment (see discussion about the Olmsted County cohort later); this information can be very useful when deciding about treatment in patients with a 5- or 10-year disease history and minimal disability (EDSS \leq 2.0). In this patient group, a careful wait and see approach with appropriate monitoring is acceptable. Counseling of

newly diagnosed MS patients is of crucial importance, and it should usually include family members. Most patients have easy access to an abundance of frequently misleading information on the Internet, or from relatives and friends with MS. It is important to realize that every case is different; however, through the rational use of natural history data, clinical and MRI features of the specific case, and the clear understanding of the available clinical trial data, the clinician should be able to provide customized and relevant advice to patients and families. Considering that the treatments are only partially effective, the wishes of an educated patient constitute an important part in the decision-making process. Ultimately, the treatment decisions should remain individualized between the patients and their treating physicians, and the physician's role as an information clearinghouse and educator cannot be overemphasized in this process.

The three interferon products and GA represent the most commonly used MS immunomodulators in the United States; therefore, it is important to draw some practical conclusions about these agents. By now, several class I studies demonstrate that these agents are effective in reducing the relapse rate in RRMS over a 2- to 3-year period; the reduction is roughly 30% with the high-dose interferons and GA. The above-mentioned NNT data are also very useful for the clinician and the well-informed patient when making treatment decisions. There is evidence for a dose-response relationship among the interferon products, mostly from the EVIDENCE and INCOMIN studies. The double dose IM interferon- β 1a study did not show a dose-response relationship; this may be related to the fact that the increased dose was given with the same frequency as the standard dose. The injectable immunomodulators have incomplete evidence for efficacy in disability-based outcome measures. Many of the long-term extension studies suffer from several drawbacks, including open label unblinded design, significant dropout rate, and lack of control subjects; this is especially true for the GA extension data. The currently available few head-to-head comparison studies are also hampered with methodological issues; new comparative studies are under way. Overall, these agents remain partially effective in relapsing forms of MS; their long-term effects on reducing the clinically most important feature of MS—disability—still remains unclear.

Altering the Course of Secondary Progressive MS. Within 15 years of onset, almost 60% of RRMS patients will enter the secondary progressive phase of the disease. Treatment approaches aimed to affect the natural course of disease are available for these patients.

Interferons. Interferon- β 1b may have a beneficial effect on the overall outcome of SPMS and may also alter MR lesions,^{86,87} but this question remains incompletely answered. In the placebo-controlled European study⁸⁸ of interferon- β 1b in SPMS, the time to worsening was extended for treated patients. Treated patients were less likely to be wheelchair-bound and had fewer hospitalizations. Another analysis⁸⁹ of this study confirmed the benefits, though the dropout rate in this study was relatively high. The patients who responded best to interferon therapy were those who experienced relapses during their disease course. MRI monitoring suggested that the benefit on T2 lesion activity was seen early and persisted into the second half of the second year of treatment. T2 lesion load increased in

placebo- but not interferon-treated patients in the first 2 years of treatment.⁹⁰

Contrasting with these results, in another trial involving patients with SPMS,⁹¹ both high dose (44 μ g) and lower dose (22 μ g) interferon- β 1a failed to change the primary outcome of time to disability worsening. Positive effects were seen on relapse rate and reduction of MRI activity, but the effect on disability did not replicate the European interferon- β 1b report. A combined analysis of the American and European trials concluded that continued relapse activity and more rapid progression over the preceding year (by >1 on the EDSS scale) are the best predictors of response.⁹²

IVIG in Secondary Progressive MS. A recent European trial reported that IVIG did not have a significant impact on clinical and disability related outcome measures. IVIG did reduce the accumulation of brain atrophy in SPMS, but did not reduce the incidence of blood-brain barrier abnormalities. There was no statistically significant change on magnetization transfer MRI measurements; however, a trend for conservation of normal-appearing brain tissue was found.⁹³

Overall Recommendations for SPMS. In general, as the evidence that interferons alter long-term disability is limited and controversial, we generally do not newly start SPMS patients on interferon products. In a subset of patients still having disabling relapses, interferon therapy may be offered to specifically reduce relapse rate. The data by Confavreux and associates, however, suggest that the EDSS in populations of SPMS patients continues to progress independent of relapses⁹⁴ once a “fixed” baseline level of moderate disability has been reached. Therefore, while interferons may reduce the relapse rate in SPMS, the rate of progression of disability may not be reduced by these treatments. More usually, SPMS patients are already on an injectable immunomodulator, and the question of whether it is worth continuing the therapy may come up, especially in patients who have a hard time tolerating these medications and feel that the side effects of the medications have a clear negative impact on their overall health. In these cases, we usually allow the patients to stop their medications. Just like in the RRMS cases, however, patient education about SPMS trials and realistic expectations about the treatment is a crucial element in the decision-making process. Understanding the patient's needs and fears and clarifying potential misconceptions constitute a very important role of the treating neurologist. In those patients who continue their interferon therapy, we must continue to follow them for toxicity and disease activity. Please also see the following discussion under mitoxantrone for recommendations on the potential use of that specific agent in SPMS.

Mitoxantrone. Mitoxantrone (Novantrone) is an anthracenedione chemotherapeutic agent licensed

...for reducing neurologic disability and/or the frequency of clinical relapses in patients with secondary (chronic) progressive, progressive relapsing, or worsening relapsing-remitting multiple sclerosis (i.e. patients whose neurologic status is significantly abnormal between relapses). Mitoxantrone is not indicated in treatment of patients with primary progressive multiple sclerosis.

Significant benefits were observed in a group of SPMS patients as in a European phase III study of mitoxantrone.⁹⁵ It has also been used in combination with methylprednisolone.⁹⁶ Several clinical and functional outcome measures

were reported to stabilize or improve with every 3-month administration of this intravenous medication. Secondary MRI outcome measures, including enhancing lesion formation and overall T2 lesion load, were also better in the treated patients. The greatest concern regarding this medication is its cardiac toxicity: the cumulative lifetime maximum dose was established at 140 mg/m². Mitoxantrone can induce a seemingly dose-dependent cardiomyopathy, leading to potentially fatal congestive heart failure. We generally avoid exceeding a total lifetime dose of 96 mg/m² (8 doses of 12 mg/m²). Patients receiving mitoxantrone should also be monitored every 3 months with echocardiograms or MUGA (multiple gated acquisition) scans to determine the ejection fraction. Reduction in the ejection fraction should prompt discontinuation of this therapy.

Besides the cardiac side effects, mitoxantrone may cause menstrual irregularities or overall ablation of the menstrual cycle, which may be permanent. In a review of the literature, Ghalie⁹⁷ estimated the risk of mitoxantrone therapy-related acute leukemia in MS patients at 0.05% to 0.1%; in an international registry of MS patients taking mitoxantrone, the risk of leukemia seems somewhat higher. This therapy has been approved by the FDA for treatment of SPMS, but no peer-reviewed full report of the MIMS study had been published until 4 years after the initial report in an abstracts form. The study⁹⁸ showed a treatment effect in RRMS and SPMS patients with “recent rapid worsening.” The study had a high dropout rate and a small sample size. Most patients (74%) had relapses in the preceding 2 years, suggesting this cohort mostly includes worsening RRMS or PRMS patients, in whom a positive treatment effect is expected; however, it does not mean that for classic SPMS patients who no longer have relapses the study outcome is applicable, and it is especially not applicable to PPMS cases. The primary outcome measure was a composite score comprised of five clinical measures: change in EDSS at 2 years; change in Ambulation Index at 2 years; change in the baseline standardized neurological status at 2 years; number of relapses requiring corticosteroid treatment; and time to first relapse. Seventy-seven percent completed 24 months of follow-up. At 24 months, benefit was reported in all five components of the composite measure for both active treatment arms, with the overall greatest benefit noted between placebo and the group receiving mitoxantrone at a dose of 12 mg/m². The magnitude of the effect on EDSS was rather modest (mean EDSS change for high-dose mitoxantrone, -0.13 [SD 0.90] versus +0.23 [SD 1.01] in the placebo group). The MRI results of the MIMS trial were published in 2005 and are frankly disappointing.⁹⁹ In a subset of 110 patients (out of 194 in the trial overall), the 12 mg/m² dose failed to reach a significant difference from placebo as measured by the primary MRI outcome (total number of scans with gadolinium-enhancing lesions). The 12 mg/m² dose reduced the number of T2-weighted lesions at month 24 ($p = 0.027$) and showed a trend at month 12 ($p = 0.069$). The number of active MR lesions showed a trend toward reduction in the 12 mg/m² group only at month 24 ($p = 0.054$).

Overall, the limited evidence to date supports the conclusion that mitoxantrone reduces relapse frequency and MRI evidence for blood-brain barrier disruption in patients with *very active* MS. *The benefit for patients*

with relapse-independent progression is uncertain at best. From the MIMS results, one would need to treat 11 patients with secondary progressive multiple sclerosis for 2 years to prevent one person from worsening by 1.0 EDSS point. This modest benefit must be carefully examined in light of the significant risk for toxicity.

Therapy of PPMS. Unfortunately, for classical PPMS cases that present with insidious progression of usually myelopathy symptoms, none of the currently available treatments offer any clear benefit. The PROMISE trial, in which over 900 PPMS patients were treated with GA, was terminated early owing to lack of effectiveness. The results of this trial have not yet been published. A small study with intramuscular interferon- β 1a was also negative.¹⁰⁰ Currently a large trial is under way with rituximab in CSF OCB-positive PPMS patients. Until we clearly understand the pathophysiology of slow progression in MS, it is unlikely that we will find a treatment that has an important impact on this form of MS. Symptomatic treatment modalities, including physical and occupational therapy, are very important, yet frequently overlooked in this patient population.

Other Immunomodulator Therapies. Cyclophosphamide is an alkylating agent that has indiscriminate cytotoxic effects on rapidly dividing cells, including lymphocytes, making it a potent immunosuppressant. Several studies have claimed a beneficial effect in both relapsing and progressive patients. Because one of the major studies included ACTH, IV methylprednisolone is sometimes given with the cyclophosphamide. Other trials have not found a favorable effect. Because of the inconsistent results, high potential for serious side effects, and adverse reactions, including hemorrhagic cystitis and malignancy, cyclophosphamide is not widely used. Some centers, however, use cyclophosphamide in patients with aggressive disease in whom more conventional treatments have failed.

Azathioprine, a purine analog antimetabolite, has marginal efficacy in the treatment of MS. A meta-analysis of all blinded, placebo-controlled studies confirmed a slight benefit of slowed progression and less frequent relapses.¹⁰¹ The toxicity of azathioprine and its slow onset of action have prevented its widespread use. Besides the liver toxicity and hematological effects, the induction of malignancies has been a concern. One retrospective study did not find an increased incidence of cancer in MS patients treated with azathioprine, but this remains a potential risk.

Methotrexate is a folate antagonist that is effective in rheumatoid arthritis. Weekly low-dose oral methotrexate was found to delay upper extremity dysfunction in SPMS patients, although it had no effect on the more traditional measures of disability, including the Expanded Disability Status Scale (EDSS).¹⁰²

The use of cyclosporine in the treatment of MS has been evaluated in three clinical trials, none of which have demonstrated a convincing benefit. In addition, side effects such as hypertension and elevation of creatinine were common.

Numerous additional therapies have been tested, and many others are undergoing evaluation. The antiherpesvirus drug acyclovir has been shown to reduce relapse frequency in a small prospective trial. Total lymphoid irradiation was found to slow the chronic progression of MS,

but because this approach precludes the later initiation of immunosuppressant drugs and may be associated with a higher mortality rate, it is not widely used. Cladribine is a nucleoside derivative that was found to decrease relapse rate and slow the progression in patients with SPMS in an initial investigation.¹⁰³ The drug is better tolerated than other parenteral immunosuppressants, although bone marrow suppression is a risk. In a more extensive clinical trial,¹⁰⁴ cladribine therapy did not change disability scores, but significant reduction in enhancing lesions and overall T2 lesion burden was observed with higher dose treatment. A study of a small number of patients treated with autologous stem cell transplantation¹⁰⁵ suggested possible clinical stabilization or minor improvement over a 15-month period of follow-up in both secondary and primary progressive MS. The induction chemotherapy (BEAM regimen) resulted in one fatality in this trial; similar incidences are known in patients undergoing this procedure. The small number of patients and the different methods used (some patients received CD34⁺ selected graft) makes the interpretation of this data very difficult. Trials with higher number of patients under standardized circumstances are needed to verify the validity of these observations.

Symptomatic Treatment of Existing Disabilities

Spasticity. Spasticity is common even in patients with only minimal weakness (Video 3, Spastic Gait). It is usually prudent to begin treatment of mild spasticity with a stretching program. A randomized controlled crossover trial¹⁰⁶ of physical therapy (8-week blocks of therapy twice a week, for 45 minutes per session) showed significant benefit on several outcome measures related to improved mobility. No apparent differences were observed between home-based or hospital-based therapy. The addition of an evening dose of benzodiazepine may help relieve extensor spasms and clonus that may interfere with sleep. As spasticity worsens, it becomes necessary to use baclofen. Doses should be escalated slowly to prevent the occurrence of overt side effects, and up to 120 mg/day may be required. Although baclofen is well tolerated in most patients, limiting side effects such as sedation and increased muscle weakness may occur, and rarely a paradoxical increase in spasticity is noted. Liver enzyme elevation and nonconvulsive status epilepticus presenting as encephalopathy have also been reported in association with baclofen. Abrupt withdrawal of baclofen may result in hallucinations or seizures, making it necessary to taper doses. Despite symptomatic improvement, antispasticity measures may not increase function or independence. In paraplegic patients with severe spasticity and intolerance to the required oral dose, intrathecal baclofen delivered by a subcutaneously implanted pump allows a much smaller dose and is often effective in alleviating intractable spasticity and may lessen urinary urgency. Tizanidine seems to be as effective as baclofen, although it may be associated with more fatigue. Dantrolene has been used for spasticity, although the therapeutic window is small.

Fatigue. For treating fatigue, medications are only partially effective. Amantadine at 100 mg twice a day is the standard initial treatment, although pemoline 37.5 mg daily is also superior to placebo. A recent, small pilot study by the Mayo group suggested that high-dose aspirin (1300 mg/day) may sometimes be effective in the treatment of

MS-related fatigue.¹⁰⁷ This finding needs to be confirmed by a second, larger trial, however. The stimulating effects of the selective serotonin reuptake inhibitors may also be somewhat effective in combating MS-related fatigue. Modafinil, a medication approved for the treatment of narcolepsy, has also been used with good success. Often, however, patients need to limit activities and schedule rest periods.

Paroxysmal Symptoms of MS. Paroxysmal symptoms are highly responsive to medical treatment. A small dose of carbamazepine is often very effective. If not tolerated, several alternative medications may be tried, including phenytoin, acetazolamide, baclofen, and gabapentin. In addition, misoprostol has been claimed to be effective in MS-related trigeminal neuralgia. After about 1 month of treatment, a periodic attempt at tapering off these medications is a reasonable approach because these symptoms usually remit.

Seizures in MS are treated no differently than in non-MS conditions.

Heat Sensitivity. Heat sensitivity may require avoidance of precipitating activities, but this depends on the nature of symptoms and the situation in which they occur. If the precipitating activity cannot be avoided, a cooling jacket may be an option. A potassium channel blocker, 4-aminopyridine, improves temperature sensitivity in some patients but occasionally causes seizures or disturbing paresthesias.

Action Tremor. Action tremor is a common disabling symptom (Video 14, Tremor with Ataxia). Unfortunately, it is often only marginally amenable to medical therapy. Clonazepam may offer some relief, but tolerance frequently develops, necessitating increasing doses. Isoniazid and carbamazepine have also been found marginally beneficial. One clinical trial showed ondansetron to reduce tremor-related disability. Anecdotal reports suggest that gabapentin may be partially effective. Improvements in stereotactic neurosurgery have made thalamotomy a legitimate option in those whose disability is mainly due to tremor and not ataxia.

Cognitive and Memory Problems. Cognitive problems can also be seen in MS patients. These symptoms are generally not very severe; however, in some patients these may be one of their subjectively most bothersome complaints. It is important to make sure that such complaints are not depression related, as mood disorders are otherwise rather common in MS, and may explain the subjective cognitive impairment. While it is not FDA approved for the treatment of MS related cognitive dysfunction, in a placebo controlled, randomized, 24-week long study of donepezil in 69 patients, significant improvement was found on the Selective Reminding Test (SRT).¹⁰⁸ This improvement was independent of MS subtype, gender, age, reading ability, and baseline SRT results. The patients did not improve on other cognitive scales, but they were twice as likely to report cognitive improvement.

Dysesthetic Pain. Dysesthetic pains are difficult to control but sometimes respond to tricyclic antidepressants, carbamazepine, or baclofen. Gabapentin, tramadol, and duloxetine may also be effective. Standard analgesics are not often useful in MS-associated pain, and narcotics should be avoided in the treatment of chronic pain.

Emotional incontinence may be amenable to a low dose of a tricyclic antidepressant (Video 10, Dysarthria).

Symptoms of Bladder Dysfunction. Symptoms of a hyper-reflexic bladder (urgency, frequency, and urge incontinence) are often manageable with anticholinergics such as oxybutynin, propantheline, or imipramine. A flaccid bladder can sometimes be aided by bethanechol, although intermittent self-catheterization is more often needed. Symptoms that suggest urinary retention (a feeling of incomplete emptying, frequency, hesitancy, or a need to apply pressure to the lower abdomen to urinate) should prompt evaluation with urinalysis and a post-void residual urine measurement. Residuals in excess of 15 mL are abnormal; and if they are above 50 mL, consideration should be given to urological consultation for more thorough investigation and to blood chemistries to determine urea and creatinine levels. Detrusor-sphincter dyssynergia, diagnosed by cystometrography, is treated with anticholinergics, sometimes with the addition of an α -1 blocking agent (terazosin) or intermittent catheterization. It is important to reassess bladder function periodically, and residual urine volumes should be monitored if there are any persistent changes in function or symptoms. Intermittent catheterization should be considered when post-void residuals reach 100 mL. A chronic indwelling urinary catheter should be avoided if reasonably possible. It is usually not necessary to use antibiotics prophylactically in the prevention of urinary tract infections. Urinary calculi may be prevented by acidification of the urine with cranberry juice.

Bowel Dysfunction in MS. Constipation can usually be managed with bulk laxatives and stool softeners. More severe cases may require osmotic agents, bowel stimulants, anal stimulation, suppositories, or enemas. Bedridden patients may develop fecal impaction unresponsive to these measures and require manual disimpaction. Fecal incontinence can be minimized by adherence to a schedule for bowel movements. Fiber supplementation may be of some benefit even in these cases.

Sexual Dysfunction in MS. The clinician should determine the precise nature of any sexual dysfunction in patients with MS. Physical difficulty from spasticity may be alleviated by premedication with baclofen, and a fast-acting anticholinergic such as oxybutynin may calm urinary urgency. Sexual dysfunction should not be automatically attributed to MS. It may be necessary to investigate hormonal levels and to obtain urological or gynecological consultation. Manual lubrication with gel is a ready solution to vaginal dryness. Erectile dysfunction responds very well to sildenafil. Less frequently, vacuum devices, intracavernous injections of papaverine (or combinations of papaverine, prostaglandins, and epinephrine; triple agent), or penile implant are also used in the treatment of erectile dysfunction. Thalamotomy or thalamic stimulation may provide some short-term clinical benefit to patients disabled by appendicular cerebellar tremor and ataxia. The benefits on disability and quality of life are much less clear, however, and the early benefits may wain within 1 to 3 years.^{109,110} Further studies are needed to clarify how best to select patients for these ablative and stimulation treatment interventions.

General Recommendations for MS Patients. It is advisable for MS patients to attain good health habits, including proper diet and fitness. Smoking, excess alcohol intake, and obesity should be avoided. Exercise can help

maximize function by increasing and maintaining joint mobility, strength, and stamina; may promote improved sleep hygiene; and may reduce the severity of fatigue. Physical and occupational therapy can play an important role in regaining independence. Canes, walkers, and wheelchairs or scooters may be needed to maintain safe mobility. Hand controls can be installed in automobiles for patients with lower extremity dysfunction. In debilitated, immobilized patients, periodic shifts in posture to change weight-bearing regions and air or water mattresses prevent bedsores. Passive range of motion exercises prevent contractures. When ventilatory dysfunction occurs, it should be evaluated and activity schedules should be appropriately modified.¹¹¹

Special Considerations during Pregnancy. Before initiation of any drug in a woman of reproductive age, the potential for teratogenicity must be discussed. In general, immunomodulator therapy should be avoided if one is planning a pregnancy. The treatment of acute exacerbation is unchanged during pregnancy, although one might have a higher threshold for treatment. Both corticosteroids and plasma exchange are relatively safe during pregnancy. None of the drugs used to alter the disease course, however, should be used during pregnancy. Interferon- β drugs should be stopped 2 to 3 months before planning pregnancy. Interferons are associated with an approximately 39% likelihood of abortions. This is close to eight times higher than the usually quoted approximately 5% spontaneous abortion rate in women. Interferon- β use is also associated with lower birth weight.¹¹² The cytotoxic immunosuppressants have teratogenic effects. The effects of many of the other drugs are unknown. It is best if these drugs are stopped several months before a planned pregnancy.

PROGNOSIS AND FUTURE PERSPECTIVES. Because most information on the prognosis of MS is reported in terms of the EDSS, it is important to have some understanding of this scale. The EDSS is a 10-point scale, with each increase representing worsening symptoms of function. The score is derived from severity scores in each of six systems as well as ambulation and work ability. A score of 0 means no signs or symptoms; 1 to 3 represent mild disability with no or minimal impairment of ambulation; 3.5 to 5.5 refer to moderate disability and impairment of gait; the need for a cane to walk one-half block (100 m) receives a score of 6; an EDSS of 8 refers to the need for a wheelchair and effective upper extremity function; an EDSS of 10 refers to death related to MS.

MS has a highly variable outcome, ranging from asymptomatic to fulminant with death ensuing in a matter of months. Autopsy series have estimated that unsuspected MS may occur in as many as 0.2% of the population. Even when symptomatic, MS may cause only nuisance symptoms. Benign MS, when defined as unrestricted ambulation or EDSS of 3 or less 10 years after onset, accounts for about one third of cases. However, many of these patients acquire more disability later. When considering all patients with MS, Weinshenker found that 15 years after onset, 80% had EDSS worse than 3, 50% had reached EDSS of 6 or more, 10% were at EDSS 8, and 2% had died. The percentage of patients with initially RRMS who develop SPMS increases steadily with disease duration.¹¹³ At 10 years, 40% to 50% have continual deterioration;

after 25 years, approximately 80% have slow progression. In the most recent study published about the Olmsted County MS prevalence cohort consisting of 161 patients, the mean change in EDSS over 10 years was 1 point, and only 20% of patients had a change larger than 2.0 points.¹¹⁴ Eighty-three percent of the patients with mild symptoms (EDSS < 3.0) were still ambulatory without cane 10 years later. Among the patients with an EDSS of 3 to 5, 51% were using a cane; in the 6 to 7 EDSS range, 51% were wheelchair bound. Strong predictors for the outcome were not identified in this study. Population-based studies with complete ascertainment can effectively remove the bias of a referral practice, which is inherently biased towards the more active and more serious cases. These studies also provide some much needed balance to the “heavily skewed for recent disease activity” clinical trial experience.

From the most recent extensions to the Olmsted County MS cohort studies conducted by the Mayo group, several conclusions can be drawn. The number of relapses in the first year of the disease do not predict long term outcome. The time to disability is not influenced by ongoing relapses once patients achieve an apparently permanent degree of moderate disability (EDSS 3.5). Overall, 80% patients who are still classified as RRMS into their second decade of disease continue to do well for 15 to 20 years with limited permanent disability. Patients doing extremely well (EDSS ≤ 2.0) after 10 years of MS generally do well in the next decade. However, very rarely patients doing well even for 2 to 3 decades may develop severe late disability. We advise that neurologists share these findings with patients who are in periods of prolonged remission during the discussions about the merits of beginning disease-modifying agents.

Natural history studies have identified several prognostic indicators that predict outcome to a limited extent. Factors associated with a better prognosis (slower accumulation of disability, longer time before chronic progression) include young age at onset, female gender, RR course (as opposed to PPMS), initial symptoms of sensory impairment or ON, first manifestations affecting only one CNS region, high degree of recovery from initial bout, longer interval between first and second relapses, low number of relapses in the first 2 years, and less disability at 5 years after onset (both EDSS and number of systems affected—sensory, motor, sphincter, brain stem, vision, cerebral). Despite the indolent nature, a PP course is the worst prognostic factor, with the median time to reach EDSS 6 of only 6 years, compared with approximately 20 years in RR patients. Men and patients with an older age at onset are more likely to have PPMS.

The survival of MS patients is only slightly below expected. Seventy-six percent of patients are alive 25 years after onset, which is 85% of that seen in age- and sex-matched control subjects.³⁵ MS is rarely the direct cause of death. Complications of MS such as pneumonia, pulmonary emboli, aspiration, urosepsis, and decubiti are responsible for 50% of deaths. Most of the other deaths are from heart disease, cancer, cerebrovascular disease, and trauma. Suicide is the only cause of death that is overrepresented among these cases. The suicide rate among MS patients may be as high as two to seven times that of non-MS persons.

NEUROMYELITIS OPTICA

Neuromyelitis optica (NMO) is an uncommon neurological illness characterized by the occurrence of optic neuritis and myelitis. The names Devic’s syndrome, Devic’s disease, and NMO are often used interchangeably, although the first name encompasses all patients who fit the preceding definition and the second and third should only be used to refer to those patients presumed to have a distinct disorder. The term *opticospinal MS* is often used in the Far East to denote patients with exclusive or predominant involvement of optic nerves and spinal cord, encompassing most patients with Devic’s syndrome. Devic’s disease (NMO) may be a monophasic illness, or may show a relapsing-remitting course.¹¹⁵ It is the first inflammatory demyelinating disease with a known serum marker, the NMO-IgG antibody.

PATHOGENESIS AND PATHOPHYSIOLOGY. Devic’s syndrome may occur with ADEM, autoimmune disorders (e.g., systemic lupus erythematosus), MS, and possibly viral infections. Also, patients with Devic’s disease may have other coexisting autoimmune conditions. Classically, acute spinal cord lesions demonstrate diffuse swelling that extend over several levels or involve nearly the entire cross section of the cord. Acutely, there is destruction with dense macrophage infiltration involving white and gray matter, loss of myelin and axons, and lymphocytic cuffing of vessels. In chronic lesions, the cord is atrophic and necrotic, occasionally with cystic degeneration and gliosis. In the absence of perivascular cuffing, these extensive lesions resemble infarctions. The prominent spinal cord swelling in the confines of the restrictive pia presumably may raise intramedullary pressure, leading to the collapse of small parenchymal vessels, further propagating tissue injury. Proliferation of vessels with thickened and hyalinized walls similar to that seen after infarction or other extensive injury may occur.¹¹⁶ Less fulminant lesions may coexist and are much more typical of inflammatory demyelination. The optic nerve lesions often involve the chiasm. Even though NMO is usually restricted to the optic nerves and spinal cord, one may see classic MS like lesions in up to 10% of cases, and hypothalamic lesions have also been described in approximately 10%. The newly discovered serum marker, NMO-IgG has a sensitivity of 73% and specificity of 91%.¹¹⁷ The discovery of this novel immune marker also clarified that most if not all cases of “opticospinal MS” reported in the Japanese literature are also cases of NMO. To the surprise of the MS research community, the antigen is neither myelin nor neuron related: it is the aquaporin-4 water channel, a component of the dystroglycan protein complex located in astrocytic foot processes at the blood-brain barrier.¹¹ NMO thus may represent the first example of a novel class of autoimmune channelopathies.

EPIDEMIOLOGY AND RISK FACTORS. Devic’s syndrome occurs in patients of varied ages (range, 1 to 73 years). The mean age at onset of monophasic Devic’s syndrome is 27, whereas relapsing NMO (see later) tends to occur in an older age group (mean age at onset of 43). Monophasic Devic’s syndrome affects males and females equally, whereas relapsing NMO affects females predominantly (F:M, 3.8:1). One third of patients have a preceding

infection within a few weeks of neurological symptom onset. Most commonly this is a nonspecific upper respiratory tract infection, flu, or gastroenteritis. The most common specific infections preceding the development of Devic's syndrome are chickenpox and pulmonary tuberculosis. Devic's syndrome has also followed vaccination for swine flu and mumps. Only a few instances of a possible familial occurrence of Devic's syndrome have been reported, and in one of these families, a unique mitochondrial mutation was found. Devic's syndrome is said to be more common in Japan and East Asia, although even there it is uncommon (less than 5 per 100,000). Three cases have been described in the literature with familial occurrence of Devic's disease in the Far East. In a genetic study, HLA-DPB1*0501 was more frequently associated with "optico-spinal MS," whereas HLA-DPB1*0301 is the most strongly associated allele with conventional MS in the Japanese.

CLINICAL FEATURES AND ASSOCIATED FINDINGS. Symptoms of ON and myelitis develop over hours to days and are often preceded or accompanied by headache, nausea, somnolence, fever, or myalgias. Continued progression of symptoms over weeks or months occasionally occurs. Most patients (greater than 80%) develop bilateral optic neuritis. Bitemporal or junctional field deficits, indicating chiasm involvement, are sometimes present early in the course of the ON. Visual loss is often accompanied by periocular pain, and myelitis onset is sometimes heralded by localized back or radicular pain. Lhermitte's sign is common. Severe degrees of neurological deficits are usual, and the degree of recovery is variable.

Approximately 35% of NMO patients have a monophasic illness, 55% develop relapses usually limited to the optic nerves and spinal cord (relapsing NMO or optico-spinal MS), and rarely patients have a fulminantly progressive course without relapses or a course typical of MS.¹¹⁵ According to a study conducted at the Mayo Clinic,¹¹⁵ patients with a monophasic course usually presented with rapidly sequential events (median, 5 days) with only moderate recovery. Patients showing characteristics of the relapsing form of Devic's had a median interval of 166 days between index events, followed within 3 years by clusters of severe relapses isolated to the optic nerves and spinal cord. Most relapsing patients developed severe disability in a stepwise manner. Approximately one third died from respiratory failure. Predictors of a relapsing course in NMO¹¹⁸ include longer inter-attack intervals (relative risk [RR]: 2.16 per month increase), older age at onset (RR = 1.08 per year increase), female sex (RR = 10.0), and less severe motor impairment with sentinel myelitis event (RR = 0.48 per severity scale point increase). Autoimmune disease history (RR = 4.15), higher attack frequency in first 2 years (RR = 1.21 per attack), and better recovery following index myelitis (RR = 1.84 per point) are associated with increased mortality rate. Features of NMO distinct from "typical" MS included normal initial brain MRI, more than 50 cells/ μ L in CSF with polymorphonuclear predominance, and lesions extending over three or more vertebral segments on spinal cord MRI. Relapsing NMO is often associated with autoimmune disorders, most commonly systemic lupus erythematosus. These patients also frequently have an elevated erythrocyte sedimentation

rate and nonspecific elevation of autoantibodies, including antinuclear antibodies, anti-ds-DNA, and antiphospholipid antibodies. Tonic spasms and neuropathic lower extremity pain are common sequelae to the spinal cord damage. Symptoms referable to brain stem lesions (nystagmus, ophthalmoparesis, and vertigo) can occur in these patients as well.

DIFFERENTIAL DIAGNOSIS. The differential diagnoses for Devic's syndrome includes MS, ADEM, pulmonary tuberculosis, and viral infection (especially in the immunocompromised patient). In patients with an apparent affected family member, consideration should be given to mitochondrial disease. Relapsing NMO should raise the suspicion for associated autoimmune disorders. Because Devic's syndrome can occur in persons older than age 60, when an unrelated ischemic optic neuropathy could occur, and because isolated or recurrent myelopathy may precede the ON, additional consideration must be given to spinal cord compression, spinal cord tumor, and spinal arteriovenous malformation (AVM) or dural fistula.

EVALUATION. Imaging is needed to exclude structural lesions and provide information on the pathological process. Optic nerve or chiasm enlargement, T2-weighted signal changes, and enhancement may be seen on head MRI during the acute phase. Increased T2-weighted signal in the medulla is not uncommon and usually represents extension of high cervical lesions. Spine MRI characteristically shows cord swelling, signal changes, and enhancement extending over at least three levels (Fig. 48-4). This appearance may resemble a spinal cord tumor, prompting consideration for biopsy.

On magnetization transfer (MT) MRI, no significant difference was found on normal-appearing white matter of Devic's patients and control subjects, whereas MS patients had a significantly lower MT ratio peak and histogram average.¹¹⁹ T1 hypointense lesions in the cord and linear lesions that cross over more than two segments are more suggestive of Devic's disease.

An occasional patient may need prone and supine myelography to exclude a spinal dural-based AVM. Laboratory investigations reveal an elevated erythrocyte sedimentation rate in one third, positive antinuclear antibodies in nearly one half, and occasionally other autoantibodies (e.g., thyroperoxidase antibodies).³⁹ It is reasonable to exclude syphilis, Lyme disease, and human immunodeficiency virus by laboratory testing. In a few patients with the Far East variety of Devic's disease, hyperprolactinemia was described predominantly with optic nerve involvement. A chest x-ray helps to exclude pulmonary tuberculosis and sarcoidosis. CSF examination is an essential part of the evaluation for Devic's syndrome, and repeated studies are sometimes necessary to ensure that there is no infection in that the CSF findings are sometimes atypical for inflammatory demyelination.

A marked pleocytosis is often present, sometimes exceeding 100 cells. Moreover, neutrophils are commonly seen in CSF and may predominate, a situation virtually unknown in MS.¹²⁰ The protein concentration is often very high and in 41% exceeds 100 mg/dL. Anti-MOG antibodies are the predominant autoantibody detected in CSF; anti-MBP or anti-S100 β antibodies are less frequently

Figure 48-4. Spine MRI of patients with relapsing NMO. **A**, Sagittal T2-weighted image of the cervical spine showing cord expansion and signal abnormalities extending through the cervical and upper thoracic cord. **B**, T1-weighted sagittal MRI showing cord swelling and extensive gadolinium enhancement from C1 to C7. Further enhancement is seen in the upper thoracic area. **C** and **D**, Sagittal T2-weighted spine MRI showing a diffuse hyperintense lesion extending from T1 to the conus.

seen. Despite the intense inflammatory response, OCBs are conspicuously absent in the majority, being present in fewer than 20% of patients. CSF serology for the herpesvirus family (HSV types 1 and 2, VZV, EBV, and CMV) is important, and polymerase chain reaction testing should be done in cases suggestive of viral infection (immunocompromised patients).

MANAGEMENT. Patients with acute or subacute Devic's syndrome may respond to corticosteroids (e.g., intravenous methylprednisolone). They may respond to plasma exchange even when intravenous methylprednisolone does not produce significant improvement. Attempts at preventing relapses and the subsequent disability are often disappointing even with the use of immunosuppressive agents. The classic injectable immunomodulators used in MS are insufficient to reduce the relapse rate in relapsing NMO. Most commonly, a combination of azathioprine and prednisone is used for secondary prevention. Other agents including mycophenolate mofetil, IVIG, and mitoxantrone have been described to be effective in some cases. A small study of rituximab, a humanized anti-CD20 antibody showed a

significant reduction in the relapse rate of 8 patients, making 6 of 8 relapse free.¹²¹ A large multicenter study of rituximab in NMO is in the planning stages.

Supportive care is important in the management of NMO. These patients are prone to many complications and require measures to prevent deep venous thrombosis and pulmonary embolism, urinary tract infection, decubiti, and contractures. Mechanical ventilation may be needed either temporarily or permanently. Patients with monophasic Devic's syndrome generally have simultaneous or rapid onset of the ON and myelitis (interval usually less than 1 month). Although some have significant residual disability, many recover remarkably and have little or no permanent deficits. A history of previous vague neurological symptoms or definite demyelinating events is predictive of future relapses, either typical of MS or relapsing NMO. Those patients destined for recurrent myelitis and ON have a longer interval between the onsets of myelitis and ON. The vast majority of patients with relapsing NMO have very aggressive disease with frequent and severe exacerbations and a poor prognosis.

ACUTE DISSEMINATED ENCEPHALOMYELITIS

ADEM is a monophasic inflammatory demyelinating disorder that characteristically begins within 6 weeks of an antigenic challenge such as infection or immunization. It occurs more often in the young and causes the rapid development of multifocal or focal neurological deficits. Perivenous inflammation, edema, and demyelination are the pathological hallmarks of ADEM, although these lesions commonly enlarge and coalesce, forming lesions pathologically indistinguishable from MS. Moreover, perivascular changes typical of ADEM are common in patients with MS. There is considerable overlap in the epidemiological, clinical, CSF, imaging, and pathological features between ADEM and MS, often making it difficult to distinguish between the two with reasonable confidence when encountering patients with a single demyelinating event.

PATHOGENESIS AND PATHOPHYSIOLOGY. ADEM closely resembles the experimental allergic encephalomyelitis animal model of MS (EAE) both clinically and pathologically, and is most likely due to a transient autoimmune response toward myelin. The occurrence of ADEM after vaccination with the rabbit spinal cord preparation of rabies virus led to the discovery of EAE. Infections and non-CNS-containing vaccinations may induce ADEM by molecular mimicry or by activating autoreactive T-cell clones in a nonspecific manner. Lymphocyte reactivity toward MBP has been identified in blood and CSF from patients with ADEM, but its absence in others indicates a role for other antigens. Increased peripheral blood γ interferon-producing T cells have been described in ADEM.

EPIDEMIOLOGY AND RISK FACTORS. ADEM can occur at any age but perhaps because of the higher frequency of immunization and exposure to new antigens; it is most common during childhood. Unlike MS, both sexes are affected with equal frequency. No association has been noted with pregnancy.

ADEM has been reported to follow a number of different immunizations, usually within 6 weeks, including those for pertussis, diphtheria, measles, mumps, rubella, influenza (postvaccination ADEM), tetanus, and yellow fever. In addition, there are case reports of ADEM following hepatitis B vaccination. However, the only epidemiologically and pathologically proved association is with rabies vaccination, which also causes demyelinating peripheral neuropathies. The original Pasteur rabies vaccine, prepared in rabbit spinal cord, was associated with an incidence of ADEM of approximately 1 per 3000 to 1 per 35,000 vaccinations and is no longer in use. A later vaccine, made in duck embryo, which contains little neural tissue, carries a risk for ADEM of 1 per 25,000 vaccines. The use of human diploid cell lines, which contain no nervous system tissue, for the production of rabies vaccine has virtually eliminated the risk of ADEM. The association of bee stings with ADEM has also been reported.

Parainfectious ADEM usually follows onset of the infectious illness, often during the recovery phase, but because of the latency between pathogen exposure and illness it may precede clinical symptoms of infection or the two may occur simultaneously. The most commonly reported associated illness is a nonspecific upper respiratory tract

infection. There have been a vast number of specific infections associated with ADEM, such as virus infections (including rubella, mumps, VZV, EBV, CMV, influenza, coxsackievirus, and hepatitis C) and infection with *Mycoplasma*, *Borrelia burgdorferi*, and *Leptospira*. Measles carries the highest risk for ADEM of any infection, occurring in 1 per 400 to 1 per 1000 cases. Although ADEM has been reported in association with measles immunization, the risk is far lower than the risk of acquiring measles and its neurological complications.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. A prodrome of headache, low-grade fever, myalgias, and malaise often precedes the onset of ADEM by a few days. In a German study of 40 cases,¹²² the most frequent clinical signs were motor deficit (80%), followed by sensory deficits, brain stem signs, and cerebellar signs. CSF findings were variable; normal results were present in up to 20% of patients. Oligoclonal bands were positive in over 60%. Almost all patients improved during the acute phase of the disease. Of the 26 patients with the final diagnosis of ADEM, 21 had minor or no symptoms, 2 died, the rest had moderate symptoms. Compared to MS patients, the ADEM patients were older, and more often had a preceding infection, clinical signs of brain stem involvement, a higher CSF albumin fraction, and infratentorial lesions. Neurological symptoms develop rapidly in the acute phase and are commonly associated with encephalopathy, stupor, coma, meningismus, and seizures. Peak severity occurs within several days, and recovery may begin soon afterward. Occasionally, ADEM may evolve over a few months and there may be a second clinical deterioration or subacute progression for a time. In these unusual cases, the distinction from MS is difficult. Three recent large retrospective series and an accompanying editorial have highlighted that there remain no clinical or laboratory features that accurately allow one to predict which adult or pediatric ADEM patients will develop.¹²²⁻¹²⁵

DIFFERENTIAL DIAGNOSIS. One of the primary concerns after a single demyelinating episode is whether other bouts can be expected (e.g., MS). Several features may tip the balance toward one or the other, but the proper diagnosis becomes apparent only with time. Classically, ADEM is characterized by the multifocal involvement at onset whereas MS often presents with monosymptomatic deficits such as ON. However, ADEM may cause unifocal symptoms and MS may present with multifocal CNS involvement, especially in children. The monosymptomatic deficits caused by ADEM are more commonly severe, such as bilateral ON and complete transverse myelitis. Although OCBs occur transiently in about one third of ADEM cases, their persistence implies a diagnosis of MS. The subsequent disappearance of OCBs, when performed by consistent techniques, is evidence against MS. The MRI appearance of these two disorders is often identical,¹²⁵ but the presence of basal ganglia or cortical lesions, or large globular white matter lesions, is more frequent in ADEM.

The fulminant development of ADEM is distinctive but not pathognomonic, because a rare form of MS known as Marburg's MS is also rapid in onset and often deadly. The appearance of brain stem, periventricular, and multiple, large cerebral white matter lesions and the presence of OCBs may distinguish Marburg's variant from ADEM.

On rare occasions, inflammatory demyelinating lesions may reach a large size and resemble tumors (especially lymphoma) on MRI, necessitating biopsy for clarification. There is usually one dominant lesion, but smaller separate lesions may be identifiable. These have been referred to as both ADEM and MS in the literature. The prognosis for recovery is often quite good, although approximately one third suffer subsequent attacks. Some develop typical MS, whereas others have recurring tumor-like lesions. The term *multiphasic ADEM* has been used when patients have large recurrences in the same location, and *relapsing ADEM* refers to recurrences at different sites. The relationship of these entities with MS is unclear.

Balo's concentric sclerosis refers to the pathological finding of alternating bands of demyelination and remyelination. These patients typically have large lesions and subacute deficits similar to those described earlier. Typical demyelinating lesions commonly coexist, and rarely CDMS patients are noted to have similar-appearing lesions. The reason for this peculiar alternating pattern is unknown.

Schilder's myelinoclastic diffuse sclerosis is another rare condition that may be confused with ADEM or other demyelinating conditions. This progressive demyelinating disorder usually begins in childhood. The features are often atypical and include dementia, aphasia, homonymous hemianopia, seizures, psychosis, elevated intracranial pressure, and the absence of OCBs. The most characteristic finding is the presence of two large, roughly symmetrical lesions on MRI, one in each hemisphere. The diagnosis is made by excluding the known inherited leukodystrophies, especially adrenoleukodystrophy.

MANAGEMENT. Treatment with intravenous methylprednisolone seems to halt progression and allow recovery to begin sooner, just as with MS. Plasma exchange can be tried in those with severe deficits and little response to corticosteroids. IVIG has also been used successfully according to case reports in the literature. One fulminant case responded to hypothermia only.

HISTORY AND DEFINITIONS

Waldrop, in 1834, reported a single patient who probably had acute inflammatory demyelinating polyradiculoneuropathy (AIDP), thereby providing the first clinical description of a demyelinating polyneuropathy. Landry, in 1859, described 10 patients who very likely had the same disorder; he recounted most of the clinical features now considered typical for AIDP. Guillain, Barré, and Strohl, in 1916, reported two soldiers who were recovering from rapidly evolving, principally motor, polyneuropathies. They emphasized the loss of the deep tendon reflexes (DTRs) and the presence, on cerebrospinal fluid (CSF) examination, of an elevated protein level with a normal cell count (albuminocytological dissociation). Their paper probably has been the most influential of all the articles concerned with demyelinating neuropathies; from it, the commonly used eponymic title for AIDP derives (Guillain-Barré syndrome, or GBS). Haymaker and Kernohan, in 1949, reviewed the pathology they had found in 50 fatal cases of AIDP. Their paper confirmed, both on a clinical and a pathological basis, that Landry's ascending paralysis and GBS were, in fact, the same disorder. In 1955, Waksman and Adams first produced experimental autoimmune neuritis (EAN) by injecting peripheral nerve tissue, with adjuvants, into rabbits. In 1969, Asbury, Arnason, and Adams observed lymphocytic infiltration and segmental demyelination on pathological examination of spinal roots and nerves in all 19 patients they studied who had died of GBS, thus establishing a pathological link between GBS and EAN.¹⁻⁴

The first diagnostic criteria for AIDP were proposed in 1935. Several others have been proposed since then. Formulated in 1978 by Asbury, Arnason, Karp, and McFarlin, the most widely used set resulted from a colloquium sponsored by the National Institute of Neurological and Communicative Disorders and Stroke; it was triggered by claims against the U.S. government for AIDP resulting

from the 1976 swine influenza vaccination program. The electrodiagnostic (EDX) features of AIDP, principally the results of the nerve conduction studies (NCS), were first described in detail by Lambert and Mulder in 1964.¹⁻⁴

Osler and Targowla described chronic progressive and relapsing forms of polyradiculoneuropathy in the 1890s, but it was not until 1958 that Austin first catalogued many of the clinical features of what is now termed chronic inflammatory demyelinating polyradiculoneuropathy (CIDP). Austin's report triggered the widespread use of corticosteroids in patients thought to have this disorder.²⁻⁴ Nonetheless, there was no generally accepted clinical presentation for CIDP until 1975, when Dyck and coworkers established it as a distinct clinical entity, based on their review of 53 patients.⁵ Because the features of CIDP are relatively nonspecific, a number of polyneuropathies and polyradiculoneuropathies associated with specific diseases resemble, and may represent instances of, it.

OVERVIEW OF PERIPHERAL NERVOUS SYSTEM MYELINATION AND ELECTROPHYSIOLOGY

The peripheral nervous system (PNS) comprises less than 0.1% of all nerve tissue. The somatic PNS, when defined anatomically by the presence of Schwann cells, includes the primary roots, dorsal root ganglia, mixed spinal nerves, plexuses, nerve trunks, autonomic nervous system, and cranial nerves III to XII. Peripheral nerve trunks are composed of a great number of axons, which are grouped into individual bundles or fascicles. These structures vary in number, depending on the nerve, its size, and the site at which it is studied. Schwann cells ensheath every PNS axon nearly throughout their extent. Peripheral nerve fibers are divided into two groups, either myelinated or unmyelinated, depending on whether they have one or several axons per Schwann cell. In the human sural nerve, the ratio of unmyelinated to myelinated axons is approximately 3.7 to 1.⁶

A myelinated peripheral nerve fiber consists of an axon and a series of Schwann cells located sequentially on its external surface. Each Schwann cell encircles the axon segment adjacent to it with a multilayered cell membrane structure, the myelin sheath. The short, constricted, myelin-free axon segment where consecutive Schwann cells about each other is called the node of Ranvier. This region contains voltage-gated Na^+ channels. The myelin-coated axon segment between two nodes of Ranvier is an internode. Saltatory conduction is the characteristic means of impulse transmission along myelinated fibers. The myelinated axon is depolarized only at the nodes of Ranvier, thereby permitting it to conduct much faster than an unmyelinated fiber. Approximate linear correlations have been noted between myelin thickness and conduction velocity (CV).⁶ Myelinated motor axons conduct impulses centrifugally to the extrafusal muscle fibers, whereas myelinated sensory axons transmit impulses centripetally from the muscle spindles and Golgi tendon organs; they subserve the sensations of touch, pressure, and vibration.^{6,7}

Segmental demyelination (SD), or damage to the myelin sheath, can be either primary or secondary. With primary SD, only the myelin portion of the nerve fiber is affected; the axon is spared. Through several different mechanisms, numerous entities can cause primary SD, including diphtheria toxin, lead salts, cold, acute and chronic compression, and disorders such as AIDP and CIDP. Nonetheless, both clinically and electrophysiologically, the demyelination that results is quantitatively the same. With secondary SD, damage to the myelin results from initial changes in the axon, typically consisting of chronic shrinking and atrophy. Axon atrophy with secondary SD occurs in some chronic polyneuropathies (e.g., uremia). Pathophysiologically, whether it is primary or secondary, SD produces conduction abnormalities—slowing or block—as well as abnormal (ectopic) impulse generation. Clinically, these abnormalities can result in muscle weakness, impairment of large fiber sensory modalities, fasciculations, myokymia, cramps, and paresthesias.^{8,10}

The underlying pathology of a specific peripheral polyneuropathy frequently can be predicted by its EDX features. Based on these patterns, most peripheral polyneuropathies can be divided into two types: (1) axonal degeneration or axon loss (frequently referred to as axonal) and (2) SD. Both familial and acquired polyneuropathies can be found in each group. For example, axon loss polyneuropathies include familial Charcot-Marie-Tooth disease type II (Dyck classification) and acquired arsenic polyneuropathy, whereas SD polyneuropathies include familial Charcot-Marie-Tooth disease type I, as well as acquired AIDP and CIDP. Most classifications make no distinctions between peripheral polyneuropathies and peripheral polyradiculoneuropathies, although often their clinical and EDX presentations differ. All of the acquired disorders discussed in this section actually are polyradiculoneuropathies, regardless of the terminology used.

With axon loss polyneuropathies and polyradiculoneuropathies, the main EDX features include the following: On NCS, there is uniform reduction of amplitudes, ultimately culminating in unelicitable responses at all stimulation points. This change is not accompanied by any significant alterations in latencies or conduction velocities (CVs),

because they are being measured along surviving, unaffected axons. On needle electrode examination (NEE), fibrillation potentials occur, accompanied by reduced motor unit potential (MUP) recruitment, if the motor nerve involvement is severe, and chronic neurogenic MUP changes, if the disorder is of more than 4 months' duration and rather severe.^{9,10}

With generalized SD disorders, the underlying pathophysiology may be conduction slowing, conduction block, or both, depending on the severity of involvement of the individual fibers. Whenever SD conduction slowing affects all, or nearly all, of the large myelinated fibers to the same degree, then only the latencies and CVs are affected on NCS. In these cases, the amplitudes and durations of the responses are unaltered. Alternatively, if conduction is slowed along different fibers to different degrees, then the NCS responses become dispersed, and as they do so, the amplitudes decrease (Fig. 49-1). With SD conduction block lesions, the NCS responses decrease in amplitude but are not dispersed (Fig. 49-2). Importantly, all types of SD lesions affect only a focal area of nerve, so the CVs, durations, and amplitudes on stimulating distal to that area (while recording still more distally) are unaffected, because conduction is being determined along a normal segment of nerve. On NEE, conduction slowing produces no changes, whereas conduction block, if severe, causes reduced MUP recruitment.^{9,10}

Some confusion exists regarding the pathophysiological and clinical correlations found with these two basic types of peripheral nerve lesions. Unelicitable responses and low-amplitude nondispersed responses are the NCS counterpart of weakness and of fixed sensory deficits, due to involvement of large myelinated fibers. They indicate that, regardless of cause, impulses are not able to traverse the nerve segments between the stimulating and recording sites. The only two pathophysiological processes that

Figure 49-1. Motor nerve conduction studies of the ulnar nerve in a patient with CIDP, recording from the hypothenar eminence with stimulation at wrist (*top trace*), distal to the elbow (*second trace*), above the elbow (*third trace*), axilla (*fourth trace*), and at supraclavicular notch (*bottom trace*). With stimulation at more proximal sites, there is a cumulative effect of segmental demyelinating lesions, resulting in the dispersion of the responses with conduction block.

Figure 49-2. Motor nerve conduction studies of the median nerve in a patient with motor neuropathy with multifocal conduction block, recording from the thenar eminence with stimulation at wrist (*top trace*) and above the elbow (*bottom trace*). A severe conduction block is noted in the segment of nerve between the two stimulating sites.

produce such NCS amplitude changes are axon degeneration and SD conduction block. In contrast, SD conduction slowing has very few clinical counterparts. If differential slowing is present, certain neurological examination techniques that require transmission of highly synchronized nerve volleys may be altered (e.g., DTRs and vibratory sensation). However, SD conduction slowing generally does not produce clinical weakness when it affects motor axons because all of the nerve impulses are reaching their target muscle fibers; the fact that they are doing so a few milliseconds later than normal is of no clinical significance.^{9,10}

Based on various EDX features, familial and acquired demyelinating disorders often can be differentiated from one another, and the acquired disorders can be subdivided into acute and chronic types. Familial SD polyneuropathies are length-dependent polyneuropathies and have predictable presentations that vary principally with the severity of the process. Some of their features are (1) NCS of the same type (i.e., motor or sensory) are affected earlier and more severely in the lower extremity than in the upper extremity; (2) in a given limb, the sensory NCS, compared with the motor NCS, tend to be involved earlier and more severely; (3) NCS of the same type, assessing nerve segments at approximately the same limb level, are affected to approximately the same degree; (4) NCS performed on corresponding nerves in contralateral limbs are affected equally; (5) along any specific nerve, conduction rate abnormalities are uniform; (6) late responses, H-responses and F waves, usually are unelicitable; (7) NEE abnormalities appear first and ultimately are most severe in the more distal lower extremity muscles.^{9,10}

In contrast to the familial demyelinating polyneuropathies, the acquired demyelinating disorders are all polyradiculoneuropathies. Nonetheless, at times they have an EDX presentation identical to that seen with the familial polyneuropathies, and in those instances, they cannot be distinguished from the familial types in the EDX laboratory. This most frequently occurs in patients with CIDP and with AIDP in the recovery stages. More often, however, the EDX findings with the acquired disorders deviate sufficiently

from those listed earlier so that they can be recognized. This is particularly the case with AIDP relatively early in its course. There are several such variations:

1. Nerves of the same type may show abnormalities that are more severe in the upper extremities than in the lower extremities—for example, the sural NCS may be normal, whereas the median sensory NCS may be grossly abnormal; this combination of changes virtually is never seen with a familial demyelinating polyneuropathy.
2. Abnormalities may be focal or multifocal, rather than generalized, along a specific peripheral nerve; thus, a conduction block or focal slowing may be found only between the elbow and wrist segment of the median nerve, whereas it may be absent from more distal and more proximal segments or, conversely, progressive conduction blocks or progressive differential slowing may be found along a nerve.
3. Nerves of the same type, in the same limb, at the same level, often show very dissimilar findings.
4. Homologous nerves in contralateral limbs may be affected differently.
5. In a given limb, motor NCS may be more abnormal than sensory NCS.
6. H-responses and F waves may be variably affected; with acute disorders they may be abnormal when the standard NCS are normal, if the SD conduction changes are restricted to the proximal segments of the PNS.
7. On NEE, abnormalities may be found in any muscle, or they may be generalized, rather than manifesting a distal-proximal gradient.^{2-4,9-12}

With acute SD polyradiculoneuropathies, conduction blocks often dominate the NCS, whereas with chronic SD polyradiculoneuropathies, conduction slowing typically is prominent. This chapter focuses on several acquired forms of neuropathies, most of which are characterized pathologically by SD.

ACUTE INFLAMMATORY DEMYELINATING POLYRADICULONEUROPATHY (GUILLAIN-BARRÉ SYNDROME)

Guillain-Barré syndrome (GBS) in developed countries in the post-poliomyelitis era, is the most common cause of acute progressive flaccid paralysis. Typically, it manifests as rapidly progressing limb weakness, accompanied by paresthesias and often cranial nerve dysfunction.¹³⁻¹⁶ For many years, GBS was considered to be a single clinical entity, a rapidly evolving sensorimotor polyradiculoneuropathy resulting from widespread demyelination in the PNS due to inflammation. Consequently, GBS was viewed as synonymous with AIDP. However, two decades ago it began to be appreciated that demyelination is only one of the causes for the constellation of clinical features labeled GBS; different pathological processes can lead to the same clinical presentation (Table 49-1).^{17,18} In 1986, Feasby and coworkers reported that some patients who were considered to have GBS had axon loss rather than SD as their

underlying pathophysiology; these cases were labeled the acute axonal form of GBS.¹⁹ More recently, it has been appreciated that this subdivision must be further separated into two groups: the first with both motor and sensory fibers affected, labeled acute motor-sensory axonal neuropathy pattern, or AMSAN,²⁰ and the second with only motor fibers affected, particularly at the root level, labeled acute motor axonal neuropathy pattern, acute motor neuropathy, or AMAN.^{20,21} In addition, Miller Fisher syndrome (MFS) is also considered one of the subgroups of GBS (Video 221, Miller Fisher Syndrome).^{13,14}

PATHOGENESIS AND PATHOPHYSIOLOGY. All subdivisions of GBS appear to be autoimmune diseases resulting from aberrant immune responses against various components of peripheral nerve fibers.²² With AIDP, both humoral and cell-mediated factors appear to be operative, with both antiganglioside antibodies and activated T cells functioning in an attack on myelin sheaths and possibly Schwann cell membranes by sensitized macrophages. However, the exact target molecules in the immune reaction is not yet known.^{23,24} The pathology that results is well documented: inflammatory lesions, consisting of circumscribed areas containing lymphocytes, macrophages, and localized demyelination scattered throughout the PNS. The roots, plexuses, proximal nerve trunks, some cranial nerves, and autonomic fibers may be involved, often with a predilection, at least soon after onset, for the roots and distal peripheral nerve fibers (the latter possibly because the blood-nerve barrier is relatively deficient in the region).^{25,26} Pathophysiologically, these focal areas of demyelination result in conduction slowing or conduction block, depending on the severity of the process. Almost invariably, some axon loss also occurs, but it is much less marked.^{11,12} With the acute axonal forms of GBS, a different pathological process occurs. Both AMAN and AMSAN probably are due to immune attacks on ganglioside antigens on the axolemma, most likely GM₁ or GD1. Macrophages invade the nodes or Ranvier and interpose themselves between the axons and their surrounding Schwann cells, sparing the myelin sheaths. One theory is that AMSAN is merely a more

severe pathological and clinical manifestation of essentially the same immune process.^{23,27} The roots are preferentially involved with both axonal subgroups of GBS: the ventral roots alone with AMAN, and both the ventral and dorsal roots with AMSAN. Just as AIDP has some minor associated axon loss, the acute axonal forms of GBS have some sparse SD present along surviving myelinated fibers; thus, the lesions are “predominately” rather than “purely” axon loss in type.²⁰ Pathophysiologically, the so-called acute axonal forms present as axon loss polyradiculoneuropathies affecting motor, or motor and sensory, fibers, depending on the particular subgroup.^{19–21} Thus, on NCS, they affect the amplitudes of the responses, rather than the CVs. With MFS, the underlying pathology is unclear, because the affected portions of the nervous system cannot be biopsied and autopsies of uncomplicated cases do not occur since it is a benign disorder. It is known that IgG antibodies against ganglioside GQ1b have been detected in the acute phase of almost all cases studied.^{14,23,27} Pathophysiologically, only the sensory NCS amplitudes are affected.²³

EPIDEMIOLOGY AND RISK FACTORS. AIDP is a relatively rare disorder, having an average yearly incidence rate of 1 to 2 cases per 100,000 population. It occurs worldwide, affects all races, and attacks more males than females. Persons of any age are at risk, although the incidence is higher in the elderly. Most cases are sporadic, but clusters have been reported. Actual common-origin clusters typically derive from an obvious trigger factor, such as antirabies vaccination. Most studies have not reported a seasonal variation, with the exception of AMAN in China. Unlike the situation with CIDP, no clear relationship has been demonstrated between AIDP and human leukocyte antigen.^{2,3} AIDP is responsible for more than 90% of the GBS cases that occur in North America, Europe, and Australia. In contrast, in Northern China, 60% to 80% of cases are AMAN. Also, in that locale its epidemiological features differ from those described earlier. It occurs principally in epidemics and during the summer months, has a very strong association with preceding *Campylobacter jejuni* infections,²⁸ and typically affects children and young adults.^{19,20} AMAN also occurs in North America, Japan, India, and Central America.^{14,22,28} The AMSAN form, which is much less common than AMAN (probably with a ratio of 10:1), affects mainly adults, regardless of the region where they live. Of all the subgroups of GBS, MFS is the least common; it also affects mainly adults.^{14,23,28}

Antecedent events (so-called triggers) are associated with GBS in approximately 60% to 70% of cases.^{14,22} These usually occur 1 to 3 weeks before the onset of clinical symptoms, rarely as much as 6 weeks earlier. The one most often reported is a mundane upper respiratory infection. However, a number of others have been described, although the linkage often has been inconclusive. Nonetheless, the evidence is convincing that connects GBS and the rabies vaccine, a few viral infections (particularly human immunodeficiency virus [HIV], Epstein-Barr virus, and cytomegalic inclusion virus), and a few bacterial infections (especially *C. jejuni*) (Table 49-2). None of these infections is exclusively linked to any particular subgroup of GBS. However, severe axon loss often follows *C. jejuni* infections, just as severe sensory involvement often is preceded by cytomegalovirus

infections.²² Major attention has been focused on *C. jejuni* infection, which clinically is manifested as a gastroenteritis.²⁻⁴ This particular bacterium appears to play a predominant role in the acute axonal form of GBS that occurs in epidemics in China.^{19,20} Although the data are not as compelling, a link between Hodgkin's disease and GBS also appears to exist.²⁻⁴ Fewer than 40 cases of GBS occurring during pregnancy have been reported. Apparently, this is an incidental coexistence, which can develop during any particular trimester. Nonetheless, a few women have experienced GBS with successive pregnancies.^{2,4}

CLINICAL FEATURES AND ASSOCIATED DISORDERS. The course of GBS can be divided into four stages: (1) preceding phase, (2) progressive phase, (3) plateau phase, and (4) recovery phase.¹⁶ The cardinal features of GBS are weakness, paresthesias, and diminished or absent DTRs.⁴ Most patients are essentially well and lack systemic symptoms, including fever, when their PNS symptoms begin. Often they have recently experienced one of the many antecedent events already described; the preceding phase, which is the latent period between that event and onset of symptoms, usually is about 2 to 3 weeks in duration. The initial neurological symptoms vary from patient to patient. Distal, usually symmetrical, paresthesias (so-called pins and needles) involving the toes, fingers, or both herald the onset of the disorder in at least 50% of patients. As the disease progresses, these paresthesias typically spread proximally but seldom extend beyond the ankles and wrists. Facial paresthesias, which are usually perioral, are less common. Weakness can be the presenting feature, but more often it is first noted a few days after the paresthesias appear. Typically, it begins in the lower extremities, especially in the proximal muscles, so that patients may experience difficulty climbing stairs and rising from chairs for a day or two before they realize that they are ill. Weakness soon spreads (ascends) to the upper extremities. Less often, weakness begins simultaneously in the upper and lower extremities, with the lower extremities usually more severely affected, or it begins cranially and spreads inferiorly. This, the progressive phase of the illness, lasts

from a few days to 3 to 4 weeks. Approximately 50% of patients reach the nadir of clinical function by 2 weeks and 80% by 3 weeks. The flaccid weakness that is ultimately present varies considerably in severity and distribution from one patient to another. However, it often is profound, involving all four limbs, the respiratory muscles, and the face. Facial diplegia, or bilateral facial weakness, is seen in approximately 50% of patients (Video 23, Cranial Nerve VII, Facial Diplegia). Occasionally, fasciculations are noted. Although the prominent features are motor in nature, pain that is deep, poorly localized, and sometimes accompanied by muscle cramping, commonly occurs. Usually, it is most prominent in the shoulder girdle, back, and posterior thighs and is notoriously more severe at night.²⁻⁴

On clinical examination, one of the earliest findings is decreased or unelicitable DTRs. This finding may either precede or follow by a few days the demonstration of weakness on formal examination. Substantial sensory abnormalities are found infrequently and contrast with the high incidence of sensory symptoms. Typically, vibration and proprioception, the sensory modalities mediated over large myelinated fibers, are the most severely affected. In some cases, profound proprioceptive loss results in sensory ataxia and pseudoathetosis (Video 5, Sensory Ataxia). Generally, once symptoms have peaked, they persist unchanged for approximately 2 to 4 weeks, the so-called plateau phase, and then begin to recede in an extremely variable fashion from patient to patient.^{2-4,16}

Several atypical presentations or clinical variants of GBS have been described. The AMAM form is more rapid in onset, often the DTRs are retained or even hyperactive, and autonomic dysfunction seldom occurs, or is mild. Two patterns of recovery are seen with AMAN: (1) rather rapid recovery, within days, and (2) quite slow and often poor recovery. Nonetheless, the mean recovery time with AMAN is similar to that of CIDP, indicating that the weakness manifested by many patients is due to other than axon loss at the motor root level.¹⁴ As noted earlier, this GBS subgroup is mainly responsible for the summer epidemics in China and is linked to a preceding *C. jejuni* infection. The Miller Fisher syndrome consists principally of a triad of ophthalmoplegia, ataxia, and areflexia essentially occurring in isolation (Video 221, Miller Fisher Syndrome). The CSF protein usually is elevated, but the EDX findings, consisting of sensory NCS changes, are more suggestive of axon loss than SD. Miller Fisher syndrome generally is a benign disorder that does not require specific immune therapy. Finally, a pure sensory form has been reported, although the diagnostic criteria for GBS proposed in 1978 exclude this variant.²⁻⁴ Nonetheless, some convincing cases have been described and suggest that the spectrum of GBS may need to be expanded to include a predominantly sensory AIDP.^{29,30}

DIFFERENTIAL DIAGNOSIS. GBS is the most common type of rapidly evolving, generalized PNS disorder. Nonetheless, a great number of other disorders can be mistaken for it, particularly early in its course (Table 49-3). Ropper and coworkers, for example, list 50 entities that must be considered in the differential diagnosis of typical GBS.⁴ Certain preconditions must be met for many of these entities to be included. Thus, generally the patient must have recently traveled to various tropical regions for fish and

snake poisonings to be considered; traveled to underdeveloped countries for rabies, poliomyelitis, and diphtheria to be included; recently been in the woods in certain areas for tick paralysis or Lyme disease to be viable diagnostic possibilities; or been receiving parenteral hyperalimentation for hypophosphatemia to occur.^{2-4,27} Transverse myelitis may superficially resemble GBS, particularly if spinal shock has occurred and the lower extremity DTRs cannot be elicited. However, asymmetrical involvement, a definite sensory level, complete absence of upper extremity weakness, urinary incontinence, and CSF pleocytosis all speak against GBS. Heavy metal intoxication, principally subacute arsenic or acute thallium poisoning, can mimic GBS clinically; moreover, in the initial phase of arsenic poisoning, both the CSF and EDX findings may be identical to typical GBS. Nonetheless, these disorders should be included in the differential diagnosis of GBS only if there were preceding bouts of gastroenteritis. Associated CNS involvement is also common, particularly with thallium poisoning, and sometimes more than one person is affected simultaneously, strongly suggesting a common source.²⁻⁴

Vasculitic neuropathies occasionally are mistaken for GBS. However, systemic signs, including fever, are common; the sensory and motor involvement in the limbs usually is both distal in location and asymmetrical; cranial nerve involvement, respiratory complications, and sphincter dysfunction are uncommon. Moreover, the CSF typically is normal (except with systemic lupus erythematosus), and EDX studies reveal changes suggestive of axon loss, rather than SD.²⁻⁴

Acute intermittent porphyria can produce a PNS disorder that can be mistaken for GBS. However, its evolution is usually longer, and abdominal pain, constipation, and altered mental status are almost constant findings. The motor deficits often begin in the upper extremities; the Achilles DTRs may be preserved; sensory loss often is proximal; and seizures may occur. Moreover, the CSF protein typically is normal, and the EDX studies demonstrate axon loss rather than SD. Finally, both porphobilinogen and α -aminolevulinic acid are excreted in the urine in increased amounts during attacks of acute intermittent porphyria.²⁻⁴

Botulism in adults, nearly always foodborne, has a clinical presentation that resembles that of GBS. However, frequently several cases occur simultaneously, excluding sporadic GBS from consideration. Even with single cases, immediately preceding gastrointestinal symptoms are prerequisite, and constipation often is prominent throughout the course. Blurred vision, dry mouth, ptosis, and dilated pupils that poorly respond to both light and accommodation are very common. Weakness descends from the bulbar region, so that neck weakness and respiratory muscle weakness may be far more prominent than limb weakness. Other features include rare sensory loss and a normal CSF. EDX changes include motor unit disintegration, affecting the motor amplitudes on NCS and highly polyphasic, disintegrated MUPs, usually with fibrillation potentials, on NEE.²⁻⁴

Finally, early in its course GBS can be mistaken for a functional disorder (e.g., hysteria). Most neurologists can recount situations in which patients were released from emergency rooms with “hysterical symptoms,” only to be admitted to an intensive care unit (ICU) a few days later to receive treatment for GBS. This most often occurs when the patient has a history of psychiatric illness: the sensory complaints are mistaken for those caused by hyperventilation, weakness is at an early stage, so that gait disturbances are present but limb strength appears intact on formal testing, and the DTRs are not yet lost.²⁻⁴

EVALUATION. Routine hematology studies usually are normal. The two critical laboratory studies are CSF analysis and EDX examination. CSF that contains increased protein concentration with a normal cell count—albuminocytological dissociation—has been considered one of the diagnostic findings in the GBS since Guillain, Barré, and Strohl’s original 1916 report. Elevated CSF protein, typically ranging from 46 to 300 mg/dL, is seen in most patients, particularly after the first week of illness. Conversely, the CSF cell count usually remains normal, although it may be elevated (greater than 10 mononuclear leukocytes per microliter) in patients whose GBS is superimposed on acquired immunodeficiency syndrome (AIDS) or Lyme disease. The CSF protein, however, often is not elevated early after symptom onset. Moreover, in approximately 10% of patients with GBS, usually those with mild cases, elevated CSF protein is never found, even with repeated sampling, during the entire course of the illness. On EDX examination, very often changes strongly suggestive of SD, particularly conduction block, less often differential slowing or focal slowing, are seen on assessment of one or more nerves. Moreover, patterns of abnormalities suggestive of an acquired SD polyradiculoneuropathy, such as sensory NCS responses that are unelicitable or of low amplitude in the

upper extremity while normal in the lower extremity, often are found. Similar to the CSF analysis, EDX studies generally are least helpful for diagnosis during the very initial phase of the illness, precisely the period when a definite diagnosis is being sought so that specific treatment can be rapidly initiated. Thus, during the first several days of the illness, in many patients the CSF protein is not elevated and the EDX studies are normal or, if abnormal, nondiagnostic.^{11,12} Among 31 patients who had EDX examinations within the first week of onset of motor symptoms (i.e., weakness), a definite diagnosis of GBS was possible in just 55%, and usually not until the fifth day. The two most helpful findings in this regard were unelicitable H-responses and low amplitude or absent median sensory NCS responses in the presence of normal sural NCS. These abnormalities were more prevalent than abnormal F waves during this critical period, although the latter are most often mentioned in reports on AIDP.³¹ One very common misconception regarding the EDX studies is that substantial slowing of motor CV is a typical finding with early GBS. In fact, such NCS slowing seldom is seen during that stage of GBS. It is far more commonly found in the late plateau or recovery stages.

MANAGEMENT. There is no known prevention for sporadic GBS, although those persons who previously had a bout after immunization should probably avoid future immunizations, even though the risk is low.^{3,14} In contrast, whenever GBS occurs in epidemic form, as it does in China and other underdeveloped countries, its incidence may be reduced by improved public health measures.

The treatment of GBS has two components: supportive care and specific therapy. Supportive care remains the cornerstone of therapy, because most patients recover function if they advance past the acute phase of the illness. The major reduction in deaths from GBS over the past few decades has been due to advances in supportive care, particularly in mechanical ventilation.²⁻⁴ A recently published article provides practical recommendations regarding such factors as prophylaxis for deep vein thrombosis, cardiac and hemodynamic monitoring, respiratory monitoring, tracheostomy timing, and late patient fatigue.³²

Most authorities recommend that patients with suspected GBS be hospitalized, regardless of how mild their disorder appears initially. This advice is based on many instances of rapid deterioration occurring over brief time periods, leading to respiratory failure. Once they are hospitalized, patients must be assessed and monitored to avoid the major life-threatening complications of GBS, including respiratory failure, dysautonomia, and venous thromboembolism. Respiratory compromise is the most common serious complication and underlies the reason that approximately 30% of GBS patients who are hospitalized require treatment in an ICU. Weakness of the respiratory muscles, particularly the diaphragm, is most often responsible for respiratory failure. Other factors include weakness of various bulbar-innervated muscles and pulmonary complications, including atelectasis, pneumonia, and pulmonary embolism.^{2-4,33} Respiratory function can be assessed with arterial blood gas analysis and peak expiratory flow pressure measurements. Vital capacity measurements provide the most useful information regarding the degree of respiratory compromise. Respiratory function must be monitored closely.^{16,34} Generally, intubation is required whenever the vital capacity falls below 20 mL/kg.

Intratracheal intubation is complicated in patients with GBS because of dysautonomia, which can result in marked hypotension, arrhythmias, and sudden death due to various drugs and to airway manipulation and because of hyperkalemia, induced by succinylcholine, which can cause arrhythmias and cardiac arrest. Tracheotomies usually are not performed unless airway assistance is still needed at the end of the second week of the illness.³⁴ An improvement over traditional tracheostomy is percutaneous dilatational tracheostomy. It reduces the risk of accidental extubation, and yields a better cosmetic outcome.³²

Dysautonomia occurs to some extent in the majority of GBS patients but more frequently and more severely in those with respiratory failure and severe motor deficits. Severe paroxysmal hypertension, orthostatic hypotension, and various cardiac arrhythmias are all complications that may prove difficult to manage.³³ Pulmonary embolism occurs in about 5% of patients immobilized with GBS, typically after the second week of immobilization. In one series, it was responsible for approximately 28% of deaths. Preventive measures include subcutaneous heparin—switched to warfarin if patients are long term—and intermittent calf pneumatic compression devices.^{2-4,33} Plain support stockings can reduce the incidence of thrombosis significantly.³² Other complications are urinary tract infections and gastrointestinal disorders, including bleeding secondary to stress ulcers and erosive gastritis, ileus, and fecal impaction. Hyponatremia can develop, usually in ventilated patients and due to inappropriate release of antidiuretic hormone. This electrolyte imbalance responds to fluid restriction.^{4,33,35}

Two non-life-threatening complications of GBS that require attention are pain and psychological trauma. Pain occurs in 33% to 71% of patients with GBS and often is severe.³² A number of medications have been used to treat GBS pain with varying success. Simple analgesics and nonsteroidal anti-inflammatory medications should be tried, but frequently they prove inadequate. Gabapentin or carbamazepine often is beneficial during the acute stage. Narcotic analgesics are required in many patients.³² However, they must be used with caution because they tend to exacerbate respiratory failure and to produce ileus. A few reports have described sustained pain relief for a few days following a single IM injection of 40 to 60 mg of methylprednisolone. Certain physical measures, such as the application of cold or hot packs, gentle massage, or repositioning with the limbs in slight flexion, may bring pain relief.³³ The psychological stress on essentially paralyzed GBS patients must also be appreciated. Their fears and concerns, particularly regarding recovery potential, must be addressed throughout all phases of the illness.^{33,35}

The specific treatment for GBS since 1978 has been plasmapheresis. It can be beneficial in patients of all ages, although there are only anecdotal reports, rather than large-scale studies, to support its value in children with GBS. Also, pregnancy is not a contraindication to plasmapheresis; at least two pregnant women have been treated with this method without incident.⁴ Although plasmapheresis has no effect on either mortality or relapse rates, measurable objective improvement occurs in nearly every other aspect of the disorder in at least 50% of treated patients. Thus, compared with nontreated patients, improvement begins

earlier in the course and is appreciably better at 1 month after onset. With plasmapheresis, less mechanical ventilation is required, and both ICU and hospitalization time is decreased. To be effective, plasmapheresis must be instituted early in the course of the disorder, preferably within the first week. The precise regimen has not been established, although most investigators have used 150 to 250 mL/kg over 7 to 10 days of treatment.²⁻⁴ Studies have shown that patients with mild AIDP benefit maximally from two plasma exchanges while those with moderate or severe disease require four.^{14,36} The drawbacks of plasmapheresis include its expense and rare complications such as hypotension and sepsis. There is a risk of acquiring viral infections, such as hepatitis and possibly AIDS, if fresh frozen plasma is used as the replacement fluid. (Plasma appears to offer no benefit over albumin with saline.⁴) Intravenous immunoglobulin (IVIG) was first used to treat AIDP more than a decade ago, and since then large-scale trials have demonstrated that it is as efficacious as plasmapheresis in this regard, given 400 mg/kg/day for 5 consecutive days. This method of treatment has advantage over plasmapheresis in that it is easier to administer.⁴ Similar to plasmapheresis, it is of value mainly when used early after onset of symptoms. Interestingly, combining plasmapheresis and IVIG does not improve outcome.¹⁴ However, the transmission of viral infections, including AIDS, is a concern, because IVIG is made from plasma pooled from thousands of donors.⁴ Both corticosteroids, in conventional doses, and adrenocorticotrophic hormone (ACTH) have not been effective in the treatment of GBS. In fact, a few studies have suggested that ACTH is actually detrimental.^{2,4} A recent study compared a combination of high-dose intravenous methylprednisolone and IVIG to IVIG treatment alone, and found no substantial difference.¹⁴

The fact that a central venous line is unnecessary for IVIG administration has made the latter treatment of choice in children with GBS. At least in this group of patients, a 2-day course of infusion may be more effective than treatment for 5 days.²⁴

During the first two trimesters of pregnancy, the management of women with GBS is identical to that of non-pregnant patients in regard to both supportive care and specific therapy. During the third trimester, owing to increased respiratory demand, supportive care becomes crucial, because the risk of respiratory failure increases, culminating during delivery. Adequate ventilation must be ensured during this period. Due to an increase in premature labor and delivery, a perinatal infant mortality rate of approximately 10% mars late pregnancy complicated by GBS.⁴ However, GBS is not considered an indication for cesarean section, and infants do not acquire GBS, even transiently, from their affected mothers.^{2,4}

PROGNOSIS AND FUTURE PERSPECTIVES. Even as late as 1953, Guillain always contended that GBS was an inherently nonfatal disorder, a benign disease that left little, if any, residual effects. Such optimism is not supported by many series published over the past 30 years. Excluding those with mild disease, most patients are hospitalized for at least 1 month and often considerably longer, particularly if mechanical ventilation is required. Overall, approximately 5% of patients die; mortality rates of 15% to 20% have occurred in ICUs, most often from adult respiratory distress syndrome. Approximately 75% of patients recover

without serious neurological residuals, and recovery typically ensues over the 6 to 12 months after onset and is usually maximal by 18 months after onset. Some patients may be left with persistent minor weakness, paresthesias, or sensory loss.⁴ Approximately 7% to 15% of patients have permanent, substantial neurological sequelae (e.g., bilateral footdrop, intrinsic hand muscle weakness and wasting, sensory ataxia, burning dysesthesias). Only a very few, however, are permanently bedridden by the disorder.²⁻⁴ Several factors during the acute phase of the illness have been linked to subsequent poor recovery. These factors include older patient age (particularly age 60 or older); rapid, early evolution, leading to quadriplegia within a week; and very low motor NCS amplitudes on distal stimulations early in the course of the disease (suggesting severe axon loss, but equally consistent, at least theoretically, with severe distal SD conduction blocks). The latter has proved to be the single most reliable outcome predictor.¹² Not surprisingly, most of the prognostic factors listed merely indicate that a poor long-term prognosis is directly related to the severity of the acute episode.

As the past decade has illustrated, much is yet to be learned about GBS. What is the exact initiating mechanism for demyelination with AIDP?²⁵ Given that a number of patients with GBS experience long-term disability, more effective treatment needs to be developed. This could be in the form of specific modulators of the immune system, such as inhibitors of cyclooxygenase-2 or complement activation, or drugs to promote regeneration of myelin or axons. Also, how can the neuropathic pain that often occurs with GBS be prevented, or at least treated more effectively?^{13-15,24,25} These questions are of much more than academic interest, because the answers to them can influence treatment and possibly prevention of this disorder.

CHRONIC INFLAMMATORY DEMYELINATING POLYRADICULONEUROPATHY

PATHOGENESIS AND PATHOPHYSIOLOGY. CIDP is an apparent immune-mediated disorder of the PNS. The term *chronic inflammatory demyelinating polyradiculopathy* was coined to emphasize that the disorder is a chronic process that results in demyelination as well as an inflammatory cell response in peripheral nerves and spinal nerve roots; typically, there is a mononuclear cell infiltration involving the endoneurium and epineurium of peripheral nerve fibers.³⁷ The predominant pathological feature is SD, although usually there is some degree of axon loss as well (Figs. 49-3 and 49-4). These pathological changes have been found to involve roots, plexuses, proximal nerve trunks, and, occasionally, cranial nerves and sympathetic trunks, as well as some autonomic nerves.³⁸ The predilection for CIDP to involve roots and proximal nerve trunks is responsible for the prominent proximal weakness that may be encountered in this disorder and helps distinguish it from most other generalized polyneuropathies. The predominant involvement of myelin in CIDP results in a characteristic pattern of findings on EDX testing, including slowed nerve CV and conduction block; the latter process correlates with the clinical deficits. Also, the distinctive distribution of NCS abnormalities that may occur with

Figure 49-3. Electron microscopy of sural nerve in CIDP. A normal myelinated fiber (*left*) is adjacent to a myelinated fiber that has thin and partially absent myelin (*right*).

Figure 49-4. Teased nerve fiber preparation showing segmental demyelination in a sural nerve in CIDP.

acquired SD polyradiculopathies (already described) is often seen.¹⁰

The evidence that CIDP is immune-mediated is compelling, although still somewhat inconclusive. In many respects, it is similar to the evidence advanced for AIDP being an immune-mediated disorder. The onset or relapses of CIDP on occasion seem to be triggered by a preceding event, such as an infection or vaccination that could initiate an immune-mediated response. In addition, most patients with CIDP respond to corticosteroids and other immunosuppressants, plasma exchange, and IVIG, therapies designed to treat immune-mediated disorders. Furthermore, CIDP shares many clinical and pathological features with experimental models of immune-mediated peripheral

neuropathy, particularly EAN. This has led to speculation that the pathogenesis of CIDP is similar to that of AIDP and EAN. Lastly, the presence of immune-effector cells and the deposition of antibody and complement on myelinated fibers is impressive but indirect evidence of an immune-mediated process in which both cellular and humoral immune systems are operative.³⁹

More recent studies have provided additional evidence of an immune-mediated mechanism for CIDP. Passive transfer of sera and IgG from CIDP patients to experimental animals has resulted in histological and electrodiagnostic evidence of demyelination of peripheral nerve fibers.⁴⁰ In addition, IgG antibodies directed at protein zero (P_0), the major integral membrane protein of peripheral myelin, have been found in 28% of CIDP patients, and in two thirds of these patients, the sera caused conduction block and demyelination when injected into experimental animals.⁴¹

A disorder clinically similar to CIDP but with pathological and EDX features, indicating an axon loss process, has been reported.³⁸ Whether this actually represents a so-called axonal form of CIDP similar to the axonal form of GBS remains to be established.⁴²

EPIDEMIOLOGY AND RISK FACTORS. The age of onset of CIDP has been reported to range from 1 year through the eighth decade or later, with a mean in the fourth decade. Both sexes are affected, although there is a slight male predominance. With the mean age of onset being in the fourth decade, women of childbearing age may develop CIDP. Furthermore, there is evidence that the disorder may relapse or worsen during pregnancy and in the postpartum period.⁴³ Patients with certain histocompatibility antigens have an increased risk of developing CIDP. In particular, there is an increased incidence of histocompatibility locus antigens AW30, AW31, A1, B8, and DRw3. Furthermore, CIDP, GBS, and multiple sclerosis have all been associated with the presence of the M3 allele of the α -1 antitrypsin system located on chromosome 14.³

CLINICAL FEATURES AND ASSOCIATED DISORDERS. By definition, CIDP is a chronic disorder that typically evolves slowly, almost always requiring a period of 8 weeks or longer for symptoms to reach their peak, and they typically do so over many months. CIDP can follow either a slowly progressive monophasic course, which occurs in approximately two thirds of patients, or a cyclical relapsing course seen in the remainder.^{5,43}

The symptoms of CIDP can be variable, but usually weakness tends to predominate over sensory symptoms.^{5,37} The distribution of weakness often conforms to a typical peripheral neuropathy pattern of symmetrical involvement, with the lower extremities being affected more than the upper extremities and distal muscles being affected more than proximal muscles. However, in many patients, the weakness is asymmetrical, and in others, it is more prominent proximally. The degree of weakness varies markedly from patient to patient. In the majority of patients, it is mild to moderate in degree, but rarely, the weakness can be severe and generalized, sometimes associated with respiratory failure necessitating ventilatory support. Muscle cramping and fasciculations are infrequent symptoms.^{5,37,38}

Sensory symptoms are usually confined to mild paresthesia or modest sensory loss. However, in those patients

with chronic progressive courses, sensory symptoms may become more prominent. In addition to numbness and paresthesia, pain sometimes is reported, although this occurs in less than 20% of patients. Very infrequently, CIDP may present with predominantly sensory symptoms, including numbness, paresthesia, and sensory ataxia (Video 87, Upward Drift; Video 98, Romberg Sign). In a subset of these patients, this PNS disorder appears essentially confined to sensory fibers, prompting speculation that the apparent immune-mediated response is directed at a unique antigen in the myelin of sensory fibers. However, in most instances in which the disorder begins as a sensory neuropathy, it later evolves to a more typical pattern of sensory and motor involvement. On occasion, the cranial nerves may be affected, causing symptoms of diplopia, facial weakness or numbness, dysarthria, and dysphagia (Video 23, Cranial Nerve VII, Facial Diplegia). Autonomic symptoms are uncommon, although incontinence and erectile impotence have been reported.^{5,37,38}

The physical signs noted in CIDP reflect the clinical symptoms. Distal symmetrical weakness, with the lower extremities more severely affected than the upper extremities, is the rule. However, asymmetrical involvement and more prominent proximal involvement can occur, and they serve as important clinical clues to the diagnosis of CIDP. Generalized hyporeflexia or areflexia is characteristic. Sensory loss often conforms to a distal to proximal gradient, in the so-called stocking-glove pattern, with all modalities affected to a nearly equal extent. Occasionally, sensory ataxia may be observed. Cranial nerve findings may include signs of facial, bulbar, and neck weakness. Papilledema is an unusual clinical feature, and its precise pathophysiology is unclear. It has been attributed to altered resorption of CSF over the arachnoid villi due to elevations of CSF protein or to increased intracranial pressure.³ Rather rare clinical features include pupil abnormalities consistent with parasympathetically denervated pupil, Horner's syndrome, and postural or cerebellar-type tremors (Video 14, Tremor with Ataxia; Video 17, Horner's Syndrome).³⁴ Occasionally, hypertrophied nerves may be palpated in patients with very chronic CIDP. Rarely, the spinal nerve roots may be hypertrophied to such an extent that they act as masses, compressing the spinal cord, and may produce a syndrome of spinal cord compression.⁴⁴

More recently, additional terminologies have been proposed to define special variants of CIDP.⁴⁵ Idiopathic distal acquired demyelinating symmetric (DADS-I) neuropathy has been suggested as a term to describe a variant of CIDP with clinical features of a sensorimotor polyneuropathy that is often predominantly sensory and strictly respects a distal to proximal gradient of involvement. In addition, DADS-I may be less responsive to the standard therapies for typical CIDP. When this phenotype occurs in the setting of a monoclonal gammopathy of uncertain significance (MGUS), it is referred to as DADS-M (see later discussion).⁴⁵ This entity will be discussed in the section dealing with MGUS. Multifocal acquired demyelinating sensory and motor (MADSAM) neuropathy, or Lewis-Sumner syndrome, has been proposed as a term to describe a multifocal or mononeuritis multiplex variant of CIDP.⁴⁶ In this syndrome, sensory and motor symptoms and signs may conform to the distribution of individual peripheral nerves. Onset is often in the upper extremities, sensory

symptoms may be prominent, and progression tends to be slow and insidious. CSF findings are similar to those seen in typical CIDP, and EDX findings are indicative of multifocal SD. These patients tend to respond to the standard therapies used for typical CIDP. MADSAM neuropathy may occasionally resemble multifocal motor neuropathy with conduction block, a disorder with different clinical, CSF, and EDX features as well as very different therapeutic implications.

Some patients with CIDP have abnormalities on MRI scans of the head consistent with multiple sclerosis.⁴⁷ Abnormalities of visual evoked potentials may also be seen in some CIDP patients.⁴⁸ Whether these isolated patients represent the coincidental occurrence of two disorders or an immune-mediated disorder of both central and peripheral myelin remains unclear.

There is no conclusive evidence that CIDP patients have a higher incidence of other medical conditions, including autoimmune disorders. However, associated disorders, including systemic lupus erythematosus, Hashimoto's thyroiditis, thyrotoxicosis, chronic active hepatitis, inflammatory bowel disease, urticaria, eczema, psoriasis, Sjögren's syndrome, melanoma, and diabetes do occur in some CIDP patients.^{3,49} A CIDP-like disorder may occur in the setting of MGUS, as well as with multiple myeloma, osteosclerotic myeloma, and other lymphoproliferative disorders. These disorders are discussed as distinct entities in the following sections.

DIFFERENTIAL DIAGNOSIS. On purely clinical grounds, CIDP may be confused with a wide variety of chronic sensorimotor polyneuropathies, including those related to diabetes, uremia, hypothyroidism, acromegaly, toxins, and alcoholic-nutritional mechanisms. Although CIDP may produce distinguishing clinical features, such as predominant motor symptoms and signs, asymmetrical involvement, proximal motor involvement, and cranial nerve symptoms and signs, the paramount factor in separating CIDP and related disorders from the rather large group of nonspecific, chronic axon loss sensorimotor polyneuropathies is the presence of acquired SD features on EDX testing. Thus, EDX evaluation is the key step in identifying the acquired SD polyneuropathies, including CIDP. The differential diagnosis of this category includes not only CIDP, but also the CIDP-like disorders that may be associated with multiple myeloma, osteosclerotic myeloma (including the POEMS syndrome, an acronym that stands for polyneuropathy, organomegaly, endocrinopathy, M-protein, and skin changes), MGUS, and Waldenström's macroglobulinemia. These disorders may be distinguished from CIDP by the presence of an M-protein in the serum or urine, the presence of lytic or sclerotic lesions on skeletal bone survey, or both. A disorder essentially identical to CIDP can result from HIV infection. Consequently, testing for HIV is indicated in patients at risk. CIDP may be a presenting feature of HIV infection, preceding seroconversion for up to 6 months. For this reason, repeating HIV testing 6 months after the onset of a CIDP-like disorder is appropriate in patients at risk.

Familial hypertrophic polyneuropathies that produce EDX features of SD along with axon loss may sometimes be confused with CIDP. With the familial disorders, a positive family history typically is recorded, but in some instances, it is not. CIDP can usually be distinguished on clinical grounds by its more rapid tempo of evolution and

a cyclical or relapsing course. The EDX findings may also be helpful in differentiating CIDP from these disorders. In the familial disorders, the SD features on NCS tend to be symmetrical, with uniform involvement of all nerves. Focal conduction block and focal conduction slowing usually are not observed. Despite these numerous distinguishing features, occasionally it still may be difficult to distinguish a long-duration CIDP from a familial hypertrophic SD polyneuropathy. In such circumstances, a trial of therapy is usually indicated.

On occasion, CIDP may be difficult to differentiate from AIDP. Patients with more subacute courses of CIDP have been described, and sometimes CIDP may begin with a relatively acute onset. Over time, CIDP usually declares itself by a typical chronic relapsing course or a more slowly progressive monophasic course. The distinction between AIDP and CIDP is significant because the ultimate course, prognosis, and treatment are different.^{38,39}

EVALUATION. As noted earlier, the performance of a comprehensive EDX evaluation to uncover findings consistent with acquired SD is key in the evaluation and diagnosis of CIDP and related disorders. These EDX findings clearly distinguish CIDP and related disorders from the vastly more common group of clinically similar axon loss sensorimotor polyneuropathies. The general laboratory features of CIDP are relatively nonspecific and are not particularly useful in confirming the diagnosis. Routine laboratory tests typically are normal. The CSF protein, however, is frequently elevated to a moderate degree; in one series, it ranged from 23 to 600 mg/dL with a mean of 138 mg/dL. Nonetheless, it should be emphasized that in 10% of patients with CIDP, the CSF protein may be normal.⁵ Even sural nerve biopsies generally do not provide specific or diagnostic features, although in the majority of patients they will document the presence of inflammation and demyelination, two features that characterize CIDP. However, these findings are not pathognomonic. Furthermore, the sural nerve biopsy may be normal in nearly 25% of patients.³⁷ It is important to appreciate that a normal CSF protein and sural nerve biopsy are not necessarily inconsistent with the diagnosis of CIDP. On the other hand, a normal EDX examination essentially excludes this diagnosis.

The critical component in the evaluation of a patient with suspected CIDP is to exclude the CIDP-like disorders. This requires careful screening of the serum and urine for the presence of M-proteins. Because a small amount of M-protein may still be undetected by routine serum protein electrophoresis testing, the search for M-protein should include an assessment incorporating immunoelectrophoresis or immunofixation techniques. The presence of an M-protein in the setting of a CIDP-like disorder may signify a polyneuropathy associated with multiple myeloma, osteosclerotic myeloma, MGUS, Waldenström's macroglobulinemia, or another lymphoproliferative disorder. Also, a skeletal x-ray study is indicated, because a significant percentage of patients with osteosclerotic myeloma may not disclose an M-protein on immunofixation. HIV testing should also be performed in all patients at risk with a CIDP-like disorder.

MANAGEMENT. CIDP is a very treatable disorder, with most patients showing favorable responses to one of the

many therapeutic modalities available. Some of the earliest reports of CIDP indicated that it was often steroid responsive.²⁸ Subsequently, a controlled clinical trial clearly established the value of corticosteroids in the treatment of CIDP, regardless of whether the course was monophasic and progressive or cyclical and relapsing.⁵⁰ Controlled trials have also established the efficacy of IVIG and plasma exchange in CIDP.^{51,52}

When constructing a treatment plan for patients with CIDP, it is important to balance clinical symptoms against the risks and potential benefits of the therapy. Clearly, patients with rather modest or minimal symptoms may not require treatment. Instead, they should be followed and observed closely. However, in those with a progressive course or with substantial clinical symptoms, treatment may begin with IVIG, plasma exchange therapy, or corticosteroids. Although both IVIG and plasma exchange are relatively expensive therapeutic modalities, either is justified as an initial treatment. Their advantage is that they obviate the need for chronic corticosteroid or other immunosuppressant treatment and thus avoid the associated side effects and complications of these therapies. Both IVIG and plasma exchange are comparable in efficacy and expense. Nonetheless, IVIG may have certain advantages over plasma exchange. It may require fewer treatments, is somewhat less invasive, and may be administered at home. It is imperative, however, that patients considered for IVIG therapy be assessed for IgA deficiency, because anaphylactic reactions have occurred following the administration of IVIG in patients with IgA deficiency. Furthermore, caution should be exercised in administering IVIG to patients who have underlying renal dysfunction, because the risk of renal failure is increased following IVIG treatment. Traditionally, IVIG therapy is administered at a dose of 400 mg/kg/day over 5 consecutive days.³⁹ An alternative recommendation is to use IVIG at 400 mg/kg/day once per week over 6 to 8 consecutive weeks.⁴⁴ Follow-up doses, typically single doses of 400 mg/kg, are administered at intervals needed to maintain the clinical response. Plasma exchange therapy requires expertise in its use and is clearly more technically demanding than is IVIG treatment. Plasma exchange usually is administered twice weekly for the first 3 weeks and then once or twice weekly for an additional 3 weeks.³⁸ Patients typically respond to IVIG or plasma exchange within the first several weeks of treatment and may demonstrate sustained improvement for many weeks or months. Relapses may require periodic isolated treatments with a single dose of IVIG or single plasma exchange. If a patient responds successfully to infrequent booster treatments of either IVIG or plasma exchange, it is reasonable to maintain this form of treatment rather than adding corticosteroids or other immunosuppressants.

In patients who are not candidates for either IVIG or plasma exchange, or in whom responses are not satisfactory, chronic immunosuppressive therapy must be considered. Corticosteroids typically are used at relatively high doses initially and then slowly tapered while monitoring the clinical response. Most patients who respond will do so during their first few months of treatment. In those patients who cannot tolerate corticosteroids and in those who do not obtain a satisfactory clinical response to them,

a trial of other immunosuppressants may be a reasonable alternative.³⁸ Anecdotal evidence suggests that azathioprine, cyclophosphamide, cyclosporine, total lymphoid irradiation, interferon- α and - β , and mycophenolate may be of value in treating some patients with CIDP.^{53,54}

In addition to these various immunosuppressive therapies, patients should undergo a thorough physical therapy assessment to determine if they require aids to ambulation, including orthotic devices such as ankle-foot orthosis for footdrop. Other physical therapy modalities, including stretching and range-of-motion exercises, may be helpful while a patient is responding to medical therapy.

PROGNOSIS AND FUTURE PERSPECTIVES. The prognosis is favorable for most patients with CIDP who are properly diagnosed and treated. In one large group of patients whose disease duration averaged 5.7 years and who were followed for a minimum of 24 months, nearly 40% were asymptomatic and nearly 50% had either minor symptoms that did not have any impact on their level of function or had only very modest restrictions in lifestyle.⁵⁵ Future research objectives will focus on the specific immune-mediated mechanisms and pathophysiology of CIDP. From a purely clinical perspective, further trials are needed to better define optimal therapeutic protocols using the modalities that have already proved effective, including IVIG, plasma exchange, and corticosteroids and to explore other immunomodulating therapies that may be effective or those patients that do not respond to the standard therapies.

MONOCLONAL GAMMOPATHIES OF UNDETERMINED SIGNIFICANCE

PATHOGENESIS AND PATHOPHYSIOLOGY. A heterogeneous group of peripheral neuropathies has been associated with the presence of an MGUS. However, the precise relationship of the monoclonal (M) protein to the peripheral nerve disorder remains unclear. By definition, MGUS indicates the presence of an M-protein of less than 3 g/dL in concentration, with less than 5% plasma cells in bone marrow, none or only a very small amount of M-protein in the urine, and the absence of other abnormalities, including lytic or sclerotic bone lesions, anemia, hypercalcemia, and renal insufficiency. Furthermore, the M-protein should remain at stable and low concentrations over time.⁵⁶ The natural history of MGUS indicates that with advancing time-specific hematological and lymphoproliferative disorders, such as multiple myeloma, Waldenström's macroglobulinemia, amyloidosis, and lymphoma, may develop. Nevertheless, most patients who undergo a comprehensive evaluation for an M-protein in their serum ultimately will have it attributed to MGUS. MGUS is rather common, occurring in up to 1.7% of patients older than age 50 and in 3% of patients older than age 70.⁵⁶

Acquired SD polyneuropathies with features similar to that of CIDP have been observed in MGUS with IgG, IgA, and IgM M-proteins. These observations, coupled with the response of these disorders to the typical therapeutic interventions used for CIDP, have fostered the belief that these disorders are also immune-mediated. However, the only strong evidence to support this theory is found in the MGUS neuropathy associated with IgM M-protein.

In this disorder, the M-protein binds and reacts to myelin and to an oligosaccharide determinant that is shared by the myelin glycoproteins myelin-associated glycoprotein (MAG) and Po and the glycolipids sulfated glucuronyl paragloboside (SGPG) and sulfated glucuronyl lactosaminyl paragloboside (SGLPG).⁵⁷ Approximately 50% of patients with IgM MGUS neuropathy have anti-MAG antibodies. The finding of deposits of anti-MAG M-protein and complement on affected myelin sheaths, the presence of widening of myelin lamellae at the sites of antibody deposition, and the experiments that document the development of polyneuropathy in animals following passive transfer of patients' serum support the concept that the IgM M-protein with anti-MAG activity plays an important pathogenetic role in the development of the polyneuropathy.⁵⁷ Other observations, however, have detracted from this theory, including the fact that the concentration of the IgM M-protein may not always correlate with the severity of the polyneuropathy nor with the clinical response after treatment.⁵⁸

Similar to CIDP, the demyelinating polyneuropathy associated with MGUS typically produces physiological alterations suggestive of an acquired SD polyradiculoneuropathy, often accompanied by a modest degree of axon loss. MGUS can also produce a pure axonal sensorimotor polyneuropathy.^{57,58}

EPIDEMIOLOGY AND RISK FACTORS. MGUS polyneuropathy tends to occur later in life than CIDP, with the mean age of onset in the mid- to late sixth decade. In most large series, a distinct male predominance is noted. There are no other particular risk factors, and MGUS neuropathy seldom occurs in women of childbearing age.^{57,58}

CLINICAL FEATURES AND ASSOCIATED DISORDERS. In general, the MGUS polyneuropathies associated with IgG and IgA conform to a sensorimotor polyneuropathy that shares many clinical features with CIDP, including predominant proximal weakness. Nonetheless, there may be some differences. Sensory symptoms usually are more prominent than in CIDP. In addition, the initial phase of the disorder often progresses much slower than it does in CIDP, and the course is less likely to be cyclical or relapsing. Also, cranial nerve involvement and autonomic involvement are rare. Nevertheless, clinical syndromes indistinguishable from CIDP may be seen with MGUS polyneuropathy.

The clinical syndrome seen with MGUS IgM polyneuropathy appears to differ from that seen both with CIDP and with MGUS polyneuropathy associated with IgG and IgA. This disorder typically conforms to a distal and symmetrical polyneuropathy and has been termed DADS-M (distal acquired demyelinating symmetrical neuropathy associated with an M-protein).⁴⁵ With this disorder, sensory symptoms may be even more prominent and can be the initial presenting feature (Video 87, Upward Drift). Typically, progressive sensory impairment is followed later by motor involvement. Sensory ataxia, particularly affecting the gait, is a common finding, as are tremors of the upper extremities that resemble essential tremor (Video 5, Sensory Ataxia; Video 60, Marked Postural Tremor).⁵⁹ Similar to the other MGUS polyneuropathies, the clinical features tend to progress more slowly and are less severe than the initial symptoms associated with CIDP. Moreover, relapsing

and cyclical courses are not seen, and cranial nerve or autonomic involvement rarely is encountered.

There is no definitive evidence that other disorders, particularly other immune-mediated disorders, are present to a greater extent in patients with MGUS polyneuropathy. It should be emphasized, however, that the diagnosis of MGUS depends on the stability of the M-protein concentration. Because a significant number of patients with MGUS will later develop malignant forms of monoclonal gammopathy, these patients require repeated evaluations and monitoring of the M-protein over time.

DIFFERENTIAL DIAGNOSIS. The differential diagnosis of MGUS polyneuropathy producing acquired SD changes on EDX examination is identical to that of CIDP. It is key to exclude the other causes for monoclonal gammopathy, including multiple myeloma, isolated plasmacytoma, Waldenström's macroglobulinemia, osteosclerotic myeloma (including the POEMS syndrome), heavy chain diseases, malignant lymphoma, and amyloidosis. It should also be noted that MGUS polyneuropathy may manifest as an axon loss polyneuropathy and, consequently, should be included in the differential diagnosis of axon loss sensorimotor polyneuropathy discussed elsewhere.⁵⁶⁻⁵⁸

EVALUATION. In IgG and IgA MGUS demyelinating polyneuropathy, the EDX examination typically shows changes suggestive of a chronic, acquired SD polyradiculoneuropathy similar to that seen in CIDP. In patients with IgM MGUS, the EDX examination may disclose a distinctive pattern of distal, symmetrical demyelinating change.^{45,60} Searching for an M-protein is an important component in the evaluation of any patient with a significant sensorimotor polyneuropathy. As noted earlier, if the serum protein electrophoresis is negative or unrevealing, additional testing should be performed using immunoelectrophoresis or immunofixation techniques. These methods are more sensitive in detecting small amounts of M-protein that may be important in the identification of MGUS polyneuropathy.⁵⁶ Once an M-protein is detected in the setting of a sensorimotor polyneuropathy, a careful evaluation must follow to assess for a lymphoproliferative disorder. This evaluation typically entails routine laboratory studies to assess for anemia, hypercalcemia, and renal insufficiency. In addition, M-protein should be sought in the urine, and a skeletal bone survey should be obtained to assess for multiple myeloma, isolated plasmacytomas, or osteosclerotic changes typical of osteosclerotic myeloma. Although radionuclide bone scans may be valuable in this assessment, the skeletal plain x-ray study is more sensitive for the detection of osteosclerotic lesions. A bone marrow aspirate should also be performed. HIV testing also should be performed in patients at risk, with guidelines similar to those noted for CIDP.

Routine laboratory studies in MGUS polyneuropathy typically are unremarkable. The CSF protein is consistently increased in a fashion similar to that seen with CIDP. Sural nerve biopsy may also disclose features of inflammation and SD with some axon loss, which are very similar to the pathological changes noted in CIDP. None of these findings, however, is specific for MGUS polyneuropathy, and none serves to differentiate it from CIDP and other related disorders.

Although it is unclear whether the presence of antibodies has any definite clinical implication regarding the

management, prognosis, or pathophysiology of IgM MGUS polyneuropathy,⁴⁵ patients with IgM MGUS are usually assessed for anti-MAG antibodies, often in conjunction with anti-SGPG and anti-SGLPG antibodies.

MANAGEMENT. The data regarding benefits of therapeutic intervention with steroids, immunosuppressants, plasma exchange, and IVIG are largely anecdotal but tend to indicate that MGUS polyneuropathy responds in a fashion similar to CIDP.^{58,61} A controlled trial of plasma exchange did disclose efficacy in MGUS polyneuropathy but appeared to demonstrate greater improvement in polyneuropathies associated with IgG and IgA M-proteins compared with those associated with IgM M-proteins.⁶² It appears that IgM MGUS polyneuropathy, especially in the setting of a distal sensory polyneuropathy phenotype (DADS-M), is the least responsive to therapy, with only 30% of patients demonstrating improvement following immunomodulating treatments.⁴⁵ Although convincing data are lacking, there is general agreement that these patients should be treated following the same guidelines used for CIDP. However, because MGUS polyneuropathy tends to be a more slowly progressive disorder than CIDP, it may be more difficult to define a precise threshold when treatment is indicated. Furthermore, treatment must be aggressive and sustained to provide ample time to observe a clinical response.

PROGNOSIS AND FUTURE PERSPECTIVES. In comparison to CIDP, the prognosis in patients with MGUS polyneuropathy as a group may be less favorable. Despite the fact that the initial severity of weakness and sensory impairment is considerably less in MGUS polyneuropathy compared with cyclical relapses of CIDP or to the peak of a monophasic course of CIDP, MGUS polyneuropathy tends to be slowly progressive and ultimately, if the condition is left untreated, may result in more severe clinical deficits and disability.⁵⁵ Also, MGUS polyneuropathy, overall, is somewhat less responsive to therapy than CIDP. Patients with MGUS polyneuropathy who have prominent features of acquired SD on EDX testing appear to have the greatest chance for significant improvement following therapeutic intervention. Those patients with DADS-M may be less responsive to plasma exchange and other interventions. In a study of 25 treated patients with MGUS polyneuropathy who had a mean duration of illness of 6.6 years and were followed for a minimum of 24 months, 12% were asymptomatic and another 60% had either minimal, non-disabling symptoms or minor symptoms that caused only modest restrictions in their lifestyle.⁵⁵

Very fundamental nosological issues regarding MGUS polyneuropathies need to be clarified. Does the presence of an M-protein in the setting of a SD polyneuropathy mimicking CIDP indicate a separate and distinct clinical entity? What is the pathogenetic role of the M-protein in MGUS polyneuropathy? Is the subset of MGUS polyneuropathy associated with IgG and IgA M-proteins distinct clinically and pathogenetically from that associated with an IgM M-protein? More specifically, does the presence of anti-MAG antibodies in IgM MGUS polyneuropathy signify a distinct clinical and pathogenetic disorder that can be separated from CIDP and the other MGUS polyneuropathies? And finally, what are the natural histories of these disorders and what represents optimal therapies for the various types of MGUS polyneuropathy?

MULTIPLE MYELOMA

PATHOGENESIS AND PATHOPHYSIOLOGY. Multiple myeloma is a hematological disorder characterized by a proliferation of a single clone of plasma cells that produces a specific immunoglobulin. This disorder may affect patients between the ages of 40 and 70, but the peak incidence is in the seventh decade. Multiple myeloma typically causes bone pain, general fatigue, and weakness and is often accompanied by anemia, chronic renal failure, and hypercalcemia. Over 99% of patients will have an M-protein detected in the serum or urine on immunoelectrophoresis or immunofixation.⁵⁶ Skeletal bone surveys reveal osteolytic or rarely osteoblastic lesions in approximately two thirds of patients. The diagnosis can be established by bone marrow aspiration, which documents prominent collections of immature plasma cells.

Peripheral neuropathy is a rare complication of multiple myeloma, and when present, it is more likely due to associated amyloidosis than a remote effect of the multiple myeloma. However, an axon loss polyneuropathy as well as an acquired SD polyneuropathy may occur as a remote effect. The precise pathogenesis of the polyneuropathy is unknown, but mechanisms similar to those proposed for MGUS polyneuropathy may be operative.

EPIDEMIOLOGY AND RISK FACTORS. Patients with polyneuropathy secondary to multiple myeloma tend to present at a younger age than patients with multiple myeloma without polyneuropathy.⁶³ Most reports document a prominent male predominance in the patients with neuropathy. In the majority of patients, polyneuropathy is the presenting sign of the multiple myeloma and, in fact, may predate the diagnosis of multiple myeloma for many months or years. It is extremely rare for multiple myeloma to affect women of childbearing age, and thus there is no known influence or risk associated with pregnancy.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Multiple myeloma typically produces a chronic, slowly progressive, symmetrical, sensorimotor polyneuropathy. However, in some patients, a more rapid evolution may occur with prominent motor weakness that can evolve to quadriplegia with respiratory involvement. Rarely, cranial nerve involvement, characterized by facial weakness or ophthalmoplegia, may be observed. Generalized hyporeflexia or areflexia is a common finding. Autonomic involvement seldom occurs, and when present in a patient with multiple myeloma, it raises the more likely possibility of an underlying amyloid neuropathy.

There are no additional disorders that are directly associated with the polyneuropathy secondary to multiple myeloma. However, the clinical disorders that often accompany multiple myeloma may be present. These disorders include metabolic abnormalities such as anemia, leukocytosis, thrombocytosis, hypercalcemia, hyperuricemia, and chronic renal failure. Amyloidosis is also a common associated disorder that may itself produce a polyneuropathy with prominent small fiber involvement characterized by burning dysesthesia and pain as well as by generalized dysautonomia. Direct involvement of bone marrow by multiple myeloma may result in compression fractures of the spine, which, in turn, may cause compressive myelopathy, compressive radiculopathies, or both.

DIFFERENTIAL DIAGNOSIS. The differential diagnosis of an acquired SD polyneuropathy occurring in the setting of multiple myeloma is identical to that already described for CIDP. In particular, the presence of an M-protein and an acquired SD polyneuropathy requires a careful, methodical evaluation for multiple myeloma, osteosclerotic myeloma, lymphoma, macroglobulinemia, and MGUS. HIV testing should be performed in patients at risk.

EVALUATION. The EDX examination shows evidence of a chronic, acquired SD polyradiculoneuropathy. The presence of an M-protein in the serum or urine occurs in nearly all patients. General laboratory studies in multiple myeloma may sometimes disclose evidence of anemia, chronic renal failure, hypercalcemia, and occasionally hyperuricemia, leukocytosis, and thrombocytosis. Skeletal survey may disclose osteolytic or occasionally osteoblastic lesions in approximately two thirds of patients. However, the diagnosis of multiple myeloma is made on bone marrow aspiration, which demonstrates increased numbers of immature plasma cells in the bone marrow. As noted earlier, the presence of a polyneuropathy in a patient with multiple myeloma is more likely to be due to amyloidosis. Confirmation of systemic amyloidosis with appropriate biopsy of such tissues as the rectal mucosa or abdominal fat pad may be helpful; however, sural nerve biopsy for amyloid may provide definitive evidence of amyloidosis as the mechanism of the underlying polyneuropathy. Amyloid neuropathy can be distinguished from polyneuropathy associated with multiple myeloma by EDX testing, which typically discloses changes of axon loss rather than demyelination.

MANAGEMENT. The treatment of acquired SD polyneuropathy caused by multiple myeloma consists of optimal treatment of the myeloma. This usually involves chemotherapy, typically with steroids and melphalan. In some patients, as the multiple myeloma clinically improves with treatment, the polyneuropathy does also. In others, however, the polyneuropathy may persist or worsen despite successful treatment of the multiple myeloma. In patients with isolated plasmacytoma, local surgery or radiation therapy may result in satisfactory improvement in the polyneuropathy.⁶³

PROGNOSIS AND FUTURE PERSPECTIVES. The published data are insufficient to define clearly the specific prognosis of acquired SD polyneuropathy occurring in the setting of multiple myeloma. Obviously, patients with associated systemic amyloidosis have a poorer prognosis than patients with polyneuropathy due solely to the remote effect of multiple myeloma.⁵⁸

Much is yet to be learned regarding the pathogenesis of the polyneuropathies associated with multiple myeloma. In particular, the role of the M-protein in their pathogenesis and the possibility of an immune-mediated pathophysiology needs to be carefully explored. However, owing to their rare occurrence, it has been difficult to amass enough clinical experience to define properly the clinical and pathogenetic mechanisms of these heterogeneous disorders.

OSTEOSCLEROTIC MYELOMA

PATHOGENESIS AND PATHOPHYSIOLOGY. Osteosclerotic myeloma may be considered a rare variant of

multiple myeloma, composing only 3% of all patients with myeloma. Many of the typical features of multiple myeloma, including anemia, hypercalcemia, chronic renal failure, fatigue, weakness, and bone pain, are rare or at least uncommon in osteosclerotic myeloma. Furthermore, the level of M-protein is lower, and there are fewer plasma cells in the bone marrow. In contrast to multiple myeloma, however, an associated polyneuropathy is relatively common in osteosclerotic myeloma, occurring in over 50% of patients.⁵⁸ Furthermore, the polyneuropathy associated with osteosclerotic myeloma may frequently be a component of the so-called POEMS syndrome.⁶⁴

The precise pathophysiology of the polyneuropathy associated with osteosclerotic myeloma and the multiorgan features of POEMS syndrome is unknown. It has been speculated that the plasma cells secrete an immunoglobulin or some other substance that may cause both the polyneuropathy and the other systemic features of POEMS syndrome.⁶⁴ However, more recent evidence suggests the role of angiogenic factors, especially vascular endothelial growth factor, in the pathogenesis of the polyneuropathy.⁶⁵

EPIDEMIOLOGY AND RISK FACTORS. Patients with polyneuropathies secondary to osteosclerotic myeloma typically range in age from the late fourth decade through the seventh decade with a mean age in the late fifth decade. There is a rather prominent predilection for the disorder to occur in males. For the preceding reasons, it would be exceedingly rare for this disorder to occur in women of childbearing age.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. The clinical features of polyneuropathy associated with osteosclerotic myeloma typically conform to those of a rather chronic, progressive sensorimotor polyneuropathy. In the majority of patients, the polyneuropathy progresses to the point of rather remarkable weakness involving proximal as well as distal muscles and may result in significant disability. Typically, weakness is a more prominent symptom than sensory impairment. Autonomic symptoms are rare, and cranial nerve involvement is absent except for instances of papilledema. General systemic symptoms of bone pain, fatigue, and weakness typical of multiple myeloma usually are not seen.⁶⁴

The neurological examination typically discloses prominent weakness that is worse distally but with occasional proximal involvement. Sensory loss is less prominent and tends to affect the large fiber modalities of touch pressure, joint position sense, and vibratory sensation more so than smaller fiber modalities of pain and temperature. Papilledema may be seen in up to 50% of patients.⁶⁴

One or more additional features of the POEMS syndrome often are observed, but in many cases, these are not prominent and must be carefully sought. Hepatomegaly may be found in up to 50% of patients, whereas lymphadenopathy and splenomegaly are less common. Manifestations of endocrinopathy include diabetes mellitus, hypothyroidism, impotence, gynecomastia, testicular atrophy, amenorrhea, hyperprolactinemia, and hyperestrogenemia. Skin changes include hyperpigmentation, thickening of the skin, hypertrichosis, skin angiomas, clubbing, and white nails. Some skin changes are suggestive of scleroderma. Peripheral edema, ascites, and pleural effusions may also be seen. POEMS syndrome, sometimes referred to as Crow-Fukase

syndrome, is not unique to osteosclerotic myeloma. It has been observed in multiple myeloma, Waldenström's macroglobulinemia, and angiofollicular lymph node hyperplasia, also referred to as Castleman's disease.⁶⁴

DIFFERENTIAL DIAGNOSIS. In nearly all patients with polyneuropathy associated with osteosclerotic myeloma, the diagnosis is made during a comprehensive evaluation for a cryptogenic polyneuropathy. The findings on EDX examination of features consistent with an acquired SD polyneuropathy provide the differential diagnosis of CIDP and the related disorders, as noted earlier. Furthermore, the presence of an M-protein necessitates a hematological evaluation, which encompasses skeletal bone study and bone marrow aspirate. Careful attention to the possibility of the systemic features of the POEMS syndrome can yield important clues to the diagnosis of polyneuropathy associated with osteosclerotic myeloma.

EVALUATION. Typically, the fact that there are EDX changes suggestive of an acquired SD polyradiculoneuropathy will already have been determined. The M-protein associated with osteosclerotic myeloma is usually IgG or IgA and is almost always of the lambda light chain type.⁵⁸ The concentration is typically low and rarely more than 3 g/dL, the usual range seen in multiple myeloma. An important point is that approximately 25% of patients with osteosclerotic myeloma may not have an M-protein detected in the serum or urine.⁵⁸ Thus, to evaluate a patient properly for this disorder, a skeletal survey is essential to uncover osteosclerotic lesions, the hallmark of the syndrome. These lesions typically involve the spine, pelvis, ribs, and proximal long bones of the limbs; occasionally they are not prominent and may be misinterpreted as benign bone sclerosis. Usually, the bony lesions show both osteosclerotic and lytic changes—sometimes they have the appearance of an osteosclerotic rim around a lytic lesion. The CSF usually is normal, except for an elevation of protein comparable to that noted in CIDP. EDX studies show features of an acquired SD polyneuropathy, although in some patients, axonal degeneration may be prominent. Sural nerve biopsies typically show combinations of both axon loss and segmental demyelination with occasional small foci of inflammatory cell infiltrates in the perivascular epineurium. Bone marrow aspirate usually discloses less than 5% of plasma cells. Routine laboratory studies most often are unrevealing, although thrombocytosis may be observed in nearly half of patients, with other features, including leukocytosis and polycythemia, present in a smaller number of patients.

MANAGEMENT. Patients with solitary osteosclerotic lesions appear to have the very best response to therapy. Local radiation of single or multiple lesions may result in substantial improvement in the polyneuropathy in the majority of patients. In patients with multiple osteosclerotic lesions, chemotherapy may result in improvement and stabilization of the polyneuropathy, although the responses appear to be less satisfactory than in those with isolated osteosclerotic lesions.

PROGNOSIS AND FUTURE PERSPECTIVES. The polyneuropathy associated with osteosclerotic myeloma tends to be slowly progressive and may produce rather prominent generalized weakness and considerable disability, including wheelchair or bed confinement. The majority of patients

with isolated osteosclerotic lesions respond to treatment, demonstrating stabilization, if not improvement, of their polyneuropathies. Patients with multiple osteosclerotic lesions do not respond as well.

Future research into this entity must provide a unifying pathophysiology that can explain the multisystem involvement of the POEMS syndrome. The pathogenetic roles of the M-protein lambda light chain and vascular endothelial growth factor are likely candidates for further study. From a clinical viewpoint, a more systematic study of the optimal mode of therapy is needed. However, the relatively rare occurrence of this entity will make it difficult to perform controlled therapeutic trials.

WALDENSTRÖM'S MACROGLOBULINEMIA

Waldenström's macroglobulinemia is a chronic lymphoproliferative disorder characterized by a clonal proliferation of B lymphocytes or lymphoplasmacytic cells in bone marrow or in lymph nodes, or both, and a high concentration of monoclonal IgM M-protein, typically exceeding 3 g/dL. In addition to the clinical features caused by the circulating macroglobulin, including hyperviscosity syndrome and cryoglobulinemic features, a polyneuropathy occurs in approximately one third of patients.⁶⁶ Half of all those with polyneuropathy are positive for anti-MAG antibodies.⁵⁸ In this latter group of patients, the pathophysiology of the polyneuropathy may be similar to that seen with MGUS IgM anti-MAG-positive polyneuropathy. However, a more heterogeneous group of polyneuropathies, predominantly axon loss in type but occasionally demyelinating, may be encountered in those patients who are anti-MAG negative, similar to what is observed in the other IgM MGUS polyneuropathies. The pathophysiology of these polyneuropathies also is similar to that noted for the MGUS polyneuropathies without anti-MAG activity. Waldenström's macroglobulinemia tends to occur in the middle to older age groups, with a mean age of onset in the early seventh decade, and there is a slight male predominance. The late age of onset essentially precludes it occurring in pregnant women.

The clinical features of the demyelinating polyneuropathy associated with macroglobulinemia and anti-MAG activity is essentially identical to that noted in MGUS IgM anti-MAG-positive patients.⁵⁸ The disorder typically is a chronic sensorimotor polyneuropathy with prominent sensory involvement, including sensory ataxia. Other peripheral nerve syndromes may occur in macroglobulinemia, however, including asymmetrical mononeuropathy associated with cryoglobulinemia and a rather typical amyloid polyneuropathy. A hyperviscosity syndrome may occur in 15% of patients with macroglobulinemia, usually in the setting of an underlying lymphoma.⁶⁶ This syndrome produces a wide spectrum of symptoms, including general fatigue, blurred vision, and dizziness. Blurred vision may be secondary to distended retinal veins, retinal hemorrhages, and papilledema. Easy bleeding of mucous membranes is also observed and usually is due to abnormal platelet function induced by the IgM M-protein. In addition, the IgM M-protein may function as a cryoglobulin and contribute to other systemic symptoms, including renal disease,

altered liver function studies, arthralgia, Raynaud's syndrome, and cryoglobulinemic neuropathy.⁶⁶ Moreover, a chronic hemolytic anemia occurs in approximately 10% of patients. Nearly one third of patients have lymphadenopathy or splenomegaly.

The presence of a high concentration of IgM M-protein in the context of an acquired SD polyneuropathy requires a careful evaluation for lymphoproliferative disorders. This usually necessitates skeletal bone survey to assess for multiple myeloma and osteosclerotic myeloma as well as bone marrow aspiration. The presence of lymphadenopathy and organomegaly coupled with the other systemic features of macroglobulinemia provide the key clinical clues to the diagnosis.

Evidence of an acquired SD polyradiculoneuropathy should be found on EDX studies. The evaluation of patients with IgM M-protein and acquired SD polyneuropathy is identical to that described for MGUS polyneuropathy. Testing for anti-MAG activity is essential to identify the subset of patients with macroglobulinemia who may have a more specific immune-mediated disorder. Results of nerve biopsies and CSF analysis are similar to those seen in MGUS IgM anti-MAG polyneuropathy. Routine laboratory studies in patients with macroglobulinemia often disclose anemia, monoclonal blood lymphocytosis, and Bence Jones proteinuria as well as elevated serum β -microglobulin in nearly half of patients. Also, the presence of cryoglobulins is not an uncommon finding. Diagnosis is confirmed by the presence of a high concentration of IgM M-protein in the setting of underlying lymphoma characterized by infiltration of bone marrow, lymph nodes, and spleen.

Waldenström's macroglobulinemia typically is treated with combinations of chemotherapy and plasmapheresis. Chemotherapy for underlying lymphoma often incorporates a combination of an alkylating agent and a glucocorticoid. Plasma exchange often is recommended for patients who develop polyneuropathy and in those with clinical features of hyperviscosity syndrome and cryoglobulinemia.⁶⁶ Waldenström's macroglobulinemia is a serious disease with a median survival time of approximately 4 years. Therapeutic intervention with chemotherapy and plasmapheresis may be helpful in stabilizing or improving the associated polyneuropathy.

MULTIFOCAL MOTOR NEUROPATHY WITH CONDUCTION BLOCK

PATHOGENESIS AND PATHOPHYSIOLOGY. Multifocal motor neuropathy (MMN) with conduction block, sometimes referred to as motor neuropathy with multifocal conduction block, is a rare disorder that is characterized by asymmetrical motor weakness and EDX features of acquired SD lesions affecting one or more localized segments of motor nerve fibers.⁶⁷ Its pathogenesis is unknown, but an immune-mediated mechanism is supported by pathological features of inflammatory demyelinating changes, favorable clinical response to immunosuppressant and immune-modulating therapies, and many striking similarities with CIDP.⁶⁷ Pathological features include demyelination, occasionally with evidence of remyelination in the form of onion bulb formation, and perivascular inflammatory infiltrates, primarily

of lymphocytes. These changes have been observed in cranial nerves as well as in proximal and distal segments of peripheral nerves examined at autopsy.⁶⁸ Although motor fiber involvement is responsible for most of the clinical and EDX features, similar pathological changes of demyelination with inflammation also have been reported in sensory nerves, including sural nerve specimens examined at nerve biopsy. Reflecting this, occasionally sensory NCS abnormalities are seen.

Antibodies to the GM₁ ganglioside have been reported in a high percentage of patients with MMN.⁶⁷ This factor has led to the concept that these antibodies are playing a pathogenetic role in this disorder. However, direct evidence in support of this proposal is lacking.⁶⁹ Furthermore, the presence of anti-GM₁ antibodies is relatively nonspecific, because they can be found in a wide range of other neuromuscular disorders. Very high titers of GM₁ antibody appear to have greater specificity for lower motor neuron syndromes, including MMN.⁷⁰ Nonetheless, patients with MMN who do not have antibodies to GM₁ still respond to immune-modulating therapies. This field is rapidly evolving. It is possible that the presence of antibodies to GM₁ and other antigens may eventually prove more useful in the diagnosis of lower motor neuron syndromes, including MMN.⁷⁰

EPIDEMIOLOGY AND RISK FACTORS. MMN is a rare disorder. The age of onset spans many decades, from the teenage years through late adult life, but the condition tends to begin in young adults. There is a slight male predominance. There is no known predilection for this disorder to affect women during pregnancy or to worsen during pregnancy or in the postpartum period.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. MMN characteristically is a progressive disorder that causes multifocal and asymmetrical weakness and occasionally muscular atrophy accompanied by cramps and sometimes fasciculations.⁶⁷ This disorder often begins in the upper extremities, and although it may spread to involve the lower extremities, it may remain localized to or more prominent in the upper extremities throughout its course. Whereas some weakened muscles may be atrophic, other involved muscles may be of normal bulk despite chronic weakness, a clinical sign suggesting that SD conduction block is the mechanism of weakness rather than axon loss. Cranial nerve involvement is uncommon, although atrophy and weakness of the tongue and other bulbar symptoms and signs have been noted. Even though the condition predominately affects motor function, most patients will eventually experience sensory symptoms, including a sense of numbness or tingling, often in the absence of objective sensory loss. Sensory symptoms and signs are most common in patients with long-standing MMN. The DTRs frequently are absent or depressed in the distribution of the affected nerves, but surprisingly, they are sometimes preserved.

MMN typically follows a very chronic indolent course that may span many years. On occasion, the disease appears episodic, with patients having a stable nonprogressive course lasting many months or years before another episode develops. Alternatively, some patients have a more subacute course that may lead to rather prominent widespread weakness and disability over several months. Rare instances of

CNS involvement have been reported in patients with typical MMN. However, these clinical features are usually modest and seldom resemble the combined features of upper and lower motor neuron disease noted in amyotrophic lateral sclerosis (ALS).⁶⁷

DIFFERENTIAL DIAGNOSIS. Many of the clinical and EDX features of MMN bear a close similarity to CIDP and related disorders. In fact, MMN has been regarded by some as a variant of CIDP.⁶⁷ Thus, patients presenting with predominately motor weakness accompanied by EDX features of acquired SD need to be assessed for the same conditions included in the differential diagnosis of CIDP. As noted earlier, MMN may on occasion resemble MADSAM. However, it is important to differentiate MMN from MADSAM, as the latter condition more closely resembles typical CIDP. Unlike MMN, in MADSAM sensory symptoms and signs may be noted early in its course, the CSF protein is often elevated, anti-GM₁ antibodies are absent, and patients may respond to all of the typical therapies known to be effective in CIDP.⁴⁵ In addition, some patients with MMN may superficially resemble patients with motor neuron disease or ALS. Usually, MMN can be differentiated from these disorders by its more chronic and indolent course, the absence of upper motor neuron symptoms and signs, and most important, the presence of acquired SD features on EDX testing. An axonal form of MMN has been described in nine patients who presented with symptoms and signs typical of MMN, including anti-GM₁ antibodies, but without conduction block or other signs of demyelination.⁷¹ Some of these patients responded to IVIG therapy. Whether these patients represent a true axonal variant of MMN or simply one aspect of the spectrum of this disorder is unclear.⁷²

EVALUATION. Because MMN may represent a variant of CIDP, it is important to evaluate patients with MMN in the same fashion as patients with possible CIDP. A careful search for an M-protein, skeletal bone survey for osteosclerotic or osteolytic lesions, and HIV testing in patients at risk should be considered in patients with clinical features suggesting MMN. The CSF is usually normal in all aspects, including its protein content, thereby signifying the predilection of MMN to involve peripheral nerves rather than spinal nerve roots. The majority of patients with MMN will have high titers of anti-GM₁ antibodies. As noted earlier, the presence of the anti-GM₁ antibody is not specific to MMN and is not required for the diagnosis. The EDX features of this disorder provide its laboratory confirmation: They disclose evidence of multifocal conduction block, generally confined to motor fibers (see Fig. 49-2). Typically, the lesion sites are not common locations for entrapment or compressive neuropathies; for example, a focal conduction block may be found along the ulnar nerve in the forearm, rather than at the elbow.

MANAGEMENT. Because MMN is a rare disorder, the data are limited regarding the efficacy of the various available treatment modalities. Anecdotal reports suggest that prednisone, azathioprine, mycophenolate mofetil, rituximab, and plasmapheresis rarely are effective.⁷² However, both IVIG and high-dose intravenous cyclophosphamide may be of benefit.^{67,73} Randomized, double-blinded, placebo-controlled trial data have confirmed the efficacy of IVIG in MMN.^{74,75} Clearly, IVIG is the preferred treatment over

IV cyclophosphamide, owing to the greater risks and complications of the latter drug. In a fashion similar to CIDP, IVIG may be administered periodically to maintain clinical improvement. It should be emphasized that the treatment of MMN must be individualized. Many patients with MMN, for example, have very modest clinical symptoms that persist unchanged for many years. The appropriate management of such patients may be observation alone rather than have them undergo the risk and expense of IVIG or cyclophosphamide treatments.

PROGNOSIS AND FUTURE PERSPECTIVES. The rarity of this disease and its relatively recent initial description in 1982 are factors that limit experience with its natural history. Nevertheless, most patients with MMN seem to display a chronic, slowly progressive or stable course over many years. With the advent of IVIG treatment as well as intravenous cyclophosphamide, it is likely that in many patients the disorder can be stabilized, resulting in modest, if any, disability.

Key fundamental issues to be resolved regarding MMN include its precise pathophysiology, including the role of anti-GM₁ antibodies and its relationship to CIDP. From a clinical perspective, more experience is required to better formulate optimal therapeutic interventions.

Behçet’s Disease

HISTORY AND DEFINITIONS

Pathological disorders mediated by immune processes directed against autologous tissues were first recognized in the early 1900s by Erlich, who used the term “horror autotoxicus” to describe this phenomenon. The first descriptions of necrotizing arteritis appeared in an 1852 treatise on aneurysms by Karl Rokitsansky.¹ In 1866, the term *periarteritis nodosa* was used to describe a single patient with a typical histological appearance of necrotizing arteritis.¹ Most of the descriptions evolved in the 1940s and 1950s by people such as Jacob Churg and Friedrich Wegener. With few exceptions, these syndromes continue to be defined by the classic pathological appearance.

The ability of the immune system to differentiate between one’s body and a wide variety of potential pathogens and toxins is remarkable. Under normal circumstances, the immune system may react against certain of its own tissues such as neoplasms and senescent red blood cells. While extensive growth in immunology has led to a better understanding of the pathophysiology of these diseases, often the etiology remains obscure.

Lymphocytes recognize foreign antigens through receptors on their surface, and the differentiation between self and nonself is essential to normal function. Several factors may account for this ability to avoid self-reactivity: self-directed T lymphocytes may be deleted from the repertoire at an early age; self-antigens may not be presented to the lymphocytes in such a way as to induce an immune response; self-antigens may be in “immunologically privileged” tissues, which are not routinely exposed sufficiently to the circulating lymphocytes; or self-response may be downregulated by other components of the immune system.² It is believed that evasion of these mechanisms leads to autoimmune disease by one of the following pathways: (1) normal regulatory control to a given self-antigen may be lost or bypassed; (2) self-antigens may express major histocompatibility complexes II (MHC-II),

normally present only on immunologically competent cells; these self-tissues may then present antigens to lymphocytes; or (3) a foreign antigen with a similar molecular structure may mimic a self-antigen and result in cross-reactivity.²

The autoimmune response may be directed at a relatively specific tissue antigen such as the acetylcholine receptor in myasthenia gravis (organ-specific response). Alternatively, the self-antigen may be in many tissues and be relatively non-organ-specific, causing diseases such as systemic lupus erythematosus.

Vasculitis is a common manifestation of a diverse group of diseases. Though they may result from etiologically and pathogenetically different diseases, all share the pathological finding of inflammation of the vessel wall. Tissue injury results from the occlusion of inflamed vessels. Vasculitides can be organized by the size of the vessels involved (e.g., large, medium, or small vessel vasculitis shown in [Figure 50-1](#)) or by the predominant cell type involved, as discussed later.¹

For *neutrophil-predominant vasculitis* to occur, an inflammatory stimulus must perturb the homeostasis of circulating leukocytes and endothelial cells. Adhesion to certain areas of the vasculature is induced by cytokine-stimulated expression of adhesion molecules (e.g., ICA-1, VCAM-1). In severe inflammation, there is mural necrosis with rupture and hemorrhage or leakage of plasma factors into tissues where soluble coagulation factors contact inflammatory debris causing fibrinoid necrosis.

Mononuclear-predominant vasculitis (lymphocytes, monocytes, macrophages) can occur as a discrete entity or can evolve from neutrophil-predominant vasculitis. Unlike neutrophils, monocytes have a regulatory role as well as an effector role in inflammation. Therefore, the histological demonstration of T lymphocytes does not prove that the process is mediated by a T lymphocyte immune response. Mononuclear-predominant vasculitis is seen in giant cell arteritis, Takayasu’s arteritis, and primary angiitis of the central nervous system.

Immune complex vasculitis results from deposition of heterologous or autoantigen immune complexes in vessel

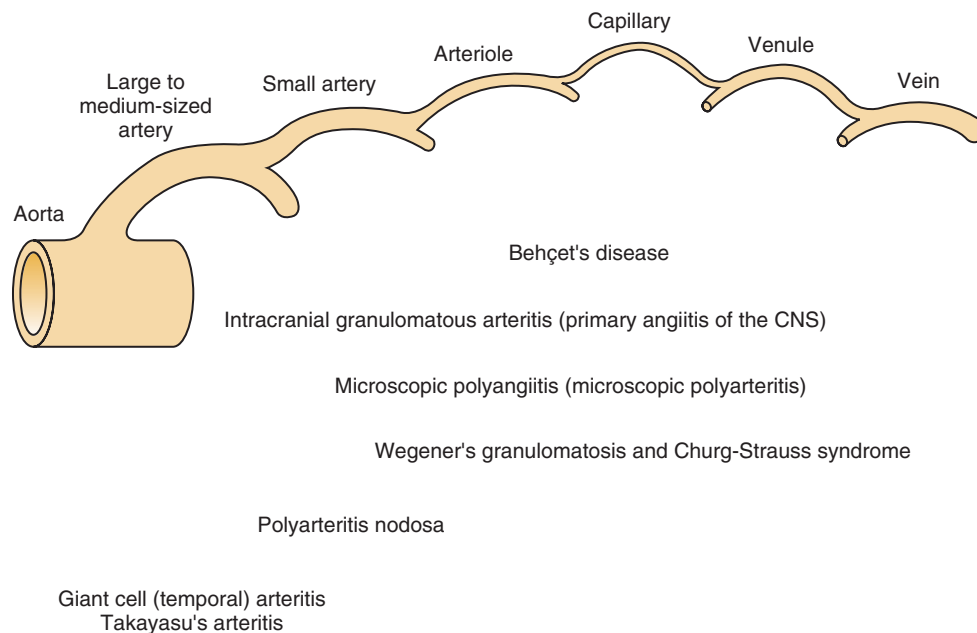

Figure 50-1. Classification of the vasculitides by vessel size. (Adapted from Jennette JC, Falk RJ: Clinical and pathological classification of ANCA-associated vasculitis: What are the controversies? Clin Exp Immunol 1995;101[Suppl 1]:18–22.)

walls either from the circulation or by in situ formation. Most circulating immune complexes are cleared from the circulation without causing vascular inflammation. Molecular size and electrical charge influence the ability to survive in the circulation and deposit in vessel walls. Medium-sized cationic particles are the most pathogenic.

Antineutrophil cytoplasmic antibodies (ANCA) are associated with some vasculitides that involve small vessels including epineurial vessels. It is not known if ANCA cause the vasculitis or are an epiphenomenon. Peripheral neuropathies are frequently encountered in ANCA vasculitides, but it is unclear how many neuropathies are ANCA associated.

Infections can cause vasculitis by direct effects of the agents themselves and by the immune-mediated response. Infectious vasculitides will not be covered in this chapter.

Connective tissue diseases as a whole are syndromes with immunological reactivity to various tissue components. Clinically, however, there may be overlap with other autoimmune conditions. Tissue components of the vasculature may be involved, and a vasculitis may dominate the clinical picture. This is demonstrated by the frequent occurrence of mononeuritis multiplex in the connective tissue diseases, as a result of peripheral nerve ischemia secondary to inflammation of the vasa nervorum.

Other autoimmune conditions are not targeted at the vessels but are part of a connective tissue syndrome. Those disorders affecting the neurological system are discussed in the last section of this chapter.

INFLAMMATORY VASCULOPATHIES: ARTERITIS

Extracranial Granulomatous Arteritis (Giant Cell "Temporal" Arteritis)

PATHOGENESIS AND PATHOPHYSIOLOGY. Giant cells are the pathological hallmark of this large vessel,

T-cell-mediated vasculitis. CD4 cells aggregate with a response centered on the internal elastic lamina. These cells may contain elastic fiber fragments. Giant cell arteritis (GCA) affects the aorta and its branches, including the cervicocephalic arteries (carotid and vertebral), reflecting its predilection for the internal elastic lamina. Intracranial arteries are usually not involved, although proximal branches of the internal carotid artery have been lesioned. The superficial temporal artery and intraorbital branches of the carotid artery are involved in many cases. Vertebral arteries may be affected in very severe cases, though basilar artery involvement is rare. Aortic rupture can also occur. There is an overlap between GCA and polymyalgia rheumatica (PMR).

EPIDEMIOLOGY AND RISK FACTORS. Age is a strong risk factor for this disease. Maximum incidence is in the 70s with the median age of onset being 75, and virtually no cases in the population less than 50 years of age. Overall, women have a higher age-adjusted incidence than men, 16.5 versus 5.7 per 100,000 per year of the U.S. population aged 50 and older. The incidence rate reported has increased each decade from the 1950s into the 1970s. Additionally, the number of negative biopsies in cases suspected of having GCA has also increased. As opposed to an actual increase in the disease, an explanation for these findings may represent better identification of potential cases as a result of heightened awareness of the disease.³ There has been a tendency to reclassify cases of PMR to GCA when the disease has been more aggressive, was accompanied by visual symptoms or headache, or was relatively resistant to low-dose corticosteroid therapy.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. GCA was first described in 1890, but was best described in 1932 as giant cell inflammation of the temporal artery with a systemic syndrome of fever, anorexia, weight loss, fatigue, and anemia. PMR was described as an illness of the elderly with proximal muscle pain and

stiffness along with a systemic syndrome. PMR was felt to be a variant of rheumatoid arthritis, with synovitis but without rheumatoid factor. In time it became clear that there was overlap between GCA and PMR. However, the greater sensitivity of PMR to steroids contributed to continued separation of the two syndromes. Most likely, both are part of a spectrum of disease characterized by variable degrees of synovitis and arteritis related to a common yet unknown etiopathogenic agent.⁴ PMR occurs in 58% of patients with GCA and is the initial symptom in 25%. Criteria for the diagnosis of GCA and PMR are listed in Table 50-1.⁵

Pain is commonly experienced by patients with GCA. Headache, sometimes with scalp tenderness, occurs in 72% of patients and is present in 33% at the time of diagnosis. Jaw claudication is an occasional feature. Neck or back pain is present in 25% of patients with GCA who do not have PMR.⁶

Vascular disease may manifest in several ways. Bruits may be audible over involved arteries. Carotid bruits occur in 10% to 20% and are frequently bilateral. Claudication or upper limb bruits occur in approximately 60% of patients, and about 40% of patients with carotid bruits will have some ischemic brain or eye complication. However, permanent visual loss and stroke occur with about the same frequency regardless of the presence of bruits. About 4% of patients with GCA will experience a transient ischemic attack (TIA) or stroke (Chapters 22 and 45). The proportion of such events occurring in the vertebrobasilar circulation is greater in GCA patients than that seen in the general stroke population. Within the vertebrobasilar system, these events may not respect distinct vascular territories. There are some reports of myelopathy in GCA, presumably from vertebral or anterior spinal artery involvement.⁶

The risk of blindness remains poorly defined in GCA and PMR. Overall, eye findings occur in 8% to 23% of people with GCA. Amaurosis fugax occurs in 10% to 12%. Anterior ischemic optic neuropathy results from

posterior ciliary and, less frequently, retinal arteritis. Occasionally, the findings are entirely retrobulbar. However, acute optic disc edema followed by the development of optic pallor over 2 to 4 weeks may be seen. Diplopia is seen in 2% to 14% of patients, usually related to extraocular muscle dysfunction, but rarely as a result of brain stem disease (Video 1, Cranial Nerve VI Palsy). Clinical findings may fluctuate daily as a characteristic feature.⁶ When permanent visual loss occurs, the onset is typically abrupt, and within 2 weeks, contralateral involvement occurs in 25% to 50% of cases.⁷

Vertigo or unilateral hearing loss may rarely be the result of an infarct of the vestibulocochlear nerve. Other cranial nerves, such as V, VII, or XII, have been affected in isolation or as part of a mononeuritis multiplex (Video 45, Tongue Atrophy). Occasionally, other cranial neuropathies have occurred, causing facial pain, hemianesthesia of the tongue, or lingual paralysis.

Peripheral nerve disorders are common in many of the vasculitides. Involvement of the vasa nervorum may result in a mononeuritis multiplex. Many areas of involvement of peripheral nerves may overlap, suggesting a distal symmetrical polyneuropathy.⁶

Although myalgia is a common symptom and localized inflammation has been described in patients with GCA, inflammatory myositis is not a recognized feature of the illness. Myopathy in GCA usually results from corticosteroid use (see Management).

DIFFERENTIAL DIAGNOSIS. Numerous symptoms occur in GCA that are not specific for the condition. Certainly, the population that is at the greatest risk for the development of GCA is also at risk for atherosclerotic vascular disease. This situation presents problems in evaluating individual patients as well as interpreting the literature. The presence of constitutional symptoms such as weight loss and fevers and an elevated erythrocyte sedimentation rate (ESR), with or without a pain syndrome, should raise GCA as a serious consideration.

EVALUATION. The examination in suspected GCA should include inspection, auscultation, and palpation of extracranial arteries. Blood pressure in both arms should be assessed for asymmetry. Routine blood work commonly shows anemia. Serological evaluation, including ESR, and C-reactive protein assessment are necessary.³ Abnormalities of the temporal artery may be apparent on color duplex ultrasonography. Characteristic signs include a dark halo around the arterial lumen and stenoses or occlusions of temporal artery segments.⁷ Angiography may demonstrate segmental stenosis or occlusion of the temporal artery. Superior temporal artery angiography is less reliable than biopsy.⁶ Biopsy of the superficial temporal artery may show giant cells, but several sections usually need to be examined.³

MANAGEMENT. Early studies evaluating steroid efficacy were flawed and some do not reach statistical significance by today's standards. Overall, however, there appears to be a modest beneficial effect of high-dose steroids consistent with the understanding of the effect of steroids on other vasculitic syndromes. The prevention of blindness is considered worth the approximately 50% risk of adverse effects (symptomatic vertebral collapse in 26%, myopathy in 17%) from steroid therapy.⁴ Prednisone remains the mainstay of treatment with initial dose of 40 to

TABLE 50-1

Criteria for the Diagnoses of Giant Cell Arteritis and Polymyalgia Rheumatica

| GIANT CELL ARTERITIS (MUST MEET ALL FIVE CRITERIA) | POLYMYALGIA RHEUMATICA (MUST MEET ALL SEVEN CRITERIA) |
|---|--|
| 1. Confirmatory biopsy | 1. Shoulder/pelvic girdle muscle pain |
| 2. Tenderness to palpation ± pulselessness in temporal artery | 2. Morning stiffness |
| 3. Any or all of: Visual disturbance Temporal or occipital headache Jaw claudication | 3. Duration of symptoms for at least 2 weeks |
| 4. Westergren ESR > 30 mm/hr or C-reactive protein > 6 µg/mL | 4. Absence of true arthritis |
| 5. Prompt response to steroid therapy Duration of symptoms for at least 2 weeks | 5. Absence of objective signs of muscle disease |
| | 6. Westergren ESR > 30 mm/hr or C-reactive protein > 6 µg/mL |
| | 7. Prompt response to steroid therapy |

ESR, erythrocyte sedimentation rate.
Modified from De Silva M, Hazelman BL: Azathioprine in giant cell arteritis/polymyalgia rheumatica: A double blind study. *Ann Rheumatol Dis* 1986;45:136-138.

60 mg/day and treatment over the next few years. Tapering should be done slowly. In the rapidly deteriorating patient or one with a neurological syndrome, IV methylprednisolone can be used, typically 1 g/day divided into two to four doses. No well-controlled trials have examined differences in dosing regimens. If relapse occurs while tapering, then the target dose to taper to should be higher than the dose at the time of relapse. ESR monitoring is very helpful in determining relapses and responses to dose changes.⁶

A number of other immunosuppressives have been used, including azathioprine, methotrexate, dapson, and cyclophosphamide, with inconsistent results. Cyclophosphamide may be the most consistently effective.⁶ Azathioprine was compared in a double-blind fashion to placebo in GCA patients already taking prednisone. Because the immunosuppressive effect of azathioprine is delayed, a statistically significant difference in prednisone dose was reached only after 1 year of therapy.⁵

Low-dose aspirin has shown benefit even perhaps by inhibition of platelet aggregation. Other actions may be related to transcriptional inhibition of inhibition of interferon- γ gene, that can reduce T-cell function in forming granulomatous infiltrates.⁸

PROGNOSIS AND FUTURE PERSPECTIVES. Although GCA can cause death, stroke, or myocardial infarction, the survival of GCA patients does not significantly differ from that of age-matched control subjects.³ In a series of 21 GCA patients who died, in only one case was the cause of death attributed to GCA.³ Catastrophic neurological sequelae such as blindness and stroke are uncommon and have been lessened in frequency by the use of steroids.

Intracranial Granulomatous Arteritis or Primary Angiitis of the Central Nervous System

PATHOGENESIS AND PATHOPHYSIOLOGY. This disorder has carried a number of names, including non-infectious granulomatous angiitis with a predilection for the central nervous system (CNS), granulomatous angiitis of the CNS, primary angiitis of the CNS (PACNS), and vasculitis confined to the CNS. First described in 1959, very few cases were described antemortem until the widespread availability of angiography in the 1960s. The term PACNS is most appropriate because it requires the absence of a systemic disease but does not require the presence of granulomatous lesions.^{9,10} Pathologically there are monocytes/histiocytes, lymphocytes, and plasma cells infiltrating the walls of small arteries, particularly in the leptomeninges.¹¹ In 85% of cases, multinucleated giant cells are seen among the inflammatory cells.¹² Small leptomeningeal arteries are preferentially affected, although occasional involvement of the internal carotid and vertebral arteries is seen. Numerous small foci of infarction are common, but there may be large areas of ischemia, sometimes with superimposed hemorrhage.¹⁰ Unlike polyarteritis nodosa, there is no predilection for the branching points of arteries.¹¹ The etiology is unknown, but there is growing speculation of a viral cause. There is no evidence that the disease is mediated by immune complexes, although there may be a direct immune interaction at the level of the vessel wall.¹⁰

EPIDEMIOLOGY AND RISK FACTORS. Most patients are young or middle aged (range, 3 to 74 years). In the

literature, early cases suggested a female predominance of 2:1; however, currently there does not appear to be a gender difference.¹³ The majority of cases do not have any identifiable preexisting condition.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Typically, the patient has a headache of gradual onset and a diffuse encephalopathy or dementia. Later, focal neurological signs develop. In one large review of 108 cases (including 99 from the literature), 53% of cases presented with both focal and diffuse findings, 32% with focal findings only, and 11.1% with diffuse findings only (Table 50-2).¹⁴ Headache is the most common presenting symptom and is often associated with nausea and vomiting. Occasionally, cranial neuropathies, cerebellar dysfunction, and cauda equina syndromes have been the initial symptoms (Video 9, Dysmetria; Video 12, Dysdiadochokinesis). Isolated cord involvement has been noted in a few patients. The syndrome may be acute or insidious and may fluctuate with periods of apparent remission. Systemic symptoms like fever, weight loss, arthralgias, and myalgias are typically absent and when present suggest an alternative diagnosis.¹²

It has been proposed that PACNS may fall into subgroups by clinical criteria.¹² According to these criteria, “true” PACNS lasts longer than 3 months, is characterized by focal and diffuse neurological dysfunction, and is associated with typical biopsy findings. The cerebrospinal fluid (CSF) is abnormal with a picture suggesting chronic meningitis. The outcome is poor if untreated. A more “benign angiopathy” of the CNS has an acute onset, normal CSF analyses, primary diagnosis by angiography, and a benign clinical course. Postpartum cerebral angiopathy has been described in women in the immediate postgravid state. There are eight well-documented cases in which headaches, nausea, vomiting, focal CNS signs, and abnormal CSF developed in women who showed no signs of toxemia or hypertension. Cerebral angiography showed alternating areas of stenosis and ectasia with “sausaging” of multiple vessels. Normalization of angiography changes demonstrated by serial studies over 4 weeks suggests that the basis of the arteritis is at least in part vasospastic.¹² The strength of the relationship between this condition and PACNS remains unclear.

PACNS associated with immunosuppressive illness represents a small subset of these cases, which include lymphomas, leukemias, myeloproliferative disorders, immunosuppressive

TABLE 50-2

Clinical Features of Primary Angiitis of the Central Nervous System

| | LITERATURE CASES N = 40 | CLEVELAND CLIN- IC CASES N = 8 | COMBINED CASES N = 48 |
|---------------------------|-------------------------------|---|-----------------------------|
| Mean age in years (range) | 45 (3–74) | 33 (10–73) | 43 (3–74) |
| Sex ratio, M:F | 21:18 | 4:4 | 25:23 |
| Abrupt onset (%) | 22 (56) | 5 (62) | 29 (60) |
| Signs and symptoms | | | |
| Focal | 4 (10) | 0 | 4 (8) |

| Both | 29 (74) | 7 (88) | 38 (78) |

therapy for inflammatory bowel disease or following renal transplant, and human immunodeficiency virus.¹² These are unique cases in which the immunosuppressed state may appear crucial to susceptibility to the condition.

DIFFERENTIAL DIAGNOSIS. Other small vessel vasculitides such as Wegener's granulomatosis have presented as temporal or CNS vasculitis. Pulmonary lesions should be helpful in this differential. GCA occurs in an older population than PACNS. Those patients with PACNS affecting large and small arteries are older than those with small vessel involvement alone. Immunological or epitope changes may be related to age.¹³ Infections and more systemic forms of vasculitis need to be considered in the differential diagnosis of PACNS. Tuberculosis and other mycobacteria, meningovascular syphilis, fungal infections, hepatitis B, and herpes ophthalmicus are other possibilities.¹² Drugs, particularly stimulants, can cause a vasculitis. Noninflammatory vasculopathies such as fibromuscular dysplasia and moyamoya may be considered, and these diagnoses are best addressed by angiography.¹⁰

EVALUATION. Most important in the diagnosis of PACNS is appropriate clinical suspicion. The ESR is elevated in 66% of the patients, on average 44 mm/hour, ranging up to 116 mm/hour. The ESR may be more helpful to exclude a systemic vasculitis than to include a CNS vasculitis.¹¹

CSF should be examined if the diagnosis of PACNS is considered. The CSF is abnormal in 81% of those examined. Mixed or lymphocytic pleocytosis is present in 68%, ranging up to 330 cells/hpf. Seventy percent have elevations of CSF protein averaging 118 mg/dL, but ranging up to 825 mg/dL. Serial lumbar punctures in the same patient may show spontaneous fluctuations in pleocytosis and protein. An abnormal electroencephalogram is 81% sensitive, and diffuse slowing is the most common finding. Focal slowing or sharp wave discharges are noted on occasion. Computed tomography (CT) brain scans have disparate findings, showing infarcts, low-density lesions, or gyriform enhancement.¹⁰ Magnetic resonance imaging (MRI) may show focal areas of infarction in multiple vascular territories. Normal MRI scans are rare but have been seen in some biopsy-proven cases.¹² The combination of normal MRI and normal CSF is a powerful negative predictor of CNS vasculitis, although rare exceptions may occur.

In patients with angiograms, "classic arteritis" is seen in 65%, and less specific abnormalities in 19%. Thirteen percent of angiograms are normal. High-resolution film magnification is preferred to digital subtraction angiography in its ability to resolve changes in small-caliber vessels. The "arteritic" appearance of vasculitis is not completely specific and has been seen in vasculopathies due to other causes such as atherosclerosis, infection, and drugs and toxins. Considered in the context of the patient's age, clinical syndrome, laboratory studies, and CSF studies, angiography remains very helpful in establishing the diagnosis short of biopsy.

If the angiogram is normal or atypical, leptomeningeal and cortical biopsy should be performed.¹⁰ Owing to the focal nature of the lesions, there is significant risk for sampling error. In a series of 108 cases (including 99 from the literature), the yield of leptomeningeal and cortical tissue was 87% and 57.9%, respectively. In 43 pathologically confirmed cases, 11 premortem biopsies were false negatives

TABLE 50-3

Treatment Outcome in Primary Angiitis of the Central Nervous System

| TREATMENT | N | DEATHS | POOR OUTCOME | COMPLETE RECOVERY |
|----------------------------|----|--------|--------------|-------------------|
| None | 20 | 19 | 0 | 1 |
| Steroids alone | 13 | 6 | 3 | 4 |
| Steroids + cytotoxic agent | 13 | 1 | 2 | 10 |

(diagnostic sensitivity, 74.4%). The morbidity of biopsy in patients with suspected vasculitis is 3.3%, but up to 50% of cases referred for biopsy in whom PACNS is suspected have an alternative diagnosis discovered. These statistics emphasize the necessity for biopsy and the potential harm of empirical immunosuppressive therapy in lieu of biopsy.

Because of the false-negative rates in biopsy and angiography, decisions about diagnosis and monitoring of treatment must be tailored to the individual case and incorporate as much clinical and laboratory information as possible. However, highly toxic therapy should not be considered unless cerebral and leptomeningeal biopsy has been performed.¹¹

MANAGEMENT. There are no controlled treatment trials to date. High-dose (60 to 80 mg/day) prednisone combined with a calcium channel blocker is recommended. With good clinical response, tapering in a few months' time is reasonable. If lack of response or recurrence develops, oral cyclophosphamide (1 to 2 mg/kg/day) should be added and continued for 6 to 12 months until all signs of disease have disappeared. Angiography can be used to reassess disease activity, and repeated biopsies may be needed in some cases. The rationale for treatment of PACNS is summarized in Table 50-3. Postpartum cerebral angiitis should be treated with a short course of high-dose steroids and calcium channel blocker.¹² Patients treated with steroids alone have a rate of relapse as high as 90%. Treatment with cyclophosphamide and low-dose prednisone for up to 6 months is associated with a relapse in 30%, and if treatment is continued for 12 months, a relapse is seen in only 10%.

PROGNOSIS AND FUTURE PERSPECTIVES. The prognosis in PACNS is guarded; outcome depends on the severity of the disease and the response to the treatments described previously. The prognosis is favorable in young women with "benign angiopathy" or "postpartum angiopathy," and poorer in those with "true" PACNS. Considerable work remains to be done to further the understanding of the etiology, pathogenesis and pathophysiology, clinical subtypes, optimal treatment, and the long-term outlook of the disorder.

Takayasu's Arteritis

PATHOGENESIS AND PATHOPHYSIOLOGY. Takayasu's arteritis (TA), first described by Takayasu and Onishi in Asian patients with absent limb pulses and retinopathy,¹⁵ is now well recognized in Western countries as well. The burden of disease is in the aorta and its main branches with symptoms attributable to vascular compromise or a systemic immune response. In tissue specimens, giant cells are seen invading the media and adventitia of affected vessels.

A number of changes suggest an immunopathogenesis, including hypergammaglobulinemia, increased ratio of CD4 to CD8 cells in the periphery, circulating immune complexes, antiaortic antibodies, and a positive rheumatoid factor. Nearly half of Japanese patients have statistically significant associations with Bw52 or DR12. The immunogenetics of TA are less well defined in Western patients.¹⁶ It is currently believed that in a genetically predisposed individual and in a conducive hormonal milieu, exposure to an unknown antigen precipitates an uncontrolled, inflammatory immune response that primarily targets large vessels.¹⁷ Because of descriptions occurring in India where tuberculosis is endemic, a relationship between TA and tuberculosis infection was briefly considered but later abandoned.^{15,17}

EPIDEMIOLOGY AND RISK FACTORS. Despite increased ascertainment, TA remains rare in the Western Hemisphere (2.6 cases per 1 million). The ratio of women to men is about 8.5:1, and TA is more common in lower socioeconomic classes.¹⁵ In a prospective study of 60 patients, in which 45 were followed for 6 months to 20 years (median, 5.3 years), mean age of onset was 21 years.¹⁶ If only Western cases are considered, the mean age of onset is 41 years.¹⁷ Within the United States, the racial makeup of cases largely reflects the relative proportions of ethnic groups among U.S. residents, except that Asians account for an unusually large number of cases (10% of cases versus 2.9% of the U.S. population).¹⁵ Occasional reports among family members suggest a possible genetic component. Associations between TA and various other autoimmune diseases have been reported.¹⁷

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Although early descriptions suggested that TA had a triphasic course with early systemic complaints followed by symptoms related to vascular inflammation and finally sequelae of vascular stenoses, this pattern is not universal. In addition, the clinical manifestations of TA may differ depending on geographic region. Aortic arch disease predominates in Japanese patients, and thoracic and abdominal aortic disease predominates in Thailand, Mexico, and India. Within a given vascular territory, the presence of symptoms depends largely on the extent of collateral circulation to involved organs. For example, gastrointestinal symptoms are rare even though stenoses and mesenteric vessel occlusions are common.¹⁷

In the preceding 60-patient series, all had vascular symptoms or signs.¹⁷ Eighty percent of patients had bruits, most in the carotid arteries. Carotodynia was present in 32% of the series. Elevated blood pressure occurred in 33%, mostly owing to lesions of the renal arteries or descending aorta. Asymmetrical blood pressures were present in 50% of the patients, a finding suggesting that four extremity blood pressures can be used in diagnosis and in clinical follow-up. Diminished or absent extremity pulses occur in over half of the patients with TA. HLA-Bw52 has been associated with an increased risk of aortic valve insufficiency and a worse prognosis in Japanese patients.¹⁶

Among the 60 patients cited previously, nervous system symptoms occurred in over half. Fifty-seven percent of those with vertebral artery involvement and 23% of those without vertebral artery involvement experienced light-headedness or dizziness. TIA and stroke each occurred in

5 of the 60 patients. These events are presumably related to artery-to-artery or cardiogenic emboli. Visual disturbances affected one third of the patients, most of whom had carotid or vertebral artery involvement. These visual disturbances are almost always bilateral; however, monocular blindness did occur in one patient (Video 200, Afferent Pupillary Defect).¹⁶ Pregnancy does not appear to potentiate disease activity, and there is no difference in fertility rates, cesarean section rates, or neonatal death among TA patients when compared with the general population. It is recommended that those who wish to become pregnant do so during an inactive disease phase. Because of increased cardiovascular demands, the third trimester may be most difficult for these patients. Aortic regurgitation or heart failure may develop, and hypertension may be a problem even in the absence of preeclampsia. Typically, these problems abate after delivery.¹⁵ Moderate doses of corticosteroids have not had significant effects on the fetus.¹⁷

DIFFERENTIAL DIAGNOSIS. Diagnostic criteria for TA are shown in Table 50-4.¹⁶ Other causes of large vessel disease should be entertained. Possible causes of inflammatory aortitis include syphilis, tuberculosis, systemic lupus erythematosus, and giant cell arteritis. Developmental abnormalities such as Ehlers-Danlos syndrome and Marfan's syndrome can give an abnormal appearance to the aorta and be misleading. Aortic abnormalities can also occur as the result of radiation fibrosis, neurofibromatosis, and ergotism.

EVALUATION. ESR greater than 20 mm/hour (>40 mm/hour during pregnancy) is considered by most to be an indicator of active disease.¹⁵ In one series, ESR was elevated in 72% during active disease and in 44% during clinical remission.¹⁶ The correlation between ESR and biopsy evidence of disease activity is poor. As many as 42% of patients with normal ESR have active lesions on biopsy. Repeated ESR evaluations over time may be most useful as an indicator of relative disease activity in a given patient. Other markers of disease activity, including endothelin-1, von Willebrand's factor, and factor VIII antigen, have not been well evaluated. The disease is presumed to be inactive when there is an absence of clinical features, the ESR is normal, and the angiogram is unchanged. Unfortunately, the correlation between ESR and biopsy evidence of disease activity is poor.¹⁸

Noninvasive tests have been used as diagnostic aids. Ultrasonography and MRI have been used with varying results, but nothing yet has the sensitivity and specificity of an angiogram.¹⁷ Angiography is considered the diagnostic

TABLE 50-4

Criteria for the Diagnosis of Takayasu's Arteritis

Onset or Worsening of Two of the Following:

- Unexplained systemic illness (fever or musculoskeletal complaints)
- Increased sedimentation rate
- Features of vascular ischemia or inflammation
 - Claudication
 - Diminished or absent pulse
 - Asymmetrical blood pressure (arms or legs)
 - Bruit
 - Vascular pain
- Typical angiographic features

Modified from Kerr GS: Takayasu's arteritis. *Curr Opin Rheumatol* 1994;6:32-38.

gold standard but carries the risks of an invasive procedure and the risk of rupture of diseased vessels (Fig. 50-2). An angiogram does not differentiate between acute and chronic lesions, however, and cannot assess disease activity. In one series, the disease burden was distributed as follows: aortic lesions 65%, carotid 58%, renal 38%, and vertebral 35%. Long stenotic lesions were seen in 98% of patients. Aneurysms were seen in 27% of patients and were present in 5% of carotid and 2% of vertebral arteries.¹⁶

MANAGEMENT. Glucocorticoids are the mainstay of therapy. Other immunosuppressive therapies are used for patients who fail to respond to steroid therapy or who relapse during steroid withdrawal. Azathioprine is frequently used, and cyclophosphamide has been used with some success. Methotrexate appears to be relatively well tolerated and is beneficial in helping patients successfully taper steroids or avoid relapse. β -Adrenergic blockers and angiotensin-converting enzyme (ACE) inhibitors can be used to treat hypertension due to vascular stenosis that is not surgically correctable. ACE inhibitors must be used with caution in patients with bilateral renal artery stenosis. Although effective for heart failure, vasodilators are not helpful in patients with renal artery stenosis.¹⁷ Antiplatelet therapy is probably not indicated to prevent thrombotic events, because native-vessel thrombosis is not a common feature.

Figure 50-2. Angiogram of a 46-year-old Hispanic woman with intercostal angina and pulseless left radial artery. Note the stenosis of the descending aorta (40%) and of the left subclavian artery indicated by the arrow (95%).

Surgical treatment has an auxiliary role, because renal artery stenosis with severe hypertension is common. Percutaneous coronary transluminal angioplasty (PCTA) successfully restores patency in as many as 80% of these patients. Bypass surgery can be done for repeated PCTA failure. Bypass of carotid arteries from the ascending aorta can be done as well. In general, success of bypass surgery is improved during disease inactivity (88% versus 53%).

PROGNOSIS AND FUTURE PERSPECTIVES. Most patients experience morbidity from TA or the treatment of the disease. Five- to 10-year survival rates are in the range of 80% to 97%. Myocardial infarction, stroke, cardiac failure, aneurysmal rupture, and renal failure are causes of death.⁵

In the future, more accurate noninvasive diagnostic tools, including vascular imaging and serum markers for disease activity, will likely improve the accuracy of TA diagnosis. Safer and more efficacious immune-modulating therapies are also needed based on a better elucidation of the etiopathogenesis of the disorder.

Polyarteritis Nodosa, Churg-Strauss Syndrome, and Overlap Syndromes

PATHOGENESIS AND PATHOPHYSIOLOGY. Classic polyarteritis nodosa (PAN) is a necrotizing, nodular vasculitis that preferentially affects medium and small arteries, and sometimes arterioles. The pathophysiology is believed to be a deposition of immune complexes in the involved arteries. PAN is associated with a number of infections, particularly hepatitis B, tuberculosis, and *Streptococcus* infection. In those cases associated with hepatitis B, hepatitis B surface antigen, IgM, and complement can be demonstrated in the vasculitic lesions. In most cases, however, no association with an infectious agent can be demonstrated.¹⁹

Churg-Strauss syndrome (CSS), also known as allergic angiitis and granulomatosis, is a systemic vasculitis marked by systemic hypereosinophilia and multiple organ involvement, which usually includes asthma. These signs and symptoms are somewhat distinctive and serve to reduce confusion with the other vasculitides. Pathological features include a necrotizing vasculitis affecting small or occasionally medium-sized arteries and veins, eosinophilic infiltration, and extravascular granulomata.²⁰

Microscopic polyangiitis (MPA) is similar to PAN but is characterized histologically by involvement of arterioles, capillaries, venules, and rarely medium-sized arteries. PAN and MPA overlap considerably, and the American College of Rheumatology criteria for diagnosis do not distinguish between the two entities.¹⁹

EPIDEMIOLOGY AND RISK FACTORS. PAN occurs from infancy to old age, with peak incidence in the fifth and sixth decades of life and an estimated male-to-female ratio of 2.5:1. In a series of patients with CSS, the mean age of diagnosis was 49.7 years (range, 17 to 75 years), and women were affected more often than men.²⁰ MPA, considered an overlap syndrome, shares the epidemiology of PAN, and an incidence separate from that of PAN is difficult to discern.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Patients with PAN typically present with systemic signs and symptoms, including weakness, leg and abdomi-

nal pain, and fever. Arthralgias and hypertension are often present. Maculopapular or nodular skin rash is common, as is livedo reticularis. Cardiac symptoms result from hypertension, pericarditis, or coronary vasculitis, and pulmonary involvement is atypical. The CNS is rarely involved, but stroke, delirium, seizures, and myelopathy have been reported (Video 74, Secondary Generalized Seizure).^{21,22}

Disease affecting the peripheral nervous system (PNS) is common in PAN and usually appears in the pattern of mononeuritis multiplex or asymmetrical polyneuropathy.²³

CSS usually begins with upper respiratory symptoms such as sinusitis and rhinitis. Symptoms of systemic vasculitis involving skin, heart, and peripheral nerves follow. In a series of 42 patients with CSS, 62% had nervous system involvement, almost entirely restricted to the PNS. Mononeuropathy multiplex (58.6%), distal symmetrical polyneuropathy (24.1%), asymmetrical polyneuropathy (3.5%), and one patient with a lumbar radiculopathy (3.5%) were included (Video 240, Fasciculation). Three of the patients in the series (10.3%) had cerebral infarctions.²⁰ Inflammatory myopathy has also been described in other series.

Little information is available on pregnancy and vasculitis. One woman with CSS worsened with two pregnancies, then died of cardiac disease during her third. Another woman had symptom remission during pregnancy.

Rapidly progressive glomerular nephritis is one of the major characteristics of MPA. The clinical outcome can be poor with chronic renal failure. Relapses may be more common than in PAN. In MPA, peripheral neuropathy occurs in only 10% to 20% of patients.¹⁹

DIFFERENTIAL DIAGNOSIS. Nonspecific systemic symptoms at presentation may lead to consideration of infection, neoplasm, or connective tissue disease.²⁴ The presence of mononeuritis multiplex strongly suggests vasculitis. In the absence of organ system involvement other than the CNS, the differential diagnosis rapidly expands to include virtually any vasculopathy, inflammation, or infectious disease. In the appropriate clinical setting, particularly with perinuclear antineutrophil cytoplasmic antibody (pANCA) positivity, the diagnosis may be made clinically without need for tissue diagnosis.²⁰

EVALUATION. The ESR is typically elevated in PAN patients, averaging 60 mm/hour.²³ Other laboratory studies may show leukocytosis, anemia, thrombocytosis, and abnormal urinary sediments. Hepatitis B surface antibody is seen in a subset of patients. pANCA is detected in almost 20% of PAN patients, and it has been suggested that these pANCA-positive PAN patients may actually have MPA.¹

Electromyography (EMG) and nerve conduction velocity studies demonstrate chronic partial denervation, impaired motor and sensory nerve conduction, and sometimes conduction block due to focal ischemic lesions.²³ Sural nerve biopsies in patients with peripheral neuropathy demonstrated pathological findings in 30 of 34 patients, showing vasculitis of epineural arterioles, resulting in a central fascicular pattern of nerve damage.²³ In suspected cases of PAN-associated myopathy, muscle enzymes, EMG, and biopsy are diagnostic.²⁵ Biopsy of symptomatic tissues such as peripheral nerve and skin may also be diagnostic. CSF may also be helpful in detecting CNS involvement with lymphocytosis and elevated protein. MRI is nonspecific but helpful in localizing involvement in the CNS. Angiography

establishes the diagnosis in about 80% of patients, demonstrating aneurysms and changes in blood vessel caliber or stenotic lesions.¹⁹

In CSS, eosinophilia in the peripheral blood (defined as greater than $1.5 \times 10^9/L$) is very helpful in leading toward a correct diagnosis. In the clinical setting of peripheral eosinophilia, asthma, and findings typical of vasculitis or multiple necrotizing cutaneous lesions, the diagnosis can be made without biopsy,²⁰ although other hypereosinophilic syndromes discussed later in this chapter must also be considered. Approximately 70% of CSS patients are pANCA positive.¹

MPA may cause mononeuritis multiplex without other defining disease features, and evaluation of the PNS as described previously is essential.²³ Skin lesions, when present, provide a convenient means of tissue diagnosis with minimal risk. Even in the presence of CNS vasculitis, visualization of arteritis by angiography is usually impossible because the involved vessels are smaller than 700 μm in diameter.²⁶ MPA is the vasculitis most closely associated with pANCA, and 50% to 90% of patients are pANCA positive.¹

MANAGEMENT. Glucocorticosteroids are the mainstay of immunosuppressive therapy for all of the vasculitides. In PAN and MPA, prednisone 1 mg/kg daily (possibly higher), in divided doses, should be given until inflammatory features are controlled. Prolonged treatment may be required, and the lowest effective dose should be sought on an alternate-day regimen. Retrospective trials of cytotoxic agents have suggested efficacy, but other studies report no added benefit. Nonetheless, if steroids are not effective or organ system damage is progressive, cyclophosphamide, at doses of 2.5 to 3.5 mg/kg/day, or another cytotoxic agent should be used. Antiviral agents, such as vidarabine, have been reported to be successful in cases of hepatitis B-associated PAN. Antiplatelet agents such as aspirin should be used throughout the course of treatment, due to a potential platelet aggregating effect of steroids in vasculitis patients.²⁷

CSS is managed in the same fashion as PAN and MPA, but CSS patients are more responsive to initial treatment with steroids and less often require cytotoxic treatment.²⁷ In a series of 29 CSS patients, only 2 required cytotoxic therapy in addition to steroids.²⁰

In a multicenter, prospective European study of ANCA-associated vasculitides, all patients were initially treated with prednisolone (1 mg/kg/day initially, and tapered to 0.25 mg/kg/day by week 12) with oral cyclophosphamide (2 mg/kg/day). Patients who achieved remission in less than 6 months were then randomized to continue with cyclophosphamide (1.5 mg/kg/day) or azathioprine (2 mg/kg/day) and both groups received 10 mg of prednisolone daily. Over 90% achieved remission initially by the 6-month point and there were not significant differences between the two groups for maintenance of remission. This suggests that azathioprine can be used to help limit the dose exposure in patients with ANCA-positive vasculitis.²⁸

PROGNOSIS AND FUTURE PERSPECTIVES. Prior to immunosuppressive therapy, patients with systemic vasculitides had a 5-year survival rate of about 13%. Most deaths were attributed to renal or pulmonary failure with vascular events in the gastrointestinal tract or CNS composing the

rest. Since the use of steroids, the 5-year survival rate has improved to about 47% to 57%, although older patients have a worse outcome.²³

With PNS involvement, if inflammatory features respond to treatment, there is often an improvement in the neuropathy.²³

All the 29 patients with CSS in the Mayo Clinic series received steroid therapy and 10 patients had improvement of their neurological syndrome. In the mean follow-up of 3.9 years, four patients died, one from a cerebral infarct. With MPA, the clinical outcome can be poor with chronic renal failure. Relapses may be more common than in PAN.¹⁹

Wegener's Granulomatosis

PATHOGENESIS AND PATHOPHYSIOLOGY. The almost universal involvement of the upper or lower airway in Wegener's granulomatosis (WG) has led to a theory that the condition results from exposure to an inhaled antigen with resultant granulomatous inflammation and altered immunoreactivity.²⁹ Cell-mediated immunity and immune complexes are felt to play significant roles. There may be genetic or other predisposing host factors. A strong association with cytoplasmic antineutrophil cytoplasmic antibodies (cANCA) suggests a pathogenic role. It has been shown *in vitro* that cANCA causes neutrophils to undergo a respiratory burst and degranulation, releasing toxic superoxides.³⁰ However, no direct evidence confirms that it is an etiological factor in WG.

EPIDEMIOLOGY AND RISK FACTORS. The incidence of WG in the United States is about 1 in 30,000. Among 180 patients referred to the National Institute of Allergy and Infectious Diseases, 97% with WG were white with equal numbers of men and women. The mean age was 41 years (range, 9 to 79 years), and 15% were younger than 19 years of age.³¹ The ease of identification of the disorder with cANCA has increased disease ascertainment.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Criteria for the diagnosis of WG are listed in Table 50-5.³² Ninety percent of patients with WG have upper or lower airway symptoms. Median duration of these symptoms at the time of diagnosis is 4.7 months. Nasal, sinus, and ear abnormalities are seen at presentation in 73% and during the illness in 92%. Lung disease develops in 85% of cases over the course of the illness, although it is asymptomatic in one third of cases. Eighteen percent of patients present with asymptomatic glomerulonephritis,

and 77% develop glomerulonephritis, usually within the first 2 years of disease onset.³¹

In a prospective series, peripheral nervous system involvement occurred in 24% of patients at the time of diagnosis of WG.³³ CNS involvement occurs in 8% of patients and includes stroke, cranial nerve abnormalities, and diabetes insipidus.³¹ In literature series, neurological involvement with WG occurs in 22% to 54% of patients. Virtually any portion of the neuraxis can be affected, but the most common manifestation is peripheral neuropathy, particularly mononeuropathy multiplex.³⁴

Headache in WG is due to sinusitis, pachymeningitis, or cerebral vasculitis. Multiple forms of cranial nerve problems occur. Exophthalmos, ophthalmoplegia, and optic nerve involvement due to granulomatous involvement may be a presenting symptom of WG.²⁹ Ocular symptoms are present in 15% of patients at onset and 52% of patients during the disease course. The most helpful diagnostic finding is proptosis (2% at onset, 15% overall), because it is highly suggestive of WG when associated with upper or lower airway disease. Proptosis is usually painful and leads to visual loss owing to anterior ischemic optic neuropathy in about half of affected patients. Extraocular muscle entrapment can cause diplopia (Video 1, Cranial Nerve VI Palsy). Recurrent serous or suppurative otitis media may cause partial (33%) or total unilateral (1%) or bilateral (1%) hearing loss.³¹ Multiple cranial neuropathies rarely occur as a result of pachymeningitis.²⁹

Intracranial vasculitis, cerebritis, and meningitis are uncommon.^{29,35} Because the small vessels are typically involved in WG, angiography is usually normal.²⁹

PNS involvement can take several forms. Mononeuritis multiplex is a frequent neurological complication (as in PAN and MPA) and is highly suggestive of vasculitis as an etiology.²⁹ Forty-four percent of peripheral nerve syndromes present in this manner with the common peroneal nerve typically involved along with one or more other nerves (Video 237, Foot Drop).³³ Polyneuropathy, either symmetrical or asymmetrical, occurs with slightly greater frequency (Video 259, Sensory Polyneuropathy).²³ Axonal features predominate on electrodiagnostic studies, and demyelinating features are uncommon.³³ Although myalgias and arthralgias are frequent complaints in WG, myopathy is a relatively uncommon manifestation.²⁹ In general, pregnancy adversely affects clinical signs.³⁶

DIFFERENTIAL DIAGNOSIS. Constitutional symptoms such as fever and weight loss occur to varying degrees and may initially lead the diagnostic evaluation toward chronic infection or malignancy. In those patients with clinical involvement of the orbit or retro-orbital space, malignancy and endocrinopathies are likely considerations. When symptoms are isolated to the respiratory tract, diagnoses of recurrent infection or allergy are common. In patients with milder disease, diagnosis may be delayed up to 5 to 15 years after the initial symptoms.³¹

EVALUATION. Routine blood studies show leukocytosis and normochromic normocytic anemia in most and thrombocytosis in many patients. ESR averages 71 mm/hour (range, 17 to 140 mm/hour) and correlates well with disease activity before treatment in 80% of patients.³¹

The high specificity of cANCA for Wegener's granulomatosis and its limited variants has been confirmed in large

TABLE 50-5

Criteria for the Diagnosis of Wegener's Granulomatosis

Two or More of the Following:

- Purulent or bloody nasal discharge or oral ulcers
- Radiographic evidence of nodules, fixed infiltrates, or cavities
- Microscopic hematuria
- Biopsy evidence of granulomatous inflammation

Modified from Nishino H, DeRemee RA, Rubino FA, Parisi JE: Wegener's granulomatosis associated with vasculitis of the temporal artery: Report of five cases [see comments]. *Mayo Clin Proc* 1993;68:115-121.

studies. In the appropriate clinical setting, a positive cANCA may obviate the need for tissue diagnosis. A negative cANCA, however, does not exclude the possibility of WG. The sensitivity depends on extent and activity of the disease process. There is greater than 90% sensitivity in the systemic vasculitic phase of disease, but only 65% in patients with predominantly granulomatous disease limited to the upper and lower respiratory tract. In patients with no active disease, the sensitivity is about 30%.³⁷

In patients with CNS manifestations of the disease, MRI is a valuable initial step in evaluation. T2-weighted sequences and gadolinium-enhanced images are most sensitive to ischemic changes secondary to vasculitis. When clinical suspicion of CNS vasculitis is high, angiography and biopsy should be pursued despite a normal MRI.²⁶ Because the size of vessels involved in CNS WG is small, the greatest utility of angiography may be the exclusion of other vasculitides or nonvasculitic vascular disease.^{26,29}

Open lung biopsy is positive greater than 90% of the time, whereas bronchoscopy-directed biopsy shows vasculitis in only 7%. The typical appearance is that of a granulomatous vasculitis with necrosis, giant cells, and microabscesses.³¹

MANAGEMENT. Treatment includes prednisone (1 mg/kg/day) and oral cyclophosphamide (2 mg/kg/day). Fulminant disease is treated with more aggressive cyclophosphamide (up to 5 mg/kg/day) with subsequent doses based on white blood cell counts. According to response, doses are adjusted to eliminate prednisone and maintain patients on cyclophosphamide alone. Then cyclophosphamide is tapered until disease recurrence or discontinuation. Using this regimen, 75% remit completely, and an additional 16% have marked improvement. Eight percent of patients have seemingly intractable disease, but achieve remission in up to 4 to 6 years. Remission is achieved at least once in 96% of patients. However, 46% of patients have at least one relapse, and 44% have relapses of more than 5 consecutive years' duration.³¹ Methotrexate may be of some value in patients with milder disease or cyclophosphamide intolerance.³²

The role of serial cANCA titers in determining the risk of relapse in treated patients is unknown, and it is premature to recommend altering immunosuppressive therapy in response to a changing titer.³⁷

PROGNOSIS AND FUTURE PERSPECTIVES. The disease and its treatment carry significant morbidity. Cushingoid features are universal among steroid-treated patients. With cyclophosphamide, there is a 2.4-fold overall increase in the rate of malignancies, including a 33-fold increase in bladder and 11-fold increase in lymphoma, compared with rates of the National Cancer Registry for a similar cohort. Serious infections occur in half of the patients, with a rate of 0.11 infections per patient year. The mortality rate is 20%; more than 50% of the deaths are attributed to active disease or treatment-related complications. Renal disease, coronary disease, infection, malignancy, and combined renal and pulmonary disease are contributory.³¹

Vasculitis Associated with Antiphospholipid Antibodies

PATHOGENESIS AND PATHOPHYSIOLOGY. Antiphospholipid antibodies (aPL) are a heterogeneous family

of antibodies of the IgG, IgM, or mixed classes with varying cross-reactivities. Antibodies within this family include anticardiolipin antibodies, antibodies responsible for the false-positive Venereal Disease Research Laboratory serology, and the lupus anticoagulant. Antiphospholipid antibodies may be detected in a number of clinical settings. Normal elderly may have aPL of unclear significance. They may be seen in patients treated with phenothiazines, antiarrhythmics, and anticonvulsants, or in the context of infections or malignancy. Antiphospholipid antibodies are commonly seen in patients with systemic autoimmune disorders such as systemic lupus erythematosus (SLE). The primary aPL syndrome comprises recurrent venous or arterial thrombosis, fetal loss, thrombocytopenia, and positive results on serological tests for lupus anticoagulant or anticardiolipin antibodies.³⁸

The nervous system antigen targeted by aPL has not been identified. All cell membranes contain phospholipids, though they are generally protected from the immune system by the bilayer membrane structure. The ability to form aPL may depend on an induced conformational change in membrane structure and interaction with cofactors. Certain known vascular risk factors such as diabetes, hypertension, cigarette smoking, and lipid disorders may trigger the conformational change, exposing the vascular endothelium to the immune system. Old age, smoking, and diabetes mellitus may elevate glycoprotein cofactors such as β -2 glycoprotein I. This cofactor normally inhibits the intrinsic coagulation pathway and adenosine diphosphate-mediated platelet aggregation; interference with its action may promote thrombosis and platelet aggregation.³⁹ In addition, aPL may interact with natural anticoagulants such as placental anticoagulant proteins, plasminogen activators, and proteins C and S. These antibodies may also provoke complement activation or may interfere with the function of prostaglandin I₂. Although the exact mechanism or mechanisms remain ill-defined, the preponderance of evidence is that aPL cause an autoimmune-mediated prothrombotic state.³⁸

Pathological examination of affected cerebral and carotid arteries shows a noninflammatory vasculopathy with fibromuscular dysplasia, fibrin thrombi, and widespread obstruction by a proliferation of intimal fibrous tissue or myointimal cells. In later stages, fibrous webs may form across arterial lumens.^{40,41}

EPIDEMIOLOGY AND RISK FACTORS. The frequency of aPL depends heavily on the population being studied. A review of a number of studies suggests that aPL can be detected in 2% to 12% of the normal population, 10% to 26% of patients with first stroke, 10% to 40% of women with recurrent fetal loss, and 40% to 50% of patients with SLE.³⁸ In a prospective study of 147 people with aPL and thromboses within or outside the nervous system, a number of concomitant risk factors for thrombosis were identified in 76%. These included pregnancy, hypertension, hyperlipidemia, and diabetes.⁴²

CLINICAL FEATURES AND ASSOCIATED DISORDERS. The complications of aPL fall into four classes: peripheral venous thrombosis and pulmonary embolism (type I), coronary or peripheral artery thrombosis (type II), cerebrovascular or retinal vessel thrombosis (type III), and mixtures (type IV).⁴³ Nervous system abnormalities

associated with aPL include cerebral or spinal arterial or venous infarction, chorea, hemidystonia, seizures, migraine, Guillain-Barré syndrome, transient global amnesia, motor neuron disease, myasthenia gravis, and behavioral abnormalities such as affective disorder or dementia (Video 15, Facial Chorea; Video 74, Secondary Generalized Seizure).^{38,44–48} Several clinical features of transient focal neurological events in aPL-positive patients distinguish these individuals from their aPL-negative cohort. Amaurosis fugax and episodes of unilateral paresthesias without headache and without a family history of migraine suggest aPL positivity in young persons.⁴⁹

The risks associated with aPL in otherwise healthy persons are ill-defined. Clearly, patients with aPL and a single thrombotic event are at greater risk of subsequent thrombotic events. However, the risk of primary thrombotic events in otherwise healthy persons with aPL remains poorly understood.

DIFFERENTIAL DIAGNOSIS. The primary aPL syndrome must be distinguished from other causes of atherosclerotic and nonatherosclerotic vascular disease. Other connective tissue diseases such as SLE or aPL associated with exposure to inciting drugs can be discerned using history, physical examination, and laboratory tests. An analysis of 1000 patients with SLE from the medical literature yielded an average frequency of 34% for the lupus anticoagulant and 44% for anticardiolipin antibody.⁵⁰ Within the context of SLE, the presence of aPL is highly correlated with a history of thrombosis, neurological disorders, and thrombocytopenia.

EVALUATION. The diagnosis of primary antiphospholipid syndrome rests on the demonstration of aPL (anticardiolipin antibodies, lupus anticoagulant, or false-positive serological test for syphilis) in a person with a characteristic syndrome. Associated connective tissue diseases such as SLE and Sjögren's syndrome should be excluded with appropriate clinical investigation and autoantibody studies. Patients with CNS focal events should be evaluated using MRI, and scans may demonstrate large infarcts or hyperintense white matter abnormalities.⁵¹

MANAGEMENT. The management of aPL employs antithrombotic agents and immunosuppression. However, there are no prospective controlled data that support a given course of therapy. Young patients with thrombotic events and aPL are generally treated with antithrombotics (warfarin, subcutaneous heparin, low-molecular-weight heparin, and antiplatelet therapy). In a prospective study of 147 patients with aPL and an index nervous system lesion or evidence of thrombosis, anticoagulation using warfarin to an international normalized ratio (INR) of greater than 3 (with or without aspirin) was superior to less aggressive warfarin therapy (with or without aspirin), aspirin alone, and no therapy. The highest risk of recurrent thrombosis in this study was within 6 months of discontinuation of warfarin, suggesting the need for chronic therapy.⁴² There remains no consensus, however, on the nature and duration of optimal anticoagulation. Corticosteroid and other immunotherapies in the aPL syndrome are also controversial. The titers of aPL may be reduced with effective doses of immunosuppressants or with plasmapheresis, but the clinical efficacy of these modalities in the prevention of recurrent thrombosis is unknown.⁵² Intravenous

immunoglobulin (IVIG) infusions, usually with concomitant corticosteroids and antithrombotic therapy, have successfully prevented fetal loss in women with aPL and recurrent fetal loss. However, there are no reliable data in women with nervous system thrombosis, and the association of IVIG therapy and thrombotic events in other nervous system conditions warrant caution in the use of this technique. More definitive recommendations are likely to result from prospective trials of various therapies in aPL-positive patients with stroke.^{38,53}

PROGNOSIS AND FUTURE PERSPECTIVES. Patients with the highest titers of IgG aPL have a relatively high risk of recurrent thrombotic events, especially stroke, deep venous thrombosis, and spontaneous abortion. Patients with aPL and cerebral thrombosis face a recurrence risk up to 20% per year for TIA or stroke and 56% per year for noncerebral thrombosis.³⁸ While the risks associated with aPL seem well defined among patients with SLE or those who have had thrombotic events, the prognostic import of a finding of isolated aPL remains obscure.

Thromboangiitis Obliterans (Buerger's Syndrome)

PATHOGENESIS AND PATHOPHYSIOLOGY. Discovered in 1879 and described in 1908, Buerger's disease, or thromboangiitis obliterans (TO), is an uncommon vasculitis of the small and medium-sized distal arteries and veins and almost exclusively affects cigarette smokers. There was confusion about the existence of TO for many years. The better classification of other vasculitides and the development of angiography have led to the identification of TO as a separate condition.

Almost all cases of TO have occurred in tobacco users, suggesting that the inflammatory response may be allergic. Smokers with and without TO demonstrate a similar cellular immune response to a purified tobacco glycoprotein. Anticollagen antibodies and cellular immune reactions to type I and III collagen are present in patients with TO. Other potential mechanisms involved include a derangement of the endothelial cell, which could be the result of decreased plasminogen activator inhibitor 1 release.⁵⁴ There are reported familial occurrences that raise the question of a genetic susceptibility, and an increased association with HLA-A9 and HLA-B5 has been demonstrated in some with the disease. Some cases have occurred in association with other disorders such as IgA nephropathy and hypereosinophilia and with positive serological tests for rickettsial organisms. It has also been proposed that the abnormality may be a hypercoagulable state with secondary inflammation. However, the exact pathogenesis remains somewhat elusive.

Pathological findings are not routinely reported because most of the surgeries are performed on limbs with severe ischemia.⁵⁴ Three stages of pathological changes have been identified. Initially, non-necrotizing panarteritis occurs with preservation of vascular wall architecture. The media and internal elastic lamina remain intact, a finding that differentiates TO from other vasculitides where there is destruction of the elastic lamina. Infiltrates of inflammatory cells and granulomas in the thrombus differentiate the occlusive lesions of TO from atherosclerosis where thrombi are composed of only fibrin, red blood cells, and

platelets. Intrathrombotic granulomas are a distinctive hallmark of TO. Following this development, there is organization of the thrombus, with the type of inflammatory cells involved changing from neutrophils to lymphocytes and occasionally with eosinophils. Lastly, recanalization occurs with evidence of perivascular fibrosis. Aneurysms are an uncommon finding because the vascular wall remains intact.

EPIDEMIOLOGY AND RISK FACTORS. TO typically occurs in young smokers. The incidence is approximately 8 to 12 per 100,000 in the general population, thereby representing less than 1% of all patients with vascular disease. According to a report from the Mayo Clinic, there has been a tenfold decline in U.S. case incidence from 1947 to 1986. Japan, Eastern Europe, Southeastern Asia, and Israel have not shown similar declines. The median age of onset is 34.5 years of age. All are tobacco users. Men are affected about three times as often as women, but this ratio varies in different countries in relation to the gender predominance of smokers.⁵⁴

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Clinically, intermittent claudication begins in the feet and involves the legs more proximally as the disease progresses. The arms become affected in 90% of cases. Large arteries are rarely involved. Symptoms include ischemic pain at rest in 80%, claudication in 60%, and Raynaud's phenomenon in 35% of patients. Common signs are ischemic ulcers in 75% and distal gangrene in 80%.^{54,55} The neurological consequences of TO are sensory symptoms, which occur in 69% of patients. Sensory polyneuropathy may be secondary to severe ischemic changes or to fibrous encasement of distal neurovascular bundles (Video 5, Sensory Ataxia).⁵⁴

DIFFERENTIAL DIAGNOSIS. Differential diagnoses include other vasculopathies and autoimmune diseases such as SLE, scleroderma, polyarteritis nodosa, antiphospholipid antibody syndrome, GCA, or TA. Other conditions such as pseudoxanthoma elasticum and Ehlers-Danlos syndrome may be considered as well. It is important to exclude proximal sources of emboli and atherosclerosis.⁵⁴

EVALUATION. The ESR is abnormal in only 15% of patients. Angiography demonstrates involvement of small and medium-sized vessels with segmental occlusions and collateral vessels in the distal vessels of the feet and hands.⁵⁴ The absence of lesions proximally strongly favors the diagnosis of TO.

MANAGEMENT. It is imperative that the patient discontinues tobacco exposure. Forty-two percent of patients who continued smoking after the diagnosis required amputation, whereas only 5% of those who ceased smoking underwent amputation. The use of anticoagulants and antiplatelet agents may be beneficial on occasion, although the results of medical therapy have been generally poor. Ilprost, a prostacyclin analogue, improves leg pain in 35% and heals ulcers in 22% of patients. Despite clear evidence of inflammation, corticosteroids have not been of benefit.

PROGNOSIS AND FUTURE PERSPECTIVES. Twenty percent of patients require limited resection of the toes or feet, and another 20% have a proximal, below-the-knee amputation. Only 6% of patients require finger or upper extremity amputation. The sensory changes parallel the course of the vascular disease and stabilize if the ischemic

changes are controlled. Survival rates at 5 and 10 years approach that of the normal population.

CONNECTIVE TISSUE DISEASES

Rheumatoid Arthritis

PATHOGENESIS AND PATHOPHYSIOLOGY. Rheumatoid arthritis (RA) is an immune complex disease. The most important autoantibody in RA is the rheumatoid factor (RF), an antibody, usually of the IgM or IgG class, which reacts with immunoglobulins. The original triggering mechanism may be exposure to a microbial antigen. Autoantibodies to other cellular antigens such as histones, single-stranded DNA, filaments, collagen, and nuclear antigens have been described. Immune complexes composed of IgG combined with IgM or IgG anti-IgG antibodies cause inflammation of the synovium in the joints. Although the largest and most pathogenic immune complexes are found in the joints, others can be detected in the blood of patients with extra-articular manifestations such as vasculitis.

EPIDEMIOLOGY AND RISK FACTORS. RA is a chronic multisystem disease that affects 1 to 2% of the population. Disease onset is between 35 and 50 years of age in 80% of cases. Women account for 75% of cases. An increased risk in nulliparous women and a putative protective effect of oral contraception suggest a hormonal role in disease expression. Although there is a genetic predisposition to developing the disorder, genetic factors probably account for only about 30% of the risk of developing RA.⁵⁶

CLINICAL FEATURES AND ASSOCIATED DISORDERS. The onset of RA is typically insidious, with prodromal malaise, fatigue, and generalized weakness. Characteristic symmetrical polyarthritis develops within weeks to months. Articular signs and symptoms preferentially affect the cervical spine and the metacarpophalangeal, proximal interphalangeal, wrist, elbow, knee, ankle, forefoot, and subtalar joints. Progression of joint disease leads to bony erosion and joint deformity. Extra-articular manifestations, including rheumatoid nodules in subcutaneous, cutaneous, connective, and pulmonary tissues; pleuritis; interstitial fibrosis; pneumonitis; and pericardial effusions tend to occur in patients with high levels of circulating RF. Felty's syndrome (RA, splenomegaly, neutropenia, anemia, and thrombocytopenia) is seen in some patients with long-standing disease.

A few patients develop systemic vasculitis, heralded by the development of ischemic skin lesions, mononeuritis multiplex, or documented visceral vasculitis. Although this syndrome is usually seen in men who have had RA for more than 10 years, it may be seen in women at disease presentation.⁵⁷

Neurological manifestations occur in patients with moderate to severe RA. They may be caused by direct effects of the disease process or secondary effects from bone or joint involvement. Rheumatoid nodules frequently form in the dura mater, where they tend to be asymptomatic except in cases of extensive involvement with pachymeningitis.⁵⁸ The occurrence of symptomatic CNS vasculitis is rare, even in the setting of active systemic vasculitis.^{59,60} Clinical

signs of rheumatoid CNS vasculitis include seizures, dementia, hemiparesis, cranial nerve palsy, blindness, hemispherical dysfunction, cerebellar ataxia, and dysphasia. Pathological examination reveals chronic perivasculitis, transmural chronic inflammatory cell infiltration, intimal collagen proliferation with luminal narrowing, and fibrinoid necrosis of the media of small arteries.⁵⁹ Changes in the articular architecture of the cervical spine may produce CNS dysfunction at the cervicomedullary junction or spinal cord level. Significant disease of the cervical spine is present in up to 70% of patients with advanced disease. The major changes in the cervical spine include vertebral body erosion and collapse,⁶¹ rheumatoid discitis, dural thickening and fibrosis with spinal cord compression, and most commonly atlantoaxial subluxation. Subluxation of C1 on C2 may be in the anterior, posterior, or vertical directions, or there may be multiple cervical subluxations resulting in a “staircase appearance” of the cervical spine.⁶² Cervical subluxation is often asymptomatic. In patients who are symptomatic, the most striking features are myelopathic. However, other symptoms have been reported, including occipital headache⁶³ and obstructive hydrocephalus.⁶⁴ Brain stem syndromes result from pseudoaneurysm of the vertebral artery,⁶⁵ direct compression of the medulla by eroded, displaced odontoid fragments, and rheumatoid granulomata. Neurological manifestations more commonly result from intermittent or sustained anterior cord compression, sometimes complicated by compression-induced ischemia in the distribution of branches of the anterior spinal artery. Most patients with radiographical evidence of subluxation are asymptomatic. Common symptoms and signs include neck pain, weakness affecting arms before legs, flexor spasms, sphincter disturbances, paresthesias, hyperreflexia, and sensory changes.⁶²

Peripheral nerve disease in RA results from nerve entrapment, segmental demyelination, or vasculitic involvement of the vasa nervorum. Entrapment or compression of peripheral nerves occurs in 45% of patients and affects the median, ulnar, posterior interosseous, tibial, common peroneal, or posterior tibial nerves (Video 218, Ulnar Neuropathy, Wartenberg Sign; Video 220, Ulnar Neuropathy, Main en Griffes).⁶⁶ Other patterns of neuropathy seen in RA are distal sensorimotor or sensory polyneuropathy and mononeuritis multiplex. Vasculitic changes underlie all types of noncompressive neuropathies in RA.⁶⁷ Myositis may be seen but is not usually a prominent feature of the disorder.

DIFFERENTIAL DIAGNOSIS AND EVALUATION. RA must be distinguished from degenerative osteoarthritis and from deforming inflammatory arthritis associated with other connective tissue disorders. The diagnosis of RA is based on a clinical picture of symmetrical polyarthritis, radiological confirmation of joint erosion, and the demonstration of antibodies including RF by immunological tests. CNS signs should be explored using MRI studies of the brain and spinal cord as clinically indicated. EMG is useful in the differentiation of various peripheral nerve syndromes.

MANAGEMENT. The treatment of RA is generally divided into first-, second-, and third-line therapies. First-line therapy for joint disease employs nonsteroidal anti-inflammatory drugs and local or low-dose systemic

corticosteroids. Second-line therapies include gold, D-penicillamine, sulfasalazine, and hydrochloroquine. Third-line agents include corticosteroids and cytotoxic agents. Most patients with significant systemic disease will be treated with corticosteroids with weekly methotrexate at doses of 7.5 to 15 mg. If ongoing disease activity is evident injectable tumor necrosis factor- α antagonists, etanercept or infliximab can reduce disease activity without significant increase in toxicity.⁶⁸ Rheumatoid vasculitis with central or peripheral nervous system manifestations should be treated as any other systemic vasculitis using immunosuppression with corticosteroids and cytotoxic agents. The role of other immunotherapies such as plasmapheresis or IVIG is not known.⁶⁹ The prognosis is similar to that of systemic necrotizing vasculitis. Cervical subluxation should be treated conservatively with analgesics, muscle relaxants, and neck immobilization. Protection from inadvertent and iatrogenic trauma is essential. Patients with severe vertebral displacement and marked or progressive myelopathy should be considered for surgical fixation.⁷⁰

PROGNOSIS AND FUTURE PERSPECTIVES. RA is a chronic disease, and the remission rate over 10 years is less than 10%.⁷¹ RA is associated with a higher mortality rate, with a threefold increase in the risk of death. Causes of death attributable to the disease process include infection and renal disease, whereas those likely related to treatment are gastrointestinal disorders.⁷² Vasculitic peripheral neuropathy often improves, but the survival of patients with systemic rheumatoid vasculitis is poorer than others with RA.²³ Atlantoaxial subluxation is most often clinically static, and surgical fixation is not necessary in the majority of cases.⁷⁰

Systemic Lupus Erythematosus

PATHOGENESIS AND PATHOPHYSIOLOGY. Systemic lupus erythematosus (SLE) is a chronic autoimmune disease of unknown etiology which causes inflammatory changes in single or multiple organ systems. SLE is defined by its clinical features and the almost invariable presence of antibodies directed against certain components of cell nuclei.⁷³ The immunological features of SLE are the lupus erythematosus cell, antinuclear antibodies, immune complexes, complement activation, tissue deposition of immunoglobulins and complement, and other autoantibodies. This results in primary damage to the subendothelial connective tissue of capillaries, small arteries, and veins.

The etiology is likely multifactorial. Tissue damage may result from vascular causes, autoantibodies, and inflammatory mediators. There is a noninflammatory vasculopathy involving small vessels which may allow antibodies to enter the central nervous system (CNS). Autoantibodies react with cell-surface or serum components.⁷³ Antiphospholipid antibodies (aPL) are associated with thrombosis in vessels of different caliber and relate to focal clinical symptoms such as transient ischemic attacks, stroke, seizures, chorea, and transverse myelitis. Antiribosomal P antibodies are linked to psychosis and depression (diffuse CNS involvement). Inflammatory mediators, such as cytokines (e.g., interleukin 6, and interleukin 10), may influence the degree and extent of inflammation in SLE-mediated disease.

The term neuropsychiatric systemic lupus erythematosus (NPSLE) has replaced common historical terms such as lupus cerebritis or lupus vasculitis in describing the clinical manifestations of CNS and peripheral nervous system (PNS) SLE. A cerebritis is not pathologically seen. Although vasculitis can be seen in other organ systems such as kidney or skin, true CNS vasculitis is rarely present in NPSLE.

More than 80 drugs, including procainamide, hydralazine, chlorpromazine, antibiotics, and anticonvulsants, can produce a lupus-like syndrome. Some of these drugs induce the formation of histone-dependent antinuclear antibodies (ANA), and the syndrome usually abates with cessation of the drug. Drug-induced lupus is milder than idiopathic SLE and does not cause renal or CNS disease.

EPIDEMIOLOGY AND RISK FACTORS. The prevalence of SLE varies throughout the world. In North America and northern Europe, the incidence is about 1 in 2500. There appears to be a higher incidence in Hispanics and African Americans and a tendency toward more severe disease; however, based in part on socioeconomic factors, a potential ascertainment bias exists. There is a predominance of disease in women with an incidence of 1 in 700, and particularly among African Americans with an incidence of 1 in 245. The incidence in children and older adults is about 1 per 100,000.⁷³ Environmental risk factors have been implicated, including exposure to ultraviolet light, viral infection, and physical or emotional stress.

Neuropsychiatric (NP) events in SLE can relate to lupus, be secondary to complications of the disease (such as infection, medication side effects, or metabolic abnormalities), or be totally unrelated to SLE. NPSLE can occur at any time during the course of the disease, and many of the NPSLE manifestations may develop before the onset or at time of the initial diagnosis. Wide variations in prevalence of NPSLE relate to differences between study cohorts or a bias in data acquisition. Prior to the 1999 American College of Rheumatology (ACR) nomenclature (see the next section), NP events were reported in 14% to 75% of SLE patients.⁷⁴ In one series, 91 patients were followed for 599 patient years. In 25% of the 288 hospital admissions, neurological problems were primary or secondary reasons for admission. Only 14% had no symptoms or signs attributable to nervous system disease.⁷⁵ However, five studies after the ACR nomenclature was introduced relate the overall prevalence of NPSLE to be between 37% and 95%.⁷⁴

CLINICAL FEATURES AND ASSOCIATED DISORDERS. SLE has diverse clinical manifestations that can affect virtually every organ system. A number of the common manifestations are not specific to SLE. The diagnosis is thus acquired through identification of a combination of clinical and laboratory data. Criteria for the diagnosis of SLE are listed in Table 50-6.⁷⁶ These criteria were revised in 1982 and further revised by the Diagnostic and Therapeutic Criteria Committee of the ACR in 1997.⁷⁷ Neurologic criteria for the diagnosis of SLE were restricted to seizures and psychosis (Video 22, Delusional Thinking; Video 74, Secondary Generalized Seizure). In 1999, the ACR published nomenclature and case definitions for NPSLE. This provided a basis for classification of NP disease, categorization of patients for clinical studies, and also served as clinical diagnostic criteria for NPSLE. There are 12 CNS syndromes and 7 PNS syndromes listed in Table 50-7.⁷⁸

TABLE 50-6

Criteria for the Diagnosis of Systemic Lupus Erythematosus

| CRITERION | DEFINITION |
|------------------------|---|
| Malar rash | Fixed erythema, flat or raised, over the malar eminences, tending to spare the nasolabial folds |
| Discoid rash | Erythematous raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring may occur in older lesions |
| Photosensitivity | Skin rash occurring as a result of exposure to sunlight, by patient history or physician observation |
| Oral ulcers | Oral or nasopharyngeal ulceration, usually painless, observed by a physician |
| Arthritis | Nonerosive arthritis involving two or more peripheral joints, characterized by tenderness, swelling, or effusion |
| Serositis | Pleuritis—convincing history of pleuritic pain or rub heard by a physician or pleural effusion <i>or</i> Pericarditis—documented by electrocardiogram or rub or evidence of pericardial effusion |
| Renal disorder | Persistent proteinuria > 0.5 g per day or greater than 3+ if quantitation not performed <i>or</i> Cellular casts—may be red blood cell, hemoglobin, granular, tubular, or mixed |
| Neurological disorder | Seizures—in the absence of offending drugs or metabolic derangements <i>or</i> Psychosis—in the absence of offending drugs or known metabolic derangements |
| Hematological disorder | Hemolytic anemia—with reticulocytosis <i>or</i> Leukopenia—less than 4000/μL on two or more occasions <i>or</i> Lymphopenia—less than 1500/μL on two or more occasions <i>or</i> Thrombocytopenia—less than 100,000/μL in the absence of offending drugs |
| Immunological disorder | Anti-DNA: antibody to native DNA in abnormal titer <i>or</i> Anti-Sm: presence of antibody to Smith nuclear antigen <i>or</i> Positive finding of aPL based on: (1) an abnormal serum level of IgG or IgM anticardiolipin antibodies (2) a positive test result for lupus anticoagulant using a standard method, or (3) a false-positive serologic test for syphilis known to be positive for at least 6 months and confirmed by <i>Treponema pallidum</i> immobilization or fluorescent treponemal antibody absorption test |
| Antinuclear antibody | An abnormal titer of antinuclear antibody by immunofluorescence or equivalent assay at any point in time and in the absence of drugs known to be associated with drug-induced lupus syndrome |

aPL, antiphospholipid antibodies.

Modified from Tan EM, Cohen AS, Fries JF, et al: The 1982 revised criteria for the classification of systemic lupus erythematosus. *Arthritis Rheum* 1982;25:1271–1277; Hochberg MC: Updating the American College of Rheumatology revised criteria for the classification of systemic lupus erythematosus [letter]. *Arthritis Rheum* 1997;40:1725.

Eight of the syndromes (mainly those peripheral) occur in less than 1% of SLE patients. None of the neurologic syndromes are specific for NPSLE, but reveal that neurologic syndromes in SLE patients are not restricted to seizures and psychosis, both of which are relatively infrequent in SLE. Cognitive impairment, the most common neurologic syndrome, is not mentioned at all in the 1982 or 1997 criteria.

The most common clinical manifestation of NPSLE is cognitive dysfunction, occurring in 17% to 80% of NPSLE cases.⁷⁹ The range in prevalence relates to differences in patient selection and the lack of a uniform definition for cognitive impairment.⁷⁴ Most patients are only mildly impaired and the pattern of cognitive decline is not specific or unique to NPSLE. Cognitive dysfunction is associated with antiphospholipid antibodies but not antiribosomal P antibodies. The presence and extent of impairment does not appear to relate to disease duration, disease activity, or to the use of corticosteroids.

Seizures represent approximately 25% of the neurological problems in patients with SLE and may occur at times of disease inactivity.⁸⁰ In most cases, the genesis of seizures was multifactorial and included preexisting epilepsy, trauma, azotemia, systemic infection, meningitis, or stroke. About 30% of patients with SLE and seizures have no other predisposing features. Seizures are positively associated with coagulopathy and stroke, and negatively associated with cardiac disease.⁷⁵

Stroke frequency has been reported from 5% to 20% of NPSLE patients and is a significant cause of morbidity.⁷⁵ Although stroke was as likely to occur during disease inactivity in the study by Kaell, 86% of another series of patients with large vessel occlusive disease stroke had

active SLE at the time of the stroke.^{80,81} In more than half the cases, strokes are multiple, although earlier strokes may have been asymptomatic.⁸⁰ Headache heralded ischemic stroke in 60% of cases in one series.⁸¹ Strokes may result from emboli, coagulopathy, accelerated atherosclerotic disease, or arterial dissection.⁸⁰ Libman-Sacks valvular disease or ventricular dysfunction may be identified in some patients. Valvular vegetations on postmortem examination can be found despite a normal echocardiogram.⁸¹ Vasculitis is a rare cause of CNS dysfunction in SLE.^{75,81} Long-term corticosteroid treatment may play a role in premature cerebral and coronary atherosclerotic disease, which may contribute to stroke risk.⁸¹ Hemorrhagic stroke occurs less commonly but frequently results in coma or death.⁷⁵

Antiphospholipid antibodies such as anticardiolipin antibody and lupus anticoagulant may play a significant role in many of the thrombotic events in SLE.⁸¹ Antiphospholipid antibodies are directed against plasma proteins bound to negatively charged phospholipids. Whereas anticardiolipin antibody is present in 2% to 5% of the normal population, it is present in 23% to 47% of SLE patients. Neurologic involvement is higher in SLE patients with antiphospholipid antibodies than SLE patients without the antibodies (49% versus 12%).⁸² They are associated with localized (vascular) NPSLE such as transient cerebral ischemia, stroke, and cerebral venous thrombosis. Statistically, the presence of these antibodies significantly raises the incidence of primary stroke; the recurrence rate among aPL-positive SLE patients with prior stroke exceeds 50%.⁷⁵ Antiphospholipid antibodies in patients with SLE are more likely to be associated with valvular and other cardiac disease.⁸¹

Behavioral changes are frequent in NPSLE patients. Mood disorders and anxiety can be seen in up to 75% of patients. True psychosis occurs in up to 8% of SLE patients.⁸³ Psychosis and depression are linked to antiribosomal P antibody but not to antiphospholipid antibodies. Steroid induced psychosis is occasionally implicated as a cause of behavioral change but can be difficult to distinguish from SLE psychosis. Determination of the presence of antiribosomal P antibody may be helpful in these patients.

Chorea (the only movement disorder included in the ACR nomenclature) has been described in patients with SLE and is associated with the presence of antiphospholipid antibodies in the absence of a radiographic lesion in the basal ganglia.⁷⁵ Chorea can be precipitated by pregnancy or by estrogen-containing oral contraceptives (Video 71, Birth Control Pill-Induced Chorea).

Peripheral nervous system abnormalities are less common than in other autoimmune disorders. A predominantly distal, axonal sensorimotor polyneuropathy is more common than mononeuritis multiplex.⁸⁴

Pregnancy in patients with active disease, particularly with nephritis and hypertension, is associated with a substantial risk of disease exacerbation and injury to the fetus. The presence of aPL has been associated with both stroke and second-trimester abortion.^{73,81} For patients in remission, however, the risks during pregnancy are similar to those of unaffected patients.⁷³

Many neurologic symptoms and signs in SLE patients may not be a primary manifestation of SLE but rather a

secondary process from infection, medication, or metabolic disturbance such as uremia or electrolyte imbalance. The symptoms and signs may also be totally unrelated to SLE.

DIFFERENTIAL DIAGNOSIS. The diagnosis of SLE is largely dependent on demonstrating a constellation of relatively specific findings to differentiate it from other systemic diseases. In approaching a patient with a given neurological syndrome, the differential diagnosis is generated by the predominant clinical picture, but SLE should always be kept in mind in a patient with CNS or PNS problems and dermatological or renal disease.

EVALUATION. Various techniques can detect serum immune complexes, but the presence or quantity of the complexes is not specific to SLE. The most common antibody in SLE is the ANA that stains homogeneously on immunofluorescence and is directed against nucleosomal DNA histone complexes. Nearly all SLE patients have a positive ANA, and thus normal ANA titers are strong evidence against the diagnosis. ANA specificity for SLE is about 60%. ANA can be positive in other autoimmune disorders such as Sjögren's syndrome, scleroderma, or rheumatoid arthritis, though often in lower titers. Antibodies to native or double-stranded DNA and Smith (Sm), a ribonuclear protein antigen, are more specific than ANA for the diagnosis of SLE.⁷³ Antiribosomal P antibody correlates with the presence of psychosis. Depressed serum complement levels are useful though not specific in recognizing disease activity and risk for renal and CNS involvement in SLE. Levels should be assessed during disease inactivity for comparison, and routine levels can serve as a guide for treatment. Antiphospholipid antibodies can be directly assessed in the serum. Anticardiolipin antibodies and lupus anticoagulant demonstrate the most consistent association with clinical disease.

There is no specific diagnostic test for NPSLE. Cerebrospinal fluid abnormalities in SLE are nonspecific. Pleocytosis, elevated protein, and oligoclonal bands do not consistently correlate with the clinical syndrome or its severity and occur in only one third of patients.⁸⁵ Hypoglycorrhacia can be seen in SLE transverse myelitis but is not present in idiopathic transverse myelitis. CSF examination should be done if a

CNS infection is suspected. Electroencephalography (EEG) may be useful in a certain number of cases. The most common finding is generalized or focal slowing, and focal epileptiform discharges are seen in patients with seizures. The demonstration of a normal EEG may be useful in differentiation of psychosis and delirium.⁷⁵

MRI abnormalities, especially white matter lesions, can be seen in up to 70% of NPSLE patients.⁸⁶ The changes, however, are nonspecific and nondiagnostic for NPSLE and are often indistinguishable from age-related small vessel disease changes. Focal neurological symptoms of NPSLE often correlate with structural (MRI) abnormalities. MRI is often normal or near-normal in NPSLE patients with depression or psychosis. On the other hand, abnormalities on MRI may appear out of proportion to the clinical presentation (Fig. 50-3). MRI, and diffusion weighted imaging in particular, is very sensitive for detection of a recent stroke.

MANAGEMENT. Hypertension and systemic or local infections need to be treated. Metabolic abnormalities should be corrected, and possible toxic effects of medications need to be addressed. Many patients with mild symptoms such as myalgias, arthralgias, low-grade fevers, or arthritis can be managed with nonsteroidal anti-inflammatory medications. Anticonvulsants, antipsychotics, and anxiolytics are given in the appropriate clinical setting.

Treatment of NPSLE syndromes depends on the pathogenic factors involved. Antiplatelet agents or anticoagulants are usually initiated in patients with positive antiphospholipid antibodies with or without an associated vascular event. Although high-dose intravenous corticosteroids (often followed by intravenous cyclophosphamide) are frequently felt to be the treatment of choice for NPSLE, there are no large controlled studies supporting this combination of medications. Other treatments suggested include azathioprine, plasma exchange, intravenous immune globulin, methotrexate, cyclosporine, mycophenolate mofetil, and autologous stem cell transplant. There are no placebo controlled trials for any of these modalities, and thus treatment success is largely anecdotal.

PROGNOSIS. The clinical course is highly variable. SLE can evolve over many years and there can be periods

Figure 50-3. A 54-year-old woman with systemic lupus erythematosus (SLE) who was exhibiting personality changes and memory loss. MRI reveals extensive white matter abnormalities on axial T2-weighted images (A) and coronal FLAIR images (B).

of remissions and relapses. The 10-year survival rate approaches 92%.⁸⁷ Patients with nephritis and systolic hypertension have a worse prognosis.⁷³ Although acutely dangerous, seizures and psychosis are generally associated with good long-term recovery. Patients with neurological episodes with more than one potential etiological factor such as hypertension, uremia, infection, drug abuse, and electrolyte abnormalities are more likely to recover significant function than those experiencing primary SLE-related events.⁸⁰ Stroke and systemic infection carry a relatively poor short-term outcome.^{75,82} The prognosis of SLE is also significantly impacted by the presence of antiphospholipid antibodies.

Progressive Systemic Sclerosis

PATHOGENESIS AND PATHOPHYSIOLOGY. Progressive systemic sclerosis (PSS) is a condition associated with thickening of the skin and tethering to subcutaneous tissues as well as smooth muscle atrophy and fibrosis of internal organs such as the gastrointestinal tract, lungs, heart, and kidneys. The disorder is characterized pathologically by increased collagen deposition and perivascular inflammation in the skin, subcutaneous tissues, and internal organs.

Antinuclear antibodies are typically found, usually in a nucleolar pattern; antibodies to Scl-70, a soluble nuclear antigen, are specific, though insensitive. The demonstration of antibodies to smooth muscle and cytotoxicity to cultured endothelial cells suggests that autoimmunity plays a role in pathogenesis. The etiology of PSS is unknown, but glandular inflammatory processes appear to be related to cell-mediated immunity or to antibody-mediated cytotoxicity rather than to immune complex deposition.⁶⁹ Immune complex disease appears to be responsible for rare cases of associated vasculitis.

EPIDEMIOLOGY AND RISK FACTORS. The incidence of PSS ranges from 0.6 to 2.3 per million.⁸⁸ Women, usually between the ages of 40 and 60 years, are affected three times as often as men. The association with certain HLA class II antigens suggests a hereditary predisposition.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Some patients have a relatively benign form of the disorder limited to cutaneous changes in the distal extremities. In the generalized form of the illness, cutaneous abnormalities may predominate, but systemic symptoms, including generalized malaise, are common. Vascular changes in the hands progress from Raynaud's phenomenon to frank necrosis and induration and fibrosis of the skin (sclerodactyly) with atrophy of the underlying muscle. Rigidity of ligamentous tissue in the inner ear leads to conductive hearing loss. There may be fibrotic changes in the myocardium, pericardium, pleura, or lung. Glomerulonephritis with renal crisis is a frequent cause of morbidity and death. Mucosal gastrointestinal lesions occur, preferentially in the distal esophagus. Keratoconjunctivitis, lens subluxation, and cataracts are typical ocular signs, and musculoskeletal changes, including atrophy and osteolytic lesions, joint symptoms, and myopathy, occur in 50% of patients.⁸⁹

The frequency of nervous system involvement varies; in one series of 727 patients, 6 had nervous system changes.⁸⁹ In a more recent report of 48 patients, 56% had neurological disturbances. Electrophysiological studies suggest

subclinical nervous system dysfunction in many asymptomatic patients.⁹⁰

Although rare, CNS disease has been reported. It may present as global cognitive decline or as a focal lesion. Encephalopathy, migraine, psychiatric changes, seizures, and focal neurological deficits have been reported.⁹¹ Three cases with presumed cerebral arteritis have been reported, one a reversible encephalopathy with angiographic evidence of vasculitis, one with hemiplegia and aphasia with angiographic evidence of vasculitis, and one with right thalamic hemorrhage.

Trigeminal neuropathy is a frequent presenting feature of PSS and is the most common cranial neuropathy found in the disorder. It develops insidiously or acutely and affects primarily the central part of the face. Pain is common and may resemble that of tic douloureux (Video 106, Trigeminal Neuralgia).⁹⁰ Median and ulnar entrapment neuropathies have been reported in up to 20% and distal polyneuropathy in up to 15% of patients.⁹² Most peripheral neuropathies can be ascribed to metabolic and nutritional factors. However, some cases of sensorimotor neuropathy occurring before the onset of other symptoms or very early in the disease course suggest that PSS may be etiological. In addition, a prospective evaluation of 29 patients with limited or widespread systemic sclerosis demonstrated raised tactile thresholds in 28, suggesting that subclinical peripheral nerve dysfunction is common in the disorder.⁹³ Autonomic neuropathy is common,⁹⁴ and recent evidence suggests that gastrointestinal dysmotility may be related to a neuropathic process.⁹⁵

EMG in most cases of sensorimotor neuropathy reveals axonopathy, and histological features include collagenous infiltration of the peripheral nerves and the adventitia of vasa nervorum. Low-grade distal nerve trunk ischemia may contribute to neuropathy.⁹⁶ Biopsy of the sural nerve reveals segmental demyelination, axonal degeneration, loss of large myelinated fibers, and an increase of collagen fibers, without evidence of vasculitis.⁹⁷

DIFFERENTIAL DIAGNOSIS. Chronic graft-versus-host disease following bone marrow transplant can mimic the picture of PSS, though esophageal and renal involvement are usually not seen. Sclerodermatous skin changes can be seen in response to certain chemotherapeutic agents.

EVALUATION. The diagnosis of PSS is generally made clinically. Evidence of disturbed gastrointestinal motility and vasculopathy on nailfold capillary microscopy are confirmatory. Generalized or focal CNS abnormalities can be investigated using MRI. Nerve conduction velocities (NCV) and EMG are useful in the elucidation of neuropathy syndromes, and NCV can be used to detect subclinical neuropathy.

MANAGEMENT. Symptomatic treatments include non-steroidal anti-inflammatory drugs for arthritis and vasoactive drugs for Raynaud's phenomenon. Neuropathic pain, especially that associated with trigeminal neuropathy, can be treated with carbamazepine or tricyclic antidepressants. Penicillamine, colchicine, prednisone, and immunosuppressants have been used for more severe disease manifestations, but their relative effectiveness has not been determined.⁶⁹

PROGNOSIS AND FUTURE PERSPECTIVES. The 10-year survival rate in PSS approximates 50%.⁹⁸ In some

cases the disease is rapidly progressive, and death occurs within 1 year. The most common causes of death are renal failure and cardiac complications. Individual survival is largely dependent on the extent of involvement. Digital sclerodactyly alone carries a very benign prognosis. Prognosis is worse with diffuse disease, older onset age, and early involvement of internal organs.⁹⁹

Mixed Connective Tissue Disease

PATHOGENESIS AND PATHOPHYSIOLOGY. In 1971, Sharp described patients in whom a new type of antibody to ribonuclease-sensitive extractable nuclear antigen was accompanied by clinical features of more than one connective tissue disease. He called the syndrome mixed connective tissue disease (MCTD) and described several serologic characteristics: (1) high titers of hemagglutinating antibody to saline-extractable nuclear antigen; (2) marked sensitivity of this antibody to ribonuclease with moderate sensitivity to trypsin and resistance to deoxyribonuclease; (3) high titers of speckled pattern on fluorescent ANA testing; and (4) absence of Smith antibody. Saline-extractable nuclear antigen appears to represent two moieties: ribonucleoprotein (RNP) and the Smith (Sm) antigen, a glycoprotein. Whereas high titers of anti-RNP antibodies appear to be associated with MCTD, the presence of anti-Sm correlates highly with the diagnosis of SLE. The etiopathogenesis of MCTD is poorly understood but is felt to relate to formation of autoreactive T cells in response to exposure to microbial antigens, which are similar to an autoantigen.¹⁰⁰ Patients with MCTD may have ANA in a speckled pattern, RF, and cold-reactive lymphocytotoxic and anticardiolipin antibodies.¹⁰¹

EPIDEMIOLOGY AND RISK FACTORS. The prevalence of MCTD is unknown. It is intermediate in frequency between SLE and systemic sclerosis.¹⁰² Women are more frequently affected than men by a factor of 4 to 79:1.¹⁰³ Although most frequently seen in the second and third decades of life, it has been reported in children and the elderly as well.¹⁰¹ There is an association between the 68-kd-U1 snRNP and the DR4 haplotype in both SLE and MCTD.¹⁰⁴ The existence of MCTD as a discrete syndrome is not universally accepted, because the serological markers are not specific for the diagnosis¹⁰² and the disorder frequently evolves over a number of years into SLE or PSS.^{102,105} Nevertheless, the term is still considered helpful to describe a number of patients with a mixed clinical picture.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Patients with MCTD have clinical features of at least two connective tissue disorders, among them SLE, PSS, and polymyositis. Nearly all have arthralgia, nondeforming arthritis, inflammatory myositis, Raynaud's phenomenon, sclerodactyly, and a tapered or sausage-like appearance of the digits, sometimes with digital ischemia and ulceration. Pitting edema of the forehead and erythematous malar or violaceous eyelid rash may be present. Disorders of esophageal motility affect more than 75% of patients. Lymphadenopathy is common and sometimes marked, suggesting lymphoma. Fever, hepatosplenomegaly, pleuritis, pericarditis, and cardiac and hair changes are seen in 20% to 40% of cases. Pulmonary disease is very common, and although it may be asymptomatic, pulmonary

hypertension is the most common cause of death.^{106,107} Frequent laboratory abnormalities include leukopenia, anemia, and hypergammaglobulinemia.¹⁰⁷ Renal disease is evident in some patients with MCTD. Proteinuria, sometimes with nephrotic syndrome, hematuria, glomerulonephritis, or proliferative vascular lesions, may be seen.

Neurological sequelae of MCTD occur in 10% to 55% of cases.¹⁰⁸⁻¹¹⁰ The CNS complications of MCTD resemble those seen in SLE, whereas the PNS complications resemble those seen in PSS. CNS effects occur in the context of active systemic disease and are largely steroid responsive, whereas PSS effects occur irrespective of systemic disease activity and are largely steroid resistant. The most common disorders are vascular-type headache, aseptic meningitis, psychosis, and convulsions.^{110,111} Ischemic and hemorrhagic cerebrovascular disorders, optic neuritis, cerebellar ataxia, chorea, and transverse myelitis occur less commonly (Video 9, Dysmetria; Video 18, Limb Chorea).^{109,110,112-114}

The PNS is a more frequent target of MCTD than the CNS. In published series, unilateral or bilateral trigeminal neuropathy occurs in about 10% of MCTD patients.^{108,110,115} The maxillary and mandibular branches are usually involved.¹¹⁶ Some patients may have involvement of the motor root with masseter atrophy.^{110,116} Although dysfunction of regional cranial nerves is rare, associations with facial neuropathy have been reported.^{116,117} Vasculitic polyneuropathy has been reported in up to 10% of patients with MCTD.¹¹⁰ There have been rare reports of carpal tunnel syndrome¹¹⁸ and neuromuscular junction dysfunction (Video 217, Anterior Interosseous Neuropathy, Pinch Sign).¹¹⁹ The importance of myositis in MCTD is underscored by its inclusion as a diagnostic criterion in virtually all series of patients.¹⁰¹ Concurrent changes of overlying skin mimic dermatomyositis in some patients.¹⁰⁹

DIFFERENTIAL DIAGNOSIS. The most important distinction is between MCTD and other connective tissue disorders such as PSS, SLE, and polymyositis. This distinction is blurred over time as the disease generally comes to resemble one of these connective tissue diseases.

EVALUATION. The diagnosis of MCTD is made in patients with symptoms and signs of more than one connective tissue disease and the characteristic serological markers. CNS manifestations are evaluated with MRI, which may demonstrate signs of vascular disease. In patients with seizures, EEG shows focal or generalized slowing and often epileptiform activity.¹¹⁰ CSF in patients with headaches or aseptic meningitis may be normal or show a lymphocytic pleocytosis or increased protein. Elevations of serum creatine kinase occur in about half of those with myopathic symptoms. EMG changes may confirm the presence of myopathy, and biopsy may show inflammatory myositis.¹⁰⁹

MANAGEMENT. The treatment of nervous system involvement in MCTD is based on anecdotal data rather than controlled clinical trials. CNS disorders such as headache, aseptic meningitis, psychosis, convulsions, optic neuritis, and transverse myelitis have been reported by various authors to be responsive to corticosteroids,^{109,110} plasmapheresis, or immunosuppressive drugs.¹¹³ Disorders of the PNS, including trigeminal and peripheral neuropathy, are relatively steroid resistant.^{110,116,118} Myositis is believed

to mirror the systemic signs of MCTD and be quite sensitive to corticosteroid therapy.

PROGNOSIS AND FUTURE PERSPECTIVES. The majority of patients with MCTD evolve clinical features typical of another connective tissue disease within 5 years of diagnosis.¹⁰⁰ Long-term follow-up of 194 patients in several series revealed that 13% to 28.2% had died by 13 years' follow-up.^{102,119} More benign prognosis appears to be associated with the presence of Raynaud's phenomenon, less widespread and severe organ system involvement, and HLA-DR2 or DR4.^{119,120}

The most compelling research questions are whether MCTD is a discrete diagnostic entity and what factors predict its evolution into other connective tissue diseases. Better elucidation of environmental triggering antigens and the autoantigen immune target may lead to more effective therapies, particularly for steroid-resistant symptoms.

Sjögren's Syndrome

PATHOGENESIS AND PATHOPHYSIOLOGY. Sjögren's syndrome (SS) is a chronic inflammatory disease of unknown cause characterized by inflammation of the salivary and lacrimal glands and synovial tissues. Involved tissues have infiltrates of lymphocytes and plasma cells. Autoantibodies include RF, ANA (SS-A and SS-B type), and antibodies directed against salivary duct antigens.

EPIDEMIOLOGY AND RISK FACTORS. SS is seen in 0.5% to 2.0% of the population; among the collagen vascular diseases, it is second in prevalence only to RA. Ninety percent of patients are women. Onset usually occurs during middle age.¹⁰⁹ Genetic susceptibility is suggested by an association with HLA-B8, HLA-DR3, HLA-DR2, and HLA-DRw52. SS occurs in isolation in 50% of cases and in the context of RA, SLE, scleroderma, or another connective tissue disease in the remaining patients.¹²¹

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Primary SS predominantly affects exocrine glands, with lymphocytic infiltration and fibrosis of lacrimal and salivary glands. Ocular, oral, and dental complications occur as a result of decreased tear and saliva production.¹²¹ Extraglandular manifestations occur in at least 25% of patients. Lymphadenopathy and hepatosplenomegaly are common. Cutaneous vasculitis may present with a picture of nonthrombocytopenic purpura or urticaria. Symmetrical, nondeforming arthritis of the small joints occurs in more than 80% of patients. Renal disease, usually interstitial nephritis, is seen in up to 40% of cases. Less commonly, the lungs may be involved, with interstitial pneumonitis and restrictive or obstructive abnormalities of pulmonary function. Vasculitis, usually localized to the skin, PNS, and muscle, occurs in up to 20%. Lymphoproliferative disorders occur, and there is an increased risk of lymphoma in these patients.

Although neurological disorders have been thought to be rare manifestations of SS, as many as 25% to 80% of patients have nervous system dysfunction, sometimes in advance of other symptoms.¹²²⁻¹²⁴ CNS complications include mild aseptic meningitis; cognitive, affective, or personality disorders; focal cerebral deficits; and seizure.^{122,123} Optic neuropathy, nystagmus, ataxia, internuclear ophthalmoplegia, and parkinsonism or other movement disorders

have occasionally been reported (Video 14, Tremor with Ataxia; Video 202, Internuclear Ophthalmoplegia).¹²⁵ Spinal cord involvement may take one of three forms: progressive myelopathy, acute transverse myelitis, or intraspinal hemorrhage.¹²²

PNS signs and symptoms occur in 10% to 32% of cases.¹²⁶ Most commonly, there is a sensory or mixed motor-sensory polyneuropathy or entrapment neuropathy (Video 218, Ulnar Neuropathy, Wartenberg Sign). The polyneuropathy may be abrupt or insidious in onset, is often asymmetrical, affects proprioceptive and kinesthetic senses, and causes mild distal motor weakness in the legs. Mononeuritis multiplex occurs somewhat less commonly, and cranial nerve involvement, specifically trigeminal, oculomotor, and abducens nerves, can occur.¹²⁷

DIFFERENTIAL DIAGNOSIS. The diagnosis of primary SS is made in the presence of two of the typical manifestations of xerostomia, xerophthalmia, and arthritis. Illnesses that should be considered in the differential diagnosis are all causes of parotitis, including malignancy, nutritional and endocrine disorders, sarcoidosis, infections, and amyloidosis.

EVALUATION. Xerophthalmia can be demonstrated by Schirmer's test, staining of the corneal and conjunctival epithelium by rose bengal dye, or demonstration of epithelial strands by slit-lamp examination. Xerostomia can be assessed by nuclear scanning of the salivary glands, radiological sialography, or calculation of salivary flow rate. Biopsy of minor salivary glands, found on the inner aspect of the lower lip, is well tolerated and diagnostic when lymphocytic aggregation is demonstrated. Anemia, leukopenia, and elevated ESR are common. Hypergammaglobulinemia and positive RF are common but not specific for the diagnosis. SS-B antibodies are relatively specific for primary SS. SS-A antibodies are seen in primary SS and SS associated with SLE. Half of SS patients have antibodies against salivary duct antigens.

The EEG is abnormal in nearly 50% of patients with CNS dysfunction, but the findings are nonspecific. CT and MRI scans usually show focal regions of abnormality in patients with clinical evidence of focal disease. Electrophysiological studies are consistent with demyelination, denervation, or both. CSF may be normal or may show pleocytosis and elevated protein. CSF is characterized by protein elevation and evidence of intrathecal immunoglobulin synthesis, with increased IgG and oligoclonal bands.¹²² Pathological studies are limited, but perivascular inflammation and diffuse vasculitis involving the cerebral blood vessels, as well as acute necrotizing arteritis of the spinal cord, have been described.¹²⁶ Peripheral nerve tissue shows demyelination and acute or chronic vasculitis or perivasculitis.¹²⁷ Dorsal root ganglionitis, with lymphocytic infiltration and degeneration of ganglion cells, has also been reported to accompany subacute sensory neuronopathy, which is a rare complication of SS.¹²⁸

MANAGEMENT. Ocular and oral symptoms are managed conservatively, with artificial tears and saliva and good oral hygiene. Corticosteroids may be needed to control arthritis and symptoms related to vasculitis.

PROGNOSIS AND FUTURE PERSPECTIVES. Primary SS is generally compatible with prolonged survival. A small number of patients develop more serious disease

manifestations, including primary biliary cirrhosis, renal disease, chronic active hepatitis, pancreatitis, visceral lymphocytic infiltration, lymphoma, immunoblastic sarcoma, or Waldenström's macroglobulinemia. Future research should focus on the etiopathogenesis of the disorder in order to increase understanding of the cause and potential treatments.

OTHER AUTOIMMUNE CONDITIONS

Myasthenia Gravis

PATHOGENESIS AND PATHOPHYSIOLOGY. Myasthenia gravis (MG), although described for many years, was first associated with decreased numbers of muscle acetylcholine receptors about 25 years ago. Since then, the identification of anti-acetylcholine receptor antibodies (AChR-ab), the development of an animal model of the disease, and an overall improved knowledge of immune mechanisms have led to a very precise understanding of the pathophysiology of MG.¹²⁹

The immune effector cells in MG are both T and B cells. Although the key to acetylcholine receptor damage is through the AChR-ab, sensitized T cells and complement play a role in the continued stimulation of B cells and in cell-mediated postsynaptic destruction at the neuromuscular junction.¹³⁰ The histological hallmarks of MG include decreased numbers of acetylcholine receptors, simplification of the postsynaptic clefts, and widening of the synaptic space with a normal presynaptic nerve terminal.¹²⁹

The thymus is unequivocally involved in the pathogenesis of the disease, and its surgical removal often is associated with improvement in disease severity.¹³⁰ Thymic abnormalities are either hyperplastic or neoplastic. Hyperplasia is associated with areas of germinal centers that may enlarge the gland beyond the normal size for age. Neoplasms occur in about 12% of patients and are usually locally invasive epithelial cell tumors (thymomas or rarely carcinomas).^{129,130}

In addition to immune activation against acetylcholine receptors, there is functional blockade of postsynaptic receptors, which can in part explain the response to acetylcholinesterase inhibitors and the relatively quick response to therapies that reduce the number of AChR-ab.¹²⁹

EPIDEMIOLOGY AND RISK FACTORS. MG can occur throughout life, with a bimodal peak of incidence in younger women (second and third decades) and older men (fifth and sixth decades).¹³⁰ Overall, MG has a prevalence of 1 in 25,000 in the United States. There are cases of overlap of MG with other autoimmune diseases and case reports of families with various autoimmune conditions including MG. This suggests a partial genetic predisposition.¹²⁹

CLINICAL FEATURES AND ASSOCIATED DISORDERS. The typical features of MG are fatigability and weakness of skeletal muscles without reflex, sensory, or coordination abnormalities (Video 42, Fatiguability). Many cases begin with involvement of ocular muscles such as diplopia and ptosis. Weakness may remain confined to ocular muscles for long periods or involve bulbar muscles, which control chewing, swallowing, and articulation. The disorder remains confined to ocular muscles in up to 15%

of patients but becomes generalized in the majority (Video 225, Myasthenia Gravis). Examination of neck extensors and flexors is often more sensitive in demonstrating generalized disease than the motor examination of other muscle groups. Under periods of physical stress, such as infection or surgery, a precipitous worsening may occur, and failure of respiratory muscles can be life-threatening. Classification of disease severity is usually assessed according to a scale devised by Osserman: grade I is ocular disease only, grade II is generalized weakness of mild (IIa) or moderate (IIb) intensity, grade III is severe generalized disease, and grade IV is myasthenic "crisis" with respiratory failure.¹²⁹

Transient neonatal MG can occur from passive transfer of maternal AChR-ab causing a myasthenic syndrome that may require ventilatory assistance.¹²⁹ These symptoms typically resolve in under 2 weeks, with routine clearance of antibodies from the neonate's circulation.

DIFFERENTIAL DIAGNOSIS. A number of disorders may mimic MG and include other disorders of neuromuscular transmission, metabolic or toxic syndromes, and neurogenic weakness. Botulism and Lambert-Eaton myasthenic syndrome (LEMS) can cause ophthalmoplegia and fatigue. Botulism affects cranial nerves early, affects the pupillary light response, and shows an incremental response on repetitive nerve stimulation. Botulinum toxin may be detectable in the stools. LEMS is often associated with a small-cell carcinoma of the lung, dry mouth and eyes, and more distal weakness that may improve with exercise. The presence of voltage-gated calcium channel antibodies in the serum and a dramatic increase in compound motor potentials on postexercise repetitive nerve stimulation are confirmatory objective signs.¹²⁹ The congenital myasthenic syndromes appear as MG but are not autoimmune in nature.¹³⁰

Certain drugs, including penicillamine, curare, aminoglycosides, quinine, procainamide, and calcium channel blockers, may cause a myasthenia-like syndrome or exacerbate weakness in MG patients. Hyperthyroidism, or Graves' disease, may cause generalized fatigue or worsen MG and is detectable by abnormal thyroid function tests. Cranial nerve abnormalities may cause symptoms that mimic MG.¹²⁹

EVALUATION. Timed endurance tasks such as prolonged upgaze, holding outstretched arms in abduction, or vital capacities at every visit are often helpful in providing objective information about fatigability.¹²⁹ Laboratory tests useful in excluding other diagnoses include thyroid function tests, antithyroid antibody, ANA, voltage-gated calcium channel antibodies, and chest x-ray.

Improvement of weakness after edrophonium chloride (Tensilon) injection is a useful sign, although false-negative and false-positive tests do occur (Video 226, Myasthenia Gravis: Edrophonium).¹³¹ The test is performed by first fatiguing the patient with a task that includes signs that can be easily clinically assessed (ptosis, vital capacity, slurred speech). The diagnostic test is then performed by injection of 1 mg as a test dose, then injecting 9 mg intravenously with attention to the fatigued muscles. A rapid improvement or recovery of the fatigued muscles (resolved ptosis, normalized vital capacity, clear and strong voice) over the subsequent 2 minutes is a positive test. If ptosis

is present, the “ice pack test” may be diagnostic. Local cooling improves the safety factor of neuromuscular junctions, possibly by slowing the kinetics of acetylcholinesterase (Video 86, Ice Pack Test in Myasthenia Gravis). In a prospective series, 80% of MG patients responded after 2 minutes of ice pack application to the affected eye, and the nonresponders with MG had complete ptosis. Ptosis due to other etiologies did not respond.¹³² This test is easier to administer in a clinic setting than edrophonium chloride and does not require cardiac monitoring.

In recent years, the detection of AChR-ab in the serum, using a commercially available immunoprecipitation test, has significantly changed the evaluation of MG patients. The sensitivity of AChR-ab in ocular myasthenia is 70% and in generalized disease is 80%.¹³¹ In addition to AChR-ab binding antibodies, antibodies that block or modulate acetylcholine receptors have been described. The Ach-modulating antibodies cross-link acetylcholine receptors and are often present in patients with thymoma. Furthermore, in patients that are AChR-ab negative, 3% to 4% possess the modulating antibodies and are worth evaluating for their presence. Striated muscle antibodies, are present in about 30% of all patients with MG and when present are strongly associated with thymoma. Of most recent importance are muscle-specific receptor tyrosine kinase antibodies (anti-MuSK). Patients with these antibodies may present with atypical features for MG such as prominent bulbar, facial, shoulder girdle, or respiratory weakness without significant ocular weakness. Patients with these atypical features should be evaluated for these antibodies, especially in AChR-binding ab negative individuals.¹³³

Repetitive nerve stimulation may demonstrate a reduction of the compound muscle action potential, potentiated after 1 minute of exercise, consistent with a postsynaptic transmission defect. For patient comfort, the test should first be performed on a distal muscle; negative studies on distal muscles should prompt more extensive study of proximal muscles. Clinically weak muscles are more likely to demonstrate the decremental response. The sensitivity of repetitive nerve stimulation is about 75%. It may be normal in ocular MG but is virtually always abnormal in generalized MG.¹³¹

The demonstration of increased “jitter” by single-fiber EMG is the most sensitive test for MG. The sensitivity ranges from 80% in ocular MG to virtually 100% in moderate generalized MG. In 9% of MG cases, this is the only abnormal test.¹³¹ Using AChR-ab, repetitive stimulation and single-fiber EMG identifies all MG cases.^{131,134}

CT scanning or MRI of the chest should be done in all patients to screen for the presence of thymoma or thymic hyperplasia. Thymic enlargement or detectable thymic tissue in a patient over age 40 raises the suspicion of thymoma.¹²⁹ Chest imaging is also indicated in patients who have had thymectomy but are experiencing unexplained worsening of MG symptoms. Residual thymic tissue may be found in some of these patients.

MANAGEMENT. Acetylcholinesterase inhibitors (mainly pyridostigmine) inhibit the enzymatic elimination of acetylcholine, increasing its concentration at the postsynaptic membrane. They play a supporting role in the management of symptoms throughout the disease course but do not affect the primary immune mechanism of the disease.¹³⁰

Cholinergic toxicity causing transient weakness can result from overuse of pyridostigmine and can be difficult to distinguish from the weakness of MG. MG is rarely controlled by symptomatic treatment alone, and immunomodulating therapy is often required.

There is general consensus that thymectomy is helpful in the treatment of MG; however, a randomized controlled study has never been done.¹²⁹ With thymoma, there is a clear role for thymectomy. For nonthymomatous MG, thymectomy may increase the likelihood of disease remission or improvement.¹³⁵ Typically, patients with generalized MG (Osserman stage 2b or worse) are selected for thymectomy. Thymectomy for ocular MG (Osserman stage 1) has been supported by nonrandomized, uncontrolled data but remains a controversial issue.¹³⁶ The beneficial effects of thymectomy usually occur in the first year but may be seen as late as 5 years from the time of surgery.¹³⁰ Thymectomy is never an urgent procedure but can be done on optimally stabilized patients and in centers with experience in managing the perioperative course of MG patients. The transsternal approach is preferred because it allows for direct visualization and complete removal of the thymus and adipose tissue of the anterior mediastinum. In contrast, the transcervical approach by indirect mediastinoscopy is associated with a higher occurrence of residual thymus tissue, although this method is cosmetically more appealing.^{129,130} Controlled comparison of these two approaches has not demonstrated superiority of one over the other.¹³⁵

Corticosteroids have been the mainstay of immunotherapy for MG. Seventy percent to 80% of patients have complete remission of their disease within weeks to months of adequate doses of prednisone.¹³⁰ The starting dose is dependent upon the severity of symptoms, but most patients require 40 to 60 mg/day. Alternate-day dosing is encouraged to lessen adverse side effects and should be tapered to the lowest effective dose.¹²⁹

Cytotoxic therapies are useful in MG and should be considered in patients who are not able to achieve sufficiently low doses of prednisone or who are having significant steroid side effects. Azathioprine 2 to 3 mg/kg/day is effective in a number of patients as an adjunct to prednisone, and its use allows lowering of the total dose of the prednisone to more tolerable levels. Some patients respond well enough to discontinue the prednisone.¹³⁰ Cyclosporine is a more effective and more toxic immunosuppressive agent. The typical dose is 5 mg/kg/day. Improvement occurs in the first several months of therapy.¹²⁹ Nephrotoxicity, hypertension, neutropenia, and remote risk of leukemia are potential complications of therapy, and blood levels need to be monitored to reduce the incidence of these toxic side effects.¹³⁰ Mycophenolate mofetil is a novel immunosuppressant that blocks purine synthesis in T- and B-cell lymphocytes, selectively inhibiting proliferation. It is relatively well tolerated with less frequent but similar side effects as other cytotoxic therapies. Dosage is 1 g given twice daily. Initial studies have shown efficacy in MG with a relatively short time to therapeutic benefit (2 weeks to 2 months), and larger studies are ongoing.^{137,138}

Plasma exchange and intravenous pooled immune globulin are effective short-term treatments for MG. For the treatment of MG crisis or before thymectomy, five courses of plasma exchange, given on alternate days, cause rapid

improvement that lasts for several weeks. Venous access, a mild increased risk of infection, hypotension during exchanges, deep venous thrombosis, and cost are drawbacks to this treatment.¹²⁹ There is preliminary evidence to support the use of pooled IVIG in the treatment of MG. Like plasma exchange, the treatment is given over a few days (0.4 g/kg/day for 5 days) and the effect is relatively short-lived, lasting a few weeks.¹³⁰

PROGNOSIS AND FUTURE PERSPECTIVES. Before 1958, approximately one third of MG patients died, one third failed to improve, and one third improved spontaneously. Currently, the mortality rate due to MG is essentially zero, and most patients lead normal lives. Lifelong immunomodulating therapy is often required.¹²⁹

Novel approaches for potential treatment of MG are increasing with advancing knowledge of the immune system. Targeting specific T cells and B cells, which are “programmed” to mediate anti-acetylcholine receptor activity, is the focus of recent experimental work. Such therapy would tightly target the effector arm of the immune system. This strategy is limited by evidence that T cells have a number of targets and lack of knowledge of which T cells are relevant to the pathogenesis of MG. Animal models suggest that the nonselective removal of the T helper cells may also be beneficial. Lastly, there is renewed interest in inducing tolerance to self-antigens by ingesting them. Oral ingestion of anti-acetylcholine receptor antibodies has been found to prevent the disease in rat models of MG.¹²⁹ New insights generated by this work will lead to safer and more effective therapies.

Dermatomyositis and Polymyositis

PATHOGENESIS AND PATHOPHYSIOLOGY. Dermatomyositis (DM) and polymyositis (PM) have been thought to have an autoimmune origin for many years. This concept is based on indirect associations with other autoimmune disorders, mononuclear inflammatory cells in affected muscles, and responsiveness to immunosuppressive agents. Genetic factors play a role, as evidenced by reports of identical twins with DM, families with other connective tissue diseases and DM or PM, and increased associations with HLA-DR3. Without convincing evidence of support, it has been hypothesized that these inflammatory myositides are the result of a viral infection.

In DM, several observations suggest that circulating immune complexes or antibodies induce vascular injury. Intramuscular blood vessels show endothelial hyperplasia with tubuloreticular profiles, fibrin thrombi, and obliteration of capillaries. Even in cases where light microscopy is normal, electron microscopy reveals microtubular inclusions and vacuoles in the lining of endomesial capillaries, suggesting that the capillary lining may be the target of the immune response. Perifascicular atrophy results from ischemic changes secondary to the endomesial vasculopathy. Similar changes occur in skin vasculature leading to the rash, which is often part of the DM syndrome.

In PM, there is strong histochemical evidence for cell-mediated immune mechanisms in the pathogenesis. The inflammatory exudate is predominantly CD8⁺ T cells within the endomysium. These exudates are seen in muscle cells undergoing necrosis and phagocytosis. Further evidence

suggests that these T cells (and monocytes) are a few distinct clones (i.e., oligoclonal) and are not simply nonspecific inflammatory effectors.

EPIDEMIOLOGY AND RISK FACTORS. Both of these syndromes affect women slightly more than men. PM typically occurs after age 20 years and rarely in childhood, whereas DM affects both children and adults. The incidence of the inflammatory myopathies is less than 1 in 100,000 population. Although the adult cases of PM and DM present in the fifth and sixth decades of life, the majority of cases of DM have childhood onset with typical age of 5 to 14 years.

The risk of cancer in association with adult PM or DM ranges from 6% to 45% in DM and 0% to 28% in PM. A population-based retrospective study in 788 DM patients and 396 PM patients over 20 years reported the rate of cancer occurrence to be 9% in the PM group and 15% in the DM group. The majority of these cancers were within 5 years of the diagnosis of the myopathy. In PM, the relative risk of malignancy was 1.7 for women and 1.8 for men, with the most common site of malignancy in men being the lung (relative risk, 5.6). In DM, the relative risk for malignancy was 2.4 in men and 3.4 in women, with the ovary most often affected (relative risk, 16.7).¹³⁹ Patients with associated malignancy have a higher than average age of DM or PM onset.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Childhood DM is a relatively uniform disorder usually characterized by erythematous rash and skin lesions and coincidental muscle weakness. This photosensitive rash usually begins as periorbital heliotrope (blue-purple) discoloration with subsequent erythematous involvement of extensor surfaces of the limbs and joints. The anterior neck and chest rash may form a “V” sign or rash over the shoulders in a “shawl” sign. The proximal muscles of the limbs are more affected than distal ones, the abductors of the leg affected more than the adductors, and the extensors more than the flexors. Ectopic calcifications are present in subcutaneous tissues and muscle in about half of the cases. Associated complications include hemorrhagic gastrointestinal vasculitis and pulmonary fibrosis.

Adult DM shares the same skin features with childhood DM and often helps secure a clinical diagnosis. On occasion the skin manifestations are subtle or absent and the diagnosis of DM over PM relies on the muscle biopsy appearance.

The clinical features of muscle involvement are similar in DM and PM. Muscle pain and tenderness are common and usually more prominent in the arms. Onset of symptoms is subacute or insidious. As the disease progresses, dysphagia and neck flexor weakness begin. Respiratory muscles are impaired in severe cases and result in a restrictive pulmonary defect. In addition, pulmonary interstitial fibrosis may appear as a complication of the disease and may even precede the muscle weakness. There is an increased frequency of electrocardiographic abnormalities (dysrhythmias, heart block, etc.), and occasionally patients may have pericarditis as part of their syndrome.

A number of other related conditions may have myositis as a feature and are considered to be “overlap” syndromes when the diagnostic criteria for both conditions are fulfilled. These are other autoimmune diseases such as PSS, SS, SLE, RA, and MCTD.

DIFFERENTIAL DIAGNOSIS. The main clinical differentiation to be made is between DM/PM and other acquired myopathies or inflammatory diseases. The rash of DM limits the potential diagnoses to the overlap syndromes. The diagnosis of PM is one of exclusion. Inclusion body myositis may appear similar to PM, and the serum creatinine phosphokinase (CK) is elevated although typically not to the same extent. Endocrinopathies such as hyperthyroidism and Cushing's syndrome can behave similarly. Toxic exposures and drugs that induce myopathy should be sought as potential etiologies. Additionally, inherited neuromuscular or metabolic disease may have a similar appearance. Serological testing and muscle biopsy should resolve the differences in most cases.

EVALUATION. In a patient with a possible inflammatory myopathy, the diagnosis is strengthened or confirmed by serum CK, EMG, and most important, muscle biopsy to help exclude overlap syndromes. ESR is neither a sensitive nor a specific indicator of PM or DM but does correlate in general with inflammatory diseases. Testing for autoantibodies such as ANA and anti-Sm (SLE), SS-A and SS-B (Sjögren's), PM-Scl and anti-Ku (scleroderma), anticentromere (CREST syndrome), and anti-U1 snRNP (MCTD and SLE) may be useful in considering the overlap syndromes.

Serum CK is the most sensitive muscle enzyme for the detection of destruction of muscle cells. Typically, tenfold elevations can be seen; however, it is possible to have normal levels even during active disease. There are elevations of both muscle and brain isoenzyme forms of CK, reflecting both necrosis and new fiber regeneration. The CK is often used for a marker of disease activity.

Certain autoantibodies are associated with the inflammatory myopathies. Of these autoantibodies (such as anti-rNRP, PM-Scl, and antisynthetases), the anti-Jo-1 is the most useful because 75% of patients with anti-Jo-1 have interstitial lung disease.

Electrodiagnostic studies are helpful to evaluate clinically weak muscles for evidence of a myopathic pattern of activity and to exclude a neurogenic component. Muscle biopsy is the gold standard in the diagnosis of inflammatory myopathies and to exclude other neuromuscular diseases. Histopathological evaluation is the mainstay of diagnosis of these conditions. Treatment of the condition, however, should not be delayed while awaiting the histopathologic results.

MANAGEMENT. Immunosuppressive therapy is the mainstay of treatment. Prednisone is the agent of choice for DM and PM, and treatment should begin with 80 to 100 mg/day (or 1 mg/kg/day) given in a single morning dose. This dose should be maintained for 3 to 4 weeks. If a clinical response has occurred, then tapering of the dose on every other day (by 5 to 10 mg every 3 to 4 weeks) should take place with an eventual goal of 80 to 100 mg every other day. This dose can then be tapered slowly over a period of months. The inability to taper the prednisone without disease reactivation or a lack of clinical response suggests the need for another agent. Corticosteroids may cause a clinical worsening secondary to steroid myopathy. Worsening in the absence of CK elevation and absence of neck flexor weakness may point to steroid myopathy in treated patients with inflammatory myopathy.

Azathioprine is most helpful in combination with corticosteroids and has a steroid-sparing effect. The recommended dose is approximately 2 mg/kg/day, and side effects may include gastrointestinal upset, a flulike syndrome, hepatotoxicity, and bone marrow suppression. A several-month delay in effectiveness is common and should be expected. Azathioprine can be used alone but is probably not as effective.

Methotrexate, cyclophosphamide, and cyclosporine A are agents that also may be useful in the treatment of DM or PM. These agents have associated potential toxicities to bone marrow, to liver, and during pregnancy. The effectiveness of these agents is not well studied, but they may be promising, particularly in patients who are not responding to prednisone, azathioprine, or both.¹⁴⁰ A randomized evaluation of methotrexate versus cyclosporine A in steroid nonresponders demonstrated clinical improvement in both groups without superiority of one therapy.¹⁴¹ Mycophenolate mofetil may also be useful but has not been well studied at this time. In a small series, clinical response occurred in patients who had not responded to the combination of prednisone and methotrexate or prednisone and IVIG.¹⁴²

IVIG is an expensive, relatively safe, and promising treatment for DM and PM. The dose is 2 g/kg, divided over 2 to 5 days initially, then 0.4 g/kg given at intervals based upon the clinical response. The exact mechanism of action is not clear but is felt to affect circulating autoantibodies, the autoimmune target, or complement activation. Side effects include increased serum viscosity with potentiation of thromboembolic events, aseptic meningitis, rash, anaphylaxis in IgA-deficient individuals, and a low risk of transmissible diseases such as hepatitis C. Many patients who have failed other treatments may respond to IVIG. Plasmapheresis has been shown ineffective in a controlled clinical trial.

PROGNOSIS AND FUTURE PERSPECTIVES. Childhood DM has a variable prognosis. Some cases may have complete reversal of signs and symptoms after months, but 7% of cases have a fatal condition. The disease may recur, even after prolonged remission. Overall, the prognosis for DM and PM is relatively favorable with 10-year survival rates as high as 90%. Patients with interstitial lung disease have a mortality rate that approaches 40% at 3 years. Other factors that adversely affect prognosis include advanced age at onset, acute onset, involvement of respiratory muscles, dysphagia, fever, and inadequate therapy.

Potential avenues for treatment include more specific immunotherapies. Proteins that could bind the antigenic targets and interfere with recognition by auto-directed T cells or products that mimic the antigenic target are possible new avenues of treatment.

Eosinophilic Myositis and Related Syndromes

PATHOGENESIS AND PATHOPHYSIOLOGY. True eosinophilic myositis occurs in the setting of a subacute or chronic unexplained peripheral blood eosinophilia. Patients with hypereosinophilia may be asymptomatic or may have end-organ damage, including myositis. The skeletal muscle

in such patients resembles polymyositis with an eosinophil-predominant infiltrate.¹⁴³

Eosinophilic fasciitis is likely a separate condition with eosinophilia, elevated ESR, and hypergammaglobulinemia. Clinically, these patients present with taut skin and flexion contractures secondary to intense diffuse fasciitis. Pathologically eosinophilic inflammation of the fascia extends into adjacent muscle, but there is no primary muscle involvement.¹⁴³

Eosinophilia-myalgia syndrome (EMS) is a more recently described condition. A number of patients developed peripheral eosinophilia, fatigue, and myalgia associated with the chronic ingestion of L-tryptophan. Biopsies demonstrate inflammatory infiltrates of small and medium-sized vessels and connective tissues consisting of various cell types (histiocytes, CD4⁺ and CD8⁺ lymphocytes, and mast cells) but few, if any, eosinophils. An autoimmune disorder or idiosyncratic response is suspected.¹⁴³ Since the withdrawal of L-tryptophan from the market, the number of cases reported has dramatically dropped.¹⁴⁴ It is likely that the vehicle, not L-tryptophan, was the responsible agent. The toxic oil syndrome, which was the result of a toxic contaminant in the production of rapeseed oil in Spain, is nearly an identical syndrome with identical pathology as EMS.¹⁴³

EPIDEMIOLOGY AND RISK FACTORS. The number of cases of eosinophilic myositis is small. The syndrome is associated with the systemic hypereosinophilic syndromes almost as a rule. With eosinophilic fasciitis, men 30 to 60 years of age are more often affected, and about half have a history of intense exertion prior to the onset.

In a study of 205 patients with EMS associated with L-tryptophan ingestion, 79% were women and almost all were white.¹⁴⁵ The EMS from L-tryptophan ingestion was associated with contamination by 1,1'-ethylidenebis tryptophan and 3-phenylamino alanine. The doses taken in the EMS patients were generally higher than the at-risk patients who did not develop the syndrome. One of the toxic contaminants in rapeseed oil was 3-phenylamino-1,2-propanediol, an alanine derivative similar to the 3-phenylamino alanine in the EMS outbreak.¹⁴³

CLINICAL FEATURES AND ASSOCIATED DISORDERS. The systemic syndrome associated with eosinophilic myositis involves other organs such as lungs, heart, and skin. There may be heart block, dysrhythmias, and pulmonary infiltrates, resulting in death. Esophageal motility can be affected in some patients. Proximal muscle weakness and elevated CK, suggestive of myositis, may be accompanied by signs of neuropathy.¹⁴³

Diffuse fasciitis presents acutely, usually after a short prodromal period with low-grade fever, myalgias, and fatigue. Thickening of the subcutaneous tissues ensues, sparing the face, with pitting edema of involved areas. Over the next weeks there may be limitations of movement of the small joints and to a lesser degree of large joints. Proximal and distal muscle weakness has been described in a few patients. Spontaneous remissions are common, and a rapid response to treatment is a rule.¹⁴³

EMS begins insidiously, with severe fatigue and myalgias. Low-grade fever, transient maculopapular rash, muscle pains, and cramps and weakness of the extremities with or without paresthesias may all be part of the

syndrome. The features of the syndrome in a given patient will vary depending on whether fasciitis, myositis, peripheral neuropathy, or mixed features predominate.¹⁴³ There are some vague reports of an acute encephalopathy at presentation.¹⁴⁴ Cognitive changes have been described 1 to 23 months after the acute syndrome. Objective neurocognitive changes were present in almost two thirds of those with subjective complaints of mental difficulties. Affected were verbal and visual memory, conceptual reasoning, and motor speed. No risk factors for the development of cognitive changes have been identified, and the pathogenesis of these changes remains unknown. Proposed mechanisms include a direct toxic effect, eosinophil-derived neurotoxin or major basic protein, and effects of cytokines.¹⁴⁴

DIFFERENTIAL DIAGNOSIS. Other conditions usually considered with this group of diseases are other autoimmune or inflammatory states such as polyarteritis nodosa, RA, allergic granulomatosis, hypersensitivity vasculitis, scleroderma, or parasitic infections. History, organ involvement, serological studies, and tissue biopsy may be necessary to distinguish among these conditions.

EVALUATION. In eosinophilic myositis, the severity of peripheral blood eosinophilia is helpful in terms of diagnosis and reflects the severity of tissue eosinophilic inflammation. RF may be present, a feature that does not occur with eosinophilic fasciitis or EMS. ESR is often moderately elevated in all of these states. Serum CK, EMG, and muscle biopsy aid in the diagnosis of eosinophilic myositis. The serum CK is often elevated with true myositis, but may be normal in eosinophilic fasciitis. In EMS and in toxic oil syndrome, the CK is normal or only slightly elevated.¹⁴⁵

The EMG reveals a myopathic pattern with eosinophilic myositis. There have been reports of myopathic changes in EMS and eosinophilic fasciitis, but this is less common. When peripheral neuropathy is associated with eosinophilic myositis, EMG may demonstrate axonal or demyelinating lesions.¹⁴³

In EMS, one should be aware of potential signs of cognitive dysfunction and differentiate them from fatigue or depression. If there is a question of an encephalopathy, neuropsychological testing is recommended with follow-up assessments. The cognitive changes in EMS may begin or progress while other symptoms and signs of the syndrome are improving.¹⁴⁴

MANAGEMENT. Treatment of eosinophilic myositis is initiated with high-dose prednisone at 1 mg/kg/day. With control of the symptoms and peripheral blood eosinophilia, gradual reduction of dose on an alternate-day regimen can be initiated. Cytotoxic agents may be of benefit if steroid doses remain high or if it is mandatory to reduce the steroid dose because of side effects. Improvement of survival has resulted.¹⁴³

Eosinophilic fasciitis often will improve spontaneously, but resolution is faster with corticosteroid treatment. Relapses are infrequent. Although the treatment and resolution are in most cases good, the acute phase of the illness can be complicated by aplastic anemia, and either a megakaryocytic or idiopathic thrombocytopenia. Delayed lymphoproliferative disorders have also occurred.¹⁴³

There are no specific recommendations on the treatment of EMS other than cessation of the inducing agent.

Corticosteroids may induce clinical improvement and remission of eosinophilia. The drugs should be tapered after clinical benefit is maintained. Beneficial responses to other medications have been reported, but the number of patients is too small to draw significant conclusions.¹⁴⁵

PROGNOSIS AND FUTURE PERSPECTIVES. In a 1982 study of 57 patients with hypereosinophilic syndromes, the average survival was 9 months, with 12% of patients surviving 3 years. Eosinophilic fasciitis has a good prognosis with spontaneous recovery or response to corticosteroids in most patients. Occasional patients develop recurrence of fasciitis or secondary myeloproliferative disorder.¹⁴³ In a follow-up of over 200 patients with EMS, at 18 to 24 months, almost all of the symptoms and signs of the syndrome had improved or resolved completely. Neurocognitive deficits and peripheral neuropathy are less likely to respond to therapy.¹⁴⁵

With the exception of EMS, the pathogenesis of these syndromes is unclear, and directing more specific therapies is difficult. The hypereosinophilic syndromes in particular are associated with high morbidity and mortality rates despite treatment with nonspecific immunosuppression. The identification of the driving force behind these inflammatory states will likely lead to novel approaches to influence the effects of these diseases, probably at the level of the cytokines and their regulatory effects.

Inclusion Body Myositis

PATHOGENESIS AND PATHOPHYSIOLOGY. The specific hallmarks of inclusion body myositis (IBM) are inflammation, vacuolated muscle fibers, intracellular amyloid deposits, and 15- to 18-nm tubulofilamentous inclusions. Although there are familial forms of this disease, either autosomal dominant or recessive, inflammation is only rarely seen in those cases,¹⁴⁶ and, therefore, the familial forms are best referred to as inclusion body myopathies.

The inflammatory cells that are present in affected muscle are mostly CD8⁺ lymphocytes or macrophages expressing MHC-II surface markers. These findings suggest a directed response against specific antigens and a role of immune-mediated cytotoxicity. In addition, there are changes in the mitochondria and the nuclei of the myofibers, amyloid protein, and abnormally present filaments that suggest a possible "neurodegenerative" pathogenic mechanism. It is also suggested that the expression of an abnormal gene product may lead to a cytodestructive process and help explain the inflammatory and neurodegenerative evidence.¹⁴⁶

EPIDEMIOLOGY AND RISK FACTORS. IBM is the most common inflammatory muscle disease occurring over the age of 50.¹⁴⁷ Patients are older than 30 years of age and usually older than 50 at the time of onset of symptoms. Men are more often affected than women, in contrast with other autoimmune and inflammatory diseases.¹⁴⁸ There are no known risk factors other than genetic risk in those families with a history of IBM.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. The clinical weakness of IBM may resemble that of PM or DM but more typically evolves over years and resembles a limb-girdle dystrophy. Distal weakness is common, and dysphagia occurs in as many as 60% of patients. The weakness and atrophy may be asymmetrical and involve solitary muscles such as the quadriceps, iliopsoas,

biceps, or triceps. Over years, there is more symmetry and weakness of the involved muscles. IBM is suspected when a patient with the diagnosis of PM does not respond to corticosteroid therapy, has early involvement of distal muscles such as long-finger flexors of the hand and wrist and extensors of the foot, or has dysphagia.¹⁴⁷ Unlike other inflammatory myopathies, patients with IBM do not have an increased risk of malignancy.

DIFFERENTIAL DIAGNOSIS. As alluded to previously, the other diagnoses to consider in these patients are PM, DM, or a myositis as the result of another systemic illness. With an earlier and gradually progressive onset, there may be features in common with limb-girdle muscular dystrophy. If there is focal atrophy or weakness, the possibility of a mononeuropathy or plexopathy should be considered. These can be differentiated with electrodiagnostic testing. The lack of respiratory involvement, EMG features, and slow course differentiate IBM from motor neuron disease. However, atypical presentations without the classical features can lead to diagnostic uncertainty. Muscle biopsy and quantitative EMG can often clarify these cases.¹⁴⁹

EVALUATION. As in DM and PM, the diagnosis of IBM relies on the assessment of CK, EMG, and most important, muscle biopsy. Suggested diagnostic criteria are listed in Table 50-8. CK levels are often mildly elevated but should

TABLE 50-8

Characteristic Features and Diagnostic Criteria for Inclusion Body Myositis

Characteristic Features

Clinical

- Duration of illness > 6 months
- Age of onset > 30 years old
- Weakness of proximal and distal arm and leg muscles; must include at least one of the following features:
 - Finger flexor weakness
 - Wrist flexor > wrist extensor weakness
 - Quadriceps muscle weakness (\leq grade 4 MRC)

Laboratory

- Serum creatine kinase < 12 times normal
- Muscle biopsy:
 - Inflammatory myopathy characterized by mononuclear cell invasion of non-necrotic muscle fibers
 - Vacuolated muscle fibers
 - Intracellular amyloid deposits or 15- to 18-nm tubulofilaments by electron microscopy
 - Electromyography consistent with inflammatory myopathy

Diagnostic Criteria

Definite inclusion body myositis

- Patients must exhibit all of the muscle biopsy features including invasion of non-necrotic fibers by mononuclear cells, vacuolated muscle fibers, and intracellular (within muscle fibers) amyloid deposits or 15- to 18-nm tubulofilaments
- None of the other clinical or laboratory features are mandatory if the muscle biopsy features are diagnostic

Possible inclusion body myositis

- If the muscle shows only inflammation (invasion of non-necrotic muscle fibers by mononuclear cells) *without* other pathological features of inclusion body myositis, *then* a diagnosis of possible inclusion body myositis can be given if the patient exhibits the characteristic clinical and laboratory features

MRC, Medical Research Council.

Modified from Griggs RC, Askanas V, DiMauro S, et al: Inclusion body myositis with IVIg: A double-blind, placebo-controlled study [see comments]. *Neurology* 1997;48:712-716.

be less than 12 times normal.¹⁴⁶ EMG may show fibrillation potentials, positive sharp waves, complex repetitive discharges, and a mixture of myopathic, normal, and neurogenic motor units. These findings are not specific to the diagnosis of IBM, though short- and long-duration polyphasic potentials may be more prominent in IBM than other myopathies. Conventional EMG may not demonstrate myopathic motor units and can lead to misdiagnosis, especially if “neurogenic” spontaneous activity is seen. Quantitative EMG, particularly of single motor unit potentials, can be useful in identifying the motor units as myopathic in these circumstances.¹⁴⁹

Muscle biopsy alone can make the diagnosis of IBM but may not always show the typical pathological features of the disease, even in patients with clinically typical presentations. Additional sections, additional stains (i.e., Congo red to assess for amyloid deposits), or another biopsy may increase this yield.¹⁴⁶

MANAGEMENT. IBM is generally resistant to all therapies, but a trial of corticosteroids and one aggressive immunosuppressive agent is probably reasonable. This has been the traditional view, although corticosteroids do not appear to be of any benefit and may actually worsen strength despite lowering of CK.¹⁵⁰ Although initial reports suggested IVIG was useful in IBM, subsequent studies, including one with placebo control, have shown response in only about one third of patients.^{146,147} A controlled study of IVIG plus prednisone versus IVIG plus placebo demonstrated no difference between the groups and no improvement in strength.¹⁵¹ A randomized pilot study of interferon- β 1a did not show benefit after 6 months of therapy.¹⁵² Supportive care, bracing, rehabilitative strategies and limitation of corticosteroid use are generally recommended.¹⁵⁰

PROGNOSIS AND FUTURE PERSPECTIVES. IBM is typically a slowly progressive disease and may even stabilize for periods of time. Further studies with currently available or novel therapies may require larger numbers of patients and a longer duration of treatment to demonstrate a pattern of benefit or predict which subset of patients may respond. A better understanding of the etiological mechanisms of the unusual constellation of pathological findings will likely tailor new approaches to treatment.

Behçet's Disease

PATHOGENESIS AND PATHOPHYSIOLOGY. In 1937, Hulusi Behçet (1889–1948), a Turkish dermatologist, described the syndrome that bears his name. Behçet's disease (BD) is a relapsing inflammatory disorder without a defined cause. It may be a viral or autoimmune disorder, although familial cases and an association with HLA-B5 and HLA-B1 support a genetic role.^{153,154} Although it was previously thought to be a hypercoagulable state, elevation of procoagulant factors such as aPL are now known to be a secondary feature of the syndrome. Pathologically, there is infiltration of smaller venules with lymphocytes and plasma cells, disrupted architecture of vessels, and occlusion with fibrin to fibrotic replacement, depending on the age of the lesion. There may be involvement of larger arteries or veins, resulting in thrombosis, aneurysm formation, or hemorrhage.¹⁵⁴

EPIDEMIOLOGY AND RISK FACTORS. The syndrome occurs with a prevalence rate as high as 37 per 100,000 in rural Turkey but only 0.4 per 100,000 in the United Kingdom.¹⁵⁵ Although children may be affected, mean age of onset is in the third decade. Neurological signs may occur at presentation but more typically occur several years later.¹⁵⁶ It is unclear if there are risk factors independent of genetic predisposition. In an autopsy series, 20% of 170 patients with BD had neurological involvement.¹⁵⁵

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Criteria established by an international study group include recurrent major or minor aphthous or herpetiform ulceration of the mouth (mandatory) and involvement of at least one of the organ systems discussed later. Ocular signs include uveitis and vitritis, which are often present bilaterally, hypopyon, and vasculitis of the retinal vessels, sometimes with permanent visual loss. Skin lesions include small, oval to round buccal and genital aphthous ulcerations, erythema nodosum, and pustules. Patients may have pathergy, the delayed development of a pustular or nodular skin reaction at the site of needle puncture. A polyarteritis may occur, and larger arteries or veins may be affected, producing superior or inferior vena cava syndrome, intermittent claudication, edema, pulmonary infarct or fistula, or myocardial infarction.¹⁵⁴

Although nervous system involvement occurs in up to 33% of patients with BD, it is not a defining criterion for the disease.¹⁵⁷ The nervous system is affected in one of a few ways, and often these syndromes may overlap. Brain stem involvement with meningoencephalitis is the most common location of parenchymal disease in two of the larger series reported.^{155,158} Usually the syndrome presents subacutely over days, with headache, oculomotor abnormalities, and ataxia (Video 230, Exotropia). Only a few patients have respiratory insufficiency resulting in ventilatory support. Isolated cranial nerve dysfunction has also been seen with the facial nerve most often affected. Intramedullary spinal cord lesions, including complete transverse myelitis, are seen less often.¹⁵⁵ Meningoencephalitis or aseptic meningitis may present with chronic headache and typically mild pleocytosis.^{142,158} Vasculitis of venules or veins may cause significant thrombosis. In a prospective study of 31 patients with BD and neurological involvement, 10 patients had intracranial venous thrombosis. All had intracranial hypertension, but only two had focal neurological deficits due to cortical vein thrombosis. Angiography may confirm a suspected thrombosis that is not visualized by MRI or may be performed in the appropriate setting if MRI is not available. CSF studies are typically abnormal with pleocytosis, elevated protein, and normal glucose but may be normal despite grossly abnormal MRI studies.¹⁵⁷ Serial CSF studies may be intermittently abnormal regardless of CNS disease activity.¹⁵⁶ In contrasting the CSF profiles of these presentations, the opening pressure was abnormal in the cases of meningitis and venous thrombosis. Pleocytosis was predominantly neutrophilic in the meningitis cases and lymphocytic/monocytic in cases of venous thrombosis or parenchymal lesions of the hemisphere, brain stem, or spinal cord.^{155,158} Glucose is typically normal.¹⁵⁸

DIFFERENTIAL DIAGNOSIS. Other diagnostic considerations include inflammatory conditions or systemic infections such as SLE, polyarteritis nodosa, and bacterial

endocarditis. The presence of arthritis may lead to the diagnosis of RA or postviral polyarthritis. Prominent neurological signs suggest other conditions including meningitis, encephalitis, stroke, and multiple sclerosis. Meningitis can be caused by bacterial or viral infection or drugs (ibuprofen, trimethoprim) or can be recurrent Mollaret's meningitis. Focal brain lesions may resemble those of multiple sclerosis or be radiologically identical to other vasculitic syndromes.¹⁵⁷

EVALUATION. Since there is no definite test to confirm the diagnosis of BD, the constellation of symptoms and signs over time allows the diagnosis to be made. A thorough history, physical examination, and review of previous symptoms are required. ESR is likely to be elevated if there is large vessel vasculitis but may be normal if the only evidence of disease is uveitis. Fibrin split products and platelet count may be elevated. Antiphospholipid antibodies are present in 15% to 35% of patients.¹⁵⁴ These changes are felt to be secondary effects of the inflammatory process.

Skin manifestations may lead to a diagnostic skin biopsy in patients with accessible lesions. Only occasionally is vasculitis proved, however. There is often infiltration of the dermis with lymphocytes and plasma cells, and deposits of IgM and C3 sometimes occur in cutaneous vessels. A test for pathergy can be done by making a few sterile puncture sites in the forearm. Formation of nodule or pustule supports the diagnosis of BD; however, the absence of pathergy does not exclude BD as a potential diagnosis.¹⁵⁴ Visual complaints should be evaluated by an ophthalmologist to prevent morbidity owing to visual loss. Neurological evaluation is guided by the clinical presentation of the patient. MRI is superior to CT in detection of BD-related lesions.¹⁵⁷ T2-weighted MRI images may show multiple high-intensity lesions. Lesions occur in the cerebral white matter (70%), brain stem (60%), and deep gray matter (40%). They may be confluent and more extensive than suspected clinically. They do not have a predilection for the periventricular white matter. A lumbar puncture with assessment of opening pressure will identify those cases of intracranial hypertension secondary to venous thrombosis and confirm the presence of meningitis or meningoencephalitis.¹⁵⁷ CSF pleocytosis may range from 0 to 850 cells/mL (mean, 82), with the percentage of lymphocytes ranging from 25% to 100% (mean, 63), protein ranging from 16 to 101 mg/dL (mean, 43), and glucose ranging from 40 to 89 mg/dL (mean, 59).¹⁵⁶ Blood-brain barrier function may be abnormal as measured by the albumin ratio of CSF to serum; oligoclonal bands may be demonstrated.¹⁵⁹

MANAGEMENT. Corticosteroids palliate inflammation at any disease stage by reducing the current vascular inflammation. Therefore, their use is justified during disease activation. However, corticosteroids are not effective in the prevention of blindness or the morbidity and mortality that can be associated with neurological sequelae.¹⁵⁴ Other agents (e.g., alkylating agents) are needed in the long-term management of the disease to prevent or reduce significant morbidity.

Chlorambucil is helpful in controlling uveitis or meningoencephalitis. The dose is 0.1 mg/kg/day with gradual reduction in the dose if the disease remains controlled. Prolonged treatment at doses of 2 to 4 mg/day may be required to keep control. Routine blood counts should be followed, and the risk of sterility is a factor if treatment

continues longer than 1 year. Cyclosporine at 6 mg/kg/day is tried if chlorambucil is ineffective or not tolerated. Monitoring of routine blood counts, blood urea nitrogen, creatinine, and cyclosporine levels is necessary owing to the renal disease that can result from cyclosporine.¹⁵⁴ Azathioprine, methotrexate, and colchicine (which is widely used in Japan) may also be effective.

The treatment of major vessel occlusion is not clearly agreed upon. Treatment with prednisone and an alkylating agent should be initiated. Anticoagulation has been shown useful in patients with intracranial venous infarction,¹⁵⁷ although this treatment should be avoided in patients with pulmonary vasculitis. Low-dose aspirin may reduce secondary thrombosis without significantly increasing the bleeding risk.¹⁵⁴

PROGNOSIS AND FUTURE PERSPECTIVES. Mucocutaneous lesions can exist for years without substantial morbidity or death. Ocular and neurological involvement, however, can lead to significant disability or death. The patients who experience intracranial hypertension and vein occlusions have a generally good prognosis if satisfactory treatment is provided at presentation. Patients with parenchymal disease often have sequelae felt to be related to the degree of axonal damage. A relapsing course of disease is seen in about 30% to 40% of neuro-BD patients, and patients with brain stem involvement and younger age of disease onset tend to have a worse prognosis.¹⁵⁵ Appropriate evaluation and prompt treatment reduce this morbidity. After several years, most patients enter a period of relative disease inactivity and are less prone to complications as a result.¹⁵⁴

INJURIES

Disorders due to head, spine, and peripheral nerve injuries are among the most commonly seen by neurologists. The impact of these injuries can be devastating for individuals and society, because injuries occurring in a fraction of time can result in death or lifelong impairments associated with chronic pain syndromes. Motor vehicle accidents continue to be a leading cause of neurological trauma despite efforts at primary prevention. Although some neurological injuries such as those due to gunshot and stab wounds reflect a violent society, others, like a lightning strike, are random and capricious. Basic and clinical neuroscience research is directed toward prevention and better treatment of traumatic neurological injury.

ACUTE HEAD INJURY

PATHOGENESIS AND PATHOPHYSIOLOGY. Head injury (HI) accounts for a disproportionate share of morbidity and death in traumatized patients. The past two decades have witnessed a significant decline, however, in overall HI mortality rate from the mid-30% range in the 1970s to less than 20% in the 1990s. This improvement has paralleled an understanding of the secondary injury process and an appreciation that all neurological damage does not occur at the moment of insult but evolves over the ensuing hours and days from various biochemical and molecular derangements. This understanding has led to the development of aggressive treatment strategies to prevent intracranial pressure (ICP) elevations and ischemia. This understanding has led also to extensive clinical therapeutic trials to identify pharmacological neuroprotective agents. The structural injury to the brain at the time of impact is rarely the sole determinant of outcome. Hypoxia, hypotension, mass lesions, increased ICP, ischemia, free radical production, excitotoxicity, and loss of calcium homeostasis are also important.

The frequent occurrence and deleterious effects of the secondary insults of hypoxia and hypotension have long been known.^{1,2} Mortality rate is doubled when these insults are superimposed on severe HI (Fig. 51-1), and similarly,

concomitant elevated ICP increases morbidity rate.³ Considerable research has focused on the biochemical and molecular mechanisms of secondary injury. Although these events are multifactorial and interrelated, their timing sequence justifies consideration of each component (Fig. 51-2).

The contribution of oxygen free radicals to secondary injury following HI is a subject of active research.^{4,5} Free radicals generated by HI, including superoxide, hydroxyl, hydrogen peroxide, singlet oxygen, and nitrous oxide, have the potential to damage proteins and the phospholipid components of cells and organelle membranes. Additionally, extensive membrane depolarization, induced by trauma, allows for a nonselective opening of the voltage-sensitive calcium channels and an abnormal accumulation of calcium within neurons and glia. Such calcium shifts are associated with activation of lipolytic and proteolytic enzymes, protein kinases, protein phosphatases, dissolution of microtubules, and altered gene expression.⁶ Another method of abnormal calcium influx is via activation of excitatory amino acid receptors such as glutamate and aspartate. Excitotoxicity occurs in a widespread fashion after trauma, resulting in cell swelling, vacuolization, and death.⁷ Concurrent with the rise in intracellular calcium, magnesium levels are often low immediately following head trauma. Magnesium is a physiological antagonist of calcium and simple replacement of magnesium might attenuate secondary brain injury.⁸ Several large clinical trials are evaluating this possibility.

Head injury can result in various types of primary injury occurring at the moment of impact, including lacerations of the scalp, skull fractures, cortical contusions and lacerations, diffuse axonal injury, and intracranial hemorrhage. A coup contusion occurs at the site of impact in the absence of a fracture. A contrecoup contusion occurs in the brain diametrically opposite the point of impact. Acceleration/deceleration forces may cause tearing of nerve fibers at the moment of impact, which is called *shearing injury* or *diffuse axonal injury*. Types of intracranial hematomas include extradural, subarachnoid, subdural, and intracerebral hematomas.

EPIDEMIOLOGY AND RISK FACTORS. The Centers for Disease Control and Prevention estimate that annually

Figure 51-1. Influence of hypoxia and hypotension on mortality after head injury.

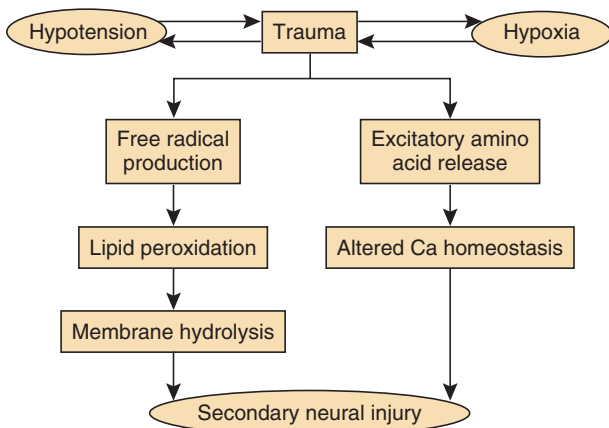

Figure 51-2. Biochemical/molecular substrates of the secondary injury cascade. (From Salaman M: Current Techniques in Neurosurgery, 2nd ed. Philadelphia, Current Medicine, 1993.)

about 1.4 million people sustain a traumatic brain injury (TBI), resulting in 235,000 hospitalizations and 50,000 deaths. Among children ages 0 to 14 years, TBI results in 435,000 emergency department visits, 37,000 hospitalizations, and 2685 deaths.⁹ Another 10,000 people sustain spinal cord injuries each year. The peak incidence occurs in men 15 to 24 years of age. Whereas motor vehicle accidents still account for the majority of injuries, the increasing mandate for seat belt use and availability of air bags appear to be reducing injuries. The incidence of penetrating HI from gunshot wounds is ever increasing, and in some urban communities it is now the most common type of injury seen.

A number of classification schemes have been developed for assessment of neurological damage after HI. The most reliable scheme, from a clinical and prognostic standpoint, is based on the Glasgow Coma Scale (GCS):

- GCS 3–8: Severe
- GCS 9–13: Moderate
- GCS 14–15: Mild

Mild HI is termed a *concussion*. Concussions are infrequently associated with structural brain injury and rarely lead to significant long-term sequelae. The postconcussion syndrome is distinct. Attention to neuropsychological testing has shown the possibility of significant cognitive disability following a concussion.¹⁰ Moderate HI may be associated with significant structural injury such as hemorrhage or contusion, but death is uncommon. Severe HI generally results in some form of cognitive or physical disability or in death, especially with very low GCS scores.

The accurate classification of HI is critical in both triage and management. Severe HI should be treated at facilities with appropriate neurotrauma resources, whereas moderate HI requires close clinical observation for possible neurological deterioration. In the setting of mild HI, the most important management issues are related to the need for computed tomographic (CT) scanning, possible inpatient observation, and appropriate follow-up.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. HI is frequently associated with skull fracture, and the significance of the fracture depends on the type of head injury. When associated with severe HI, linear fractures have little practical significance, whereas with mild HI, the presence of a skull fracture increases the risk of an intracranial abnormality by as much as fourfold.¹¹ Basilar skull fractures may be complicated by cerebrospinal fluid (CSF) leak, infection, and cranial nerve palsies. Patients with basilar skull fractures generally deserve closer clinical monitoring than those with linear skull fracture. In infants and young children, however, linear fractures may be complicated by leptomeningeal cysts or “growing” skull fractures. When such lesions occur, a mass may develop over the fracture site as CSF collects from a disruption of arachnoid integrity underlying the injury. Cysts always require surgical correction; it is important to follow young children for several months for this possible occurrence.

Infrequently, blunt trauma to the head can tear the middle meningeal artery, diploic veins, or the dural sinuses, resulting in a collection of blood in the epidural space, which is an epidural hematoma. Epidural hematomas are associated with a skull fracture in 85% of cases. They most commonly occur in the temporal region, although they can also occur in other locations such as the frontal or parietal regions or within the posterior fossa. The classically described lucid interval associated with this entity is rarely seen because most patients are unconscious from the time of injury. Examination of the head may reveal a laceration and skull fracture over the region of the hematoma. If uncal herniation (i.e., herniation of the mesial temporal lobe) occurs from mass effect, findings may include an ipsilateral cranial nerve III palsy and contralateral hemiparesis (Video 4, Pronator Drift). An ipsilateral hemiparesis can occur as a result of compression of the contralateral cerebral peduncle against the edge of the tentorium. Most epidural hematomas require immediate surgical intervention; however, there are exceptions, particularly in alert pediatric patients.¹²

Acute subdural hematomas occur in approximately 20% of patients with severe HI. Impact injury to the brain can rupture the parasagittal bridging veins (which drain blood from the surface of the hemisphere into the dural venous sinuses) leading to hematoma formation within

the subdural space. Subdural hematomas can also occur without head injury in patients with a coagulopathy or on anticoagulants. Subdural hematomas can also be due to rupture of cerebral aneurysms. Subdural hematomas are usually located over the hemispheres, although other locations, such as between the occipital lobe and tentorium cerebelli or between the temporal lobe and base of the skull, can occur. About 50% of patients with acute subdural hematomas are unconscious from the time of injury. Focal findings can occur because of herniation, as described for epidural hematomas. Surgery within the first 4 hours from injury is generally associated with improved outcome; however, this basic tenet of HI management has been challenged.^{13,14}

A subdural hematoma becomes subacute between 2 and 14 days after the injury when there is a mixture of clotted and fluid blood. A subdural hematoma becomes chronic when the hematoma is filled with fluid more than 14 days after the injury. Most patients with chronic subdural hematomas are late middle age or elderly. Up to 50% of those with chronic subdural hematomas, however, have no history of head injury. Patients with chronic subdural hematomas may have multiple types of presentations such as the following: headache and nausea without focal findings; a slow progression of focal signs; altered mental status, apathy, and unsteady gait; an acute focal neurological deficit; fluctuating neurological deficits that may clear; and seizures. Thus, it is easy to see how the various presentations of chronic subdural hematoma can lead to misdiagnoses such as stroke, transient ischemic attack, brain tumor, depression, and dementia. Although occasionally chronic subdural hematomas can be treated with diuretics and corticosteroids, symptomatic patients generally require surgery.

Cerebral contusions are frequently associated with intracranial mass lesions, although they may occur as a result of the coup-contrecoup phenomenon, especially in the temporal and inferior frontal regions. The clinical presentation depends upon the location and severity of the contusion and whether other lesions are present. Patients with small focal contusions can present with speech or motor deficits, whereas larger contusions can act as a mass lesion. Contusions themselves rarely require surgical intervention; however, they necessitate careful clinical and CT follow-up because they may evolve into delayed post-traumatic intracerebral hematomas.¹⁵

Diffuse axonal injury (DAI) is a frequent CT and pathological correlate of severe head injury, accounting for about 50% of primary brain injuries. It is a result of rotational acceleration of the brain inducing shear, stretch, and deformation of white matter. DAI is usually associated with a poor outcome.¹⁶ DAI when severe is readily identifiable on CT as multiple punctate hemorrhages, typically in the deep white matter and corpus callosum and occasionally in the brain stem. DAI may also occur as a result of mild head injury and may culminate in subtle types of cognitive deficits.

Approximately 10% to 15% of patients with clinically severe HI have a normal CT scan. In such situations, the possibility of extracranial or intracranial vascular disruptions must be considered, and angiography should be considered. A normal CT scan does not preclude the presence of

increased ICP. A repeat scan should also be obtained as often abnormalities can be demonstrated in the latter scan. Occasionally, magnetic resonance imaging (MRI) may demonstrate lesions not appreciated on CT in this setting.

Approximately 5% to 10% of patients with severe HI have an associated spine or spinal cord injury. Initial HI evaluation and management thus require simultaneous evaluation and management for potential spinal injuries. The majority of patients with severe HI have multisystem injury. Possibility of other significant and potentially life-threatening injuries should be evaluated and the proper treatment priorities accordingly established.

Multiple medical complications can also occur after HI.¹⁷ Cardiovascular effects of head injury include neurogenic hypertension and cardiac dysrhythmias. Respiratory complications such as neurogenic pulmonary edema, aspiration pneumonia, and pulmonary emboli usually caused by deep venous thrombosis are rather common. Other complications include disseminated intravascular coagulation, hyponatremia due to the syndrome of inappropriate antidiuretic hormone secretion, diabetes insipidus, and stress gastritis.

DIFFERENTIAL DIAGNOSIS. Many nontraumatic disorders may mimic HI, including drug or alcohol intoxication, metabolic disturbances, and subarachnoid or other types of intracranial hemorrhages. When an intoxicated person falls or becomes involved in a fight and sustains a head injury, the emergency evaluation can be further complicated. Often, a patient presents after an apparent traumatic event that itself was precipitated by primary underlying intracranial pathology. Examples include the following: a stroke that causes loss of control while driving; a generalized seizure resulting in a head injury (Video 77, Clonic Seizure); a gait disturbance (due, for example, to Parkinson's disease, diabetes with a sensory ataxia [Video 5, Sensory Ataxia], or cervical spondylitic myelopathy) causing a fall and an HI; and delirium or dementia as a cause of the fall. The physician should not only treat the injury, but should also try to find out if there is an underlying cause.

EVALUATION. The primary evaluation of a patient with HI necessitates a careful neurological evaluation. Because a significant number of these patients have multiple types of trauma, however, systemic evaluation and stabilization take precedence. The ABCs of trauma resuscitation must be followed. As noted previously, correction of hypoxia and hypotension has a significant impact on outcome from HI.

The neurological evaluation of these patients is often complicated by many physical and iatrogenic factors. In comatose patients, a cervical spine series should be performed to exclude fractures before checking the oculocephalic reflex. Severe ocular trauma may obviate examination of pupillary reflexes. Alcohol intoxication and the use of sedatives or muscle relaxants to facilitate patient transport adversely affect the trauma-related neurological findings. Extremity fractures limit the extent of the neurological examination.

The GCS score has been the most reliable indicator of the severity of injury and deterioration or improvement. The initial GCS score often influences early treatment decisions. Thus, an intimate familiarity with the examination essentials to establish the GCS score is important: eye opening, verbal response, and motor response (Table 51-1).¹⁸

TABLE 51-1

Glasgow Coma Scale

| EVALUATION | SCORE |
|-------------------------|-------|
| Eye opening | |
| Spontaneous | 4 |
| To voice | 3 |
| To pain | 2 |
| None | 1 |
| Verbal response | |
| Oriented | 5 |
| Confused | 4 |
| Inappropriate | 3 |
| Incomprehensible | 2 |
| None | 1 |
| Motor response | |
| Obeys commands | 6 |
| Localizes pain | 5 |
| Withdraws | 4 |
| Flexion | 3 |
| Extension | 2 |
| Flaccid | 1 |
| Total score range: 3–15 | |

Once the GCS score has been established, a more detailed head and neurological examination can be pursued. A careful examination of the head is essential for findings such as scalp lacerations, skull fractures, blood in the external auditory canal, a hemotympanum, or Battle's sign (ecchymosis of the scalp overlying the mastoid bone). Any laterality to the neurological findings (i.e., a dilated pupil, hemiparesis) suggests a focal mass lesion. The higher the GCS score, the more important a detailed mental status examination becomes in determining management. For penetrating HI and especially gunshot wounds, there must also be a full and careful documentation of entry and exit wounds, powder burns, and foreign bodies.

In pediatric patients, the possibility of child abuse must be borne in mind, especially when the primary structural brain injury is subdural hematoma. The *shaken baby syndrome* refers to violent shaking of an infant or small child resulting in retinal hemorrhages and subarachnoid or subdural hemorrhage, but with minimal or no external evidence of severe trauma.¹⁹ When such concerns arise, there must be a careful systemic survey for evidence of other injuries—retinal hemorrhages, skin bruising, new and old long bone fractures.

The more severe the HI, the greater the urgency for CT scanning as an integral part of initial evaluation to exclude lesions that require neurosurgical intervention. The only exception is when other life-threatening injuries take precedence. With minor HI, CT is not routinely indicated. Similarly, if CT is to be obtained, plain skull radiographs are unnecessary. Additional diagnostic evaluations such as MRI, cerebral angiography, and transcranial Doppler examination may be appropriate depending on clinical and CT findings.

MANAGEMENT. The management of minor HI is primarily directed toward a determination of which patients require CT scanning or in-hospital observation. Considerable effort has been expended to determine the risk of deterioration in this group of patients so that appropriate triage protocols may be established. A meta-analysis of a

large number of series indicates that approximately 2.5% of patients presenting to an emergency room with minor HI require neurosurgical intervention.²⁰ This observation has led to current recommendations that only patients with GCS scores of 15 be discharged without prior CT scanning. Risk factors that must be taken into consideration when making this determination include palpable depressed skull fracture, seizures, extremes of age, persistent headache or vomiting, therapeutic anticoagulation, and suspected abuse. Unless there are significant associated extracranial injuries, it is rare for a minor HI to necessitate more than 24 hours of hospital observation.

Moderate HI is generally associated with significant symptoms and findings and necessitates CT scanning and hospitalization for serial neurological monitoring. Repeat CT scanning is indicated if there is any deterioration in neurological functioning. Delayed hematomas are occasionally seen after moderate HI. They usually represent bleeding into areas of contusion not well visualized initially, and patients typically present 24 to 48 hours after injury.²¹

The management of severe HI requires intensive support and monitoring. Because all patients are comatose, intubation and artificial ventilation are mandatory. Blood pressure monitoring and support are crucial to prevent hypotension. Monitoring via Swan-Ganz catheterization may be helpful to maximize perfusion. The first priority is complete and rapid physiological resuscitation. Hypotension (systolic blood pressures less than 90 mmHg) and hypoxia (Pao₂ less than 60 mmHg) should be avoided if possible and corrected if present. Each episode of hypotension and hypoxia cumulatively increases the morbidity and mortality rates from severe head injury, and adequate resuscitation improves outcome from severe head injury.²²

The institution of ICP monitoring remains somewhat controversial; however, ICP monitors are generally considered appropriate in this setting (GCS 8 or lower) and provide the most reliable guide to treatment of the underlying brain injury. Even patients with severe TBI, with a normal CT scan have a 10% to 15% chance of suffering from elevated intracranial pressures. If they are older than 40 years of age, have unilateral or bilateral posturing or have a systolic blood pressure less than 90 mmHg, then their risk of intracranial hypertension is increased considerably. ICP measurement guides therapy, helps make rational decisions about blood pressure management, and is a strong predictor of outcome. When a ventriculostomy is used to monitor ICP, then a therapeutic tool also exists to treat elevated ICP. Because elevation of ICP more than 20 mmHg is a significant predictor of a poor outcome, an appropriate threshold to begin aggressive ICP treatment appears to be 20 to 25 mmHg.^{3,23}

Considerable interest has been focused on cerebral perfusion pressure (CPP) in treating severe HI.²⁴ CPP is determined by subtracting the ICP value from mean arterial blood pressure and represents the pressure driving cerebral blood flow. Thus, CPP and cerebral blood flow can be positively affected by either lowering ICP or elevating systemic blood pressure. It is generally believed that active attempts to maintain CPP above 70 mmHg enhance cerebral blood flow to ischemic areas of the brain and improve outcome. In patients with intact autoregulation, increasing the

blood pressure increases cerebral arteriolar tone, decreases intracranial blood volume, and reduces ICP. Even in patients with defective autoregulation, a large majority do not experience significant elevation in ICP when the mean arterial pressure is increased.²⁵

The primary treatments for elevated ICP include hyperventilation, diuretics, hypertonic saline, and in extreme circumstances, barbiturates. If a ventriculostomy is in place, the drainage of CSF may have significant therapeutic benefits. Hyperventilation has generally been discarded as a primary therapy for increased ICP because of its potential to cause or exacerbate cerebral ischemia. Cerebral blood flow is low in the first few days after severe TBI and hyperventilation can significantly lower it further. For this reason alone hyperventilation should be avoided in the first 3 to 5 days after severe TBI. Chronic hyperventilation (beyond a few hours) is ineffective because of compensatory changes in CSF restoring the pH toward normal. Hyperventilation may be used for short durations in situations while other measures to control ICP are being initiated. PaCO₂ levels lower than 30 mmHg are rarely indicated. When extreme hyperventilation is required, methods of monitoring for cerebral ischemia, such as jugular venous oxygen saturation (SJVO₂), may provide useful clinical information.^{26,27} Recently attempts have been made to correlate cerebral perfusion with noninvasive cerebral oximetry.²⁸ Mannitol is the primary diuretic used to control ICP. Effective doses range from 0.25 to 1.0 g/kg, which are typically given as intermittent boluses. Care must be taken to prevent hypovolemia and hyperosmolarity when giving frequent boluses.

Hypertonic saline is being increasingly used in the management of increased ICP. The blood-brain barrier is impermeable to sodium ions. Since the concentration of these ions, in blood, is several orders of magnitude higher than protein molecules, serum osmolarity is the prime determinant of the movement of water into the brain. Hypertonic saline increases serum osmolarity and intravascular volume, both reducing ICP and enhancing cerebral perfusion. The usual goal is to maintain a serum osmolarity between 300 and 320 mOsm/L.

High-dose barbiturate therapy is generally reserved for those situations in which ICP becomes refractory to other available therapies.²⁹ The goal of barbiturate therapy is to put the patient in burst suppression. Approximately 60% of oxygen utilized by the brain is used for the maintenance of electroencephalographic activity. Thus, burst suppression reduces the cerebral metabolic rate by about 60%, thereby reducing the cerebral blood flow and cerebral blood volume. This in turn lowers the ICP and improves perfusion of ischemic areas. Many potential complications, including cardiovascular instability, are associated with barbiturate use, however, and extremely careful monitoring is necessary. Although steroids have been often used to treat severe HI, there are no data to support their use to either control ICP or to affect its long-term outcome.³⁰ A recent randomized, placebo-controlled trial used either a methylprednisolone infusion or a placebo in the first 48 hours after TBI and looked at outcomes within 2 weeks of randomization. An increase in the risk of death from all causes was found in the corticosteroid group.³¹ The use of steroids in the setting of TBI should be abandoned.

Decompressive craniectomy for intractable brain swelling is an older treatment that has recently received renewed attention. A number of operations have been developed for or applied to decompression of the brain at risk for the sequelae of uncontrollable intracranial hypertension. These procedures include Cushing's subtemporal decompression, temporal lobectomy, and the more widely utilized hemispheric and bifrontal decompressive craniectomies. Recent literature suggests, but does not prove, that decompressive procedures, in the appropriate setting, may decrease mortality rate and improve outcome for these patients.

Research has focused on attempting to identify neuroprotective agents to ameliorate secondary injury and thus improve outcome from severe HI. Two large-scale prospective randomized trials of the free radical scavengers tiriladaz mesylate and polyethylene glycol-superoxide dismutase (PEG-SOD) have been reported to show no significant reduction in mortality rate or to improve outcome.³² Recently completed trials with *N*-methyl-D-aspartate (NMDA)-receptor antagonists in an attempt to limit excitotoxicity have not shown any benefit in the clinical setting; however, final results have yet to be published. A small randomized controlled trial reported by Marion and colleagues demonstrated that moderate hypothermia for 24 hours in patients with severe traumatic brain injury and GCS of 5 to 7 on admission hastened neurological recovery and may have improved the outcome. However, a large, multicenter clinical trial did not bear out these positive findings, actually demonstrating a nonstatistically significant increase in mortality rate in GCS 3–4 patients treated with hypothermia.

PROGNOSIS AND FUTURE PERSPECTIVES. Minor HI is rarely associated with significant long-term sequelae. It is well established, however, that a significant minority of patients suffer chronic disability attributable to neurobehavioral sequelae.³³ The exception to this is sports-related minor HI in which death from the second impact syndrome or cognitive disability from cumulative concussions may occur.

Second impact syndrome refers to malignant cerebral edema resulting from relatively mild head trauma occurring after a recent concussion. The syndrome is believed to be due to impaired cerebral autoregulation. It has been well documented that fatal brain swelling may occur in the setting of one minor HI followed in short order by a second minor HI in athletes who are still symptomatic from the first injury.³⁴ The cumulative effects of multiple minor HIs is recognized in boxing as the *punch drunk syndrome*; however, the occurrence of this syndrome in association with other sports is controversial.

For sports-related minor HI, the American Academy of Neurology has defined three grades of concussion and recommended guidelines for return to play.³⁵ For grades 1 and 2, there is transient confusion and no loss of consciousness. Resolution of concussion symptoms or mental status abnormalities occurs in less than 15 minutes in grade 1 and more than 15 minutes in grade 2. Grade 3 concussion is any loss of consciousness. Players with grade 1 concussion may return to play the same day if they have a normal sideline neurological assessment including a detailed mental status examination. Players with grades 2 and 3 concussions should not return to play the same day. Guidelines for

TABLE 51-2

When to Return to Play After Removal from Contest

| Grade of Concussion | Time Until Return to Play ^m |
|---|---|
| Multiple grade 1 concussions | 1 week |
| Grade 2 concussion | 1 week |
| Multiple grade 2 concussions | 2 weeks |
| Grade 3—brief loss of consciousness (seconds) | 1 week |
| Grade 3—prolonged loss of consciousness (minutes) | 2 weeks |
| Multiple grade 3 concussions | 1 month or longer, based on clinical decision of evaluating physician |

From Practice parameter: The management of concussion in sports (summary statement). Report of the Quality Standards Subcommittee. *Neurology* 1997;48:584.

return to play after removal from the contest (Table 51-2) are necessary because of concern over the cumulative effects of even mild HI and the rare occurrence of second impact syndrome.³⁶

Dementia, long recognized as a sequela of multiple head injuries in boxing, was termed *punch drunk* by Martland in 1928 and *dementia pugilistica* by Millspaugh in 1937. Neuropathological study of brains of boxers with dementia pugilistica demonstrate β -amyloid protein-containing diffuse plaques and neurofibrillary tangles, which are pathological features of Alzheimer's disease. Increased expression of β -amyloid precursor protein is part of an acute-phase response to neuronal injury, which can lead to deposition of β -amyloid protein.³⁷

Patients with moderate HI usually experience both cognitive and physical disabilities and typically require rehabilitation services after acute hospitalization. Nevertheless, the incidence of severe long-term disability is small.

In contrast, few patients with severe HI recover completely to their preinjury state. The most common system to rate recovery is the Glasgow Outcome Scale: good recovery (GR), moderate disability (MD), severe disability (SD), vegetative (V), and death (D).³⁸ The tirilazad mesylate and PEG-SOD trials provide excellent information on current severe HI outcomes (Table 51-3).

The most active area of research in head injury today is in the field of molecular genetics. It has been noted that certain genes are upregulated, whereas others are downregulated, after both trauma and ischemia. Particular atten-

tion has been focused on the apolipoprotein E gene and its various alleles. Certain alleles have been associated with an increased susceptibility and severity of head injury, and others have been linked to improved recoveries after head injury.^{39,40} Considerably more research will be required to more completely define and ultimately understand and possibly clinically manipulate these “head injury” genes.

POSTCONCUSSION SYNDROME

Sequelae of mild HI have been recognized for the past few hundred years.⁴¹ In 1866, Erichsen initiated the controversy with his description of patients with persistent complaints after mild head and neck injury due to “molecular disarrangement” of the spinal cord. This condition was known as *railway spine* because many cases were the result of railway accidents. Rigler introduced the concept of compensation neurosis in 1879, because he believed that many persons with persistent symptoms were trying to obtain financial compensation for the injuries. Charcot believed that the impairment was actually the result of hysteria and neurasthenia. Similar debates about the organicity of persistent complaints after mild head injury are still common today, especially in medicolegal cases. The use of the term *postconcussion syndrome* dates back to 1934.

PATHOGENESIS AND PATHOPHYSIOLOGY. Mild head injury may result in cortical contusions due to coup and contrecoup injuries and diffuse axonal injury resulting from sheer and tensile strain damage. Subdural and epidural hematomas can also occasionally result. Release of excitatory neurotransmitters, including acetylcholine, glutamate, and aspartate, may be a neurochemical substrate for mild HI.

EPIDEMIOLOGY AND RISK FACTORS. Mild HI accounts for 75% or more of all brain injuries. The annual incidence of mild HI in the United States is about 140 in 100,000 population, with the relative causes as follows: motor vehicle accidents, 45%; falls, 30%; occupational accidents, 10%; recreational accidents, 10%; and assaults, 5%. Falls are the more likely cause in the elderly, whereas motor vehicle accidents are more common in the young. Men are more commonly injured, with a 2:1 ratio, and about one half of all patients are between the ages of 15 and 34 years. Between 20% and 40% of persons with mild HI in the United States do not seek treatment. Approximately 50% of patients with mild HI develop the postconcussion syndrome.⁴²

CLINICAL FEATURES AND ASSOCIATED DISORDERS. The postconcussion syndrome, which is usually the result of mild head trauma, comprises one or more of a large array of symptoms and signs (Table 51-4).^{43,44} The most common complaints are headaches, dizziness, fatigue, irritability, anxiety, insomnia, loss of concentration and memory, and noise sensitivity (Video 104, Sound-Induced Vertigo). Loss of consciousness does not have to occur for the postconcussion syndrome to develop. Headaches have been estimated to occur in 30% to 90% of patients who are symptomatic after mild injury. Headaches may occur more often and with longer duration in patients with mild rather than severe HI. Tension-type headaches account for about 85% of all post-traumatic headaches.

TABLE 51-4

Sequelae of Mild Head Injury

Modified from Evans RW: Post-concussion syndrome. In Evans RW, Baskin DS, Yatsu FM (eds): *Prognosis of Neurological Disorders*, 2nd ed. New York, Oxford University Press, 2000.

Neck injuries, which often occur at the time of the HI, may cause referred headaches due to myofascial, intervertebral disc, and facet joint injury. Greater occipital neuralgia may occur from a direct blow to the nerve or

may be associated with muscle spasm of the superior trapezius and semispinalis capitis muscles in the suboccipital region. Similar headaches may arise from the C2–C3 facet joint and are known as *third occipital headaches*. Temporomandibular joint injury may also cause tension-type headaches.

Migraine headaches with and without aura can develop in the hours to weeks after a mild HI. Immediately after mild HI in sports such as soccer, football, rugby, and boxing, children, adolescents, and young adults may have a first-time migraine with aura. This syndrome may be triggered multiple times after additional mild HI and has been termed *footballer's migraine*. Cluster headaches can rarely develop after mild HI. Various other less common causes of post-traumatic headaches are found, including supraorbital and infraorbital neuralgia, dysesthesias over scalp lacerations, carotid or vertebral artery dissections, and subdural and epidural hematomas (see Table 51-1). Subdural hematomas can result in headaches that are nonspecific and that can be mild to severe, paroxysmal or constant, and bilateral or unilateral.

Cranial nerve symptoms and signs also occur. About one half of patients after mild HI report dizziness, which can be caused by various types of central and peripheral pathology, including labyrinthine concussion, benign positional vertigo, and brain stem injury. Blurred vision, reported by 14% of patients, is usually caused by convergence insufficiency. Blurred vision is occasionally the result of cranial nerve III, IV, and VI palsies (Video 32, Cranial Nerve III Palsy). Decreased smell and taste are reported by 5% of patients after mild HI; the symptoms can be due to damage to the olfactory filaments. Approximately 10% of patients describe light and noise sensitivity after mild HI.

Nonspecific psychological symptoms such as personality change, irritability, anxiety, and depression are reported by over one half of patients within 3 months of mild HI. Fatigue and disruption of sleep patterns are also often reported. Post-traumatic stress disorder, which has many symptoms similar to those of the postconcussion syndrome, may occur after mild HI.

Four weeks after a mild HI, 20% of patients complain of impaired memory and concentration. Neuropsychological testing has documented cognitive impairments, including a reduction in information processing speed, attention, reaction time, and memory for new information.

DIFFERENTIAL DIAGNOSIS. The incidence of complications that require neurosurgical consultation after mild HI has been estimated to be between 1% and 3%. For adults with mild HI and an initial GCS score of 13 to 15, the incidence of subdural hematomas is approximately 1% and epidural hematomas about 0.5%.

EVALUATION. Single photon emission computed tomography and positron-emission tomography (PET) scans, brain stem auditory evoked potential studies, and brain mapping currently lack adequate sensitivity and specificity to justify use in the evaluation of the postconcussion syndrome. Electroencephalographic (EEG) studies are usually not indicated except for evaluating post-traumatic seizure disorders. Neuropsychological testing can be quite useful for the evaluation of patients with persistent cognitive complaints.

MANAGEMENT. Treatment should be individualized after the patient's particular problems are diagnosed. Tension- and migraine-type headaches can be treated with the usual prophylactic and symptomatic medications. Greater occipital neuralgia may improve with local anesthetic nerve blocks, which can be combined with an injectable corticosteroid. Physical therapy and transcutaneous electrical nerve stimulators (TENS units) may also help tension-type headaches. For patients with cognitive difficulties, cognitive retraining might be helpful, although the efficacy has not been established by prospective studies. Patients with prominent psychological symptoms may benefit from supportive psychotherapy and use of antidepressant and anti-anxiety-type medications. Simple reassurance is often the major treatment because most patients improve after 3 months. One of the most important roles for the physician is education of the patient and family members, other physicians, and, when appropriate, employers, attorneys, and representatives of insurance companies.

PROGNOSIS AND FUTURE PERSPECTIVES. The probability of having persistent symptoms and neuropsychological deficits is the same whether a patient is only dazed or loses consciousness for less than 1 hour.⁴⁵ Persistent symptoms occur more often in women than men, in patients over the age of 40 years, and in those with a prior history of head trauma. Two years after the injury, about 20% of patients still complain of headaches. Cognitive deficits usually resolve within 3 months after the injury, although a small minority of patients report persistent problems for months or years. When patients have unusual or persistent complaints, the possible contributions of personality disorders, psychosocial problems, or secondary gain should be considered.

A compensation case or lawsuit is often filed in circumstances in which another party may be responsible for the HI, such as a motor vehicle accident or on-the-job injury. In this circumstance, when patients have persistent complaints, many physicians are appropriately concerned about compensation neurosis or malingering being the cause. Patients with claims, however, have similar symptoms that improve with time and similar cognitive test results as those without claims. For many claimants, the end of litigation does not mean the end of symptoms or return to work. They are not cured by a verdict.

CRANIAL NEUROPATHIES

Blunt trauma can result in a stretching injury of cranial nerves, which, when severe, can result in nerves being torn loose from the brain stem. Stretching injuries often occur at points of attachment or at points of angulation. Skull fractures and penetrating trauma such as gunshot wounds can cause nerve lacerations.

Blunt trauma most often damages cranial nerves I, VII, and VIII; less often II, III, IV, and VI (Video 1, Cranial Nerve VI Palsy); and least often V, IX, X, XI, and XII (Video 45, Tongue Atrophy). The incidence of cranial neuropathies increases with more severe HI. For example, the overall incidence of anosmia is about 7% but increases to 30% in patients with anterior fossa fractures or severe HI (Video 230, Exotropia). Even trivial HI can result in

anosmia. Injury to the optic nerves and chiasm has been reported in up to 5% of patients with HI. Ocular motility disorders occur in up to one third of patients sustaining closed HI; the abducens nerve is the most commonly injured. Trigeminal nerve and branch injuries often occur as a result of facial trauma (Video 106, Trigeminal Neuralgia). Facial nerve injuries frequently occur with temporal bone fractures.

The site of likely trauma, clinical features, evaluation, management, and prognosis are summarized in Table 51-5.

POST-TRAUMATIC EPILEPSY

PATHOGENESIS AND PATHOPHYSIOLOGY. Post-traumatic seizures may be associated with the typical pathological changes that may be seen in brain injuries, including reactive gliosis, axon retraction balls, wallerian degeneration, microglial scar formation, and cystic white matter lesions.⁴⁶ When a contusion or cortical laceration is present, the breakdown of hemoglobin releases iron. Based on animal and cell culture studies, iron may increase intracellular calcium oscillation and may increase free radical formation through activation of the arachidonic acid cascade, producing increased intracellular calcium resulting in excitotoxic damage, neuronal death, and glial scarring, which lead to epileptiform activity.⁴⁷ These findings suggest a possible role for neuroprotective treatment in the future. There is also evidence suggesting that post-traumatic seizures may be a result of alterations of intrinsic membrane properties of pyramidal neurons together with enhanced NMDA synaptic conductances.⁴⁸

EPIDEMIOLOGY AND RISK FACTORS. Head injury is the cause of about 4% of all cases of epilepsy. In teenagers and young adults, HI is the most common cause of symptomatic epilepsy. Post-traumatic seizures can be divided into different types based on the time of onset after the injury. Immediate seizures occur within minutes of the injury. Early seizures occur within 1 week, whereas late seizures occur after 1 week.

The incidence of early post-traumatic seizures is about 4%. Early seizure rates are higher in patients with more severe HI, intracranial and subdural hematomas, depressed skull fractures, focal neurological signs, loss of consciousness, or post-traumatic amnesia present for more than 24 hours, and in children under the age of 5 years.

Late seizures have an incidence of about 2%.⁴⁷ Risk factors for late seizures include penetrating missile wounds; an early seizure; intracerebral, epidural, and subdural hematomas; GCS score of 10 or less; depressed and linear skull fractures; and cortical contusions.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. About one third of early seizures occur during each of the following times: within the first hour, between 1 and 24 hours, and between 1 and 7 days. Over 60% of early seizures are partial, whereas the others are generalized tonic-clonic (Video 74, Secondary Generalized Seizure; Video 79, Tonic/Atonic Seizure). About 10% of patients develop status epilepticus. Immediate convulsive convulsions are not an epileptic phenomenon but instead are due to a brief traumatic functional decerebration resulting from loss of cortical inhibition.⁴⁹ Antiepileptic medication is not indicated for convulsive convulsions.

TABLE 51-5

A Summary of Traumatic Cranial Neuropathies

| CRANIAL NERVE | SITE OF LIKELY TRAUMA | CLINICAL FEATURES | EVALUATION | MANAGEMENT | PROGNOSIS |
|----------------------|--|---|--|--|---|
| I | Any part of head. More common with occipital than frontal trauma | Decreased or absent sense of smell | Check for possible ethmoid fractures, CSF rhinorrhea, and injury to orbital surface of frontal lobes | Educate patient | Reso in up to 50% of cases, usually during first 3 months but up to 5 years after injury |
| II | Intracranial often associated with a skull base fracture | Decreased or loss of vision. Scotomas, sector, and altitudinal defects can occur | Check visual acuity, fields, and for afferent pupillary defect. CT scan and ultrasound A and B are useful to assess for possible compressive lesions | Controversial for indirect optic neuropathy: include observation, high-dose steroids, and surgery. Surgical decompression often recommended in cases of delayed onset of visual loss | Extremely variable; from 0–100% depending upon the study |
| III | Where the nerve enters the dura at the posterior end of the cavernous sinus. Uncal herniation much less common | Dilated pupil and turned out eye present in complete palsy. Anisocoria and diplopia in partial lesions | CT and/or MRI scans to look for a compressive lesion | Symptomatic such as eyepatch, semitransparent tape to glasses and prisms for diplopia. Muscle shortening procedures may be helpful for permanent diplopia | Recovery begins within 2–3 months when nerve in continuity. Aberrant regeneration often occurs with findings such as lid elevation or pupillary constriction with attempted adduction or depression |
| IV | Stretching or contusion of the nerve as it exits the dorsal midbrain near the anterior medullary velum | Trauma is the most common cause of trochlear palsies. Bilateral palsies are rather common | Same as above | Same as above | Only 50% recover because of frequent avulsion of the trochlear nerve |
| V | Trigeminal nerves and branches are commonly injured with facial trauma, especially supraorbital and supratrochlear nerves. The infraorbital nerve is often injured in orbital floor blowout fractures | Injury to the gasserian ganglion and trigeminal trunk is rare after closed head trauma | Imaging studies to exclude underlying fractures | Decompression of the infraorbital nerve in orbital floor fractures. Symptomatic for hyperpathia due to supra- and infraorbital neuropathies with medications such as carbamazepine, tricyclics, and baclofen | Hyperpathia in the distribution of the nerve may be permanent |
| VI | As the nerve ascends the clivus, in fractures of the petrous bone along with VII and VIII, in the superior orbital fissure along with III and IV, and in its subarachnoid course due to raised intracranial pressure | Bilateral palsies are rather common | Same as above | Same as above | Recovery often occurs after 4 months |
| VII | Most commonly within the petrous bone but can be injured anywhere along its course | Injured in 50% with a transverse temporal bone fracture. Facial palsy in 25% with a longitudinal fracture, often with a delayed onset | CT scan to evaluate temporal bone trauma. A nerve conduction study 5 or more days after the injury is helpful to assess the degree of nerve injury | Facial nerve decompression is usually indicated for transverse fractures. Artificial tears and eye patch at night to prevent exposure keratitis | Spontaneous recovery usual after longitudinal fractures. When due to transverse fractures, 50% recovery after decompression |

Continued

TABLE 51-5

A Summary of Traumatic Cranial Neuropathies—cont'd

| CRANIAL NERVE | SITE OF LIKELY TRAUMA | CLINICAL FEATURES | EVALUATION | MANAGEMENT | PROGNOSIS |
|----------------|--|---|---|---|---|
| VIII | Labyrinthine concussion without a skull fracture is the most common site. Conductive hearing loss follows longitudinal temporal bone fractures in over 50% of cases. Transverse fractures result in vestibular and cochlear nerve laceration in over 80% | Findings associated with a fracture of the petrous portion of the temporal bone include hemotympanum or tympanic membrane perforation with blood in the external canal, hearing loss, vestibular dysfunction, peripheral facial nerve palsy, CSF otorrhea, and ecchymosis of the scalp over the mastoid bone (Battle's sign). Benign positional vertigo occurs in about 25% of patients following head trauma | Examine the external canals and tympanic membranes. An audiogram including pure-tone and speech audiometry, acoustic reflexes, and middle ear function is used to assess hearing loss. An electronystagmogram (ENG) is used to assess vestibular function. CT scan to evaluate temporal bone trauma | A hearing aid may help those with sensorineural hearing loss. Surgical correction is indicated for conductive hearing loss due to ossicular chain disruption. Positioning maneuvers, such as Epley's or Semont's, which move the debris out of the semicircular canal and into the utricle, can be curative for benign positional vertigo | Following temporal bone fractures, patients with low- or high-frequency hearing loss may have some recovery, but those with low- and high-frequency loss usually do not recover. Vertigo due to a labyrinth concussion usually resolves within a year |
| IX, X, XI, XII | Gunshot or stab wounds occasionally cause injury. A fracture of the occipital condyle, Collet-Sicard syndrome, can injure all four nerves. The peripheral portion of XI can be injured in surgical procedures such as posterior cervical lymph node biopsies. The hypoglossal and recurrent laryngeal nerves can be traumatized in anterior neck operations such as carotid endarterectomy | Lower cranial nerve findings associated with signs of brain stem compression are consistent with an intracranial lesion, whereas the presence of a Horner's syndrome is consistent with an extracranial lesion | A careful clinical examination is mandatory. CT and MRI are both useful, depending upon the case | Treatment of Collet-Sicard syndrome is supportive with elevation of the head for drainage of excess saliva and IV or nasogastric nutrition until normal swallowing returns. Accessory nerve injuries in the neck may require exploration with neurolysis or resection and repair or grafting, depending on the degree of injury | Collet-Sicard syndrome may show slow partial recovery. Patients with vagal, spinal accessory, and hypoglossal nerve injuries associated with carotid endarterectomy often recover |

About 50% of patients with late seizures have their first seizure within 1 year of the injury and about 80% within 2 years. Over 60% of the seizures are generalized tonic-clonic with or without focal onset, whereas the others are simple or complex partial seizures.

DIFFERENTIAL DIAGNOSIS. In some cases, post-traumatic seizures must be distinguished from disorders that can result in psychogenic nonepileptic events including conversion, factitious behavior, malingering, reinforced behavior pattern, somatization, post-traumatic stress disorder, hypochondriasis, panic disorder, depersonalization, dissociative disorder, and hyperventilation syndrome. Because mild HI uncommonly results in seizures, nonepileptiform events should be considered when these patients have “funny spells,” or episodes that are atypical for epilepsy.⁵⁰

EVALUATION. A detailed history from the patient and witnesses, if any, of the event; review of pertinent medical records; and general and neurological examination are often the bases for diagnosing post-traumatic seizures. Although an EEG study is certainly important, epileptiform activity is seen in only 50% of patients. Video or ambulatory EEG studies may be worth while in occasional cases when the diagnosis is unclear. A CT or MRI scan of the brain may also be indicated.

MANAGEMENT. In patients with risk factors for early seizures, prophylactic treatment with phenytoin reduces the incidence of early seizures. After the first week, however, phenytoin can be gradually withdrawn because the incidence of late seizures is not reduced by continuing treatment.⁵¹ Instituting long-term anticonvulsant treatment is beneficial for patients after an initial late seizure.

PROGNOSIS AND FUTURE PERSPECTIVES. The remission rate for post-traumatic epilepsy is about 50%. An EEG is of no specific value in predicting either the development or remission of post-traumatic epilepsy. A greater number of seizures and abnormal findings on neurological examination decrease the chance of remission.

POST-TRAUMATIC MOVEMENT DISORDERS

An association between injuries and involuntary movements has been suggested since the 19th century speculation of Parkinson, Charcot, and Gowers. When a movement disorder begins shortly after a brain injury, a cause-and-effect relationship is apparent. An association is less obvious with longer latencies after the injury and after peripheral trauma where there may be a temporal but not causal relationship.⁵² In some cases, the patient may not have noticed or reported a mild movement disorder that was present before the injury.^{53,54}

PATHOGENESIS AND PATHOPHYSIOLOGY. Direct trauma to subcortical and substantia nigral neurons can result in movement disorders occurring shortly after an injury. Movement disorders occurring months following the injury have been hypothesized to be related to sprouting, remyelination, ephaptic transmission, inflammatory changes, oxidative reactions, and central synaptic reorganization. Peripheral trauma that precedes the development of a movement disorder may alter sensory input, leading to central cortical and subcortical reorganization.^{55,56}

EPIDEMIOLOGY AND RISK FACTORS. Movement disorders due to trauma are rare, and specific epidemiological and risk factor studies have not been performed.

CLINICAL FEATURES AND ASSOCIATED FINDINGS. Although HI does not result in Parkinson's disease with pathological findings of Lewy bodies, HI may result in a temporary exacerbation of motor function in patients with pre-existing Parkinson's disease.⁵³ Parkinsonism is a rare complication of single closed HI and may also occur after penetrating bullet and knife injuries of the brain stem. Repeated HI as in the case of boxers with dementia pugilistica may result in parkinsonism in association with many other neurological signs. Parkinsonian tremor may rarely be associated with peripheral body trauma, although a direct causal relationship cannot be established.⁵⁷

Postural and kinetic tremor can be due to direct traumatic lesions of the dentatothalamic circuit. Benedikt's syndrome (unilateral cranial nerve III palsy and contralateral ataxic hemiparesis) can be associated with rest and postural and kinetic tremor (Video 14, Tremor with Ataxia). Postural-kinetic tremors of the arms, legs, or head may occur within weeks of mild HI even without loss of consciousness. Peripheral trauma can induce tremor, which can occur along with complex regional pain syndrome, dystonia, and myoclonus (Video 57, Myoclonus).^{56,57} Myoclonus, dystonia, and athetosis may be present in patients with post-traumatic tremors.

Contralateral dystonia can be due to a lesion in the striatum, particularly the putamen (Video 242, Post-traumatic Dystonia). Causes include perinatal trauma, closed HI (severe much more often than mild), and thalamotomy. The onset of dystonia may have a latency period from 1 month to 9 years. Spastic dystonia due to pyramidal and extrapyramidal injury and paroxysmal nocturnal dystonia are variants of post-traumatic dystonia. Often patients develop post-traumatic dystonia as a delayed sequela of severe HI, initially characterized by coma and quadriplegia. After the patient awakens and the plegia improves, severe action dystonia develops. Minor or moderate local peripheral trauma can be associated with focal dystonia, sometimes in patients with reflex sympathetic dystrophy. Examples of peripherally induced dystonia include the following: blepharospasm after surgery on the eyelids (Video 47, Blepharospasm); oromandibular dystonia after dental procedures; spasmodic dysphonia after facial injuries (Video 48, Spasmodic Dysphonia); cervical dystonia after neck injuries such as whiplash; and foot dystonia after stubbing a toe.

A report by Kraus and colleagues studied survivors of severe HI admitted to the hospital with GCS of 8 or less. Of the 264 survivors, follow-up was obtained on 221, and 22% reported or showed evidence of movement disorders, half transient and half persistent. Tremor, usually kinetic, and dystonia were the most common disorders and usually developed with a post-trauma latency of 2 to 24 months.

Chorea, choreoathetosis, and ballismus can follow blunt head trauma with injury to the striatum, subthalamic nucleus, and anterior thalamus (Video 18, Limb Chorea). The onset is usually days to months following the trauma.

Action myoclonus, palatal myoclonus, and segmental myoclonus may result from head injury not associated with

anoxia or epilepsy (Video 57, Myoclonus). Segmental myoclonus may also occur after spinal cord injury.

A deep, burning pain followed by persistent, involuntary, and irregular movements of the toes and feet, termed *painful legs and moving toes*, can be associated with minor foot and ankle injuries. Hemifacial spasm has been rarely associated with trauma. Additionally, after amputation, the remaining stump can involuntarily jerk.

DIFFERENTIAL DIAGNOSIS. Because the relationship between many injuries and the movement disorder may be circumstantial and retrospective, an idiopathic movement disorder is always a diagnostic consideration. The possibility of psychogenic movement disorders, which may be more common in women, should also be considered. Because movement disorders often develop several weeks or months after trauma and because patients often receive neuroleptic medications after acute injuries, drug-induced movement disorders are another possible cause.

EVALUATION. Neuroimaging such as MRI and occasionally PET can demonstrate responsible brain lesions. Depending on the case, testing to exclude other potential causes of the movement disorder such as Wilson's disease may also be appropriate.

MANAGEMENT AND PROGNOSIS. Post-traumatic parkinsonism may respond to dopaminergic and cholinergic medications. Post-traumatic action tremors only occasionally respond to standard medical treatment. Selected cases may benefit from botulinum toxin injections into involved muscles and ventrolateral thalamotomy. Medications are usually not helpful for dystonia associated with central and peripheral trauma, although botulinum toxin injections can produce temporary relief.⁵⁵ Post-traumatic chorea and choreoathetosis may respond to valproic acid and haloperidol, whereas trauma-induced cortical myoclonus can be treated with clonazepam.

SPINAL CORD INJURY

Over the past decade there have been significant advances in transport, emergency management, pharmacological resuscitation, comprehensive acute care, and rehabilitation. Nevertheless, spinal cord injury (SCI) remains a physically and emotionally devastating problem. The neurologist may thus be confronted with the need for recognition of a potential spinal injury or SCI and institute appropriate stabilization procedures.

PATHOGENESIS AND PATHOPHYSIOLOGY. The pathophysiology of SCI may be divided into two distinct phases—primary and secondary injury. Primary injury refers to the structural damage occurring instantly after the traumatic event. Further primary injury may occur, however, if an injured spine is not adequately immobilized. Secondary injury refers to a pathophysiological cascade initiated shortly after injury, including such insults as ischemia, hypoxia, edema, and various harmful biochemical events. Because it is extremely rare for the primary injury to cause transection of the spinal cord, and it has been shown that less than 10% of the cross-sectional area of the spinal cord supports locomotion, it is very important to focus clinical attention on the secondary injury process.⁵⁸

Ischemia is a very prominent feature of post-SCI events. Within 2 hours of injury there is a significant reduction in spinal cord blood flow. This ischemia may be confounded by loss of the normal autoregulatory response of the spinal cord vasculature. When autoregulation is lost, blood flow becomes dependent on systemic pressures. Thus, in the multitraumatized patient or the patient with vasogenic spinal shock complicating the SCI, severe systemic hypotension may exacerbate the spinal cord ischemia. Hypovolemia and hypotension should be corrected rapidly. Hypotension in particular may increase the area of secondary injury in the spinal cord and worsen outcome. Crystalloids, colloids, and blood products may be used to replace volume as needed. If hypotension persists despite an adequate volume status, vasopressors should be used to maintain a mean arterial pressure of approximately 80 mmHg.

Edema formation is another feature of the secondary injury process. Edema develops first at the injury site and subsequently spreads into adjacent and sometimes distant segments of the cord. The relationship between this edema and worsening of neurological function is not well understood.

Many biochemical mechanisms have been implicated in the evolution of the pathological changes and physiological derangements occurring after SCI. Electrolyte disturbances have been well documented, including increased intracellular calcium level, increased extracellular potassium level, and increased sodium permeability. Other events such as excitatory neurotransmitter accumulation, arachidonic acid release, endogenous opiate activation, and prostaglandin production have all been implicated as damaging elements of the post-injury cascade. Other events, free radical production and lipid peroxidation, are believed to play a central role in this process. Ultimately, however, all of these events cumulatively result in ischemia, edema formation, membrane destruction, cell death, and eventually permanent neurological deficits.

EPIDEMIOLOGY AND RISK FACTORS. Spinal cord injury occurs at a rate of 30 to 40 per 1 million population per year, resulting in approximately 10,000 new cases each year. The prevalence of SCI is over 200,000.⁵⁹ SCI occurs primarily in young males 18 to 25 years of age. The primary precipitant of injury is motor vehicle accidents, although in some areas of the country, swimming and diving-related accidents may take precedence. Sports-related injuries account for less than 5% of the total. In some urban areas the incidence of gunshot-related SCI is increasing (Fig. 51-3). SCI rarely occurs in isolation, and over 75% of these patients have some other systemic injury. In 10% to 15%, there is an associated head injury. This concern has led to the widely quoted clinical maxim that all multitraumatized patients or any patient with a severe head injury should be presumed to have a spine injury or SCI until proved otherwise.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Although general physical assessment of the patient may raise concerns over a possible SCI, a detailed neurological assessment is the only reliable means to rule out this diagnosis. A standardized means of performing and recording the neurological examination has been advocated by the American Spinal Injury Association (ASIA) and has been accepted internationally by both clinicians and researchers (Fig. 51-4). With a complete transverse myelopathy, all

motor and sensory function below the level of injury is absent. The neurological level of injury is the most caudal or lowest spinal cord segment with normal sensation and a muscle strength of 3/5 or better. An incomplete injury is

Figure 51-3. Epidemiology of spinal cord injury. MCA, motor cycle accident; MVA, motor vehicle accident.

present when there is preservation of any motor or sensory function below the zone of injury, including sacral sparing.

Apart from weakness, paralysis, and sensory changes, in the acute stage, depending on the level of injury, certain physiological changes are often evident. These changes include spinal shock, paradoxical respiration, low body and high skin temperature, priapism, and a reduced sweating level. Spinal shock is usually seen in injuries above T6 level and is characterized by hypotension, bradycardia, and an absence of motor and sensory function as a result of spinal cord injury. The higher the level of injury and the more complete the injury, the greater the intensity and duration of spinal shock. The motor and sensory functions usually recover (if any recovery is possible) within an hour, but the autonomic component of spinal shock (loss of sympathetic function) may persist for days to months. Paradoxical respiration is the result of diaphragmatic contraction in the face of intercostal muscle paralysis. The skin is warm because of a loss of sympathetically mediated peripheral vasoconstriction; this also causes the core temperature to fall. Priapism may result from an unopposed

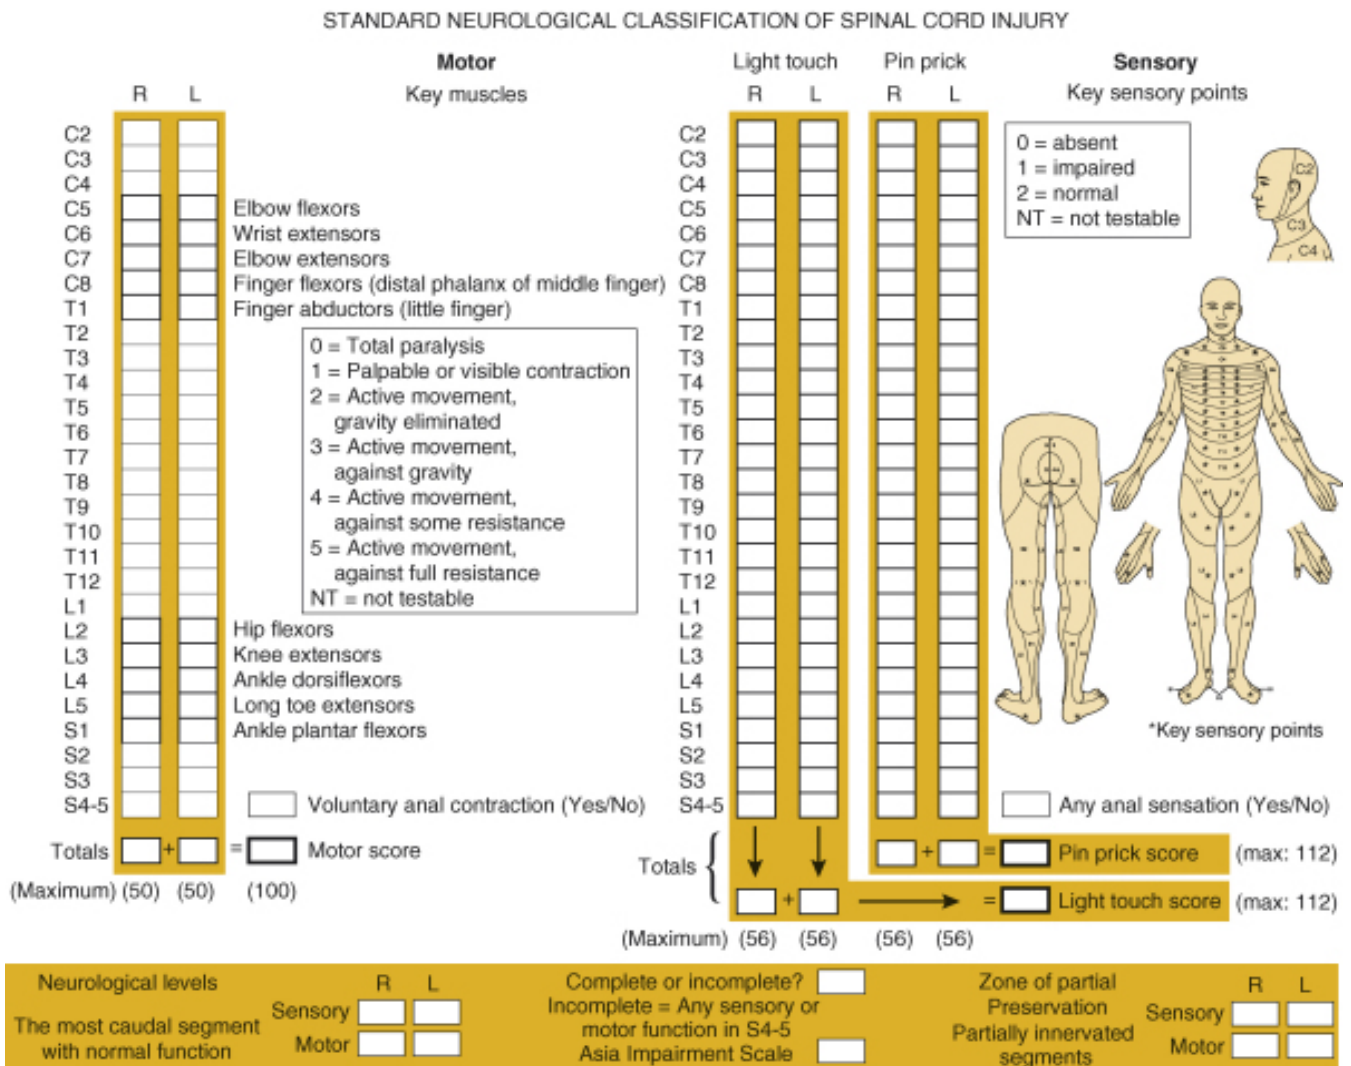

Figure 51-4. The ASIA system for examination and classification of spinal cord injury. (From American Spinal Injury Association: Standards for Neurological and Functional Classification of Spinal Cord Injury, Revised 1992, p 278.)

parasympathetic function, and sweating is lost because of loss of sympathetic activity.

Basic knowledge of myotomes, dermatomes, and deep tendon reflexes is essential for localization. Injury to the upper cervical cord can also damage brain stem structures either because of direct trauma or because of vascular injury of the vertebral arteries. This cervicomedullary syndrome is characterized by respiratory dysfunction, hypotension, variable tetraparesis, hyperesthesia from C1–C4, and sensory loss of the face with an onion-skin pattern.

Partial or incomplete lesions of the spinal cord can result in four patterns of deficit. In the central cervical cord syndrome, the paresis involves the upper extremities, especially the hands, more than the lower extremities. The mechanism of injury is acute cord compression between bony bars or spurs anteriorly and thickened ligamentum flavum posteriorly, resulting in relatively more injury to the medial segments of the corticospinal tracts, which control arm function. The anterior cord syndrome, complete paralysis and hyperesthesia at the level of the lesion but intact light touch and vibration sense, is due to a large disc herniation compressing the anterior cord but without compression of the dorsal columns. The posterior cord syndrome is posterior column damage with impaired light touch and proprioception resulting from hyperextension injuries with fractures of the vertebral arch. The Brown-Séquard syndrome, caused by a lesion of half of the spinal cord, is defined by ipsilateral motor and proprioceptive loss and contralateral pain and temperature loss with the upper level one or two segments below the level of the lesion. This syndrome can occur after various injuries, including penetrating trauma, hyperextension and flexion injuries, locked facets, and compression fractures.

The conus medullaris syndrome is due to a compression injury at T12 that can occur from a disc herniation or a burst fracture of the body of T12. Because almost all the lumbar cord segments are opposite the T12 vertebral body, a severe compression can produce dysfunction in any or all of the lumbar as well as the sacral segments. Flaccid paralysis of the legs and anal sphincter with variable sensory deficits can be present. Because the spinal cord usually terminates at the L1–L2 disc space, trauma below this level injures the nerve roots. The cauda equina syndrome, which is compression of nerve roots below the L1 level, can be caused by fractures and dislocations of the spine or large posterocentral intervertebral disc herniations. Lower motor neuron deficits result with variable sensorimotor, reflex, bladder, bowel, and sexual dysfunction.

In the unconscious patient, neurological evaluation for SCI is very difficult. The only clues to the presence of a significant SCI may be a lack of facial grimacing to peripherally applied painful stimuli, indicating a sensory loss over the trunk, or a lack of withdrawal behavior in the arms or legs in response to painful stimulation applied to the head or face.

The biomechanics of the pediatric spine are fundamentally different from that of the adult. These differences—ligamentous laxity, wedge-shaped vertebrae, horizontally oriented facets—account for distinct clinical presentations. The clinical differences between adult and pediatric SCI include the following: disproportionate involvement of the upper cervical spine in pediatric patients, high frequency

of spinal cord injury without radiographic abnormality, high susceptibility to the delayed onset of neurological deficits in children, and a higher proportion of complete neurological injuries in children (Table 51-6).^{60,61}

A unique SCI syndrome—the burning hands syndrome—was first described in sports injury.⁶² This syndrome appears to be a variation of central cord syndrome associated with severe burning paresthesias and dysesthesias in the hands or the feet. Other signs of neurological dysfunction are minimal or absent. Over 50% of the time there is an underlying spine fracture-dislocation. It is important to differentiate this syndrome from the much more common and usually innocuous “burner” or “stinger” of brachial plexus origin.

The syndrome of neurapraxia is also of special concern after athletic injury. Affected individuals experience dramatic, although transient, neurological deficits including quadriplegia. Frequently this syndrome is associated structurally with degenerative or congenital spinal canal stenosis. Many attempts have been made to quantitate the level of risk to these individuals from continued athletic participation; however, considerable controversy still exists.^{63,64}

The majority of spinal cord-injured patients have at least one other system injury. Occasionally these injuries take precedence in evaluation and treatment. If one level of bony injury has been identified, it is necessary to survey the entire spine because there is a 10% to 15% incidence of spine injury at other levels.

Various problems may occur with chronic SCIs. Within a few weeks of the injury, hyperactive reflexes develop, which are associated with hypertonicity of the extremities (Video 80, Hyper-reflexia). Although moderate spasticity is not a problem for the patient, severe spasticity may lead to flexor spasms and contractures (Video 20, Tonic Spasms). Central deafferentation pain, dysesthesias described as burning, stinging, or freezing, may be present. Autonomic dysfunction can occur as early as 2 to 3 weeks after complete or incomplete lesions of the cervical or thoracic cord. This is characterized by massive sympathetic outflow in response to certain noxious stimuli, usually genitourinary manipulations. In severe cases marked elevations in blood pressure, bradycardia, flushing, headache, nausea, and cardiovascular collapse may occur. There is severe vasoconstriction below the level of the cord injury and vasodilatation above it. This unopposed reflex sympathetic activity may be seen after the

TABLE 51-6

Spine and Spinal Cord Injuries

| CHARACTERISTICS | ADULT | PEDIATRIC |
|--------------------------------------|-------------------------|------------------|
| Mechanism of injury | Motor vehicle accidents | Pedestrian/falls |
| Level of injury | | |
| C1–C3 | 1–2% | 60% |
| C3–C7 | 85% | 30–40% |
| Thoracolumbar | 10–15% | 5% |
| Type of injury | | |
| Fracture-dislocation | >70% | 25% |
| Subluxation alone | <20% | >50% |
| SCIWORA | Rare | Up to 50% |
| Delayed neurological deficits | Rare | Up to 50% |

SCIWORA, spinal cord injury without radiological abnormalities.

period of the spinal shock, and is usually treated by withdrawing the initiating stimulus and administering vasodilators. Spinal anesthesia eliminates this reflex sympathetic outflow and should be considered for patients undergoing genitourinary procedures in the operating room.

Orthostatic hypotension is frequent when the patient is first allowed to sit. Autonomic hyper-reflexia or “mass reflex” may be triggered by noxious stimuli such as fecal impaction, urinary tract infections, distention of the bladder, uterine contraction, and decubiti. Manifestations include nausea, throbbing headache, skin blanching and diaphoresis below the level of the cord lesion, and paroxysmal hypertension.

When patients develop progressive neurological deficits any time from several months to many years after SCI, post-traumatic syringomyelia may be responsible. Present in up to 3% of patients, four kinds of trauma may be responsible: repeated microtrauma, arachnoiditis, severe single trauma, and minor single trauma.⁶⁵ One mechanism of syrinx formation is an initial hematomyelia with subsequent resorption and formation of a cyst cavity.

DIFFERENTIAL DIAGNOSIS. Very few disorders mimic acute SCI. Occasionally a patient with hysterical paralysis presents a diagnostic and therapeutic dilemma. It should be borne in mind that true SCI is almost always associated with obvious physiological disturbances such as bradycardia, hypotension, and respiratory compromise.

EVALUATION. The injured spine may become a radiological diagnostic dilemma, and one must constantly bear in mind the normal radiological appearance of the spine. The initial evaluation should always include plain radiographs of the cervical or thoracolumbar spine, depending on the neurological findings.^{66–68} If an abnormality is identified, complete spine films must be obtained because there is a 10% to 15% incidence of multiple fractures following trauma.

Additional useful information can often be obtained by performing flexion-extension views. Extreme caution must be taken if instability is suspected, however. To better interpret plain films or to better define a definite abnormality, CT is extremely helpful. MRI is sometimes necessary for the complete evaluation of SCI. MRI is the only diagnostic modality that allows direct visualization of the injured cord.⁶⁹

A number of guidelines have been developed to aid the clinician in clearing the potentially injured spine. The most widely quoted of these are the Eastern Association for the Surgery of Trauma guidelines.⁷⁰

The first principle in evaluating the cervical spine is a clear visualization of all seven cervical vertebrae. At times, a swimmer’s view is necessary to visualize this region. If the C7–T1 junction cannot be imaged on plain films, a CT should be performed.

All films should be reviewed for alignment of the vertebral bodies and the facet joints, vertebral body height, and interpedicular distance and normal soft tissue configuration. When evaluating the C1–C2 region, careful attention must be given to the distance separating the anterior arch of C1 and the odontoid process. In an adult, this distance is normally less than 2 mm; in children up to 5 mm distance is acceptable. If any questions arise over possible pathological separation, flexion-extension films may be helpful.

Alternatively, MRI may be employed to evaluate the competency of the transverse axial ligament.⁷¹

Another important consideration when evaluating cervical spine films is the entity of pseudosubluxation. Pseudosubluxation of up to 3 to 4 mm of C2 on C3 may appear in up to 40% of normal radiographs in children younger than 8 years old. A similar abnormality can occur at C3–C4 in up to 20%. If there is any question about this entity, flexion-extension views should be helpful. A true subluxation cannot be reduced, as contrasted with a pseudosubluxation.

The usual mechanism for atlas fractures involves axial compression of the head with downward displacement of the occipital condyles into the lateral masses of C1. The most important radiographical view is the open-mouth odontoid. With a C1 fracture, the lateral masses of C1 are offset laterally with respect to C2. CT scanning clearly demonstrates the associated C1 ring fractures (Fig. 51-5).

Dens fractures occur as a consequence of either forced hyperextension or hyperflexion of the head. With hyperflexion injuries and associated transverse axial ligament damage, the dens is displaced anteriorly with forward subluxation of C1 on C2. With hyperextension injuries the dens is displaced posteriorly with associated posterior subluxation of C1 on C2. Three types of dens fractures may be seen—type 1, fracture line across tip of dens; type 2, at the base of the dens; and type 3, with a fracture extending into the body of C2. CT scanning may not demonstrate a dens injury if the fracture line is axially oriented.

Another type of axis fracture is the hangman’s fracture, usually resulting from hyperextension. Typically there are fractures through both pedicles of C2 with associated forward subluxation of C2 on C3 (Fig. 51-6).

Except in infants and young children, over 85% of cervical fractures occur below C3. Locked facets, either unilateral or bilateral, and compression fractures are the most common lesions. These types of injuries are characteristically produced by flexion complicated by axial loading.

Compression fractures are characterized radiographically by loss of vertebral height, retropulsion of bone into

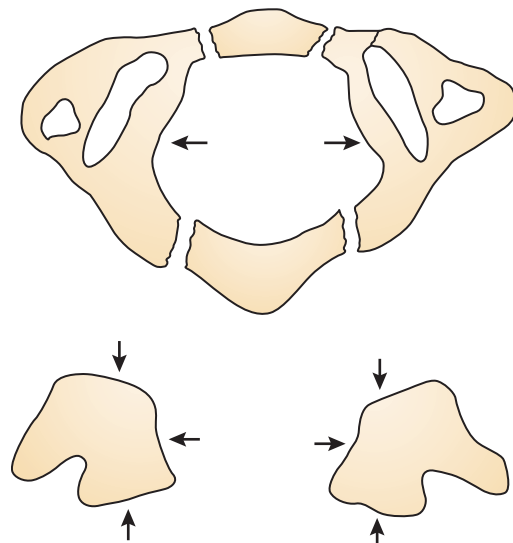

Figure 51-5. A C1 burst or Jefferson’s fracture.

Figure 51-6. Plain radiograph of a typical C2-hangman's fracture.

Figure 51-7. Plain lateral radiograph demonstrating C5–C6 subluxation secondary to bilateral facet dislocation. (From Wilberger JE: *Spinal Cord Injuries in Children*. Mount Kisco, NY, Futura Publishing, 1986, p 29.)

the spinal canal, and kyphotic angulation. The hallmark of facet dislocation is subluxation (Fig. 51-7).

The most common fracture of the thoracolumbar spine is the compression or burst fracture brought about by flexion and axial loading. The T12–L1 level is the one most frequently affected. Typical radiographical features are loss of vertebral height, retropulsion of bone fragments, and kyphotic angulation. The degree of bony disruption and spinal canal compromise is well demonstrated on CT (Fig. 51-8).

A small but definite subtype of SCI occurs without any demonstrable radiographical abnormality, including the appearance on MRI. This type is more likely to occur in children rather than adults; it is often associated with a delayed onset of symptoms after injury, and there is a very poor prognosis for neurological recovery.⁷²

MRI is becoming increasingly useful in the evaluation of SCI. MRI is adequate for demonstrating most bony injury and is superior to all other modalities for exposing the soft tissue and ligaments. Additionally, MRI is the only modality that allows direct visualization of the injured cord (Fig. 51-9).

Several patterns of cord injury have been identified on MRI—transection, contusion, hemorrhage, edema—and preliminary studies suggest a correlation between initial and follow-up MRI findings and neurological prognosis.⁷³ When MRI is not available, not feasible, or contraindicated, intrathecally enhanced CT scan is the best alternative. Myelography can also be performed initially when movement of the patient is feasible.

MANAGEMENT. Resuscitation and stabilization of the patient's condition must be accomplished simultaneously

Figure 51-8. CT scan slice of an L1 compression-burst fracture with significant spinal canal compromise.

with immobilization and stabilization of the spine in the patient with SCI. Because of the frequent occurrence of multisystem injury, the principles of advanced trauma life support must be methodically applied. If significant chest or abdominal injuries coexist, immediate treatment should be directed to those injuries considered most life-threatening.

In the initial management, establishment and maintenance of the airway take precedence. With known or suspected SCI, neck manipulation should be minimized.

Figure 51-9. Sagittal MRI image showing a large dorsal epidural hematoma after posterior element fracture.

Appropriate large-bore intravenous lines should be placed and fluid resuscitation provided. If possible, both a Foley catheter and a nasogastric tube should be placed. When SCI is related to sports injury, the sensational nature of these cases often generates considerable interest. When these injuries do occur it is important to immobilize the athlete on the field and to leave intact any protective headgear, unless airway maintenance is threatened.

During the process of general stabilization, the clinician must remain constantly aware of the principles of spine stabilization. As noted earlier, intubation when necessary should be accomplished with the neck in as neutral position as possible. Adequate stabilization of the cervical spine requires both a hard cervical collar to prevent flexion or extension and side supports to prevent rotation. This immobilization can be accomplished by using sandbags or bolsters on the sides of the head or by taping the head to a rigid backboard. Thoracolumbar injuries are stabilized on a backboard. It is important to remember, however, that insensate patients with SCI left on hard backboards rapidly develop decubiti.

Once the patient's condition is stabilized and appropriate diagnostic studies have been accomplished, more definitive spine stabilization can be undertaken. For cervical injuries, this involves immobilization and reduction of any dislocations, usually by skeletal traction. Many devices are currently available for this purpose; the most commonly used are Gardner-Wells tongs and halo rings. Once a traction device has been placed, weights can be added to aid in spinal realignment. It has been generally recommended that no more than 5 pounds of weight be applied for each cervical level involved (i.e., for a C5 level dislocation no more than 30 pounds should be applied). In routine clinical

practice, however, especially for injuries such as bilateral facet dislocations, weights in excess of 50 pounds may be necessary to achieve reduction. Some controversy exists over how rapidly reduction should be undertaken; however, most agree that with incomplete SCI, rapid intervention is most appropriate.

When traction is applied, the patient must be continually monitored both radiographically and clinically. Overtension of the spine may cause cranial nerve deficits or neurological worsening. Muscle relaxants such as diazepam are often helpful adjuncts in reducing spasm, which may inhibit efforts at reduction. Fluoroscopy may be useful for frequent radiographical monitoring during active attempts at reduction through traction. If closed reduction through traction fails, a decision must be made about open reduction and surgical stabilization. Although there are no good scientific data to indicate any definite advantages with respect to neurological improvement from rapid aggressive surgical intervention in these cases, there is a growing tendency to advocate such an approach.⁷⁴⁻⁷⁷

Generally, realignment of the thoracolumbar spine cannot be accomplished with external traction. Affected patients are immobilized on rotating beds until a decision is made regarding surgical intervention.

The best current initial medical and pharmacological therapy of SCI is based on the potentially reversible pathophysiological changes that occur in relation to spinal cord blood flow and the beneficial effects that have been demonstrated with high-dose methylprednisolone treatment.

Because of the known tendency for spinal cord perfusion to fall abruptly after SCI, systemic blood pressure should be vigorously supported and on occasion mild hypertension induced to ensure adequate perfusion for at least the first 24 hours after injury.⁷⁸ Fluid resuscitation should consist of an appropriate combination of crystalloid and colloid or blood replacement, if necessary. In most instances, lactated Ringer's solution or normal saline is the best initial fluid. If, despite adequate fluid replacement, the blood pressure cannot be normalized, pressors such as dopamine or phenylephrine hydrochloride (Neo-Synephrine) may be instituted. An additional temporary measure to improve peripheral vascular resistance may be a pneumatic antishock garment.

Because spinal cord blood flow is dependent not only on perfusion pressure, but also on blood rheology, it is important to consider measures to reduce blood viscosity, thereby increasing perfusion. Optimal viscosity for this purpose is achieved with a blood hematocrit in the range of 33% to 37%.

A wide variety of hemodynamic derangements is seen in association with SCI, and there is some indication that their correction improves the chances for neurological recovery. Thus, placement of a Swan-Ganz catheter is appropriate after SCI to better detect and treat these problems.

If treatment is initiated within 8 hours of injury, methylprednisolone can be given as an intravenous bolus of 30 mg/kg followed by continuous infusion of 5.4 mg/kg/hour. If treatment is initiated within 3 hours of injury, the continuous infusion should be continued for 24 hours. Patients initiating treatment 3 to 8 hours after injury should have the continuous infusion for 48 hours. The odds of a methylprednisolone-treated patient improving motor

function is greater than 2:1 when compared with other pharmacological therapies, whereas the odds of improving sensory function is 3:1.^{79,80} Methylprednisolone should not be given if more than 8 hours have elapsed since the SCI, because patients treated in this manner have a slightly worse outcome. Recently, considerable controversy has arisen over the scientific validity of the studies showing the benefits of methylprednisolone, and the clinician should weigh the potential benefits versus the possible risks of this treatment. In patients treated for 48 hours one must be particularly vigilant for infectious complications and gastrointestinal bleeding.

The only other pharmacological treatment of SCI that has demonstrated potential benefit is GM₁ ganglioside (SYGEN). When given after methylprednisolone on a daily basis for up to 2 months following injury, this therapy increases the rate of neurological recovery. Ultimately, however, the final degree of functional improvement was no different than the level attained by placebo treatment.⁸¹

Once the immediate problems attendant on the SCI have been stabilized, attention must be directed to preventing the many complications—pulmonary, cardiovascular, urinary tract, gastrointestinal, skin—that typically threaten in the first week to 10 days after SCI (Fig. 51-10).

Pulmonary problems are the single most common cause of morbidity and death following SCI. The higher the anatomical level of injury, the greater the risk of neurological problems. Impaired deep breathing and coughing, on the basis of either pain or neurological compromise, increase the risks of atelectasis and pneumonia. Additionally, the need for maintaining recumbency to allow for immobilization of the spinal injury further compromises respiratory status.⁸² Careful serial observation must be maintained to guard against the insidious development of respiratory insufficiency. Measurements of arterial blood gases or pulse oximetry should be supplemented by measurements

of vital capacity at regular intervals. Pulmonary toilet is enhanced by regular nasotracheal suctioning, frequent chest physiotherapy, and the use of rotating beds or frames.⁸³

Several cardiovascular problems may complicate acute management—vasogenic spinal shock, paroxysmal hypertension, arrhythmias, and thermoregulatory dysfunction. Vasogenic spinal shock results from peripheral pooling of blood from loss of sympathetic vasomotor control; it generally requires treatment with vasopressors. The most common arrhythmia is bradycardia, which may be so pronounced as to produce hypotension. On occasion, temporary pacing may be required. Thus, all patients with SCI should be monitored hemodynamically for the first several days after injury.

The gastrointestinal (GI) tract must be monitored for the development of paralytic ileus, which almost universally occurs. Associated abdominal distention may adversely affect respiratory function. Judicious use of nasogastric suctioning should prevent these problems. Once the ileus has resolved, it is important to initiate and maintain regimens of bowel regulation and retraining to prevent constipation and impaction and their undesirable effects.

The primary source of infection after SCI is the genitourinary tract. The bladder can also account for significant long-term disabilities consequent to associated renal damage if appropriate care is not taken early on. Because reflex micturition almost always begins within several days of injury, long-term Foley catheterization is discouraged in favor of intermittent catheterization. Prophylactic antibiotics are not indicated, and bladder re-education should begin promptly.

Attention to skin care is vitally important. Immobility and lack of sensation predispose to skin breakdown. Prolonged pressure over bony prominences must be avoided. Pressure reduction can only be accomplished by frequent turning.⁸⁴

Considerable disagreement exists regarding the place of surgery after SCI and, should surgical treatment be decided upon, what should be done and when.

General agreement exists as to the necessity for immediate immobilization and early stabilization of fractures and dislocations of the spine. Immobilization and early stabilization can be accomplished without surgical intervention (i.e., with external orthoses such as the halo) in over 60% of SCI cases. The timing and method of internal surgical stabilization are points of controversy. The single widely accepted indication for acute surgical intervention is documented neurological deterioration in association with ongoing spinal cord compression from bone and disc fragments, hematoma, or unreduced subluxation. Nevertheless, the presence of an incomplete SCI with persistent spinal cord deformity and presence of complete SCI when the perceived possibility exists for recovering some neurological function have been advocated as rationales for early aggressive surgical intervention.¹²⁻¹⁴

Oral and injectable diazepam, baclofen, dantrolene, and clonidine are helpful for the treatment of spasticity. When these medications are inadequate, other treatments include motor point blocks with phenol, botulinum toxin injections, and intrathecal perfusion with baclofen or morphine. Central deafferentation pain may respond to treatment with tricyclic antidepressants, valproic acid, carbamazepine,

Figure 51-10. Frequency of acute complications after spinal cord injury. MI, myocardial infarction; PE, pulmonary embolus. (From American Spinal Injury Association: Standards for Neurological and Functional Classification of Spinal Cord Injury, Revised 1992, p 278.)

mexiletine, and intrathecal morphine. Occasional patients may be helped by surgical approaches such as dorsal root entry zone lesions and implantation of a dorsal column stimulator.

PROGNOSIS AND FUTURE PERSPECTIVES. It is important to attempt to quantify the natural history of the degree and extent and time course of neurological recovery after SCI to prognosticate function, determine the effectiveness of various interventions, and develop a comprehensive rehabilitation plan.

Waters and coworkers⁸⁵ reported a study of 148 patients with complete SCI followed for 5 years with annual examinations using the ASIA scoring system. Very little, if any, significant recovery was documented after 1 year of follow-up. In these patients, however, 18% had at least one level of improvement at 1 year in their neurological level of injury and 7% had two levels of improvement. Ditunno and coworkers⁸⁶ undertook a study to determine the recovery of key muscles of the upper extremities in motor-complete quadriplegics. One hundred fifty patients were followed for 24 months. Recovery persisted in muscles with no initial motor power from the ninth to twenty-fourth months, with ultimately 64% achieving some increased function. The recent National Acute Spinal Cord Injury Study found a plateauing of recovery between 6 and 12 months after injury.^{83,84} If an athlete suffers an SCI, return to any level of competition is medically precluded. Risks to the individual from other less severe spinal injuries are debated, however. In general, any injury that necessitates internal surgical spinal stabilization probably obviates return to contact sports. More minor injuries that heal correctly with bracing may not limit athletic involvement.⁸⁷

WHIPLASH INJURIES

The term *whiplash* refers to the mechanism of the neck injury, which can result from hyperextension followed by flexion that occurs when an occupant of a motor vehicle is hit from behind by another vehicle. Some clinicians use the term to also describe other types of collisions wherein the neck is subjected to different sequences and combinations of flexion, extension, and lateral motion. The term was first used in 1928. Other terms used include cervical sprain, cervical myofascial pain syndrome, acceleration-deceleration injury, and hyperextension injury.^{88,89}

PATHOGENESIS AND PATHOPHYSIOLOGY. Animal and human studies have demonstrated structural damage, including muscle tears, rupture of ligaments, avulsions and herniations of intervertebral discs, retropharyngeal hematoma, nerve root damage, cervical sympathetic chain injury, and hemarthrosis of facet joints.

EPIDEMIOLOGY AND RISK FACTORS. In 2004, there were 10,900,000 motor vehicle accidents, including 3,330,000 rear-end collisions, in the United States. Although neck injuries can commonly occur after side or front impact collisions, rear-end collisions are responsible for about 85% of all whiplash injuries. More than 1 million people sustain whiplash-type injuries per year in the United States. Women have persistent neck pain more often than men, especially women in the 20- to 40-year age group, by a ratio of 7:3. The greater susceptibility of women to whiplash injuries may be due to a narrower neck with

less muscle mass supporting a head of roughly the same volume compared with men.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Following a motor vehicle accident with a whiplash-type mechanism of injury, 62% of patients presenting to the emergency room complain of pain. The onset of pain is within 24 hours in 93% of the injured. The most common cause of the neck pain is myofascial injury. Cervical disc herniations, cervical spine fractures, and dislocations are uncommon. Cervical facet joint injury can also be a source of pain.⁹⁰

Eighty percent of patients with whiplash-type injuries complain of headaches during the first 4 weeks after the accident. The headaches are usually of the muscle contraction type and are often associated with greater occipital neuralgia. Whiplash trauma can also injure the temporomandibular joint and can cause jaw pain often associated with headache. Headache may be referred from the C2–C3 facet joint that is innervated by the third occipital nerve. Occasionally, whiplash injuries can precipitate new migraine with recurring episodes including classic migraine with aura, migraine attacks without aura, and basilar migraine.

Dizziness is a common complaint and can be due to dysfunction of the vestibular apparatus, cervical proprioceptive system, brain stem, and cervical sympathetic nerves.

Paresthesias of the upper extremities can be referred from trigger points, brachial plexopathy, facet joint disease, entrapment neuropathies, cervical radiculopathy, and spinal cord compression. Thoracic outlet syndrome, which occurs four times more often in women than men, is a common cause of paresthesias, which often radiate down the ulnar arm and forearm into the fourth and fifth fingers. Eighty-five percent of these cases are of the non-neurogenic type with subjective complaints but no objective findings.

Cognitive impairment due to a whiplash injury without direct head trauma is a controversial topic with evidence for and against.⁹¹

Interscapular pain and low back pain are frequent complaints after whiplash injuries and are reported in 20% and 35% of patients, respectively, after the injury. Visual symptoms, especially blurred vision, are often reported by patients and are usually due to convergence insufficiency, although oculomotor palsies can occasionally occur (Video 32, Cranial Nerve III Palsy). Rare sequelae include cervical dystonia or torticollis, transient global amnesia, esophageal perforation and descending mediastinitis, hypoglossal nerve palsy, cervical epidural hematoma, superior laryngeal nerve palsy, and internal carotid and vertebral artery dissections (Video 52, Torticollis).

DIFFERENTIAL DIAGNOSIS. Whenever patients have pain complaints without objective findings, nonorganic explanations should be considered. Other possible causes of pain complaints after whiplash injuries include psychological problems, secondary gain and malingering in cases in which litigation is pending, and social and peer copying.^{92,93}

EVALUATION. A cervical spine MRI study is helpful to evaluate patients with persistent complaints of neck pain and paresthesias or those with abnormal results on examination. When radiographical abnormalities are present, the possibility that they are pre-existent should be considered.

Cervical spondylosis, degenerative disc disease, and cervical disc protrusions occur with increasing frequency with older age and are often asymptomatic.

MANAGEMENT. Neck pain is often treated initially with ice, then with heat, nonsteroidal anti-inflammatory drugs, muscle relaxants, and pain medications. Use of soft cervical collars should be kept to a minimum during the first 2 to 3 weeks and then avoided. Range-of-motion exercises, physical therapy, trigger point injections, and TENS units may be helpful for patients with persistent complaints. Percutaneous radiofrequency neurotomy may be beneficial for the treatment of chronic facet joint pain documented by anesthetic blocks.⁹⁴

PROGNOSIS AND FUTURE PERSPECTIVES. Neck pain and headaches can persist for months and sometimes years in a minority of patients. According to various studies, neck pain and headache, respectively, have been reported as persisting for the following intervals after the accident^{95,96}: 1 month, 64% and 82%; 3 months, 38% and 35%; 1 year, 19% and 21%; and 2 years, 16% and 15%. Psychosocial factors and personality traits are not predictive of the duration of symptoms. Risk factors for more severe symptoms include older age, female gender, a rear-end collision, and a rotated or inclined head position at the moment of impact. Despite the common belief that pending litigation is responsible for persistent symptoms, litigants and non-litigants have similar psychological profiles and similar recovery rates. Most patients who are still symptomatic at the time when litigation is settled are not cured by a verdict.

BRACHIAL AND LUMBOSACRAL PLEXOPATHIES

PATHOGENESIS AND PATHOPHYSIOLOGY. Trauma can result in variable injury to the myelin, axon, and connective tissue covering of plexus elements. Mild injuries may result in focal demyelination with conduction slowing. More severe injuries may cause demyelinating conduction block (neurapraxia), which can occur alone or in association with axon degeneration. Axonotmesis, which is loss of the relative continuity of the axon and myelin but preservation of the connective tissue framework, leads to Wallerian degeneration. *Neurotmesis* refers to an injury in which the axons and investing connective tissues lose their continuity. A combination of different grades of injury can occur. An axonal nerve injury in continuity may heal as a neuroma that consists of axons growing in all directions surrounded by connective tissue. Root avulsion is the traumatic separation of a nerve root from the spinal cord.⁹⁷

EPIDEMIOLOGY AND RISK FACTORS. Closed lesions usually resulting from traction are the most common causes of traumatic brachial plexopathy. Stretch injuries are responsible for about 70% of serious brachial plexus injuries. High-velocity closed injuries, which usually involve the supraclavicular plexus, are primarily due to motor vehicle accidents, occupational injuries, and falls. Falls, which result in scapular and proximal humeral fractures and humeral head dislocations, are the most common causes of infraclavicular injuries. Brachial plexus injury, usually involving the lower trunk or medial cord, occurs in 5% of patients undergoing coronary artery bypass surgery. Brachial plexus injury is probably due to traction

associated with sternal retraction.⁹⁸ Most brachial plexus avulsion injuries are due to motor vehicle accidents, especially motorcycle accidents; industrial accidents; obstetrical injury; falls; objects falling on the shoulder; and sports injuries (most commonly football, bicycling, skiing, and equestrian activities). Root avulsions more commonly involve the C7, C8, and T1 roots, whereas extraforaminal ruptures more commonly affect the C5 and C6 roots.

The less common open lesions, which most often affect the infraclavicular plexus, are often associated with injuries to major limb vessels and the lung. Gunshot wounds, which account for 25% of the cases of surgical repair of the brachial plexus in the United States, usually involve the infraclavicular or retroclavicular plexus and less often the supraclavicular plexus. Laceration injuries of the brachial plexus are usually the result of broken glass and knives.

Injury to the lumbosacral plexus is uncommon because it is protected by the pelvic bony ring. Pelvic fractures, which are usually due to motor vehicle accidents, crush injuries, and falls from a height, result in lumbosacral plexus injury in about 7% of cases.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Plexus injuries can result in sensory loss, paresthesias, motor loss, and pain, which can be particularly severe after root avulsions. A detailed knowledge of the anatomy of the brachial and lumbosacral plexus is essential to localizing lesions (see Chapters 15, 19, and 20).

Burners and *stingers* are synonymous terms that refer to the radicular and plexus symptoms following sudden depression of the shoulder in contact sports, usually football. The player experiences burning dysesthesias going down the ipsilateral upper extremity, often into the thumb, and sometimes weakness of the biceps and shoulder girdle muscles. The symptoms usually resolve within a few minutes, although occasional cases last for weeks.

Other causes of acute compression of the brachial plexus include the following: prolonged compression in someone inebriated or comatose; compression of the plexus against the first rib due to heavy backpacks carried by students or soldiers; prolonged firing of shotguns or rifles; and shoulder restraints in motor vehicles. In addition to coronary artery bypass surgery, other intraoperative causes of plexus injury include malpositioning of the arm, often affecting the upper plexus; damage during other procedures such as radical mastectomies, transaxillary arterial bypasses, and biopsies; orthopedic procedures on the humerus or shoulder; and ironically, first rib resections and scalenotomies performed to treat thoracic outlet syndrome.⁹⁸ False aneurysms of the axillary artery due to trauma and hematomas from transaxillary percutaneous angiograms can also injure elements of the plexus. Stretch injuries of the plexus in neonates, often resulting from shoulder dystocia, most commonly involve the upper trunk (Erb's palsy) and only occasionally the lower trunk (Klumpke's palsy).

Repetitive activity such as working at a keyboard or playing a musical instrument and single injuries such as a fall or whiplash-type injury commonly result in the non-neurogenic type of thoracic outlet syndrome. Patients may complain of aching of the shoulder and arm with paresthesias going down the arm into the fourth and fifth fingers. The symptoms may be worse at night, with

repetitive activity, or with use of the arm overhead. Although they are nonspecific causes, medial supraclavicular palpation and the exaggerated military posture may reproduce the symptoms. Most of the patients are women; long necks, droopy shoulders, and pendulous breasts may be contributing factors. No objective findings appear on examination or electrodiagnostic studies.⁹⁷

In addition to pelvic fractures and gunshot wounds, there are other important causes of lumbosacral plexus injury. During labor and delivery, pressure on the lumbosacral trunk by the fetal head or forceps may result in a postpartum footdrop. Ischemic injury of the plexus can result from inadvertent injection of drugs into the gluteal arteries, leading to a propagating thrombus to the iliac arteries. Blunt trauma to the abdomen can rarely result in a retroperitoneal hemorrhage into the psoas muscle, which compresses the lumbar plexus, causing pain and extremity weakness. Neuromas may form after partial or complete injuries to peripheral nerves. The only neuromas that are symptomatic are those that contain sensory nerve fibers. Sensory nerves of the hands and feet are especially likely to form painful neuromas. Symptomatic neuromas produce a burning or aching pain that may radiate proximally or distally. Tinel's sign may be present. The diagnosis can be confirmed by temporary relief of symptoms after injection of local anesthetic. Injection of a corticosteroid may significantly improve or cure symptoms in some cases. Various surgical approaches such as nerve grafting, decompression and translocation, excisional neurectomy, and transposition may be appropriate, depending on the case.⁹⁹

DIFFERENTIAL DIAGNOSIS AND EVALUATION. Cervical and lumbosacral disc herniations and peripheral nerve injuries should be considered. The clinical examination can often localize the lesion as pre- or postganglionic or to various elements of the plexus. For example, the presence of Horner's syndrome indicates lesions of the roots of C8 and T1 proximal to the site where the white rami communicans exits to enter the sympathetic chain. Depending on the specific injury, various imaging techniques including plain radiographs, CT and MRI scans, arteriography, venography, and myelography may be indicated.¹⁰⁰ Pseudomeningoceles, which are formed when a nerve root is avulsed and the meninges are pulled through the neural foramina, may be detected on myelography, followed by CT scan as well as MRI. Electromyography (EMG) and nerve conduction studies can be helpful in localizing and determining the extent of the lesion.

MANAGEMENT. Management depends on the location of the lesions, the grade of nerve injury, and the presence of root avulsions. Patients with acute transections of the brachial plexus due to lacerations with a knife or glass should undergo relatively rapid primary repair. For closed stretch injuries with severe axonal degeneration present on electrophysiological studies 3 to 5 months after the injury, surgical exploration and repair are indicated.¹⁰¹ Because missile wounds usually leave the nerve in continuity, initial management is often conservative. Although avulsion of nerve roots has been regarded as an untreatable injury, animal and experimental human studies suggest that implantation of ventral roots into the spinal cord may lead to recovery of motor function especially with use of neurotrophic factors.¹⁰²⁻¹⁰⁴

Up to 80% of patients with obstetrical palsy have no paresis or mild paresis by the age of 1 year. Surgery for infants with obstetrical palsy not improving is controversial, with recommendations for the time of surgery ranging from 3 to 9 months of age. Non-neurogenic thoracic outlet syndrome may respond to Peet's exercises, which strengthen the muscles of the pectoral girdle and improve posture. In very occasional cases, scalenotomy or first rib resection may be indicated. Physical and surgical rehabilitation may help to improve function after brachial plexus injuries.

Pain following brachial plexus injuries may be difficult to manage with various treatments depending upon the type and severity of the pain. Treatments range from pain pills, anticonvulsants, and TENS units to stellate ganglion blocks and sympathectomy, dorsal column stimulators, and dorsal root entry zone lesions. Similar considerations apply to lumbosacral plexus injuries. When indicated, surgery may be helpful in some cases of pelvic fractures, gunshot wounds, stab wounds or lacerations, and iatrogenic injuries.

PROGNOSIS AND FUTURE PERSPECTIVES. In cases of neurapraxia, spontaneous recovery may occur within 3 to 4 months of the injury. Because of the long regeneration distances and lack of collateral sprouting, the intrinsic hand muscles with lower trunk lesions and the muscles below the knee with sacral plexopathies reinnervate poorly after severe axon loss lesions. For severe brachial plexus lesions, satisfactory results may occur postoperatively in up to 70% of patients after primary repair and up to 48% after a nerve graft. Fifty percent to 85% of patients with non-neurogenic thoracic outlet syndrome may improve with exercises.¹⁰³

COMPLEX REGIONAL PAIN SYNDROME (REFLEX SYMPATHETIC DYSTROPHY AND CAUSALGIA)

In 1864, the Philadelphia neurologist S. Wier Mitchell and colleagues reported the cases of Union soldiers who sustained gunshot wounds at the battle of Gettysburg resulting in partial nerve lesions of the brachial plexus and peripheral nerves followed by a severe burning pain of the hand or foot associated with trophic changes.¹⁰⁵ Mitchell coined the term *causalgia*, which is from the Greek for "burning pain," to describe this syndrome. In 1995, a consensus development conference grouped these disorders under the term complex regional pain syndrome (CRPS) type I (corresponding to reflex sympathetic dystrophy) and type II (formerly termed *causalgia*).¹⁰⁶

PATHOGENESIS AND PATHOPHYSIOLOGY. The pathophysiology of CRPS is poorly understood. Various mechanisms proposed include the following: sympathetic hyperactivity, ephaptic transmission between sympathetic and primary afferents, a reverberating circuit in the spinal internuncial pool, sensitization of wide dynamic range neurons in the dorsal horn, and neurogenic inflammation. Despite common perception and former nomenclature, some researchers strongly argue that the sympathetic nervous system is not involved.¹⁰⁷

EPIDEMIOLOGY AND RISK FACTORS. CRPS II may occur in up to 5% of patients after partial peripheral nerve

injury, but it does not occur when a nerve is completely severed. The incidence of CRPS I is 1% to 2% after various fractures but is particularly common following Colles' fracture, occurring in about 30%. CRPS I may occur after various other injuries, including minor soft tissue trauma, operations such as carpal tunnel release and arthroscopic knee surgery, myocardial and cerebral infarction, and frostbite and burns. In up to 25% of CRPS I cases, a precipitant cause is not identified. CRPS I occurs in all ages with a median of 40 years. Females account for about 70% of cases.

CLINICAL FEATURES AND ASSOCIATED DISORDERS.

CRPS I is a syndrome with variable major components of burning pain, autonomic dysfunction, edema, dystrophy and atrophy, and sometimes a movement disorder.¹⁰⁸ When this pain syndrome follows peripheral nerve injury, the term *CRPS II* is used. Various other terms for CRPS I are used in addition to reflex sympathetic dystrophy including Sudeck's atrophy, algodystrophy, post-traumatic dystrophy, reflex neurovascular dystrophy, shoulder-hand syndrome, and sympathetic maintained pain syndrome.

The symptoms of CRPS may develop within days to months after injury. The pain, which begins in the area of the injury or event, may then spread throughout the extremity and, in perhaps 5% of cases, involves the contralateral extremity (rarely, three and four extremities may become involved). The burning, aching, or constant pain is associated with hyperalgesia (lower pain threshold with enhanced pain perception), allodynia (pain induced by innocuous mechanical and thermal stimuli, especially cold), and hyperpathia (an exaggerated response to a stimulus, which may be delayed and may persist after cessation of the stimulus). Spontaneous paroxysmal shooting, sharp, or electrical sensations may be described. Decreased sensation may be present in affected areas. Proprioception may be limited. As in other pain disorders, CRPS I patients are often depressed and anxious.

Edema over the site of injury and distally may be present. At first, the involved extremity is usually warm, red, and dry but occasionally may be cold. Over time, the extremity usually becomes cool, pale, cyanotic, and hyperhydrotic. Early on, the nails may become thickened and the hair darker. Later, the hair may be lost in the affected areas, the skin may become shiny, and the nails may break. Dystrophy and atrophy of subcutaneous tissue, muscles, and bone may be present. Nodular fasciitis of the palmar or plantar skin may be present. CRPS I affecting the hand may be associated with a frozen shoulder.¹⁰⁹ Motor manifestations variably present include weakness, an enhanced physiological tremor, spasm and increased reflexes, focal dystonia, and an inability to initiate movement. Exercise or use may aggravate CRPS I complaints.

DIFFERENTIAL DIAGNOSIS. Other disorders that may have some features of CRPS I include chronic arterial insufficiency, thrombophlebitis, infection, collagen vascular disorders, postherpetic neuralgia, entrapment neuropathies (which can coexist with CRPS I), painful neuromas, plexopathies and radiculopathies, phantom limb pain, and central pain syndromes. When pain complaints are the major problem, psychological causes such as depression, factitious disorders, conversion, and malingering should be considered.

After amputation of an extremity, up to 85% of patients describe phantom limb pain, which may still be present in

about 30% 1 year later. The patients describe pain, which may be a continuous numbing or an intermittent sharp, stabbing, shooting, cramping, or burning sensation, as being present either in the stump or in the absent limb. Both peripheral and central mechanisms for the pain have been suggested, with one study showing evidence of plastic changes in the primary somatosensory cortex.¹¹⁰ Despite various medical and surgical treatments, the pain is often intractable.

EVALUATION AND MANAGEMENT. The diagnosis of CRPS is based on the symptoms and signs. Laboratory testing sometimes used includes thermography and a triple-phase bone scan (which may reveal abnormal uptake and increased periarticular uptake in 30% of patients); abnormal findings are not specific. Pain relief following sympathetic blockade or an intravenous phentolamine test is supportive of the diagnosis. The possibility of a placebo response should be considered.

The inciting disorder should be appropriately diagnosed and treated. Although many treatments have been proposed, there is a lack of prospective and controlled studies with controversy over inclusion criteria. Medications reported as useful include the following: narcotic and nonsteroidal anti-inflammatory drugs; adrenergic blockers such as clonidine and prazosin; tricyclic antidepressants; anticonvulsants such as carbamazepine and gabapentin; corticosteroids; topical DMSO cream; and intranasal calcitonin. Physical therapy modalities, rehabilitation, TENS units, and psychological treatment are often worth while. A series of five sympathetic anesthetic blocks of the stellate ganglion for upper extremity or lumbar chain for lower extremity cases can be beneficial. If the blocks improve the pain but only temporarily, many clinicians recommend sympathectomy. Dorsal column stimulators and morphine intrathecal pumps are sometimes recommended for refractory cases. Some patients with dystonia associated with reflex sympathetic dystrophy may respond to treatment with intrathecal baclofen. Recently spinal cord stimulation has been successfully used in the management of CRPS. These electrodes implanted over the posterior columns relieve pain, thereby allowing physical therapy, and activity to break the cycle of disuse.¹¹¹ Spinal cord stimulators were initially inspired by the gate control theory but their action clearly involves more than just modulation in the dorsal horns. While the exact mechanisms of pain relief by spinal cord stimulation are not known, the following have been proposed:

1. Orthodromic stimulation causing supraspinal pain modulation
2. Modulation of activity in the sympathetic system
3. Release of neuromodulators within the brain or spinal cord
4. Inhibition of transmission in the spinothalamic tract
5. Inhibition of C fibers in the substantia gelatinosa by antidromic conduction through A- β fibers

PROGNOSIS AND FUTURE PERSPECTIVES. Prognostic information is quite limited. Many clinicians believe that recovery occurs more frequently when treatment is begun early in the course. Pain may still be present in 25% of cases with CRPS I after 1 year and in 60% of patients with CRPS II after 3 years. Reported response rates for surgical

sympathectomy range from 12% to 97%. RSD may resolve early in the clinical course only to return weeks or months later.

MOUNTAIN SICKNESS

PATHOGENESIS AND PATHOPHYSIOLOGY. As the partial pressure of oxygen decreases with increasing altitude, ventilation rises, leading to respiratory alkalosis. Although hypocapnia alone results in cerebral vasoconstriction, hypoxia produces a net decline of cerebral vascular resistance and increased cerebral blood flow. Hypoxia can result in cerebral edema, which may be due to cerebral vasodilatation and elevated cerebral capillary hydrostatic pressure. An increase in sympathetic activity follows, causing an elevated heart rate, pulmonary vasoconstriction, and an initial increase and later decrease of cerebral blood flow.¹¹²

EPIDEMIOLOGY AND RISK FACTORS. Acute mountain sickness (AMS) develops in about 25% of visitors to moderate altitudes (6300 to 9700 feet). About 100 million tourists visit altitudes above 2000 meters worldwide per year. Symptoms usually occur within the first 12 hours of arrival but may be delayed 24 hours or more. Risk factors for AMS include those who are younger than 60 years, are less physically fit, live at sea level, have a history of AMS, are obese or female, or have underlying lung problems.¹¹³ AMS develops into high-altitude cerebral edema (HACE) in perhaps 1.5% of cases. Alcohol use inhibits acute ventilatory adaptation to mild hypoxia at moderate altitude and may be a risk factor.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. AMS, which usually occurs above 8200 feet, is defined by the presence of a headache and at least one of the following symptoms: gastrointestinal upset (anorexia, nausea, or vomiting), fatigue or weakness, dizziness or lightheadedness, and difficulty sleeping.¹¹⁴ The headache is usually bilateral but may be unilateral. HACE, which is uncommon below 12,000 feet, is defined by the presence of a change in mental status or ataxia in a person with AMS or the presence of both mental status change and ataxia in a person without AMS. HACE, which can lead to coma and death, may be associated with urinary incontinence, papilledema, cranial nerve palsies, tremor, and abnormalities in limb tone (Video 1, Cranial Nerve VI Palsy; Video 214, Stance Ataxia).

High-altitude pulmonary edema (HAPE), which can occur along with HACE, usually occurs above 9840 feet. High-altitude retinal hemorrhage is common in people who go above 15,000 feet.

EVALUATION AND MANAGEMENT. The diagnosis is usually a clinical one that is made in the setting of a recent altitude ascent. Altitude sickness may be prevented in those planning higher ascents by starting below 8000 feet, resting the first day, and then ascending about 1000 feet per day. Sleeping at a lower altitude at night may be helpful because hypoxia is worse with sleep. It is also important for climbers to keep well hydrated and avoid alcohol. Acetazolamide, at a dose of 250 to 500 mg twice daily starting 24 hours before ascent and continuing for 2 days, may prevent AMS and improve sleep. Other medications

which may reduce the risk and symptoms of AMS include the following: aspirin 320 mg 1 hour before arrival at high altitude and then one dose every 4 hours for two doses (for a total of three doses)¹¹⁵; and dexamethasone 2 mg every 6 hours or 4 mg every 12 hours orally starting 24 to 48 hours before arrival at high altitude and continuing for several days.

AMS may be treated symptomatically with rest, mild analgesics, alcohol avoidance, and adequate hydration. Depending upon the severity of symptoms, avoiding going any higher or slowing the rate of ascent or descent may be necessary. Acetazolamide 250 mg orally twice a day may also help acute symptoms. For HACE, immediate descent should be initiated if possible, and, if not, HACE may be treated with the use of a portable hyperbaric bag (2 to 4 psi for a minimum of 2 hours), administration of oxygen (2 to 4 L/minute), and dexamethasone (8 mg orally, IM, or IV initially and then 4 mg every 6 hours). Acetazolamide should be given in instances when descent or evacuation is delayed.

PROGNOSIS AND FUTURE PERSPECTIVES. AMS usually resolves after 16 to 72 hours at altitude. When descent is impossible and treatment is unavailable, HACE and HAPE have a mortality rate up to 50%.

DECOMPRESSION SICKNESS

PATHOGENESIS AND PATHOPHYSIOLOGY. With descent, the partial pressure of the gases breathed by the diver increases proportionately, according to Dalton's law. Although oxygen is metabolized, tissues soak up inert nitrogen and become saturated. With ascent, the nitrogen moves from the tissues to the blood and is exhaled by the lungs, which is a process termed *decompression*. When ascent is too rapid and the tissues are supersaturated, dissolved gas changes to free gas, which creates bubbles. When the filtering capacity of the pulmonary capillaries is exceeded, the bubbles enter the arterial circulation. Symptoms depend on those tissues in which the bubbles accumulate. Bubbles in the paravertebral veins, Batson's plexus, can result in stasis and venous infarction in the spinal cord. Cerebral injury can develop from bubbles occluding vessels or directly disrupting tissue. Symptoms may also result from secondary effects such as activation of complement, platelet aggregation, and release of vasoactive mediators.

EPIDEMIOLOGY AND RISK FACTORS. Decompression sickness (DCS), also referred to as *the bends* or *caisson disease*, usually affects divers and caisson workers but can also occur in pilots during rapid ascent in a nonpressurized cabin. About 900 cases of DCS are reported yearly in the United States among recreational scuba divers. Most accidents occur in inexperienced divers. The incidence of DCS for recreational divers is 1 per 5000 to 10,000 dives, and for commercial divers, one incident per 500 to 1000 dives. Up to 50% of cases of DCS occur in divers who claimed to have been diving within the limits set by a standard table or decompression computer. Divers with a patent foramen ovale are five times more likely to sustain serious decompression problems because bubbles can go directly from the right to left atrium without being filtered

by the lungs.¹¹⁶ Right-to-left shunts are more common in those with migraine with aura who are more likely to suffer DCS.¹¹⁷

CLINICAL FEATURES AND ASSOCIATED DISORDERS. DCS, which can occur after diving to a depth of more than 25 feet, usually appears within a few minutes to a few hours after the end of a dive. Mild DCS (type I) is defined by pain usually in the joints (bends) and itching of the skin. Serious DCS (type II) is characterized by neurological problems. Involvement of the thoracic spinal cord, the most commonly affected area, leads to low back or pelvic pain and dysesthesias, which may be accompanied by sensory loss, weakness, and incontinence. Less often, the brain may be involved, resulting in various symptoms and signs such as headache, confusion, lethargy, vertigo, speech disturbance, hemiparesis, visual impairment, and seizures, depending upon the site of the insult (Video 4, Pronator Drift).¹¹⁸

Rupture of alveoli, which may occur when a diver ascends without venting air from the lungs or from blockage of part of the bronchial tree, can result in additional arterial gas embolism. During ascent or shortly after surfacing, divers may develop various problems ranging from acute respiratory distress and headache to cardiorespiratory arrest and seizures. Depending on the site of embolism to the brain, cortical blindness, dysphasia, and hemiplegia may occur (Video 3, Spastic Gait). Arterial gas embolism and DCS may coexist.

EVALUATION AND MANAGEMENT. DCS is typically diagnosed based on the findings on history and physical examination. The results of MRI studies of the brain and spinal cord may often be normal or may show only nonspecific abnormalities in cases of DCS.¹¹⁸ Initially, high concentrations of oxygen should be administered by face mask to increase the resorption of gas bubbles. Fluid administration, ideally a hyperosmolar drink, may result in more rapid elimination of gases and treat dehydration. As soon as possible, the patient should undergo recompression in a hyperbaric chamber while breathing oxygen.¹¹⁹

PROGNOSIS AND FUTURE PERSPECTIVES. Prompt treatment usually results in a complete recovery. Neurological deficits may persist in patients in whom recompression is delayed or not done.¹²⁰

LIGHTNING AND ELECTRICAL INJURIES

PATHOGENESIS AND PATHOPHYSIOLOGY. Although incompletely understood, the two major causes of tissue damage are thermal injury and electroporation, which is the production and expansion of transient aqueous pores in the lipid bilayer component of the cell membrane.¹²¹

EPIDEMIOLOGY AND RISK FACTORS. About 100 lightning- and 1500 technical electricity-related deaths per year occur in the United States. The following routes can produce lightning injury. A direct strike is the most damaging, which is more common if the person is carrying a metal conductor such as an umbrella or golf club above shoulder level. A side flash or splash injury occurs when lightning first strikes a tall object such as a tree and then arcs to the person standing next to the object or when lightning first strikes a person or animal and then the second

victim. A ground or stride current occurs when lightning strikes the ground first and then travels along the surface before reaching the person. Occasionally, people can sustain injury indoors while on the telephone from current conducted through the lines or in the bath or shower from ground current traveling along the water pipes.

Technical electrical injuries can occur from exposure to high-voltage electricity (1000 volts or more) and low-voltage electricity. High-voltage electricity injuries, which are almost always work related, account for about 70% of electrical injuries and deaths. Low-voltage injuries typically happen in the home with the following common circumstances: the use of electrical appliances while standing on a wet floor or while in the bathtub, children playing with outlets or wires, or use of faulty electrical equipment. When the energized conductor is held in the hand, alternating current exposure in the range of 8 to 22 mA at 60 Hz may result in long exposure due to a state of tetanic contraction of flexor muscles of the forearm and hand, which is paradoxically termed *let go current*.¹²²

CLINICAL FEATURES, AND ASSOCIATED DISORDERS. Lightning and electrical injuries may result in sudden death or cerebral hypoxia from inducing ventricular fibrillation. Transient loss of consciousness, confusion, and amnesia may also occur.¹²³ Lightning injury may result in keraunoparalysis, which is a transient paralysis usually of the lower extremities associated with sensory loss and pale skin. Lightning and electrical injuries may also cause acute spinal cord, focal brain, and peripheral nerve damage and rhabdomyolysis. Deep burns are more common with electrical than with lightning injuries. Delayed neurological disorders associated with lightning and electrical injuries include cognitive deficits, motor neuron disease, parkinsonism, choreoathetosis, dystonia, myoclonus, basilar artery thrombosis, seizures, myelopathy, generalized polyneuropathy, and complex regional pain syndrome.^{124–126} An additional type of injury is secondary trauma, such as from falls.

MANAGEMENT, PROGNOSIS, AND FUTURE PERSPECTIVES. Evaluation and management depend on the sites, types, and extent of injury.¹²⁷ About one third of lightning strikes are fatal. The symptoms and signs of keraunoparalysis typically resolve within a few hours. Victims of lightning and electrical injuries who are comatose due to a hypoxic encephalopathy as a result of cardiac arrest usually have a poor prognosis. Most patients with spinal cord injuries due to lightning and electrical injuries have permanent disability.

HISTORY AND DEFINITIONS

Epilepsy, from the Greek *epilepsia* (a taking hold of or seizing), is a chronic disorder characterized by a spontaneous tendency for recurrent seizures. Seizures are the clinical manifestation of abnormally hyperexcitable cortical neurons. Whereas all patients with epilepsy have seizures, many more patients have a single seizure during life and are not considered to have epilepsy.

The earliest descriptions of epilepsy appear in Mesopotamian writings from the fifth millennium BC. Persons with epileptic seizures were believed to be possessed by demons or evil spirits, and as a result, the disorder became known as the *sacred disease*. In the book *On the Sacred Disease*, a collection of Hippocratic writings from around 400 BC, the notion that epilepsy was caused by the gods and should be treated by the invocation of supernatural powers was challenged. In these writings, epilepsy was described as a hereditary disease caused by an overflow of phlegm in the brain. Treatment interventions, including proper diet and hygiene, were suggested in lieu of superstitious remedies. Nevertheless, during the middle ages, the drinking of human blood, trephination, skull cauterization, and sterilization were routinely practiced to cleanse the body of evil spirits and reduce the likelihood of transmission.¹

By the eighteenth century, epilepsy became recognized as a chronic disorder of cerebral function. In the latter half of the nineteenth century, the British neurologist John Hughlings Jackson hypothesized that epilepsy was due to hyperexcitable cerebral gray matter. By correlating focal motor seizure semiology with postmortem pathological examinations, Jackson was the first to localize epileptogenic lesions. In 1886, the first surgery for epilepsy was performed by Sir Victor Horsley, who resected a traumatic cortical scar in a patient with focal motor seizures, rendering him seizure-free.

The invention of the electroencephalogram in 1929 had a profound impact on the diagnosis and classification of

the epilepsies. During the 1930s and 1940s, Wilbur Penfield and colleagues mapped the primary sensory and motor cortices in human subjects, advancing the concept of functional localization. In the past several decades, a universally accepted classification of epileptic seizures and syndromes emerged through advancements in electrophysiology, neuroimaging, and molecular biology.

Epilepsy affects 6 to 7 per 1000 population in the United States, and 40 to 50 new cases per 100,000 develop annually.² The risk of epilepsy increases from approximately 1% at birth through early adulthood to 3% by age 75 years. Epidemiologic studies indicate that the incidence of epilepsy increases sharply after the age of 60, exceeding that of other groups, including children. In two thirds of cases, the etiology is not identified.

BASIC MECHANISMS OF EPILEPTOGENESIS

To understand the mechanisms related to the development of epilepsy, some basic principles of normal neurophysiology must be reviewed. Electrical signals in neurons take two forms: the action potential, which propagates down the axon of the neuron from the soma to the axon terminal, translocating information within a neuron; and transmission of information between neurons, which is accomplished primarily by chemical synapses.

A complex series of events underlie these electrical signals. Central to the understanding of these events is that the neuronal membrane is semipermeable to different ions carrying electrical current. The neuronal membrane's permeability exhibits rapid changes that can dramatically alter the voltage across it. At the resting membrane potential, sodium ions (Na^+), which are concentrated in the extracellular space, flow into the cell, and intracellular potassium ions (K^+) flow out. A Na^+ - K^+ pump, utilizing adenosine triphosphate (ATP), replaces the displaced ions. Influx of positively charged ions (Na^+ and calcium ions [Ca^{2+}])

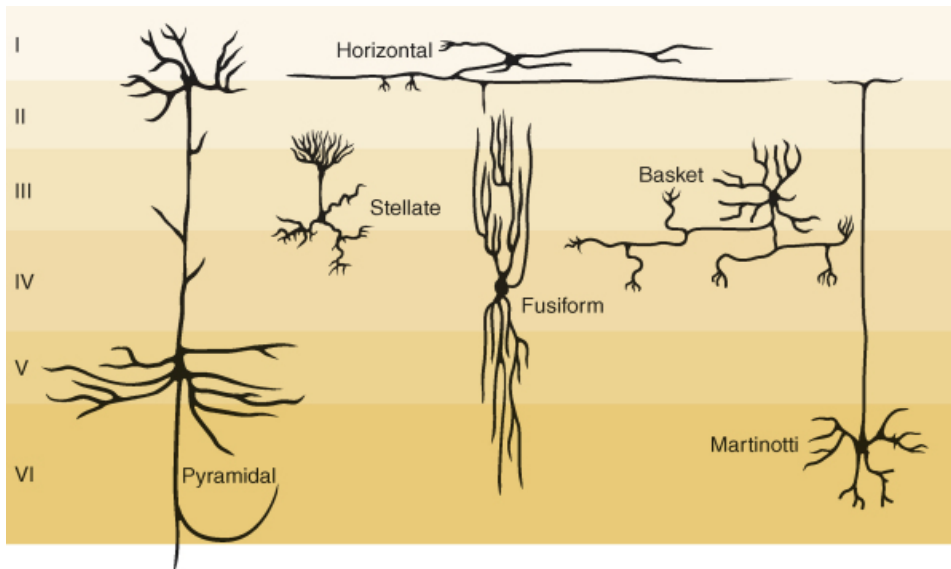

FIGURE 52-1. Types and orientation of neurons within the six-layer neocortex. (From Pansky B, Allen DJ: Review of Neuroscience. New York, Macmillan, 1980, p 287.)

raises the membrane potential in the direction of depolarization, whereas chloride ion (Cl^-) influx and K^+ efflux hyperpolarizes the membrane. When a cell membrane is depolarized to threshold, Na^+ channels open, allowing the ions to flow intracellularly, which produces an action potential. Potassium efflux from the cell leads to repolarization of the membrane. The propagation of action potentials along axons transmits information throughout the nervous system. When the presynaptic axon terminal is stimulated by an action potential, there is an influx of Ca^{2+} , triggering the release of neurotransmitters that bind to postsynaptic membrane receptors. This process produces excitatory and inhibitory postsynaptic potentials (EPSPs and IPSPs) whose summation and synchronization compose the electrical activity recorded from the surface electroencephalogram (EEG). Glutamate and aspartate are the primary excitatory neurotransmitters in the central nervous system. γ -Aminobutyric acid (GABA) is the major inhibitory neurotransmitter in the brain.

A number of cortical cytoarchitectural and anatomical factors influence the propagation of electrical activity. The cerebral cortex is subdivided into neocortex, paleocortex, and archicortex. The archicortex includes the hippocampus and dentate gyrus, and the paleocortex consists of the piriform and olfactory cortices. The neocortex constitutes the remaining cortical regions characterized by the infolding of gyri and sulci. Epilepsy is a disorder that affects neocortical and archicortical neurons and their interconnections with brain stem and diencephalic structures.

The gray matter of the neocortex contains six types of neurons: pyramidal, stellate, horizontal, fusiform, basket, and Martinotti's cells (Fig 52-1). The vertically aligned pyramidal cells are the main output neurons; they have extensive dendritic arborizations and excitatory synaptic endings that facilitate propagation of electrical activity. The granule, or stellate, cells are the major interneuronal pool. They are the second most numerous cells in the neocortex and are responsible for the propagation of both excitatory and inhibitory information. Axons of the horizontal and granule cells and collaterals of pyramidal and fusiform cells

traverse parallel to the surface of the cortex. Pyramidal, fusiform, stellate, and Martinotti's cell axons form radial networks that travel vertically as projection or association fibers.

Projection fibers are afferent and efferent fibers conveying impulses to and from the cortex. Efferent fibers arise from the cortex and descend through the corona radiata and internal capsule. Afferent fibers arise primarily from the thalamus and project via the internal capsule to all regions of the cortex. Fibers interconnecting various cortical regions within the same hemisphere are known as *association fibers*. These include three main bundles: the uncinate fasciculus, connecting the orbital frontal gyri with anterior portions of the temporal lobe; the arcuate fasciculus, connecting the superior and middle frontal gyri with parts of the temporal lobe; and the cingulum, connecting medial regions of the frontal and parietal lobes with parahippocampal and adjacent temporal cortical regions. Commissural fibers interconnect corresponding cortical regions of the two hemispheres and are represented by the corpus callosum and the anterior commissure. These pathways are important in the relay of information between hemispheres.

The pathophysiology of epilepsy involves alterations of normal physiological processes. An epileptic seizure is produced by synchronous and sustained firing of a population of neurons in the brain. The behavioral manifestations of a seizure reflect the function of the cortical neurons involved in the generation and spread of abnormal electrical activity. Epileptogenicity refers to the excitability and synchronization of neuronal networks that produce epileptiform activity in the brain. Both excitatory and inhibitory influences may be altered, creating a predisposition to excessive synchrony within neuronal populations.

Differences exist between patients who experience a single seizure and those with a tendency for recurrent seizures. Single seizures have various causes, including electrolyte disturbances, drugs, and toxins. Increased extracellular K^+ leading to regenerative hyperexcitability underscores seizures that accompany metabolic aberrations. In hyponatremia, the extracellular space shrinks, leading to an increased concentration of extracellular K^+ and increased nonsynaptic

or ephaptic coupling. This rise in K^+ facilitates neuronal firing. Similarly, because membrane excitability varies inversely with the extracellular concentration of Ca^{2+} , hypocalcemia can contribute to the synchronization and spread of abnormal electrical activity. Other metabolic disturbances such as hypomagnesemia, hyperglycemia, hypoxia, and ischemia can also produce seizures.

Alterations of neurotransmission, the ionic milieu, neuronal morphology, and neuronal networks are instrumental in the production of recurrent unprovoked seizures. Animal models using maximal electroshock and chemoconvulsants such as pentylenetetrazol have been used for decades to investigate the pathophysiology of generalized and focal seizures.

Experimentally induced focal epilepsies have been produced by the application of topical metals, such as cobalt, aluminum, and iron, to the sensorimotor cortex. Pathological examination of these lesions reveals gliosis and neuronal loss. Neurons in the surrounding area may demonstrate abnormal dendritic morphology, including denuded spines and reduced branching. Iron salts applied or injected into the cortex of experimental animals have been used in the investigation of post-traumatic epilepsy. Although the precise mechanisms of iron-induced epilepsy are unclear, iron is known to bind strongly with ATP and inhibit $Na^+-K^+-ATPase$ activity, leading to neuronal hyperexcitability. Additionally, iron reacts with the neuronal cell lipid membrane, producing free radicals and resulting in lipid peroxidation.

The kindling model is currently used in the study of partial epilepsy, particularly that involving the mesial temporal structures. *Kindling* refers to the processes that mediate long-lasting changes in brain function in response to repeated, gradually augmented stimulation of the brain. In the kindled animal, there is a permanent state of enhanced seizure susceptibility. These models are important not only in the understanding of the pathophysiological basis of epilepsy, but also in the screening of new compounds that may have anticonvulsant activity.

The structures most susceptible to the development of recurrent seizures include the motor cortex and the hippocampal formation and amygdaloid complex of the limbic system. The motor cortex comprises three areas: primary motor cortex, premotor cortex, and supplementary motor area. The motor cortex exerts its control by way of descending corticospinal and corticobulbar tracts and pathways originating in the brain stem. The motor cortex receives input from the thalamus, parietal lobe, and prefrontal cortex. These afferents allow seizures arising in restricted areas to propagate diffusely.

The amygdaloid complex (see Chapter 3) is an aggregate of subcortical nuclei within the rostral pole of the mesial temporal lobe having reciprocal interconnections with the septal area, hypothalamus, and brain stem nuclei. The hippocampal formation extends along the floor of the temporal horn of the lateral ventricle and comprises the dentate gyrus, hippocampus proper (CA fields), and the subicular complex (see Chapter 5). Hippocampal or mesial temporal sclerosis is characterized by variable degrees of pyramidal cell loss and gliosis in the hippocampal subfields and dentate gyrus. This condition represents the most common pathological substrate of partial epilepsy in adolescents and adults.

The notion that epilepsy is an inherited disorder was suggested more than 2000 years ago. The prevalence of epilepsy in relatives of affected individuals ranges from 0.5% to 15%.³ Rates are higher in idiopathic than symptomatic epilepsies. Studies of twins have demonstrated concordance rates as high as 70% in monozygotic and 10% in dizygotic pairs,³ implying that factors other than genetics play a role in the occurrence of seizures in these groups. However, several epilepsy syndromes are caused by mutations in single genes including benign familial neonatal convulsions, generalized epilepsy with febrile seizures, autosomal dominant nocturnal frontal lobe epilepsy, absence epilepsy, and multiple forms of myoclonic epilepsy.⁴ Most of the recently identified epilepsy-associated genes encode ion channels. Additionally, as the result of metabolic abnormalities, tumor formation, or impairment of normal brain growth or differentiation, epilepsy is also a common manifestation of a large group of inherited neurologic disorders.

EPILEPTIC SEIZURES

Efforts to classify epileptic seizures date back to the earliest of medical literature. In 1964, the Commission on Classification and Terminology of the International League Against Epilepsy proposed the first official classification of epileptic seizures, which was revised in 1981.^{5,6} Based on this classification, seizures are divided into *focal*, those in which the first clinical and electrographic manifestations indicate initial activation of a limited population of neurons in part of one hemisphere, and *generalized*, those in which the initial manifestations suggest initial activation of neurons throughout both hemispheres. Focal seizures are further subdivided into *simple* and *complex*, based on level of consciousness. Seizures in which consciousness is preserved are referred to as *simple partial seizures*. Those in which consciousness is impaired are classified as *complex partial seizures*. Secondly generalized seizures are generalized seizures preceded by focal clinical or electrographic manifestations that occur in patients with focal epilepsy. The revised classification uses seizure semiology and EEG features to establish whether seizures are focal or generalized. For example, a seizure characterized by staring and loss of awareness is classified as *absence* when generalized spike-wave complexes are noted on the EEG, and as *complex partial* when associated with focal epileptiform discharges. This classification is currently under revision. Debate continues regarding terminology and the classification of seizures in infants and neonates.

The following discussion describes the clinical semiology of the various types of seizures. A later section describes epilepsy syndromes, which are characterized by combinations of seizure types and clinical, historical, and electrographic manifestations.

Generalized Seizures Tonic-Clonic Seizures

Tonic-clonic seizures (TCS) are the most common type of seizure encountered in childhood, adolescence, and adulthood. The manifestations of generalized TCS can be

divided into several phases beginning with vague prodromal symptoms that may occur hours to days before the actual convulsion. Common premonitory symptoms include headache, mood change, anxiety, irritability, lethargy, changes in appetite, dizziness, and lightheadedness. The tonic phase may be preceded by a series of brief, bilateral muscle contractions lasting a few seconds. The tonic phase begins with brief flexion of the trunk, accompanied by upward deviation of the eyes, mydriasis, and a characteristic vocalization as contraction of abdominal muscles produces forced expiration across a spasmodic glottis. This process is followed by a period of generalized extension lasting 10 to 15 seconds. With evolution of the clonic phase, tonic contractions alternate with periods of muscle atonia of gradually increasing duration until contractions cease. The seizure terminates with a final generalized tonic spasm. Loss of consciousness and autonomic alterations occur during the tonic and clonic phases. Secondarily, generalized seizures may be preceded by focal or lateralized clinical behaviors such as involuntary jerking of an extremity or head version before the onset of bilateral motor manifestations. Similarly, focal weakness of an extremity during the postictal state (Todd's paralysis) indicates seizure origin from the contralateral hemisphere. TCS commonly produce hypocarbia, owing to a combined respiratory alkalosis and lactic acidosis, transient hyperglycemia, mild cerebrospinal fluid (CSF) pleocytosis, and elevated serum prolactin. The immediate postictal state is characterized by coma that is gradually replaced by a confusional state. Once consciousness is regained, lethargy, myalgia, and headache are often reported. Most TCS are less than 1 minute in duration. Potential complications include oral and head trauma, vertebral body stress fractures, aspiration pneumonia, pulmonary edema, and death.

Generalized TCS occurring in patients with idiopathic generalized epilepsies are associated with normal background activity and bilaterally synchronous and symmetrical spikes, polyspikes, or spike-wave complexes on the interictal EEG. Secondarily generalized TCS are usually associated with background abnormalities and focal or lateralized slowing and epileptiform activity. During the tonic phase of a TCS, generalized low-amplitude 20- to 40-Hz activity evolves into a bilaterally synchronous and symmetrical 10-Hz rhythm, which is referred to as the *epileptic recruiting rhythm*. Generalized polyspikes interrupted by slow waves characterize the clonic phase. The postictal period is characterized by generalized suppression or low-amplitude slow activity.

Experimental animal models using systemic chemoconvulsants and maximal electroshock provide some insight into the neuronal structures involved in the production of TCS. Lesions involving the pontine reticular formation produce the tonic phase in several animal models. Involvement of forebrain structures is required for the production of clonus, suggesting that an interaction of brain stem and neocortical structures takes place. These findings, however, have not been confirmed in humans.

TCS are observed in patients with idiopathic and symptomatic epilepsies and in association with systemic disease.⁷ Hyponatremia, hypoglycemia, alcohol withdrawal, and drugs are common causes of isolated seizures particularly in hospitalized patients. Drugs that may precipitate

TCS include tricyclic antidepressants, antipsychotics, anticholinergics, antihistamines, methylxanthines, antibiotics, and withdrawal from barbiturates and benzodiazepines. The prognosis for patients with idiopathic generalized TCS is better than that for those with focal or secondary generalized seizures (Video 74, Secondary Generalized Seizure), which tend to persist if untreated. The remission rate is greatest in patients who develop TCS in childhood in the absence of other seizure types.

Tonic, Atonic, and Clonic Seizures

Tonic and atonic seizures are clinically distinct, although they are often present in the same patient. Tonic seizures are characterized by sustained, nonvibratory contractions of axial musculature, usually involving flexion of the upper extremities and flexion or extension of the lower extremities (Video 79, Tonic/Atonic Seizure). Impairment of consciousness and autonomic alterations occur, but to a lesser extent than in TCS. Seizures last typically less than 10 seconds, but they may be as long as 1 minute in duration. Tonic seizures are typically abrupt in onset and are followed by a rapid return to baseline. Seizures commonly occur in clusters during drowsiness and non-rapid-eye-movement (non-REM) sleep, frequently occurring dozens of times per day. Tonic seizures during wakefulness commonly produce injuries owing to sudden, unexpected falls. The interictal EEG typically shows a poorly organized background with generalized spike-wave discharges of less than 3.0 Hz (slow spike-wave complexes) or focal or multifocal spikes and sharp waves. Ictal patterns include generalized attenuation, known as an *electrodecremental response*, low-voltage fast activity (15 to 25 Hz), high-amplitude 10-Hz rhythms, and generalized theta or delta activity.

The pathophysiology of tonic seizures is poorly understood. Lesions of brain stem nuclei produce the tonic phase of TCS and are implicated in the generation of tonic seizures as well. Other animal studies have suggested that discharges in the reticular gray matter caudal to the thalamus may produce EEG desynchronization, autonomic phenomena, and tonic seizures. Tonic seizures are typically observed in children with symptomatic generalized epilepsy, such as Lennox-Gastaut syndrome. Prolonged tonic seizures may be mistaken for generalized TCS, decerebration, paroxysmal dystonia, convulsive syncope, and the tonic spasms seen in patients with neurodegenerative disorders such as multiple sclerosis. Tonic seizures arising from the supplementary motor area are characterized by bilateral electrographic manifestations on surface EEG, although motor activity is asymmetrical and consciousness is usually preserved.

Atonic seizures, or drop attacks, are characterized by abrupt loss of postural tone lasting 1 to 2 seconds. Consciousness is usually impaired, although recovery is rapid. Seizures may be limited to head and neck musculature producing a head drop, or they may involve all postural musculature resulting in sudden unexpected falls and injuries. The loss of tone may be preceded by a series of myoclonic jerks. The terms *atonic* and *astatic* are not synonymous. The latter refers to loss of erect posture resulting in a fall, which may occur with atonic, tonic, and myoclonic seizures. Like tonic seizures, atonic seizures are observed in

FIGURE 52-2. 3.0-Hz spike-wave complexes during a seizure in a child with absence epilepsy.

neurologically abnormal children with symptomatic generalized epilepsy syndromes. Atonic seizures may be mistaken for breath-holding spells, syncope, and cataplexy. The ictal EEG demonstrates polyspike-wave or spike-wave discharges. More prolonged seizures may be accompanied by generalized spike-wave discharges followed by diffuse generalized slowing that is maximal at the vertex and central regions. This slow wave activity can be accompanied by severe, generalized hypotonia. Postictal changes are not prominent. With no experimental animal models available, the pathophysiology of atonic seizures is poorly understood. Because corpus callosotomy is effective in some patients with atonic seizures, interhemispheric mechanisms are suspected.

Generalized clonic seizures are rare and are usually seen in children with febrile illnesses (Video 77, Clonic Seizure). These seizures are characterized by an abrupt loss of consciousness with hypotonia or a generalized tonic spasm, followed by a series of myoclonic jerks. Motor involvement may be asymmetrical, migratory, or focal. Significant autonomic changes and postictal confusion usually do not occur. Clonic seizures may be mistaken for TCS, when the onset is not observed, and myoclonic seizures when the phenomenology of the movement is more arrhythmic and random. In addition, nonepileptic clonic jerks may be seen in syncope and breath-holding spells and during the recovery phase of cataplexy. The interictal EEG in patients with clonic seizures reveals generalized spike- or polyspike-wave discharges. Seizures are accompanied by a generalized 10-Hz rhythm intermixed with slow waves of variable frequency. As in TCS, neocortical structures are implicated in the generation of clonic seizures.

Absence Seizures

Absence seizures (AS) are subdivided into typical and atypical forms. Typical AS are characterized by sudden behavioral arrest and unresponsiveness that may be accompanied by eyelid or facial clonus; automatisms; and autonomic, tonic, or atonic features (Video 75, Absence Seizure). The duration rarely exceeds 10 seconds, and no aura or postictal state is observed. Atypical AS generally

exceed 10 seconds in duration, begin and end more gradually, and produce less marked alteration of consciousness. Tonic, atonic, and myoclonic features are commonly observed.

Brief AS without automatisms or motor features may be mistaken for daydreaming or inattention. Absences with automatisms must be differentiated from temporal lobe complex partial seizures because treatment and natural history differ. Temporal lobe complex partial seizures usually exceed 30 seconds in duration and are characterized by prominent oral and hand automatisms, auras, and postictal confusion. Frontal lobe complex partial seizures may be more difficult to differentiate owing to their brevity, tendency to cluster, and higher incidence of bilateral EEG changes.

The interictal EEG in patients with typical AS reveals generalized 3.0-Hz spike-wave complexes superimposed on normal background activity. Bursts of generalized 3.0- to 4.0-Hz spike-wave complexes slowing to 2.5- to 3.0-Hz complexes are observed during seizures (Fig 52-2). Typical AS are commonly precipitated by hyperventilation and infrequently by photic stimulation. Behavioral changes are usually observed during bursts exceeding 3 seconds. Atypical AS are associated with 0.5- to 2.5-Hz slow spike-wave complexes superimposed on abnormal background activity. Unlike typical AS, atypical absences are rarely provoked by hyperventilation or photic stimulation.

Animal models of generalized absence seizures and in vitro electrophysiologic techniques have shed light on the pathogenesis of AS.⁸ The corticoreticular theory postulates that typical AS involve the generation of abnormal oscillations within thalamocortical circuitry. Thalamic neurons have the ability to shift between oscillatory and tonic firing modes. During normal wakefulness, EEG desynchronization and tonic thalamocortical neuronal firing take place. With oscillatory rhythmic firing, the thalamic EPSP threshold is raised, which produces dampening of signal transmission to the cortex, resulting in impairment of consciousness. Oscillatory behavior relies on the nucleus reticularis thalami, which is composed of GABAergic neurons that project to thalamic relay nuclei and to one another. The nucleus reticularis thalami receive excitatory glutaminergic

inputs as well. Biochemically, a phase-locked GABA_A/GABA_B-mediated inhibition followed by glutamate-mediated excitation appears to be operative within the thalamocortical circuitry. The GABA_A/GABA_B-mediated inhibition triggers the key event, a low-threshold Ca²⁺ current in the nucleus reticularis thalami neurons, leading to recurrent depolarization and repetition of the cycle. Neurons of the reticular nucleus of the thalamus and voltage-dependent Ca²⁺ channels (T-channels) of thalamic relay neurons are required to sustain the series of oscillatory burst firings between thalamic relay neurons and neocortical pyramidal cells. Generalized AS represent a potentiation of the rhythmicity so that the rhythmic firing mode predominates. The anti-absence agents ethosuximide and valproic acid suppress T-channel currents, as does zonisamide, whereas other agents do not.

The high concordance for seizures and the 3.0-Hz spike-wave trait in monozygotic twins supports a genetic basis for AS. Typical AS occur in neurologically normal children with idiopathic generalized epilepsy. Atypical absences are observed in patients with diffuse or multifocal cerebral dysfunction resulting from acquired or inherited neurologic disorders such as Lennox-Gastaut syndrome.

Myoclonic Seizures

Myoclonic seizures are single or repetitive, bilaterally synchronous and symmetrical, rapid muscular contractions. Jerks are often restricted to facial and shoulder girdle muscles, although involvement of the trunk and limbs may occur (Video 46, Myoclonic Epilepsy). Consciousness is usually preserved. The EEG reveals generalized polyspikes or spike-wave complexes, which may or may not be time-locked to the muscular contraction. Interictal findings vary from normal background rhythms with generalized epileptiform discharges to severe background abnormalities with multifocal spike discharges, depending on the etiology (Video 105, Myoclonic Seizure).

Myoclonic seizures are commonly observed in neonates and children with idiopathic or symptomatic epilepsy. These seizures should be differentiated from nonepileptic events, including movement disorders, hypnic jerks, nocturnal myoclonus, and segmental myoclonus of spinal cord or brain stem origin. Nonepileptic reticular and cortical reflex forms of myoclonus may occur in the setting of anoxia, trauma, stroke, or degenerative or neoplastic disorders.

The pathophysiology of myoclonic seizures is poorly understood, partly because of the diversity of syndromes in which they appear and the difficulty in differentiating nonepileptic from epileptic myoclonus. Three subgroups of epileptic myoclonus have been described based on etiology, distribution, and the back-averaged EEG.⁹ In idiopathic generalized epileptic myoclonus, generalized myoclonic jerks preceded by spike discharges are thought to be produced by abnormal subcortical influences on a diffusely hyperexcitable neocortex. Reticular reflex myoclonus consists of generalized, synchronous muscle contractions that precede the electrographic correlate and originate in brain stem structures. Cortical reflex myoclonus is characterized by unilateral or asynchronous jerks restricted to a few contiguous muscles preceded by spike discharges in the

contralateral sensorimotor cortex. This form of myoclonus is thought to represent a form of focal epilepsy.

Partial (Focal) Seizures

Simple Partial Seizures

Simple partial seizures are epileptic seizures characterized by motor, sensory, autonomic, or psychic symptomatology during which consciousness is preserved. The term *aura* is reserved for subjective symptoms of epileptic origin reported by the patient in the absence of objective signs. Simple partial seizures can occur in isolation or preceding complex partial or tonic-clonic seizures. Multiple symptoms or signs may occur during a single seizure. Simple partial seizures with motor features include focal tonic and clonic activity, vocalizations, speech arrest, and version, defined as sustained, forced, involuntary turning of the eyes or head (Video 94, Partial Seizure). The epileptic focus is usually in the hemisphere contralateral to the motor manifestations. The classic “Jacksonian march” in which focal clonus in distal muscles gradually spreads proximally along the motor homunculus occurs only rarely. Simple partial seizures with sensory symptoms include somatosensory, visual, auditory, vertiginous, gustatory, and olfactory disturbances. Autonomic phenomena include epigastric sensation, pallor, sweating, flushing, piloerection, and pupillary dilatation. Seizures with psychic symptoms include affective and cognitive disturbances and illusions or hallucinations of memory (*déjà vu*, *jamais vu*), visions, sounds, self-image, and time.

Simple partial seizures should be differentiated from the prodromal symptoms that precede complex partial seizures and TCS. Movement disorders, including paroxysmal dyskinesias and tonic spasms, transient ischemic attacks, migraine, and psychiatric disease, should be considered in patients with transient symptoms without impairment of consciousness.

Less than one third of simple partial seizures are associated with changes on surface EEG recordings. EEG changes are more common when the epileptic focus is close to the recording electrodes, such as in seizures arising from the perirolandic area. Neurons within an epileptogenic focus produce a synchronized burst of action potentials known as the *paroxysmal depolarization shift*, which is responsible for the generation of partial seizures. This paroxysmal depolarization shift is believed to produce focal interictal epileptic discharges.

Complex Partial Seizures

Complex partial seizures are partial seizures that are associated with an alteration of consciousness (Video 248, Complex-Partial Seizures with Automatism). The term *psychomotor* describes a particular semiology characterized by automatisms and impairment of consciousness, usually of temporal lobe origin. Complex partial seizures are also observed in frontal, parietal, and occipital lobe epilepsies. As in simple partial seizures, the clinical manifestations reflect the origin and propagation pattern of the epileptic focus. Seizures often begin with a motionless stare or arrest of activity followed by orolimentary, hand, or gestural automatisms, eye movements, speech disturbances, and automatic behavior.

Complex partial seizures must be differentiated from typical and atypical AS. Psychogenic seizures, fugue states, panic attacks, inattention, sleep disorders, syncope, transient global amnesia, metabolic derangements, drug and alcohol ingestion, migraine, transient ischemic attacks, and fluctuations in mental status in patients with dementia should also be considered in the evaluation of patients with transient alterations in consciousness (Video 78, Frontal Lobe Complex-Partial Seizure).

The interictal EEG in patients with complex partial seizures demonstrates focal or lateralized sharp waves, spikes, and slow waves. Several ictal patterns are observed. Rhythmic sinusoidal activity or repetitive spike discharges maximal over one region or hemisphere is most common. Nearly one third of complex partial seizures are not accompanied by EEG changes. A lack of EEG correlate is more likely to occur with brief seizures arising from deep regions such as orbitofrontal cortex or interhemispheric structures. The neuronal substrates of complex partial seizures are the same as in simple partial seizures except that alteration of consciousness implicates more extensive spread, usually involving both cerebral hemispheres.

The signs and symptoms of partial seizures reflect the function of the cortex involved in the generation and propagation of the abnormal electrical activity. A strong association exists between semiology and site of seizure origin.¹⁰ Seizures with motor manifestations usually arise from the frontal lobes, although tonic activity and version may be seen in parietal and occipital lobe epilepsy. Autonomic, affective, and psychic phenomena are produced by activation of temporal lobe and, less commonly, frontal lobe structures. Activation of epileptogenic foci in the insula and parietal operculum produces gustatory symptoms. Olfactory disturbances occur with orbitofrontal and mesial temporal lobe seizures. Elementary visual or auditory phenomena indicate activation of primary visual and auditory cortices in the occipital and superior temporal lobes, respectively. Complex illusions and hallucinations occur with activation of association areas. Whereas the first sign or symptom of a focal seizure aids in the localization of the epileptogenic focus, postictal focal motor, sensory, or visual field deficits can reliably identify the hemisphere of seizure origin. Consequently, whenever possible, a careful neurologic examination should be performed immediately following a seizure.

Common pathologic substrates of partial seizures include mesial temporal sclerosis, developmental malformation, neoplasm, CNS infection, head trauma, and cerebrovascular disease. With modern neuroimaging techniques, the ability to detect neuronal migration disorders, mesial temporal sclerosis, and low-grade gliomas has improved dramatically. The most common etiologies for partial seizures in children are congenital malformations and low-grade gliomas. Mesial temporal sclerosis predominates in young adults, and cerebrovascular disease is the most common cause of new-onset partial epilepsy in older adults.

GENERAL APPROACH TO THE INITIAL SEIZURE

Approximately 6% of the population experiences an afebrile seizure at least once in their lifetime.¹¹ The decision to initiate antiepileptic drug (AED) therapy after a single

seizure is based on the risk of recurrence versus that of treatment.¹² Nearly 30% of treated patients experience unacceptable side effects requiring discontinuation of anti-convulsant medication.¹³ In addition, although the initiation of AED therapy significantly reduces the risk of recurrence, it does not guarantee remission. Recurrence rates after single unprovoked seizures range from 27% to 71%.¹¹ The most reliable predictors of recurrence are (1) evidence of a neurologic abnormality based on known etiology, neurologic examination, or neuroimaging studies; (2) epileptiform abnormalities on EEG; and (3) partial versus generalized seizures. The risk of recurrence increases with the number of abnormalities identified.

Adolescents and adults who experience their first seizure should be evaluated with an EEG and a high-resolution magnetic resonance imaging (MRI) study. The need for imaging should be determined based on patient age and the clinical circumstances in children experiencing a first nonfebrile seizure.¹⁴ The need for laboratory studies, toxicologic screens, and CSF analysis should be determined on an individual basis. Seizures due to drugs, alcohol, and metabolic disturbances require treatment of the underlying cause instead of AED therapy. Patients with evidence of neurologic abnormalities that are likely to persist should be treated with AEDs after discussing the potential risks and benefits. Treatment is generally continued for a period of 1 to 2 years, after which medication is gradually withdrawn if seizures have not recurred. Approximately 80% of recurrences appear within 2 years, and the majority do so within 6 months.¹¹ As a result, most states have laws requiring that driving be restricted for periods ranging from 3 to 12 months after a single unprovoked seizure. Individual state laws vary, as do the requirements for the reporting of patients to state authorities by physicians.

EPILEPSIES AND EPILEPSY SYNDROMES

Certain epileptic disorders are characterized by specific clusters of signs and symptoms that are considered epileptic syndromes. Because most of these syndromes have numerous etiologies, few have been defined as specific diseases. Proposed in 1989, the current classification of the epilepsies subdivides epilepsies and epileptic syndromes into three categories based on clinical history, EEG manifestations, and etiology.¹⁵ *Localization-related epilepsies and syndromes* are typified by seizures that originate from a localized cortical region. The *generalized epilepsies and epilepsy syndromes* are characterized by seizures with initial activation of neurons within both cerebral hemispheres.

The syndromes are further divided into idiopathic and symptomatic types. *Idiopathic* refers to syndromes that arise spontaneously without a known cause, presumably having a genetic basis. Most affected patients are of normal intelligence and have normal results on neurologic examinations. *Symptomatic* denotes epilepsies with an identified cause such as mesial temporal sclerosis. The term *cryptogenic* describes syndromes that are presumed to be symptomatic but have no known etiology and that occur in patients with or without abnormalities on neurologic examination. Epilepsies that are characterized by both partial and generalized seizures and focal and generalized epileptiform

discharges, but without a clear predominance of one over the other, are classified as *undetermined*. The term *lesional* epilepsy refers to focal epilepsy in which a lesion is identified on neuroimaging studies that is the probable cause of seizures. Lesions include mesial temporal sclerosis, developmental malformations, neoplasms, vascular malformations, and ischemic insults. The distinction between lesional and nonlesional focal epilepsy is particularly important in patients being considered for epilepsy surgery. In this population, surgical outcome is dependent upon the completeness of resection of epileptogenic lesion, which is accomplished more readily when a well-defined structural abnormality is present. In addition to the classic dichotomy between localization-related and generalized epilepsies, a number of special syndromes are also highlighted.

Localization-related (Focal) Epilepsies and Epileptic Syndromes

Benign Focal Epilepsies of Childhood

Benign focal epilepsies of childhood are idiopathic localization-related epilepsies characterized by partial seizures, focal EEG abnormalities, and absence of a known etiology. These are age-related syndromes occurring in neurological normal children that have a tendency for spontaneous remission. Benign childhood epilepsy with centrotemporal spikes (BCECT) is the most common, composing 15% to 20% of all childhood epilepsies.¹⁶ In comparison, benign childhood epilepsy with occipital paroxysms (BCEOP), benign frontal epilepsy of childhood, and benign epilepsy with affective symptoms are rare.

Age of onset of BCECT ranges from 2 to 13 years, with peak incidence of 9 years. Simple partial seizures with sensorimotor symptoms of the face and oropharynx, hemiconvulsions, and TCS followed by Todd's paralysis occur typically during non-REM sleep. Nearly 80% of patients experience isolated or infrequent seizures. A family history of epilepsy is reported in 15% to 30% of patients. Centrotemporal sharp waves are observed in the EEGs of 15% to 30% of first-degree relatives. An autosomal dominant mode of inheritance with age-dependent penetrance is suspected. In BCEOP, seizures consist of visual symptoms with frequent evolution to hemiclonic, complex partial, and tonic-clonic seizures. Tonic eye deviation and vomiting with alteration of consciousness are also observed. Headache, nausea, and vomiting occur postictally in 20% to 30% of patients.

BCECT can be distinguished from the symptomatic epilepsies by seizure semiology, EEG manifestations, response to AEDs, and absence of abnormalities on neurologic examination and neuroimaging studies. Similar seizure patterns and electrographic features may be seen in patients with lesions of the operculum and perirolandic cortex, however. Migraine, lesional occipital lobe epilepsy, MELAS (mitochondrial myopathy, lactic acidosis, and stroke-like episodes), and bilateral occipital cortico-subcortical calcifications with focal motor seizures should be considered in patients presenting with symptoms of BCEOP.

The interictal EEG in BCECT shows stereotypical unilateral or bilateral high-voltage diphasic centrotemporal sharp waves superimposed on normal background activity.

Epileptiform activity tends to be markedly enhanced during non-REM sleep. The results of neuroimaging studies are normal. In BCEOP, high-amplitude, rhythmic, unilateral or bilateral occipital or posterior temporal spikes or sharp waves appear with eye closure and attenuate with eye opening.

Children with benign focal epilepsy who experience isolated or rare nocturnal seizures do not necessarily require treatment with AEDs. Treatment should be considered in patients with frequent TCS or seizures during wakefulness, however. Phenytoin, carbamazepine, phenobarbital, valproic acid, and gabapentin are effective; however, carbamazepine and gabapentin are often preferred for their lower incidence of adverse reactions. Other agents may also be effective, but there are insufficient data to support a recommendation. Antiepileptic drug withdrawal should be considered after 1 to 2 years of seizure control or by age 16 years, when spontaneous remission usually occurs. Spontaneous remission by 16 to 18 years occurs in all patients with BCECT, although 1% to 2% experience rare TCS in adulthood. Satisfactory seizure control is achieved in only 60% of patients with BCEOP, 5% of whom develop new seizure types in adulthood.

Temporal Lobe Epilepsy

Temporal lobe epilepsy (TLE) constitutes nearly two thirds of localization-related epilepsies that appear during adolescence and adulthood.¹⁷ Mesial temporal lobe epilepsy (MTLE), in which seizures arise from the hippocampus or amygdala, is most common, although neocortical onset occurs. The natural history is variable, and as many as 30% to 40% of patients continue to have seizures despite appropriate medical management.¹⁷ Seizure onset ranges from the latter half of the first decade of life to early adulthood. In many cases, seizures begin several years after febrile seizures, head trauma, or CNS infection. Complicated febrile seizures are reported in 40% of patients with refractory TLE.

Visceral sensations, fear, anxiety, olfactory disturbances, and psychic phenomena are commonly reported by patients with seizures arising from the mesial temporal lobe. Auditory hallucinations or complex visual phenomena usually indicate neocortical temporal origin. Complex partial seizures are characterized by behavioral arrest, staring, automatism and occasionally, dystonic posturing of an extremity contralateral to the seizure focus. Seizure duration typically ranges from 30 to 120 seconds. Postictal confusion usually occurs, and language disturbances may follow seizures arising from the dominant hemisphere. Approximately 50% of patients also experience secondarily generalized TCS. Stress, sleep deprivation, and menstruation are common provoking factors. Status epilepticus is rare, and the results of the neurologic examination are usually normal.

Mesial temporal sclerosis is the most common pathologic substrate of TLE and is commonly associated with pharmacoresistance.¹⁸ Marked neuronal loss in the CA1, CA3, CA4, and the dentate granule cells is observed. The pyramidal cells in CA2, subiculum, entorhinal cortex, and temporal neocortex are relatively spared. Loss of granule cell innervation leads to reactive synaptogenesis, which

FIGURE 52-3. Interictal EEG on an adult woman with left mesial temporal lobe epilepsy due to mesial temporal sclerosis. Spike discharges are present in the left mesial temporal region maximal at the left sphenoidal (SP1) electrode.

results in an excitatory process capable of initiating and propagating seizures. The coexistence of mesial temporal sclerosis and extralimbic lesions, particularly developmental malformations, is observed in 30% of surgical specimens. Seizure semiology may be indistinguishable in epilepsy arising from the orbitofrontal cortex, cingulate gyrus, and temporal lobe. Temporal lobe seizures should be differentiated from fugue states, syncope, psychogenic seizures, transient global amnesia, and absences.

The interictal EEG reveals slowing and spikes or sharp waves in the temporal region that are accentuated during non-REM sleep. The yield of EEG abnormalities is increased with sphenoidal or additional anterior temporal electrodes (Fig 52-3). Bitemporal independent discharges are observed in 30% of cases. The ictal EEG commonly begins with a regionalized or generalized attenuation followed by a gradual buildup of rhythmic theta or alpha frequencies intermixed with epileptic discharges (Fig 52-4). EEG manifestations are typically maximal in the anterior or mesial temporal region in patients with MTLE and lateral or posterior temporal area in neocortical TLE.

High-resolution MRI demonstrates hippocampal atrophy and abnormal signal intensities that are highly correlated with mesial temporal sclerosis in many patients with MTLE. Fluorodeoxyglucose (^{18}F FDG) positron-emission tomography (PET) demonstrates temporal lobe hypometabolism in over 80% of cases. Both ictal and interictal single-photon emission computed tomography (SPECT) show unilateral abnormalities, although the spatial resolution is inferior to that of PET, and technical factors, such as time of injection in relation to seizure onset, dramatically influence results.

Carbamazepine, phenytoin, phenobarbital, valproic acid, oxcarbazepine, lamotrigine, gabapentin, and topiramate have efficacy as monotherapy in newly diagnosed adolescents and adults with partial seizures and secondary generalized TCS.¹⁹ The choice of an AED depends on a variety of issues including adverse effect profile, compliance, and cost, among others. Outcome is poorer and the incidence of adverse effects is higher with phenobarbital or primidone monotherapy.²⁰ A comparison study of carbamazepine and valproic acid revealed similar efficacy against TCS, although carbamazepine was superior for

the control of complex partial seizures and produced fewer adverse effects.²¹ All of the newer AEDs are effective as adjunctive therapy in patients with refractory partial seizures.²² Most have been shown to be more effective at higher doses. Oxcarbazepine, topiramate, and lamotrigine are most effective and may be used as monotherapy in refractory patients. Between 60% and 70% of patients achieve good control or remission with appropriate medical management. Factors predictive of less favorable outcome include onset before 2 years of age, frequent complex partial and tonic-clonic seizures, known etiology, status epilepticus, and history of febrile convulsions. Those who fail to respond to medical management after adequate trials of 2 appropriate AEDs should be referred to an epilepsy center for surgical evaluation.

Extratemporal Neocortical Epilepsy

The incidence of neocortical epilepsy is derived from surgical series of medically refractory patients. Consequently, the incidence and natural history of extratemporal epilepsy are unknown. Frontal lobe epilepsy is most common after TLE, followed by parietal and occipital lobe epilepsies.²³

Various seizure patterns are observed in frontal lobe epilepsy (Video 78, Frontal Lobe Complex-Partial Seizure; Video 94, Partial Seizure). Frontal lobe complex partial seizures are differentiated from those of temporal lobe origin by their abrupt onset, shorter duration, absence of prolonged postictal state, and tendency for status epilepticus and seizure clusters. Generalized motor activity, sexual automatisms, vocalizations, version, and focal clonic and tonic activity are observed. Seizures arising from the orbitofrontal cortex and cingulate gyrus produce staring, automatisms, and autonomic and affective manifestations. Brief, recurrent, nocturnal seizures characterized by asymmetrical tonic posturing and vocalizations with preserved consciousness are observed in supplementary motor area epilepsy. Opercular area seizures are associated with salivation, mastication, speech arrest, laryngeal symptoms, autonomic signs, and gustatory or epigastric disturbances. Seizures originating in the dorsolateral frontal convexity are characterized by focal tonic and clonic activity, version,

FIGURE 52-4. Rhythmic theta activity maximal at the left sphenoidal electrode during a seizure in a patient with mesial temporal lobe epilepsy.

and speech arrest. Koshewnikow's syndrome, characterized by repetitive focal motor seizures, myoclonus, and focal motor status epilepticus, is observed in seizures originating in the perirolandic region.

In parietal lobe epilepsy, auras consist of lateralized somatosensory symptoms, vertigo, and epigastric or cephalic sensations. Automatisms and asymmetrical tonic posturing are observed with ictal propagation to the temporal or frontal lobes, respectively. Occipital lobe seizures are characterized by elementary visual hallucinations that may be limited to the contralateral hemifield, sensations of eye movement, eye blinking, and ictal blindness.

With the exception of head trauma, which commonly produces contusions of the frontal and temporal polar regions and orbitofrontal cortex, the location of the epileptic focus does not predict etiology. The various etiologies of neocortical epilepsies include developmental malformation, neoplasm, head injury, CNS infection, and vascular malformation. No cause is identified in 25% of cases.

Neocortical epilepsy should be differentiated from MTLE, which has a more favorable response to surgical intervention. Movement disorders, parasomnias, and psychogenic seizures may mimic frontal lobe seizures. Parietal and occipital lobe seizures may be mistaken for transient ischemic events. The differentiation of migraine and occipital lobe epilepsy may be difficult because both commonly produce transient visual phenomena followed by nausea, vomiting, and headache.

The yield of EEG abnormalities is dependent on the size of the epileptogenic focus and its distance from the recording electrodes. The EEG recording may be normal when seizures arise from deep, midline, or basal locations unless special recording techniques or montages are employed. Abnormalities consist of nonspecific slowing, focal or bilateral epileptiform discharges, and low-voltage fast activity. Secondary bilateral synchrony, in which a unilateral deep or midline focus produces bilaterally synchronous and symmetrical epileptiform activity, may be mistaken for generalized epileptic discharges found in idiopathic generalized epilepsy. In comparison with MTLE, a higher

incidence of nonlocalized and nonlateralized ictal EEG patterns is observed. Consequently, intracranial monitoring is usually required in medically refractory cases when MRI fails to reveal focal pathology.

The management of neocortical epilepsy is similar to that for patients with TLE. No studies comparing the response to AEDs and remission rate in neocortical epilepsy and TLE are available. Patients with structural abnormalities on MRI and those who prove to be medically resistant should be referred to an epilepsy center for surgical consideration. The outcome of surgical treatment depends on the extent of resection of the epileptogenic zone, which may be limited by involvement of cortical regions subserving motor or language functions. The prognosis is less favorable when imaging studies fail to reveal a focal abnormality.

Generalized Epilepsies and Epileptic Syndromes Idiopathic, Age-related Forms

BENIGN NEONATAL FAMILIAL AND NONFAMILIAL CONVULSIONS. Benign idiopathic neonatal convulsions and benign familial neonatal convulsions (BFNC) are rare neonatal syndromes, characterized by seizures beginning in the first week of life. Most infants are neurologically normal, and spontaneous remission usually occurs. Benign neonatal convulsions account for 2% to 7% of neonatal convulsions.²⁴ BFNC is less common, with only 150 cases having been reported in the literature.²⁴

Seizures in benign neonatal convulsions have been referred to as *fifth-day fits* because of their presentation between the fourth and sixth days of life. Recurrent focal or generalized clonic seizures, apneic events, and status epilepticus are observed. A family history of epilepsy may be present. In BFNC, seizures begin on the second or third day of life and tend to recur for several months. Although most infants have no other abnormalities on examination, minor neurologic findings have been reported. The etiology and pathophysiology of benign neonatal convulsions are unknown; BFNC is an inherited disorder with three known genetic defects.

A diagnosis of BFNC can be made only when other causes of convulsions are excluded and a family history of neonatal seizures with spontaneous remission is present. The diagnosis of both syndromes is usually made retrospectively after neurologic deterioration and other seizure disorders fail to emerge. Laboratory and neuroimaging study results are unrevealing, although the EEG commonly shows “theta pointu alternant,” which is a discontinuous, unreactive theta rhythm associated with neonatal seizures of various etiologies. In other cases, the EEG recording is normal or shows focal or multifocal abnormalities.

Anticonvulsant therapy has not had a consistent effect on the duration of seizures. Neonates with infrequent seizures and those in whom a family history of BFNC is present do not require AED therapy. Prognostically, both syndromes are considered benign, although follow-up beyond early childhood has not been reported. Febrile and afebrile seizures during childhood have been described in 11% of patients with BFNC and in 0.5% of patients with benign neonatal convulsions.²⁴

MYOCLONIC EPILEPSIES OF INFANCY AND CHILDHOOD. Myoclonus and myoclonic seizures are observed in various disorders affecting infants and children (Video 105, Myoclonic Seizure). Myoclonic seizures may be overshadowed by more striking seizure patterns and neurologic abnormalities. As a result, the classification of these disorders is imprecise. Several syndromes demonstrating consistent etiologic, clinical, and electrophysiologic features have been described, however.²⁵

Early myoclonic encephalopathy is a disorder affecting severely neurologically impaired infants shortly after birth. Erratic fragmentary myoclonus and generalized myoclonic, tonic, and focal motor seizures are observed. The EEG shows a suppression-burst pattern that evolves to hypsarhythmia or multifocal spike discharges within months. Antiepileptic medications are ineffective, and 50% of patients do not survive beyond the first year of life. Inborn errors of metabolism and congenital malformations are present in some cases.

Benign myoclonic epilepsy of infancy is characterized by myoclonic seizures in neurologically normal children in the first or second years of life. TCS may develop in adolescence. A history of febrile seizures is common, and a family history of seizures is reported in 30% of cases. The interictal EEG is usually normal, and seizures are readily controlled with valproic acid.

Severe myoclonic epilepsy in infancy appears in the first year of life as prolonged, recurrent febrile seizures. Other seizure patterns including atypical absences, myoclonic seizures, and myoclonic status epilepticus appear in early childhood. Affected children are initially normal but develop psychomotor retardation by the second year of life, which is often accompanied by ataxia, pyramidal signs, and myoclonus. The EEG reveals generalized epileptiform discharges. Medical treatment is generally ineffective, and prognosis is poor.

ABSENCE EPILEPSY. Previously referred to as “petit mal,” absence epilepsy (AE) accounts for 3% to 4% of all seizure disorders (Video 75, Absence Seizure).²⁶ Childhood AE, which appears in children between the ages of 4 and 8 years, accounts for 80% of cases. Juvenile AE constitutes the remainder, in which seizures begin around the

age of 12 years. Typical AS occur several to hundreds of times per day. TCS occur in approximately 30% of childhood-onset AE (CAE) and 80% of juvenile-onset AE (JAE) patients. Absence status, consisting of prolonged periods of mental clouding associated with repetitive spike-wave complexes, occurs in 10% to 20% of CAE and 40% of JAE cases. Myoclonic seizures, which are not routinely seen in CAE, occur in 15% of JAE. Neurologic examination results and intelligence are normal. AE is presumed to be an inherited disorder, although the gene responsible for its expression has not been identified. A family history of epilepsy is present in approximately 30% of patients. In one study, the concordance rate for seizures and the spike-wave trait in monozygotic twins was found to be 64% and 82%, respectively, suggesting that a combination of genetic and nongenetic factors is operative.²⁷

AE should be distinguished from daydreaming, inattention, and temporal or frontal lobe seizures. In general, the diagnosis is readily confirmed by EEG, which demonstrates 3.0-Hz spike-wave complexes in CAE. Irregular 3.5- to 6.0-Hz polyspike-wave complexes are more commonly observed in juvenile-onset cases. Background activity is otherwise normal. Hyperventilation accentuates spike-wave complexes in nearly 80% of cases. Additionally, nearly 30% of patients are photosensitive. Neuroimaging, including MRI and CT scans, is usually unrevealing and is not required unless atypical features are present.

Ethosuximide, valproic acid, and lamotrigine are effective treatment for absence seizures. Because ethosuximide is not effective against TCS, valproic acid and lamotrigine are more appropriate in patients with both seizure types; however, the latter has a more favorable adverse effect profile. Levetiracetam and topiramate may also be effective. The disease in 5% to 20% of patients is not satisfactorily controlled with monotherapy, and refractory patients may benefit from a combination of agents, with or without benzodiazepines.

AS typically go into remission by early adulthood, although TCS are more likely to persist. Rhythmic occipital delta activity on EEG is associated with a more favorable course and lower incidence of TCS. Subnormal intellect, resistance to antiepileptic medication, and presence of myoclonic seizures portend a worse prognosis. A meta-analysis showed remission rates ranging from 21% to 89% with differences relating to inclusion criteria, follow-up lengths, and outcome definitions.²⁸ Seventy-eight percent of patients with AS alone were seizure-free compared with 35% when TCS were also present.

JUVENILE MYOCLONIC EPILEPSY. Juvenile myoclonic epilepsy (JME) accounts for 4% to 10% of all epileptic syndromes.²⁷ JME appears in neurologically normal adolescents between the ages of 12 and 18 years. Myoclonic seizures consist of bilaterally synchronous and symmetrical jerks of the neck, shoulders, and arms that may be single or repetitive. Consciousness is usually preserved. TCS preceded by a series of myoclonic jerks occur in over 90% of patients. One third have absences as well. Myoclonic seizures and TCS occur predominantly in the early morning hours shortly after awakening and are provoked by sleep deprivation, alcohol ingestion, fatigue, and menstruation.

Juvenile myoclonic epilepsy is a genetically determined syndrome. Once believed to have a gene locus on the short arm of chromosome 6 (6p), recent studies revealed that

FIGURE 52-5. Generalized polyspike-wave complexes in a patient with juvenile myoclonic epilepsy.

JME is a heterogeneous disorder related to several gene mutations. Nearly 50% of JME patients have relatives with seizures and 30% have asymptomatic family members with generalized epileptiform abnormalities on EEG. JME should be differentiated from the progressive myoclonic epilepsies (PMEs) and other idiopathic epilepsies in which absence, myoclonic, and tonic-clonic seizures are observed. The PME are characterized by progressive neurologic deterioration, myoclonus, and seizures, and may be mistaken for JME early on before severe neurologic disabilities develop.

The interictal EEG reveals bilaterally synchronous 4.0- to 6.0-Hz polyspike-wave complexes superimposed on normal background activity (Fig 52-5). A photoparoxysmal response is elicited in 30% of patients. Myoclonic seizures are accompanied by bursts of generalized, synchronous, and symmetrical 10- to 24-Hz polyspikes followed by irregular slowing. AS are associated with 3.0-Hz spike-wave or 4.0- to 6.0-Hz polyspike-wave complexes. MRI and CT studies generally yield normal results and need not be routinely performed unless atypical features are present.

Patients should be advised to avoid precipitating factors. Photosensitive patients should also limit their exposure to flashing lights. Valproic acid has long been considered the drug of choice and is effective in 85% to 90% of patients. Lamotrigine and topiramate are being used as first-line therapy with increasing frequency due to a lower incidence of adverse effects and a recent retrospective cohort study found these agents to be effective alternatives.²⁹ Ethosuximide may be used for refractory absences. Uncontrolled myoclonic seizures may respond to benzodiazepines. Phenytoin, carbamazepine, primidone, phenobarbital, levetiracetam, and zonisamide may be effective against refractory TCS. Women of childbearing age should be counseled of the teratogenic potential of the AEDs, in particular, the association of valproic acid with congenital malformations. The prognosis of JME is excellent, and seizures are well controlled in most patients if precipitating factors are avoided. Because over 90% of patients relapse after medication withdrawal, AED therapy should be maintained even in patients with long seizure-free intervals.

EPILEPSY WITH GENERALIZED TONIC-CLONIC SEIZURES. Generalized TCS are observed in several idiopathic generalized epilepsy syndromes, which include CAE, JAE, JME, and epilepsy with generalized TCS on awakening. A significant degree of overlap exists between these syndromes.

By definition, idiopathic generalized TCS are not preceded by auras, although vague prodromal symptoms such as headache and malaise have been described hours or days before seizures. Seizures are usually infrequent; they tend to occur at the same time in the sleep-wake cycle of a given patient. Sleep deprivation, photic stimulation, alcohol consumption, menstruation, and stress are potent activators. The age of onset ranges from 6 to 20 years, usually peaking in puberty. Neurologic examination results and intelligence are normal.

The family history of epilepsy exceeds that of the general population, suggesting a genetic etiology. Linkage to the gene locus of JME was demonstrated in a group of adolescents with generalized TCS on awakening, but such a phenomenon was not seen in patients with randomly occurring generalized TCS.³⁰ A higher incidence of microdysgenesis exists in patients with idiopathic generalized epilepsy compared with control subjects, but the significance of this finding is unknown. The differential diagnosis includes generalized TCS due to drugs, alcohol intoxication and withdrawal, and medical disorders, including metabolic derangements and electrolyte imbalance.

The EEG reveals diffuse, bilaterally synchronous 3.0-Hz or 4.0- to 6.0-Hz spike-wave or polyspike-wave complexes, similar to that seen in the other idiopathic generalized epilepsies. Background activity and neuroimaging study results are normal. The older AEDs including phenytoin, valproic acid, and phenobarbital are effective as are the newer agents such as lamotrigine, topiramate, zonisamide, and levetiracetam. Patients should be instructed to avoid sleep deprivation and other precipitating factors. From 80% to 95% of patients experience prolonged seizure-free periods. Relapses after medication withdrawal are variable, tending to be lower in children than adults.

Cryptogenic or Symptomatic Forms

WEST SYNDROME. West syndrome is an age-dependent epilepsy consisting of the triad of infantile spasms, psychomotor retardation, and a characteristic EEG pattern known as *hypsarrhythmia*. The syndrome is named for W J. West, the nineteenth century neurologist who described the features he observed in his own son. Infantile spasms occur in 2 to 5 of 10,000 births.³¹ Spasms and psychomotor retardation appear in the first year of life in 85% of cases, the majority between 3 and 7 months. Infantile spasms are sudden, brief, usually bilaterally symmetrical flexor contractions of the neck, trunk, or limbs (Video 261, Infantile Spasms). Eye movements, autonomic signs, and brief lapses of consciousness may be observed. Less commonly, extension of the head, trunk, and limbs may be seen. Spasms are commonly repetitive, occurring in clusters on awakening, or during drowsiness, handling, feeding, or fever. Initially, the movements can be so slight that they may go unnoticed. Neurodevelopmental abnormalities may precede the onset of spasms. Moderate to severe cognitive disability occurs in 76% to 95% of patients. Associated abnormalities include generalized hypotonicity, microcephaly, paralysis, ataxia, blindness, and deafness. Because one third of patients lack the characteristic EEG features and 5% do not develop psychomotor retardation, the distinction between West syndrome and the myoclonic epilepsies of infancy may be difficult. In addition, infantile spasms may be mistaken for nonepileptic phenomena that occur in infants with diffuse cerebral dysfunction, such as head-banging, colic, and decerebration.

West syndrome is classified as symptomatic or cryptogenic based on the presence or absence of a known etiology. The proportion of symptomatic cases has increased in the years paralleling advances in neuroimaging. Tuberous sclerosis is one of the most common etiologies, composing 10% to 30% of prenatal cases. Symptomatic cases due to congenital malformations, infection, neurocutaneous disorders, metabolic disorders, and chromosomal abnormalities account for 70% to 80% of all cases.³¹

Although the underlying pathophysiology of infantile spasms is unknown, the age-dependency and diffuse EEG abnormalities imply widespread cortical dysfunction. Increased synthesis and activity of corticotropin-releasing hormone (CRH) has been postulated as a mechanism that might predispose to the development of spasms. Increased CRH may follow an abnormal stress during early life or an errant response to common stressors, resulting in growth or hyperfunction of certain CRH-containing neuronal pathways. Supporting this theory are various animal studies demonstrating the excitatory effects of CRH on neurons, including those in the hippocampus, and the beneficial effects of corticotropin (also known as adrenocorticotrophic hormone [ACTH]) and glucocorticoids in the treatment of spasms. Although ACTH and glucocorticoids may have intrinsic anticonvulsant activity, they may also suppress CRH production via the hypothalamic-pituitary-adrenal axis and thereby alleviate the excitatory effects of CRH on certain neuronal networks.

The typical EEG reveals hypsarrhythmia, a chaotic pattern of high-amplitude slow waves with multifocal epileptiform discharges and poor interhemispheric synchrony (Fig 52-6). Sleep is markedly disrupted and REM sleep is reduced. An electrodecremental response consisting of generalized low-voltage fast activity accompanies spasms. By 3 years of age, hypsarrhythmia typically evolves to slow spike-wave complexes or multifocal spikes and sharp waves. Abnormalities on neuroimaging studies are found in over 60% of infants. These abnormalities include generalized atrophy, white matter hyperintensities, and focal or multifocal lesions. Regional hypometabolism on PET studies has been demonstrated in some patients with focal cortical lesions.

The dose and duration of steroid therapy has not been standardized. The most common treatment is ACTH 40 IU/day administered intramuscularly. Approximately 75% of patients achieve initial seizure control using this regimen. The response rate tends to increase with duration of therapy. Within 2 months of remission, however, approximately 30% to 50% of patients suffer relapse after the first course of steroids. The relapse rate may be somewhat

FIGURE 52-6. Hypsarrhythmia in an infant with West syndrome.

lower in cryptogenic than symptomatic cases. No differences in long-term response rates are observed with low- and high-dose therapy. Side effects are common and include electrolyte disturbances and cardiac, infectious, and neuropsychiatric complications. Valproic acid, pyridoxine, vigabatrin, lamotrigine, topiramate, and immune globulin have shown some efficacy, as has nitrazepam, which is not currently commercially available in the United States. Favorable results have been reported following lesionectomy or hemispherectomy in patients with focal abnormalities on MRI or PET scans.

Infantile spasm and the hypsarrhythmia tend to diminish with increasing age, but the disorder is fatal in approximately one third of cases. Over 50% of patients develop Lennox-Gastaut syndrome, multifocal or secondarily generalized epilepsy, or other forms of epilepsy during childhood. Only 5% of patients experience spontaneous remission without neurologic sequelae. Mental retardation is observed in approximately 50% of cases. Factors associated with a poor prognosis include etiology of hypoxic-ischemic encephalopathy or lissencephaly and intractable seizures.

LENNOX-GASTAUT SYNDROME. Lennox-Gastaut syndrome is responsible for 2% to 3% of childhood epilepsies.³² The syndrome is characterized by multiple seizure types, slow spike-wave complexes, and cognitive dysfunction. Seizure onset ranges from 1 to 8 years of age, with a peak incidence between 3 and 5 years of age. Tonic seizures during sleep or on awakening occur in virtually all cases. Atonic, atypical absence, and myoclonic seizures are commonly observed. Status epilepticus, consisting of repetitive tonic seizures or clouding of consciousness lasting hours to weeks, is seen in nearly two thirds of patients. Severe mental retardation is found in 50% of cases, preceding the onset of seizures in 20% to 60%. In addition, disturbances of behavior and personality are common.

Approximately 70% of cases occur in children with acquired or genetic disorders affecting the nervous system. Developmental malformations, hypoxic-ischemic encephalopathy, CNS infections, and neurocutaneous disorders, particularly tuberous sclerosis, are frequent causes. Thirty percent of patients have a history of West syndrome. A family history of epilepsy may be found in cryptogenic cases; however, familial Lennox-Gastaut syndrome has not been reported. This syndrome should be differentiated from epilepsy with myoclonic astatic seizures. In the latter, multiple seizure types occur in previously normal children, 50% of whom develop mental retardation. A genetic etiology is suspected for myoclonic astatic seizures.

The EEG reveals 2.0- to 2.5-Hz slow spike-wave complexes and multifocal spikes superimposed on abnormal background activity. Runs of generalized paroxysmal fast activity and rhythmic 10-Hz spikes are observed during sleep. Atypical AS are associated with runs of slow spike-wave complexes. Tonic seizures are accompanied by an electrodecremental response or generalized 10- to 25-Hz spikes. Neuroimaging studies commonly demonstrate generalized cerebral atrophy and focal or multifocal abnormalities.

In general, seizures respond poorly to anticonvulsant treatment, and polytherapy is usually required. Benzodiazepines, such as clonazepam, valproic acid, lamotrigine,

and topiramate are effective. However, benzodiazepines may precipitate tonic status. Sedation should be minimized because of the tendency for seizures to increase in sleep. Phenytoin and rectal diazepam are effective for serial tonic seizures and status epilepticus. Refractory cases may benefit from a trial of felbamate, the ketogenic diet, or corpus callosotomy, which reduces tonic and atonic seizures in some cases.

The prognosis for seizure control and mental development is poor. Daily seizures occur in most patients. Factors that portend a poor prognosis include known etiology, onset before 3 years of age, prior West's syndrome, refractory tonic seizures, and severe mental retardation. Seizures usually persist into adulthood, and fatal injuries related to seizures occur in 5% of cases.

Special Epilepsy Syndromes

Progressive Myoclonic Epilepsies

The PME's represent a group of disorders of various etiology that collectively account for 1% of all epilepsy syndromes (Table 52-1; Video 46, Myoclonic Epilepsy).²⁵

The natural history varies with the specific disorder from mild neurologic impairment to severe disability progressing to death in early childhood. Onset is typically during childhood or adolescence, although some of the disorders may appear at any age. Clinically, the PME's are characterized by myoclonus, seizures, variable degrees of cognitive impairment, and other neurologic deficits. Myoclonus is commonly precipitated by action, sustained posture, or sensory stimulation including touch, cold, or light. Fragmentary and asynchronous myoclonic jerks primarily involving the limbs occur without associated alteration of consciousness. Myoclonus varies from mild to debilitating, depending on the specific disorder. Dementia is a characteristic sign of many of the PME's but is not a universal feature. The severity of intellectual deterioration is related to the degree of cortical loss and varies among individuals affected with the same disorder. Other neurologic findings include ataxia, spasticity, visual impairment, hearing loss, peripheral neuropathy, and extrapyramidal signs such as choreoathetosis. TCS represent the most common seizure type, although atypical absence and focal seizures are observed in some patients.

Unverricht-Lundborg disease is the classic form of PME with a high incidence around the Baltic Sea and in the Mediterranean region. The disease is autosomal recessive due to a mutation of the cystatin B (CSTB or EPM1) gene on chromosome 21q. The syndrome is characterized by stimulus-sensitive myoclonus with the subsequent development of TCS beginning between the ages of 8 and 13 years in individuals with no prior neurologic abnormalities. The myoclonus is severe and usually precipitated by passive joint movement, or auditory or light stimuli. Repetitive myoclonic jerks in the morning may culminate in generalized TCS later in the day. Ultimately, myoclonic jerks interfere with speech, swallowing, and ambulation. Gradual intellectual decline is observed, although severe dementia does not occur. The disorder progresses slowly over 10 to 20 years. The EEG shows generalized polyspike and 3- to 5-Hz spike-wave discharges similar to those

TABLE 52-1

Etiologies of the Progressive Myoclonic Encephalopathies

| DISORDERS | AGE AT ONSET | CLINICAL FEATURES | PROGNOSIS | LABORATORY/DIAGNOSIS | INHERITANCE/DEFICIENCY |
|--|--------------------------|---|-----------------------------------|---|---|
| Unverricht-Lundborg disease | 6–15 | Myoclonus, TCS, ataxia, dysarthria, depression, dementia absent | Variable, usually mild impairment | None | AR, Chr 21q /EPM1 mutation |
| Lafora body disease | 10–18 | Myoclonus, occipital/TCS, ataxia, dementia, ↓ vision, depression | Death 2–10 years after onset | Lafora bodies on axillary skin biopsy | AR, Chr 6/EPM2A-B mutation |
| Neuronal ceroid lipofuscinosis Late infantile | 1–4 | Myoclonus, visual failure, optic atrophy, ataxia, speech alterations, dementia, TCS | Death by 10 years | Storage lipopigment in lysosomes on biopsy of skin, conjunctiva, rectum | AR/Chr 11p/CLN2,5,6,7, mutations |
| Juvenile | 4–15 | Myoclonus, ↓ vision, optic atrophy, dementia, ataxia, EPS, seizures, dysarthria, psychosis | Death by 20 years | Same as above | AR, Chr 16/CLN3,8 mutations |
| Adult | ≥15 | Myoclonus, ataxia, seizures, dementia, vision not impaired | Death 10 years after onset | Same as above | AR or AD/Locus not identified/CLN4 |
| <i>MERRF</i> | Any age | Myoclonus, TCS, dementia, ataxia, lipomas, myopathy, neuropathy, deafness, short stature, optic atrophy, migraine, diabetes | Variable | Ragged-red fibers in skeletal muscle; lactate; respiratory chain defect | Substitution at pair 8344-mitochondrial DNA, sporadic |
| Sialidoses Type I | 8–15 | Myoclonus, visual deficit, CRS, TCS, ataxia, spasticity, burning sensation in extremities | Poor | Urinary sialyloligosaccharides Demonstration of enzymatic deficiency | AR, Chr 20q α -N-Acetyl-neuramidase |
| Type II | Adolescence or adulthood | Myoclonus, visual deficit, CRS, TCS, ataxia, coarse facies, dysostosis multiplex, ↓ hearing, corneal opacities, dementia | Poor | Urinary sialyloligosaccharides Demonstration of enzymatic deficiency | AR, Chr 20q β -Galactosidase α -N-Acetyl-neuramidase |
| Sphingolipidoses Gaucher's type III | Childhood to adulthood | Myoclonus, SNGP, impaired saccades, dementia, seizures, ataxia | Poor | β -Glucocerebroside storage in lymphocytes Demonstration of enzymatic deficiency | AR β -Glucocerebroside |
| GM ₂ gangliosidosis | Childhood to adolescence | Myoclonus, ataxia, spasticity, dystonia, tremor, seizures, optic atrophy, dementia | Poor | Demonstration of enzymatic deficiency | AR β -N-Acetylhexosaminidase |

AR, autosomal recessive; CRS, cherry-red spat; EPS, extrapyramidal signs; MERRF, myoclonic epilepsy with ragged-red fibers; SNGP, supranuclear gaze palsy; TCS, tonic-clonic seizures. Adapted from Berkovic SF, Cochiu J, Andermann E, Andermann F: Progressive myoclonus epilepsies: Clinical and genetic aspects. *Epilepsia* 1993; 34(suppl 3):S19–S30.

observed in JME. Photosensitivity is observed in over 90% of cases.

Lafora body disease is a rapidly progressive autosomal recessive disorder affecting individuals in late childhood or adolescence, although adult onset rarely occurs. Eighty percent of cases are caused by a mutation of the EPM2A gene on chromosome 6q, which codes for laforin. Laforin is a protein tyrosine phosphatase, active in the growth, development, and survival of neurons, dendrites, and synapses. Generalized TCS or partial seizures of occipital lobe origin are usually the initial manifestation. Progressive cognitive decline and myoclonus are universal features. Ataxia, decreased vision, and spasticity are variably present. Death occurs within 2 to 10 years of onset. Like Unverricht-Lundborg disease, the EEG at the onset shows polyspike-wave discharges and a photoparoxysmal response superimposed on normal background activity similar to JME. Eventually, background rhythms slow and nearly continuous generalized and multifocal epileptiform discharges are seen. Para-aminosalicylic acid–positive cytoplasmic inclusions containing polyglucosans, known as Lafora's bodies, are a hallmark of the disease and are found in brain, heart muscle, spinal cord, liver, skin, and sweat glands.

The *neuronal ceroid lipofuscinoses (NCLs)* are the most frequent neurodegenerative disorders in children and are divided into four subtypes based on age of onset. The infantile form is not considered a PME owing to its early age of onset and rapid progression. The late-infantile form (Jansky-Bielschowsky) is characterized by myoclonic, generalized tonic-clonic, and atypical absence seizures beginning between the ages of 2 and 4 years. Soon thereafter, cognitive deterioration, ataxia, spasticity, and visual impairment develop and death usually occurs. The EEG shows background slowing with generalized and bioccipital spikes that enhance with photic stimulation. Giant visual and somatosensory evoked potential responses are observed. Biopsy of skin, conjunctiva, or rectum reveal curvilinear bodies, pathognomonic for the disease. The juvenile form of NCL (Spielmeyer-Vogt) is the most common subtype, characterized by rapidly progressive visual loss, myoclonus, and generalized tonic-clonic and absence seizures beginning between 4 and 7 years of age. Neurologic deterioration ensues and death usually occurs in the early twenties. The EEG findings are similar to those of the juvenile form and the diagnosis is confirmed by skin biopsy. The adult form of NCL (Kufs) presents with myoclonus, ataxia, dementia, behavioral problems, and extrapyramidal features between 15 and 50 years of age. The EEG and diagnostic evaluation are similar to the other forms.

In general, treatment of the PMEs is difficult. Myoclonus and seizures often respond to valproic acid and benzodiazepines, particularly clonazepam. Piracetam, levetiracetam, *N*-acetylcysteine, zonisamide, and oral 5-hydroxy-L-tryptophan may also be useful. Phenytoin typically exacerbates ataxia and myoclonus and should be avoided. Mechanical techniques may be useful in lessening the incapacitating effects of action myoclonus.

Neonatal Seizures

Seizures are a common manifestation of cerebral dysfunction in the first 4 weeks of life. The incidence of neonatal

seizures is unknown owing to the lack of consensus on which behaviors constitute epileptic seizures in this population.²⁵ Neonatal seizures are paroxysmal events associated with alteration in neurologic function that may or may not have an electrographic correlate. Brief, recurrent, focal or multifocal clonic, focal or generalized tonic, and myoclonic seizures are observed. Although these seizure types have already been discussed, brief mention as to their clinical appearance in neonates is appropriate.

Focal clonic seizures consist of rhythmic twitching of a limb or one side of the face that may be sustained for long periods without apparent spread. Multifocal clonic seizures are characterized by random, migratory clonic movements involving limb and facial muscles bilaterally. Tonic seizures may be focal or generalized. Generalized tonic seizures are characterized by bilaterally symmetrical extension of the trunk and limbs often associated with apnea and upward deviation of the eyes. Focal tonic seizures include asymmetrical flexion of the trunk and eye deviation. Myoclonic seizures consisting of focal or generalized brief muscle jerks occur rarely. The term *subtle seizures* includes behaviors that are not clearly epileptic, including oral-buccal-lingual movements, eye movements, pedaling, swimming, and autonomic phenomena. These signs are commonly observed in premature infants. Because of incomplete CNS myelination, which prevents synchronous and symmetrical propagation patterns, generalized TCS are not observed in the neonatal period.

Neonatal seizures are caused by a wide variety of disorders affecting the brains of neonates. Clinically, the etiologies of neonatal seizures may be classified based on age of seizure onset (Table 52-2). Hypoxic-ischemic encephalopathy is the most common cause of neonatal seizures overall and the most common cause encountered within the first 24 hours of life. Other causes of seizures within the first day of life include bacterial meningitis, sepsis, subarachnoid hemorrhage, intrauterine infection, laceration of the tentorium or falx, drug effects, and pyridoxine dependency. From 24 to 72 hours of life, additional etiologies include cerebral contusion with subdural hemorrhage, drug withdrawal, developmental malformations, and metabolic disorders. When seizures appear beyond the third day of life, inborn errors of metabolism, herpes simplex infection, kernicterus, and neonatal adrenoleukodystrophy should be considered. Neonatal seizures should be differentiated from tremor, clonus, decerebration, and jitteriness, which commonly occur in neonates with diffuse cerebral dysfunction. Unlike epileptic events, these nonepileptic phenomena can often be elicited by limb repositioning or tactile stimulation and suppressed by physical restraint.

The EEG is important in determining adequacy of therapy and in predicting neurologic outcome. Prolonged or serial recordings should be performed in pharmacologically paralyzed infants at risk for developing seizures. The severity of background abnormalities is correlated with the extent of neurologic impairment. Infants with suppressed, undifferentiated, or suppression-burst patterns have a high incidence of neurologic and developmental sequelae. In contrast, isolated sharp waves are commonly seen in neurologically normal neonates without seizures and are not predictive of seizures or the future development of epilepsy. Ictal patterns are more variable in neonates

TABLE 52-2

Etiologies of Neonatal Seizures by Peak Time of Onset

| DISORDER | 24 HOURS | 24-72 HOURS | 3-7 DAYS | 7-28 DAYS |

than in older patients; typically, they consist of runs of focal paroxysmal activity of varying frequency and polarity. Clonic, focal tonic, and generalized myoclonic seizures are consistently accompanied by EEG changes, whereas generalized tonic, focal or multifocal myoclonic, and subtle seizures are not.

Neuroimaging studies should be performed to rule out structural lesions. CSF analysis and metabolic screens are indicated when infection or inborn errors of metabolism are suspected.

Severely impaired neonates with clinical seizures unaccompanied by EEG changes do not necessarily require AED therapy. In this setting, AEDs are not likely to reduce the clinical manifestations and affected patients have a high incidence of adverse reactions. Antiepileptic drug therapy is recommended when recurrent clinical events are accompanied by EEG seizure patterns. Phenobarbital is the most widely used agent, although phenytoin and benzodiazepines are also effective. Because protein binding is altered in sick infants, monitoring of total and free drug levels is advised. Pyridoxine, 50 to 100 mg, should be administered intravenously with simultaneous EEG recording when seizures are refractory to conventional agents. In the absence of CNS pathology and significant EEG abnormalities, neurologically normal infants do not require prolonged therapy and should be withdrawn from medication before hospital discharge. Neonates with abnormal findings on neurologic examinations and focal cerebral pathology have a high risk of recurrence and should be treated for longer periods.

The mortality rate for neonates with seizures is 40% for full-term and 50% for premature infants. Epilepsy develops in nearly 25% of patients. Aside from etiology and findings on neurologic examination, the presence and severity of

background abnormalities on EEG are the most reliable predictors of outcome. Most infants with normal background features on EEG have normal development, whereas severe background abnormalities, independent of electrographic seizures, portend a poor prognosis.

Febrile Convulsions

Febrile seizures occur in 2% to 5% of children, representing the most common seizure disorder in this age group.³³ Approximately 30% of patients experience a single recurrence, and of this group, half will experience multiple seizures. The age of onset ranges from 3 months to 5 years with a peak incidence from 18 to 24 months. Seizures occur during a sudden rise in temperature early in the course of an illness in the absence of intracranial infection or a defined etiology. Simple febrile seizures, which are single, generalized convulsions less than 15 minutes in duration, comprise 80% to 90% of cases. Seizures that exceed 15 minutes in duration, occur more than once in a 24-hour period, or show focal motor manifestations are classified as complex or complicated febrile seizures. Patients with complex febrile seizures have a higher rate of subsequent epilepsy.

The risk of seizures in family members of patients with febrile seizures is two to three times that of the general population. Generalized epileptiform activity and photosensitivity have been reported in asymptomatic relatives of affected patients. These findings support a genetic etiology, although the mode of inheritance is unknown. Similarly, the relationship between febrile seizures and MTL is poorly understood. Prolonged febrile convulsions are associated with various physiologic alterations capable of producing ischemic changes in hippocampal neurons. Whether these changes are operative in the development

of epilepsy or whether they simply represent the effect of recurrent seizures remains a matter of debate.

Febrile seizures should be distinguished from seizures due to intracranial infection, electrolyte disturbance, inborn errors of metabolism, and nonepileptic events such as breath-holding spells. The American Academy of Pediatrics published two practice parameters for managing the child with first febrile seizures.^{33,34} The extent of laboratory and radiologic evaluation depends on results of the clinical history and examination. Because the condition of most children with simple febrile seizures has returned to baseline by the time of evaluation, laboratory testing, EEG, and neuroimaging studies are generally unrevealing. Patients with complex febrile seizures, especially those with focal motor manifestations, should undergo a neuroimaging study to rule out structural lesions. CSF analysis is indicated in cases of suspected CNS infection. Patients presenting with their first febrile seizure before 6 months and after 5 years of age should be thoroughly evaluated because secondary causes are more likely. Single seizures do not require treatment with AEDs as the benefits of treatment do not outweigh the risks. Repetitive seizures and status epilepticus should be terminated with intravenous benzodiazepines or phenobarbital. Prophylactic AEDs are often not recommended even in these settings because of the high incidence of behavioral and cognitive adverse effects and their failure to reduce the risk of subsequent epilepsy. Parents should be assured of the benign nature of the disorder and instructed in the administration of antipyretics, tepid sponge bathing, and emergency first aid. Rectal diazepam should be considered in children with frequent febrile illnesses. The risk of recurrent febrile seizures is highest in children younger than 1 year of age and those with complicated seizures. Two percent to 9% of affected children develop afebrile seizures. Patients with abnormal findings on neurologic examinations or abnormal development, family history of afebrile seizures, and complicated seizures have a higher risk of subsequent epilepsy.

Acquired Epileptic Aphasia

Approximately 300 cases of acquired epileptic aphasia, or Landau-Kleffner syndrome, are reported in the literature.³⁵ This syndrome is characterized by an acquired aphasia with epileptiform activity over the temporal or temporo-parieto-occipital regions and psychomotor and behavioral difficulties. An auditory verbal agnosia and reduction of spontaneous speech typically begin before 6 years of age, after the initial acquisition of verbal language. Consequently, many patients are misdiagnosed as deaf or autistic. Infrequent tonic-clonic, focal motor, and atonic seizures are observed in 75% of cases. Psychomotor disturbances or personality disorders occur in 70% of patients. Seizures persisting into adolescence tend to be infrequent and nocturnal. Males are affected twice as often as females. Interruption of subcortical fibers resulting in the deafferentation of language cortex has been hypothesized as the underlying pathogenesis; however, no etiologic factors have been identified. In cases in which brain biopsies were performed, no specific abnormalities have been identified.

The waking EEG in Landau-Kleffner syndrome is characterized by multifocal spikes in the temporal and parieto-

occipital regions superimposed on normal background activity and markedly enhanced sleep. Audiography, auditory evoked potentials, and neuroimaging study results are normal. Landau-Kleffner syndrome bears striking resemblance to epilepsy with continuous spike waves during slow-wave sleep (CSWS). In both disorders, EEG abnormalities are markedly accentuated, and at times continuous, during sleep. Seizures are more frequent and global neurologic deterioration emerges rather than aphasia in CSWS, however.

Administration of intravenous diazepam may produce dramatic but transient improvements in language and EEG abnormalities. The benefit of long-term AED therapy has not been demonstrated, however. In most cases, seizures and EEG abnormalities undergo remission spontaneously by 15 years of age, and speech typically recovers by adulthood. Onset after 6 years of age and early speech therapy are associated with a more favorable prognosis.

Epilepsy and Women's Health

Beyond seizure control, women with epilepsy face a variety of issues that are often unaddressed by health care professionals. These include pregnancy and the risk of abnormal fetal outcomes, breast-feeding, family planning, menstrual cycle abnormalities, bone health, the effects of female hormones on seizure susceptibility, and sexual dysfunction.^{36,37}

Epilepsy is the most common neurologic disorder encountered by obstetricians. Approximately 0.3% to 0.5% of all pregnancies and over 1 million women of childbearing age are affected.³⁷ Seizure frequency during pregnancy typically parallels preconception seizure control, and 50% to 75% of women experience no significant change. Breakthrough seizures are usually due to noncompliance, stress, or sleep deprivation. The incidence of status epilepticus is similar to nonpregnant epileptic control subjects. The risk of spontaneous abortion, bleeding diatheses, premature labor, preeclampsia, eclampsia, and placental defects in women with epilepsy is two to four times higher than in nonepileptic women. In most cases, labor and delivery progress without complications. Elective cesarean section should be performed when there is poor seizure control during the third trimester, in cases of severe stress-induced seizures, and in patients with neurologic deficits interfering with labor. Emergency cesarean section is indicated in women with recurrent seizures during labor and delivery and when seizures result in fetal distress.

Seizures may be the initial manifestation of a host of diseases that present during pregnancy. Ischemic stroke, paradoxical embolus, vasculitis, and metastatic choriocarcinoma may appear at any time during pregnancy with seizures and focal neurologic deficits. Vascular anomalies should be considered when seizures develop in pregnancy because the risk of bleeding due to arteriovenous malformations and aneurysms tends to increase as pregnancy progresses. Eclampsia, oxytocin-induced water intoxication, toxicity of local anesthetics, amniotic fluid embolus, thrombotic thrombocytopenic purpura, cerebral venous thrombosis, pheochromocytoma, and subarachnoid hemorrhage may produce seizures in the peripartum period. These disorders should be considered in the differential diagnosis of patients with new onset of seizures during pregnancy.

Most seizures during pregnancy occur in association with subtherapeutic AED levels. The serum concentration of AEDs gradually declines during pregnancy, reaching a nadir near term and returning to preconception levels at variable rates post partum. During pregnancy, a reduction in protein binding leads to a higher percentage of unbound, free drug that is more rapidly excreted by the kidneys. The dilutional effects of water retention and increased hepatic microsomal activity, which enhances drug metabolism, are additional factors that contribute to subtherapeutic drug concentrations and breakthrough seizures. Levels of the older AEDs may take 8 to 12 weeks to return to preconception levels after delivery. With one exception, the pharmacokinetics of the newer AEDs during pregnancy are unknown. Lamotrigine is approximately 55% protein bound and is extensively hepatically metabolized by an isozyme of the UDP glucuronosyltransferase enzyme system. The metabolism of lamotrigine changes dramatically during pregnancy with clearance increasing to over 300% of baseline during the second trimester, often resulting in breakthrough seizures and dosage adjustments. Dose reduction is often required within days of delivery to prevent toxicity as the pharmacokinetics rapidly revert to preconception levels.

Offspring of women with epilepsy have an increased incidence of congenital malformations, growth retardation, cognitive deficiencies, and epilepsy. A variety of factors contribute to these findings, including AED exposure, folic acid deficiency, genetics, socioeconomic status, and maternal health. The older AEDs phenobarbital, phenytoin, valproic acid, and carbamazepine are classified as Pregnancy Category D, indicating that there is evidence of human fetal risk, although the benefits may outweigh the risks. All of the newer AEDs and ethosuximide are Pregnancy Category C, indicating that either animal studies have shown adverse effects on the fetus and there are no controlled studies in humans, or studies in humans and animals are unavailable. The risk of major malformations in infants born to women with epilepsy is twice that of the general population, in the range of 4% to 6%.³⁸ The most common major malformations observed in infants exposed to AEDs include neural tube defects, congenital heart disease, orofacial clefts, intestinal atresia, and urogenital defects.

Various international and industry-based pregnancy registries accepted in the last decade are extending earlier observations. Most notable are the European Registry of Antiepileptic Drugs in Pregnancy (EURAP), the North American AED Pregnancy Registry, the UK Epilepsy and Pregnancy Registry, and the largest industry-based registry, the Lamotrigine Pregnancy Registry. EURAP has reported an overall major malformation rate of 6%, 5% with monotherapy and 8% with polytherapy. The North American registry has published data on phenobarbital and valproic acid only. Interim UK results suggest that the risk of major malformations for monotherapy-exposed infants (3.5%) is no greater than in unexposed infants (3.7%), while the risk is greater (6.0%) for polytherapy exposures. There is growing support for the concept of drug-specific variations in teratogenic potential. The Lamotrigine registry found comparable major malformation rates in offspring exposed to monotherapy (2.8%) and polytherapy combinations excluding valproic acid (2.7%); whereas rates were higher

in lamotrigine polytherapy including valproic acid (11.8%). Preliminary findings of the Neurodevelopmental Effects of Antiepileptic Drugs (NEAD) trial, a prospective, observational study of 361 mother-child pairs from 25 centers, suggest that the risk of serious adverse outcomes in infants exposed to valproic acid may exceed that of phenytoin, carbamazepine, and lamotrigine. In a recent study of pregnancy outcomes abstracted from the Finnish National Medical Birth Registry, the risk of malformations was substantially higher in the offspring of women taking valproic acid as monotherapy or polytherapy as compared to untreated women and women on polytherapy excluding valproate.³⁸ Others have found that infants exposed to valproate were significantly more likely to require special educational needs compared with those exposed to other agents.

The management of epilepsy during pregnancy begins prior to conception. Although more than 90% of patients have uneventful pregnancies, all women with epilepsy must be counseled about the potential increased risk for obstetric complications, worsening seizure control, and adverse neonatal outcomes. AED regimens should be reassessed and optimized prior to conception to ensure appropriate treatment of seizure type(s) and epilepsy syndrome. The ideal agent during pregnancy is the one that most effectively controls seizures at serum concentrations that are well tolerated. AED discontinuation should be considered in women who have been seizure free for 2 to 5 years and have a single seizure type, normal neurologic examination, and normal electroencephalogram on treatment. Whenever possible, polytherapy should be avoided and the lowest effective serum concentration maintained. Supplementation with a multivitamin and additional folic acid (0.8 to 5 mg/day) beginning preconception, is advised.

Pregnant women with epilepsy should be jointly managed by a team of professionals that includes a neurologist, obstetrician, pediatrician, and, in some cases, geneticist. Major changes in AED therapy should be avoided, because the risk for seizures is usually greater than the risk for teratogenicity once pregnancy is identified. Women should be advised about the importance of proper sleep and medication compliance, particularly in the last trimester, when AED levels tend to be lowest. Seizures during labor are best treated with intravenous fosphenytoin or short-acting benzodiazepines. Serum AED concentrations should be monitored monthly and in the postpartum period, particularly in women with seizures during pregnancy and in those taking newer AEDs. Laboratory monitoring may need to be performed more often in women with frequent seizures, signs or symptoms of toxicity, suspected noncompliance, or a history of increased seizure frequency or status epilepticus during a prior pregnancy. Medication adjustments should be made to control seizures and maintain serum concentrations in the therapeutic range near term. Women should be monitoring clinically for signs and symptoms of toxicity beginning immediately after childbirth until serum concentrations stabilize and necessary medication adjustments should be made.

Most major malformations can be identified in utero. Maternal serum α -fetoprotein obtained between 16 and 18 weeks' gestation is elevated in 85% of fetuses with open neural tube defects (NTDs) and has a false-positive rate

of 3% to 4%.³⁹ Level II fetal ultrasonography should be performed between 18 and 22 weeks to identify major malformations. More than 90% of NTDs, life-threatening cardiac anomalies, and major skeletal malformations are detected by ultrasonography at this time.³⁹ Less severe cardiac anomalies and orofacial clefts may be identified on a second examination performed at 22 to 24 weeks' gestation. Amniocentesis should be offered to women at high risk for NTDs and to those with an elevated serum α -fetoprotein level in whom ultrasonography is nondiagnostic. Some centers advocate offering amniocentesis to all women being treated with valproic acid or carbamazepine because of the increased incidence of NTDs in exposed infants. Elevation of amniotic fluid α -fetoprotein and acetylcholinesterase can identify more than 99% of open NTDs.³⁹ Genetic counseling should be offered to all women when fetal malformations are identified. Chromosomal analysis should be performed at the time of amniocentesis.

In North America, pregnant women with epilepsy should contact the North American Registry for Epilepsy and Pregnancy at 1-888-233-2334 so that pregnancy outcomes can be more thoroughly studied.

Contraception and pregnancy counseling should be provided to all women with epilepsy of childbearing potential. The risk of failure of oral contraceptive agents is increased several-fold in women taking enzyme-inducing AEDs including phenobarbital, phenytoin, carbamazepine, and primidone. Phenytoin and phenobarbital induce the production of sex hormone binding globulin to which the progestins are tightly bound, resulting in lower concentrations of free progestin that may also lead to a failure to suppress ovulation. Topiramate and oxcarbazepine reduce the concentration of female sex steroids at higher doses only. No interaction between oral contraceptive agents and valproic acid, levetiracetam, gabapentin, tiagabine, zonisamide, or pregabalin have been reported. Oral contraceptives increase the clearance of lamotrigine resulting in seizures when hormonal agents are initiated or toxicity during pill-free weeks. To prevent unplanned pregnancy, formulations containing higher-dose estrogen have traditionally been recommended. However, in recent years, health care providers have grown increasingly concerned about their potential systemic adverse effects. Depot medroxyprogesterone acetate (Depo-Provera) has long been used as a contraceptive alternative in women with epilepsy. When used correctly, barrier methods are an effective option.

The opposing effects of estrogen (proconvulsant) and progesterone (anticonvulsant) on seizure threshold have been well described in both animals and humans. Hormone levels fluctuate throughout the menstrual cycle. In some women with epilepsy, these fluctuations lead to periods of seizure susceptibility, a condition known as catamenial epilepsy. At least 30% of women with epilepsy are affected.³⁶ The diagnosis of catamenial epilepsy requires careful assessment of menstrual and seizure diaries and characterization of cycle duration and type. There are several approaches to the treatment of catamenial epilepsy, although each is based on small, unblinded studies, or anecdotal reports. Progesterone has been shown to be effective in some cases.

Women with epilepsy are at increased risk for polycystic ovary syndrome (PCOS) and other reproductive endocrine

disorders. PCOS, characterized by chronic anovulation and hyperandrogenism (hirsutism, obesity, acne, elevated androgens, and LH/FSH ratio) affects approximately 5% of women in the general population.³⁶ Women with PCOS are at increased risk for carbohydrate intolerance, hyperlipidemia, and endometrial cancer. Features of PCOS are more significantly more common in women taking valproic acid than other AEDs. Women with epilepsy experiencing menstrual irregularities warrant investigation.

Finally, bone health in women taking AEDs has been a recent area of intense investigation. Osteopenia, osteoporosis, and fractures are more common among persons with epilepsy than the general population. A recent, large prospective study involving 9704 elderly community-dwelling women found that AED use increased the rate of bone loss.⁴⁰ The average rate of decline in total hip bone mineral density for non-AED users was 0.7% per year as compared to 1.16% per year for continuous AED users. The highest rate of bone loss was observed in patients treated with PHT (2.68% per year). AED use increased hip fracture rate by 29% in women over 65 years of age. Bone health should be periodically assessed in women treated with long-term AEDs.

Status Epilepticus

Status epilepticus (SE) is a medical emergency that demands prompt diagnosis and treatment if severe neurologic sequelae and death are to be minimized. An estimated 125,000 to 195,000 episodes of SE occur in the United States annually, resulting in 22,000 to 42,000 deaths.⁴¹ Despite improvements in medical management, the incidence of significant morbidity and death remains high. SE is defined as continuous clinical or electrical seizure activity or repetitive seizures with incomplete neurologic recovery interictally for a period of at least 30 minutes. Patients having continuous seizure activity for 10 minutes or longer should be treated as if in SE, because most seizures terminate spontaneously within 1 to 2 minutes. In addition, impending SE should be suspected in patients experiencing three or more TCS within a 24-hour period, particularly when this represents an increase from the typical frequency.

Status epilepticus is classified as generalized or partial (focal), and convulsive or nonconvulsive. Generalized convulsive status includes tonic-clonic, tonic, clonic, or myoclonic SE, although the majority of cases consist of recurrent TCS. Nonconvulsive SE includes absence and complex partial SE, both of which are characterized by clouding of consciousness with or without minor motor manifestations. EEG is usually required to distinguish the two. Any type of simple partial seizure, including seizures with sensory, motor, language, autonomic, or psychic manifestations, can evolve into SE. Partial SE characterized by focal clonic activity is referred to as *epilepsia partialis continua*. This condition is seen in patients with lesions involving the perirolandic region such as in children with Rasmussen encephalitis.

In adult patients, the most common type of SE is secondary generalized convulsive SE (GCSE), characterized by intermittent or continuous overt convulsive activity accompanied by coma and epileptiform activity on EEG.

TABLE 52-3

Management of Status Epilepticus

Step 1

Assess Airway, Breathing, Circulation

1. Administer O₂, monitor cardiac rhythm, oxygen saturation, and vital signs
2. Establish intravenous line with normal saline
3. Bedside glucose test
4. Draw blood for AED (antiepileptic drug) levels, complete blood count, electrolytes, calcium and magnesium, glucose and toxicology screen
5. Administer thiamine 100 mg and dextrose 50% 50 mL IV (D₂₅ 2 mL/kg in children)
6. Obtain history and perform examination

Step 2

1. Administer intravenous lorazepam 0.1 mg/kg in adults, 0.05 to 0.5 mg/kg in children (up to 2 mg/min) or diazepam 0.25 mg/kg in adults, 0.1 to 1.0 mg/kg in children (up to 5 mg/min); repeat after 10 min if seizures persist
2. Administer fosphenytoin 20 PE (phenytoin equivalents)/kg load (up to 150 PE/min)
3. If seizures persist, give additional fosphenytoin 5–10 PE/kg to a total dose of 30 PE mg/kg or serum concentration of 30 µg/mL

Step 3

1. Intubate, place arterial line, and draw arterial blood gas and phenytoin level
2. Consider intravenous phenobarbital 20 mg/kg (100 mg/min or 3 mg/kg/min in children)

Step 4

1. Consider pharmacological coma with pentobarbital 5–8 mg/kg load, followed by continuous infusion of 2–4 mg/kg/hr titrated to burst-suppression for 6 to 48 hr
or
2. Midazolam 0.2 mg/kg load followed by continuous infusion beginning at 1 µg/kg/min increasing by 1 µg/kg/min every 15–30 min as needed to a maximum rate of 10 µg/kg/min

The manifestations change over time such that discrete convulsions give way to increasingly subtle clinical manifestations, which is a condition known as *subtle SE*. Eventually, electrical status without clinical manifestations is all that remains. Occasionally, subtle SE occurs without prior convulsive activity in patients with severe diffuse cerebral dysfunction. Generalized convulsive activity produces various systemic effects, including hypoxia, hyperpyrexia, blood pressure instability, and cerebral dysautoregulation. Metabolic derangements, including respiratory and metabolic acidosis, hyperazotemia, hypokalemia, hyponatremia, hyperglycemia followed by hypoglycemia, and marked elevations of plasma prolactin, glucagon, growth hormone, and corticotropin may be observed. Rhabdomyolysis may produce myoglobinuria and renal failure.

Acute CNS insults, including anoxia, head injury, stroke, neoplasm, and infection, account for 50% of cases. In children, the most common precipitants are fever and infection, whereas cerebrovascular disease predominates in older adults. Approximately 20% of all SE cases occur in epileptic patients during medication adjustment or as a result of noncompliance. In one third of patients, the cause for SE is undetermined. SE should be suspected in patients with unexplained coma with or without motor manifestations. Nonepileptic phenomena, including tremor, myoclonus, eye movements, and oral-buccal movements that frequently occur following anoxia, brain stem or bilateral cerebral ischemia, drug overdose, and severe metabolic and electrolyte disturbances may be difficult to differentiate clinically from nonconvulsive SE. Occasionally, prolonged psychogenic seizures are misinterpreted and treated as SE.

A protocol for the treatment of GCSE is provided in Table 52-3. Treatment should begin with assessment of cardiorespiratory function. An oral airway should be secured and oxygen administered when needed. Blood should

be drawn for AED levels, glucose, blood urea nitrogen, electrolytes, calcium, magnesium, and drug screens. An intravenous infusion with isotonic saline solution should be placed and glucose 25 g and thiamine 100 mg administered. A history and neurologic examination should be performed once the patient's condition is stabilized. When an acute CNS insult or infection is suspected, further investigations, including neuroimaging (cranial CT) and lumbar puncture, should be performed once treatment is initiated. EEG is useful when the diagnosis of GCSE is in doubt, during pharmacologic coma, or when assessing the adequacy of treatment.

Generalized convulsive seizures and electrical seizures in patients with subtle SE should be terminated as rapidly as possible, because the duration of SE is a major determinant of morbidity and death. Absence, complex partial, and focal motor SE are often treated less aggressively, because the risk of neurologic sequelae is believed to be significantly lower. However, the mortality rate was 18% in a recent study of 100 patients with NCSE and was higher in patients with acute systemic or neurologic causes (27%) versus patients with epilepsy (3%) and those without epilepsy or an acute medical problem on presentation (18%) and in patients with severe mental status impairment (39%).⁴² GCSE should be treated with medications administered intravenously until seizures are aborted. The most common cause of treatment failure is when the appropriate medication is administered in inadequate dosages via an inappropriate route.

Once an intravenous line has been secured, lorazepam (0.1 mg/kg, no faster than 2 mg/minute) should be administered. Because of its high lipid solubility and rapid CNS entry, diazepam frequently abolishes seizure activity within minutes, only for seizures to recur within 30 minutes as the drug redistributes to other fatty tissues. Consequently, lorazepam is preferred for its longer duration of action.

In most circumstances, following treatment with a benzodiazepine, fosphenytoin should be administered. Fosphenytoin, a phosphate ester of phenytoin, was released by the Food and Drug Administration (FDA) in 1996 for use in the treatment of escalating seizures requiring parenteral treatment and SE. Its advantages over phenytoin include a more rapid rate of infusion (150 mg/minute) and lower incidence of hypotension and cardiac arrhythmias. If seizure activity continues after fosphenytoin loading, additional boluses should be given to achieve a serum concentration of 25 to 30 $\mu\text{g/mL}$. This regimen is effective in terminating over 90% of cases. Anticonvulsant medications should be administered in a setting equipped to provide advanced cardiac life support. Patients should be continuously monitored during parenteral administration of AEDs for signs of respiratory depression, hypotension, and cardiac arrhythmias.

If seizures persist, elective intubation should be performed before further treatment is administered, particularly if other CNS depressants have been previously administered. Only 6% of cases prove refractory to this approach and require anesthetic doses of barbiturates titrated to achieve burst-suppression. With the availability of agents with shorter half-lives, phenobarbital is used less frequently. Pentobarbital is the most commonly used agent for refractory SE. A loading dose of 5 mg/kg followed by a maintenance infusion of 1 to 3 mg/kg/hour titrated to burst-suppression is recommended. Treatment is continued for 6 to 48 hours, after which the drug is withdrawn and the EEG observed for recurrence of seizure activity. Midazolam, lidocaine, and propofol have been used for refractory SE; however, no controlled studies using these agents are available. For the treatment of absence SE, intravenous benzodiazepines followed by ethosuximide or valproic acid are usually effective. Depending on the situation, simple and complex partial SE may be treated with oral anticonvulsants, fosphenytoin (IM or IV), or intravenous benzodiazepines. The use of phenobarbital or pharmacologic coma is rarely indicated.

Morbidity and death in SE are largely dependent on the speed of intervention, age of the patient, and etiology. Although the mortality rate in adults ranges from 1% to 32%, subtle SE and GCSE exceeding 1 hour in duration carry a poor prognosis. A favorable outcome is observed in children, patients with pre-existing epilepsy, and individuals with drug-induced SE.

Nonepileptic Seizures

Nonepileptic seizures, also referred to as *psychogenic* or *pseudo* seizures, constitute 15% to 20% of admissions to epilepsy units.⁴³ Affected women outnumber men by a factor of 3.5:1. Psychogenic seizures are infrequent before 12 years of age but have been observed in children as young as 5 years old. Peak incidence is in the third to fourth decades, although onset may occur later in life. The incidence of epilepsy in patients with psychogenic seizures ranges from 10% to 60%.⁴³

Psychogenic seizures are episodes involving affective, autonomic, or sensorimotor manifestations that are precipitated by emotional distress. Palpitations, choking sensations, dizziness, malaise, acral paresthesias, sensory disturbances, crying, and alterations in consciousness with or without motor manifestations are observed. Unlike epileptic seizures,

motor activity generally consists of side-to-side head movements, opisthotonus, pelvic thrusting, trembling, and random asynchronous movements. Micturition, injuries, amnesia, and postictal somnolence may occur. Psychogenic seizures tend to be less stereotyped, more gradual in evolution, and longer in duration than epileptic seizures.

Psychogenic seizures are believed to represent subconsciously mediated behavior resulting from emotional distress. Unlike malingerers, affected individuals do not feign illness for obvious secondary gain. Psychogenic seizures occur in patients with conversion disorders, anxiety and panic disorder, depression, post-traumatic stress disorder, schizophrenia, and personality disorders. Additionally, over two thirds of patients have a history of sexual or physical abuse in childhood.

Patients with psychogenic seizures frequently present to neurologists or epilepsy monitoring units having been diagnosed with epilepsy and treated with anticonvulsants. Seizures may be difficult to differentiate from frontal lobe seizures characterized by violent motor activity and sexual automatisms. Malingering and physiologic nonepileptic events such as cerebral hypoperfusion, hypoxia, hypoglycemia, electrolyte disturbances, alcohol and drugs effects, migraine, gastroesophageal reflux, parasomnias, and movement disorders including paroxysmal dyskinesias may produce similar symptoms.

The EEG is the most valuable diagnostic tool. The persistence of normal background activity in a comatose patient essentially rules out epilepsy as a cause of that spell. Because 30% of complex partial seizures and 70% of simple partial seizures are not accompanied by EEG changes, however, events characterized by subtle behavior without complete loss of consciousness should be interpreted with caution. Induction procedures are commonly employed to provoke seizures in the EEG laboratory. Elevated serum prolactin when measured 10 to 20 minutes after a suspected event is useful in differentiating complex partial and TCS from nonepileptic psychogenic seizures.⁴⁴ Serum prolactin does not differentiate epileptic seizures from syncope. Normal values do not reliably predict a nonepileptic event, however.

The patient should be informed of the diagnosis of psychogenic seizures, and consideration should be made for AED withdrawal. A psychiatric evaluation should be obtained and underlying psychological disorders addressed. Psychotherapy and pharmacologic treatment of psychiatric disease is indicated in most cases. Typically, a team approach involving neurologist, psychiatrist, and therapist is most effective.

NEUROPHARMACOLOGY OF THE ANTIPILEPTIC DRUGS

Pharmacologic Principles

Pharmacokinetics refers to drug concentrations and their variability over time based on absorption, distribution, and elimination (Table 52-4). Absorption is defined as the passage of a drug from the site of administration to the vascular space. Absorption is measured in terms of rate and bioavailability, which is the amount of drug that

TABLE 52-4

reaches the systemic circulation. Both vary with route of administration and drug formulation. Bioavailability is 100% following intravenous administration, the route against which others are measured. With oral administration, absorption is influenced by gastric pH, bowel motility, splanchnic blood flow, and concomitant medications and food intake. Large variations in absorption occur with intramuscular administration, making this an undesirable route if high drug concentrations are required rapidly.

Following absorption, drugs are distributed into other compartments. The extent of distribution is expressed as the volume of distribution (V_d), a hypothetical volume of total body fluid within which a drug is evenly distributed. Distribution depends on extent of protein binding, solubility, and blood flow. Most AEDs are partially protein bound, and only the free, or unbound, fraction penetrates the blood-brain barrier to produce an effect. The V_d required to dissolve an amount of drug (D) to achieve a given concentration (ΔC = desired minus actual concentration) can be calculated by using the equation

$$V_d = D \div \Delta C$$

By solving for D

$$D = V_d \times \Delta C$$

the dose of drug required to achieve a particular serum concentration can be determined.

Elimination of AEDs occurs through hepatic metabolism and renal excretion. The major metabolic pathway in humans is the hepatocyte endoplasmic reticulum P-450 mixed oxidase system. Phenobarbital, primidone, phenytoin, carbamazepine, felbamate, topiramate, and oxcarbazepine (the latter two agents at higher doses only) induce this enzyme system, thereby facilitating metabolism of other hepatically metabolized drugs, including oral contraceptives, folic acid, warfarin, quinidine, and steroids. Conversely, valproic acid is an enzyme inhibitor which, when combined with other

hepatically metabolized agents, impairs their metabolism, potentially leading to toxicity. Analgesics, cardiac drugs, antimicrobials, antiulcer agents, and psychotropics may also interfere with the metabolism of AEDs and produce toxic reactions. Carbamazepine, valproic acid, primidone, oxcarbazepine, and diazepam are converted to active metabolites having additional anticonvulsant properties.

Half-life (t_{1/2}) is the time required for the serum concentration of a drug to decrease by 50% following complete absorption and distribution of a single dose. A drug's half-life determines the dosing frequency and, as a rule, the dosing interval should not exceed one half-life. Drugs with short half-lives should be administered multiple times per day to prevent large fluctuations in serum concentration that may produce adverse effects or breakthrough seizures. Those with longer half-lives may be administered once daily, which generally improves compliance.

A drug's half-life may be altered by hepatic enzyme induction or inhibition and impaired renal function. With the exception of phenytoin, metabolism of anticonvulsant medications follows linear, or first-order, kinetics, in which the rate of metabolism is directly proportional to serum concentration. Phenytoin is metabolized through nonlinear, or zero-order, kinetics. The enzymes responsible for the elimination of phenytoin become saturated at levels within the therapeutic range. Once enzyme systems are saturated, the rate of metabolism fails to increase proportionately with further dosage increments, and modest increases in dosage result in marked increases in serum concentration. To avoid toxicity, the daily dosage of phenytoin should be increased by no more than 50 mg when serum concentration exceeds 10 to 12 μg/mL.

Special treatment considerations are necessary when treating the very young and the elderly due to age-related pharmacokinetic changes. For example, hepatic metabolism is slower and renal clearance reduced in older adults. Therefore, these individuals may respond to smaller doses

of medication and demonstrate greater sensitivity to adverse effects. Reduced compliance, comorbid illnesses, and co-medications must also be considered in the geriatric population with epilepsy. A recent study of nearly 600 elderly adults with newly diagnosed seizures found that lamotrigine and gabapentin were better tolerated than carbamazepine, although seizure control was similar between groups.⁴⁵

Principles of Antiepileptic Drug Treatment

The selection of an AED is based on efficacy against specific seizure types and the adverse effect profile (Table 52-5).⁴⁶ Phenytoin, carbamazepine, valproic acid, oxcarbazepine, lamotrigine, and topiramate are appropriate agents for initial monotherapy in patients with generalized TCS. Ethosuximide, valproic acid, lamotrigine, and zonisamide are effective against AS. Valproic acid, lamotrigine, and perhaps zonisamide are effective against tonic-clonic, absence, and myoclonic seizures. Myoclonic seizures are responsive to valproic acid, lamotrigine, and benzodiazepines. Carbamazepine, phenytoin, oxcarbazepine, lamotrigine, topiramate, and valproic acid are effective in the treatment of new onset partial seizures. All the newer AEDs may be used as adjunctive therapy in patients with refractory partial seizures with or without secondary generalized TCS. Although primidone and phenobarbital are effective against tonic-clonic and partial seizures, they are not considered first-line agents because of their sedative properties. In controlled trials, most of the newer AEDs have been shown to produce a 30% to 50% reduction in seizures in approximately one third of patients with partial epilepsy. Lamotrigine is also effective in the treatment of seizures in patients with Lennox-Gastaut syndrome and topiramate is FDA-approved as initial treatment of primary generalized TCS. Felbamate has a broad spectrum of action but its use is limited due to the potential of hematologic and hepatic toxicity.

A variety of factors including weight, bone health, reproductive status, compliance, affordability, and comorbid conditions including psychiatric disorders, headache, and other pain syndromes should be considered when choosing

an AED. Dose-related adverse effects occur in over 50% of patients and usually resolve spontaneously or with dose reduction. Gastrointestinal distress, dizziness, sedation, dysarthria, diplopia, ataxia, and asthenia are most common. The benzodiazepines, phenobarbital, and primidone are particularly likely to produce sedation and cognitive impairment. Skin eruptions represent the most commonly encountered idiosyncratic reaction associated with AEDs. Generally appearing within the first 3 months of treatment, rashes are usually benign, and resolve with dosage reduction or discontinuation. Severe reactions, including Stevens-Johnson syndrome, exfoliative dermatitis, and toxic epidermal neurolysis, are rare. Some AEDs can produce megaloblastic anemia, leukopenia, thrombocytopenia, aplastic anemia, asymptomatic elevations of hepatic transaminases, and life-threatening hepatotoxicity. Chronic idiosyncratic reactions include disorders of connective tissue and nervous system, endocrinopathies, and autoimmune disease.

Monotherapy is preferred whenever possible, and monotherapy is sufficient for most patients. Treatment with a single agent has several advantages, including fewer adverse effects, less chronic toxicity, less potential for pharmacokinetic and pharmacodynamic interactions, increased compliance, lower cost, and less risk for teratogenicity. Older AEDs have several advantages including long-term experience, lower cost, and known efficacy. However, the newer AEDs may be better tolerated than the old and demonstrate equivalent efficacy. Some of the newer agents have simpler pharmacokinetics, absence of hormone interactions, and require less laboratory monitoring. Long-term complications have not been firmly established for the newer AEDs. Consideration should be made for withdrawal of AEDs in patients seizure free for 2 to 5 years on therapy.⁴⁷ A single seizure type, normal neurologic examination and IQ, and EEG normalization with treatment are predictive of a greater chance of successful drug withdrawal. As many as two thirds of seizure-free patients remain so after AED withdrawal.

The goal of treatment is to produce a seizure-free state as soon as possible and without significant adverse effects. If seizures persist, the dosage should be gradually increased until seizure control is achieved or intolerable side effects appear. Trough blood levels should be obtained during steady-state conditions, generally no sooner than five half-lives after a dosage adjustment. A second agent is introduced only after an adequate trial of the first drug has failed. If polytherapy is required, drugs should be chosen with different mechanisms of action and side effect profiles to maximize anticonvulsant benefit and minimize toxicity. Interactions among the various AEDs must also be kept in mind in the selection of drug combinations (Table 52-6). Patients whose seizures continue despite adequate trials of two appropriate AEDs should be referred to an epilepsy center for further evaluation.

Clinical and laboratory monitoring is routinely performed in patients taking the older AEDs. The utility of routine laboratory monitoring in patients treated with the newer agents is unclear. Blood levels help to achieve maximal medication effect and identify patients who are noncompliant. The older agents have an established therapeutic range within which most patients experience an improvement in seizure

control and few or no adverse reactions. The therapeutic range should serve as a general guide only. Some patients become seizure-free with subtherapeutic serum concentrations, whereas others require levels in the “toxic” range to achieve satisfactory seizure control.

No standard recommendations exist for the timing of laboratory monitoring. Hematologic parameters should be assessed periodically during carbamazepine, ethosuximide, and valproic acid therapy. Hepatic transaminases should be monitored in patients taking carbamazepine, valproic acid, phenytoin, primidone, and phenobarbital. Hematologic and hepatic status must be monitored regularly in patients treated with felbamate. Laboratory monitoring is particularly important in the setting of hepatic or renal dysfunction and during pregnancy. Free levels are useful when protein binding is altered, such as in pregnancy, uremia, and hypoalbuminemia, and with highly protein-bound drugs such as phenytoin and valproic acid.

Clinical Use and Adverse Effects of Specific Antiepileptic Drugs

Phenobarbital, first marketed in the United States in 1912, is the oldest of the currently available AEDs. It is effective against partial, tonic-clonic, tonic, and clonic seizures and is the most commonly prescribed agent for neonatal seizures. Phenobarbital enhances GABA transmission by interacting with the GABA_A receptor–chloride channel complex, and it acts at glutamate receptors to decrease excitatory synaptic transmission. Long-term use is associated with chronic connective tissue disorders. Safety, affordability, and a broad spectrum of action contribute to its continued use in the United States and worldwide. Common neurologic side effects include sedation, nystagmus, ataxia, and irritability and hyperactivity in children. Phenobarbital is available in 16 mg capsules; 8-, 15-, 16-, 30-, 32-, 60-, 65-, and 100-mg tablets; elixir (15 mg/5 mL and 20 mg/5 mL); and injectable formulations.

Primidone has been available in the United States since 1954 for the treatment of partial and generalized seizures. Primidone is metabolized to phenobarbital and phenylethylmalonamide, both of which possess anticonvulsant properties. The adverse effects are similar to phenobarbital, although initiation of primidone is associated with a higher incidence of gastrointestinal distress, dizziness, ataxia, and diplopia. Primidone is available in 50- and 250-mg scored tablets and elixir (250 mg/5 mL).

Phenytoin became available in 1938 and remains a first-line agent in the treatment of tonic-clonic and partial seizures and status epilepticus. Its primary mechanism of action is inhibition of sustained high-frequency firing through blockade of voltage-gated Na⁺ channels. Phenytoin precipitates in muscle and can cause tissue necrosis if administered intramuscularly. Long-term complications include gingival hyperplasia, hirsutism, coarsening of facial features, hyperpigmentation, acne, pseudolymphoma, cerebellar degeneration, movement disorders including chorea and dystonia, and disorders of vitamin D metabolism, including osteopenia and osteoporosis. Phenytoin is available in 30-, 100-, 200-, and 300-mg extended release capsules; 30- and 100-mg prompt release capsules; 50-mg chewable tablets; suspension (125 mg/5 mL); and injectable forms. *Fosphenytoin sodium*,

a phosphate ester prodrug of phenytoin, has essentially replaced the injectable formulation of phenytoin. Because of its higher water solubility, fosphenytoin can be safely administered intramuscularly and intravenously at a rate of 150 mg phenytoin equivalent per minute.

Ethosuximide has been marketed in the United States since 1960 for the treatment of AS. It is the drug of choice in AE without TCS, against which it is ineffective. Ethosuximide blocks T-type Ca²⁺ channels that trigger and sustain rhythmic burst discharges in thalamic neurons. Trimethadione, which is no longer available in the United States, is the only other agent with a similar mechanism of action. Ethosuximide does not induce hepatic microsomal enzymes and is not protein-bound. Idiosyncratic reactions include headache, hiccups, blood dyscrasias, lupus-like syndromes, behavioral disturbances, and parkinsonism. Ethosuximide is available in 250-mg capsules and syrup (250 mg/5 mL).

Carbamazepine, available in the United States since 1974, has a similar mechanism and spectrum of action as phenytoin. The carbamazepine-10,11-epoxide metabolite also possesses anticonvulsant properties. Autoinduction occurs during the first several weeks of therapy, necessitating gradual titration. Concomitant use of propoxyphene, erythromycin, and cimetidine results in significant accumulation of carbamazepine. Despite its association with aplastic anemia, serious hematologic complications are rare. A mild, dose-related leukopenia may occur, which does not require discontinuation of the drug unless the total white blood cell count falls below 2500/μL or the total granulocyte count is less than 750/μL. Neurologic side effects include drowsiness, vertigo, ataxia, and diplopia. Idiosyncratic reactions include hyponatremia due to inappropriate antidiuretic effect; disturbances of thyroid, adrenal, and sex hormones; cardiac conduction disturbances; impaired renal function; movement disorders; and a lupus-like syndrome. Carbamazepine is available in 200-mg tablets; 100-mg chewable tablets; 100-, 200-, and 400-mg extended-release capsules (Tegretal XR); 200- and 300-mg extended-release capsules (Carbatrol); and suspension (100 mg/5 mL).

Valproic acid is a branched-chain fatty acid that was approved for use in the United States in 1978. The enteric-coated preparation, divalproex sodium, became available in 1983. Multiple mechanisms likely contribute to its broad spectrum of action, including inhibition of sustained repetitive firing through blockade of voltage-gated Na⁺ channels. Valproic acid is effective against generalized and partial seizures, including absence, myoclonic, and tonic-clonic seizures. High protein binding and hepatic enzyme inhibition contribute to the high incidence of drug interactions. Adverse reactions include tremor, weight gain, alopecia, hyperammonemia, carnitine deficiency, and thrombocytopenia. Fulminant hepatic failure and fatal pancreatitis have been reported. Valproate is available in 250-mg tablets and syrup (250 mg/5 mL), and divalproex sodium in 125-, 250-, and 500-mg tablets and 125-mg sprinkles for mixture with food. A long-acting formulation (Depakote ER) is available in 250- and 500-mg tablets. An intravenous formulation (Depakon) is available for use in patients who are unable to take oral formulations.

For the past 30 years, benzodiazepines have been used in the treatment of nearly every type of seizure disorder. As a

class, benzodiazepines bind to their receptor on the GABA_A receptor–chloride ionophore complex, increasing the frequency of Cl⁻ channel opening and potentiating GABA transmission. Long-term usage is limited by their sedative properties and development of tolerance to the anticonvulsant effect. Only clonazepam and clorazepate are used for the long-term treatment of seizures. Lorazepam and diazepam have a major role in the treatment of status epilepticus. Clonazepam is available as 0.5-, 1-, and 2-mg tablets. Clorazepate is available as 3.75-, 7.5-, and 15-mg capsules and 3.75-, 7.5-, 11.25-, 15-, and 22.5-mg tablets.

Felbamate was approved in the United States in 1993 for the treatment of partial seizures in adults and as adjunctive therapy in patients over 2 years of age with Lennox-Gastaut syndrome. Just over 1 year later, the FDA recommended limiting its use owing to its association with aplastic anemia. Currently, the FDA recommends that felbamate be used only in situations in which the risk of seizures exceeds the risks of the drug. As of December 1995, there have been 32 cases of aplastic anemia reported, including 10 fatalities, and numerous cases of hepatitis. The mechanism of action of felbamate is unknown, although it likely has multiple actions, including blockade of voltage-gated Na⁺ channels, potentiation of GABA transmission, and inhibition of excitatory neurotransmission through interaction with the NMDA receptor. Felbamate is effective against partial and generalized seizures, including AS. Common adverse effects include insomnia, weight loss, nausea, anorexia, dizziness, and lethargy. Although there is no evidence that laboratory monitoring will prevent serious complications, the manufacturer currently recommends monitoring liver function studies, complete blood count, and reticulocyte count monthly. Felbamate is available in 400-mg capsules, 600-mg tablets, and suspension (600 mg/5 mL). To avoid drug interactions, concomitant AEDs should be reduced by 20% to 30% when felbamate therapy is initiated.

Gabapentin was approved in the United States in 1993 and is currently indicated as adjunctive therapy of partial and secondary generalized seizures in patients over 3 years of age. Despite being an amino acid derivative of GABA, gabapentin does not interact with GABA receptors or potentiate gabaminergic transmission. Absorption is dose-dependent, and doses exceeding 1200 mg produce only modest increases in bioavailability. Lack of protein binding and hepatic metabolism contribute to the absence of significant drug interactions. Gabapentin is eliminated by the kidneys unchanged, which necessitates dosage adjustments in renally compromised patients. The most common adverse effects include somnolence, peripheral edema, and weight gain. Gabapentin is available in 100-, 300-, and 400-mg capsules and 800-mg tablets and syrup (250 mg/mL).

Lamotrigine received FDA approval in the United States in 1994 for the adjunctive treatment of partial seizures in patients older than 12 years of age. Since then, it has also been approved in conversion to monotherapy in adults with partial seizures and as adjunctive treatment of generalized seizures in patients with Lennox-Gastaut syndrome over the age of 2 years. Its mechanism of action and spectrum of activity are similar to those of phenytoin and carbamazepine. Lamotrigine does not induce hepatic microsomal enzymes and does not significantly affect the metabolism

of other drugs. The half-life of lamotrigine, however, is significantly prolonged by the concomitant use of valproic acid and shortened by agents that induce hepatic microsomal enzymes, including hormonal contraceptives. The most common adverse effects are dizziness, headache, diplopia, ataxia, somnolence, and vomiting. Hepatic or hematologic abnormalities have not been reported, and routine laboratory monitoring is not required. Tics have been observed in children. Lamotrigine is associated with skin rash in approximately 10% of patients. Severe hypersensitivity reactions may also occur, particularly in very young patients receiving valproic acid, and in the setting of rapid initiation or high initial doses. Lamotrigine is available in 25-, 100-, 150-, and 200-mg tablets and 2-, 5-, and 25-mg chewable tablets.

Topiramate received FDA approval in December 1996 for monotherapy and adjunctive therapy in adults and children with partial seizures with and without secondary generalized TCS and more recently for initial monotherapy in adults with primary generalized TCS. Topiramate has several mechanisms of action, including effects at voltage-gated Na⁺ channels, enhancement of GABA activity at GABA_A receptors, and antagonism of glutamate receptors. The drug does not affect the metabolism of concomitant AEDs. Adverse effects include language dysfunction, weight loss, metabolic acidosis, and hypohidrosis. Topiramate is not associated with organ toxicity, although renal stones develop in 1.5% of patients and open-angle glaucoma is rarely observed. It is available in 25-, 50-, 100-, and 200-mg tablets and 15- and 25-mg sprinkles.

Tiagabine was FDA approved in 1997 and is indicated as adjunctive treatment of partial seizures in patients over 12 years of age. Tiagabine is a potent inhibitor of GABA uptake, the primary inhibitory neurotransmitter in the CNS. By blocking uptake, the drug increases the extracellular concentration of GABA and prolongs its inhibitory effect. Common adverse effects include dizziness, asthenia, somnolence, and nervousness. Spike wave stupor is a rare complication. Tiagabine is available in 4-, 12-, 16-, and 20-mg tablets.

Levetiracetam received FDA approval in 1999 for use as an adjunctive agent in adults with partial and secondary generalized seizures. Its mechanism of action is unknown, however, levetiracetam is effective in a broad range of animal models of partial and generalized epilepsy. There are no significant drug interactions, as this agent is excreted in the urine largely unchanged. Adverse effects include somnolence, headache, and behavioral change. Levetiracetam is available in 250-, 500-, and 750-mg tablets.

Oxcarbazepine received approval for use in the United States in 2000 as monotherapy or adjunctive treatment of partial seizures in adults and adjunctive treatment of partial seizures in children 4 years of age and older. The 10-monohydroxy metabolite (MHD) of the drug is responsible for its anticonvulsant effect. Unlike carbamazepine, oxcarbazepine does not induce its own metabolism. The major advantage of this drug over carbamazepine is the lower incidence of adverse effects. Severe hyponatremia (sodium < 125 mmol/L) is reported in 2% to 3% of patients, and rash is occasionally observed. Oxcarbazepine is available in 150-, 300-, and 600-mg tablets and suspension (300 mg/5 mL).

Zonisamide was approved in the United States in 2000 as an adjunctive agent in adults with partial seizures. It may also be effective against generalized seizures and infantile spasms. The precise mechanism of action is unknown. However, zonisamide appears to block sodium and calcium channels, binds to the GABA/benzodiazepine receptor complex, and weakly inhibits carbonic anhydrase. Zonisamide is chemically classified as a sulfonamide and is therefore relatively contraindicated in patients with sulfonamide hypersensitivity. Common adverse effects include weight loss, irritability, photosensitivity, rash, and hypohidrosis. Nephrolithiasis is reported in 2% to 3% of patients. Zonisamide has a long half-life and may be administered once per day. It is available in 25-, 50-, and 100-mg capsules.

Pregabalin was approved in the United States in 2005 as adjunctive therapy for partial seizures in adults. Pregabalin binds with high affinity to the $\alpha_2\text{-}\delta$ subunit of voltage-gated calcium channels in animal models. Like gabapentin, it does not interact with GABA receptors or potentiate gabaminergic transmission. Common adverse effects include dizziness, somnolence, dry mouth, weight gain, edema, and impaired concentration and attention. It is available in 25-, 50-, 75-, 100-, 150-, 200-, 225-, and 300-mg capsules.

Vagus Nerve Stimulation

Vagus nerve stimulation (VNS) is a treatment for medically refractory epilepsy in patients over age 12 years who are deemed not candidates for resective epilepsy surgery.⁴⁸ The treatment consists of intermittent stimulation of the left vagus nerve in the neck using a pulse generator implanted in a subcutaneous pocket below the midportion of the left clavicle and a bipolar electrode lead that fits around the vagus nerve in a corkscrew fashion. The device is programmed using a wand and hand-held computer. A magnet can be used to activate the generator if a patient or caretaker feels or observes the onset of a seizure. Treatment with VNS produces an improvement in partial seizures similar to that of the newer AEDs in refractory epilepsy patients by providing a 50% reduction in seizure frequency in one quarter to one third of cases at 12 weeks of follow-up. This improvement is sustained and recent studies suggest that over time, a greater number of patients respond favorably. However, few patients achieve a seizure-free state, although they do receive some benefit considerably allowing for reduction of AED therapy. VNS is also effective in some patients with idiopathic generalized epilepsy and symptomatic generalized epilepsy; however, there are no randomized, controlled studies to date in these populations. Subjective improvements in alertness, mood, and cognition are also reported. Side effects occurring during stimulation delivery include voice alteration, coughing, paresthesias or discomfort in the neck or throat, and dyspnea. Isolated cases of vocal cord dysfunction have been reported.

SURGICAL TREATMENT

General Principles

Candidates for epilepsy surgery are those patients with seizures refractory to appropriate medical management and a

well-defined epileptogenic focus not involving eloquent cortex. Surgery is contraindicated in patients with generalized epilepsy, benign childhood epilepsy, progressive diseases, and significant noncompliance. Mental retardation, psychiatric disease, and the coexistence of epileptic and nonepileptic seizures are not absolute contraindications. Dominant hemisphere seizure origin, bilateral or multifocal epileptic discharges on EEG, and neurologic deficits on examination should not preclude surgical consideration. Rarely, surgery is considered in patients with seizures arising from more than one epileptogenic focus.

Although epidemiologic studies have shown that the majority of people with epilepsy enter long-term remission, seizures remain refractory to medical therapy in as many as 40% of cases. In a study of 470 adolescents and adults who had never received AED therapy, 64% entered remission for at least 1 year.⁴⁹ Forty-seven percent of patients became seizure free on the first AED, 13% on the second AED, and only 4% on the third AED or on combination therapy. Response to the first AED was the strongest predictor of prognosis. Only 11% of patients in whom the first AED failed due to lack of efficacy became seizure free. Pharmacoresistance should be identified as soon as possible because the consequences of refractory seizures are severe and include physical injury, cognitive impairment, psychiatric disease, social disability, and even sudden, unexpected death. Once adequate trials of two appropriate, first-line AEDs fail to completely control seizures, the likelihood of achieving seizure freedom with additional agents is low.

Surface and Intracranial Electroencephalography

The goal of the presurgical evaluation is to define the epileptogenic zone, which is the region of cortex capable of generating seizures. Complete removal of the epileptogenic zone is necessary to produce a seizure-free state.⁵⁰ The clinical history and EEG are used to identify patients who may be candidates for surgery. The yield of surface EEG, however, is limited by the attenuating effects of the skull and intervening tissue, distance of the recording electrodes from the generator of ictal activity, and variable orientation of generator. Cerebral activity from mesial or basal cortical areas is particularly apt to escape detection. Modified electrode placements and semi-invasive techniques such as sphenoidal electrodes increase the yield of surface recordings. In general, the distribution of interictal abnormalities extends beyond the epileptogenic zone. Nevertheless, interictal epileptiform discharges generally provide more reliable localizing information than ictal recordings because of the tendency for seizures to spread rapidly to contiguous regions.

Intracranial EEG may be required when surface EEG and neuroimaging studies fail to delineate the epileptogenic zone adequately. Although more sensitive than surface EEG, intracranial EEG provides a limited view of cerebral activity, because recordings are obtained only from areas where electrodes are placed.

The successful use of intracranial EEG requires that non-invasive studies provide enough information to ensure appropriate electrode placement. Intracranial monitoring is performed with depth and subdural electrodes. Depth

electrodes are multiple-contact wires placed stereotactically into the brain. Their primary indication is for the identification of the epileptogenic zone in patients with TLE and bitemporal abnormalities on surface EEG or MRI. Electrodes embedded in thin silastic plates arranged in strips or grids can be placed through burr holes or craniotomy within the subdural space over cortical areas of interest. This technique allows for the recording of multiple regions over one or both hemispheres and mapping of eloquent cortex. Complications of depth and subdural electrodes include intraparenchymal hemorrhage, infection, and cerebral edema in 1% to 2% of patients.

Neuroimaging

Advances in neuroimaging have revolutionized the approach to patients with partial epilepsy. MRI has replaced CT as the study of choice, although CT remains superior in the detection of calcified lesions. SPECT and PET scans measure functional changes produced by seizures. Patients with partial epilepsy should undergo an MRI during the course of their illness to rule out structural lesions. The use of special imaging sequences and thin cuts increases the detection of neoplasms, developmental malformations, and mesial temporal sclerosis. In most cases, mesial temporal sclerosis is associated with unilateral hippocampal atrophy on T1-weighted images and increased signal in the mesial temporal structures on T2-weighted sequences (Fig 52-7). These findings are highly predictive of seizure remission and lack of material-specific memory deficits following mesial temporal resection.

Cerebral glucose metabolism measured with 18 F-DG PET is reduced in some patients with partial epilepsy. Temporal lobe hypometabolism is seen in 60% to 90% of patients with intractable TLE (Fig 52-8).⁵¹ The extent of abnormality is usually larger than the epileptogenic zone, frequently extending into the ipsilateral basal ganglia, thalamus, and frontoparietal cortices. The yield of PET in nonlesional extratemporal epilepsy is significantly lower. The short half-life of the isotope precludes its use for ictal studies.

SPECT is more readily available than PET because it utilizes commercially available isotopes and does not require an on-site cyclotron. Technetium 99m-hexamethylene-

FIGURE 52-7. MRI showing atrophy (T1-weighted image on left) and increased signal (fluid-attenuated inversion-recovery sequence on right) in the right hippocampus in a patient with right mesial temporal lobe epilepsy.

propylene-amine-oxime SPECT reveals hypoperfusion in the epileptogenic temporal lobe during the interictal state in over 50% of patients with TLE.⁵² False lateralization has been reported in 15% to 20% of cases. The resolution of SPECT is inferior to that of PET, and quantitative analysis is not available. The long half-lives of the isotopes make ictal and immediate postictal SPECT a useful noninvasive localizing tool. The results of ictal SPECT depend on the time of injection of the isotope from seizure onset. Under optimal circumstances, 65% to 90% of studies demonstrate hyperperfusion ipsilateral to seizure origin (Fig 52-9).⁵² Delayed injections produce widespread hyperperfusion and a higher incidence of false lateralization.

Specific Surgeries

Temporal Lobectomy

Anterior temporal lobectomy is the most common surgical procedure for the treatment of intractable epilepsy in adolescents and adults. The resection typically includes the anterior 3.0 to 3.5 cm of the inferior and middle temporal gyri, uncus, part of the amygdala, and the anterior 2.0 to 3.0 cm of the hippocampus and adjacent parahippocampal gyrus. In patients with mesial temporal sclerosis, selective amygdalo-hippocampectomy may suffice. Lesionectomy with preservation of the mesial temporal structures may be indicated in patients with discrete temporal lobe lesions without evidence of mesial involvement. Language mapping is required when lesions are located near the language cortex. The use of tailored resections based on intraoperative electrocorticography remains controversial. The benefits of anteromesial temporal resection for disabling complex partial seizures is greater than continued treatment with AEDs, and the risks appear to be comparable.⁵³ One randomized, controlled trial of surgery for MTLE found that 58% of patients randomized to surgical evaluation (64% who received surgery) were free of disabling seizures and only 10% to 15% were unimproved at the end of 1 year, as compared with 8% free of disabling seizures in the group receiving medical therapy.⁵⁴ In general, a seizure-free state is achieved at 1 to 2 years in 65% to 80% of patients, although auras may persist and relapses may occur after an initial period of seizure freedom.^{53,55} A risk of verbal memory impairment exists in patients with normal preoperative memory scores undergoing dominant hemisphere anterior temporal lobectomy. Transient dysnomia after dominant anterior temporal lobectomy occurs in approximately 30% of patients.

Extratemporal Lesion Resection, Hemispherectomy, Corpus Callosotomy

The procedure of choice for patients with extratemporal epilepsy due to a structural brain lesion is complete resection of the lesion and surrounding epileptogenic cortex. Lesionectomy is the most common type of epilepsy surgery performed in infants and children. Subtotal removal of a structural lesion is associated with a lower likelihood of seizure remission. Patients with nonlesional extratemporal epilepsy generally require intracranial monitoring to delineate the epileptogenic zone, and cortical mapping if the

FIGURE 52-8. ¹⁸F-DG PET demonstrating significant hypometabolism involving the left temporal lobe in a patient with left mesial temporal lobe epilepsy. The darkness scale is divided into 10 equal intervals, each representing a 10% change in hypometabolism. The level of darkness at the top of the scale represents an increase in metabolism as compared to the normal state, with glucose metabolism decreasing as one progresses down the darkness scheme. (Photo courtesy of C. Oliver Wong, MD, PhD, FACP.)

proposed resection is located in or around eloquent cortex. Surgical outcome in these cases depends on the certainty with which the epileptogenic zone is defined and the completeness of the resection. Seizure outcome is less favorable following extratemporal neocortical resection. In a recent, multicenter study, 56% of subjects who underwent neocortical resection (including some in the temporal neocortex) achieved a 1-year remission at some point during follow-up.⁵⁵

Hemispherectomy is indicated in patients with intractable partial and secondarily generalized seizures in whom an entire hemisphere is considered epileptogenic with little or no remaining functional cortex. The procedure is usually performed in patients with Rasmussen encephalitis, Sturge-Weber syndrome, hemimegacephaly, or large hemispheric infarctions. Functional hemispherectomy consists of the removal of the frontal and temporal lobes and complete

disconnection of the remaining cortex and corpus callosum. This procedure is an alternative to total hemispherectomy, which is associated with a high rate of cerebral hemosiderosis and hydrocephalus. Recent studies report that 60% to 80% of patients are rendered seizure free.⁵⁶

Corpus callosotomy should be considered in patients with frequent secondary generalized tonic-clonic, tonic, and atonic seizures that lead to falls and injuries. The goal of the procedure is to disrupt the major central pathways necessary for the propagation of generalized seizures. Complete callosal section may result in mutism, apraxia, or frontal lobe dysfunction. For this reason, the procedure is often performed in two stages beginning with sectioning of the anterior two thirds followed by section of the remainder of the corpus callosum, if necessary. Nearly two thirds of patients experience a significant reduction in seizures, although few are rendered seizure free.⁵⁷

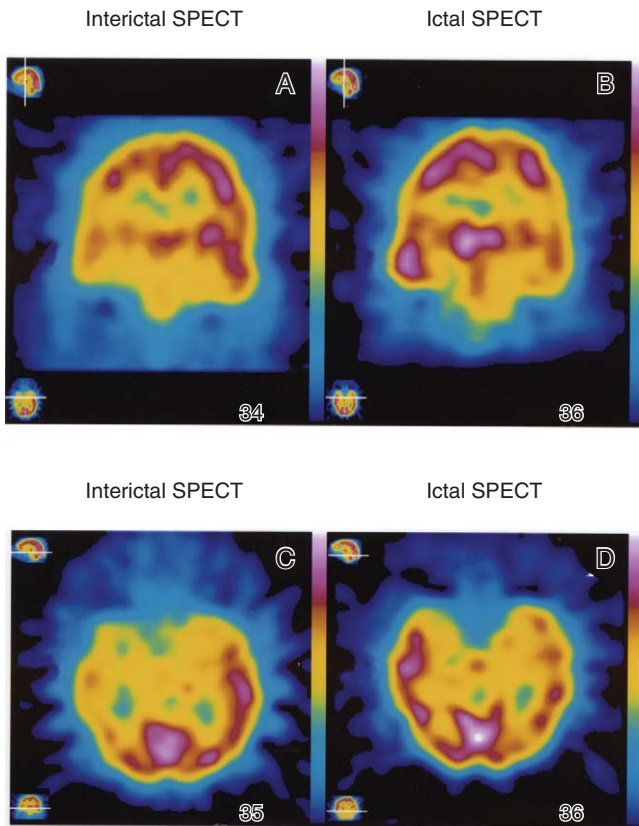

FIGURE 52-9. Interictal and ictal Tc-99m SPECT in coronal and transverse planes in a patient with right mesial temporal lobe epilepsy. There is a reduction in blood flow in the right temporal lobe interictally and hyperperfusion in the same region during a typical partial seizure. (Photo courtesy of C. Oliver Wong, MD, PhD, FACP.)

Glossopharyngeal Neuralgia
Carotidynia

HISTORY AND DEFINITIONS

Headache is a problem that has plagued humans since the beginning of recorded time. The earliest written reference to migraine is found in an epic poem written in Sumeria around 3000 BC¹: “The sick-eyed says not I am sick-eyed. The sick-headed not I am sick-headed.” From Mesopotamia comes a description of a headache sufferer with an associated visual disturbance, in which “the head is bent with pain gripping his temples...and his eyes are afflicted with dimness and cloudiness.” Hippocrates described the visual aura that can precede the migraine headache and the relief that can be induced by vomiting.² Aretaeus of Cappadocia is credited as the discoverer of migraine because of his classic description of the symptoms in the second century AD.² Migraine clearly was well known in the ancient world.

In 1778, Fothergill introduced the term fortification spectra to describe the visual aura of migraine. A hundred years later, Airy gave a vivid description of the same phenomenon, which he called teichopsia, quoting Tennyson¹: “...as yonder walls rose slowly to a music slowly breathed, a cloud that gathered shape.” In 1783, Tisso distinguished migraine from common headache and ascribed it to a supraorbital neuralgia “provoked by reflexes from the stomach, gallbladder, or uterus.”³ Over the next century, DuBois, Reymond, Mollendorf, and later Eulenburg proposed different vascular theories for migraine.

Living wrote the first monograph on migraine, entitled *On Megrin, Sick-headache, and Some Allied Disorders: A Contribution to the Pathology of Nerve-Storms*⁴ and was the originator of the neural theory of migraine, ascribing the problem to “disturbances of the autonomic nervous system,” which he called “nerve storms.” In 1900, Dey¹ suggested that migraine resulted from intermittent swelling of the hypophysis with compression of the trigeminal nerve. Later in the 20th century (1950), Harold Wolff developed the experimental approach to the study of headache¹ and elaborated the vascular theory of migraine, which has come under attack as the pendulum again swings to the neurogenic theory.¹

In 1962, an Ad Hoc Committee established descriptive definitions of migraine, tension-type headache (TTH), and

other headache disorders. In 1988, the International Headache Society (IHS) published a formal classification system for the diagnosis of headache disorders.⁵ This system has been updated and improved (ICHD-2).⁶ The IHS classification system (Table 53-1) continues to divide headache into primary and secondary disorders. In a primary headache disorder, headache itself is the illness and no other etiology is diagnosed. In a secondary headache disorder, headache is attributed to an identifiable structural or metabolic abnormality.

HEADACHE

Migraine Headache

PATHOGENESIS AND PATHOPHYSIOLOGY. The migraine aura was previously believed to be caused by cerebral vasoconstriction and the headache by reactive vasodilation.⁷ This explained the headache’s throbbing quality and its relief by ergots. It is now believed that the migraine aura is due to neuronal dysfunction, not ischemia; ischemia rarely, if ever, occurs. Headache often begins while cortical blood flow (CBF) is reduced^{8–10}; thus, headache is not due to simple reflex vasodilation.^{11,12}

The migrainous fortification spectrum corresponds to an event moving across the cortex at 2 to 3 mm/minute.¹³ Noxious stimulation of the rodent cerebral cortex produced a spreading decrease in electrical activity that moved at 2 to 3 mm/minute (CSD).¹⁴ CSD is characterized by shifts in cortical steady state potential; transient increases in potassium, nitric oxide, and glutamate; and transient increases, followed by sustained decreases, in CBF.⁸

The aura is associated with an initial hyperemic phase followed by reduced CBF, which moves across the cortex and is called spreading oligemia.¹⁵ The rates of progression of spreading oligemia are similar to those of migrainous scotoma and CSD, suggesting that they are related.^{12,14,16} Additional studies^{9,10,17–20} support the hypothesis that CSD produces the aura.

Blood oxygenation level-dependent (BOLD) functional MRI reflects the relative concentration of deoxyhemoglobin in venous blood. Visual stimulation was used to trigger

headache in migraineurs.¹⁷ A wave of increased (hyperoxygenated blood) and then decreased (possibly reflecting neuronal metabolic-flow coupling) BOLD signal propagated into the contiguous occipital cortex at 3 to 6 mm/minute. When visual stimulation was used to test the visual cortex response, the BOLD signal and the BOLD response to visual activation diminished following progression of the visual aura.¹¹

Magnetoencephalography demonstrates changes in migraineurs, but not control subjects, consistent with CSD.^{21,22} Transcranial magnetic stimulation applies magnetic fields of increasing intensity to evaluate occipital cortex excitability. Aurora and associates²³ and Young and associates,²⁴ but not Afra and associates,²⁵ found that phosphenes were generated in migraineurs at lower thresholds than in control subjects, and that it was easier to visually trigger headaches in those with lower thresholds. Other evidence of increased CNS excitability comes from

studies of visual and brainstem auditory evoked potentials.²⁶ Migraine with aura may be due to neuronal hyperexcitability, perhaps due to cortical disinhibition.

Headache probably results from the activation of meningeal and blood vessel nociceptors combined with a change in central pain modulation. Headache and its associated neurovascular changes are subserved by the trigeminal system. Reflex connections to the cranial parasympathetics form the trigeminoautonomic reflex. Activation results in vasoactive intestinal polypeptide release and vasodilation.¹²

Trigeminal sensory neurons contain substance P (SP), calcitonin gene-related peptide (CGRP), and neurokinin A.²⁷ Stimulation results in SP and CGRP release from sensory C-fiber terminals²⁸ and neurogenic inflammation.²⁹ The neuropeptides interact with the blood vessel wall, producing dilation, plasma protein extravasation (PPE), and platelet activation.³⁰ One study suggests that neurogenic inflammation occurs in humans.³¹ Neurogenic inflammation sensitizes nerve fibers (peripheral sensitization) that now respond to previously innocuous stimuli, such as blood vessel pulsations,³² causing, in part, the pain of migraine.³³ Central sensitization (CS) can also occur. After meningeal irritation, *c-fos* expression (a marker for neuronal activation) occurs in the trigeminal nucleus caudalis³⁴ and in the dorsal horn at the C1 and C2 levels.^{35,36}

Applying an inflammatory soup to the dura sensitizes second order trigeminovascular neurons (increased spontaneous activity and response to mechanical and thermal skin stimulation).³² Triptans administered early prevented CS: dural and facial receptive fields did not expand and spontaneous activity and mechanical and thermal sensitivity did not increase. Late triptan intervention did not reverse CS but shrunk the expanded dural receptive fields and normalized intracranial mechanosensitivity. CS may play a key role in maintaining the headache.^{37,38}

Patients often develop cutaneous allodynia (CA) during migraine attacks due to trigeminal sensitization.³⁷ Triptans can prevent, but not reverse, CA.³⁸ CA can be used to predict triptans' effectiveness.³⁷ Without allodynia, triptans completely relieved the headache and blocked the development of allodynia. In 90% of attacks with established allodynia, triptans provided little or no headache relief and did not suppress allodynia. However, late triptan therapy eliminated peripheral sensitization (throbbing pain aggravated by movement), even when pain relief was incomplete and allodynia was not suppressed.³⁷ Early intervention may work by preventing CA and CS.

Brain stem activation occurs in migraine without aura. Using positron emission tomography, patients with right-sided migraine headache showed increased regional CBF (rCBF) in the left brain stem. Sumatriptan relieved the headache and associated symptoms but did not normalize brain stem rCBF. This suggests that activation is due to factors other than, or in addition to, increased activity of the endogenous antinociceptive system.³⁹ A second report corroborates these findings.⁴⁰

A link exists between the migraine aura and headache. CSD activates trigeminovascular afferents, causing a long-lasting increase in middle meningeal artery blood flow and PPE within the dura mater.⁴¹ CSD results in upregulation of inducible nitric oxide synthetase and inflammatory cytokines. This mechanism couples meningeal blood

flow and neurogenic inflammation to CSD but does not explain headache ipsilateral to the aura.^{12,41} What initiates activation of trigeminovascular afferents in the absence of a clinical aura? A potential mechanism is CSD in silent areas of the cerebral cortex or cerebellum. In addition, trigeminal afferents may be activated by events initiated in the brain stem. Stress can also activate meningeal plasma cells via a parasympathetic mechanism, leading to nociceptor activation.⁴²

There are seven classes of 5-HT receptors: 5-HT₁, 5-HT₂, 5-HT₃, 5-HT₄, 5-HT₅, 5-HT₆, and 5-HT₇.⁴³ In humans, there are five 5-HT₁ receptor subtypes: 5-HT_{1A}, 5-HT_{1B}, 5-HT_{1D}, 5-HT_{1E}, and 5-HT_{1F}.⁴⁴ The 5-HT_{1B} receptor is located on intracranial blood vessels and CNS neurons. The 5-HT_{1D} receptor is located on CNS neurons and trigeminal nerve endings. 5-HT_{1F} receptors are located on trigeminal nerve endings.⁴⁵ Ergots and triptans act at the 5-HT_{1B}, 5-HT_{1D}, and, in part, at the 5-HT_{1F} receptors. They constrict extracerebral intracranial vessels, inhibit trigeminal neurons, and block transmission in the trigeminal nucleus. They minimally constrict human coronary arteries. They block PPE²⁹ by activating prejunctional trigeminal 5-HT_{1D} and 5-HT_{1F} heteroreceptors, blocking neuropeptide release. PPE can also be blocked by nonsteroidal anti-inflammatory drugs (NSAIDs),⁴⁶ GABA agonists,^{47,48} neurosteroids,⁴⁹ SP antagonists,⁵⁰ and the endothelin antagonist bosentan.⁵¹ Dihydroergotamine (DHE) and the centrally penetrant triptans label nuclei in the brain stem and spinal cord involved in pain transmission and modulation.⁵² The caudal trigeminal nucleus is activated by stimulation of the sagittal sinus, and this activity is transmitted to the thalamus. Ergots and triptans suppress this activation.

EPIDEMIOLOGY AND RISK FACTORS. Migraine occurs in 18% of women, 6% of men, and 4% of children in the United States.⁵³ This disorder usually begins in the first three decades of life, with prevalence peaking in the fifth decade (Fig. 53-1). Most migraineurs have a family history of migraine. At least 60% of women with migraine experience clear improvement during later pregnancy, yet some women experience worsening migraine during the first trimester. Additionally, many women experience improvement of their migraine with natural, but not surgical, menopause.

Figure 53-1. Migraine prevalence by age. (From Silberstein SD, Lipton RB: Epidemiology of migraine. *Neuroepidemiology* 1993;12:179-194. Reproduced with permission of S. Karger AG, Basel.)

Lance and Anthony found improvement in 58% of 120 women migraineurs who had borne children.⁵⁴ Bousser found that migraine disappeared or was improved in 69.4% of pregnancies, worsened in 6.8%, was unchanged in 7.9%, was variable in 5.4%, and appeared for the first time in 10.9%.⁵⁵ Although disappearance or improvement did not differ significantly in migraine with or without aura, worsening was much more common in migraine with aura. Headache occurs frequently in the postpartum period, particularly in known migraineurs. Migraineurs do not have an increased risk of complications during pregnancy, and the children of migraineurs do not have an increased incidence of birth defects.⁵⁶

Migraine is very common among neurologists. The 1-year and lifetime prevalences of migraine in the 220 neurologists and neurologist headache specialists who attended a headache review course were as follows: male neurologists, 34.7%, 46.6%; male headache specialists, 59.3%, 71.9%; female neurologists, 58.1%, 62.8%; and female headache specialists, 74.1%, 81.5%.⁵⁷ Contrary to the findings of clinic-based studies, population-based studies have shown migraine to be more prevalent in families of lower socioeconomic class. In addition, the economic impact of migraine and other headaches is enormous; the annual cost of headaches in terms of absenteeism, decreased productivity, and the cost of diagnostic tests and treatment ranges from \$5 billion to \$17 billion. Despite 10 million physician visits each year, migraine is still underdiagnosed and undertreated.⁵³

The term *chronic daily headache* (CDH) refers to a group of disorders characterized by very frequent headaches (15 or more days a month). When headache duration is greater than 4 hours, the major primary disorders for which there are operational diagnostic criteria as defined by the Second Edition of the International Classification of Headache Disorders (ICHD-2) are chronic migraine (CM), hemicrania continua (HC), chronic tension-type headache (CTTH), and new daily persistent headache (NDPH).⁶

Patients who have daily headaches that persist for months often have transformed migraine, with a past history of episodic migraine typically beginning in their teens or twenties.⁵⁸ Most of these patients are women, 90% of whom have a history of migraine without aura. The headaches grow more frequent, and the associated symptoms of photophobia, phonophobia, and nausea become less severe and less frequent than during typical migraine. Patients often develop a pattern of daily, or nearly daily, headaches that phenomenologically resemble CTTH, with mild to moderate pain but with photophobia, phonophobia, or gastrointestinal features. Other features of migraine, including unilaterality and aggravation by menstruation and other trigger factors, may persist. Attacks of full-blown migraine superimposed on a background of less severe headaches often occur. In the past, this was called mixed tension-vascular headache. Many patients with transformed migraine overuse symptomatic medication. Stopping the overused medication frequently results in distinct headache improvement. Eighty percent of patients with transformed migraine have depression. The depression often lifts when the pattern of medication overuse and daily headache is interrupted.

The ICHD-2 now classifies most of the patients with transformed migraine as chronic migraine. To meet the definition

patients must (A) have current migraine or a history of migraine; (B) have headaches at least 15 days a month for 3 months; (C) have 8 or more days a month of migraine, probable migraine, or a headache that the patient believes is migraine and for which he or she takes a triptan or ergot. In addition, the headache cannot be attributed to another disorder, including medication overuse headache.⁶

The prognosis of migraine, frequent episodic tension-type headache, and CTTH was favorable in a Danish cross-sectional follow-up study of 549 persons. Of 64 migraineurs at baseline, 42% had experienced remission, 38% had low migraine frequency, and 20% had more than 14 migraine days per year (poor outcome) at follow-up. Poor outcome was associated with high migraine frequency at baseline and age at onset younger than 20 years.⁵⁹ Migraine is a risk factor (that is, comorbid) for affective disorders. Compared with nonmigraineurs, migraineurs have a 4.5-fold increased risk of major depression, a six-fold risk of manic episodes, a three-fold increase in anxiety disorder, and a six-fold prevalence in panic disorder. Migraineurs without depression develop depression at follow-up at three times the rate of nonmigraineurs. Furthermore, depressed patients without migraine develop migraine at three times the rate of nondepressed patients⁶⁰ and reported that the risk for new episodes of major depression (or panic disorder) did not vary by the proximity of migraine attacks.⁶¹ The prospective data indicates that the cross-sectional or lifetime association between migraine and major depression could result from a bidirectional influence. This bidirectional association, with each disorder increasing the risk for first onset of the other, was not observed in relation to other severe headaches.⁶² These recent epidemiological studies support the association between migraine and major depression previously reported in clinic-based studies. Migraineurs may have affective spectrum disorders with associated irritable bowel syndrome, fibromyalgia, and chronic fatigue syndrome. Epilepsy, stroke, and mitral valve prolapse are also more common in migraineurs.

It has been proposed that major depression in migraineurs might represent a psychological reaction to repeated, disabling migraine attacks. Migraine has an earlier average age of onset than major depression in the population and in persons with comorbid disease. Nonetheless, the bidirectional influence of each condition on the risk for the other is incompatible with the simple causal model.⁶⁰ Specifically, persons with depression but not migraine have an increased risk for migraine before painful attacks ever develop.⁶⁰

A lifetime diagnosis of migraine was not associated with cognitive deficits in middle-aged subjects. This finding was based on a large population sample of middle-aged twins in whom headache diagnoses were established by neurologists.⁶³

CLINICAL FEATURES AND ASSOCIATED DISORDERS.

The migraine attack can be divided into four phases: (1) the prodrome, which occurs hours or days before the headache; (2) the aura, which immediately precedes the headache; (3) the headache itself; and (4) the postdrome.⁶⁴ Although most migraineurs experience more than one phase, no phase is obligatory for diagnosis. Migraine with aura may occur with or without the headache, but migraine without aura

requires the headache for its diagnosis (Table 53-2). The phenomena of the premonitory phase have been elucidated using an electronic diary.⁶⁵ These phenomena occur hours to days before headache onset in about 60% of migraineurs (Table 53-3). Features include constitutional, autonomic, psychological (depression, euphoria, irritability, restlessness), mental slowness, hyperactivity, fatigue, and drowsiness), and neurologic (photophobia, phonophobia, and hyperosmia) features. Some patients report having a poorly characterized feeling that a migraine attack is coming. The most common premonitory symptoms were feeling tired/weary (72%), having difficulty concentrating (51%), and stiff neck (50%). Poor functioning commonly predicted headache.⁶⁶ Migraineurs who reported premonitory symptoms accurately predicted their full-blown headaches 72% of the time. Among patients who were almost certain that attacks would occur, 93% had attacks.

The migraine aura is a complex of focal neurological symptoms (positive or negative phenomena) that precedes or accompanies an attack. Most aura symptoms develop over 5 to 20 minutes and usually last less than 60 minutes. The aura can be characterized by visual, sensory, or motor phenomena and may also involve language or brain stem disturbances. If the aura is prolonged, it may meet the criteria of what was formerly termed a complicated migraine. Headache, when present, usually occurs within 60 minutes of the end of the aura, and most patients do not feel well during the period from the end of the aura to the beginning of the headache. Many patients experience a variety of cognitive or emotional symptoms during this time.⁶⁷

The most frequently occurring aura is visual in nature. Elementary visual disturbances, including scotomata, photopsia, phosphenes (simple flashes), specks, geometrical forms, shimmering, or undulations are the most common, and may occur singly or number in the hundreds.

TABLE 53-2

Diagnostic Criteria for Migraine

Migraine with Aura (Classic Migraine)

Diagnostic Criteria

At least three of the following four characteristics:

1. One or more fully reversible aura symptoms
2. At least one aura symptom over more than 4 minutes or two or more symptoms occurring in succession
3. No single aura symptom lasts more than 60 minutes
4. Headache follows aura with a free interval of less than 60 minutes (it may also begin before or simultaneously with the aura)

Migraine Without Aura

Diagnostic Criteria

At least five attacks fulfilling criteria A–D:

- A. Headache lasting 4 to 72 hours (untreated or unsuccessfully treated)
- B. Headache has at least two of the following characteristics:
 1. Unilateral location
 2. Pulsating quality
 3. Moderate or severe pain intensity
 4. Aggravation by or causing avoidance of routine physical activity (e.g., walking or climbing stairs)
- C. During headache at least one of the following:
 1. Nausea and/or vomiting
 2. Photophobia and phonophobia
- D. Not attributed to another disorder

TABLE 53-3

Migraine Prodrome Symptoms

| Psychological | Constitutional and Autonomic |
|--------------------------|------------------------------|
| Depression | Stiff neck |
| Hyperactivity | Food cravings |
| Euphoria | Cold feelings |
| Talkativeness | Anorexia |
| Irritability | Sluggishness |
| Drowsiness | Diarrhea or constipation |
| Restlessness | Thirst |
| | Urination |
| | Fluid retention |
| Neurological | |
| Photophobia | |
| Difficulty concentrating | |
| Phonophobia | |
| Dysphasia | |
| Hyperosmia | |
| Yawning | |

Interestingly, these elementary visual disturbances are more likely to occur during than before the headache. An occipital lobe origin is presumed based on their presence in both eyes and often in a hemifield distribution. More complicated hallucinations include teichopsia or fortification spectrum, which is the most characteristic visual aura and nearly diagnostic of migraine. An arc of scintillating lights, usually but not always beginning near the point of fixation, may form into a herringbone-like pattern that expands to encompass an increasing portion of a visual hemifield. It migrates across the visual field with a scintillating edge of often zigzag, flashing, or occasionally colored phenomena.^{67,68} Visual distortions and hallucinations, speculated to represent some of Lewis Carroll's descriptions in *Alice's Adventures in Wonderland*, occur more commonly in children. They are characterized by a complex disorder of visual perception that may include metamorphopsia, micropsia, macropsia, zoom vision (opening up or closing down in the size of objects), or mosaic vision (fracturing of image into facets).⁶⁸

Paresthesias are the second most common aura. They typically start in the hand, migrate up the arm, and then extend to involve the face, lips, and tongue. Paresthesias can become bilateral and may be followed by numbness and loss of positional sense.^{67,68} They typically progress over a period of more than 5 minutes and are often associated with a visual aura. More complex symptoms include difficulties in the perception and use of the body; speech and language disturbances; states of double or multiple consciousness associated with *déjà vu* or *jamais vu*; and elaborate, dreamy, nightmarish, trancelike, or delirious states. Motor symptoms, when they occur, are usually associated with sensory symptoms, but true weakness is rare and usually unilateral. By definition, the presence of motor symptoms defines hemiplegic migraine (Video 4, Pronator Drift).

The typical migraine headache is unilateral, throbbing, moderate to marked in severity, and aggravated by physical activity. Not all of these features are required. The pain may be bilateral at the onset or start on one side and become generalized.^{67,69} The onset is usually gradual. The pain peaks and then subsides, and usually lasts between 4 and 72 hours in adults and 2 and 48 hours in children. The frequency of attacks is extremely variable, from a few in a lifetime to several a week, but the average

migraineur experiences from one to three headaches a month. The head pain varies greatly in intensity, although most migraineurs report pain ratings of 5 or greater on a 0 to 10 pain scale. Pain is throbbing in 85% of cases,^{67,69} although throbbing pain is not diagnostic of migraine because it is often described in other headache types.

The pain of migraine is invariably accompanied by other features. Anorexia is common, and nausea occurs in almost 90% of patients, while vomiting occurs in about one third of patients.⁷⁰ Many patients experience sensory hyperexcitability manifested by photophobia, phonophobia, and osmophobia, and seek a dark, quiet room. Blurred vision, nasal stuffiness, diarrhea, polyuria, pallor, or sweating may be noted during the headache phase. There may be localized edema of the scalp or face, scalp tenderness, prominence of a vein or artery in the temple, or stiffness and tenderness of the neck. Impairment of concentration and mood are common. Lightheadedness, rather than true vertigo, and a feeling of faintness may occur. The extremities tend to be cold and moist. Following the headache, during the postdrome phase, the patient may feel tired, "washed out," irritable, and listless, and may have impaired concentration, scalp tenderness, or mood changes. Some people feel unusually refreshed or euphoric after an attack, whereas others note depression and malaise.

A variety of migraine clinical subtypes have been described. Attacks of migraine lasting longer than 72 hours define *status migrainosus*. It is often associated with pernicious nausea, vomiting, dehydration, and despair.⁶⁷

Basilar-type migraine, previously called "basilar artery migraine," was originally believed to be a disorder of adolescent girls, and although there is a clear female predominance, it is now known to affect all age groups. Severe headache is preceded by a visual aura, then brain stem signs of ataxia, vertigo, tinnitus, diplopia, nausea and vomiting, nystagmus, dysarthria, bilateral paresthesia, and a change in level of consciousness and cognition (Video 211, Gait Ataxia). Confusional migraine, which occurs more commonly in boys than in girls, is characterized by headache accompanied by inattention, distractibility, and difficulty maintaining speech and other motor activities. Spells of basilar and confusional migraine can present a confusing picture and should be considered in patients with paroxysmal brain stem disturbances.^{6,67}

Hemiplegic migraine occurs in two forms, sporadic and familial, both of which typically begin in childhood and cease with adulthood.^{71,72} The age of onset of hemiplegic migraine may be earlier than that of common migraine. The attacks are frequently precipitated by minor head injury. Accompanying changes in consciousness ranging from confusion to coma are a feature of hemiplegic migraine, especially in childhood, and occur in 23% of patients. The hemiplegia may be part of the aura and last less than 1 hour, or it may continue through the headache phase and last for days or weeks. Familial hemiplegic migraine (FHM) has an autosomal dominant mode of inheritance with variable penetrance. FHM is an autosomal dominant disorder associated with attacks of migraine, with and without aura, and hemiparesis (Video 11, Hemiplegic Gait). The gene has been mapped to chromosome 19p13 in approximately two thirds of cases.^{73,74} The defect is due to at least 10 different missense mutations in the

CACNA1A gene, which codes for the α_1 -subunit of a voltage dependent P/Q Ca^{2+} channel.⁷⁵ The same gene is associated with episodic ataxia with cerebellar vermal atrophy.⁷³ P-type neuronal Ca^{2+} channels mediate 5-HT and excitatory neurotransmitter release. Dysfunction may impair 5-HT release and predispose patients to migraine attacks or impair their self-aborting mechanism.⁷⁶ A second gene (FHM2) has been mapped to chromosome 1 q 21-23. The defect is a new mutation in the α_2 -subunit of the Na/K pump (ATP1A2).⁷⁷ This mutation results in reduced activity or decreased affinity for K^+ of Na^+/K^+ pump leading to impaired clearance of K^+ and glutamate from the extracellular space. A third gene (FHM3) has been linked to chromosome 2q24. It is due to a missense mutation in gene SCN1A (Gln1489Lys) which encodes an α_1 -subunit of a neuronal voltage-gated Na^+ channel (Na_v 1.1). The mechanisms have been recently reviewed.⁷⁸

Periodic focal neurological dysfunction, which may be part of the migraine aura, can occur in isolation without the headache.^{67,68} These phenomena can be part of migraine, but they are accepted as migraine only after a full investigation and prolonged follow-up. Occasional headaches occurring in association with the same symptoms as an aura help confirm the migraine diagnosis for the episodes without headache because patients who have migraine with aura often experience aura without headache.

Late-life migrainous accompaniments are transient neurological phenomena that frequently are not associated with headache.⁷⁹ Attacks of episodic focal neurological dysfunction, which last from 1 minute to 72 hours, can occur with variable recurrence. Fisher considered scintillating scotoma to be diagnostic of migraine, even when it occurred in isolation, whereas other episodic neurological symptoms (paresthesias, aphasia, and sensory and motor symptoms) needed more careful evaluation (Table 53-4; Video 96, Conduction Aphasia). Transient migrainous accompaniments may occur for the first time after the age of 45 and can easily be confused with transient ischemic attacks of cerebrovascular origin.

A number of disorders may present with migraine symptoms. Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) is an inherited arterial disease of the brain that has been mapped to chromosome 19.⁸⁰ The complete CADASIL syndrome consists of recurrent episodes of focal brain deficits (recurrent strokes) that start in midadult life and often lead to dementia, residual motor disability, and pseudobulbar palsy. Even before clinical symptoms or signs have developed, at-risk individuals may demonstrate an abnormal MRI, with extensive areas of increased T2 signals in the white matter. Many cases of FHM (all with associated cerebellar features) map to chromosome 19, close to the gene locus for CADASIL. The main clinical presentation of CADASIL consists of recurrent subcortical events, either transient or (more often) permanent (Video 215, CADASIL Stroke). The arteriopathy underlying CADASIL is neither atherosclerotic nor amyloid and involves the media of small cerebral arteries and to a lesser extent extracerebral arteries, including skin arterioles. Skin biopsy can be diagnostic. Ultrastructural examination reveals abnormal patches of agranular osmophilic material within the basal membranes of vascular smooth muscle cells.⁸¹

TABLE 53-4

Main Criteria for the Diagnosis of Late-Life Migrainous Accompaniments

| |
|--|
| Scintillations (or other visual display), paresthesias, aphasia, dysarthria, and paralysis |
| Build-up of scintillations |
| March of paresthesias |
| Progression from one accompaniment to another, often with a delay |
| Two or more similar attacks |
| Headache in 50% of attacks |
| Episodes last 15 to 25 minutes |
| Characteristic mid-life "flurry" of attacks |
| Generally benign course |
| Normal angiography |
| Rule out cerebral thrombosis, embolism and dissection, epilepsy, thrombocytopenia, polycythemia, and thrombotic thrombocytopenia |

In 1996, Joutel and associates identified Notch3 as the defective gene in CADASIL.⁸² Members of the Notch gene family encode evolutionarily conserved transmembrane receptors and are involved in cell fate specification during embryonic development. The Notch3 gene includes 33 exons encoding a protein of 2321 amino acids. Its extracellular domain contains 34 epidermal growth factor-like repeats that are involved in ligand-binding, whereas the intracellular domain carries the intrinsic signal-transducing activity. CADASIL gene identification has provided the information needed to set up a direct genotypic diagnostic test.⁸¹

The syndrome of mitochondrial encephalopathy with lactic acidosis and stroke-like spells (MELAS) may present with otherwise typical migraine or migraine with neurological deficits. Ornithine transcarbamylase deficiency, a urea cycle enzyme abnormality, may resemble confusional migraine in children and young adults, with migraine-like headaches, cyclic vomiting, confusion, hallucinations, visual disturbances, and ataxia.

DIFFERENTIAL DIAGNOSIS. Migraine-like headaches, with or without aura, may occur as a result of a wide variety of structural abnormalities of the brain, including tumors, infections, and vascular malformations. Such headaches may be thought of as secondary migraine. Cerebrovascular disorders such as infarction, transient ischemic attack, venous thrombosis, vasculitis, and carotid or vertebral dissection should be included in the differentiation of migraine. Idiopathic intracranial hypertension (IIH), low pressure headache, and intracranial neoplasms may also mimic migraine, as may metabolic abnormalities, hypoxia, hypoglycemia, dialysis, pheochromocytoma, and various chemicals and medications. Raeder's syndrome, with carotid artery abnormalities along the base of the skull, may also resemble migraine. Sinusitis or glaucoma may occasionally resemble migraine, and sometimes epilepsy produces intermittent headaches. Although rare, the aura of migraine may lead directly to a partial or complex partial seizure, termed migralepsy.⁸³ Other primary headache disorders such as TTH, cluster headache, and hypnic headache should be considered (see Table 53-1).⁶⁷

EVALUATION. Patients who have normal neurological examinations and benign recurrent headaches that fit the IHS criteria of migraine do not require brain imaging.⁸⁴ Patients who have abnormal neurological examinations, atypical histories, or a sudden unexplained change in the

frequency or major characteristics of their headaches should be imaged. There is no consensus whether all patients with chronic daily headaches should be imaged with CT or MRI, even if they fulfill the criteria for typical migraine. Unless a metabolic abnormality is suspected, blood tests for diagnostic purposes are rarely indicated. However, routine blood tests and an electrocardiogram are often valuable before initiating therapy for migraine.

MANAGEMENT. The U.S. headache consortium guidelines helped organize and prioritize treatment options.^{85,86}

Acute Treatment. Treatment choice depends on attack severity, frequency, associated symptoms, coexistent disorders, prior treatment response, and the medication's efficacy, potential for overuse, and adverse events (AEs). Most migraineurs describe headache-provoking (trigger) factors (Table 53-5), with alcohol, stress, menstruation, and diet being the most common. Patients should attempt to avoid these triggers and keep regular exercise, meal, and sleep patterns.⁸⁷ In the pharmacologic treatment of migraine, there are two strategies: (1) acute medications (Table 53-6), which are used to terminate attacks, and (2) preventive medications (Table 53-7), which are used to prevent future ones. Acute headache treatment medication can be specific or nonspecific. Nonspecific medications (analgesics, antiemetics, anxiolytics, nonsteroidal anti-inflammatory drugs [NSAIDs], steroids, neuroleptics, and opioids) are used to control the pain and associated symptoms of migraine or other pain disorders, while specific medications (ergots and selective 5-HT₁ agonists [triptans]) control the migraine attack but are not useful for nonheadache pain disorders. A nonoral route of administration and an antiemetic should be considered for severe nausea or vomiting.⁸⁶ Injections provide rapid relief. Headaches can be stratified by severity and disability (using MIDAS or HIT). Analgesics are used for mild to moderate headaches.⁸⁶ Triptans or DHE are first-line drugs for severe attacks and for less severe attacks that do not adequately respond to analgesics.⁸⁶ Patients with moderate or severe headaches with moderate or severe disability who were stratified to a triptan did better than patients who were given aspirin and metoclopramide.⁸⁸

When there is significant early nausea or vomiting, patients will need to be treated with antiemetics or with nonoral drugs for migraine control.⁸⁹ The sooner treatment is begun, the more effective it will be. Early intervention prevents escalation and may increase efficacy.⁹⁰ Triptans can prevent the development of CA, and CA predicts

triptans' effectiveness.³⁷ Caffeine, butalbital, isometheptene, and dichloralphenazone are adjunctive medications included in combination preparations to improve efficacy.⁸⁷

For patients with mild-to-moderate headaches, analgesics, NSAIDs, or a caffeine adjuvant compound can be useful. The authors use a triptan or DHE as a first-line drug for severe attacks and as a backup for less severe attacks that do not adequately respond to simple or combination analgesics. The subcutaneous injection is useful for patients who need rapid relief. Oral triptans may be used for gradual-onset headache, when rapid pain relief is not required. In given patients, more than one treatment plan can be used; for example, patients may successfully use naproxen sodium for mild-to-moderate headaches, but require a triptan for more severe headaches.^{87,91}

A self-administered rescue medication is needed when other treatments fail. Rescue medications include potent opioids, neuroleptics, and corticosteroids. The triptans are effective but expensive, and about one third of patients have recurrent headaches with this drug. Patient-administered triptans and DHE have the best efficacy-to-adverse-effect ratio of all the acute treatment medications and are the most cost-effective because their use results in fewer emergency room visits. Because nausea and vomiting are symptoms that are commonly associated with migraine headaches, oral medications may be unsuitable, and alternative formulations, as well as antiemetics, are often needed. Intravenous (IV) neuroleptics, corticosteroids, and DHE are highly effective. Patients with medication overuse headache, significant psychiatric or medical comorbidity, or a severe intractable headache that has failed to respond to outpatient treatment may require inpatient treatment with IV medication.⁸⁷ Before deciding that a drug is ineffective, at least two attacks should be treated. One must be sure that the dose is adequate and no other factors interfere with its effect. When the response is inadequate, the headache recurs, or AEs are bothersome, it may be necessary to change the formulation or route of administration or to add an adjuvant. Changing the drug should be considered when the response is incomplete or too slow, the headache recurs, the results are inconsistent after an adequate trial at an adequate dose, or the side effects are bothersome. When headaches are very frequent, early intervention may not be appropriate. Medication-overuse headache is a serious clinical problem and, in general, treatment with acute headache medication should be limited to 2 to 3 days per week. Medication-overuse headache results from the too-frequent use of acute headache medications, often resulting in more frequent headaches that are refractory to treatment.⁹¹

Preventive Treatment. The goals of preventive treatment are to reduce the frequency, duration, or severity of attacks, improve responsiveness to acute attack treatment, improve function, and reduce disability. It may also prevent episodic migraine's progression to chronic migraine and result in health care cost reductions.^{67,89} Preventive drug treatments (see Table 53-7) include antidepressants, β-blockers, calcium channel blockers, NSAIDs, serotonin antagonists (methysergide, cyproheptadine), and anticonvulsants. Preventive treatment is used when there is (1) recurring migraine that significantly interferes with the patient's daily routine despite acute treatment; (2) failure of, contraindication to, overuse of, or troublesome side effects from acute

TABLE 53-5

Trigger Factors of Migraine

| | |

medications; (3) special circumstances, such as hemiplegic migraine or attacks with a risk of permanent neurological injury; (4) very frequent headaches (more than two per week) with the risk of developing rebound headache; and (5) patient preference, that is, the desire to have as few acute attacks as possible.

If preventive medication is indicated, the agent should be chosen from one of the major categories, based on documented efficacy, side effect profiles, ease of use, and co-existent comorbid conditions. Medications used to treat migraine can be divided into five major categories: (1) drugs with documented high efficacy and mild-to-moderate adverse effects (AEs), which include β -blockers, amitriptyline, divalproex, and topiramate⁹²; (2) drugs with documented high efficacy but with significant AEs or complex management limitation, which include methysergide (no longer sold in the United States) and monoamine oxidase inhibitors; (3) drugs with lower documented efficacy and mild to moderate AEs, which include selective serotonin reuptake

inhibitors, calcium channel antagonists, gabapentin, riboflavin, and NSAIDs; (4) drugs without trial-document data on efficacy and used because of open-label observations with mild-to-moderate AEs or major AEs or complex management limitation; and (5) drugs with limited or no efficacy, which include cyproheptadine, lithium, and phenytoin. Choice should be made based on a drug's proven efficacy, the patient's preferences and headache profile, the drug's AEs, and the presence or absence of coexisting or comorbid disease. The drug used should be the one that has the best risk-to-benefit ratio for the individual patient and takes advantage of the drug's AE profile. An underweight patient would be a candidate for one of the medications that commonly produce weight gain, such as a TCA; in contrast, one would try to avoid these drugs in the overweight patient and consider using topiramate. Tertiary TCAs that have a sedating effect would be useful at bedtime for patients with insomnia. Older patients with cardiac disease or patients with significant hypotension may not be able to use TCAs

TABLE 53-7

Preventive Pharmacotherapy for Various Headache Types

| AGENT | STARTING DAILY DOSE* | MAXIMUM DAILY DOSE* | HEADACHE TYPE USE |
|---------------------------------------|----------------------|---------------------|-------------------|
| β-Blockers | | | |

| Lithium | 300 mg | 1800 mg | C |

*All doses are oral.

C, cluster headache; M, migraine; T, tension-type headache.

or calcium channel or β -blockers, but could use divalproex or topiramate. In the athletic patient, β -blockers should be used with caution. Medication that can impair cognitive functioning should be avoided when patients are dependent on their wits.^{89,93}

Medication should be started at a low dose and increased slowly until headache severity or frequency decreases, the maximum recommended dose is reached, or adverse effects develop. Dose titrations may take several months. When the headaches have been controlled for 6 months, attempts can be made to taper and discontinue therapy. Patients should be monitored for acute medication overuse, which may result in chronic refractory headaches and withdrawal symptoms when the medication is discontinued.⁸⁷ Recently, botulinum toxin type A injection has been reported to be effective in migraine prevention.⁹⁴

There are no U.S. Food and Drug Administration approved treatments for CM. Some studies support the use of topiramate, tizanidine, and gabapentin. Amitriptyline is perhaps the most commonly used medication but evidence exists only for CTTH, not for CM. Evidence suggests that botulinum toxin type A is effective for monotherapy patients using a modified follow-the-pain strategy but not a fixed-site strategy.^{95,96}

The pregnant headache patient should be treated conservatively, with nonpharmacological treatments the first choice. If the patient does not respond to this form of

therapy, acetaminophen (alone or with prochlorperazine or narcotics) can be used, and NSAIDs may be used in the first two trimesters. Very severe attacks should be treated with IV fluids, prochlorperazine, or narcotics. Prednisone has occasionally been used, but aspirin, barbiturate, and benzodiazepine use should be limited. Ergotamine and sumatriptan should be avoided completely. In the breast-feeding migraineur, ergotamine and lithium should not be used, because these drugs readily transfer to the baby via breast milk and can cause significant toxicity. Benzodiazepines, antidepressants, and neuroleptics may be used cautiously. Acetaminophen is preferable to aspirin.⁸⁷

PROGNOSIS AND FUTURE PERSPECTIVES. The prognosis of migraine is generally good. It usually improves, and it may disappear in the sixth or seventh decade of life. The natural history of transformed migraine is less certain. With aggressive treatment, most patients improve, although many continue to have lower intensity chronic daily headache or frequent episodic migraine. Future research will involve the search for the migraine gene and gene-directed therapy may be a therapeutic option in the next decade. The gene for CADASIL has been cloned.

Tension-type Headache

PATHOGENESIS AND PATHOPHYSIOLOGY. Although many patients with TTHs have muscle tenderness, TTH is not the result of sustained contraction of the pericranial muscles with subsequent ischemic pain in response to emotion or stress. Muscle ischemia is not present during headache. Electromyographic activity is increased in some muscles, independent of tenderness and pain. Reduced CNS 5-HT levels may be responsible for abnormal pain modulation, producing the decreased pain thresholds that are observed in patients with chronic TTH. A “myofascial-supraspinal-vascular” model has been proposed for TTH.⁹⁷ When pain facilitation is present, normal subthreshold stimuli may produce significant pain even if myofascial nociceptor hypersensitivity is not present. The cranial muscle ache of a TTH attack may, therefore, be due to increased neuronal sensitivity and pain facilitation due to chronic or intermittent dysfunction of the monoaminergic or serotonergic function in the hypothalamus, brain stem, and spinal cord.⁹⁸ Chronic TTH may be associated with a perceived increase in stressful life events. Depression is common in patients with chronic TTH, and neurotransmitter abnormalities in 5-HT, norepinephrine, dopamine, and enkephalins have been proposed as the etiology.

EPIDEMIOLOGY AND RISK FACTORS. TTH is the most common headache type, with a lifetime prevalence of 69% in men and 88% in women.⁶⁹ TTHs can begin at any age, but onset during adolescence or young adulthood is most common. About 40% of patients evaluated in headache clinics suffer from daily headache, whereas only 3% of the population has daily headache.⁵⁸ Headache prevalence declines with increasing age, and severity decreases in the women who continue to report headaches but does not change in men. Only patients with more severe frequent headaches that are unresponsive to over-the-counter preparations seek medical attention.

The prognosis of frequent episodic TTH and CTTH was favorable in a Danish follow-up to a cross-sectional

headache study of 549 persons. Among 146 subjects with frequent episodic TTH and 15 with CTTH at baseline, 45% experienced infrequent or no tension-type headache (remission), 39% had frequent episodic TTH, and 16% experienced CTTH (poor outcome) at follow-up. Poor outcome was associated with baseline CTTH, coexisting migraine, not being married, and sleeping problems.⁵⁹

CLINICAL FEATURES AND ASSOCIATED DISORDERS.

Episodic TTHs are now classified as either infrequent (<1 day/month or 12 days/year) or frequent (>1 but <15 days/month or >12 but <180 days/year). The IHS criteria for a TTH require that patients experience at least 10 previous headaches, each lasting 30 minutes to 7 days (median, 12 hours), with at least two of the following characteristics: a pressing/tightening (nonpulsating) quality, mild to moderate intensity, bilateral location, and no aggravation with physical activity. In addition, the patient should not have nausea or vomiting or a combination of photophobia and phonophobia. Episodic TTH occurs less than 15 days a month, whereas CTTH occurs 15 or more days a month.⁵⁸ The pain is a dull, aching, nonpulsatile feeling of tightness, pressure, or constriction (viselike or hatband-like), and it is usually mild to moderate, in contrast to the moderate-to-severe pain of migraine. Pain intensity increases with headache attack frequency.⁹⁹ Most patients have bilateral pain, but the location varies considerably within and between patients and can involve the frontal, temporal, occipital or parietal regions, alone or in combination, and can change locations during an attack.¹⁰⁰ An occipital location is less common than a frontal or temporal location. Some patients have neck or jaw discomfort or have frank problems with their temporomandibular joint.^{101,102}

The onset of TTH is gradual, often occurring after or during stress, and is typically worse late in the day. There is no prodrome. The pain is usually a nagging, tight, or viselike bilateral pressure that is located in the forehead, the temples, or the back of the head. It may radiate to the neck and shoulders. There are no associated autonomic or gastrointestinal symptoms except for occasional anorexia. The frequency of episodic TTH ranges from 2 to 12 days a month, with a median of 6 days a month. The headaches may be associated with menstruation.^{58,98}

Twenty-five percent of TTH patients also have migraine.¹⁰³ What we call episodic TTH may be two distinct disorders. The first disorder may be attacks of mild migraine. The second may be a pure TTH that is not associated with other features of migraine (nausea, photophobia or sensitivity to movement) or with attacks of severe migraine.⁶ The fact that sumatriptan is effective for TTH that occurs in migraineurs but not for TTH that occurs in nonmigraineurs supports this concept.¹⁰⁴

Patients with episodic TTH are no different from control subjects in terms of stress, depression, anxiety, emotional conflicts, sleeping problems, and fatigue. Patients with CTTH are often depressed.⁹⁸

DIFFERENTIAL DIAGNOSIS. Migraine is the primary headache disorder that may be confused with TTH. Both can be bilateral, nonthrobbing, and associated with anorexia. Migraine is more severe, often unilateral, and frequently associated with nausea. ITH, brain tumor headache, chronic sphenoid sinusitis, and cervical, ocular, and temporomandibular disorders need to be considered.^{58,98}

EVALUATION. Most patients with a long history of unchanged episodic TTHs do not require extensive evaluation if they have normal neurological examinations and are otherwise healthy. Patients with chronic TTHs should be imaged with CT or MRI, even if their general and neurological examinations are normal. A metabolic screen, complete blood count, electrolytes, and kidney and thyroid function studies are also appropriate.⁹⁸

MANAGEMENT. TTH patients usually self-medicate with over-the-counter analgesics (aspirin, acetaminophen, NSAIDs), with or without caffeine. If these medications are not effective, prescription NSAIDs or combination analgesic preparations can be used. Narcotics and combination analgesics that contain sedatives or caffeine should be limited, because overuse may cause dependence. Symptomatic medication overuse can cause episodic TTHs to convert to CTTHs. Patients with both migraine and TTHs benefit from specific migraine medication such as sumatriptan or DHE (see Tables 53-6 and 53-7).^{58,98}

Preventive therapy should be administered when a patient has frequent headaches that produce disability or may lead to symptomatic medication overuse. Medications used for TTH prevention include antidepressants, β -blockers, and anticonvulsants. Antidepressants, the medication of first choice, should be started at a low dose and increased slowly every 3 to 7 days. An adequate trial period of at least 1 to 2 months must be allowed. The addition of biofeedback therapy or β -blocking agents may improve the therapeutic benefit derived from antidepressants.^{58,98}

PROGNOSIS AND FUTURE PERSPECTIVES. Episodic TTH is a benign recurrent condition that usually improves with time. Some patients may, however, progress to CTTH, especially when analgesic overuse is present. The prognosis of CTTH is controversial, because many studies include patients with more severe headaches and coexisting conditions, such as migraine and psychiatric disorders.

Cluster Headache

PATHOGENESIS AND PATHOPHYSIOLOGY. The pathogenesis of cluster headaches is increasingly clear. Trigeminovascular system involvement has been demonstrated by a marked increase in the level of calcitonin gene-related peptide in the cranial venous circulation during attacks.¹⁰⁵ Parasympathetic system activation in cluster headache has been corroborated by the finding of dramatically elevated levels of vasoactive intestinal polypeptide during attacks¹⁰⁵ with robust ipsilateral autonomic features. This finding provides an anatomical basis for the expression of first division trigeminal pain and ipsilateral autonomic symptoms that occur during cluster attacks. Cluster events are probably related to alterations in the circadian pacemaker, which may be due to hypothalamic dysfunction. Attacks increase following the beginning and end of daylight savings time, and there is a loss of circadian rhythm for blood pressure, temperature, and hormones, including prolactin, melatonin, cortisol, and β endorphins. Evidence for the role of the hypothalamus in cluster headache pathogenesis has come from functional and morphometric neuroimaging. Using positron-emission tomography imaging, May and colleagues demonstrated marked activation in the ipsilateral ventral hypothalamic

gray matter during nitroglycerin-induced acute cluster headache attacks.¹⁰⁶ Neurogenic inflammation, carotid body chemoreceptor dysfunction, central parasympathetic and sympathetic tone imbalance, and increased responsiveness to histamine have been proposed as the cause of cluster pain.¹⁰⁷

EPIDEMIOLOGY AND RISK FACTORS. With an incidence of 0.01% to 1.5% in various populations, cluster headache prevalence is lower than that of migraine or TTH. Prevalence is higher in men than in women and in African-American patients compared with white patients. Recent evidence suggests a progressively decreasing male preponderance and the male-to-female ratio based on the year of onset in Manzoni's study¹⁰⁸ decreased from 6.2:1 in the 1960s to 2.1:1 in the 1990s.¹⁰⁹ A family history of cluster headache is rare. The most common form of cluster headache is episodic cluster. The rarest form is chronic cluster headache without remissions, with only about 10% of patients suffering from this variety of cluster. Cluster headache can begin at any age, but it generally begins in the late twenties. Cluster headache rarely begins in childhood, and only about 10% of patients develop cluster when they are in their sixties.^{107,110}

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Patients with cluster headache have multiple episodes of short-lived but severe, unilateral, orbital, supraorbital, or temporal pain. At least one of the following associated symptoms must occur: conjunctival injection, lacrimation, nasal congestion, rhinorrhea, facial sweating, miosis, ptosis, or eyelid edema. Episodic cluster consists of headache periods of 1 week to 1 year, with remission periods lasting at least 14 days, whereas chronic cluster headache has either no remission periods or remissions that last less than 14 days.^{107,110}

The pain of a cluster attack rapidly increases (within 15 minutes) to excruciating levels. The attacks often occur at the same time each day and frequently awaken patients from sleep. If the condition is left untreated, the attacks usually last from 30 to 90 minutes, but may last up to 180 minutes. The pain is deep, constant, boring, piercing, or burning in nature, located in, behind, or around the eye. It may radiate to the forehead, temples, jaws, nostrils, ears, neck, or shoulder. During an attack, patients often feel agitated or restless and feel the need to isolate themselves and move around. Gastrointestinal symptoms are uncommon. In a small subset of patients, typical migraine aura may precede attacks of cluster headache.¹¹¹ The attack frequency varies from one every other day to eight a day, occurring in cluster periods that last a week to a year. Remissions between cluster periods generally last 6 months to 2 years. Most patients have one or two cluster periods a year that last 2 to 3 months, with one to two attacks a day.¹⁰⁷

Peptic ulcer disease is the only known associated medical disorder. Secondary cluster-like headache may occur due to structural lesions near the cavernous sinuses.^{107,110}

DIFFERENTIAL DIAGNOSIS. The differential diagnosis of cluster headache includes chronic paroxysmal hemicrania, migraine, trigeminal neuralgia, temporal arteritis, pheochromocytoma, Raeder's paratrigeminal syndrome, Tolosa-Hunt syndrome, sinusitis, and glaucoma.¹⁰⁷ Raeder's syndrome has characteristics similar to cluster headaches. It may be associated with severe pain, unilateral and

supraorbital distribution, and an associated partial Horner's syndrome. It is distinct from cluster headache in that there are no distinct attacks and the pain is constant.

EVALUATION. There are no studies that address the need for testing in cluster-like headache. In most cases, a careful history is all that is needed to make the diagnosis. MRI of the head is justified only in atypical cases or cases with an abnormal neurological examination (except when the abnormality is Horner's syndrome).

MANAGEMENT. Patients with cluster headaches should avoid alcohol and nitroglycerin, yet other dietary and drug restrictions have little effect. Pharmacological treatment for cluster headaches is divided into abortive and preventive therapy, and recommendations are mainly based on uncontrolled trials (Table 53-8).^{107,110} Oral preparations are absorbed slowly and are not recommended for the treatment of acute attacks. Effective abortive treatments that provide rapid onset of action include oxygen, sumatriptan, DHE, and (perhaps) topical local anesthetics. Inhaled oxygen, 7 to 10 L/minute for 10 minutes following headache onset, is 70% effective and is often the treatment of first choice. Parenteral injections of sumatriptan or DHE mesylate provide significant relief for about 80% of

TABLE 53-8

Cluster Headache Prophylaxis

| DRUG | DOSAGE | ADVERSE EFFECTS |
|-----------------------------------|--------------------------------------|---|
| Episodic Cluster Headache* | | |
| Divalproex | 500–3000 mg/d | Nausea, lethargy, tremor, bodyweight gain, hair loss; rarely abnormal liver function, pancreatitis |
| Ergotamine | Up to 4 mg/d | Nausea, paresthesia, intermittent claudication, ergotism |
| Lithium | 300 mg bid or tid (0.4–0.8 mmol/L) | Weakness, nausea, thirst, tremor, lethargy, slurred speech, blurred vision |
| Methysergide | 2–14 mg/d | Muscle cramps, nausea, diarrhea, abdominal discomfort |
| Prednisone | 40–100 mg/d, taper over 1 to 2 weeks | Insomnia, restlessness, personality changes, hyponatremia, edema, hyperglycemia, osteoporosis, myopathy, gastric ulcers, hip necrosis |
| Topiramate | 50–200 mg/d | Weight loss, paresthesia, renal stones, cognitive dysfunction |
| Verapamil | 120–720 mg/d | Constipation, edema, dizziness, nausea, hypotension, fatigue |
| Chronic Cluster Headache† | | |
| Divalproex | 500–3000 mg/d | Same as episodic |
| Lithium | 300 mg bid or tid (0.4–0.8 mmol/L) | Hypothyroidism and polyuria |
| Methysergide | 2–14 mg/d | Fibrotic reactions |
| Topiramate | 50–200 mg/d | Weight loss, paresthesia, renal stones, cognitive dysfunction |
| Verapamil | 120–720 mg/d | Same as episodic |

*Begin early in the cluster period and continue until the patient has been headache-free for at least 2 weeks.

†Combinations are often required.

bid, twice daily; tid, three times daily.

patients. An intranasal local anesthetic may provide relief for some patients.^{107,110}

Most patients with cluster headache require preventive treatment because each attack is too short in duration and too severe in intensity to treat with only abortive medication. In addition, ergotamine, DHE, sumatriptan, and oxygen may just postpone rather than abort the attack. Preventive therapy for cluster includes ergotamine, calcium channel blockers, lithium, corticosteroids, divalproex, topiramate, melatonin, and capsaicin. Occasionally, indomethacin is effective. If medical therapy fails completely, surgical intervention may be beneficial for the psychologically stable patient with strictly unilateral chronic cluster. The surgery consists of neuronal ablation procedures directed toward the sensory input of the trigeminal nerve and autonomic pathways and is effective in 75% of patients.¹¹² Gamma knife radiosurgery was reported to be effective in six medically recalcitrant cluster headache patients, but delayed radiation necrosis can occur.¹¹³ Deep brain (hypothalamic) stimulation has been reported to be effective in intractable chronic cluster headache.¹¹⁴ Since cluster headache is a chronic headache disorder that may last for the patient's life, the prognosis is guarded. Drug therapy may help convert some patients from chronic to episodic cluster.¹⁰⁷

Chronic Paroxysmal Hemicrania

Chronic paroxysmal hemicrania resembles cluster headache in character but distinguishes itself by its dramatic responsiveness to indomethacin therapy. The pathophysiology of chronic paroxysmal hemicrania is unknown. Changes in intraocular pressure that occur during attacks suggest autonomic dysfunction, and the periodicity of this disorder suggests a central generator.¹¹⁵ Chronic paroxysmal hemicrania is a rare disorder that affects women more than men (ratio approximately 7:1), in contrast to cluster headache. It appears to have approximately 2% the prevalence of cluster headache.¹¹⁵

Like cluster headache patients, chronic paroxysmal hemicrania patients have severe unilateral headaches associated with unilateral nasal stuffiness, lacrimation, conjunctival eye tearing, ptosis, and eyelid edema. Headaches average 13 minutes in duration and occur an average of 11 times a day. Occasionally, there is a continuous dull ache between attacks. In 10% of patients, attacks may be triggered by flexing, rotating, or pressing the upper portion of the neck.¹¹⁵ Typically, there are no remissions. Rarely, a patient may present with episodic paroxysmal hemicrania with remissions that last weeks or months. Patients may evolve from the episodic to the chronic form of the illness. By definition, chronic and episodic hemicrania are responsive to indomethacin. No other medical or psychiatric disorders have been associated with chronic paroxysmal hemicrania.¹¹⁵

The differential diagnosis of chronic paroxysmal hemicrania is similar to that of cluster headache. In addition, patients with "jabs and jolts syndrome" might occasionally resemble chronic paroxysmal hemicrania patients. A rare headache disorder called short unilateral neuralgiform headache with conjunctival injection and tearing should be considered, although these headaches are much shorter in duration (15 to 30 seconds) and occur much more

frequently (many times per hour) than those of chronic paroxysmal hemicrania.

In the evaluation of chronic paroxysmal hemicrania, a trial of indomethacin is necessary to establish the diagnosis. Brain imaging with MRI or CT should be undertaken to exclude symptomatic causes of apparent chronic paroxysmal hemicrania. The treatment of choice is indomethacin (in a dose up to 200 mg/day). Aspirin may also be beneficial, but the relief afforded is usually not complete. Chronic paroxysmal hemicrania may last indefinitely, but the indomethacin requirement may be reduced over time. Temporary remissions and spontaneous cures have been described. Selective prostaglandin synthesis inhibitors, indomethacin-like drugs without the gastrointestinal side effects of the current NSAIDs, are in development and may be beneficial.

Idiopathic Intracranial Hypertension

PATHOGENESIS AND PATHOPHYSIOLOGY. Idiopathic intracranial hypertension (IIH) is a disorder of increased intracranial pressure (ICP) of unknown cause. Postulated mechanisms include increased cerebrospinal fluid (CSF) production, decreased CSF absorption, and increased venous sinus pressure. Some studies suggest that interstitial brain edema and a decreased rate of absorption at the arachnoid villi are the major contributors. The disturbances of CSF hydrodynamics in IIH persist for years.¹¹⁶ Increased CSF pressure in IIH may result from a rise in venous sagittal sinus pressure secondary to extracellular edema causing venous obstruction or from low conductance for CSF reabsorption producing a compensatory increase in CSF pressure. Patients evaluated with cerebral venography and manometry demonstrated elevated venous pressure in the superior sagittal and proximal transverse sinuses. This elevated pressure dropped at the level of the lateral third of the transverse sinus. Imaging revealed abnormalities resembling a mural thrombosis. Two patients with intracranial hypertension due to minocycline did not have venous hypertension. The authors suggested that most patients with IIH may have partial venous outflow obstructions, blurring the distinction between idiopathic and symptomatic causes.^{117,118} In another study, the authors suggested that IIH was due to either venous obstruction or elevated central venous pressure, despite the absence of signs or symptoms of heart failure. Farb and associates¹¹⁹ determined the prevalence and nature of sinovenous structural abnormalities in IIH using auto-triggered elliptic-centric-ordered three-dimensional gadolinium-enhanced MR venography (ATECO MRV). Substantial bilateral sinovenous stenoses were seen in 27 of 29 patients with IIH and in only 4 of 59 control patients. Using ATECO MRV, they could identify IIH patients with 93% sensitivity and specificity. Unresolved by the study of Farb and colleagues is whether the venous conduit narrowing may be secondary to IIH. A plausible explanation remains that the increased CSF pressure, through external compression, could account for the caliber changes in the venous sinuses.¹²⁰

EPIDEMIOLOGY AND RISK FACTORS. IIH with papilledema occurs with a frequency of about 1 case per 100,000 per year in the general population and 19.3 cases

per 100,000 per year in obese women aged 20 to 44.¹¹⁷ The patient with IHH is commonly a young, obese woman with chronic daily headaches, normal laboratory studies, an empty sella, and a normal neurological examination (except for papilledema) (Fig. 53-2).¹¹⁷

CLINICAL FEATURES AND ASSOCIATED DISORDERS.

The symptoms of IHH consist of generalized increased intracranial pressure, with headache occurring in most, but not all, patients. Bifrontotemporal headache is most common. Unilateral headache with increased CSF pressure due to IHH may be an exacerbation of migraine or a new local phenomenon. Transient visual obscuration (an episode of visual clouding in one or both eyes usually lasting seconds) occurs with all forms of increased intracranial pressure with papilledema but is not a specific symptom. Transient visual obscurations can occur in patients without increased intracranial pressure who have elevated optic discs from other causes. Those who do not have papilledema do not have transient visual obscurations. Pulsatile tinnitus, diplopia, and visual loss can occur. Some patients report shoulder and arm pain (perhaps secondary to nerve root dilation) and retro-orbital pain.¹¹⁷ Friedman and Jacobson¹²¹ have proposed diagnostic criteria:

- Symptoms: only those of generalized intracranial hypertension or papilledema
- Signs: only those of generalized intracranial hypertension or papilledema
- Documented elevated intracranial pressure
- Normal CSF composition
- MRI/MRV: no hydrocephalus, mass, structural or vascular lesion except for empty sella
- Not attributable to another cause

IHH without papilledema has been described in some patients. The headache and demographic characteristics are identical to those of patients with IHH with papilledema except for (1) possible association with prior head trauma or meningitis; (2) extended delay in diagnosis, which requires lumbar puncture in the absence of papilledema; and (3) no evidence of the visual loss seen in patients with

IHH with papilledema.¹¹⁷ There are no disorders associated with IHH other than obesity. The pathophysiology of IHH without papilledema is presumably similar to that of IHH with papilledema.

DIFFERENTIAL DIAGNOSIS. IHH may be either truly *idiopathic*, with no clear identifiable cause, or *symptomatic*, a result of venous sinus occlusion, radical neck dissection, hypoparathyroidism, vitamin A intoxication, systemic lupus erythematosus, renal disease, or drug side effects (nalidixic acid, danocrine, steroid withdrawal).

EVALUATION. The diagnosis of IHH (with or without papilledema) is based on lumbar puncture following neuroimaging (paying attention to empty sella and sinus thrombosis). If CSF biochemical and cytological analyses are unremarkable and intracranial pressure is elevated to greater than 200 mm H₂O (in nonobese subjects), IHH is the likely diagnosis. Secondary causes should also be considered in the evaluation. Over 50 diseases, conditions, toxins, or pharmaceuticals have been associated with IHH. Patients, particularly obese women, with chronic daily headaches and symptoms of increased intracranial pressure—for example, pulsatile tinnitus, a history of head trauma or meningitis, an empty sella on neuroimaging studies, or a headache that is unrelieved by standard therapy—should have a diagnostic lumbar puncture.¹¹⁷

MANAGEMENT. The treatment of IHH is multidimensional (Table 53-9). Obese patients should be encouraged to lose weight. If patients are asymptomatic and do not have visual loss, treatment is not indicated. In these cases, careful ophthalmological follow-up is necessary. If there is headache with visual loss or papilledema, aggressive treatment should be instituted.

Headache associated with IHH and papilledema frequently responds to the same treatments used for migraine and TTH. If rigorous headache therapy is unsuccessful, or if there is visual loss, then a 4- to 6-week trial of furosemide or a potent carbonic anhydrase inhibitor (acetazolamide) should be given. Others are using topiramate because it is also a carbonic anhydrase inhibitor. High-dose steroids may be effective, but headache commonly recurs when the drugs are withdrawn. Lumbar puncture typically relieves headache in patients with IHH and papilledema. Some intractable headache patients have a dissociation between the CSF pressure and the headache. In some patients, lumbar puncture reduces the pressure and relieves the headache; in others, there is no improvement. Surgical treatment of IHH has been directed toward preventing visual loss secondary to papilledema, and headache

Figure 53-2. An empty sella is shown.

TABLE 53-9

Possible Treatments of Idiopathic Intracranial Hypertension

| |
|---|
| Eliminate symptomatic causes |
| Weight loss if obese |
| Standard headache treatment |
| Carbonic anhydrase inhibitors, loop diuretics, and topiramate |
| Short course of high-dose corticosteroids |
| Serial lumbar punctures |
| Lumboperitoneal or ventriculoperitoneal shunt |
| Optic nerve sheath fenestration |

improvement occurs in many patients when optic nerve sheath fenestration is performed.¹¹⁷

PROGNOSIS AND FUTURE PERSPECTIVES. Most patients with IIH and papilledema can be managed successfully. The prognosis for headache control of IIH without papilledema is more guarded, although there appears to be no risk of visual deterioration. The development of drugs to control CSF production, perhaps acting via 5-HT_{2C} receptors, may revolutionize the treatment of IIH in the near future.

Low Pressure Headache

PATHOGENESIS AND PATHOPHYSIOLOGY. The most common cause of low pressure headache is a lumbar puncture. Head or back trauma, craniotomy, and spinal surgery can produce CSF hypotension as a result of a dural tear or traumatic avulsion of a nerve root resulting in a CSF leak. In addition, craniotomy and trauma can produce intracranial hypotension not associated with a CSF leak. This may be a result of decreased CSF formation, decreased CBF, or both. Low pressure syndromes can occur secondary to CSF rhinorrhea, either spontaneous, post-traumatic, or due to a pituitary tumor. Spontaneous dural tears must be ruled out in all cases of spontaneous intracranial hypotension. Infusion of hypertonic solution or a systemic medical illness, including severe dehydration, hyperpnea, meningoencephalitis, uremia, and severe systemic infection, can cause CSF hypotension. Postural headache can also occur in patients who have had CSF shunts, and this can be one of the complications of treating IIH (see Table 53-9).¹¹⁷ Intracranial hypotension may also respond to caffeine and an epidural blood patch even without correction of an underlying leak, suggesting that the CSF pressure indicator of some patients may be set too low. Mokri believes that the disorder is primarily that of hypovolemia; hypotension is usually, but not always, present.¹²²

Cases of spontaneous intracranial hypotension have been reported in which the radionuclide cisternogram showed rapid uptake in the bladder and kidneys and rapid transport of isotope with no evidence of a CSF leak. This finding is abnormal and was believed to be consistent with CSF hyperabsorption. Many researchers now believe that this abnormality is solely due to an occult CSF leak. Slowing of isotope flow, which is evidence for decreased CSF production, has also been reported. Low CSF volume leads to brain sagging with compression of the pituitary-hypothalamic axis and further reduction in CSF production. Slit-like ventricles and tight basilar cisterns have been reported on CT scans of patients with spontaneous intracranial hypotension, leading to speculation that this contributed to decreased CSF production. However, small ventricles (due to a compensatory increase in brain volume) are most likely a result, rather than a cause, of decreased CSF production.¹¹⁷

Occult CSF leakage may also be a major cause of IIH, according to some studies. A history of minor trauma is often elicited. In one report, approximately half the patients had a history of minor trauma or an inciting event. Traumatic rupture of spinal epidural cysts (formed during development), perineural cysts, or a nerve sheath tear could then produce a cryptic CSF leak. CSF can also leak into the

petrous or ethmoidal regions or through the cribriform plate, and the patient may swallow the fluid and be unaware of the leak.

EPIDEMIOLOGY AND RISK FACTORS. The incidence of spontaneous intracranial hypotension or secondary intracranial hypotension is unknown. Post-lumbar puncture headache is more common in women, who are affected twice as often as men, and in younger patients. The incidence depends on the type of procedure: surgical lumbar puncture, 13%; obstetrical, 18%; and diagnostic, 32%.¹²³ Using an atraumatic needle dramatically reduces the risk of postlumbar puncture headache.¹²⁴

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Low pressure headache is the most common complication of lumbar puncture, occurring in 15% to 30% of patients. Onset varies from 15 minutes to 4 days following lumbar puncture, but it can take as long as 12 days. If it is left untreated, the headache can last 2 to 14 days (most commonly 4 to 8 days) or even months.¹¹⁷ The headache of intracranial hypotension may be frontal, occipital, or diffuse. It is accentuated by the erect position and relieved with recumbency. The pain is severe, dull, or throbbing in nature and is usually not relieved with analgesics. It is aggravated by head-shaking, coughing, straining, sneezing, and jugular compression. The more severe the headache, the more frequently it is associated with dizziness, nausea, vomiting, and tinnitus, and the longer the patient is upright, the longer it takes the headache to subside with recumbency. Physical examination is usually normal; however, there may be mild neck stiffness and a slow pulse rate (so-called vagus pulse).^{117,123} Spinal fluid pressure usually ranges from 0 to 65 mm. The CSF composition is usually normal, but there may be a slight protein elevation and a few red blood cells in the fluid. Reversible Arnold-Chiari type malformation has been reported in association with a low CSF pressure headache.^{123,125}

DIFFERENTIAL DIAGNOSIS. The differential diagnosis of a spontaneous positional headache is limited, but other disorders, such as a colloid cyst of the third ventricle, need to be considered.

EVALUATION. The diagnosis of low CSF pressure headache is easily made in the presence of orthostatic headache, particularly if there is an obvious etiology, such as head or back trauma, a recent lumbar puncture or craniotomy, or an associated medical illness. If no obvious cause is apparent or the diagnosis is uncertain, lumbar puncture (perhaps at the time of cisternography) is indicated, following a neuroimaging procedure (CT or MRI). The opening pressure usually ranges from 0 to 70 mm H₂O. However, in the Mayo Clinic series of spontaneous intracranial hypotension, the opening pressure was, at times, in the normal range, especially if the measurement was made after a period of recumbency.¹²³ This suggests that the primary issue is CSF hypovolemia.

Diffuse pachymeningeal enhancement is the most common head MRI abnormality in CSF leaks and CSF volume depletion. This enhancement is limited to the pachymeninges without any evidence of leptomeningeal involvement. Descent of the brain ("sagging" or "sinking") is also a common finding and is manifested by descent of the cerebellar tonsils (which may sometimes mimic type I Arnold-Chiari malformation),¹²⁶ decrease in the size of the

prepontine cistern, inferior displacement of the optic chiasm, effacement of perichiasmatic cisterns, and crowding of the posterior fossa.

Subdural fluid collections are usually but not always bilateral. Decrease in the size of the ventricles, or “ventricular collapse,” is sometimes obvious, though often subtle, and is best noted by comparing a head MRI obtained after recovery with a previous MRI taken during the symptomatic phase. Other abnormalities include pituitary enlargement¹²⁷; engorged venous sinuses⁹⁹; and elongation of the brain stem in the anteroposterior plane.¹⁰⁰ Spine MRI may reveal extra-arachnoid or extradural fluid.^{101,102} Dural enhancement¹²⁸ and engorgement or prominence of the epidural venous plexus can occur.

If the cause of the low pressure is known, one should proceed with the appropriate treatment modalities. If the cause is unknown, treatment with an epidural lumbar blood patch is indicated before searching for the leak. If, however, treatment is unsuccessful, one should re-evaluate the patient with radioisotope cisternography, using nasal pledgets if a cribriform plate leak is possible, or ionic myelography to identify CSF leaks, which can be caused by very small dural tears or nerve avulsions.¹¹⁷ MRI of the spine may also identify cryptogenic leaks.

MANAGEMENT. The treatment of low CSF pressure headache begins with noninvasive therapeutic modalities. If these modalities fail, a brief trial of steroids with a quick taper is recommended. Intravenous or oral caffeine therapy may also be highly effective. If the patient continues to be symptomatic after noninvasive therapies, a blood patch should be used. If the headache of intracranial hypotension recurs, a repeat blood patch can be performed¹²⁹ or a continuous intrathecal saline infusion attempted. In the latter procedure, an epidural catheter is placed at the L2–L3 level and a saline infusion begun at a rate of 20 mL/hour and continued for as long as 72 hours.^{117,130} A cervical or upper thoracic blood patch has been reported to be effective when lumbar blood patches fail.¹³¹

PROGNOSIS. Most patients with intracranial hypotension can be cured once a diagnosis is made. Occasionally, none of the treatments provide relief for a patient with a refractory CSF leak or a refractory low pressure headache without apparent cause.^{117,123} The development of atraumatic lumbar puncture needles has resulted in a decreased incidence of post-lumbar puncture headache.¹²³

Other Headache Syndromes

Headache of Intracranial Neoplasms

Headache occurs at presentation in up to half of patients with brain tumors and develops in the course of the disease in 60%. Headache is partly dependent on the location of the tumor, and it is a rare initial symptom in patients with pituitary tumors, craniopharyngiomas, or cerebellopontine angle tumors.¹¹⁷ In a modern series, 111 consecutive patients with primary (34%) or metastatic (66%) brain tumor were diagnosed using neuroimaging. In this series, headache was present in 48% of patients with primary and metastatic tumor and was similar in quality to TTH in 77% and migraine in 9% of patients. Unlike primary TTH, brain tumor headaches were worsened by bending

in 32% of patients, and nausea or vomiting was present in 40%.¹³² Increased intracranial pressure was defined by the presence of papilledema, obstructive hydrocephalus, communicating hydrocephalus from leptomeningeal metastasis, or a lumbar puncture opening pressure greater than 250 mm of CSF.

Eighty-six percent of patients with increased intracranial pressure had headache that was typically constant, bilateral, and frontal in location with a pressure-like or aching character. Only 1% had unilateral headache. The pain was severe in intensity, associated with nausea and vomiting, and resistant to common analgesics. Ataxia occurred in 61% (Video 91, Cerebellar Ataxia). In contrast, only 36% of patients with a supratentorial tumor without increased intracranial pressure had headache. These headaches were milder and more likely to be intermittent, yet they were constant in 20% of patients. Nausea, vomiting, and ataxia were much less common.¹³²

Patients with a history of prior headache were more likely to have a brain tumor headache. In many cases, this headache was similar in character to the prior headache, but it was more severe or frequent, or associated with neurological signs or symptoms.¹³² There is a significant overlap between brain tumor headache and migraine or TTH. Morning or nocturnal headache associated with vomiting and increased headache frequency can be seen with both migraine and brain tumors. Brain tumor headache is more common in patients with a history of prior headache, increased intracranial pressure, and large tumors with a midline shift.¹¹⁷ Headache of recent onset or a headache that has changed in character requires a thorough evaluation, particularly if the headache is severe or is accompanied by nausea or vomiting. Any neurological sign or symptom that is accompanied by a headache and cannot be easily explained by the aura of migraine must be carefully evaluated as well.

Cough and Exercise Headache

Although coughing and exertion rarely provoke headache, these maneuvers can aggravate any type of headache. However, transient, severe head pain on coughing, sneezing, weight-lifting, bending, straining at stool, or stooping defines exertional headache.¹³³ Exertional headache mainly affects middle-aged men, and it runs its course over a few years. It is uncommon, and only 93 diagnoses were made at the Mayo Clinic over a 14-year period by Rooke,¹³⁴ who proposed the term benign exertional headache. In a population-based study,¹³⁵ benign cough headache and benign exertional headache each occurred with a prevalence of about 1%.

The IHS distinguishes between benign cough headache and benign exertional headache, entities that do not have identical clinical features, diagnostic evaluations, and treatment responses.⁶ Benign cough headache is defined as a bilateral, throbbing headache of sudden onset lasting less than 1 minute and precipitated by coughing in the absence of any intracranial disorder. Benign exertional headache lasts from 5 minutes to 24 hours and is produced by physical exercise without any associated systemic or intracranial disorder. In general, benign exertional headache starts at a much younger age than benign cough headache. Benign

cough headache has been infrequently reported, and the mean age of onset is 55, with a range of 19 to 73 years. Benign cough headache is twice as common in patients older than 40 years of age and is four times more common in men than in women.¹³⁶ The pain begins immediately^{136,137} or within seconds after muscular effort, coughing, sneezing, lifting, straining at stool, blowing, crying, or singing. The pain is severe in intensity with a bursting, explosive, or splitting or stabbing quality that lasts a few seconds or minutes. The headache is unilateral 35% of the time and may be maximal at the vertex or in the occipital, frontal, or temporal region. Bending the head or lying down may be impossible.^{136,137} Benign cough headache is not generally associated with nausea or vomiting, and the neurological examination is usually normal. Vomiting, if present, suggests an organic basis for the headache.^{136,137} Up to 25% of patients with benign cough headache have an antecedent respiratory infection.

Benign exertional headache and benign cough headache can be confused with other mechanically precipitated disorders, such as effort migraine and coital headaches. In fact, 40% of patients with coital headache of the vascular type had benign exertional headache, suggesting a relationship between these entities. Most patients are free of pain between attacks of head pain, but in some cases, the paroxysms are followed by dull, aching pain that may persist for hours. Benign exertional headache lasts longer than benign cough headache and is bilateral and throbbing.^{136,137} Five of the 21 patients reported by Symonds had such additional headaches.¹³³ Because these patients often describe the problem as a continuous headache, they should be asked directly about the role of exertion as a trigger factor for their headaches. Autonomic symptoms are unusual in this disorder.

If a patient presents with cough or exertional headache, MRI must be performed to rule out posterior fossa abnormalities, which can cause this headache syndrome. These abnormalities include brain tumors, such as posterior fossa meningiomas, acoustic neurinomas, and other tumors; midbrain cysts; basilar impression; and Chiari malformations.^{136,137}

Of the 219 cases of exertional and cough headache reviewed by Sands and colleagues,¹³⁶ 48 had an identifiable organic etiology. Pascual and coworkers¹³⁷ have suggested that symptomatic cough headache is more likely to be associated with a Chiari malformation and begin at an earlier age in life than benign cough headache. Symptomatic exertional headaches began later in life and lasted longer than benign exertional headaches. Most acute cases of exertional headaches were due to subarachnoid hemorrhage.

The long-term outlook for these patients is favorable. If the headaches are frequent or severe, prophylactic therapy is required, because the short duration of the headaches usually renders abortive therapy impractical. Patients with benign cough headache often respond dramatically to indomethacin in doses ranging from 25 to 150 mg daily.¹³⁸ If there is gastrointestinal intolerance to indomethacin, concomitant treatment with misoprostol, sulcralfate, proton-pump inhibitors, or antacids may be helpful. When indomethacin fails, Raskin¹³⁸ reports that naproxen, ergonovine, and phenelzine are useful, but propranolol is not. Patients with benign exertional headaches often respond

to ergotamine or propranolol. Symonds¹³³ performed four lumbar punctures or pneumoencephalograms on 21 patients with benign cough headache syndrome. One patient, a 38-year-old woman, developed a typical post-lumbar puncture headache; her cough headache syndrome remitted for 3 weeks but then recurred. On the basis of this observation, some specialists recommend lumbar puncture to treat this disorder.^{138,139}

Coital Headache and Benign (Idiopathic) Thunderclap Headache

Headache associated with sexual activity may be precipitated by masturbation or coitus, in the absence of any intracranial disorder. Three types of sexual headaches are recognized in the IHS classification.⁶ The first, the dull type, is described as a dull ache in the head and neck that intensifies as sexual excitement increases, peaking at orgasm. Type 2, also known as vascular or explosive coital headache, is a sudden, severe, explosive headache that occurs just before or at orgasm and persists for a few minutes to 48 hours. Type 3 is a postural headache, resembling that of low CSF pressure, that develops after coitus.^{137,139} Following the IHS criteria, Rasmussen and Olesen¹⁴⁰ have shown that the lifetime prevalences of these headaches are 1% in each case (95% confidence interval [CI], 0 to 2%). Another study found type 2 to be the most common, type 1 next most common, while type 3 is extremely rare.¹⁴¹

When a patient presents with a new type 2 coital headache of sudden onset, a CT scan should be performed, and even if this is negative, a lumbar puncture should be obtained. Aneurysm without rupture has presented as coital headache. MRA may be a reasonable alternative. Coital headache is often associated with benign exertional headache.^{137,142}

Benign Thunderclap Headache

Thunderclap headache is often but not exclusively caused by a subarachnoid hemorrhage.^{143,144} An extensive neurological evaluation, including CT and lumbar puncture, is indicated when patients present with their first or worst headache, particularly one associated with focal neurological signs, stiff neck, or changes in cognition. CT can miss subarachnoid blood in as many as 25% of cases, particularly if it is not performed until days after the headache onset.¹⁴³ MRI is unreliable in detecting an acute subarachnoid hemorrhage. Only with a lumbar puncture can one unerringly diagnose subarachnoid hemorrhage. Based on reports of unruptured aneurysms presenting as thunderclap headaches,¹⁴⁵ Day and Raskin¹⁴⁴ have stated that all patients presenting with severe, sudden-onset headache should be evaluated for an aneurysm, even if CT, MRI, and lumbar puncture do not show evidence of subarachnoid hemorrhage. As imaging technology improves, clinicians are less likely to accept the risks of invasive procedures.

Raps and associates¹⁴⁶ looked at the clinical spectrum of unruptured intracranial aneurysms. Acute, severe thunderclap headache, comparable to subarachnoid hemorrhage but without nuchal rigidity, was seen in 7 of 111 patients (6.3%) with unruptured aneurysms, most of which were located in the anterior circle of Willis. Because the true

frequency of unruptured aneurysm among patients with thunderclap headache is unknown, all patients in whom unruptured aneurysm is a possibility should undergo at least an MRA. The routine use of cerebral angiography is proscribed by the risk of permanent (0.1%) and transient (1.2%) deficits in this low-yield population.¹⁴⁶

Benign (idiopathic) thunderclap headache is a sudden-onset headache (maximum intensity in less than 30 seconds). It usually lasts up to several hours with a less severe headache that lasts weeks. A significant minority may have recurrence. Attacks may be precipitated by exercise or sexual intercourse. They may be accompanied by nausea and vomiting, a variant of which has been called “crash migraine.” Some feel that this term should be abandoned until the pathogenesis of idiopathic thunderclap headache is elucidated, and in order to avoid diagnostic complacency. Thunderclap headache may be accompanied by diffuse focal vasospasm in very large arteries at the circle of Willis and second and third order segments. If focal symptoms or stroke accompany the vasospasm, Call-Fleming syndrome is present. The differential diagnosis of thunderclap headache is listed in Table 53-10.¹⁴⁷ Diagnostic evaluation includes early CT, lumbar puncture, MRI with MRA or CTA, and venography.

Ophthalmoplegic Migraine

*Ophthalmoplegic migraine*⁶ is now classified as a cranial neuralgia. It is associated with acute attacks of cranial nerve III palsy associated with a dilated pupil and migrainous unilateral eye pain. Cranial nerves IV and VI may rarely be involved. The duration of ophthalmoplegia varies from hours to months. The differential diagnosis includes intracranial aneurysms and chronic sinusitis with a mucocele. Some cases of ophthalmoplegic migraine fit the criteria for the Tolosa-Hunt syndrome of painful ophthalmoplegia (Video 227, Orbital Pseudotumor)¹⁴⁸: (1) steady, gnawing, boring eye pain; (2) involvement of nerves of the cavernous sinus; (3) symptoms lasting days or weeks; (4) spontaneous remission, with recurrent attacks occurring after months or years; (5) CT or MRI limiting the disorder to the cavernous sinus; and (6) steroid responsiveness. Using contrast-enhanced MRI, Mark and associates¹⁴⁹ reported six patients with typical clinical features of ophthalmoplegic migraine who had enhancement of the cisternal segment of the oculomotor nerve during the acute phase of headache. This was followed by resolution of the enhancement over several weeks as the symptoms resolved. Enhancement can occur in a variety of conditions.^{150–153} A lumbar puncture is

needed to rule out infectious and neoplastic causes. This disorder may be due to a viral infection of the oculomotor nerve similar to Bell’s palsy (a viral neuritis with nerve enhancement).¹⁵⁴ Contrast-enhanced MRI and MRA are the procedures of choice in evaluating patients with oculomotor palsy. If MR shows enhancement of the cisternal portion of the oculomotor nerve and lumbar puncture is negative, a presumptive diagnosis of ophthalmoplegic migraine can be made, but follow-up is necessary to be sure the symptoms resolve.¹⁴⁹

Trochleitis and Primary Trochlear Headache

Trochleitis is an unusual headache characterized by local pain in the inner canthus of the orbit, increased with eye movements that depend on the trochlear muscle and often associated with an enlarged, tender trochlea on palpation and CT scan. Migraine symptoms may be present. Primary trochlear headache¹⁵⁵ has similar unilateral ocular pain that sometimes extends well beyond the trochlear area, but no motility restrictions or abnormal radiologic findings. Headache and eye pain may be chronic. Steroids injected into the region of the trochlea relieve the eye pain and improve the headache for both conditions 90% of the time.

Sinus Headache

Sinus infections are much less common today than they were in the preantibiotic era. The diagnosis of sinusitis is usually based on symptoms indicating maxillary or frontal sinus involvement. This may occur secondary to, and is frequently a result of, ethmoid disease. The ultimate cause is usually obstruction of the sinus ostia. Acute sinusitis lasts from 1 day to 3 weeks. Subacute sinusitis lasts from 3 weeks to 3 months, whereas chronic sinusitis lasts for more than 3 months. The IHS criteria for acute sinus headache include a purulent discharge, abnormal neuroimaging, and the simultaneous onset of headache and sinusitis. These criteria may not be valid for sphenoid sinusitis, because purulent discharge is often lacking and headache may precede sinus drainage. Once drainage begins, obstruction is relieved and the headache may begin to abate.

Maxillary sinusitis pain is typically located in the cheek, the gums, and the teeth of the upper jaw; ethmoid sinusitis pain is located between the eyes; and frontal sinusitis pain is located in the forehead. Ethmoid and maxillary sinusitis are usually associated with rhinitis. Sphenoid sinusitis is an uncommon infection that accounts for approximately 3% of all cases of acute sinusitis. It is usually accompanied by pansinusitis; less commonly, it occurs alone. Although sphenoid sinusitis is an uncommon cause of headache, it is potentially associated with significant rates of morbidity and mortality and requires early identification and aggressive management. The physical examination may not be helpful, because not all patients are febrile and sinus tenderness is not always present.

Standard radiography is inadequate for the evaluation of sinusitis, because it does not evaluate the anterior ethmoid air cells, the upper two thirds of the nasal cavity, or the infundibular, middle meatus, and frontal recess air passages. Neuroimaging (CT or MRI) is necessary to definitively diagnose sphenoid sinusitis, because plain x-ray studies are

TABLE 53-10

Differential Diagnosis of Thunderclap Headache

| |

| Acute hypertensive crisis |
| Carotid artery dissection |
| Cerebral venous sinus thrombosis |
| Idiopathic thunderclap headache |
| Pituitary apoplexy |
| Spontaneous intracranial hypotension |
| Spontaneous retroclival hematoma |
| Subarachnoid hemorrhage |
| Unruptured intracranial aneurysm |

nondiagnostic in about 26% of cases. Diagnostic endoscopy with the flexible fiberoptic rhinoscopy allows direct visualization of the nasal passages and sinus drainage areas (ostiomeatal complex), and is complementary to CT or MRI.

Management goals for the treatment of sinusitis include (1) treatment of bacterial infection, (2) reduction of ostial swelling, (3) sinus drainage, and (4) maintenance of sinus ostia patency. Uncomplicated sinusitis, other than sphenoid sinusitis, should be treated with a broad spectrum oral antibiotic for 10 to 14 days. Treatment failure and recurrent infections are indications for neuroimaging and endoscopy to search for a source of obstruction. Treatment of complications consists of high doses of intravenous antibiotics and surgical drainage, if appropriate, of any enclosed space.¹⁵⁶

NECK AND FACIAL PAIN

Trigeminal Neuralgia

Trigeminal neuralgia (TN) probably results from the focal demyelination of the trigeminal nerve or ganglia.^{157,158} Symptomatic causes include intrinsic and extrinsic tumors near the gasserian ganglia and multiple sclerosis (MS) plaques located around the root entry zone of the trigeminal nerve. In the past, dental disease or dental procedures were thought to occasionally cause TN. However, the delineation of the syndrome of pretrigeminal neuralgia, which mimics dental illness, casts doubt on whether dental procedures can ever cause TN.¹⁰³ Most cases of so-called idiopathic TN may be due to pulsations of an aberrant vascular loop on the trigeminal nerve.¹⁵⁷ These pulsations induce a series of neural events that result in changes in wide dynamic range neurons in the trigeminal nucleus caudalis.

The annual prevalence of TN is approximately 6 per 100,000 persons. Women are affected more than men. TN usually affects the elderly, with onset in the sixth or seventh decade in over 50% of patients. MS is the disease most clearly linked with TN, and 2% to 8% of patients with TN also have MS.¹⁵⁸ The second and third divisions of the trigeminal nerve are most frequently affected by the brief, repetitive, lightning-like pains of TN. In over 90% of cases, there is a trigger zone that, when stimulated, induces a train of painful sensations. Eating, talking, a light touch, or even a draft of air may induce an attack. During a severe attack, the face may contort; in some patients, it remains in that position until the pain eases—hence, the term *tic douloureux*. After a paroxysm, there is a relatively refractory phase during which it is difficult to trigger an attack (Video 106, Trigeminal Neuralgia).¹⁵⁸

There are no known associated disorders except for the known or suspected causes of secondary TN. Psychological problems may occur secondary to chronic pain. Secondary causes of idiopathic TN other than MS include syringomyelia, postmedullary infarction, aneurysm, basilar impression, and tumors, which include acoustic neuromas, epidermoids, meningiomas, schwannomas, and cholesteatomas. In the evaluation of suspected TN, an MRI of the brain is indicated, even if there is no loss of sensation or other abnormality on neurological examination. The value of a dental evaluation is uncertain.

Medical therapy should be tried first. Carbamazepine, gabapentin, baclofen, and IV phenytoin are the most effective treatments. Oral phenytoin, valproic acid, clonazepam, topiramate, lamotrigine, and pimozide are alternatives. Distal nerve blocks or ablative procedures generally are not recommended owing to a high incidence of early recurrence. More proximal procedures include retrogasserian glycerol injections and radiofrequency gangliolysis, which have acceptable recurrence rates and minor complications. Focal radiation (radiosurgery) has better long-term results.¹⁵⁹ The Jannetta procedure involves intracranial exploration of the trigeminal nerve root and removal of aberrant blood vessels. It is the most successful surgical procedure, but it also has the most complications.¹⁵⁸ Most patients with TN can be successfully treated with medical therapy; many will require lifelong medication, and some will require surgical intervention.

Cervicogenic Headache and Occipital Neuralgia

Cervicogenic headache is a controversial entity whose existence has been questioned. Pain from cervical structures is referred to the head through the C1–C4 cervical roots. Accepted causes of head pain from the neck include developmental abnormalities, tumors, ankylosing spondylitis, rheumatoid arthritis, and osteomyelitis. Controversial causes include cervical disc herniations, degenerative disc disease, and whiplash injuries.¹⁶⁰ Occipital neuralgia is thought by some to occur as a result of an injury to the occipital nerve, which may be vulnerable to compression as it passes through the semispinalis capitis muscle. Referred pain of cervical origin has often been referred to as occipital neuralgia, modifying the definition of this disorder. The prevalence of cervicogenic headache and occipital neuralgia is unknown. Risk factors include whiplash injury.

Some patients who are said to have cervicogenic headache have a pattern of unilateral pain that originates in the neck and spreads to the oculo-frontal area. The headache is of moderate severity. The upper cervical region is often tender and palpation often results in radiation of pain to the head. Relief may occur after anesthetizing the occipital nerve or C2 cervical root. Some authors believe that nausea, vomiting, photophobia or phonophobia, and eye changes may accompany this headache, thus confusing its diagnosis with migraine. The situation is further complicated by the ability of occipital nerve blocks to relieve migraine headaches.¹⁶⁰ Successful facet blocks may be a more accurate way of diagnosing at least one cause of cervicogenic headache and may predict the success of rhizotomy at the appropriate level.¹⁶¹ Occipital neuralgia is an even more controversial entity. The pain, which is in the distribution of the occipital nerve, is aching or burning in quality.

Even if a structural abnormality of the neck is identified, migraine and TTH should be considered in the differential diagnosis of cervicogenic headache. Abnormal cervical x-ray studies and MRIs are common and cannot be used by themselves to establish the diagnosis. A positive response to neuroblockade should *not* be considered diagnostic as it successfully treats both migraine and cluster headache. Physical therapy, muscle relaxants, low doses

of tricyclic antidepressants, and nerve blocks or trigger point injections are appropriate for most cases of so-called cervicogenic headache. Correction of anatomical abnormalities has been advocated, although surgery is often useless or harmful. Occipital neurectomy is usually unsuccessful and may cause anesthesia dolorosa. Most patients respond slowly to conservative management. There are no valid outcome studies. The results of ablative procedures are uncertain; with longer term follow-up, the initial benefit was lost.

Glossopharyngeal Neuralgia

The pathophysiology of glossopharyngeal neuralgia (GN) is similar to that of TN because the pain characteristics are so remarkably similar. Most cases are idiopathic, although vascular compression has been described.¹⁶² Secondary GN may be due to oropharyngeal malignancies, peritonsillar infection, an osteophytic stylohyoid ligament, and carotid aneurysm. The incidence of GN is reported to be between 1/70 and 1/100 the incidence of TN.¹⁶³ The pain of GN is similar to that of TN, although a few patients experience a dull pain that persists for minutes or hours. The pain is located in the ear, tonsil, larynx, tongue, or combinations of these areas. Triggers include swallowing, chewing, or talking. Coughing may accompany the pain. Anesthetizing the throat may temporarily relieve the pain. Unlike TN, MS has not been associated with GN. The differential diagnosis of GN includes TN, geniculate neuralgia, and neck/tongue syndrome. MRI of the brain, x-ray studies to visualize the stylohyoid ligament and styloid process, and careful examination of the pharynx are indicated when evaluating the patient with a diagnosis of GN. Medical management is identical to the treatment of GN. Surgical options include ablation of the glossopharyngeal nerve and microvascular decompression.

Carotidynia

The existence of carotidynia as a single pathological entity has been appropriately questioned.^{164,165} Acute monophasic carotidynia may have a viral etiology. Carotidynia often means nonspecific neck pain with carotid artery tenderness. Many cases of recurring carotidynia, however, are due to migraine. At present, the epidemiology and risk factors are not known. The clinical features of carotidynia generally include neck pain and carotid artery tenderness, particularly near the bifurcation. Occasionally, there is face pain rather than neck pain. A number of temporal patterns have been reported, with pain lasting seconds, minutes, hours, days, weeks, or months. Some cases of carotidynia may be associated with migraine. Symptomatic causes of carotidynia include carotid dissection, stenosis or occlusion with or without intraplaque hemorrhage, aneurysm, fibromuscular dysplasia, giant cell arteritis, and post-carotid endarterectomy. If the temporal profile suggests a monophasic illness rather than a recurrent condition, anatomical investigation, including ultrasound, MRI, MRA, or angiography, may be necessary. Indomethacin is often effective in treating the pain of carotidynia and migraine treatment may also be effective.^{164,165} Because carotidynia does not represent a single illness, the prognosis depends on the cause.

HISTORY

Sleep disorders are common age-old problems that can lead to distress and discomfort, impaired daytime functioning, and serious complications. In ancient Greece, Democritus believed that physical illness was the cause of daytime sleepiness and that poor nutrition was the main cause of insomnia. Effects of sleep on epilepsy and asthma were recognized in the Middle Ages, and Thomas Willis, a British physician of the 17th century, described nightmares and restless legs. For most of recorded history, however, sleep problems were considered a result of medical or psychiatric illnesses rather than primary disorders. Sleep was viewed as a passive process, akin to death, and the idea that disordered sleep physiology could lead to specific syndromes was unknown.

With the discovery of rapid-eye-movement (REM) sleep in 1953, the concept of sleep as a passive shutting down of cortical activity began to change to a view of sleep as an active process initiated by specific events of the nervous system and with two distinct states: REM and non-REM (NREM). The discovery of the association of narcolepsy with sleep-onset REM periods, as opposed to the usual onset of sleep in the NREM state, led to the idea that narcolepsy was a primary disorder of the sleep process and to the corollary that clinical syndromes could be caused by such disruption of sleep processes.

Forty years ago, the only sleep disorder of interest to most neurologists was narcolepsy; all other sleep problems generally were considered manifestations of psychiatric problems. The discoveries of sleep apnea and periodic leg movements, the use of sleep laboratories to study sleep patterns, the discovery of effective treatments for sleep apnea, and the recognition that untreated sleep apnea is associated with increased cardiovascular morbidity and death have dramatically changed the approach to sleep disorders. At present, most sleep medicine specialists have primary training in neurology or pulmonar്യmedicine, and the practicing neurologist is often expected by colleagues to be familiar with the major sleep disorders.¹

INSOMNIA

Insomnia refers to the subjective sense that sleep is inadequate, insufficient, or interrupted. It is subjective because sleep requirements vary among individuals and because the restorative aspect of sleep is difficult to measure. Insomnia has many causes, and effective treatment requires an understanding of the basis for the symptoms.

PATHOGENESIS AND PATHOPHYSIOLOGY. Causes of insomnia include emotions and thoughts that interfere with sleep; medication use or withdrawal and use of illicit drugs or alcohol; external stimuli, such as noise, excessive heat or cold, or bright light; alterations in the central nervous system (CNS) processes that initiate and maintain sleep; and bodily dysfunctions such as pain, decreased mobility, arousals, and disturbing sensations or movements. Mental activity during sleep may contribute to the impression that sleep is not restorative. In most patients, several elements contribute to insomnia, and it is useful to identify the predisposing, precipitating, and perpetuating factors.²

Personality and age affect the predisposition to insomnia. Tense, nervous, worried persons who internalize problems and have somatic responses to stress are at higher risk for insomnia than relaxed, phlegmatic types. Medical illnesses, deterioration of CNS functions responsible for sleep initiation and maintenance, and increased sensitivity to the sleep-disrupting effects of medications and other drugs contribute to the increase in insomnia with age.

Stress often precipitates insomnia. Medical or psychiatric illness and the medications used to treat them, death or illness of a loved one, divorce or separation, a move to a new location, and a change in occupational status are common precipitants. A change in sleep-wake schedule or a change in the sleeping environment may also bring on insomnia.

Once insomnia begins, anxiety about sleep, conditioned negative associations, poor sleep habits, or secondary gain often perpetuate insomnia. Performance anxiety associated with the belief that good sleep is a requirement for effective functioning the next day makes falling asleep difficult. As sleep fails to occur, the patient becomes increasingly

anxious. Soon the entire process of preparing for sleep becomes tied to anxiety and fear of insomnia. Some patients respond to insomnia by increasing the amount of time spent in bed with the hope that they will then obtain enough sleep. The usual result is increased time awake in bed rather than increased time asleep, which increases the negative conditioning associated with sleeplessness. The secondary gain associated with nighttime snacks and alcohol use, television use, time off from work, and the role of sickly child or dependent adult also may perpetuate insomnia.

Some insomniacs have the impression that they sleep very little, even when laboratory recordings reveal normal or near-normal sleep. The cause of this faulty impression, referred to as *paradoxical insomnia* or *sleep state misperception*, is unknown. Ruminative thoughts that recur with each awakening during the night may give the impression of uninterrupted consciousness and thereby contribute to the failure to perceive sleep. A subtle disturbance of sleep undetected by standard polysomnography could also be a factor.

EPIDEMIOLOGY AND RISK FACTORS. About 10% of adults in the United States have chronic insomnia, and another 15% have short-term insomnia. The prevalence is higher in women and in older persons. Community residents older than 50 years have a prevalence of insomnia of 23%.³ Depression, anxiety disorders, and substance abuse disorders are substantially more common in insomniacs than in the general population.⁴ Although insomnia is distressing to many individuals, less than one third of insomniacs complain about the problem to physicians, perhaps because they believe that physicians are not interested in the problem or are unable to treat it effectively.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Patients with insomnia complain of difficulty falling asleep, difficulty staying asleep, early morning awakening, or a sense that sleep is nonrestorative. During nocturnal sleeplessness, some patients toss and turn in bed. Others watch television, read, eat, drink, or use the bathroom. Persons who do not like to waste time often do housework or homework. Common daytime symptoms include poor concentration, fatigue, irritability, mood changes, anxiety, proneness for errors or accidents, headaches, and muscle aching. Fatigue is sometimes accompanied by sleepiness, but most insomniacs are unable to nap even if they lie down. Insomnia appears to be associated with high health care utilization, reduces quality of life, and hinders social functioning.

As insomnia continues, many patients become preoccupied with sleep. Evening rituals designed to promote relaxation may last for an hour or more. Many patients ruminate at night and during the day about the ill effects of poor sleep and its effects on daytime function. For some patients, insomnia is less severe on weekend nights and during vacations, when concerns about the effects on daytime function are less.

Although most insomniacs have significant sleep disruption, patients with sleep state misperception describe severe chronic insomnia even though they have relatively normal sleep. Such patients often report that they obtain as little as 2 hours of sleep per night and frequently have no sleep at all. Some describe long periods of resting in bed without sleeping.

TABLE 54-1**Medical and Psychiatric Disorders Associated with Sleep Disturbances**

| CATEGORY | DISORDERS |
|------------------------------------|--|
| Infectious diseases | Sleeping sickness, febrile illnesses |
| Cardiac diseases | Congestive heart failure, nocturnal angina |
| Pulmonary diseases | Chronic obstructive pulmonary disease, asthma |
| Gastrointestinal diseases | Gastroesophageal reflux, peptic ulcer disease, inflammatory bowel disease |
| Neurological disorders | Degenerative disorders of the CNS, neuromuscular disorders |
| Rheumatological disorders | Rheumatoid arthritis |
| Renal disorders | Chronic renal failure |
| Psychiatric disorders | Acute psychosis, depression, anxiety disorders, panic disorder, alcoholism |
| Endocrine disorders | Cushing's disease, hyperthyroidism, hypothyroidism, diabetes, menopause |
| Skeletal and soft tissue disorders | Achondroplasia, craniofacial malformations, Down syndrome, mucopolysaccharidoses |
| Miscellaneous | Cancer, pruritus, Prader-Willi syndrome |

CNS, central nervous system.

Insomnia can occur with virtually any sleep disorder as well as with a host of medical and psychiatric disorders (Table 54-1). A psychiatric disturbance is present in about 40% of insomniacs.⁴ Overuse and abuse of alcohol and sedative medications is common. Several community-based studies have found that sleep disturbances are powerful risk factors for the development of new episodes of major depression in the following year.⁵

DIFFERENTIAL DIAGNOSIS. The differential diagnosis of insomnia is extensive (Table 54-2), and a given patient may have several contributing factors, such as poor sleep hygiene, environmental factors, maladaptive conditioning, hypnotic dependence, and a predisposition to poor sleep.

TABLE 54-2**Causes of Insomnia in Adults**

| DISORDER | KEY DIAGNOSTIC FEATURE |
|---|---|
| Psychophysiological insomnia | Conditioned negative associations and excess focus on sleep |
| Paradoxical insomnia | Marked discrepancy between subjective and objective sleep |
| Idiopathic insomnia | Insomnia caused by constitutional factors |
| Restless legs syndrome | Leg discomfort relieved by movement |
| Periodic limb movement disorder | Kicking movements during sleep |
| Sleep apnea and related disorders | Snoring, witnessed apnea |
| Inadequate sleep hygiene | Poor sleep habits |
| Environmental sleep disorder | Unsuitable sleeping environment |
| Drug- and medication-related insomnia | Insomnia caused by medications |
| Circadian rhythm sleep disorders | Schedule-dependent insomnia |
| Sleep disorders due to medical or psychiatric illness | Insomnia fluctuates with severity of the underlying illness |

It is critical to determine whether the insomnia is secondary to a psychiatric or medical disorder; in such cases, the insomnia is treated at least in part by optimal management of the underlying disorder.

It is sometimes difficult to determine whether insomnia is due to depression, especially a masked depression in which the patient denies sadness or hopelessness, because dysphoria is a common feature of all types of insomnia. A history of depressive episodes before insomnia began, a history of episodic insomnia at times of mood disturbance, and the occurrence of other depressive symptoms favor a primary diagnosis of an affective disorder. Although most insomniacs are anxious, the anxiety is usually focused on sleep, and generalized anxiety disorder as a cause of insomnia should be suspected only if anxiety affects many aspects of life.

When insomnia is caused by learned sleep-preventing associations, the diagnosis is *psychophysiological insomnia*, the most common form of primary insomnia.¹ Patients with psychophysiological insomnia tend to prefer regular routines and view good sleep as a necessity. For such patients, an awakening that would ordinarily be just long enough for a change in body position is instead followed by anxiety that sleep will not return or will not be restful. The anxiety about the consequences of not sleeping induces full alertness, and a rapid return to sleep becomes impossible.

Inadequate sleep hygiene as the cause of insomnia should be suspected in patients who have never had good sleep habits, perhaps because they were not required to sleep at regular times as children or because their internal sleep systems were initially so robust that they were able to sleep well despite poor habits. Insomnia due to caffeine or medication is common. With increasing age or because of other factors, some people may become less able to tolerate the effects of poor sleep habits. Paradoxical insomnia should be suspected in patients who do not toss and turn or get out of bed despite complaints of severe insomnia.

Loud snoring, witnessed apneas, or frequent kicking movements suggest that insomnia may be due to sleep apnea or periodic leg movements. Patients with periodic breathing patterns with central apneas, such as Cheyne-Stokes pattern, frequently complain of insomnia. If the main problem is difficulty falling asleep, an anxiety disorder or a delayed sleep phase disorder may be responsible. Early morning awakening with excessive rumination suggests depression or obsessive-compulsive disorder.

EVALUATION. The history is the most crucial part of the evaluation. Circumstances at the onset of insomnia should be assessed, and the course of the insomnia should be determined, along with any factors the patient has identified that make insomnia better or worse. Times of going to bed, falling asleep, nighttime awakenings, and getting out of bed for good nights and bad nights should be determined, along with associated behaviors, thoughts, and emotions. Information about the patient's weekday and weekend schedule of work, alcohol use, caffeine intake, meals, and medication use is also essential. Sleep logs that contain this information are very useful.

Psychiatric evaluation is helpful if a psychiatric etiology is a consideration. Polysomnography is useful if there is a suspicion that apnea or periodic leg movements are the

TABLE 54-3

Principles of Sleep Hygiene

| |
|--|
| Go to bed and arise from bed at the same time each day |
| Avoid daytime naps or limit them to one midday nap |
| Avoid evening alcohol use |
| Avoid caffeinated drinks late in the day |
| Reduce or eliminate tobacco use, especially at night or in the evening |
| Exercise regularly; avoid evening exercise |
| Use the bed only for sleep and sexual activity |
| Keep the bedroom dark, quiet, and cool |
| Avoid stress and worrisome thoughts in the evening before sleep |

cause of the symptoms, if there is a failure to respond to treatment, or if sleep state misperception is suspected. However, most patients with insomnia do not require polysomnography.

MANAGEMENT. Treatment of insomnia is based on the underlying causes. From a therapeutic perspective, the factors that perpetuate insomnia are often the most important because they may be most amenable to change. Improved sleep hygiene can lead to marked improvement (Table 54-3), but poor sleep hygiene is sometimes a result of other problems, particularly psychiatric problems.

Cognitive behavioral therapy is a major part of treatment for patients with psychophysiological insomnia.² Between 70% and 80% of patients treated with nonpharmacological interventions benefit from treatment.⁶ With sleep restriction therapy, mild sleep deprivation produced by eliminating naps and temporarily restricting time in bed to 1 to 2 hours less than the nightly reported amount of sleep tends to make sleep more continuous. Once sleep is consolidated, the time in bed can be gradually increased. With stimulus control therapy, the principle is to associate the bed and sleep environment only with sleep and intimacy; no reading, eating, or watching TV in bed is permitted. Patients are encouraged to get out of bed and to do something relaxing if unable to sleep after 15 to 20 minutes.

Hypnotics are often helpful in patients with acute situational insomnia and in some patients with chronic insomnia. In randomized trials among patients with insomnia, both behavioral and pharmacological approaches have been shown to be effective in the short term, but improvement in sleep may be sustained better over time after behavioral treatment.⁷ Some chronic insomniacs do well using hypnotics 1 to 2 nights per week when they feel they simply must have a good night's sleep. Others find it reassuring to have a hypnotic available in the medicine cabinet; the knowledge reduces anxiety, and actual use may be minimal. Others use a hypnotic nightly for years with good response and no dose escalation. Still others obtain no benefit from hypnotics, become dependent, or both. Other problems with hypnotics include nocturnal confusion, next-day memory impairment, and sedation. Low doses of sedating tricyclic antidepressants are sometimes useful as alternatives to standard hypnotics (Table 54-4). As a sedative to be taken near the time of desired sleep onset, melatonin is much less effective than conventional hypnotics. However, a melatonin agonist was recently developed and approved for use as a hypnotic.

Patients with paradoxical insomnia should be educated about the distinction between subjective insomnia and

TABLE 54-4

Medications Used for Insomnia

| CATEGORY OF DRUG | DRUG AND DOSAGE |
|-------------------------------------|---|
| Short-acting benzodiazepines | Triazolam 0.125 to 0.25 mg Midazolam 7.5 to 15 mg |
| Intermediate-acting benzodiazepines | Temazepam 15 to 30 mg Oxazepam 15 to 30 mg Lorazepam 1 to 2 mg |
| Long-acting benzodiazepines | Alprazolam 0.25 to 0.5 mg Flurazepam 15 to 30 mg Diazepam 2.5 to 10 mg Clorazepate 7.5 to 15 mg Clonazepam 0.5 to 2 mg Prazepam 10 mg Halazepam 20 mg |
| Benzodiazepine-receptor agonists | Chlordiazepoxide 10 to 20 mg Zaleplon 5 to 10 mg Zolpidem 5 to 10 mg Zopiclone 7.5 to 15 mg Eszopiclone 1 to 3 mg |
| Melatonin receptor agonist | Ramelteon 8 to 16 mg |
| Antihistamines | Diphenhydramine 25 to 50 mg |
| Sedating antidepressants | Amitriptyline 10 to 75 mg Doxepin 10 to 75 mg Trazodone 25 to 100 mg Imipramine 25 to 100 mg |

objective sleep disruption; they may be reassured to know that restorative sleep-related processes are occurring even though they do not sense it. Behavioral treatment and hypnotics are helpful for some, perhaps in the latter case because amnesic effects interrupt the subjective impression that consciousness has been maintained during sleep.

PROGNOSIS AND FUTURE PERSPECTIVES. The course of insomnia is variable; many patients have a lifetime of sleep problems, whereas others have episodic bouts of poor sleep separated by years of tranquil nights. Insomniacs who continue with symptoms after 12 months have an increased risk for depression, anxiety disorders, and alcohol abuse.⁴ Other complications include benzodiazepine dependence, decreased job performance and self-esteem, and an increased risk of motor vehicle accidents.

PRIMARY DISORDERS OF DAYTIME SOMNOLENCE

Narcolepsy

Narcolepsy is a genetically based neurological disorder associated with abnormalities of REM sleep and of sleep-wake control. Although the disorder has been recognized for more than 100 years, the discoveries of sleep apnea, other syndromes of excessive sleepiness, and the association of narcolepsy with REM sleep abnormalities and specific human leukocyte antigen (HLA) markers helped delineate narcolepsy as a distinct syndrome. The more recent discovery that deficiency of the neurotransmitter *hypocretin*, also called *orexin*, plays an important role in narcolepsy with cataplexy has led to the distinction of that diagnosis from narcolepsy without cataplexy.

PATHOGENESIS AND PATHOPHYSIOLOGY. Animal models of narcolepsy show either loss of dorsolateral hypothalamic neurons that produce hypocretin or lack of

receptors for this neurotransmitter.⁸ Hypocretin levels in cerebrospinal fluid were undetectable in seven of nine narcoleptic patients,⁹ and brains of such patients also showed reduced numbers of hypocretin neurons.¹⁰ One human hypocretin mutation has been identified, in a patient with atypical early-onset and severe narcolepsy (Fig. 54-1).¹¹

More than 90% of narcoleptics have a specific HLA haplotype that includes HLA-DQB1-0602, which is present in less than one third of the general population.¹² The penetrance of the HLA-associated gene is low, and the risk for narcolepsy in first-degree relatives, although 40 times greater than in the general population, is only about 1%.¹³

The low penetrance of the HLA-associated gene and discordance for narcolepsy in identical twins indicates that unknown environmental factors play an important role in the pathogenesis of narcolepsy.¹⁴ A gene that confers susceptibility for narcolepsy is likely to be located on chromosome 21.¹⁵ Canine narcolepsy, which is clinically similar to the human disease, is associated with monoaminergic abnormalities, and the gene that causes one form of canine narcolepsy has been isolated.¹⁶ The gene for canine narcolepsy is tightly linked to a DNA region involved in immune regulation.¹⁷ Despite the association of human narcolepsy with an HLA-associated gene, there is no direct evidence to indicate that narcolepsy is an autoimmune disease. Recent SPECT studies have suggested alterations in the striatal dopaminergic system in narcolepsy with cataplexy.¹⁸

Abnormalities of REM sleep control probably contribute to narcoleptic symptoms. The muscle atonia that occurs with sleep paralysis and cataplexy is similar to the muscle atonia of REM sleep, and hypnagogic hallucinations may represent an intrusion of REM sleep imagery into consciousness during transitions between wakefulness and sleep. However, the REM sleep abnormalities appear to be part of a broader problem of impaired sleep-wake regulation that includes an inability to sustain sleep, along with the daytime inability to remain awake.

EPIDEMIOLOGY AND RISK FACTORS. The prevalence of narcolepsy with cataplexy in a white population is about 1 in 4000.¹⁹ Estimates for other populations range from 1 in 600 to less than 1 in 10,000. Narcolepsy affects men and women equally.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Most patients report symptoms beginning gradually in the second decade of life. The appearance of symptoms before age 5 is rare; occasional patients develop narcolepsy after age 50. The primary symptoms include sleepiness and sleep episodes, cataplexy, sleep paralysis, hypnagogic and hypnopompic hallucinations, and nocturnal sleep disruption. Sleepiness and cataplexy may develop simultaneously, or cataplexy can begin years or decades later (Video 72, Cataplexy). Excessive sleepiness is present most of the time, although the severity fluctuates during the day and is variable among individuals. Boring sedentary situations and warm afternoons following lunch are especially difficult settings. Work performance is most often affected in sedentary jobs requiring sustained vigilance. Physical activity usually provides relief, but sleepiness returns as soon as the patient sits down. Brief daytime sleep episodes, often called sleep attacks, are common.

Cataplexy is a brief episode of bilateral weakness, without altered consciousness, that is brought on by strong

FIGURE 54-1. Distribution of hypocretin-containing cells in the human hypothalamus. The preprohypocretin mRNA expressing neurons are localized discretely in the perifornical area. Their distribution is illustrated on schematic diagrams of representative coronal planes through the human hypothalamus. Each black circle represents three to five cells detected in emulsion-coated sections. 3V, third ventricle; DHA, dorsal hypothalamic area; DMH, dorsal hypothalamic nucleus; f, fornix; H2, lenticular fasciculus; Inf, infundibular nucleus; LHA, lateral hypothalamic area; MM, mammillary nucleus; opt, optic tract; Pa, paraventricular hypothalamic nucleus; PaF, paraformal nucleus; TM, tuberomammillary nucleus; VMH, ventromedial hypothalamic nucleus. (Reprinted with permission from Peyron C, Faraco J, Rogers W, et al: A mutation in a case of early onset narcolepsy and a generalized absence of hypocretin peptides in human narcoleptic brains. *Nat Med* 2000;6:991–997.)

emotion. Laughter, anger, embarrassment, excitement, elation, surprise, shock, and humor without actual laughter can induce the attacks. These events last a few seconds and are associated with buckling of the knees, sagging of the jaw or face, drooping eyelids, and mild dysarthria. Twitching around the face or eyelids may accompany the weakness. Severe attacks produce almost complete paralysis, and prolonged episodes may be associated with auditory, visual, or tactile hallucinations. Cataplexy can be dangerous if it occurs during driving. Unlike sleepiness, definite cataplexy—defined as brief bilateral loss of strength without altered consciousness that responds to tricyclic antidepressants—is virtually pathognomonic for narcolepsy.

Sleep paralysis refers to episodes of partial or total paralysis that last a few seconds or minutes and occur at the beginning or at the end of a sleep period. The paralysis, which occurs in about 60% of narcoleptics, may be accompanied by a struggle to move, to speak, or to wake up. Patients often feel awake or half-awake and are usually aware of being in bed. Frightening hallucinations and a sense of suffocation may accompany the paralysis. Despite the intense psychic experience, patients appear to be asleep with eyes closed and with occasional twitches, slight moans, or irregular respirations.

Hallucinations are referred to as hypnagogic when they occur at the onset of sleep, and they are termed hypnopompic when they occur at the end of sleep. The hallucinations, which almost always include visual imagery, differ from dreams in that a thematic story is lacking and some awareness of the surroundings is preserved. Sometimes the hallucinations are so vivid and realistic that the subject may have difficulty believing that they are not real and may take actions to escape from the images.

Daytime drowsiness may also lead to complaints of memory difficulties, blurred vision, and amnesic episodes of automatic behavior lasting seconds to an hour or more during which patients drift in and out of sleep while engaging in aimless or semipurposeful activity. Disrupted

nighttime sleep with frequent awakenings may be a prominent complaint. Other sleep disorders, such as obstructive sleep apnea, periodic limb movement disorder, and REM sleep behavior disorder, are more common than in the general population.

DIFFERENTIAL DIAGNOSIS. Sleepiness should be distinguished from tiredness, fatigue, apathy, and weakness. Sleepiness is more likely to occur in boring sedentary situations, is relieved to some extent by movement or stimulation, and is associated with a feeling of impending sleep or a need to fight against sleep onset. Descriptions of daytime sleep episodes as periods of loss of awareness may suggest a diagnosis of syncope, partial complex seizures, or absence seizures. Premonitory drowsiness, sleeplike appearance with absence of pallor, ease of arousability, and the association with sedentary situations are useful differentiating features. There are several causes of excessive sleepiness (Table 54-5). Unplanned daytime sleep episodes, or so-called sleep attacks, are an indication of severity of sleepiness rather than a marker of a qualitatively different process. They can occur with any disorder that causes severe sleepiness and are not specific for narcolepsy.

The association with emotion, the duration of episodes, and the preservation of consciousness help differentiate cataplexy from atonic seizures, myasthenia gravis, periodic paralysis, or drop attacks associated with vertebrobasilar insufficiency. Because cataplexy is not invariably present in narcoleptics, its absence does not exclude the diagnosis.

Sleep paralysis and hypnagogic hallucinations are less useful for diagnosis because they can occur as isolated symptoms in otherwise normal persons, often precipitated by sleep deprivation or a change in sleep schedule, as well as in other sleep disorders.

EVALUATION. Because a variety of conditions can cause excessive sleepiness, sleep studies are generally required for accurate diagnosis. Nocturnal polysomnography can determine the presence and severity of sleep apnea, periodic limb movements, and nocturnal sleep disturbance.

TABLE 54-5

Causes of Daytime Sleepiness

| |
|--|
| Narcolepsy |
| Sleep apnea and other breathing disorders of sleep |
| Insufficient sleep |
| Medication effects |
| Periodic limb movement disorder |
| Idiopathic hypersomnia |
| Brain lesions that compromise pathways involved in sleep-wake regulation |
| Circadian rhythm sleep disorders |
| Nocturnal sleep disruption caused by medical, neurological, or psychiatric illness |

A multiple sleep latency test (MSLT), usually performed the following day, provides a measure of the severity of sleepiness and an indication of the presence or absence of early onset of REM sleep.²⁰

Early onset of REM sleep occurs with about 50% of sleep episodes, and the presence of two or more sleep-onset REM periods during the four to five nap opportunities provided by the MSLT is the usual diagnostic criterion for narcolepsy. However, this finding is not specific. Other potential causes of early-onset REM sleep include circadian rhythm disturbances, REM sleep deprivation, sleep apnea, and drug or alcohol withdrawal.²¹ Some patients with brain pathology in areas concerned with sleep-wake regulation also may have early onset of REM sleep.

HLA typing has limited value for diagnosis. As the HLA haplotype associated with narcolepsy is present in about 20% to 35% of the general population, more than 99% of persons with the haplotype do not have narcolepsy.

MANAGEMENT. Medications and behavioral measures should be designed to enhance alertness during critical times of the day such as at work, during school, and while driving. The importance of good sleep hygiene and the risks associated with sleepiness while driving must be emphasized. Brief, regularly scheduled naps during lunch or other breaks are often helpful.

Modafinil, methylphenidate, dextroamphetamine, and pemoline improve alertness in most narcoleptics (Table 54-6). These agents should be initiated at low doses and increased gradually until symptoms are controlled or side effects appear. In general, the lowest effective dose should be used, but some patients may not recognize the severity of their sleepiness, and reports from family members should also be obtained to assess the effectiveness of treatment.

Although chronic use of stimulants can lead to irritability, insomnia, habituation, addiction, and psychosis, the risk for amphetamine abuse is no higher among narcoleptics than in other population groups. With appropriate management, most narcoleptics are able to take stimulants regularly for decades without harmful side effects. When sleepiness fails to respond to medications after a period of good control, the possibility of sleep apnea or chronically insufficient sleep should be considered.

γ -Hydroxybutyrate (GHB) taken at night reduces daytime cataplexy and is the only medication approved by the Food and Drug Administration for this purpose. This medication also increases slow-wave sleep and improves

TABLE 54-6

Medication Dosages for Treatment of Sleepiness in Narcolepsy and Other Disorders

| TYPE | DRUG AND DOSAGE |
|----------------------|--|
| Amphetamines | Dextroamphetamine 5 to 60 mg/day Methamphetamine 5 to 40 mg/day |
| Nonamphetamines | Methylphenidate 5 to 80 mg/day Pemoline 18.75 to 112.5 mg/day Mazindol 2 to 8 mg/day |
| Wake-promoting agent | Modafinil 100 to 400 mg/day |
| CNS depressants | Sodium oxybate (GHB) 4.5 to 9 gr/night |

CNS, central nervous system.

daytime sleepiness in narcoleptics. It is available in the United States with special regulations to prevent abuse. Nonsedating tricyclic antidepressants and serotonin reuptake inhibitors also can be effective for cataplexy, and sleep paralysis, probably by blockade of norepinephrine and serotonin reuptake (see Table 54-6). Patients with severe cataplexy may develop tolerance to the effects of tricyclics, and abrupt withdrawal can lead to a temporary rebound increase in cataplexy.

PROGNOSIS AND FUTURE PERSPECTIVES. Sleepiness is a lifelong problem for most narcoleptics, whereas cataplexy, hypnagogic hallucinations, and sleep paralysis improve with age in about one third of patients. Sleepiness is often adequately but not completely controlled by current therapeutic strategies. In the future, new strategies based on better understanding of hypocretin functions may improve the lives of many affected patients.

Idiopathic Hypersomnia

Idiopathic hypersomnia is clinically similar to narcolepsy in that daytime sleepiness occurs despite adequate amounts of apparently normal sleep at night, but cataplexy does not occur and there is no association with specific HLAs. The pathogenesis is unknown. Circulating somnogenic factors or focal lesions that affect systems involved in sleep-wake regulation may play a role in some cases. Idiopathic hypersomnia is less common than narcolepsy by a ratio of about 1:10. Recent viral illness may be a risk factor for onset of the condition.

Symptoms often develop gradually during adolescence or young adulthood. There appear to be at least two types of idiopathic hypersomnia, with or without long sleep times. With the long sleep times, patients complain of an increased need for sleep, difficulty awakening in the morning, and sleep drunkenness with disorientation and confusion in the morning.¹ Daytime naps are long and unrefreshing, and patients may sleep as much as 14 to 18 hours during the day and night.

Other diagnostic considerations in patients who complain of long periods of unrefreshing sleep include atypical depression and chronic fatigue syndrome. In both of these disorders, patients often spend many hours in bed, but actual sleep time is increased only mildly or not at all. Idiopathic hypersomnia is usually considered in a patient who complains of sleepiness and has no apparent cause for sleepiness based on the clinical history and a nocturnal polysomnogram.

For such patients, the differential diagnosis includes narcolepsy, upper airway resistance syndrome, insufficient sleep syndrome, and obstructive sleep apnea that occurs during some nights but not others. The differential diagnosis may also include recurrent hypersomnia (such as Kleine-Levin syndrome), and hypersomnia due to a medical condition (such as trauma, brain tumors, or infections). The diagnosis of idiopathic hypersomnia is not simple because it requires ruling out other causes of daytime sleepiness.

Evaluation should include one or more nights of polysomnography, MSLT, psychiatric assessment, and a trial of increased sleep. The upper airway resistance syndrome may be difficult to detect on polysomnography unless nasal pressure or esophageal pressure are monitored during polysomnography to detect subtle respiratory event-related arousals.²² Patients with narcolepsy may not have REM sleep abnormalities on an initial MSLT. Atypical depression or other psychiatric conditions may be associated with complaints of sleepiness, although the MSLT is usually not abnormal. Sleepiness caused by chronically insufficient sleep should improve after a trial of 1 to 2 hours of additional sleep each night. After these diagnoses have been excluded, one is left with the diagnosis of idiopathic hypersomnia.

Management is similar to the approach used for narcolepsy. Patients with the narcoleptic type of sleepiness often respond to stimulants, whereas those with long sleep periods and difficult awakening may not. For most patients, the disorder is chronic. A minority of patients improve with time, and in some, the disorder resolves completely.

Obstructive Sleep Apnea

Obstructive sleep apnea syndrome (OSA) is characterized by airway narrowing during sleep that leads to nighttime sleep disruption and associated daytime symptoms. The recognition that OSA is a common and treatable disorder with serious complications has been the most important factor in the growth of sleep medicine over the past 20 years.

PATHOGENESIS AND PATHOPHYSIOLOGY. Narrowing and occlusion of the upper airway during sleep is the basis for OSA. Obstruction usually occurs in the pharynx, which lacks supporting cartilage and bone, and is therefore more collapsible than other portions of the upper airway. Upper airway size is determined by the anatomy of the bones and soft tissues of the neck and face, by the pressures acting on the pharyngeal tissues, and by their compliance. During wakefulness, contraction of pharyngeal muscles occurs just before the onset of inspiration and increases the outward pressure on the pharyngeal wall by pulling the soft palate, tongue, mandible, and hyoid bone forward. This outward pressure balances the inward pressure produced by negative pressure developed within the thorax and helps maintain airway patency. Activity of upper airway dilator muscle is affected by arterial blood gas concentration; by proprioceptive input to respiratory neurons from the jaw, mouth, and thorax; and by receptors sensitive to changes in upper airway transmural pressure. For example, increased negative upper airway pressure leads to increased activity of the genioglossus, which pulls the tongue forward and tends to open the airway.

Pharyngeal muscles relax during sleep, which leads to narrowing of the pharyngeal airway and increased resistance to airflow. The relaxation alone may be sufficient to close the airway in some persons. In others, inspiratory muscle activity increases to compensate for the increased airway resistance, and the increased negative pressure generated by the extra effort leads to airway collapse. Ultimately, the airway opens only after an arousal, or brief awakening leads to increased activity of pharyngeal dilators. The patient then takes a few deep breaths and returns to sleep, whereupon the cycle repeats itself. Pharyngeal narrowing without complete occlusion may cause decreased ventilation. These episodes, referred to as hypopneas, lead to arousals, sleep fragmentation, daytime sleepiness, and hypoxemia and thus have the same functional effect as apneas.

Pharyngeal narrowing with high resistance to airflow is sometimes associated with compensatory increased respiratory effort that minimizes changes in tidal volume, ventilation, and oxygenation but still leads to arousals and sleep fragmentation. The functional effect is similar to OSA but without the associated hypoxemia. When such episodes are the predominant type of respiratory event, the disorder is referred to as the *upper airway resistance syndrome*.²² The body weight of patients with this disorder is often normal or near-normal, and there appears to be a higher proportion of women and children with the syndrome than occurs with OSA, perhaps because their upper airways tend to be less compliant.

Airway narrowing may be due to a variety of causes (Table 54-7), including craniofacial malformations (high arched hard palate, a long low-placed soft palate, dental malocclusion, or retrognathia), neurological diseases with incoordination of preinspiratory activation of upper airway dilators, mouth breathing with posterior displacement of the mandible, or weakness from neuromuscular diseases. The site of airway occlusion may be at the level of the velopharynx, the oropharynx, the hypopharynx, the epiglottis, or the larynx. In some patients, the occlusion may be at more than one level or at different sites during

TABLE 54-7

Causes of Upper Airway Narrowing

| |
|--|
| Genetic and developmental factors that influence craniofacial development |
| Anatomical malformations that affect craniofacial structures such as Crouzon's syndrome, Treacher Collins syndrome, Pierre Robin syndrome, Arnold-Chiari malformation, achondroplasia, rheumatoid arthritis, and Klippel-Feil syndrome |
| Enlarged tongue, soft palate, or uvula associated with obesity, Down syndrome, hypothyroidism, and acromegaly |
| Pharyngeal dilator weakness associated with neuromuscular diseases and medullary lesions |
| Infiltration of pharyngeal tissue associated with obesity, mucopolysaccharidoses, and mucosal edema and inflammation |

| Dyscoordinated breathing from abnormal respiratory control associated with Arnold-Chiari malformation, dysautonomias, and degenerative CNS disorders |
| Abnormally compliant airway associated with Marfan's syndrome |

CNS, central nervous system.

different stages of sleep owing to differential activity of muscles involved in maintenance of airway patency.

The reason for the more frequent occurrence of OSA in men than in women is not known. Men tend to have longer, narrower upper airways, which may predispose them to airway collapse. The airway may be more compliant in men and may close at lower pressures for a given airway diameter. Women also show a greater augmentation of genioglossus activity in response to inspiratory loading, which may indicate a less collapsible airway. Testosterone may lead to increased bulk of neck muscles and may lead to a preferential deposition of fat in upper airway structures. For poorly understood reasons, the frequency and severity of OSA syndrome in women after menopause is higher than in premenopausal women.²³

In susceptible persons, OSA may be precipitated or made worse by sleep deprivation, evening alcohol use, sedative medications, and the supine sleeping position. Even small doses of alcohol enhance upper airway muscle relaxation that occurs during sleep, thereby exacerbating OSA. Alcohol also blunts chemoreceptor responses to blood gases and raises the arousal threshold, which increases the duration of apneas.

Arterial oxyhemoglobin saturation (SaO₂) falls during apneas and hypopneas at a rate of 0.1% to 1.6% per second. The severity of hypoxemia is a function of baseline oxygenation, lung oxygen stores, the degree of airway narrowing, and apnea duration. Drops in SaO₂ to below 70% are common in severe OSA. Apneas during REM sleep tend to produce greater decreases in SaO₂ owing to decreased lung oxygen reserves and increased duration of apneas.

Arteriolar constriction as a result of hypoxemia, acidosis, and increased sympathetic tone contribute to increases in blood pressure during apneas that may reach 190 mmHg systolic and 110 mmHg diastolic. Right-to-left shifts of the cardiac interventricular septum and decreased cardiac output may occur as a result of increased negative intrathoracic pressure associated with attempts to breathe. Increased vagal tone associated with fluctuations in intrathoracic pressure, stimulation of the carotid body by hypoxemia, and increased sympathetic tone that accompanies the arousals at the end of apneas contribute to bradycardia, periods of asystole, atrioventricular block, premature ventricular contractions, and ventricular tachyarrhythmias. Sleep-disordered breathing is associated strongly with systemic hypertension.^{24,25}

The repeated arousals to resume breathing appear to be a major cause of daytime sleepiness in patients with OSA. Additional contributions may stem from hypoxemia; subtle but numerous microarousals in synchrony with labored respiratory cycles²⁶; or cytokines such as tumor necrosis factor- α .²⁷

EPIDEMIOLOGY AND RISK FACTORS. Habitual snoring, which is more common in males than in females, occurs in 6% to 12% of children and 5% to 20% of adults. OSA has a prevalence of about 1% in children, 2% in adult women, and 4% in adult men.^{28,29}

CLINICAL FEATURES AND ASSOCIATED DISORDERS. The usual presenting symptoms are snoring, excessive sleepiness, daytime sleep episodes, and a sense that sleep is not restful. Morning headaches, frequent nocturnal urination, and nocturnal restlessness are also common.

Some patients have no complaints and present only because the bed partner has noted periods of apnea. Others are referred because of a suspicion that OSA contributes to headaches, pulmonary or systemic hypertension, cardiac arrhythmias, or impotence.

Loud snoring, sometimes exceeding 90 dB, occurs in more than 80% of patients and usually begins years before the onset of sleep apnea. Some patients report that they cannot go on camping trips and must have separate hotel rooms on business trips because of their obnoxious snoring. Increasing volume of snoring, snoring that has changed in character, and loud rhythmical snoring punctuated by snorts and choking noises are suggestive of OSA. Snoring is produced by vibration of the soft tissues of the upper airway. The intensity and quality vary depending on the stage of sleep, the position of the body, the rate of airflow, the anatomical structure of the individual's nose and throat, and the amount of floppy airway tissue with potential to vibrate. Although snoring is common in patients with OSA, it is not universal. Snoring will not occur even with a very narrow pharynx if floppy tissue is absent.

Restless sleep is caused by the arousals at the end of apneas, which may be accompanied by jerks, twitches, and gross body movements. Changes in body position may occur several times per hour as patients attempt to find a sleeping position compatible with airway patency. With severe apnea, patients may sleep in a chair, on the couch, sitting up on the side of the bed, or leaning against a wall. Despite the restlessness, patients usually have the impression that sleep has been continuous or interrupted only by a few trips to the bathroom. A few patients describe repeated awakenings and complain mainly of insomnia.

Tiredness, sleepiness, and a sense that sleep is not refreshing are characteristic symptoms of sleep apnea, often accompanied by impaired memory and concentration. The sleepiness often increases gradually over several years as patients gain weight. Some patients feel mentally dull or disoriented each morning. Daytime sleepiness is usually most apparent after lunch, while driving or reading, or in other boring sedentary situations. Patients often minimize difficulties with sleepiness and describe it as no worse than in colleagues or peers. With more severe apnea, patients may fall asleep on the telephone or during sexual intercourse and may have episodes of "automatic behavior" during which complex activities are performed such as driving for miles with no recollection. Although daytime sleepiness is common, its absence does not rule out OSA.

Other common symptoms include irritability, impotence or reduced libido, excessive sweating at night, and dry mouth. Symptoms of gastroesophageal reflux may be present if the repeated episodes of negative intrathoracic pressure associated with apneas lead to passage of gastric contents through the lower esophageal sphincter.

In children, snoring and restless sleep are common complaints, along with poor attention, decreased school performance, enuresis, and hyperactivity. Daytime sleepiness is often less pronounced than in adults but is frequently endorsed in response to specific questioning.

On physical examination, patients are often obese and have thick necks. Long narrow facies, high arched palate, retrognathia, an enlarged edematous uvula, prominent tonsils, and redundant pharyngeal tissue are other common

findings. Patients with severe OSA may have findings consistent with right-sided heart failure.

Obstructive sleep apnea occurs in 10% to 40% of obese persons and in at least 25% of patients with hypertension. In untreated severe OSA, the prevalence of hypertension may be as high as 50%. A number of other disorders contribute to the development of OSA (see Table 54-7).

Central sleep apnea, which is much less common than OSA, is a disorder in which apneas occur but there is no associated attempt to breathe. The disorder may be idiopathic, or it may be caused by congestive heart failure or brain stem pathology. Many patients have both central sleep apnea and OSA, presumably because activation of upper airway afferents during airway occlusion leads to inhibition of attempts to breathe.

DIFFERENTIAL DIAGNOSIS. Loud snoring with gasping or choking sounds, witnessed apneas, restless sleep, hypertension, and neck circumference greater than 16.5 inches are useful predictors of OSA, but a definitive diagnosis usually requires polysomnography. Among children, snoring or noisy breathing, daytime mouth breathing, and parental observation of apneas and struggles to breathe are suggestive symptoms. The absence of snoring and obesity does not rule out OSA in either adults or children. In patients with excessive daytime sleepiness, other diagnostic considerations include narcolepsy, idiopathic hypersomnia, periodic limb movement disorder (PLMD), central sleep apnea, and the insufficient sleep syndrome. The differential diagnosis of nocturnal choking and gasping includes gastroesophageal reflux, nocturnal asthma, congestive heart failure, nocturnal panic attacks, and sleep-related laryngospasm.

EVALUATION. A nocturnal polysomnogram with monitoring of sleep stage, airflow, respiratory effort, electrocardiogram, leg movements, and body position is the most commonly used tool for diagnosis. If upper airway resistance syndrome is suspected, esophageal pressure measurements or at least nasal pressure monitoring should be obtained as part of the polysomnogram. The polysomnogram helps determine the presence and type of apnea, assess the relation of breathing disturbance to sleep stage and body position, determine the severity of hypoxemia and sleep disturbance, and identify cardiac arrhythmias. Apneas and hypopneas usually last 10 to 30 seconds and typically are followed by transient arousals. During REM sleep, apneas and hypopneas are usually longer, sometimes as long as 2 to 3 minutes, and are more likely to be associated with hypoxemia and cardiac arrhythmias. There are usually reduced amounts of stages 3 and 4 sleep and REM sleep. With mild OSA, apneas may occur only after alcohol ingestion or only when the patient is supine. With severe OSA, apneas occur continuously throughout the night and in all body positions.

In patients with high pretest probability of moderate or severe OSA, a home-monitoring study may be sufficient for diagnosis. A variety of home-monitoring devices are available; the simplest types measure only a single variable, such as oxygen saturation, whereas more complex devices may record as many channels as a typical laboratory polysomnogram. Home-monitoring studies cost less than laboratory studies, but they do not allow for visual observation, correction of artifacts or faulty sensors, or therapeutic interventions. It is also more difficult to assess mild sleep apnea. Finally, current models suggest that even inexpensive home

studies with excellent sensitivity and specificity still may not be cost-effective in comparison to laboratory polysomnography.³⁰

Additional studies may be indicated in some patients. An MSLT helps assess the presence and severity of excessive sleepiness. Although fiberoptic endoscopy of the upper airway, cephalometric radiographs, and magnetic resonance imaging (MRI) can be used to assess airway anatomy, such studies during wakefulness are of limited value in determining the site of obstruction because airway dynamics differ in sleep and wakefulness. Arterial blood gases and pulmonary function tests are indicated if obesity-hypoventilation syndrome or other causes of hypoventilation are suspected but they are not needed for routine evaluation of suspected OSA. In selected cases, evaluation for hypothyroidism may be indicated.

Some patients described as loud snorers do not snore during sleep studies. In such cases, snoring may be intermittent and related to alcohol use, body position, or allergies. Loud snoring that cannot be verified with objective assessment is sometimes an indication of marital problems.

MANAGEMENT. The goal of treatment is to keep the airway open during sleep, which should lead to improved sleep, better oxygenation, and enhanced daytime alertness. Treatment for OSA depends on the severity of the disorder. There is little doubt that treatment is needed for severe OSA because it is associated with increased risks of motor vehicle accidents, hypertension, stroke, myocardial infarction, cardiovascular death, and death while sleeping, if left untreated or treated ineffectively.^{31,32} For patients with a mild case of the disorder—those with fewer than 20 apneas plus hypopneas per hour of sleep, little or no nocturnal hypoxemia, mild or absent daytime sleepiness, and no hypertension or serious cardiac arrhythmias—the health benefits of treatment are less certain, and it is unknown at present whether asymptomatic patients with mild sleep apnea need to be treated.

The introduction in the 1980s of continuous positive airway pressure (CPAP) administered via a nasal mask revolutionized the management of OSA.³³ Nasal CPAP functions as an air splint to maintain positive intraluminal pressure in the upper airway. Although nasal CPAP can be used by children as well as by adults and is effective in 80% to 90% of patients, the proportion who use CPAP on a regular basis is substantially less. If nasal obstruction prevents the use of nasal CPAP, treatment with decongestants, steroid inhalers, septoplasty, or other forms of nasal surgery may be required. Other factors that may prevent the use of CPAP or reduce its benefit include a poorly fitting or uncomfortable mask, sinus infections, claustrophobia, chronic mouth breathing, incomplete efficacy, and lack of motivation. The more expensive bilevel positive airway pressure (BPAP) devices provide different pressures during inspiration and expiration and are sometimes better tolerated, particularly by patients with claustrophobia. Other problems associated with nasal CPAP include noise from the machine, air swallowing, allergic rhinitis, and discomfort from misdirection of airflow into the eyes. Barotrauma to the lungs is extremely rare.

For patients who cannot tolerate CPAP or prefer not to use it, a number of other treatments may be used. Removal of enlarged tonsils and adenoids is often successful in children and sometimes in adults. Uvulopalatopharyngoplasty

(UPPP) with removal of the uvula, portions of the soft palate, and redundant pharyngeal tissue eliminates snoring in more than 80% and produces improvement of OSA in about 50% of patients, but complete resolution of sleep apnea is uncommon. Laser-assisted UPPP is a staged outpatient procedure that eliminates snoring in about 60% of patients but is probably less effective for OSA than standard UPPP. Maxillofacial surgery, with advancement of the mandible, the maxilla, or both, appears to be beneficial for selected patients. Orthodontic appliances that advance the tongue or mandible can improve airway patency during sleep, reduce snoring, and decrease the frequency of respiratory events during sleep, but they rarely eliminate sleep apnea completely. Weight reduction is often helpful, but it may be difficult to achieve. For some patients with mild OSA, avoidance of precipitating factors such as sleep deprivation, evening alcohol use, sedative medications, and the supine sleeping position is the only treatment needed. Whatever treatment is used, the outcome should be assessed with a sleep study because many patients experience more subjective than objective improvement.

PROGNOSIS AND FUTURE PERSPECTIVES. Some patients develop increasingly severe apnea with age, but worsening of the condition may be due to weight gain. The natural history of sleep apnea in the absence of weight gain is unknown. Habitual snoring remits in as many as 35%.

Restless Legs Syndrome and Periodic Limb Movement Disorder

Restless legs syndrome (RLS) is characterized by unpleasant leg sensations or urges to move the legs. These symptoms are worse with rest; worse in the evening and at night; and relieved by movement.¹ Most patients with RLS also have movements of the legs that occur periodically at 20- to 30-second intervals for minutes to hours during sleep. Although the term nocturnal myoclonus sometimes is used to describe these movements, they usually are not sudden lightning-like movements. Rather, they typically last for about 1 second and consist of extension of the great toe with variable degrees of ankle extension, knee extension, and hip extension or flexion. With periodic limb movement disorder (PLMD), periodic movements occur during sleep, but the unpleasant evening and nighttime sensations are absent. In PLMD, the leg movements occur in association with complaints of insomnia or daytime sleepiness.

PATHOGENESIS AND PATHOPHYSIOLOGY. Although the pathophysiological basis for RLS and PLMD is unknown, disinhibition of a CNS pacemaker that affects reticular excitability may contribute. The similarity of PLMs to the extensor response to plantar stimulation (Babinski's sign) or to a triple flexion response suggests that pyramidal or dorsal reticulospinal tract dysfunction is involved. Functional dopamine insufficiency, perhaps related to abnormal iron metabolism, may also play a role. Abnormal sensory input may be a factor in some patients.

EPIDEMIOLOGY AND RISK FACTORS. The prevalence of RLS is about 2% to 10% for the adult population and increases with age. Men and women are affected equally, and symptoms begin after age 40 in many patients. About one third to one half of patients report that other family

members are affected, and in some families, the syndrome occurs in a pattern consistent with an autosomal dominant inheritance. Periodic leg movements without attributable symptoms are exceedingly common, but the prevalence of such leg movements with symptoms that allow diagnosis of PLMD is unknown and believed to be rare.¹

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Patients with RLS complain of a gradual buildup of a subcutaneous crawling, pulling, itching, aching, or pins-and-needles sensation that affects the muscles or bones of the calves and thighs (Video 73, Restless Leg Syndrome). As the sensation builds, the associated urge to move gradually becomes irresistible and movement provides temporary relief. Most patients have insomnia with difficulty getting to sleep and frequent awakenings during which they may flex and extend the legs, repeatedly turn over in bed, or get out of bed and walk. About 80% to 90% of patients with RLS have PLMs, usually during light NREM sleep, that contribute to awakenings and arousals.

During the day and especially during attempts to remain still, many patients fidget, swing their legs, or have movements that are similar to the extensor movements during sleep. Apart from the movements, neurological examination is usually normal.

Periodic leg movements during sleep are often associated with arousals (Video 251, Periodic Leg Movements). However, the movements have not been proved to cause the arousals and the occurrence of such arousals does not predict daytime sleepiness. Although severely affected patients may produce movements throughout sleep, periodic leg movements may also be entirely asymptomatic, causing no disruption of sleep patterns, and is sometimes brought to medical attention either as an incidental finding on a polysomnogram or because the spouse is unable to sleep owing to the leg jerks and kicks.

The RLS and PLMD may be induced or aggravated by a variety of conditions, including iron deficiency, anemia, and chronic renal failure. Peripheral neuropathy may be a factor in some cases, although peripheral nerve function is clinically normal in most affected patients. Symptoms occur in 10% to 20% of pregnant women and usually resolve post partum. Other disorders that may be associated with PLMD or RLS include venous disease, degenerative CNS disorders, and vitamin deficiency.

DIFFERENTIAL DIAGNOSIS. The diagnosis of RLS is based on the history. The essential elements are the urge to move associated with sensory phenomena in the legs, motor restlessness, and exacerbation at rest and in the evening and night.³⁴ The differential diagnosis may include akathisia, peripheral neuropathy, claudication, and leg cramps. With akathisia caused by phenothiazines, there is restlessness of the body and a compulsion to move, but the sensory component is less than with RLS and it is usually not exacerbated at night. Neuropathic dysesthesias are usually more distal than proximal, are felt more on the surface than in deeper structures, and are not relieved by movement. Claudication is brought on by exercise and relieved by rest, which is the reverse of the pattern with RLS. Leg cramps are associated with palpable tightness of muscles that does not occur with RLS.

Differential diagnosis of PLMD includes sleep starts and a variety of other movements during sleep. Sleep starts are

vigorous myoclonic jerks of the extremities or trunk that occur at sleep onset but do not recur periodically. Most other types of movements and behaviors during sleep are not periodic.

EVALUATION. Evaluation of patients with suspected RLS should include complete blood count and serum iron and ferritin levels. Renal function tests and electromyography and nerve conduction studies are indicated only in selected patients. Polysomnography is useful for suspected PLMD.

MANAGEMENT. Evening and bedtime doses of dopaminergic agonists or levodopa-carbidopa provide considerable benefit in RLS and PLMD.^{35,36} Some patients require additional doses during the night or controlled-release formulations. Some patients treated with levodopa develop tolerance and require increasing doses, whereas others develop increased daytime symptoms of restless legs. Levodopa-carbidopa given around the clock to such patients is less advisable than careful use of lowest-possible doses or drug holidays. As most patients treated with dopamine agonists do not develop these complications, pramipexole and ropinirole are usually used instead of levodopa. At the time of this writing, ropinirole is the only medication approved by the Food and Drug Administration for restless legs syndrome.

Benzodiazepines, particularly clonazepam, can be used either alone or in combination with dopaminergic agents for RLS and for PLMD. Daytime sedation, tolerance, and loss of efficacy are the major problems encountered with these drugs. Opiates such as propoxyphene, codeine, and hydrocodone also reduce the unpleasant sensations and can be used alone or in combination with dopaminergic agents and benzodiazepines. Clonidine, baclofen, carbamazepine, and gabapentin are sometimes helpful.

PROGNOSIS AND FUTURE PERSPECTIVES. The RLS has a variable course. Some patients have long periods of relative stability, whereas others worsen with age. Permanent remissions are rare.

CHRONOBIOLOGICAL DISORDERS

People who sleep at the wrong time of day or who cannot sleep at the right time of night often have one of the six major types of chronobiological disorders: delayed sleep phase type, advanced sleep phase type, irregular sleep-wake type, free-running type, jet lag type, or shift work type.¹

PATHOGENESIS AND PATHOPHYSIOLOGY. Circadian rhythm disturbances are caused by a shift in the usual phase relation between the internal biological clock and the desired sleep-wake schedule. The suprachiasmatic nucleus of the hypothalamus functions as the biological clock. In the absence of entraining influences, the output of the nucleus has a period slightly longer than 24 hours. Thus, persons living in temporal isolation adopt a 24.5- to 25-hour sleep-wake schedule and cycle in and out of phase with the external environment. The phase of the biological clock can be shifted by only a few stimuli, of which the most potent is bright light.³⁷ Bright light exposure helps maintain synchronization between the internal clock and the external world, but the phase-shifting effects

of light are limited in most circumstances to no more than 2 hours each day. The retinohypothalamic pathway, the primary afferent tract to the suprachiasmatic nucleus, mediates the effects of light on circadian rhythms. Intensity, duration, and timing of light exposure determine its effect on the phase of the circadian system. Light pulses just before or during the first half of the dark phase produce phase delays, whereas light pulses during the second half of the dark phase or just after the end of the dark phase produce phase advances. Melatonin, a pineal hormone that is secreted mainly at night in humans, appears to have phase-shifting properties that are opposite to the effects of bright light: Melatonin administered in the afternoon produces phase advances, whereas melatonin given in the morning produces phase delays.

With east-west jet travel or with changing work schedules, most persons attempt to shift their schedule of sleep and wakefulness quickly to meet the social demands of the new schedule, but the internal clock cannot adjust and sleep-wake patterns are disrupted. Night workers also sleep about 1 to 1.5 hours less than day workers, and their attempts to sleep at night when they are not working often prevent them from synchronizing the internal clock to the night shift schedule. As the internal clock shifts by about 1 hour per day after a phase advance—such as an eastbound flight—and by 1.5 hours per day after a phase delay—such as a westbound flight—it may be several days before sleep-wake patterns and the internal clock shift to the new schedule.³⁸

Phase shifts also may occur during weekends if bedtimes and rise times are delayed, at least in part because of altered timing of light exposure. In patients with delayed sleep phase disorder³⁹ phase delays induced by sleeping later are not corrected during the week. Adolescence, the usual time of appearance of delayed sleep phase disorder, is associated with increased sleep needs, but social factors and greater independence usually prevent earlier bedtimes. As a result, many adolescents sleep later on weekends and develop delayed sleep phase disorder. Leaving home for college may exacerbate delayed sleep phase disorder because parents can no longer act as backups to the alarm clock. In advanced sleep phase disorder, the pattern is the opposite, with excessively early bedtimes and early awakenings due to phase advance of the biological clock.

Degeneration or destruction of the suprachiasmatic nucleus or its effector pathways is the usual cause of irregular sleep-wake rhythm. Free-running, or nonentrained circadian rhythm sleep disorder is usually caused by retinal, prechiasmatal, or chiasmatal lesions that interrupt the retinohypothalamic tract. Although most affected persons are blind, chiasmatal lesions that interrupt the retinohypothalamic tract may cause the syndrome even when visual loss is incomplete. Without retinal input, the internal clock moves in and out of phase with the environmental clock. When the phase difference is small, patients may be able to maintain sleep hours close to the societal norm, but when the phase difference is large, synchronization cannot be maintained and sleep times become highly irregular. Prolonged periods of wakefulness lasting up to 40 to 50 hours may be followed by sleep periods of 12 to 20 hours and then resumption for a few days of a relatively normal schedule.

The first mammalian circadian clock gene was cloned recently, and its mutation causes altered behavior, affecting

the free-running rhythm period and causing loss of persistence of circadian rhythms. Additional circadian clock genes have already been described.⁴⁰

EPIDEMIOLOGY AND RISK FACTORS. Circadian rhythm sleep disorders are common. Jet lag symptoms affect the majority of persons who fly across five or more time zones. Sleep disruption is a problem for a large proportion of the more than 20 million shift workers, particularly for older workers during the days and nights following a shift change. Delayed sleep phase disorder may affect as many as 7% of urban adolescents. The other disorders are less common. The irregular sleep-wake rhythm occurs mainly in institutionalized persons with severe static or progressive encephalopathies. The free-running type of circadian rhythm sleep disorder appears to be a major cause of sleep-wake complaints in blind persons.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Symptoms of jet lag, which may last as long as 7 to 10 days after trips across five or more time zones, include difficulty falling asleep or remaining asleep in the new environment, along with sleepiness during the new daytime. Symptoms, which are usually worse with eastward flight than with westward flight, may be exacerbated by sleep loss and alcohol use during the flight. Chronic jet lag with sleepiness, sleep disruption, malaise, irritability, and reduced performance may occur in airline personnel and in other frequent jet travelers. Night workers and those who work rotating shifts often develop sleep problems similar to jet lag because an 8-hour shift in the sleep schedule produces effects similar to flight across eight time zones. Nighttime sleep on weekends may prevent shifts in phase to match the new schedule and may exacerbate sleep problems during the week. Adolescent patients with delayed sleep phase disorder have difficulty falling asleep at night and difficulty waking up on time when they try to maintain a conventional sleep-wake schedule. Patients with advanced sleep phase disorder complain of evening sleepiness and early morning awakening. Sleep onset between 6 and 9 PM and awakening between 1 and 3 AM are typical.

With the irregular sleep-wake rhythm, sleep episodes of varying length occur at irregular intervals. Patients or caretakers complain of difficulty falling asleep, difficulty remaining asleep, and daytime somnolence. The picture is often complicated by nocturnal agitation and by the use of sedatives or antipsychotic medications to control the agitation.

Patients with the free-running type of circadian rhythm sleep disorder may complain of difficulty falling asleep in the evening, difficulty waking up in the morning, or difficulty staying awake during the day. Cyclical fluctuation in severity of the complaints is typical because sleep problems are much greater when the phase difference between the temperature rhythm and the desired sleep-wake schedule is high.

Delayed sleep phase disorder may be the initial manifestation of depression in adolescents. In adults with poor social adaptation, the syndrome may provide secondary gain as a means to reduce or avoid social interaction. Irregular sleep-wake rhythm is often associated with encephalopathy and free-running rhythm with blindness.

DIFFERENTIAL DIAGNOSIS. The differential diagnosis of chronobiological disorders includes most of the other disorders that cause insomnia or sleepiness. Inadequate sleep hygiene and chronically insufficient sleep often

contribute to sleep disturbance in shift workers and night workers; temporal association of sleep disturbance with night or rotating shift work and remission during vacations is suggestive of shift work sleep disorder. Depression, marital or family problems, job dissatisfaction, or other psychosocial factors should be considered in a permanent shift worker who develops sleep problems after years of stable functioning.

Delayed sleep phase disorder that presents in adolescence is sometimes misdiagnosed as narcolepsy, depression, chronic fatigue, or a learning disorder. Knowledge that sleepiness occurs mainly in the morning and continuous restful sleep occurs when patients go to bed late and arise late helps the clinician arrive at the correct diagnosis.

EVALUATION. The history and sleep logs provide the most useful information for diagnosing circadian rhythm sleep disorders. Maintenance of a sleep log for 2 to 4 weeks is usually sufficient except for patients with the free-running type of circadian rhythm sleep disorder, in which cyclical sleep patterns may only be revealed after several weeks of maintaining sleep logs. In delayed sleep phase disorder, sleep logs show sleep onset and awakening from sleep that are much later than the social norm. Bedtimes and wakeup times are often even later on weekends. Sleep logs in patients with irregular sleep-wake rhythm show no consistent sleep times: There may be several 2- to 4-hour sleep periods scattered over the 24-hour period, with marked variability in the timing and duration of sleep from one day to the next.

If sleep apnea or narcolepsy is suspected, polysomnography and MSLT may be helpful, but MSLT interpretation is difficult if the patient has not been on a regular schedule. Psychiatric assessment is indicated if depression appears to be a contributing factor.

MANAGEMENT. Appropriate scheduling of sleep and of exposure to bright light are the keys to management of circadian rhythm sleep disorders. To minimize jet lag, the pretravel sleep schedule should be shifted 1 to 2 hours closer to the destination schedule. Although hypnotic use during the trip may minimize in-flight sleep loss, the potential for effects on memory and cognition must be considered, especially in the elderly. After travel, correctly timed exposure to bright light and immediate adoption of the new time zone schedule help reduce symptoms. At present, melatonin, which may be beneficial for jet lag, is not available in the United States except as an unregulated health food supplement.

Treatment of shift work sleep disorder depends on the frequency of shift changes, the direction of shift rotation, the desired schedule during nights of work, and the daytime obligations of the shift worker.³⁸ Shift rotations from days to evenings to nights tend to be better tolerated than rotations in the opposite direction. Although sleep is usually best for night workers who sleep during the day 7 days per week, most persons are unwilling to spend days off asleep. A biphasic sleep schedule with a 2- to 3-hour nap in the afternoon and 4 to 6 hours of sleep in the morning after work is sometimes the best option. Bright light at night and dark bedrooms in the daytime are beneficial, but daytime sedative use is usually of no value.

For delayed sleep phase disorder, the patient should be instructed to advance the times of going to bed and arising

from bed by about 15 minutes each day or two beginning with the usual weekend sleep times. Alternative approaches with more rapid phase shifts are quicker, but they are more socially disruptive and require strong motivation. Once the desired schedule is achieved, it must be rigorously maintained 7 days per week. Morning bright light is helpful, but patients should understand that the schedule is the most critical element. In difficult cases, melatonin can be considered several hours before the desired bedtime, or bedtime can be delayed rather than advanced, by 3 to 4 hours each night for several days, until the patient reaches the desired bedtime.

Although delayed sleep phase disorder almost always can be treated effectively with strict scheduling, psychosocial factors often interfere with the planned treatment. Awakening in time to get to school often has become a focus for conflict between the parents and the patient, and many patients, particularly those with depression, lack the motivation to maintain the schedule. Failure to attempt even a minimal shift in schedule is usually an indication of major family discord, depression, or poor motivation.

Advanced sleep phase disorder can be treated with daily 15-minute delays in bedtime and evening exposure to bright light. Treatment of the irregular sleep-wake rhythm is difficult, although morning exposure to bright light, increased daytime activity, and prohibition of morning and evening naps may be helpful. Management of the free-running type of circadian rhythm sleep disorder is also difficult, but blind patients who retain some retinal input to the suprachiasmatic nucleus benefit from appropriately timed exposure to high-intensity bright light.

PARASOMNIAS

Parasomnias are disorders that involve undesirable physical events or experiences that occur during sleep, entry to sleep, or arousal from sleep (Table 54-8).¹ This section reviews selected parasomnias that are of particular interest to neurologists.

TABLE 54-8

Examples of Parasomnias

| DISORDER | KEY FEATURES |
|------------------------------------|--|
| Confusional arousals | Sudden arousals, usually from slow-wave sleep, associated with confusion and disorientation |
| Sleepwalking | Arousal with complex motor behavior, usually from slow-wave sleep; walking, running, talking, and eating may occur |
| Sleep terrors | Sudden arousal, usually from slow-wave sleep, with fearful agitated behavior, often with screaming or crying and inconsolability |
| Nightmare disorder | Recurrent, disturbing dreams |
| Recurrent isolated sleep paralysis | Paralysis occurring at the onset or end of sleep or during nocturnal awakenings |
| REM sleep behavior disorder | Dream-enacting behavior with loss of the normal muscle atonia during REM sleep |
| Sleep enuresis | Bed wetting during sleep, after 5 years of age |
| Sleep-related eating disorder | Repeated involuntary eating or drinking after sleep onset |

REM, rapid eye movement.

Arousal Disorders

PATHOGENESIS AND PATHOPHYSIOLOGY. The arousal disorders—confusional arousals, sleepwalking, and sleep terrors—are grouped together based on the hypothesis that impaired ability to arouse fully from slow-wave sleep is responsible for the phenomena.⁵¹ The disorders, which are most common during childhood when the amount of slow-wave sleep is at its peak, probably exist on a continuum. Confusional arousals are associated with low levels of motoric and autonomic activation; sleepwalking with motoric activation but little autonomic activation; and sleep terrors with pronounced autonomic, emotional, and motoric activation. The variable activation patterns lead to considerable overlap between the three syndromes.

EPIDEMIOLOGY AND RISK FACTORS. Children are affected more than adults with a peak incidence between ages 4 and 10 years; however, onset in adulthood can occur. About 1% to 6% of children have recurrent sleep terrors. An increased prevalence in first-degree relatives suggests that genetic factors may play a role. In susceptible persons, sleepwalking and sleep terrors may be precipitated or aggravated by stress, sleep deprivation, fever, and noise. Many patients with arousal disorders may have sleep-disordered breathing (usually in subtle forms) or periodic leg movements, treatment of which can resolve the parasomnia.⁴¹

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Sleep terrors are episodes of fearful agitation with decreased responsiveness and inconsolability that begin abruptly, usually from slow-wave sleep in the first third of the night. Severe episodes are often accompanied by screaming and attempts to leave the bed or the room. Patients may fall down stairs and may react violently to attempts to restrain them. After several minutes the patient calms down and returns to sleep. Morning recall is usually absent, although some patients have a vague recollection of a terrifying situation such as suffocation and occasional patients recall more elaborate dreamlike experiences.

Sleepwalking is characterized by complex automatisms during sleep typified by getting out of bed and walking. Some subjects eat⁴²; others attempt to leave the home through a door or window. Patients sometimes sit or stand in bed without getting out of bed. Although sleepwalkers often respond inappropriately, they sometimes follow instructions to return to bed.

Confusional arousals are brief episodes associated with talking, moaning, or agitation that rarely require treatment.

Although sleep terrors and sleepwalking may be precipitated by stress in susceptible individuals, most affected children do not have severe psychopathology. Arousal disorders appear to be increased in Tourette's syndrome, post-traumatic stress disorder, and children with violent, abusive families.

DIFFERENTIAL DIAGNOSIS. The differential diagnosis of arousal disorders includes sleep-related epilepsy, REM sleep behavior disorder (RBD),⁴³ nightmares, confusional states, and nocturnal delirium (Video 241, REM Behavioral Disorder). Although the patient's history is often sufficient for diagnosis, symptoms of screaming, walking, running, and vague, frightening perceptions may accompany nocturnal complex partial seizures. Atypical presentations that suggest the possibility of seizures include onset in adulthood;

multiple nightly episodes; stereotyped behaviors with chewing, swallowing, and salivation; and poor or no response to medications.⁴⁴ The RBD occurs mainly in adults and is usually associated with dream recall; the vague recollections that accompany some episodes of sleep terrors are usually fragmentary without the plot or story that characterizes dream mentation. Behavior may, however, be similar to that observed with sleep terrors, and some patients have a so-called overlap syndrome with elements of sleep terrors and RBD.

In hysterical dissociative phenomena, such as fugue states and multiple personalities, the patient is not asleep and behavior is purposeful, more complex, and longer lasting. The electroencephalogram (EEG) is consistent with waking state.

EVALUATION. For otherwise normal children with typical behaviors of sleepwalking or sleep terrors that occur during the first third of the night, the diagnosis can usually be made based on clinical criteria. When the diagnosis is uncertain, polygraphic monitoring with simultaneous video monitoring is indicated for 1 or 2 nights, particularly if the events are occurring several times per week. If nocturnal seizures are a consideration, several additional EEG channels should be included in the recording montage, along with a video recording of the patient and the capability to record or play back activity at a sufficient paper speed to identify interictal and ictal epileptiform activity.⁴⁴ Standard polysomnographic recording techniques used for identifying sleep apnea are generally insufficient for a definitive diagnosis.

Polysomnographic monitoring usually demonstrates the onset of sleep terror episodes during stage 3 or 4 sleep. The EEG during the episode may show rhythmical δ activity or other nonwaking patterns, whereas the EEG shows waking activity during psychogenic dissociative episodes and REM sleep activity during RBD. Psychiatric evaluation is indicated if a dissociative disorder is suspected, because many patients have severe psychopathology.

MANAGEMENT. Sleep terrors and sleepwalking usually improve with age and resolve before adolescence. Treatment may be required if the associated behaviors are potentially injurious or if the behavior is excessively disruptive to the family. Good sleep hygiene with regular sleep hours and adequate amounts of nocturnal sleep are important initial recommendations. Ground-floor bedrooms, window locks, and absence of sharp objects or toys on the bedroom floor are other useful measures. If injuries have occurred or appear likely to occur, treatment of the patient at bedtime with imipramine, diazepam, or clonazepam is usually effective. Hypnosis or other behavioral treatments may be helpful for some patients, and psychiatric treatment is indicated when the disorder is linked to significant psychopathology.

PROGNOSIS AND FUTURE PERSPECTIVES. Episodes tend to decrease in frequency and severity during adolescence. The natural history of adult-onset arousal disorders is unknown.

REM Sleep Behavior Disorder

Normal REM sleep is associated with skeletal muscle atonia interrupted by irregular muscle twitches. With the

RBD, the muscle atonia that accompanies REM sleep is incomplete, and patients have motor automatisms in which they appear to act out their dreams.⁴⁵

The RBD occurs mainly in older persons and is more common in men than in women. Patients with Parkinson's disease, Alzheimer's disease, dementia with Lewy bodies, multi-infarct dementia, multiple system atrophy, olivopontocerebellar degeneration, narcolepsy, and focal brain stem lesions are at increased risk for RBD, but over half of patients have no major abnormality on neurological examination or MRI. Some studies have suggested that the disorder may be an early marker or risk factor for parkinsonian syndromes.⁴⁶

The disorder may begin fairly abruptly, or it may be preceded by months of progressively increasing nocturnal movements, vocalizations, and disturbing dreams. Presenting complaints include nocturnal shouting, violent behavior with "acting out" of dreams, and injuries during sleep to the patient or bed partner.⁴³ During the episodes, which usually last a few minutes, behavior may be limited to talking, laughing, and waving of the arms or it may include punching, kicking, or jumping out of bed. Some patients have a so-called Jekyll and Hyde syndrome with quiet peaceable behavior during the day that contrasts with the swearing and violence that accompanies REM sleep.

The timing and duration of episodes parallel the distribution of REM sleep across the night. Some patients have complex behaviors with virtually every REM period, whereas others have the behaviors less than once per week. Episodes usually do not occur during naps or during the first hour of sleep because REM sleep is uncommon at these times. Patients can usually be awakened from an episode without the confusion or difficulty arousing that characterizes sleep terrors.

Dream mentation and dream-enacting behaviors are uncommon with other disorders associated with complex motor activity during sleep (Table 54-9). The recurrence of episodes at approximately 90-minute intervals and the rapid return to full alertness on awakening are also useful distinguishing features.

TABLE 54-9

Causes of Episodic Nocturnal Complex Motor Activity

| DISORDER | STAGE OF SLEEP OR WAKEFULNESS IN WHICH EPISODES ARISE |
|--|---|
| Sleepwalking | NREM sleep, usually slow-wave sleep |
| Sleep terrors | NREM sleep, usually slow-wave sleep |
| Partial complex seizures of temporal lobe origin | Usually NREM sleep |
| Partial complex seizures of frontal lobe origin | Usually NREM sleep |
| Hypnogenic paroxysmal dystonia | Usually NREM sleep |
| Panic disorder | NREM sleep |
| REM sleep behavior disorder | REM sleep |
| Nightmares | REM sleep |
| Nocturnal delirium | Wakefulness |
| Dissociative episodes | Wakefulness |
| Malingering | Wakefulness |

REM, rapid eye movement; NREM, nonrapid eye movement.

Polysomnography with simultaneous audio and video monitoring and additional channels for limb movement monitoring is indicated when RBD is suspected. On polysomnography, the atonia that normally accompanies REM sleep is disrupted by periods of increased tone and increased phasic muscle activity, even during REM periods that are not associated with disruptive behavior. One night of recording is usually sufficient, but sometimes two nights are required. Brain imaging, daytime EEG, or neuropsychological tests may be indicated in patients with abnormal neurological examinations, but they are not needed in patients with idiopathic RBD.

In 80% to 90% of patients, behavior is eliminated or reduced to minor movements and vocalizations with bedtime doses of clonazepam, which appears to be more effective than other benzodiazepines. Incomplete atonia persists during REM sleep even with treatment. If clonazepam is ineffective or not tolerated, imipramine, levodopa-carbidopa, diazepam, temazepam, clonidine, or carbamazepine are occasionally useful.

Idiopathic RBD is a chronic disorder with few if any remissions. A substantial proportion of patients who are otherwise neurologically normal at the time of presentation develop Parkinson's disease over the next several years.

Hypnogenic Paroxysmal Dystonia

The clinical characteristics of hypnogenic paroxysmal dystonia (also called nocturnal paroxysmal dystonia) closely resemble partial seizures originating in the supplementary motor area, and in most patients, the attacks are epileptic. This form of epilepsy is no longer classified as a parasomnia, but it is discussed here as a condition that can be of interest to neurologists when parasomnias are a diagnostic consideration. Unusual cases with long-lasting attacks are presumed to be caused by a basal ganglia disturbance.

The disorder is rare. Lesions of the supplementary motor area or of mediobasal regions of the frontal lobe appear to be the major risk factors.

Patients with this disorder have brief spells of ballistic choreoathetoid movements and dystonic postures that arise abruptly from NREM sleep. The violent movements are usually bilateral, but they may predominate on one side and the patient usually is awake with eyes open during the episode.

Differential diagnosis includes partial seizures of temporal lobe origin, sleep terrors, nocturnal dissociative disorder, and RBD. Although the bizarre behaviors may suggest a psychiatric disorder, the abrupt onset from sleep, the highly stereotyped behaviors, and the absence of dream mentation and dream-enacting behaviors are helpful distinguishing features. Sleep terrors rarely occur more than 3 to 4 times per night, whereas episodes of hypnogenic paroxysmal dystonia often occur 10 to 40 times per night.

Polysomnography with video-EEG monitoring is the most useful diagnostic test.⁴⁴ The documentation of abrupt onset from sleep with stereotyped behavior is usually sufficient to exclude psychiatric causes, but definitive determination of whether the episodes are epileptic is often difficult. In some cases, ictal discharges may be recorded from frontal regions, but it may be necessary to record dozens of episodes over the course of several nights before a focal ictal discharge is revealed. In some cases, intracranial electrode placement is required.

Epileptic and nonepileptic forms may respond to carbamazepine and other antiepileptic agents, but as in other patients with seizures of frontal lobe origin, some patients show no response to any anticonvulsant.

The course is variable. Spontaneous remissions may occur that last for years, even when the disorder is epileptic. Other patients have numerous nightly episodes that are refractory to all treatments. Daytime seizures sometimes develop.

SLEEP ABNORMALITIES IN NEUROLOGICAL DISORDERS

Sleep Disordered Breathing and Neuromuscular Diseases

Breathing disturbances in neuromuscular diseases are due to weakness of respiratory muscles, upper airway muscles, or both. Respiratory muscle weakness is usually severe in Duchenne muscular dystrophy and also occurs in myotonic dystrophy, limb-girdle dystrophy, polymyositis, poliomyelitis, amyotrophic lateral sclerosis, myasthenia gravis, and congenital myopathies.

Weakness of the diaphragm is the most important cause of respiratory disturbance during sleep. Diaphragmatic workload increases in NREM sleep owing in part to airway narrowing caused by decreased tone in upper airway muscles, in part to sleep-related changes in lung mechanics and respiratory muscle activation, and in part to the increased load associated with the horizontal position. With neuromuscular disorders, weakness of upper airway muscles may further reduce airway diameter, leading to increased respiratory load. Diaphragm workload increases even further during REM sleep, because accessory muscles of respiration are inhibited and the diaphragm must perform almost all the work of breathing. The increased workload during sleep may lead to diaphragm fatigue with hypoxia, hypercapnia, acidosis-induced muscle dysfunction, and progressively worsening hypoventilation during the latter portion of the night.

Weakness of upper airway muscles may also lead to obstructive apneas and hypopneas, but weakness of inspiratory muscles may prevent generation of sufficient force to produce snoring.

Obesity, kyphoscoliosis, and other factors that increase work of breathing may precipitate sleep-related hypoventilation in patients with diaphragm weakness. Patients with bulbar symptoms are at increased risk for upper airway obstruction during sleep. Although patients with daytime respiratory symptoms are at greatest risk, many patients without daytime complaints have significant sleep-related hypoventilation.

Patients may complain of frequent awakenings, nocturnal dyspnea or restlessness, inability to sleep supine, or morning headaches. Patients with marked diaphragm weakness may be unable to sleep in a bed and may sleep in a chair or on the couch. Daytime sleepiness is usually not a prominent complaint until sleep disturbance is severe. In occasional patients with motor neuron disease or myopathy, sleep complaints caused by nocturnal hypoventilation are the initial manifestation of the neuromuscular disease.

Other causes of sleep disturbance, including PLMD and the effects of medications, must be considered. Patients with progressive disorders may have sleep disturbance caused by depression.

Evaluation should include spirometry obtained in the sitting and supine positions because patients with diaphragm weakness may have a pronounced reduction in vital capacity when they are supine. Arterial blood gases, assessment of diaphragm motion with fluoroscopy, and complete pulmonary function testing are helpful in selected patients. Polysomnography allows assessment of breathing in REM and NREM sleep in various body positions and sleep stages. Measurement of end-tidal PCO_2 , which can be performed as part of the recording, provides a quantitative assessment of ventilation.

Weight reduction may produce marked benefits if obesity has led to decompensation of marginal pulmonary function during sleep. Nocturnal oxygen may be beneficial if hypoventilation is not severe, but it must be administered cautiously in patients with daytime hypercapnia because of the risk of precipitating respiratory failure in patients whose breathing is dependent on hypoxic drive. For patients with upper airway obstruction, nasal CPAP is excellent treatment, and if hypoventilation is not reversed with CPAP, BPAP devices that provide a higher pressure during inspiration than during expiration can be used, especially for patients with expiratory muscle weakness. Negative-pressure cuirass ventilators and intermittent positive-pressure ventilation can be used if additional ventilatory support is needed. Tracheostomy combined with positive-pressure ventilation may be needed for some patients. The prognosis depends on the underlying neuromuscular disorder.

Sleep Disorders Associated with Degenerative Disorders of the Central Nervous System

Degenerative neurological diseases can lead to sleep disturbance through effects of the disease on neuronal systems involved in sleep-wake regulation, on systems involved with regulation of breathing during sleep, or on systems involved with motor control during sleep.⁴⁷ Degenerative processes that affect the suprachiasmatic nucleus or the retina may produce circadian rhythm disturbances. OSA may occur if weakness, spasticity, or rigidity affect bulbar muscles, and central or obstructive apneas may occur if respiratory control systems of the lower brain stem are involved. Patients who have degenerative processes that affect motor systems are at increased risk for PLMD, RLS, and RBD. Deficient dopaminergic transmission may explain, at least in part, the occurrence of RBD in patients with multiple system atrophy.⁴⁸

Degenerative disorders may also cause sleep disturbance due to the effects on sleep continuity of immobility, discomfort, and nocturnal disorientation. Depression and the effects of psychoactive medications also contribute to sleep problems in many patients, but sleep disturbance is also common in unmedicated nondepressed patients.

Frequent awakenings scattered throughout the night represent the most common pattern of sleep disturbance in these patients. Awakenings combined with disorientation in demented persons often lead to the so-called sundown syndrome with nocturnal wandering, confusion, and agitation. This problem is highly stressful to family members and is a

major cause of institutionalization of the demented elderly. Daytime somnolence, often caused by nocturnal sleep disruption, may exacerbate difficulties with memory and attention.

Obstructive and central sleep apneas and irregular respiratory patterns during sleep are common in patients with autonomic disturbances, in those with bulbar symptoms, and in those with degeneration of pontomedullary systems involved in the coordination of breathing.

For the patient with a degenerative neurological disorder and sleep complaints, the differential diagnosis may include direct and indirect effects of the disease, medication effects, poor sleep hygiene with excessive time in bed, circadian rhythm sleep disorders, RLS and PLMD, sleep-related breathing disorders, sundowning, and RBD.

The history is the most important element for diagnosis. The relation of the onset of sleep disturbance to the onset of the degenerative disorder helps determine whether the two are related. For patients with insomnia or disruptive nocturnal behavior, the frequency and duration of awakenings should be noted, along with the times of naps and medications. Mood should be assessed because depression is a common contributor to sleep disturbance in this population. A sleep log may provide evidence of a circadian rhythm disorder and also helps quantify the sleep disturbance and its effect on the caregiver. Sleep laboratory evaluation may be required in some cases, particularly if sleep apnea, PLMD, or RBD are suspected.

The management of disturbed sleep in patients with degenerative disorders requires a determination of the severity of sleep disturbance and its probable causes, an assessment of the impact of disrupted sleep on the patient and family, and a consideration of the benefits and drawbacks associated with particular treatments. Although the underlying pathology usually cannot be halted or reversed, there may be elements contributing to disordered sleep that can be ameliorated or removed. Good sleep hygiene with a regular sleep-wake schedule, exposure to bright light in the morning, and minimal amounts of time spent in bed during the day are important first steps. Morning and evening naps should be avoided in most patients, but afternoon naps may help some patients obtain more total sleep. Caffeine and alcohol should be eliminated, and psychoactive medications should be minimized.

Sleep-related breathing disturbances should be treated to the greatest extent possible, particularly in patients with autonomic disturbances because they appear to be at high risk for death during sleep. OSA may respond to treatment with nasal CPAP. Although the CPAP apparatus may be manageable initially, its use may become impossible as the degenerative disorder progresses, particularly if dementia is a prominent symptom. In most patients with advanced disease, the complications associated with tracheostomy outweigh its benefits.

Disruptive nocturnal behavior that is due to RBD usually responds to treatment with clonazepam in patients who can tolerate the medication, but it is a difficult symptom to manage when the condition is due to other causes. Benzodiazepines exacerbate nocturnal confusion and impair memory in the demented. Some patients benefit from low doses of thioridazine, butyrophenone, or sedating tricyclic antidepressants, but their anticholinergic properties may worsen cognitive disturbance.

HISTORY AND DEFINITIONS

Adverse reactions to prescription or over-the-counter medications are a frequent cause of neurological morbidity and patient hospitalization. Therefore, it is essential that the possibility of an iatrogenic condition be considered in any patient presenting with acute, subacute, or chronic neurological symptoms. Identification of the responsible agent is simple when neurological symptoms are highly characteristic of the offending agent. However, in most cases, symptoms of intoxication are nonspecific and mimic neurological entities, or they exacerbate pre-existing neurological disease. Some effects relate directly to neurotoxicity, and others are secondary to damage of other organ systems such as renal or hepatic.

The nervous system may be adversely affected by several mechanisms. There may be interference with energy production necessary to maintain normal neural structure and function; exposure to foreign material may result in allergic or other immunological phenomena; drugs may affect the nervous system through their effects on neurotransmitters; the offending agent may interfere with nerve nutrition through involvement of the nutrient vessels; and alterations in acid-base balance or in ionic concentrations may occur.

Advances in molecular biology research techniques are being applied to understanding the biochemical foundations of toxic reactions and to identifying subjects at risk of intoxication.

TRANQUILIZERS, ANTIDEPRESSANTS, AND ANXIOLYTICS

Neuroleptics

The neuroleptic agents or major tranquilizers (Table 55-1) exert their antipsychotic activity by blocking dopaminergic receptors at the level of the limbic system, forebrain, and basal ganglia. They also have antihistaminergic, anticholinergic, and anti- α_1 -adrenergic properties. The newer so-called atypical agents include clozapine, olanzapine, quetiapine, risperidone, and aripiprazole. Many newer agents have some affinity for 5-HT₂ serotonin receptors as well (clozapine, risperidone, aripiprazole). The atypical neuroleptics have become favored due to their lower side effect profile in terms of extrapyramidal features. Neuroleptics, as a class, are associated with a variety of important neurological complications. These can be classified as acute, subacute, and chronic side effects (Table 55-2).

TABLE 55-1

Selected Neuroleptics

| NONPROPRIETARY/TRADE NAME | SEDATIVE EFFECTS | EXTRAPYRAMIDAL EFFECTS | HYPOTENSIVE EFFECTS |
|--|------------------|------------------------|---------------------|

*Neuroleptic malignant syndrome can occur as an acute, subacute, or chronic side effect of neuroleptics.

Encephalopathy

Neuroleptics may cause a toxic confusional state, especially in the elderly, and confusion occurs more frequently with the low-potency, high-anticholinergic activity subclass (chlorpromazine, thioridazine, mesoridazine). These drugs can also produce profound sedation, especially with initiation of therapy.¹

Seizures

Neuroleptics also lower the seizure threshold and have been associated with exacerbation of pre-existing epilepsy as well as the de novo appearance of seizures. Clozapine use has been associated with generalized and myoclonic seizures that may develop during the titration phase at low dosages (<300 mg/day) and at high dosages during maintenance therapy (>600 mg/day).²

Neuroleptic Malignant Syndrome

The pathogenesis of neuroleptic malignant syndrome (NMS) is not completely understood. Alterations in dopaminergic transmission, changes in sympathetic outflow, alterations in central serotonin metabolism, and abnormalities in muscle membrane function have been implicated. NMS has been associated with all groups of neuroleptics, although high-potency agents, specifically haloperidol and fluphenazine, have been most frequently cited. Neuroleptic malignant syndrome has been described with the atypical neuroleptic medications clozapine, risperidone, and olanzapine.³⁻⁵

Neuroleptic malignant syndrome tends to occur with the initiation of treatment or increases in dose and is more common with depot forms of neuroleptics. Affective disorder, concomitant lithium carbonate administration, psychomotor agitation, dehydration, exhaustion, and mild hyperthermia seem to increase susceptibility toward this condition.⁶

The principal features of NMS are hyperthermia, muscle rigidity, autonomic dysfunction, and mental status changes. Laboratory findings include elevated creatine kinase (CK), polymorphonuclear leukocytosis, elevated aldolase, alkaline phosphatase, lactic dehydrogenase, alanine aminotransferase and aspartate aminotransferase, hypocalcemia, hypomagnesemia, low iron, proteinuria, and myoglobinuria.⁶ Approximately 40% of patients with NMS develop medical complications that may be life threatening. NMS is a clinical diagnosis based on the presence of the proper historical setting and the characteristic constellation of signs. Disorders with similar features include malignant hyperthermia, heat stroke induced by neuroleptics, lethal catatonia, other drug reactions, and vascular, infectious, or postinfectious brain damage.

Neuroleptic malignant syndrome is a potentially fatal disease, and a high index of suspicion is required for early recognition and intervention. Treatment includes discontinuing

the offending agent, providing supportive measures, and administering dantrolene or bromocriptine or a combination of the two.

Acute Dystonia

Acute neuroleptic-induced dystonia can be seen early in the course of neuroleptic therapy or with dosage increases. It is often seen following a single parenteral dose of neuroleptics. The manifestations can be diverse, although the most typical clinical signs involve oculogyric crises and opisthotonic posturing. Risk factors include young age, male gender, and use of high-potency neuroleptics.⁷ Acute dystonic reactions are self-limited and, if left untreated, usually subside within 24 hours. Parenteral administration of anticholinergics, such as benztropine or diphenhydramine, offers immediate relief in the majority of cases, but oral anticholinergics should be continued for a few days until the causative neuroleptic is cleared.

Acute Akathisia

Akathisia is a severe form of restlessness associated with the need to move. Typically the patient paces incessantly in place and cannot sit down without continual volitional movement of the legs or feet. The pathophysiology of the syndrome is not well understood but may relate to the development of acute imbalance between the dopaminergic and cholinergic systems. This neuroleptic side effect usually occurs within the first days of therapy or with dosage increases, and it resolves with withdrawal of the neuroleptic agent. Anticholinergics, amantadine, β -blockers, clonidine, and benzodiazepines have also been used with variable success.^{1,6} Late-onset akathisia may be a form of tardive dyskinesia (TD) and may be more difficult to treat (Video 258, Akathisia).

Parkinsonism

Neuroleptic-induced parkinsonism is the result of striatal dopaminergic underactivity due to dopaminergic D_2 receptor blockade. Clinically, it cannot be distinguished from idiopathic Parkinson's disease, although its development occurs as a subacute syndrome within the first weeks of drug introduction or dosage increase (Video 59, Rest Tremor; Video 62, Parkinsonian Gait). Parkinsonian symptoms resolve over a few weeks to 6 months after stopping the causative agent or with the use of antiparkinsonian drugs. Proposed risk factors for development of neuroleptic-induced parkinsonism are female gender, older age, and the use of high-potency agents.^{1,7} Treatment consists of discontinuing or reducing the dosage of the offending agent. Substitution with an atypical neuroleptic, such as clozapine or quetiapine can be considered. In a retrospective cohort study of 25,769 adults prescribed antipsychotics in Ontario, Canada, patients prescribed typical agents were 30% more likely to develop parkinsonism compared to individuals dispensed an atypical antipsychotic. Nevertheless, the risk of development of parkinsonism associated with the use of high-dose atypical antipsychotics was similar to that associated with the use of typical antipsychotics.⁸ Anticholinergics, amantadine, and electroconvulsive therapy are also possible treatments.

Tardive Dyskinesia

Tardive dyskinesia usually appears after several months or years of treatment with antipsychotic medications and almost never before 3 months. No consistent neuropathological changes have been seen in patients with TD, and the predominant hypothesis for its genesis is denervation supersensitivity of the striatal dopamine receptors following chronic blockade.⁶ Risk factors for the development of TD include old age, female gender, presence of affective disorders, history of neuroleptic-induced parkinsonism, presence of organic brain disease, high-potency neuroleptics, sufficient duration of treatment with neuroleptics, and possibly the use of anticholinergic medications, previous electroconvulsive treatment, and drug holidays.

In addition to the well-known oral-buccal-lingual masticatory movements and generalized chorea, dystonia, akathisia, tics, and myoclonus have been described (Video 66, Tardive Dyskinesia). Once TD has appeared, its peak severity is reached rapidly and is often maintained. Following neuroleptic withdrawal, TD may transiently worsen, but this exacerbation is short lived. TD resolves in up to 33% of patients within 2 years after discontinuation of the offending agent.⁹ A recent prospective study comparing risperidone and haloperidol in 350 patients who had not been exposed to neuroleptics before showed that each drug had a similar incidence of dystonia, parkinsonism, akathisia, and dyskinesia.¹⁰

At present, prevention is the treatment of choice for TD. Therefore, neuroleptics should be used only when specifically needed and at the lowest possible doses. Once TD develops, the causative agent should be discontinued, if possible. Alternatively, the patient should be switched to an atypical neuroleptic such as clozapine, which not only does not regularly cause TD but may even relieve its symptoms.⁶ If neurological impairment, disfigurement, or discomfort exists, treatment with the dopamine depleters reserpine or tetrabenazine should be considered. Noradrenergic antagonists (propranolol, clonidine), γ -aminobutyric acid (GABA) agonists (clonazepam, diazepam, valproate, baclofen), botulinum toxin injections, and, to a lesser degree, vitamin E, buspirone, and calcium channel blockers have been used with variable success.^{1,6}

Risk of Death

In a meta-analysis of 15 clinical trials investigating the efficacy of atypical antipsychotics for the treatment of psychotic features in elderly patients with Alzheimer's disease, atypical antipsychotics were found to be associated with a small increase in the risk for death compared to placebo.¹¹ As a consequence, the U.S. Food and Drug Administration (FDA) issued an advisory stating that atypical antipsychotics increase mortality rate in elderly patients. A subsequent retrospective review of 22,890 patients 65 years of age or older who received conventional or atypical antipsychotics between 1993 and 2003 found that conventional antipsychotics are at least as likely as atypical agents to increase the risk of death among elderly patients.¹² Both of these studies are observational in methodology and it should be taken into consideration that observational studies on overall mortality rates are particularly susceptible to numerous biases and should be viewed with extreme care.

Antidepressants

Tricyclic Antidepressants

Tricyclic antidepressants (TCAs) act by blocking primarily norepinephrine or serotonin reuptake and also affect the cholinergic and histaminergic systems (Table 55-3). They have a narrow therapeutic index and can be associated with significant central nervous system (CNS) toxicity. Risk factors for CNS toxicity include plasma level, type of TCA, and concomitant administration of other psychotropic drugs.¹³

Sedation is a very common side effect of TCAs and is most prominent when drug therapy is initiated or when the dosage is increased. Sleep in TCA-treated patients is associated with a decrease in rapid-eye-movement (REM) sleep and may result in a hangover.¹⁴ Confusional states and delirium occur particularly in the elderly or in those treated with high doses, concomitant administration of neuroleptics, or antiparkinsonian medications. Confusion also occurs especially with the use of TCAs with high anticholinergic activity (amitriptyline, imipramine).^{14,15} Anticholinergic effects of TCAs are also responsible for memory impairment, especially in the elderly. TCAs can exacerbate the naturally occurring tendency for depressed patients to become manic and are responsible for a rare but unusual difficulty in articulation that resembles stammer and has been called speech blockade.¹³

Tricyclic antidepressants lower the seizure threshold and may be associated with an increased risk of seizures in individuals who have a history of epilepsy or who are predisposed to have seizures. For imipramine, the most frequently studied TCA, the literature indicates a seizure rate of between 0.3% and 0.6% at effective doses. In general, seizures are observed after long-term treatment with high doses of TCAs or after a rapid increase in dose.¹³

A high-frequency postural and kinetic tremor may be present in as many as 10% of patients treated with imipramine. Myoclonus, akathisia, and choreoathetoid movements are additional rare side effects seen with TCAs (Video 57, Myoclonus).^{1,13}

Tricyclic antidepressants are a serious cause of drug-related death in the United States. The signs and symptoms of TCA overdose are cardiovascular instability, CNS depression, and anticholinergic toxicity. TCA-induced drowsiness and coma can be reversed by the cholinergic agonist physostigmine.¹⁴

TABLE 55-3

Action of Tricyclic Antidepressants

| DRUG | ANTICHOLINERGIC ACTION | SEROTONIN REUPTAKE INHIBITION | NOREPINEPHRINE REUPTAKE INHIBITION |

| Doxepin | ++ | + | + |
| Clomipramine | ++ | +++ | + |

+ + +, significant; + +, moderate; +, low; +/-, inconsistent.

Selective Serotonin Reuptake Inhibitors

The selective serotonin reuptake inhibitors (SSRIs) are potent and selective inhibitors of serotonin reuptake at the presynaptic terminal. They are considered first-line therapy for depression because of their prescribing ease and superior side effect and safety profile. SSRI-induced side effects are usually transient and rarely result in discontinuation of the medication. In addition, they appear to be safer than TCAs when an overdose occurs.

The major side effects of the SSRIs referring to the CNS include nausea, headache, dry mouth, insomnia and somnolence, agitation, nervousness, sweating, dizziness, tremor, and sexual dysfunction.¹⁵ Fluoxetine is often associated with anxiety, nervousness, insomnia, and anorexia. Paroxetine, fluvoxamine, and nefazodone are associated with sedation. Sexual dysfunction manifests itself as ejaculatory delay in men and anorgasmia in women.¹⁶ SSRIs have been shown to inhibit the cytochrome P-450 system both in vitro and in vivo and, therefore, to result in increased levels of drugs that are substrates of cytochrome P-450 as well (i.e., TCAs). Escitalopram, has no effect on the cytochrome P-450 and citalopram has only limited effect. There has been debate over whether the combination of SSRIs and monoamine oxidase inhibitors (MAOIs) or TCAs can lead to the serotonin syndrome, characterized by hyperpyrexia, myoclonus, rigidity, hyper-reflexia, shivering, confusion, agitation, restlessness, coma, autonomic instability, low-grade fever, nausea, diarrhea, diaphoresis, flushing, and, rarely, rhabdomyolysis and death.^{15,17} This occurrence is probably uncommon but should be watched for and immediately handled with supportive care and drug withdrawal if it occurs. Several case reports in the literature suggest that SSRIs can produce extrapyramidal symptoms in the form of akathisia, dyskinesia, acute dystonia, and deterioration in Parkinson's disease, but controlled clinical studies are needed to determine the validity of these observations. In a review of 514 cases with subarachnoid hemorrhage, concurrent use of SSRIs was found to be a risk factor for subarachnoid hemorrhage-related vasospasm.¹⁸

Several scientific publications have suggested the possibility of an increased risk of suicidality in adults being treated with antidepressant medications. Most systematic reviews of randomized controlled trials failed to reveal any evidence of an increased risk of suicide or nonfatal self-harm in adults prescribed SSRIs but found some weak evidence in those aged 18 or younger.¹⁹

Monoamine Oxidase Inhibitors

Monoamine oxidase is an intramitochondrial enzyme responsible for the breakdown of intracellular dopamine, norepinephrine, and serotonin. MAOIs inhibit monoamine oxidase, resulting in an increase in the concentration of monoamines in the synapse. Therefore, when patients taking MAOIs ingest vasoactive amines in foods and beverages (e.g., cheese, chocolate, pickled herring, chicken livers, caviar, broad beans, wine, beer), or take certain medications (e.g., amphetamines, ephedrine, reserpine, L-dopa, tryptophan), the vasoactive amines are not catabolized but enter the bloodstream and are taken up by the nerve terminals (Table 55-4). The result is a cataclysmic

TABLE 55-4

Potential Interactions with Monoamine Oxidase Inhibitors

syndrome consisting of sudden severe headache, stiff neck, profuse sweating, mydriasis, neuromuscular irritability, extreme hypertension, and cardiac arrhythmias. The most effective treatment is phentolamine, or sodium nitroprusside, and for less severe cases, chlorpromazine.^{1,13,15,16} When MAOIs are taken in combination with TCAs in high doses or in overdose, or when MAOIs are taken with the narcotic analgesic meperidine, a severe condition of hyperpyrexia can occur.¹⁵

The MAOIs cause odd mixtures of sedation and stimulation. All three available drugs—tranylcypromine, phenelzine, and isocarboxazid—can cause insomnia, daytime sedation, aberrant changes in the sleep-wake cycle, and suppression of rapid-eye-movement sleep. In some patients, tranylcypromine can have amphetamine-like effects such as tremor and heightened locomotion activity about 1 hour after each dose, but it also causes sedation. This and other drugs in the group can produce mild euphoria as a prolonged effect.¹⁶ Other side effects include myoclonic jerks, paresthesias of the extremities, and sexual dysfunction.

Lithium Carbonate

Lithium carbonate is indicated for the treatment of mania and for maintenance therapy in patients with a history of bipolar disorder. The majority of patients suffer side effects at therapeutic doses, although most patients classify them as mild. A fine postural or intentional tremor occurs in up to 80% of patients on lithium therapy (Video 69, Lithium-Induced Postural Tremor). This side effect may resolve spontaneously, respond to a decrease in dose, or be treated with β -adrenergic blockers.²⁰ Additionally, multifocal action myoclonus without reflex activation and only rare occurrence at rest has been recorded in association with lithium treatment. A cortical focal EEG (electroencephalogram) transient over the contralateral sensorimotor cortex, preceding the myoclonus EMG (electromyogram) discharge, was associated the myoclocus.²¹ Case reports have described

choreiform movements or parkinsonism associated with lithium treatment.²²

Poor memory, loss of concentration, fatigue, muscle weakness, slowed reaction time, and lack of spontaneity are common during the course of treatment. These side effects cannot be consistently related to drug serum levels, duration of treatment, dose, age, or other variables. A toxic confusional state may occur in the absence of signs of toxicity and at relatively low serum lithium levels. This is characterized by disorientation, confusion, lack of continuity of thought, memory loss, lability of mood, and reduced comprehension. The symptoms are preceded by a steady or precipitous rise in oral lithium dose, often within the first weeks of treatment, but may occur at serum lithium levels as low as 1.0 mEq/L. The condition usually remits within a few days following reduction or withdrawal of the dose.¹ Chronic lithium administration has been associated with psychomotor slowness and impaired verbal memory.²³

Lithium intoxication manifests itself with nausea, vomiting, diarrhea, tremor, drowsiness, ataxia, muscle twitching, and slurred speech. As intoxication advances, ataxia, alteration of the level of consciousness, and, eventually, seizures and coma occur. Until recently, it was thought that patients who survived severe lithium intoxication suffered no permanent neurological damage. However, reports indicate that the basal ganglia and the cerebellum can be permanently damaged following lithium intoxication.¹

Finally, lithium has been associated with syndromes similar to myasthenia gravis, NMS, lowering of the seizure threshold, pseudotumor cerebri, headaches, polyneuropathy, and downbeating nystagmus. A case report with neuropathological evaluation of a patient who expired due to lithium toxicity showed severe cerebellar atrophy of the internal granule and Purkinje cell layers with attendant Bergmann gliosis.²⁴ Finally, downbeat nystagmus and periodic alternating nystagmus have been reported with lithium therapy (Video 223, Downbeat Nystagmus).²⁵ Rarely, a syndrome of irreversible lithium-effectuated neurotoxicity (SILENT) can occur, defined as persistence of neurological sequelae at least 2 months after cessation of lithium administration. Persistent cerebellar dysfunction was the commonly reported sequela.²⁶ Although the pathogenesis of this syndrome is unclear, demyelination has been postulated (Video 211, Gait Ataxia).

Benzodiazepines

Benzodiazepines potentiate GABA action in the nervous system and act on the spinal cord as well as in many areas within the brain, including the cerebellum, the limbic system, and the cerebral cortex. Although the therapeutic index of benzodiazepines is 10 to 30 times that of the barbiturates and hence their absolute toxicity is less, adverse reactions are 7 times more frequent with benzodiazepines.¹ This statistic apparently relates to the vast number of patients consuming these agents.

The most frequent toxic symptoms are increased drowsiness or paradoxical excitation. After large doses, exacerbation of depression and antisocial behavior have been reported. Withdrawal seizures can occur as well. Encompassing the range from subtle cognitive impairments to frank delirium, toxicity due to benzodiazepines is associated

with impairment of immediate and delayed memory, psychomotor performance, and rebound insomnia.

Physiological dependence on benzodiazepines is accompanied by a withdrawal syndrome that is typically characterized by sleep disturbance, irritability, increased tension and anxiety, panic attacks, hand tremor, sweating, difficulty in concentration, nausea, weight loss, palpitations, headache, muscular pain, and stiffness. Factors that contribute to the development of withdrawal symptoms are primarily dose, duration, concurrent medication, and pharmacokinetics of individual drugs. The shorter-acting drugs can produce a more intense withdrawal syndrome following chronic administration.²⁷ No specific treatment exists for the withdrawal syndrome, which commonly lasts for up to 6 weeks, although tapering the benzodiazepine dose, sedative antidepressants, or the substitution of a longer-acting benzodiazepine may help.

Even short-term benzodiazepine use can lead to the development of tolerance, necessitating larger doses of drug to be administered.

ANESTHETICS

Inhalational General Anesthetics

Halothane, Enflurane, Isoflurane, and Sevoflurane

Halothane, a halogenated hydrocarbon, was first synthesized in 1951. It was introduced into clinical practice in 1956 in the United Kingdom and in 1958 in the United States. It quickly replaced the other volatile agents because it was nonflammable, easy to administer, and relatively safe. Halothane, enflurane, isoflurane, and sevoflurane depress cerebral metabolism, with isoflurane having the greatest effect.²⁸ Electrical activity of the cerebral cortex recorded by a fronto-occipital electroencephalogram (EEG) shows progressive replacement of fast, low-voltage activity by slow, high-amplitude waves as anesthesia gets deeper.²⁹ Since cerebral blood flow generally increases during halothane anesthesia, cerebrospinal fluid (CSF) pressure increases. After several hours of anesthesia with halothane, the changes in cerebral blood flow and metabolism return to normal. Recovery of mental function after anesthesia with halothane is not complete for several hours.²⁹ Behavioral disturbance following general anesthesia with inhalational general anesthetics in children is a relative frequent event and includes emergence delirium, maladaptive postoperative behavioral changes, and sleep disturbances that can last up to 1 month following the administration of the anesthetic. Some reports have found a higher incidence of immediate postoperative changes with sevoflurane,³⁰ but other reports have failed to find a difference between the two anesthetics.³¹

Tonic-clonic activity and spike and wave EEG complexes have been reported with enflurane anesthesia (Video 77, Clonic Seizure). Deepening anesthesia and hyperventilation may exacerbate these phenomena. This excitatory action of enflurane does not appear to be associated with aggravation of seizures in epileptic patients; nevertheless, enflurane is best avoided in such patients.^{28,29} Sevoflurane has been found to consistently produce epileptiform discharges and is dose dependently epileptogenic at surgical levels of anesthesia.³²

Rarely, the induction of anesthesia with halothane or any of the other halogenated inhalational anesthetics triggers an uncontrolled hypermetabolic reaction in the skeletal muscle of susceptible patients. There is defective uptake of Ca^{2+} by the sarcoplasmic reticulum, resulting in elevation of intracellular free Ca^{2+} levels. The resultant syndrome of malignant hyperthermia has an incidence of 1 in 12,000 and a mortality rate of 24%.²⁸ It is more common in men and children, in association with various myopathies, and in genetically susceptible individuals. Mutations in the gene encoding the skeletal muscle ryanodine receptor (RYR1) are considered a common cause of the disorder, and to date, more than 20 RYR1 mutations have been reported in European and Canadian families.³³ Malignant hyperthermia is produced most often by halothane, which is more common than enflurane, which, in turn, is more common than isoflurane. The concomitant use of suxamethonium and gallamine, neuroleptics, infection, stress, heat, and alcohol tend to increase the risk of malignant hyperthermia. Larach and colleagues demonstrated that generalized muscle rigidity that occurs as a result of an anesthetic is a valuable, but not absolute, predictor of a patient's susceptibility to malignant hyperthermia, its presence being associated with an 18-fold increase in risk of being susceptible, as determined by subsequent muscle biopsy testing.³⁴

Clinically, there is a rapid rise in body temperature, generalized muscular rigidity, high metabolic rate with increased oxygen consumption and carbon dioxide production, tachycardia, tachyarrhythmias, metabolic acidosis, and hyperkalemia. The most reliable method of diagnosis is by muscle biopsy and in vitro contracture tests with halothane and caffeine.²⁹ Treatment consists of cessation of known triggering agents, supportive measures, and the administration of dantrolene.

Nitrous Oxide

Nitrous oxide (N_2O), or so-called laughing gas, was first used as a dental anesthetic. When used by itself, it produces a light level of anesthesia; when used to supplement more potent anesthetics, it reduces the dose requirements for those agents. However, its euphorogenic properties, ready availability, and low cost have contributed to its popularity as a recreational gas. Human nitrous oxide toxicity is associated with its occupational, iatrogenic, and recreational use.

Nitrous oxide toxicity is due to inactivation of methionine synthase, a vitamin B_{12} -dependent enzyme, resulting in defective biosynthesis of DNA and myelin in nervous tissue. Monkeys exposed to 15% nitrous oxide develop the biochemical changes and neurological signs of vitamin B_{12} deficiency very rapidly. Morphologically, their spinal cords show degeneration of both the myelin sheaths and axis cylinders in the posterior columns and in the lateral and anterior corticospinal and spinocerebellar tracts.³⁵

Nitrous oxide is more likely to produce megaloblastosis or subacute combined degeneration-like clinical presentation when it is used repetitively or for periods longer than 3 hours or in individuals with vitamin B_{12} deficiency. Reversible nitrous oxide myelopathy and a case of

generalized hypotonia, seizures, apnea, and eventual respiratory arrest and death have been described in patients with 5,10-methylenetetrahydrofolate reductase (MTHFR) deficiency after anesthesia with nitrous oxide. Patients with MTHFR deficiency characteristically have high homocystine and low methionine plasma concentrations.^{36,37} Occupational exposure of medical and dental personnel during its use as an analgesic is not likely to produce adverse neurological effects except in vitamin B₁₂-deficient individuals or in those routinely exposed to high nitrous oxide levels.³⁸ An epidemiological survey of over 30,000 dental personnel occupationally exposed to nitrous oxide found an incidence of neurological complaints of less than 2% in the population at risk.³⁵ In the elderly, in whom subclinical vitamin B₁₂ deficiency reportedly ranges from 7.3% to 21%, the frequency of neuropathic symptoms after anesthesia due to nitrous oxide may be under-recognized.³⁹

Clinically, nitrous oxide neuropathy presents with numbness, paresthesias, ataxia, and clumsiness in the extremities (Video 5, Sensory Ataxia). Many but not all of the symptoms resolve with time if exposure is discontinued. With further exposure, weakness, gait disturbance, impotence, and loss of sphincter control can occur.³⁵ Administration of folinic acid or methionine have been shown to protect against megaloblastosis and neurotoxicity occurring following nitrous oxide administration.³⁸

Tension pneumocephalus can follow any intracranial neurosurgical procedure if nitrous oxide has been used. Following dural closure, the increase in volume due to nitrous oxide can result in pressure changes that may lead to seizures, brain stem herniation, and death. Discontinuing nitrous oxide at the time of dural closure can prevent tension pneumocephalus. Nitrous oxide can expand air emboli in the bloodstream. In patients undergoing posterior fossae exploration in the sitting position, nitrous oxide increases the risk of air emboli and should be avoided.³⁵

Local Anesthetics

When applied locally, local anesthetics reversibly block the action potentials responsible for nerve conduction. The most commonly used local anesthetics are cocaine, lidocaine, bupivacaine, chlorprocaine, etidocaine, mepivacaine, prilocaine, ropivacaine, procaine, and tetracaine. Local anesthetics entering the systemic circulation produce adverse effects primarily on the CNS. Usually, when they are administered locally, they cannot reach sufficient systemic concentrations to interfere with the function of organs where conduction or transmission of impulses occurs.⁴⁰ Nevertheless, when systemic absorption occurs after topical use of local anesthetics, as is the case in children when tetracaine, adrenaline, and cocaine is applied to mucous membranes, CNS toxicity has been described.^{41,42}

The first sign of systemic toxicity following administration of local anesthetics is drowsiness, followed by tremor, restlessness, convulsions, and, ultimately, CNS depression with respiratory failure.⁴³ Lidocaine and cocaine can produce changes in mood and behavior. Finally, local anesthetics can affect neuromuscular transmission. This effect is due to blockade of the ion channel of the acetylcholine receptor.⁴⁰

Epidural and Spinal Anesthesia

Epidural anesthesia is administered by injecting local anesthetic into the epidural space and can be performed in the sacral hiatus or in the lumbar, thoracic, or cervical regions of the spine. Spinal anesthesia follows the injection of local anesthetic into the CSF in the lumbar space. Significant differences between epidural and spinal anesthesia are that the dose of local anesthetic used in epidural anesthesia can produce high concentrations in blood following absorption from the epidural space and that there is no zone of differential sympathetic blockade with epidural anesthesia; thus the level of sympathetic block is close to the level of sensory block.⁴⁰

Probable causes of neurological complications following epidural and spinal anesthesia include trauma, the nature of the injected material, infection, vascular lesions, or pre-existing pathology. The incidence of transient paralysis following epidural anesthesia is 0.1%, and the incidence of permanent paralysis is 0.02%.⁴⁴ Neurological sequelae after spinal anesthesia are rare as well. Neurological complications of spinal or epidural anesthesia tend to be more severe in the presence of spinal stenosis.

During the administration of epidural anesthesia, damage to a single nerve can occur and is the most frequent complication. Paresthesia, with or without motor weakness, is the presenting symptom, and the majority of patients recover completely. Paraplegia, resulting from myelopathy or cauda equina syndrome, can occur secondary to epidural hematoma or abscess, adhesive arachnoiditis, or anterior spinal artery occlusion. An epidural hematoma or abscess should be suspected if severe backache appears in combination with weakness and hypoalgesia of the lower extremities. Signs and symptoms of extradural abscess may be delayed for several days until the abscess has developed. Adhesive arachnoiditis may result from inadvertent sub-arachnoid administration of toxic chemicals or chemical contamination of anesthetic solutions. Chemical contaminants such as detergents or antiseptics act as irritants and induce a meningeal reaction that may progress to constrictive adhesive arachnoiditis. Clinically, gradual progressive weakness and sensory loss of the lower extremities occurs beginning several weeks to months after the procedure. Precontrast and postcontrast magnetic resonance imaging (MRI) scans are usually sufficient to diagnose arachnoiditis. Spinal cord infarction is usually associated with prolonged arterial hypotension and can occur whether or not epinephrine was added to the local anesthetic.⁴⁴⁻⁴⁶ Finally, dural puncture may cause severe and prolonged headache because of leakage of CSF into the extradural space. The incidence of dural puncture is about 1%.⁴⁵ Fortunately, most patients never develop a spinal headache or the problem resolves spontaneously in a few days. The use of an extradural injection of autologous blood (a so-called blood patch) is usually effective in treating spinal headaches.

The neurological syndromes that appear after spinal anesthesia are similar to the ones described following epidural anesthesia. The most benign is aseptic meningitis, characterized by high fever, headache, nuchal rigidity, and photophobia. Symptoms usually appear within 24 hours of spinal anesthesia, and recovery occurs spontaneously within several days to a week.⁴⁴ Cauda equina syndrome is characterized

by urinary and fecal incontinence, localized sensory loss in the perineal area, and varying degrees of leg weakness. These symptoms are evident after the effect of anesthesia has worn off and may be permanent or may show gradual regression over weeks or months. Single nerve injury, lumbosacral polyradiculopathy, adhesive arachnoiditis, spinal cord ischemia, and postural headache can occur under circumstances similar to the ones described for epidural anesthesia. Two large prospective studies found a low rate of transient neurological symptoms and an 8.5% of postdural puncture headache (4% mild and 4% moderate to severe) following spinal anesthesia.^{47,48}

Spinal anesthesia is sometimes regarded as contraindicated in patients with pre-existing disease of the spinal cord. Although there is no experimental evidence to support this hypothesis, it is prudent to avoid spinal anesthesia in patients with progressive diseases of the spinal cord.⁴⁰

DRUGS USED TO TREAT MYASTHENIA GRAVIS

Cholinesterase Inhibitors

Cholinesterase inhibitors interfere with the hydrolysis of acetylcholine at the cholinergic synapses. Peripherally active agents have been the mainstay of myasthenic treatment until the advent of immunosuppressive therapy in the 1960s. Pyridostigmine bromide and neostigmine bromide are the most commonly used cholinesterase inhibitors. Pyridostigmine bromide is preferred because it has fewer gastrointestinal side effects and a longer duration of action.

Side effects of cholinesterase inhibitors result from overstimulation of the cholinergic system at the level of the muscarinic receptors of the smooth muscle, the nicotinic receptors of the skeletal muscle, the autonomic glands, and the CNS. Signs of cholinergic excess include nausea, abdominal cramps, excessive secretions, and bronchospasm. This syndrome is distinct from myasthenia gravis and is usually diagnosed accurately. However, because overstimulation can lead to subsequent depolarization blockade and enhanced weakness, exacerbation of myasthenia and cholinergic crisis can be dangerously confused. In situations in which there is a question of too much or too little cholinesterase inhibition, edrophonium (Tensilon) given in 1-mg increments may be helpful. More likely, however, admission to an intensive care unit (ICU) for transient cessation of cholinesterase inhibition is needed to elucidate whether the dose should be raised or lowered.

It has been suggested that chronic administration of cholinesterase inhibitors may damage the neuromuscular junction. This concern is based in part on the chronic effects on the neuromuscular junction known to occur in animals after large doses of prostigmine and reported decrease in improvement after thymectomy when the use of cholinesterase inhibitors increased. Nevertheless, the latter was a retrospective review, and therefore, there is no evidence that would discourage the use of cholinesterase inhibitors to treat myasthenia gravis when needed.⁴⁹

Glucocorticosteroids

Neurological side effects of glucocorticosteroids are well described and may be as serious as the diseases being

treated. Neuropsychiatric disorders and myopathy are common. Most of the neurological sequelae are often related to dosage and duration of therapy and may be reversible by modification of the drug regimen.⁵⁰ Glucocorticosteroid use can be associated with a broad spectrum of neuropsychiatric disorders, ranging from emotional lability and anxiety to confusion, mood disorders, and psychosis. Behavioral symptoms usually begin within 5 to 14 days of starting steroids, but they may also occur during withdrawal of therapy. With the exception of multiple sclerosis, pre-existing neurological disease does not appear to increase the risk of steroid-induced mental status abnormalities. Alternate-day steroid therapy may decrease the overall incidence of behavioral changes, although it may rarely induce a cyclic behavior, with mania occurring on high-dose days and depression occurring on low-dose days. Steroid treatment is frequently associated with transiently impaired attention, concentration, and memory. In rare cases, cognitive changes may be prominent and may persist for substantial periods of time after steroid discontinuation.⁵¹

Steroid myopathy is probably the most common drug-related disorder of muscle. There are two forms of myopathy: a common, well-known, chronic form involving type II fiber atrophy and a rare acute form that occurs during treatment for status asthmaticus and may be associated with rhabdomyolysis. The exact incidence of the more typical chronic myopathy is uncertain, but in one series of patients with rheumatic disease, it was reported to be 7%.⁵⁰ The syndrome consists of insidious onset of painless, symmetrical proximal muscle weakness and atrophy, with the lower extremities involved first. Bulbar muscles are spared, but the diaphragm may be involved. The time of onset is variable, and the symptoms may begin from several weeks to several months after beginning treatment. The serum CK is normal and EMG reveals short-duration, low-amplitude motor unit action potentials. Muscle biopsy shows type II atrophy, and electron microscopy reveals glycogen accumulation and enlarged mitochondria. Treatment consists of tapering and discontinuing the offending agent or substituting another steroid. The uncommon acute myopathy has been reported mainly in asthmatic patients who are receiving IV steroids, paralytic agents, and mechanical ventilation. The pathogenesis is unclear.⁵⁰

Steroid-induced deposition of fat in the epidural space occurs in patients taking more than 40 mg of prednisone for at least 4 months. Most of these patients are already cushingoid when consequent neurological symptoms occur. The earliest and most common feature is low back pain, and depending on the level of the lipomatosis, signs of myelopathy, cauda equina syndrome, or radiculopathy may develop. MRI can be a very useful diagnostic tool. Fat appears to be hyperintense on T1-weighted images and less intense on T2-weighted images, in contrast with inflammatory processes, which are brighter on T2-weighted images. Unless it is contraindicated, laminectomy has been the treatment of choice. Further studies are needed to clarify the response to steroid tapering without surgical decompression before the onset of significant myelopathy. There have been isolated reports of corticosteroid-induced lipomatosis in the perineural spaces of peripheral nerves, leading to entrapment neuropathies.⁵⁰

Increased intracranial pressure (ICP) has been associated with steroid use, and the vast majority of cases involve male children. No particular dose has been implicated, but the duration of treatment is usually prolonged. Symptom onset generally occurs after discontinuation, tapering, or change in the type of steroid. Signs and symptoms are consistent with elevated ICP: headache, nausea, vomiting, papilledema, and diplopia with abducens nerve palsy (Video 1, Cranial Nerve VI Palsy). The disorder is usually self-limited. Patients have improved after changing the type or dose of steroids (using lower or higher dose) or lumbar puncture.⁵⁰

Glucocorticosteroids have been reported to enhance physiological tremor. Propranolol can be useful in controlling this movement disorder if steroid withdrawal is not possible. Intrathecal administration of glucocorticosteroids can be associated with sterile meningitis, arachnoiditis, and pachymeningitis. Epidural steroids can have the same complications because the epidural and subarachnoid spaces are not totally separate but communicate via arachnoid villi and epidural veins. Additionally, inadvertent subarachnoid injections occur during about 2.5% of epidural attempts.⁵⁰

Azathioprine

Side effects due to azathioprine (the nitroimidazole derivative of 6-mercaptopurine) can be classified as toxic (myelosuppression, hepatotoxicity) and idiosyncratic (fever, rigors, arthralgias, pneumonitis, and gastrointestinal symptoms). Although the toxic effects are due to 6-mercaptopurine, the hypersensitivity reactions are believed to be caused by the nitroimidazole moiety.

Azathioprine toxicity can occur during long-term treatment of myasthenia gravis.^{52,53} Among 104 treated patients with myasthenia gravis, side effects occurred in 35% and included, in decreasing frequency, hematological, 18%; gastrointestinal, 13%; infectious, 13%; and elevation of liver enzymes, 6%. The medicine was discontinued temporarily in 11% of the patients. In five patients, a malignant tumor was diagnosed, but a causal relationship seemed likely in only one.⁵² Neurological toxicity is rare with azathioprine. Two patients with recurrent meningitic reactions following azathioprine ingestion have been presented in the literature; they were being treated for lupus of the CNS.⁵⁴ A rare complication of long-term treatment with azathioprine is the development of primary central nervous system lymphoma. The incidence of primary central nervous system lymphoma associated with chronic azathioprine therapy is directly associated with the duration of treatment and is higher for older individuals.⁵⁵

Cyclosporine

Cyclosporine is reviewed under section titled Transplant Drugs.

ANTIBIOTICS (Tables 55-5 and 55-6)

Antibacterial Agents

Penicillins, Cephalosporins, and Imipenem

Historically, radiculitis, paraplegia, hemiplegia, and convulsions occurred after penicillin was administered into

M, motor; S, sensory.

the CSF, but because this route of administration has been abandoned, such reactions are exceedingly rare. The neurotoxic clinical manifestations of penicillins, cephalosporins, and imipenem include myoclonus, seizures, confusion, hallucinations, encephalopathy, nystagmus, and agitation.^{56,57} Imipenem, cefazolin, and benzyl penicillin are the most epileptogenic.⁵⁸ These drugs antagonize the inhibitory neurotransmitter GABA. Status epilepticus occurred in two patients treated with cefapime; seizures did not respond to anticonvulsant therapy but subsequently resolved with discontinuation of this fourth-generation cephalosporin.⁵⁹

Risk factors for neurotoxicity are high-dose intravenous use (e.g., >30 to 40 million units of benzyl penicillin per

day), decreased renal function, abnormal blood-brain barrier, cardiopulmonary bypass, age more than 50 years, pre-existing CNS disease, concurrent use of drugs that may lower the seizure threshold (such as theophylline or ciprofloxacin), and concomitant use of nephrotoxic drugs. Blockade of a system for transporting the β -lactams out of the CSF in diseases causing meningeal inflammation adds to the risk of increased meningeal antibiotic penetration during inflammation.

Penicillin gluteal injection may cause sudden and irreversible paraplegia. The actual incidence of such a complication is not known, but there have been eight cases reported in the literature. The proposed mechanism is accidental intra-arterial injection, causing distal spasm and the upstream ascent of penicillin with ensuing embolic or spastic occlusion, or both, of the anterior spinal artery. Treatment of this complication is unsatisfactory, but it can be prevented by giving injections in the lateral thigh.⁶⁰

Penicillins and cephalosporins have also been reported to cause recurrent aseptic meningitis.⁶¹ Ampicillin has been reported to aggravate weakness in myasthenia gravis. Intrathecal β -lactams have the potential to cause adhesive arachnoiditis.⁵⁸

Aminoglycosides

The toxicity of all aminoglycosides is similar—mainly ototoxicity and neuromuscular blockade (Table 55-7). Acute ototoxicity is based on calcium antagonism and blockade of ion channels, and chronic mechanisms are related to tissue-specific toxicity of a noxious metabolite. Genetic analyses suggest that ototoxicity to aminoglycosides may be related to genetic mutations in mitochondrial ribosomal RNA in susceptible individuals.⁶² Excitotoxicity has also been implicated as the mechanism for ototoxicity with aminoglycoside use. A recent animal study showed that spiral ganglion neuronal loss can be prevented by neurotrophin 3, and protection against hair cell damage occurs with *N*-methyl-D-aspartate receptor antagonists.^{63,64}

The frequency of ototoxicity ranges from 2% to 4% in retrospective studies and up to 25% in studies with specialized testing. The incidence and severity of damage appear to increase with patient age, total drug dose, and concomitant use of other ototoxic drugs.⁶⁵ Auditory toxicity is more common with the use of amikacin and kanamycin, whereas vestibular toxicity predominates following gentamicin and streptomycin therapy. Tobramycin is associated equally with vestibular and auditory damage.

TABLE 55-7

Aminoglycoside Neurotoxicity

| DRUG | COCHLEAR TOXICITY | VESTIBULAR TOXICITY | NEUROMUSCULAR TOXICITY |
|--------------|-------------------|---------------------|------------------------|
| Neomycin | + | ++ | +++ |
| Kanamycin | ++ | + | + |
| Streptomycin | + | ++ | ++ |
| Gentamicin | + | ++ | ++ |
| Tobramycin | + | + | + |
| Amikacin | ++ | + | ++ |
| Netilmicin | ++ | + | +++ |

+++ , very common; ++ , moderately common; + , rare.

Cochlear toxicity is more often silent, as the hearing loss first affects the high frequencies (>4000 Hz) before involving the speech frequencies. Cochlear toxicity presents clinically as deafness, tinnitus, and ear pain, whereas vestibular toxicity presents as ataxia, dizziness, vertigo, chronic sense of imbalance, nystagmus, or oscillopsia.⁵⁸ Routine audiometry or studies of auditory brain stem evoked responses can be used to monitor ototoxicity. Monitoring vestibular toxicity is complex and needs even more specialized testing.⁵⁸ Aminoglycoside hearing loss is usually irreversible and may even progress following discontinuation of drug therapy.⁶⁵ Careful monitoring of peak and trough levels, especially in high-risk groups, helps prevent toxicity.

A potentially fatal neurotoxic effect of all aminoglycosides is neuromuscular blockade, due in part to a curare-like effect of the aminoglycosides and also to a competition with calcium by these antibiotics (Video 42, Fatigability). This side effect is related to dose and serum level. Aminoglycosides are relatively contraindicated in both presynaptic (e.g., botulism) and postsynaptic (e.g., myasthenia gravis) disorders of neuromuscular transmission.⁵⁸ They may further potentiate ether and other drugs used to induce muscular relaxation during anesthesia. Neomycin and netilmicin are the most toxic, and tobramycin and kanamycin are the least toxic. Sudden or prolonged respiratory paralysis due to aminoglycosides may be reversed by calcium infusion, cholinesterase inhibitors, and aminopyridines.⁵⁸

Sulfonamides

Sulfonamides inhibit the synthesis of tetrahydrofolic acid, the one-carbon donor needed for the synthesis of methionine, serine, and purines. Although sulfonamides are associated with low incidence of neurotoxicity, a variety of adverse reactions can occur during therapy.¹ Recurrent aseptic meningitis is a well-recognized side effect of sulfonamide therapy, more specifically trimethoprim-sulfamethoxazole, and presents clinically with episodes of headache, nuchal rigidity, confusion, and myalgias. CSF analysis may show low glucose levels with or without pleocytosis; however, this study is not a reliable method to differentiate antibiotic-induced meningitis from partially treated bacterial meningitis.⁶¹

In addition, headache, fatigue, tinnitus, generalized convulsions, optic neuritis, agraphia, aphasia, stammering, teleopsia, macropsia, polyneuritis, and myelopathy can occur with sulfonamides. Euphoria, nausea, vomiting, somnolence, poor concentration, and impairment of judgment may be observed on the second or third day of treatment. The pathophysiology of the neurotoxic signs may relate to a drug-induced hypersensitivity reaction, because they often occur in the context of serum sickness or drug-induced vasculitis. Pathologically, a variety of lesions have been reported in fatal cases, including focal necrosis and demyelination of the cerebral white matter, hypothalamus, and pons, as well as hemorrhages in the fourth ventricle, brain stem, cerebral gray matter, and nuclear structures.^{1,58}

Quinolones

Seizures have been reported with ciprofloxacin as well as other quinolones, and the use of nalidixic acid, the first

clinically useful quinolone, is contraindicated in patients with a history of epilepsy. In vitro studies suggest that the epileptogenic effect of the quinolones may be due to inhibition of GABA binding to its receptor site in the brain. This effect seems to be related to quinolone concentrations at the receptor site (dose related) and to particular substituents in quinolone structure. Simultaneous use of theophylline or nonsteroidal anti-inflammatory drugs may increase the risk for quinolone-associated toxic effects on the CNS, as the combination has an additive inhibitory effect on GABA sites.⁶⁶

CNS side effects are seen in 1% to 4% of patients but are usually minor, including dizziness or mild headache. Quinolones have been reported to cause tremor, restlessness, hallucinations, delirium, psychosis, and benign intracranial hypertension, especially in high-dose therapy.⁶⁶ Especially in cases of renal impairment, the dose should be carefully monitored to avoid CNS toxicity.

Metronidazole

Metronidazole, a nitroimidazole derivative, is used for anaerobic and protozoal infections, as well as for the treatment of Crohn's disease. It is generally well tolerated, but it is associated with minor, transient adverse side effects. However, peripheral neuropathy is a potentially serious effect associated with the use of metronidazole. The mechanism of metronidazole peripheral neuropathy is undetermined, but the drug binds to the RNA of rat nerve cells, which may diminish protein synthesis and lead to subsequent nerve degeneration.

Neuropathy is particularly prevalent in patients who receive more than 2 g/day, a total dose of 50 g or more, and a treatment duration of at least 30 days. In long-term administration, 10% to 50% of patients develop a sensory neuropathy that is predominantly distal and symmetrical (Video 259, Sensory Polyneuropathy). Sensory deficits are prominent, with the sural and peroneal nerves most often affected. The paresthesias and discomfort associated with metronidazole neuropathy usually improve when metronidazole is discontinued or the dose is decreased. Symptoms gradually subside within 4 to 48 months following drug cessation. Rarely, neuropathic symptoms persist for an extended duration, worsen, or are irreversible. These atypical clinical courses may be related to metronidazole-induced nerve degeneration.

Metronidazole has rarely been associated with seizures in humans. It is believed that the total cumulative dose of metronidazole is more closely associated with seizure potential than the serum level.⁶⁷ Confusion, irritability, depression, headache, optic neuropathy, and aseptic meningitis have been reported as drug complications. Additionally, there are case reports of cerebellar lesions and diffuse encephalopathy associated with abnormalities on magnetic resonance imaging.^{68,69} These rare complications can be associated with large doses or prolonged administration, and they disappear rapidly with cessation of the drug.

Erythromycin and Newer Macrolides

Macrolides are among the safest anti-infective drugs in clinical use. An uncommon neurological side effect is

temporary hearing loss. Whereas erythromycin-induced hypoacusis is a dose-dependent effect, its occurrence in patients otherwise free from predisposing factors suggests that it is idiosyncratic.⁷⁰ Usually, this reaction has occurred during treatment with 4 g or more of the lactonate derivative of oral erythromycin. Because erythromycin is metabolized by the liver, patients with hepatic abnormalities may be at higher risk for this ototoxic reaction. Tinnitus rather than a distinct difficulty hearing is the usual complaint.¹ This adverse reaction is reversible with dose reduction or discontinuation, and in patients with impaired renal or liver function, a lower prescribed daily dose may prevent or reduce its development. Azithromycin, a new macrolide antibiotic, has also been reported to cause sensorineural hearing loss.^{71,72} Erythromycin interacts with carbamazepine, causing carbamazepine levels to increase rapidly when erythromycin is introduced. Careful monitoring of the carbamazepine blood level and clinical symptoms of toxicity should be performed in patients receiving both drugs. Worsening of weakness in patients with myasthenia gravis, through a possible presynaptic mechanism, is generally mild, although respiratory failure may be precipitated.⁵⁸ Azithromycin and clarithromycin treatment has been associated with acute psychotic episodes.^{73,74}

Tetracyclines

Vestibular toxicity has been reported in approximately 50% of patients receiving minocycline, a tetracycline derivative. Toxicity is more common in women, and the incidence is estimated to be at 70%. Although vestibular toxicity is more likely in patients with pre-existing vestibular disease, many patients have no such history. The symptoms begin a few days after the initiation of treatment and consist of light-headedness, dizziness, loss of balance, nausea, and extreme vertigo. The reaction is transient, and even in the most severe cases, it resolves within a few days.⁷⁵

Pseudotumor cerebri occurs in both adults and infants taking tetracyclines, but infants are more susceptible. The syndrome is characterized by headache, papilledema, elevated CSF pressure, and bulging fontanelles in infants. Signs and symptoms disappear within a few days after drug discontinuation, although papilledema may persist for weeks.⁷⁵ The intravenous administration of tetracyclines has rarely been reported to exacerbate myasthenia (Video 225, Myasthenia Gravis). This may be the result of magnesium in the diluent, binding of calcium by nonprotein-bound tetracycline, or direct action at the neuromuscular junction.⁵⁸

Nitrofurantoin

Nitrofurantoin therapy has been associated with polyneuropathy. Generally seen with prolonged therapy, neuropathy can occur as early as the first week of treatment. It is usually subacute, begins in the distal extremities with paresthesias, and tends to ascend progressively to involve the motor system with weakness and areflexia. Although this polyneuropathy clinically resembles Guillain-Barré syndrome, the spinal fluid is usually normal, except for 25% of patients, in whom there is a slight increase in protein without pleocytosis. When neuropathy is recognized, drug withdrawal is essential, although 10% to 15% of patients

do not improve, and 15% have only partial recovery. The prognosis appears to relate to the extent of the neuropathy at the time of drug withdrawal but not to the total dose exposure or the duration of therapy.¹

Antituberculous Drugs

Isoniazid

Isoniazid (INH) inhibits the phosphorylation of pyridoxine and chelates whatever pyridoxal phosphate remains. Because pyridoxal phosphate is a cofactor that is important to the GABA system, it has been hypothesized that the centrally diminished GABA activity may relate to the pathophysiology of isoniazid-induced seizures. In chronic toxicity, isoniazid predominantly inhibits the phosphorylation of pyridoxine to induce a peripheral neuropathy.¹ INH has a narrow therapeutic window making drug intoxication easily possible. The usual dosage of INH is 5 mg/kg/day for adults and 10 to 15 mg/kg/day for children. Seizures have been reported with dosages as low as 20 mg/day and severe neurotoxicity with dosages of 80 mg/day.⁷⁶

The incidence of pyridoxine-associated polyneuropathy is 0.2% to 2%, and the clinical features include numbness and tingling of the feet with diminished or absent deep tendon reflexes and occasional optic neuropathy. Isoniazid-associated neuropathy can be prevented by concomitant administration of pyridoxine, 50 mg/day.⁵⁸ In patients not receiving pyridoxine, high-risk groups for neuropathy include slow acetylators, adults, alcoholics, malnourished individuals, and those receiving more than 5 mg/kg/day.

Acute isoniazid intoxication due to overdosage is associated with generalized seizures, ataxia, psychosis, and coma. Metabolic acidosis, hyperglycemia, and aciduria may accompany the acute neurological syndrome. Pyridoxine should be administered immediately, along with standard anticonvulsant and supportive measures. Because seizures are a complication of isoniazid therapy, the drug is not recommended for patients with pre-existing seizure disorder if another drug can be chosen. When isoniazid is required in patients who are already receiving phenytoin, the phenytoin dose has to be adjusted because isoniazid decreases its clearance.^{1,58}

More unusual isoniazid-related neurotoxic syndromes include drug-induced lupus with meningitis, psychosis, obsessive-compulsive disorder, and acute mania.

Rifampin

Rifampin may induce an encephalopathy with features suggestive of a psychosis. Other rare adverse reactions are dizziness, headache, drowsiness, confusion, inability to concentrate, and ataxia.⁵⁸ Rarely, paresthesias and pain suggestive of peripheral neuropathy are reported.

Ethambutol

Optic neuropathy has been associated with ethambutol treatment. This appears to be a demyelinating process, and the reason for the optic nerve's sensitivity to this drug is unknown. Symptoms are seen in as many as one third of patients taking doses of 35 mg/kg/day for 6 months. Doses

of 25 mg/kg/day are safe for not more than 2 months, and the safe maintenance dose is 15 mg/kg/day. Toxicity is manifested by impairment of visual acuity, loss of color discrimination, constricted visual fields, and central and peripheral scotomata. The drug should be stopped at the first sign of visual change, and recovery can be anticipated, although it may take weeks to months.⁷⁷ Ten patients with ocular toxicity due to ethambutol were followed for up to 3 years. Only 50% of these patients experienced visual recovery, and permanent ocular toxicity was highest in patients over 60 years of age.⁷⁸ Animal studies suggest that the visual loss from ethambutol may be mediated through excitotoxic mechanisms on the retinal ganglion cells by decreased ATPase activity and perturbed mitochondrial function.⁷⁹ Other side effects include mild peripheral neuropathy and a metallic taste in the oral cavity.

Antifungal Drugs

Amphotericin B

Encephalopathy, occasionally with parkinsonian features, can be associated with intravenous administration of amphotericin B. Autopsy examination of afflicted patients discloses diffuse noninflammatory degeneration of the white matter, characterized by demyelination and infiltration by foamy macrophages. The leukotoxic effect of amphotericin B is related to its binding to myelin and an increase in membrane permeability, resulting in leakage of intracellular components.⁸⁰ Clinically, the patients develop a subacutely evolving neurological disorder characterized by personality change and confusion, rapidly progressing to akinetic mutism. Neuroimaging studies disclose diffuse nonenhancing lesions of the cerebral white matter that include hypodensity on computed tomography and increased signal on T2-weighted MRI. Amphotericin-associated leukoencephalopathy can be fatal, although there have been cases of slow recovery after discontinuation of the drug.

Polymyxin B

The incidence of neurotoxicity from parenteral polymyxin B averages 7%. Polymyxin has both presynaptic and postsynaptic effects, and it can worsen neuromuscular weakness, leading to respiratory failure, particularly in patients with renal failure or in combination with other drugs known to block neuromuscular transmission.⁵⁸ The various adverse effects of polymyxins include paresthesias, peripheral neuropathy, diplopia, dysphagia, ototoxicity, muscle weakness, dizziness, ataxia, seizures, and confusion (Video 91, Cerebellar Ataxia).^{1,58}

Antimalarials

Chloroquine

Chloroquine, once considered too toxic for humans, has been the antimalarial of choice for 40 years. Although a range of serious CNS effects has been documented during chloroquine therapy, the incidence is unclear.⁸¹ Abnormal involuntary movements, including torticollis, blepharospasm, and dystonic tongue protrusion, have been reported

during chloroquine therapy, especially in patients younger than 30 years of age (Video 52, Torticollis).¹ Headache, nausea, and tinnitus with progressive hearing loss, optic nerve dysfunction, seizures, psychosis, mania, and myasthenic syndrome have also been reported.

When used chronically, as in rheumatoid arthritis, chloroquine has been implicated in the development of peripheral neuropathy, cranial nerve palsies, and myopathy (Video 32, Cranial Nerve III Palsy). The peripheral neuropathy is a distal sensorimotor polyneuropathy that is reversible after drug withdrawal.¹

ANTIRETROVIRAL MEDICATIONS

Patients infected with the human immunodeficiency virus (HIV) are living longer than before due to a better understanding of the disease process and newer pharmacological agents often used in combination to control viral loads. Their use, however, comes with a price of toxic side effects. The currently available classes of antiretrovirals for HIV infection include protease inhibitors, nucleoside reverse transcriptase inhibitors (NRTI), and non-nucleoside reverse transcriptase inhibitors (NNRTI). New drug regimens support the use of concomitant medications from each class in HIV-positive individuals to prevent the complications of acquired immunodeficiency syndrome. Table 55-8 contains a list of available HIV medications.⁸²

Protease Inhibitors

The major side effects of protease inhibitors are metabolic in nature and include diabetes, hyperlipidemia, and fat redistribution.⁸² These effects are not directly neurological.

Nucleoside Reverse Transcriptase Inhibitors

The most frequent neurological side effect of NRTI is peripheral neuropathy. This problem is typically a distal,

symmetrical, predominantly sensory neuropathy and has been described with zalcitabine, didanosine, and stavudine.⁸³ EMG demonstrates an axonal neuropathy. It may be difficult to determine the origin of the neuropathy, because HIV infection can also cause a distal sensory neuropathy. The treatment includes removal of the offending agent.^{82,84,85} Myopathy of mitochondrial origin has been reported with both NNRTI and NRTI. This proximal and symmetrical myopathy is associated with a mitochondrial pattern of ragged-red fibers on histological examination. Removal of the offending agent is the best treatment. The onset of this syndrome in association with NRTI and NNRTI likely occurs preferentially in subjects who already have a genetic predisposition to mitochondrial disorders.⁸⁶

Non-nucleoside Reverse Transcriptase Inhibitors

The major neurological side effects of the NNRTI include dizziness, somnolence, diminished concentration, and confusion. The patient may also experience psychiatric disturbances, including agitation, depersonalization, hallucinations, insomnia, vivid dreams, depression, and euphoria. These symptoms are most severe at initiation of therapy and typically resolve with elimination of the offending medication.⁸² Mild and clinically tolerable neuropsychiatric disorders may persist in patients taking efavirenz after a mean of two years,⁸⁷ but their severity appears to decline over time.⁸⁸

ANTINEOPLASTIC CHEMOTHERAPY (Table 55-9)

Alkylating Agents

Nitrogen Mustard (*Mechlorethamine*)

Nitrogen mustard (NM) administered intravenously in a dose of 0.4 mg/kg is not usually associated with neurotoxicity. Hemiplegia, coma, chills, and fever, with increased ICP and CSF pleocytosis, however, were reported in one patient 7 days after each of two standard intravenous doses of NM (0.4 mg/kg).⁸⁹ On both occasions the signs and symptoms subsided after therapeutic measures to decrease ICP. When the patient died 4 years later from unrelated reasons, a gross and microscopical examination of the brain revealed focal areas of gliosis with loss of neurons. Massive intravenous injections of NM have caused hearing loss and vertigo, presumably from damage to cranial nerve VIII, seizures, somnolence, and confusion.⁹⁰ Intracarotid NM injection has been associated with hemiplegia, seizures, coma, and death (Video 11, Hemiplegic Gait).⁸⁹ One pathological study showed diffuse cerebral edema, which was greater on the side of the injection, and extensive gliosis and demyelination, presumably from a previous injection.¹

associated with facial or scalp burning, oropharyngeal tingling, nasal congestion, rhinorrhea, sneezing, and lacrimation. These uncomfortable sensations of the skin and mucous membranes occur more frequently than was previously noted, and changing infusion duration or the concentration of cyclophosphamide, or administering anticholinergics intranasally, can result in variable degrees of improvement.⁹¹

Inappropriate secretion of antidiuretic hormone has occurred rarely and is exacerbated by the high fluid loading required in high-dose cyclophosphamide therapy to prevent renal toxicity. Biopsy-proven progressive multifocal leukoencephalopathy (PML) has been described in a man treated with cyclophosphamide and prednisone for Wegener's granulomatosis. On discontinuation of immunosuppression, dramatic recovery took place.⁹²

Ifosfamide

Ifosfamide, an analogue of cyclophosphamide, is derived from nitrogen mustard and is used to treat a wide variety of pediatric and adult tumors. CNS effects of ifosfamide are frequent, are often severe, and can limit drug use.⁹³ In a retrospective cohort study of 237 patients who received ifosfamide in an oncology clinic, 16% developed encephalopathy.⁹⁴ Neurotoxic effects include changes in mental status ranging from drowsiness to coma, ataxia, tremor, myoclonus, seizures, facial spasms, and focal neurological signs.^{93,95–97} Symptoms are usually self-limited, clearing 48 to 72 hours after cessation of therapy, but persistent neuropsychological abnormalities and even fatalities can occur. The encephalopathy and accompanying seizures that can manifest as nonconvulsive status epilepticus may respond to intravenous diazepam.^{97,98} Predisposing factors for CNS toxicity include dehydration, decreased renal function, previous cerebrovascular events or brain metastases, pelvic tumors, and decreased serum albumin.⁹⁹

Chlorambucil

Seizures have rarely been reported with chlorambucil administration. They occur almost exclusively in children, in the setting of overdosage or nephrotic syndrome. They consist of myoclonic seizures followed by generalized tonic-clonic seizures (Video 77, Clonic Seizure). The EEG can show paroxysmal discharges that continue for several days after seizure activity.¹ Although the drug is generally considered to be non-neurotoxic, acute CNS abnormalities consisting of lethargy, ataxia, seizures, and coma have been reported with overdose.⁹⁰ PML has occurred in a patient with rheumatoid arthritis after treatment with chlorambucil. Of interest is that PML can develop as a late complication, even after the medicine is stopped.¹⁰⁰

Thiotepa

Owing to its low neurotoxicity, thiotepa, an intravenously administered alkylating agent, is one of the few anticancer drugs that can be injected into the CSF. In one series of 10 patients with meningeal leukemia and carcinomatosis treated with multiple courses of intrathecal thiotepa, clinical neurotoxicity developed in only two patients.¹ This neurotoxicity consisted of progressive myelopathy, manifested as progressive lower extremity weakness, back and leg pain, areflexia, and sensory deficits. EMG revealed diffuse lower motor neuron abnormalities. The histopathological changes in the spinal cord were localized to the white matter and consisted of demyelination and gliosis of the posterior columns and the nerve roots of the cauda equina.¹⁰¹

Busulfan

Generalized seizures are a frequent side effect of high-dose busulfan (total dose 16 mg/kg) as part of a preparative regimen for allogeneic bone marrow transplantation. No neurological deficits are found after the episodes, and there are no recurrences. Maintenance of therapeutic blood concentrations of anticonvulsant prophylactic regimens is recommended.¹⁰² There has been one case of busulfan administration associated with the development of myasthenia gravis, although the relationship among the myasthenia, the busulfan, and the leukemia was not clarified.¹

Antimetabolites**Methotrexate**

Methotrexate is a competitive inhibitor of dihydrofolate reductase, acting primarily during DNA synthesis (S-phase) as an antifolate antineoplastic drug. It prevents two primary reactions, the conversion of folic acid to tetrahydrofolic acid and the conversion of tetrahydrofolic acid to folinic acid, thereby blocking DNA, RNA, and protein synthesis by limiting the availability of reduced folates.^{1,90,103} As an oral or intravenous drug in the usual prescribed doses, methotrexate is a neurologically safe agent. It has limited ability to cross the blood-brain barrier, and the CSF concentration is less than 10% of that in plasma after oral or parenteral administration. When given intrathecally or in higher doses, however, methotrexate is associated with a

number of neurological syndromes. Proposed mechanisms of methotrexate neurotoxicity include depletion of cerebral reduced folates, reduced cerebral protein, altered blood-brain barrier permeability, and impaired neurotransmitter synthesis.⁹⁰ The risk of neurotoxicity is increased with increasing total intrathecal methotrexate dose, prolonged elevated CSF methotrexate levels, concurrent radiation therapy, or systemic high-dose methotrexate therapy. Toxicity is also more frequent and severe in younger patients and when methotrexate is used as treatment for meningeal tumor rather than for prophylaxis.⁹⁰

Acute methotrexate neurotoxicity includes an acute chemical meningitis with fever, headache, nuchal rigidity, and CSF leukocytosis. This condition is usually mild to moderate; begins within hours of intrathecal administration; lasts for 1 to 3 days, although it may persist for 2 weeks; resolves spontaneously; and does not recur with subsequent therapy.^{1,90,103} An acute stroke-like encephalopathy with seizures, confusion, hemiparesis, and coma may complicate high-dose methotrexate (more than 1 g/m²) in as many as 15% of patients.⁹⁰ Other acute complications that occur within hours of intrathecal administration are acute transverse myelopathy with paraplegia, which may be permanent, and transient radiculopathies, possibly related to epidural or subdural injection, or the development of hematomas.^{90,103} Accidental intrathecal methotrexate overdose may produce an ascending myelopathy and necrotizing leukoencephalopathy.⁹⁰ Doses of 50 mg or less probably produce few serious sequelae. A moderate overdose (50 to 100 mg) without early CSF drainage may produce an acute chemical meningitis. Massive overdose (more than 500 mg) causes myelopathy and encephalopathy, which may be fatal. Intensive systemic support, high-dose leucovorin, and alkaline diuresis, plus rapid CSF drainage and ventriculolumbar perfusion, may permit survival and recovery of neurological function.

Delayed neurotoxicity from repeated intrathecal or intraventricular methotrexate is more frequent than acute intoxication, and encephalopathy is the most important late effect. Pathologically, this is a leukoencephalopathy, with areas of coagulative necrosis, demyelination, and mineralizing microangiopathy. Clinically, it is characterized by progressive personality and intellectual decline, dementia, hemiparesis, and sometimes seizures. MRI and CT usually show extensive, patchy white matter lesions. The long-term effects of the treatment (or prophylaxis) of childhood leukemia and brain tumor include behavioral changes, poor school performance, memory loss, intellectual decline, growth retardation, hormonal disturbances, and abnormal CT scans. Although radiotherapy may account for many of these complications, intrathecal methotrexate alone may produce intellectual and behavioral problems or exacerbate those produced by radiotherapy.⁹⁰ Treatment of primary CNS lymphoma has been associated with neurologic deterioration in the absence of tumor recurrence.¹⁰⁴ Most regimens include methotrexate and intravenous or intrathecal and cytarabine among other agents, followed by radiation. In a cohort of 18 patients with primary CNS lymphoma treated with chemotherapy and radiation 63% had cognitive impairment; among them 21% showed severe cognitive deficits and 14 out of the 18 had white matter abnormalities on imaging.¹⁰⁵

5-Fluorouracil

5-Fluorouracil is a fluorine-substituted analogue of the pyrimidine uracil. It inhibits the enzyme thymidylate synthetase, blocking DNA synthesis by reducing thymidine monophosphate formation. It is associated with a characteristic cerebellar syndrome in 1% of patients when the recommended doses are used. When doses exceed the usual recommendations, the incidence of this cerebellar syndrome may be as high as 3% to 7%. The mechanism of 5-fluorouracil neurotoxicity is unknown, but its conversion to fluocitrate and fluoacetate in the CNS with subsequent inhibition of the Krebs cycle has been postulated.^{90,103,106} Concomitant administration of α -interferon, cisplatin, leucovorin, or thymidine potentiates the toxic effects.⁹⁰

Clinically, 5-fluorouracil induces pancerebellar dysfunction, characterized by the acute or subacute onset of gait ataxia, limb incoordination, dysarthria, nystagmus, and, sometimes, diplopia (Video 214, Stance Ataxia; Video 228, Saccadic Dysmetria). The symptoms are usually controlled by dose reduction or increase in intervals between treatments. Although the syndrome is reversible, cases of re-emergence after subsequent treatment have been reported.^{90,103,106}

Other neurotoxic reactions associated with 5-fluorouracil include encephalopathy, seizures, as well as a parkinsonian syndrome in 40% of patients.^{106,107} The encephalopathy is usually mild to moderate but can range from lethargy to coma with high-dose infusions. All the neurological symptoms associated with 5-fluorouracil are usually reversible on cessation of the drug, and no pathological changes have been noted in the brain at postmortem examination.¹⁰⁶

Cerebral demyelination has been described with 5-fluorouracil monotherapy. In a patient who completed chemotherapy with 5-fluorouracil, an MRI showed areas of demyelination that enhanced with contrast. A repeat MRI of the brain was completed in 2 months and showed a decreased number of demyelinating lesions. The demyelination was felt to be causally related to partial dihydropyrimidine dehydrogenase deficiency in combination with 5-fluorouracil administration.^{108,109} Ischemic strokes following administration of 5-fluorouracil and cisplatin have occurred in five patients. In each, no other cause for stroke could be identified in spite of an extensive workup. Each patient developed ischemic stroke in the second or third treatment cycle with development of symptoms in close relation to medication administration.¹¹⁰ Peripheral neuropathy associated with 5-FU is rare but has been reported with both 5-FU and capecitabine, a pro-drug of 5-FU, which is rapidly metabolized to 5-FU in patients with normal liver function. The neuropathy is reversible upon discontinuation of the drug but can recur with re-initiation.^{111,112}

Cytosine Arabinoside (Cytarabine)

Cytosine arabinoside is an analogue of pyrimidine nucleosides and readily crosses the blood-brain barrier. The drug destroys proliferating cells as an S-phase-specific cytotoxic agent. In many animals, in which cellular proliferation is active in the external granular layer of the cerebellum, cytosine arabinoside selectively destroys this layer and causes disarrangement and abnormal arborization of the Purkinje cells.¹¹³

Although the drug has little neurotoxicity following usual intravenous doses, in high doses it can cause an acute cerebellar syndrome in up to 14% and less commonly seizures and encephalopathy. When given intrathecally, it may result in myelopathy or cauda equina syndrome that is incompletely reversible. Combined intrathecal cytarabine and cranial irradiation may lead to necrotizing encephalopathy.¹¹⁴ Intravenous therapy may cause a peripheral neuropathy.¹¹³ The incidence and severity of neurotoxicity increases with increasing dose (more than 18 g/m²/course), increasing age (rare in patients younger than age 20, occurring in 3% of those from age 20 to 50, and in 19% of those older than age 50), and following subsequent rather than initial courses.⁹⁰ Symptoms of neurotoxicity typically begin 6 to 8 days after the initiation of cytosine arabinoside with nystagmus and ataxia, peak over the following 2 to 3 days (confusion, somnolence, ataxia, dysarthria, and sometimes seizures or coma), start to improve within 1 week, and resolve completely within 2 weeks in most patients.⁹⁰ Cerebellar atrophy may be seen on CT or MRI, and pathological changes are remarkable for Purkinje cell loss, reactive Bergmann's gliosis, and, occasionally, demyelination.

Natural Products

Vinca Alkaloids

Vincristine and vinblastine are alkaloid derivatives of the periwinkle plant, whose major and dose-limiting toxicity is neurological. The mechanism of action of these agents is probably related to inhibition of microtubule formation in the mitotic spindle, resulting in an arrest of dividing cells at the metaphase stage. Peripheral neuropathy is almost universal in patients receiving these drugs, and neurotoxicity is attributed to the inhibition of axoplasmic transport by their effect on axonal microtubules.^{89,90,114} Patients with pre-existing neuropathy (diabetic, familial, compressive, or nutritional) may have more severe neuropathy. Generally, the longer the exposure, the more numerous and severe the neuropathic side effects.

The earliest and most consistent objective manifestation of vincristine neurotoxicity is suppression of the Achilles tendon reflex. This is followed rapidly by losses of other reflexes, distal symmetrical sensory loss (pin and temperature more than vibration and proprioception), weakness, footdrop, and muscle atrophy (Video 237, Foot Drop). Autonomic neuropathy with constipation, ileus, urinary retention, impotence, or postural hypotension may occur. Cranial neuropathy occurs, usually involving the oculomotor nerve, often causing bilateral ptosis. Affected nerves include the abducens, trigeminal, facial, and recurrent laryngeal nerves, the latter resulting in hoarseness or stridor (Video 44, Dysphonia). Nerve conduction velocities are normal, because the process is an axonopathy.^{1,89,90,106} Cases of life-threatening vincristine neuropathy have been described in patients with an underlying neuropathic disorder such as hereditary sensory motor neuropathy. To avoid vincristine exposure to subjects with pre-existing neuropathy, a pretreatment neurological examination and careful family history are useful.¹¹⁵ A proximal myopathy can occur with prolonged vincristine therapy even in the absence of neuropathy and is distinguishable because of its proximal

distribution of weakness.^{116,117} A painful myopathy may occur in children. Vincristine does not cross the blood-brain barrier, so CNS toxicity is rare, although seizures may develop as a result of inappropriate secretion of antidiuretic hormone.¹⁰⁶ Vinblastine has similar neurotoxic reactions but only at doses that are usually not prescribed because of concomitant severe hematological reactions.¹⁰⁶

L-Asparaginase

L-Asparaginase is an enzyme that hydrolyzes asparagine to aspartic acid and ammonia, depleting asparagine and inhibiting protein synthesis. When it was first introduced, the drug was used at high doses that produced an acute encephalopathy that proved to be dose limiting. At usually prescribed doses, the encephalopathy is not seen.¹⁰⁶

Because L-asparaginase inhibits protein synthesis, plasma protein deficits occur, including those involved in coagulation and fibrinolysis. Decreased levels of fibrinogen, factor IX, factor XI, plasminogen, antithrombin III, protein C, protein S, α_2 -antiplasmin, histidine-rich glycoprotein, and α_2 -macroglobulin also occur.¹¹⁸ L-Asparaginase has been linked to hemorrhagic and thrombotic cerebrovascular complications, including cortical infarction, capsular infarction, intracerebral hemorrhage, hemorrhagic infarction, and cerebral venous and dural sinus thrombosis.¹¹⁹ During treatment, progressive prolongations in prothrombin time, partial thromboplastin time, and thrombin time are seen. In patients who have had complications resulting from L-asparaginase and who require further treatment, therapy to prevent subsequent complications is controversial. Fresh frozen plasma alone or with low-dose heparin or antithrombin III has been proposed.¹¹⁸ Because fresh frozen plasma lessens the decrease in coagulation proteins normally seen with L-asparaginase, it is a reasonable treatment for patients with thromboembolic complications from the medicine.

Antibiotic Antineoplastic Agents

Bleomycin

The existence of pure bleomycin toxicity has not been established because the drug is ordinarily used in conjunction with other chemotherapeutic agents. Mental status changes and peripheral neuropathy have been reported with bleomycin therapy, although no pathological changes have been associated in brain or peripheral nerves in such patients. In animals, cochlear damage has been demonstrated, although there is no comparable clinical evidence in humans.¹

Adriamycin and Actinomycin D

Adriamycin and actinomycin D produce no neurological side effects in humans in the usually prescribed doses, and when administered systemically, the drugs do not enter the CSF. Adriamycin can produce a severe form of myelopathy and encephalopathy after accidental intrathecal injection. Experimentally, it can produce cerebral damage after intracarotid injection and anterior horn cell loss after direct injection into a peripheral nerve.⁹⁰

Actinomycin D causes tremors, myoclonus, seizure, ascending myelopathy, and encephalopathy when it is injected

into the CSF in animal models. In pathological studies, demyelination and necrosis have been found in the brain.¹

Other Chemotherapeutic Agents

Nitrosoureas

The nitrosoureas include BCNU (carmustine), CCNU (lomustine), methyl-CCNU (semustine), PCNU, and ACNU. As alkylating agents, they bind DNA and produce interstrand and intrastrand cross-links and carbamoylated proteins. They readily cross the blood-brain barrier and have little or no neurotoxicity at the usual dose regimens used (BCNU IV 200 mg/m² or 80 mg/m²/day for 3 days). Encephalopathy with confusion and seizures may follow high doses of the drug (BCNU IV 600 to 800 mg/m² or more).⁹⁰ Several patients developed multifocal neurological abnormalities 3 to 12 weeks following high doses of BCNU (1500 to 3000 mg) followed by autologous bone marrow transplantation to rescue the bone marrow from the drug toxicity. Postmortem examination revealed foci of coagulative necrosis.¹⁰⁶ Intracarotid BCNU (usually 100 to 200 mg/m²) can produce severe local pain in the ipsilateral face, eye, and head during infusion and, sometimes, retinopathy, blindness, or ocular necrosis. Intracarotid infusions above the ophthalmic artery may prevent ocular toxicity. A severe ipsilateral encephalopathy with seizures, hemiparesis, progressive neurological deficits, and cerebral necrosis (pathologically similar to radiation necrosis) has been described following intracarotid BCNU administration.⁹⁰ Concurrent cranial radiotherapy and intracarotid BCNU may increase the risk of neurotoxicity.

Cisplatin

Cisplatin most likely acts by binding to DNA, forming intrastrand and interstrand cross-links. Cisplatin neurotoxicity is common and dose limiting. Ototoxicity is a dose-limiting complication, occurring most commonly at doses of 120 mg/m² or more. Direct toxicity of the drug on the organ of Corti appears to be the cause of the induced deafness, because nystagmus and vertigo have rarely been reported. Deafness is more common in elderly patients and is exacerbated by radiation therapy to the head. The patient cannot hear high-frequency sounds; the hearing loss is bilateral and largely reversible, but it can be permanent. Deafness often begins within 3 to 4 days of the initial treatment and slowly improves over the succeeding weeks after treatment is stopped. The combination of slow infusion and pretreatment with intravenous hydration and often mannitol to enhance renal excretion has reduced the problem of ototoxicity.^{90,106}

Peripheral neuropathy is a second prominent complication and involves predominantly large fibers. It is dose related and cumulative (with a total dose usually more than 300 to 600 mg/m²). Symptoms may begin or progress even after cisplatin has been stopped.⁹⁰ Encephalopathy with confusion and seizures can occur, especially with high doses, but may be due to fluid or electrolyte disturbances that accompany cisplatin therapy, such as hyponatremia, hypocalcemia, and hypomagnesemia. Cerebral herniation with severe headache, increasing hemiparesis, seizures, coma,

and death has been reported in patients with large intracranial tumors receiving cisplatin, possibly due to overhydration and electrolyte disturbances producing cerebral edema and seizures.^{1,90} Finally, retinopathy and cranial neuropathy occasionally follow cisplatin therapy.

Procarbazine

Procarbazine is a weak MAOI that acts primarily as an alkylating agent. High-dose intravenous or intracarotid procarbazine can produce severe encephalopathy. At usual oral doses (60 to 150 mg/m²/day), a mild reversible encephalopathy (drowsiness, confusion, agitation) or peripheral neuropathy (paresthesias, reduced deep tendon reflexes, and muscle aches) develop in as many as 20% of patients.⁹⁰

Because of its monoamine oxidase inhibition, procarbazine can predispose the patients receiving it to a variety of drug interactions, including synergistic sedative effects with phenothiazines, barbiturates, and narcotics, as well as alcohol intolerance. The caution advised with other MAOIs regarding the tyramine effect with cheese or wine has not been a clinical problem with procarbazine.^{1,89,90}

Hexamethylmelamine

Hexamethylmelamine can act as an alkylating agent or as an antimetabolite. It has both central and peripheral neurotoxic effects. In the usual doses administered (8 mg/kg/day), neurological problems are seen in up to 20% of patients. The clinical manifestations include encephalopathy (confusion, agitation, hallucinations, parkinsonism) and peripheral neuropathy (distal sensory loss, weakness). In the case of the peripheral neuropathy, pyridoxine may be beneficial.^{1,90}

TRANSPLANT DRUGS

Cyclosporine

Neurotoxicity is a well-recognized sequela of cyclosporine, and the most common complications are tremor and altered mental status. Cyclosporine neurotoxicity can occur in 1 in 10 patients after liver transplantation. Behavioral signs include acute psychosis, restlessness, wide mood swings with inappropriate crying and laughing, cortical blindness, visual hallucinations, stupor, and akinetic mutism (Video 22, Delusional Thinking). Additionally, seizures, extrapyramidal symptoms, action myoclonus, and quadriparesis have been reported. In patients with neurological signs, cyclosporine levels are usually outside the normal range, and after lowering the dose or withholding administration, neurotoxicity clears in most cases. MRI abnormalities are consistent with cortical or white matter high-signal changes with a predilection for the occipital lobes.^{120–124} One autopsy case of a patient who died from cyclosporine toxicity revealed diffuse patchy white matter edema and astrocytic injury without infectious/inflammatory process.¹²² Although the mechanism of cyclosporine neurotoxicity has not been fully elucidated, one theory suggests that hypocholesterolemia may result in upregulation of the low-density lipoprotein receptors, which increases intracellular transport of cyclosporine. Access may be particularly

high in the white matter with a relatively high density of low-density lipoprotein receptors. Another theory implicates endothelin, a potent vasoconstrictive neuropeptide, in combination with breakdown of the blood-brain barrier, resulting in local ischemia. Other possible etiological mechanisms of cyclosporine neurotoxicity include hypomagnesemia, hypertension, aluminum overload, and high-dose methylprednisolone administration.^{120,125} In a study examining the variable incidence of cyclosporine and FK 506 neurotoxicity in allogeneic bone marrow transplantation it was found that the highest incidence of neurotoxicity was associated with multiple myeloma and the lowest with lymphoma.¹²⁶ The rate of cyclosporine and FK 506 neurotoxicity varies with the conditioning regimen of chemotherapy agents used with lengthier regimens associated with a higher rate of neurotoxicity.¹²⁷ One study used in vitro multinuclear magnetic resonance to study the effects of cyclosporine on high-energy phosphate metabolism in brain cells and perfused rat brain slices.¹²⁸ Both the clinical manifestations and the neuroimaging abnormalities of cyclosporine neurotoxicity usually resolve with a reduction or discontinuation of cyclosporine.^{120,125}

New Transplant Immunosuppressives

These are relatively new drugs, so more extensive use will be needed to determine the entire realm of neurological side effects. Among the new transplant immunosuppressives are basiliximab, daclizumab, mycophenolate mofetil, sirolimus, and tacrolimus. Typical neurological effects of long-term immunosuppression, including infections such as meningitis, encephalitis, and abscess formation, are similar with the newer agents.¹²⁹ Direct neurological toxicity is more common with tacrolimus, a calcineurin inhibitor like cyclosporine, while the others exhibit toxicity that spares the nervous system.

Although tacrolimus may be a better immunosuppressant than cyclosporine, it may have worse neurological effects.^{130,131} In a multicenter, randomized, parallel-group study of 545 patients undergoing primary liver transplantation, tacrolimus was associated with a higher incidence of neurological symptoms than cyclosporine.¹³² The risk of tacrolimus-treated patients developing tremor was related to the initial intravenous dose, the rate of administration, and the total daily dose. Headache was significantly correlated with dose while insomnia was not.¹³² Factors that may promote the development of serious complications include advanced liver failure, hypertension, hypocholesterolemia, elevated serum levels, hypomagnesemia, and methylprednisone.¹³³ Calcineurin inhibition by tacrolimus and cyclosporine alters sympathetic outflow, which may play a role in the mediation of neurotoxic and hypertensive adverse events. The symptoms may be reversed by reducing the dose of immunosuppressant or by discontinuation. However, some patients have experienced permanent or even fatal neurological damage even after discontinuation of tacrolimus.^{133,134} Occipital white matter appears to be uniquely susceptible to the neurotoxic effects of tacrolimus as is the case with cyclosporine. The encephalopathy associated with tacrolimus has been reported to involve the cortex as well.¹³⁰ MRI has been reported to reveal bilateral symmetrical regions of signal abnormality with abnormal

contrast enhancement. The abnormal signal was more evident in FLAIR (fluid-attenuated-inversion-recovery) sequences.¹³⁵ Epilepsy¹³⁶ and cerebral hemorrhage¹³⁷ have been reported with tacrolimus-induced neurotoxicity.

In contrast to CNS toxicity, peripheral nervous system involvement is uncommon. Nevertheless, both demyelinating¹³⁸ and axonal polyneuropathy¹³⁹ have been described. Tacrolimus-associated myositis has been reported in a renal transplant patient. This reversed upon discontinuation of the offending agent.¹⁴⁰

CARDIAC DRUGS (Table 55-10)

Digitalis

Adverse effects on the CNS occur in 40% to 50% of patients with clinical digitalis toxicity and may develop before, with, or after signs of cardiac toxicity. Neurological complications include nausea, vomiting, visual disturbances, seizures, confusion, delirium, mania, hallucinosis, and syncope. Explanations for the high frequency of neurotoxicity with digitalis have been inadequate, and the few pathological studies compiled have not demonstrated consistent lesions.¹

The most frequent and often the first neurotoxic reaction is nausea due to direct stimulation of the medullary chemoreceptor trigger zone. Nausea associated with digitalis toxicity is often accompanied by vomiting, and when vomiting is chronic, it may lead to malnourishment and cachexia. The incidence of digitalis-related visual disturbances has been estimated at 40%. Clinically, it presents with blurred vision, scotomas, diplopia, defects of color vision, and amaurosis. Electrodiagnostic and labeled tracer studies have implicated retinal dysfunction in the pathogenesis.¹⁴¹

Seizures are most commonly seen in the pediatric population. The mechanism by which digitalis induces seizures has been postulated to involve inhibition of membrane ATPase and subsequent neuronal irritability. Confusion, delirium, mania, and hallucinosis have been reported in as many as 15% of patients with digitalis toxicity.¹ Although the

TABLE 55-10

Neurological Complications of Cardiac Medications

| | |
|--------------------------------|----------------------------|
| Ataxia | Insomnia |
| Amiodarone | β-Blockers |
| Encephalopathy/Delirium | Sedation |

| Amiodarone | Visual Disturbances |
| Calcium channel blockers | Digoxin |
| Hallucinations | Quinidine |
| β-Blockers | |
| Digoxin | |
| Headaches | |
| Lidocaine | |
| Quinidine | |

mechanism for the symptoms is unknown, they are not the result of altered cardiac function. On the other hand, transient cognitive changes that are believed to be due to intermittent cerebral hypoperfusion can resemble transient global amnesia or be manifested as syncope.

β-Blockers

Neuropsychiatric symptoms occur frequently during treatment with β-blockers. The pharmacology of CNS side effects is unclear, although presynaptic and postsynaptic adrenergic inhibition has been implicated, as has serotonergic antagonism.¹ Nonselective β-blockers seem to cause CNS-related side effects to a greater extent than β₁-selective blockers.¹⁴² It is unclear to what degree lipophilicity is responsible for this kind of side effect. Lassitude or insomnia and depression are the most common reactions, although vivid dreams, nightmares, hypnagogic hallucinations, and psychotic behavior have been reported with high doses (more than 500 mg/day of propranolol). Pre-existing major psychiatric illness and hyperthyroidism may predispose to the preceding symptoms.

Calcium Channel Blockers

Calcium channel blockers, particularly flunarizine and cinnarizine, have been associated with dystonia, parkinsonism, akathisia, and TD. Theoretical explanations for these events include the inhibition of calcium influx into striatal cells and direct dopaminergic antagonistic properties. Recent evidence also suggests that inhibition of proton pumping and catecholamine uptake are possible mechanisms.¹⁴³ In addition, the chemical structures of flunarizine and cinnarizine, which are related to neuroleptics, may explain the greater incidence of such side effects with these agents compared with those of calcium channel blockers available in the United States. Suggested risk factors appear to be advanced age and a family history of tremors or Parkinson's disease, or both.¹⁴⁴ The onset and type of presentation is unpredictable. The long-term evolution was assessed in a prospective follow-up study of 32 patients with diagnoses of calcium channel blocker-induced parkinsonism. Eighteen months following discontinuation of the offending agent, 44% of the patients had depression, 88% had tremor, and 33% still had criteria for diagnosis of parkinsonism (Video 59, Rest Tremor).¹⁴⁵

Angiotensin-converting Enzyme Inhibitors

The incidence of CNS effects with angiotensin-converting enzyme (ACE) inhibitors is similar to that of β-blockers. The precise role of ACE in the CNS is not well defined. Mild lethargy, sedation, and fatigue are the most common complaints.¹⁴⁶ As opposed to β-blockers, ACE inhibitors appear to have the lowest association with depression and, therefore, are the drugs of choice when depression is a risk.

Approximately 2% to 4% (depending on renal function and dose) of 100 patients on captopril develop diminution or loss of taste perception. This sign is reversible and usually resolves within 2 to 3 months, even with continued drug administration.

Nitrates

The major problem with nitrate therapy is headache. According to proposed mechanisms, nitric oxide is the common mediator in experimental vascular headaches possibly resulting in headache through vasodilatation of extracerebral arteries.¹⁴⁷ Nitroglycerin produces a throbbing or pulsating sensation in many patients and an overt headache in many others. Often, the headaches attenuate or disappear with time, but 15% to 20% of patients are not able to tolerate long-acting nitrates because of headache. Patients should be encouraged to use analgesics during the initial days or weeks of nitrate therapy and should be educated as to the nature of this problem and its probable resolution with time.¹⁴⁸

Nitroglycerin therapy can cause dose-related increases in ICP, which, in rare cases, can result in a clinically overt syndrome. Finally, the hypotensive effects of nitroglycerin can result in dizziness and lightheadedness or even syncope.

Antiarrhythmic Agents

Amiodarone

Amiodarone is a di-ionated benzofurane derivative used primarily in the treatment of refractory ventricular and atrial arrhythmias. Amiodarone can be toxic for almost every organ in the body, including the central and peripheral nervous systems, especially when taken at high doses for long periods of time. The most common neurotoxic findings include tremor, ataxia, proximal muscle weakness, and wasting. Tremor usually appears early in the course of therapy and is usually a bilateral 6- to 10-Hz action tremor of the arms, which is indistinguishable from essential tremor (Video 60, Marked Postural Tremor). It can involve all limbs and may be asymmetrical, although to date it has not been reported to be unilateral. Rarely, the tremor is associated with parkinsonian features. Other manifestations of basal ganglia dysfunction that have been reported in association with amiodarone include myoclonus, hemiballismus, and dyskinesias of the extremities and orofacial area. Basal ganglia dysfunction associated with amiodarone is dose related, and reversibility is inversely related to duration of therapy.¹⁴⁹ Additionally, severe ataxia resolving after amiodarone discontinuation has been reported as well.¹⁵⁰

More recently, an association of amiodarone treatment and optic neuropathy has been recognized. Most cases present within the first year of therapy.¹⁵¹ In a study comparing patients on chronic amiodarone treatment with normal control subjects a significant prolongation of visual evoked potentials (VEP) was found.¹⁵²

Lidocaine

Lidocaine is widely administered parenterally and topically. It is oxidized to active and inactive metabolites by hepatic enzymes in the cytochrome P-450 mixed oxidase system. Toxic effects of lidocaine occur frequently and involve the cardiovascular system and CNS. Although lidocaine-associated CNS effects can be seen with other local anesthetics, lidocaine is far more common as the causative drug, and this relates to its rapid absorption across the blood-brain barrier. The high frequency of toxicity is probably

due to a diffuse excitation of neuronal systems and begins as altered behavior.¹ At concentrations less than 6 µg/mL, dizziness, drowsiness, paresthesias, and visual disturbances predominate; confusion, dysarthria, coma, convulsions, cardiac arrhythmias, and respiratory arrest are more often seen at concentrations greater than 6 µg/mL. The toxicity of lidocaine can be viewed as a self-enhancing phenomenon: If administration is not terminated immediately, a marked respiratory acidosis results, which creates more of the active, ionized form of the drug.¹⁵³ Treatment focuses on adequate oxygenation and support because the half-life of bolus lidocaine given immediately is 6 to 8 minutes. However, because repeated injections change the kinetics of lidocaine and prolong its half-life to approximately 90 minutes, more long-lasting effects can be seen.¹⁵³ Although most reports of adverse reactions involve intravenous lidocaine, toxic signs have also been reported with topical or oral use. Pain in the lower extremities following initial recovery from spinal anesthetics is more frequent with lidocaine compared to other local anesthetics.¹⁵⁴

Quinidine

Quinidine is present in the cinchona bark, along with quinine and other alkaloids. Nervous system manifestations are usually not significant, but with overdosage or in susceptible individuals, quinidine causes a type of intoxication similar to that of quinine. The corresponding clinical syndrome, namely cinchonism, is manifested as headache, nausea, vomiting, blurring of vision, transient visual obscurations, and ringing of the ears.¹ The visual symptoms are short lived but can be confused with visual transient ischemic attacks or the visual accompaniments of migraine. More persistent quinidine amblyopia is the result of direct damage to the retinal ganglion cells.¹⁵⁵ Finally, there have been two case reports of dementia associated with chronic quinidine use, which reversed after drug discontinuation.¹⁵⁶

DIETARY COMPOUNDS AND MISCELLANEOUS DRUGS

Caffeine

Caffeine and other xanthine derivatives, including aminophylline, are CNS stimulants that excite all levels of the CNS, with the cortex being the most sensitive. Caffeine increases energy metabolism throughout the brain but decreases cerebral blood flow, inducing a relative brain hypoperfusion. The drug activates noradrenaline neurons and may act as a second messenger at dopamine receptors to affect the local release of dopamine.¹⁵⁷ Mobilization of intracellular calcium and inhibition of specific phosphodiesterases occurs at high, nonphysiological concentrations of caffeine. The most likely mechanism of action of methylxanthine is the antagonism at the level of adenosine receptors.

Caffeine's psychostimulant action on humans is often subtle and difficult to detect. Its effects on learning, memory, performance, and coordination are related to methylxanthine-induced arousal, vigilance, and fatigue. An increased awareness of the environment or hyperesthesia may be an unpleasant experience to some patients. The patient becomes

loquacious and restless and often complains of ringing in the ears and giddiness. In high doses, xanthines affect the spinal cord, resulting in increased reflex excitability, tremulous extremities, and tense muscles.¹ Caffeine clearly alters sleep patterns, and if taken within 1 hour of attempted sleep, it increases sleep latency, decreases total sleep time, and worsens the subject's estimate of sleep quality. Less time is spent in stage 3 and 4 sleep and more in stage 2 sleep. Xanthine-associated seizures are seen as a complication of aminophylline therapy, especially when the drug is administered intravenously. They are usually generalized but can be focal. Epidemiological evidence suggests that dietary and medicinal consumption of caffeine is a modest risk factor for chronic daily headaches.¹⁵⁸ Cessation of the use of products containing caffeine can cause a withdrawal syndrome that includes headaches, drowsiness, fatigue, decreased performance, and, in some instances, nausea and vomiting. These symptoms begin within 12 to 24 hours after the last use of caffeine, peak at 20 to 48 hours, and last approximately 1 week.¹⁵⁹ Excessive caffeine ingestion can cause low serum potassium levels. Caffeine-induced hypokalemia resulted in paralysis in a pregnant woman, which resolved after potassium supplementation and decrease in caffeine intake.¹⁶⁰

Nicotine

Nicotine increases circulating levels of norepinephrine and epinephrine, and it stimulates the release of striatal dopamine. It exerts stimulant effects through specific nicotinic receptors, whose activation may facilitate dopaminergic transmission centrally.¹⁶¹ Nicotine has been reported to affect a number of neurological diseases, such as spinocerebellar degeneration, multiple system atrophy, multiple sclerosis, tic disorders, parkinsonism, and myoclonic epilepsy.¹⁶²

Nicotine, despite being a powerful stimulant, has no major therapeutic application. Unaccustomed smoking may elicit transient nystagmus, dizziness, unsteadiness, and nausea. Nystagmography and posturography performed in nonsmokers or occasional smokers has found multidirectional nystagmus (mainly horizontal or upbeat), associated with significant increase in postural sway.¹⁶³ Its high toxicity and presence in tobacco smoke give nicotine a considerable medical importance. Clinically, tremors and convulsions are major neurological signs of nicotine intoxication. Respiration is stimulated, and vomiting is induced. Nicotine also has marked antidiuretic activity resulting from direct hypothalamic stimulation. If nicotine is acutely ingested, it can be fatal at approximately 60 mg of the base product. Autonomic overactivity with dilated pupils, irregular pulse, sweating, and muscle twitching are characteristic signs of nicotine toxicity. Coma may supervene rapidly, although convulsions are usually not present. If death occurs, it is due to paralysis of respiratory muscles. Cardiac arrhythmias are significant and are another potential cause of demise.¹ Chronic intoxication due to nicotine, consisting of nausea, vomiting, dizziness, and prostration, occurs among tobacco pickers or croppers. The illness lasts intermittently between 12 and 14 hours and clears, only to recur when workers return to work. There are no deaths or long-term sequelae, however. During the 1973 harvesting season, an estimated 9% of the 60,000 tobacco growers in North

Carolina reported illnesses. Ingestion of leaves from the tree tobacco plant (*Nicotiana glauca*) has been reported to result in severe muscle weakness, bulbar palsies, flexor muscle spasms, hypertension, nausea, vomiting, and respiratory compromise (Video 20, Tonic Spasms).¹⁶⁴

Vitamins

These vital trace substances are generally associated with vitamin deficiency syndromes, but because health enthusiasm has reached passionate proportions for many individuals, physicians are encountering neurotoxic syndromes from overdosage. The first recognized toxicity of vitamins was related to the fat-soluble vitamins, but water-soluble vitamins have been found to be harmful at times when they are ingested in large quantities.

Vitamin A

Vitamin A toxicity results in a syndrome of increased ICP, headaches, blurred vision, and cranial nerve VI palsy. On funduscopic examination, gradual papilledema develops.^{165,166} The mechanism whereby increased ICP develops is not known, although biochemically, the vitamin stimulates the synthesis of glycoproteins and mucopolysaccharides, which may alter fluid balance centrally. The generally recommended daily vitamin A allowance is 5000 IU, and toxicity occurs with intake as little as four times that dose.¹⁶⁶ Similar toxicity has been noted with one of the vitamin A-like substances, *cis*-retinoic acid, when used for acne in a person taking recommended intakes of vitamin A.¹⁶⁶ In addition there is considerable evidence of the teratogenic effects of vitamin A in the mouse, rat, hamster, and guinea pig. Malformations include cleft palate, fused ribs, spina bifida, meningocele, hydronephrosis, and heart and genitourinary abnormalities.¹⁶⁵

Vitamin D

Massive amounts of vitamin D mobilize bone calcium and phosphorus. Where there is bone demineralization and degeneration, nerve root and spinal cord compression can occur. Meningeal symptoms and trigeminal neuralgia are two additional reported findings without clear pathogenesis. Trigeminal neuralgia may relate to bony foraminal changes (Video 106, Trigeminal Neuralgia). Alterations in the calcium balance in the form of hypercalcemia can produce metastatic calcifications in the brain with resultant mental retardation or a clinical picture of generalized weakness, muscle aches, cramps, and mild metabolic encephalopathy.¹⁶⁶ When renal impairment occurs, progressive secondary encephalopathy, not directly related to the vitamin, develops. Vitamin D, like vitamin A, is a teratogen, and when the vitamin is consumed in large amounts by pregnant women, it can produce specific abnormalities of the facies, brain, heart, and kidney of the fetus.¹⁶⁶

Vitamin E

Excessive vitamin E ingestion may produce subtle signs and symptoms of toxicity, such as easy fatigability, muscle weakness, headache, and delayed wound healing.

Symptoms usually disappear with cessation of excessive intake. Increased bleeding tendencies have also been reported with large amounts of vitamin E, but no intracranial bleeding has been reported as resulting from it. No toxic effects have been reported at doses of 800 IU daily.¹⁶⁶ Even with supraclinical doses, associated with high levels of plasma tocopherol, ventricular CSF levels are exceedingly low.¹⁶⁷

Thiamine

Effects of excess thiamine on the CNS include nervousness, convulsions, headache, weakness, trembling, and neuromuscular paralysis.¹⁶⁵ The decreased use of thiamine, especially parenterally for various functional disorders, appears to have resulted in a reduction of toxic reactions.

Thiamine deficiency results in Wernicke's encephalopathy, manifesting with ophthalmoplegia or nystagmus, ataxia and confusion, or mild memory impairment (see Chapter 40) (Video 229, Wernicke's Encephalopathy). It can therefore mimic brain stem stroke.¹⁶⁸ Thiamine deficiency has also been reported to manifest as polyneuropathy¹⁶⁹ or chorea.¹⁷⁰ Iatrogenic causes include total parenteral nutrition, drastic weight-reducing diet, hemodialysis, colonic surgery, or gastrectomy.¹⁷¹⁻¹⁷³ MRI can demonstrate high-signal lesions on T2 in the diencephalon, mesencephalon, as well as enhancing lesions of the floor of the hypothalamus.¹⁷⁴

Pyridoxine

Pyridoxine, previously considered benign, has been found to have direct toxic effects on the peripheral nervous system. Animals treated with high doses of pyridoxine develop vacuolation and degeneration of dorsal root and ganglion cells, along with a widespread degeneration of sensory nerve fibers. When consumed in daily doses of 2 g or more, it has been reported to produce a syndrome consisting of difficulty walking with lightning-like dysesthesias in the back. Numbness of the extremities occurs, and most important, facial dysesthesias, so uncommon with most toxic neuropathies other than trichloroethane, quickly develop. Areflexia, stocking-and-glove sensory loss, and profound sensory ataxia with preserved strength are typical (Video 5, Sensory Ataxia). On EMG, marked slowing of the sensory nerve conduction is seen with normal motor conduction.^{1,166} Treatment consists of cessation of pyridoxine, and in some cases there is a dramatic, although often slow, recovery.

When low to moderate doses of pyridoxine are added to the diet of a parkinsonian patient receiving levodopa without carbidopa supplementation (e.g., Sinemet), it will precipitously cause an exacerbation of the disease. Pyridoxine is a cofactor for dopa decarboxylase and enhances the systemic conversion of dopa to dopamine: Because dopamine cannot cross the blood-brain barrier, this enhanced peripheral synthesis of dopamine in fact diminishes central delivery of dopa for effective antiparkinsonian therapy. When sufficient carbidopa is added to levodopa (usually at least 100 mg/day), this pyridoxine toxicity is probably insignificant.

Monosodium Glutamate

In 1968, Kowk, a Chinese physician, described a transient neurological syndrome that occurred when he ate at American-Chinese restaurants. He suggested that monosodium glutamate could be the provoking agent because this product is used widely in Chinese restaurants to enhance the flavor of food. The pathophysiology of the syndrome has been suggested to relate to glutamate. As an excitatory agent, glutamate may alter synaptic transmission. Some authors suggest that the symptoms of monosodium glutamate syndrome may relate to cholinergic overstimulation or non-neurological vascular mechanisms. The syndrome has three major symptoms, occurring within 15 minutes after ingestion of Chinese food and lasting approximately 1 hour: a dysesthetic facial pressure, burning dysesthesias over the trunk, and chest pain. Headache, which may be migrainous in quality, is more frequently seen in patients with a prior history of headaches. Other vague symptoms such as malaise and lightheadedness may accompany the triad. It is not fully established that monosodium glutamate is, in fact, the causative agent. Therefore, important contributing influences may also be the vehicle, whether the subject has been fasting, and whether a load of carbohydrate accompanies the ingestion of monosodium glutamate.¹

Sex Hormones and Contraceptive Agents

Female hormones in the form of oral contraceptives or postmenopausal replacement therapy have become widely prescribed. It is clear that oral contraceptives increase by three to eight times the risk of stroke in women taking them. Oral contraceptive-associated strokes can occur in any vascular distribution. Factors predisposing to cerebrovascular disease in women on birth control pills include the use of compounds containing high levels of estrogen, multiparity, and a change in migraine headache pattern. Of probable but less certain importance are previous thrombotic or embolic disease and hypertension. Inherited resistance to activated protein C, which is caused by a single factor V gene mutation, is a frequent risk factor for thrombosis. Activated protein C resistance was found to be highly prevalent in women with a history of thromboembolic complications during pregnancy or use of oral contraceptives. The gene defect is common in the general population, and the question is raised as to whether it would be reasonable to perform general screening for activated protein C resistance early during pregnancy or before prescription of oral contraceptives.¹⁷⁵

Chorea is another serious problem related to oral contraceptives (Video 71, Birth Control Pill-Induced Chorea). The involuntary movements appear days or weeks after starting birth control pills and may be more frequent in patients with a prior history of Sydenham's chorea. The chorea starts abruptly and may involve only one side of the body.¹⁷⁶ A similar phenomenon occasionally occurs during pregnancy when a woman develops severe involuntary movements that spontaneously resolve when the pregnancy ends (chorea gravidarum). Birth control chorea may disappear within 48 hours of cessation of the medication, although the abatement can take longer.

Whereas pseudotumor cerebri can occur in patients taking oral contraceptives, other conditions that may cause blurring of the optic disc are papilledema related to venous sinus obstruction or retrobulbar optic neuritis, which also occurs in patients on birth control pills. Vascular headaches may also appear for the first time or suddenly change in pattern when oral contraceptives are started. Common migraine may become classic migraine, with patients experiencing symptoms or signs of focal cerebral dysfunction at the onset of the headache. In cases in which migraines either appear for the first time, increase in frequency, or become focal, cessation of oral contraceptives is suggested. On the other hand, a subgroup of headache patients finds relief of headache pain while taking oral contraceptives. These headaches may have a close relationship to menstruation, and while on the oral contraceptives, the patient has minimal pain.

Chelating Agents

2,3,-Dimercaptol-1-Propranol

2,3,-Dimercaptol (British antilewisite [BAL]) was synthesized during World War II as an antidote for arsenic-containing lewisite gas. This compound has also been found to be effective against the toxic manifestations of arsenic, mercury, gold, antimony, and other heavy metals. With doses of 2.5 mg/kg of body weight, toxic symptoms develop in less than 1% of individuals; with twice that dose, there is a 50% to 60% increase in the occurrence of intoxication. Symptoms appear within 10 to 20 minutes after injection of the drug and subside within 50 to 90 minutes. The usual reaction consists of headache, burning sensations in the mouth and eyes, muscular aches, paresthesias, pain in the teeth, lacrimation, salivation, rhinorrhea, and profuse sweating. Restlessness, anxiety, and general agitation may also develop, with progression in some instances to generalized convulsions and stupor. Abdominal pain, apprehension, blepharospasm, piloerection, tachycardia, and palpitations may also occur. Because of the transient nature of the toxic symptoms, no treatment is needed in BAL poisoning. Twenty-five milligrams of ephedrine sulfate given before the injection of BAL may lessen the incidence of toxic reactions.¹

Penicillamine

The most commonly encountered neurotoxic effect of penicillamine is loss or abnormality of taste, which has been correlated with high doses and long duration of therapy.¹ Hypogeusia occurs in 25% to 30% of patients at doses of 1 g daily within 6 weeks (Video 25, Taste Testing). It may be reversible by decreasing the dosage or discontinuing the drug and may not occur at all in dosages of 500 mg or less. Zinc infiltration of taste receptors has been postulated as causing the hypogeusia induced by penicillamine.

Dermatomyositis and polymyositis characterized by typical tender proximal muscle weakness with elevation of muscle enzymes may occur during penicillamine therapy. Another neurological side effect of penicillamine therapy, especially in rheumatoid arthritis patients, is a myasthenic syndrome. This can start as ptosis, diplopia, or dysphagia

but progresses to generalized weakness if early signs go undetected. The edrophonium test usually confirms the clinical suspicion, and laboratory studies demonstrate auto-antibodies to acetylcholine receptors (Video 226, Myasthenia Gravis: Edrophonium). Withdrawal of the drug and treatment with cholinesterase inhibitors reverse the weakness over several months.¹⁷⁷

Cholesterol-lowering Agents

Clofibrate

Clofibrate, an aromatic monocarboxylic acid, is capable of inducing myotonia in humans and experimental animals, and this is clinically significant because it is widely used to reduce serum triglyceride levels. The mechanism by which it induces myotonia is believed to be through a decrease in chloride conductance.

Statins

Lovastatin, simvastatin, fluvastatin, atorvastatin, rosuvastatin, and pravastatin are HMG-CoA (3-hydroxy-3-methylglutaryl coenzyme A) reductase inhibitors that are effective cholesterol-lowering agents used in the treatment of hypercholesterolemia. They can induce myotonia by blocking chloride channels on the muscle membrane.¹⁷⁸ Lipid-lowering agents can also cause a myopathy and neuropathy.¹⁷⁹ The risk of neuromyotoxicity is highest when multiple lipid-lowering agents are used together and can be as high as 5%. Other risk groups for development of myopathy include elderly or female patients, dose, specific agent used, and concomitant metabolic processes.¹⁸⁰ Evidence suggests that latent or previously minimal symptomatic muscle disease may predispose to the development of myopathy.¹⁷⁹ Clinically, patients have myalgias, elevated CK levels, and proximal weakness. Recovery is typical after discontinuation of the offending medications for the signs and symptoms of myopathy. Less information is available regarding the natural history of the sensorimotor neuropathy, but it appears to be less reversible if large fiber function is clinically manifest.¹⁷⁹ In one series rhabdomyolysis requiring hospitalization occurred in 13% of the patients.¹⁸¹ Table 55-11 lists the lipid-lowering agents associated with myopathy.^{182,183} Dermatomyositis-like syndrome and Guillain-Barré syndrome have been described with statin use.^{184,185}

NEUROLOGICAL SEQUELAE OF DIAGNOSTIC AND THERAPEUTIC PROCEDURES

Coronary Artery Bypass Graft Surgery

Coronary artery bypass graft (CABG) surgery is the most frequently performed cardiac surgery in North America, with nearly 400,000 procedures performed annually in the United States and Canada.¹⁸⁶ Early retrospective studies of open heart surgery found that stroke and anoxic encephalopathy were common postoperative neurological complications, occurring in more than 20% of patients. Improvement in surgery and extracorporeal circulation

may have initially reduced the frequency of permanent, disabling neurological sequelae. Nevertheless, subsequent prospective studies have shown that neurological complications account for the major adverse sequelae of this procedure. Because these problems can be severe, they must be taken into account when decisions are weighed as to whether medical or surgical therapy would be more appropriate in a given case.

Central Nervous System Complications

Stroke as a complication of CABG procedures occurs in 0.9% to 5.9% of cases.¹⁸⁶ Off-pump CABG has been reported to carry a smaller risk for stroke.¹⁸⁷ Most territorial infarcts result from macroemboli from diseased valves, left ventricular thrombus, or atheromatous emboli from a rigid ascending aorta. Stroke occurs more frequently with valvular heart surgery than with CABG operations. A permanent neurological disability after valve replacement occurs in 5% to 10% of patients. In contrast, the risk of a severe disability complicating CABG surgery is less than 2% to 5%.^{188,189} The difference is due to the greater risk of cardiac macroemboli with operations that require opening of the heart chambers. Removal or repair of diseased, calcified mitral or aortic valves is associated with the dispersion of tissue and surgical debris in the cardiac chambers. Extracranial carotid artery disease is often suggested as an important cause of stroke during CABG surgery. This theory proposes that severe carotid occlusive disease, combined with intraoperative hypotension, results in cerebral ischemia. However, most perioperative strokes occur in the absence of carotid occlusive disease or have their onset in the postoperative period. Most studies have failed to demonstrate a correlation between perioperative stroke and asymptomatic carotid artery stenosis. Nevertheless, it is common practice in some hospitals to perform a prophylactic staged or combined carotid endarterectomy in asymptomatic patients discovered to have carotid stenosis.¹⁸⁸ Because the majority of patients undergoing combined carotid endarterectomy and CABG have asymptomatic carotid stenosis, one has to take into consideration the added stroke risk from carotid stenosis.¹⁹⁰ Additional intracranial carotid artery disease may be an independent factor for

stroke after CABG, and, therefore, a comprehensive evaluation of the arterial tree to delineate the risk assessment for CABG surgery is warranted.¹⁹¹ Although CABG surgery frequently results in a tendency for bleeding (as a result of heparin administration, low fibrinogen levels, and thrombocytopenia induced by hemodilution and sequestration) and occasional disseminated intravascular coagulation, intracranial hemorrhage is an infrequent cause of stroke.¹⁸⁸

Attempts to prevent neurological sequelae after cardiac surgery have focused on improved surgical and cardiopulmonary bypass techniques, as well as identifying the high-risk patient. Age, preoperative stroke (within 3 months), severe aortic atheroma, opening of cardiac chambers, and sustained mean arterial pressure of less than 30 to 40 mmHg are probable risk factors for postoperative neurological sequelae. Less proven but still possible risk factors are prolonged cardiopulmonary bypass, severe carotid or cerebrovascular disease, postoperative atrial fibrillation, congestive heart failure, and diabetes mellitus.^{186,188}

Minor cognitive impairment following CABG procedures occurs in as many as 75% of patients tested 8 days postoperatively and may be present in up to a third of patients, even 1 year after surgery. These patients show a reduction of one standard deviation in neurocognitive testing postoperatively.¹⁸⁶ In a prospective longitudinal cognitive assessment of 261 patients who underwent CABG, the incidence of cognitive decline was 53% at discharge, 24% at 6 months, and 42% in 5 years.¹⁹² The pathogenesis of the cognitive decline following CABG is believed to be secondary to disseminated brain microemboli occurring during cardiac surgery. An alkaline phosphatase map of the afferent cerebral microvasculature has revealed thousands to millions of focal, small capillary and arteriolar dilatations in patients and dogs who have recently undergone CABG. These capillary and arteriolar dilatations are usually empty, suggesting that gas bubbles or fat emboli are a prime cause. Some authors believe that membrane oxygenators and 40- μ m arterial line filters are an essential part of protecting the brain against microembolic events, although this remains to be proved in practice.¹⁸⁶ In a study assessing cognitive function and cerebral perfusion following bypass surgery with the use of extracorporeal circulation, short-term neurocognitive dysfunction was found in 96% and long-term neurocognitive dysfunction was found in 55% of cases. Decrease in regional cerebral blood flow as measured by SPECT, was found in 68% of patients in the early period and in 55% after 6 months.¹⁹³ Several lines of evidence suggest that the late cognitive decline between 1 and 5 years after surgery may be secondary to high rates of cerebrovascular disease among candidates for CABG. A history of hypertension and other risk factors for vascular disease are known to be associated with increased risk for long-term cognitive decline in community-dwelling elderly individuals.¹⁹⁴

The global encephalopathy that can follow heart surgery varies from confusion to coma or a psychotic delirium. Nonmetabolic coma is a rare complication of open heart surgery, occurring in less than 1% of patients. It may be due to global anoxia-ischemia, massive stroke, or multiple strokes. On the other hand, the incidence of clinically detectable diffuse encephalopathy varies from 3% to 12%.¹⁸⁶ Post-CABG encephalopathy is often multifactorial

and can be related to medications, hypoxia, fever, sepsis, metabolic derangements, hemodynamic instability, and ICU psychosis. These patients may be slow to emerge from anesthesia, are often agitated or restless, and have poor visual fixation, small reactive pupils, and, occasionally, Babinski's sign. Improvement usually occurs during the first postoperative week. In otherwise uncomplicated cardiac surgery, disseminated microemboli during extracorporeal circulation may be the cause of this encephalopathy.¹⁸⁸ Seizures occur in less than 1% of patients and can accompany coma, encephalopathy, or delirium, or they may occur independently. The vast majority occur within the first 24 hours after surgery.

Peripheral Nervous System Complications

In a prospective analysis of 412 consecutive patients undergoing coronary bypass surgery, 55 (13%) developed new peripheral nervous system complications postoperatively.¹⁹⁵ The most common complication was brachial plexopathy, occurring in 23 patients. Most frequently the lower trunk or the medial cord of the brachial plexus was involved. The plexus injuries may be due to torsional traction, compression, or cannulation of the jugular vein. Male gender and hypothermia during surgery were associated with an increased risk. The usual clinical presentation involves intrinsic hand weakness and a decreased or absent triceps reflex. Sensory loss is sometimes present in the affected hand; some patients have prominent pain, and a minority of them have Horner's syndrome (Video 17, Horner's Syndrome). In a study examining neelettrophysiological studies of both upper extremities before 112 patients who underwent either CABG or heart valve surgery or peripheral vascular surgery, electrophysiological evidence of upper extremities nerve damage was found in 14% of CABG and 8% of valve replacement patients.¹⁹⁶ Most brachial plexus injuries are reversible within 1 to 3 months, implicating conduction block as the primary pathophysiological mechanism. Such injuries may be prevented by minimizing the opening of the sternal retractor, placing the retractor in the most caudal location, and avoiding asymmetrical traction. Unilateral phrenic nerve injuries with hemidiaphragmatic paralysis occur in at least 10% of patients during open heart surgery and can be manifested as atelectasis or persistent singultus. Finally, mononeuropathies resulting from compression or trauma during surgery may involve the accessory, facial, lateral femoral cutaneous, peroneal, radial, recurrent laryngeal, saphenous, and ulnar nerves (Video 219, Ulnar Neuropathy, Froment Sign).¹⁹⁵

Cardiac Catheterization

CNS complications of cardiac catheterization are rare and occur in 0.1% to 1.0% of patients. The majority of these complications are focal neurological deficits, which are believed to result secondary to embolism from either manipulation of the guidewire or catheter flushing in the ascending aorta when the brachial route is chosen.¹⁸⁸ Resolution of the focal deficits within 48 hours occurs in approximately half of the patients. In one big series, the carotid circulation accounted for 30% to 40% of focal deficits

and consisted of hemiparesis, hemisensory deficits, and dysphasia (Video 96, Conduction Aphasia). The vertebro-basilar circulation accounted for 60% of the deficits, with combinations of cortical blindness, hemianopic visual field defects, and intrinsic brain stem signs.¹⁸⁸

Percutaneous Transluminal Coronary Angioplasty

Focal neurological complications following percutaneous transluminal coronary angioplasty occur in 0.2% to 0.3% of patients and are similar to those seen in catheterization patients.¹⁸⁸

Cardiac Transplantation

Neurological complications recognized in the first weeks after cardiac transplantation are similar to those seen after routine CABG surgery or heart valve repair (Table 55-12). They include cerebrovascular disease, anoxic-ischemic encephalopathy, seizures, and peripheral nerve disorders.¹⁹⁷ Vascular headaches accompanied by nausea and vomiting may occur the first week after transplantation and are felt to be associated with a rapid shift from low preoperative to high postoperative mean arterial pressures. Psychotic behavior with hallucinations, delusional thought process, and disorganized behavior can occur during the first 2 weeks after transplantation or as a late complication (Video 22, Delusional Thinking). When it occurs in the first 48 hours and is accompanied by disorientation and impaired memory, it probably represents a behavioral response to intraoperative cerebral ischemia-hypoxia. If it begins 2 to 5 days after surgery, memory is preserved, and there is rapid resolution with environmental reorientation, then a multifactorial ICU psychosis may be present. If psychotic behavior presents 2 to 4 weeks following transplantation, then a full evaluation for an opportunistic infection is indicated.¹⁹⁷

Immunosuppression remains the major cause of late neurological complications after cardiac transplantation. Opportunistic infections can occur as early as 2 weeks after surgery and immunosuppression, but usually there is an interval of at least a month. Focal meningoencephalitis

or brain abscess, meningitis, and encephalitis are three common presentations of infections in cardiac transplant recipients. *Aspergillus*, *Toxoplasma gondii*, *Cryptococcus*, *Listeria*, *Candida*, and *Nocardia* are the most frequent non-viral organisms. The most frequent viral infections are caused by the herpesviruses, with cytomegalovirus being the most common.^{188,197} Aseptic meningitis has been reported in 5% of patients receiving OKT3 and presents as mental status and behavioral changes.¹⁸⁸

The use of cyclosporine since the early 1980s has allowed significant lowering of corticosteroid requirements and has reduced the frequency of its side effects. There have been a number of neurological effects ascribed to cyclosporine, however, including tremor, lowered seizure threshold, confusion, muscle weakness, ataxia (Video 7, Abnormal Tandem Gait), paresthesias, visual hallucinations, and a leukoencephalopathy with cortical blindness.^{188,197} These neurotoxic side effects rapidly remit with reduction of the dose of cyclosporine. When seizures occur and anti-convulsants are indicated, selection of the best agent may be difficult because phenytoin, phenobarbital, and carbamazepine can decrease the blood levels of cyclosporine. Finally, immunosuppression predisposes the patient to the development of primary or secondary lymphoma of the brain.

Radiation Damage

Therapeutic radiation may affect the nervous system in two settings: (1) damage to neural structures or blood vessels when they are included in the radiation port, whether the cancer undergoing radiation therapy is within or outside the nervous system (Table 55-13); (2) secondary nervous system involvement when radiation causes new tumors to develop or when radiation damages endocrine organs that are necessary for nervous system function. The presence and severity of these reactions are governed by a number of factors, including the total radiation dose, the radiation fraction size, and the volume of tissue irradiated. The age of the patient, the presence of pre-existing brain injury by

tumor or surgery, infection, vascular disease due to hypertension or diabetes mellitus, and chemotherapy may influence the susceptibility of the patient to injury as well.¹⁹⁸

Primary Brain Damage

Injury to the brain resulting from the radiosensitivity of normal brain tissue encompassed in the treatment volume can be classified as acute, early delayed, and late delayed reactions. Acute reactions occur during or immediately after the course of radiation therapy and typically develop in patients with increased ICP from primary or secondary brain tumors, particularly in the absence of corticosteroid coverage. Clinically, patients present with symptoms suggesting increased ICP or exacerbation of pre-existing neurological symptoms or signs.¹⁹⁹ The pathogenesis of the disorder is unknown, although it is thought to be due to radiation-induced edema secondary to blood-brain barrier breakdown. Acute symptoms are uncommon with dose-fractionation schedules consisting of 180 to 200 rad/day, given 5 days per week to a total dose of 6000 rad. Daily doses of up to 600 rad are well tolerated, but higher daily dose fractions should be administered with caution. Acute reactions, when they occur, are usually mild and transient. The preceding situations have two implications for the clinician: First, patients with large brain tumors and signs of increased ICP should not receive more than 200 rad per fraction. Second, all patients undergoing brain radiation should be given dexamethasone, preferably at least 24 hours before starting radiation therapy.

Early delayed reactions occur a few weeks to a few months after radiation. The symptoms often simulate tumor progression, with accentuation of pre-existing signs and symptoms, or may present as somnolence and lethargy without lateralizing signs. The early delayed reaction is transient and usually associated with an uneventful recovery. Rarely, however, it can be fatal. This is more likely to occur following radiation of the posterior fossa resulting in brain stem encephalopathy.^{198,199} Pathologically, there is extensive demyelination with central necrosis, absence of oligodendroglia, and gliosis accompanied by minimal vascular change and preservation of neurons and axons. The pathogenesis of the early delayed reaction is thought to be a temporary inhibition of myelin synthesis due to radiation-induced effects on the oligodendroglial cells. The turnover time of myelin is 5 weeks to 2 months, which corresponds to the latency and recovery time of the syndrome. The main significance of early delayed radiation injury lies in the need to differentiate this condition, which is transient and requires no therapy, from late radiation injury and tumor progression.

Late delayed reactions occur several months to years after treatment. Late delayed injury constitutes the major hazard of CNS exposure to therapeutic radiation. There are several theories as to the pathogenesis of late delayed brain injury. These theories include vascular injury, direct effect on glial cells, or autoimmune demyelination. It is probable that several mechanisms are involved, and the importance of each depends on the radiation dose and the latent interval. Evidence suggests that demyelination is important in the early delayed reaction and that the effect on the small and medium arterioles becomes progressively

more important with time. Histologically, the typical lesion is an area of coagulative necrosis in the white matter, with relative sparing of the overlying cortex. Microscopically, the most striking abnormalities are found in blood vessels, with hyalinized thickening and fibrinoid necrosis of the walls often associated with vascular thrombosis, vascular hemorrhages, and accumulation of perivascular fibrinoid material.

There is little information on the incidence of late radiation injury, because there is a paucity of prospective, well-controlled studies. The available data suggest that the risk of injury increases with doses in excess of 6000 rad delivered in 30 fractions over 6 weeks.¹⁹⁹ The daily fraction size in addition to total dose has a substantial effect on the risk of inducing damage to the CNS. Concomitant administration of chemotherapeutic agents may potentiate radiation injury.

In patients who were treated for primary or metastatic brain tumors, symptoms of radiation damage usually recapitulate those of the brain tumor, leading the physician to suspect tumor recurrence. In patients irradiated for head and neck tumors, whose brains were included in the radiation portal, new focal neurological signs are the rule. When injury occurs at the site of an intracerebral tumor, it is not possible to differentiate the effects of radiation from those of residual or recurrent tumor on the basis of CT or angiographic findings. MRI provides no additional information that can be used to differentiate between lesions. In both conditions, an increase in tissue water content causes an increase in mobile proton density and prolongation of T1 and T2 relaxation times. These changes result in decreased signal in T1-weighted images and increased signal in T2-weighted and proton density images. Contrast enhancement, resulting from blood-brain barrier breakdown, can be seen as well. Diffuse white matter injury is seen as periventricular white matter lesions, appearing as high-signal areas on proton density and T2-weighted images. These abnormalities are usually symmetrical and indistinguishable from the deep white matter changes seen in older people with risk factors for cerebral vascular disease.^{199,200} The CT, MRI, and angiographic picture of radiation necrosis cannot be differentiated from tumor recurrence. This differentiation is reliably achieved by fluorodeoxyglucose (FDG [¹⁸F]) positron-emission tomography examination, based on the decreased FDG accumulation in an area of necrosis.²⁰¹

Surgical resection of favorably situated focal lesions may result in considerable improvement or in complete recovery from the secondary effects of brain injury. After surgery, improvement most commonly occurs in patients with focal necrosis who have been irradiated for primary extracranial lesions. Resection is of little value in patients with diffuse lesions or brain stem involvement. Corticosteroids may result in improvement or stability of neurological deficit by reducing brain edema, although they cannot reverse the ongoing process.¹⁹⁹ Other agents that have been used in the treatment of radiation necrosis include heparin, coumadin, pentoxifylline, low-iron diet, desferrioxamine, pentobarbital, and hyperbaric oxygen therapy. New agents that are still in different stages of study include cytokine inhibitors, antiapoptotic agents, and drugs preventing radiation-induced loss of endothelial cells when given prior to radiation.²⁰²

Primary Spinal Cord Damage

Although there are no acute effects of radiation on the spinal cord, early delayed radiation myelopathy is common, especially after radiation of the neck. The patient develops Lhermitte's sign, which persists for weeks and months with spontaneous resolution; the sign is believed to be caused by demyelination of the posterior columns of the spinal cord.

Late delayed radiation myelopathy appears either as progressive myelopathy or a motor neuron syndrome. Radiation myelopathy usually presents as Brown-Séquard syndrome, which progresses to cause paraparesis or quadraparesis over weeks to months. Pathologically, there are areas of necrosis with a predilection for the white matter. Vascular changes are similar to those of the brain and sometimes can result in hemorrhage.²⁰³ The myelogram and MRI are usually normal, although in the acute phase, spinal cord swelling or contrast enhancement of focal lesions may be seen. Motor neuron syndrome characteristically follows pelvic radiation for testicular tumors. This is characterized by muscle weakness, accompanied by atrophy, fasciculations, and areflexia. There are no sensory, sphincter, or sexual changes. The symptoms progress over months to years and eventually stabilize.¹⁹⁹

Cranial and Peripheral Nerve Damage

Radiation injuries to the cranial and peripheral nervous systems are rare. The risk of brachial plexus injury increases with total dose in excess of 6000 rad, with daily fraction sizes of 200 rad, and with the use of large daily fraction sizes. Optic nerve and chiasmal injury are major risks in patients with pituitary or paraspituitary tumors who are treated with high daily dose fractions. In patients with pituitary tumors, the use of fraction sizes of 180 to 200 rad, with the total dose limited to 4500 rad, minimizes the risk of such injury. The retina is sensitive as well, and clinically evident injury may occur with doses as low as 4600 rad when the whole retina is included in the radiation field.¹⁹⁹

Secondary Involvement of the Nervous System

Secondary involvement of the nervous system following head and neck radiation for tumors not involving the nervous system can result in the development of radiation-induced tumors years to decades later. These radiation-induced tumors can be meningiomas, sarcomas, gliomas, thyroid cancer, and malignant schwannomas. The development of vascular malformations as a complication of radiotherapy is well described in the literature. In a study investigating the cumulative incidence of radiation-induced cavernomas in long-term survivors of medulloblastoma it was found that 5.6%, 14%, and 43% of children developed cavernomas at 3, 5, and 10 years, respectively. Most of these lesions were found to follow a benign course and do not require intervention.²⁰⁴ Lesions of large intracranial or extracranial blood vessels may also follow radiation therapy by years. The supraclinoid portion of the internal carotid artery is particularly vulnerable to the occlusive effects of radiation.

Finally, radiation of the head and neck can result in primary hypothyroidism, hypercalcemic hyperparathyroidism,

and hypothalamic-pituitary dysfunction. Radiation-induced hypothyroidism can present as encephalopathy, ataxia, and peripheral neuropathy (Video 7, Abnormal Tandem Gait). Thyroid function should be part of the evaluation of every patient with neurological dysfunction who has undergone prior radiation to the head and neck.

Vaccinations

Worldwide vaccination programs have had unparalleled success during this century in reducing the incidence of serious infectious diseases. Neurological sequelae of vaccinations have been reported, although assigning a causative relationship for vaccine injuries is difficult because randomized double-blind placebo-controlled studies have not been systematically conducted. A systematic medline search of all neurological adverse events reported following vaccination found that the most frequently reported autoimmune neurological problems following vaccinations were as follows: hepatitis A virus (HAV)—none; hepatitis B virus (HBV)—vasculitis, encephalitis, neuropathy; measles, mumps, and rubella (MMR)—transverse myelitis; influenza: Guillain-Barré syndrome; poliovirus—Guillain-Barré syndrome; varicella—mainly neurological syndromes. Whenever controlled studies of autoimmunity were undertaken, no evidence of an association was found.²⁰⁵ There are five types of vaccines available: whole-killed organisms, live-attenuated viruses, toxoids or components, conjugated vaccines, and recombinant vaccines (Table 55-14).

Whole-killed Organisms

Vaccines composed of whole-killed organisms include the influenza, poliomyelitis (IPV), pertussis, and rabies vaccines. Administration of the inactive antigens provokes an immune response that creates immunity without causing the disease. Vaccines made from whole-killed organisms may cause a variety of immune-mediated reactions.

PERTUSSIS. Standard pertussis vaccine prepared from killed whole cell *Bordetella pertussis* organisms has been in widespread use since the early 1950s.²⁰⁶ It has been effective in reducing the incidence of pertussis in the United States to low levels. Despite marked reduction in disease, the use of the vaccine has caused concern because of questions of encephalopathy resulting in permanent brain damage or death. Pertussis vaccine is ordinarily

TABLE 55-14

Types of Vaccines

| | |
|-------------------------|--------------------------------------|
| Killed organisms | Toxoids (Components) |
| Influenza | Acellular pertussis |
| Japanese encephalitis | Diphtheria |
| Pertussis | Tetanus |
| Poliomyelitis (IPV) | Conjugated |
| Live-attenuated viruses | <i>Haemophilus influenzae</i> type B |
| Measles | Recombinant |
| Mumps | Hepatitis B |
| Poliomyelitis (OPV) | Smallpox |
| Rubella | |
| Varicella | |

combined with diphtheria and tetanus toxoids (DPT), and all reported side effects are based on DPT and not pertussis vaccine alone. The Child Neurology Society, after reviewing the reports linking the whole-cell pertussis vaccine and neurological illness, has issued a consensus statement concluding that the pertussis vaccine is associated with a short-term increased risk of seizures, most of which are febrile seizures, and complete recovery is expected. The risk for febrile seizures is elevated on the day of receipt of DPT vaccine and 8 to 14 days after the receipt of measles-mumps-rubella vaccine, but these risks do not appear to be associated with any long-term adverse consequences.²⁰⁷ In regard to encephalopathy, the report concluded: "At present, there is no means by which a diagnosis of pertussis vaccine-encephalopathy can be established in an individual basis."

INFLUENZA. Annual vaccination against influenza is constituted depending on the prevalent strains that are expected to appear in the United States the following year. A small increase in the incidence of Guillain-Barré syndrome has been reported after the 1976 vaccination against the so-called swine flu. The significance of this association was initially questioned but later confirmed.²⁰⁸

INACTIVATED POLIOMYELITIS VACCINE. IPV was introduced in 1955, is still preferred in most European countries, and is devoid of neurological complications. In spite of this safety, the vaccine was not used in the United States until recently. Since the risk of contracting poliomyelitis is extremely low in the United States and all of the new cases are associated with the oral poliomyelitis vaccine, IPV has again become the vaccination of choice.

RABIES. The rabies vaccine used in the United States is both safe and efficacious. It is prepared by inactivated rabies virus grown on human diploid cells. Unfortunately, many underdeveloped countries prepare the vaccine by growing inactivated virus in the brains or spinal cords of mature animals. The myelin basic protein present in this vaccine (Semple) is responsible for encephalomyelitis and polyneuritis.

Live-attenuated Viruses

Vaccines composed of live-attenuated viruses include the measles, mumps, rubella, oral poliomyelitis, and varicella vaccines. They are intended to cause an asymptomatic infection. The immunity provided by these vaccines is lifelong, but they can occasionally cause symptomatic infection, sometimes with associated neurological involvement.

MEASLES-MUMPS-RUBELLA (MMR). MMR vaccine may cause fever, rash, conjunctivitis, or other measles-like symptoms in the second week after immunization. A double-blind placebo-controlled crossover study of the MMR vaccine performed in twins living in the same household found that statistically significant differences between placebo and vaccine occur during the second week and can be attributed to the development of measles infection.²⁰⁹ Seizures can also occur during the second week following immunization and are almost always simple febrile seizures.²⁰⁷ The evidence is inadequate to accept or reject a causal relationship between encephalopathy, subacute sclerosing panencephalitis, residual seizure disorder, sensorineural deafness, optic neuritis, transverse

myelitis, multiple sclerosis, Guillain-Barré syndrome, inflammatory bowel disease, type 1 diabetes mellitus, idiopathic thrombocytopenic purpura, rheumatoid arthritis, or other autoimmune disease and MMR.²¹⁰⁻²¹³

Reports have suggested an association with mumps vaccines and aseptic meningitis and sensorineural deafness. This is probably associated with the Urabe mumps strain, which is not used in the United States. Finally, with regard to the rubella vaccine, the Institute of Medicine concluded that there is insufficient evidence to indicate a causal relationship between the rubella vaccine and radiculoneuritis and other neuropathies.²¹⁴

There has been an attempt to associate a recent increase in the incidence of autism to MMR vaccination. Nevertheless, there is no evidence that any correlation exists between the prevalence of MMR vaccination and the rapid increase in the risk of autism over time.²¹⁵⁻²¹⁸

ORAL POLIOMYELITIS VACCINE. The oral poliomyelitis vaccine (OPV) consists of live-attenuated virus, and after its introduction in 1961, it replaced IPV in the United States because of ease of administration, combined intestinal as well as serum immunity, and spread from immunized to nonimmunized persons. The main disadvantage of OPV is that it can cause paralytic disease in 1 of 2.5 million doses distributed. At present, all cases of poliomyelitis in the United States are vaccine related.²¹⁰ High-risk groups are infants receiving their first dose and immunocompromised individuals who either receive the vaccine or are in contact with vaccine recipients. Finally, evidence favors acceptance of a causal relationship between OPV and Guillain-Barré syndrome.²¹⁰

Toxoids

Toxoid vaccines include tetanus and diphtheria and acellular pertussis. They are denatured bacterial toxins that prevent disease but not infection.

TETANUS AND DIPHTHERIA. Adverse reactions to diphtheria and tetanus immunizations cannot be assessed separately because they are always given together. Several reports have implicated DT in causing polyradiculoneuritis, brachial plexus neuritis, and acute transverse myelitis. The Institute of Medicine has reported that current evidence favors acceptance of a causal relationship between diphtheria and tetanus toxoid and Guillain-Barré syndrome and brachial neuritis.²¹⁰ It has also concluded that evidence rejects a causal relationship between diphtheria and tetanus toxoid and encephalopathy and infantile spasms.²¹⁰

ACELLULAR PERTUSSIS. Acellular pertussis vaccines contain two or more denatured elements of *Bordetella pertussis* required for immunity but do not contain endotoxin. In a recent study, the five-component acellular pertussis vaccine has been found to have a favorable safety profile with sustained protection against pertussis. The two-component acellular vaccine and the whole-cell vaccine were less efficacious.²¹⁹ A review of all Vaccine Adverse Events Reporting System (VAERS) for all events reported within 3 days following whole-cell and acellular pertussis among those residing in the United States from 1997 to 1999 found an association between serious neurological disorders and whole-cell pertussis vaccination.

Acellular pertussis, with the exception of cerebellar ataxia, had a safer profile.²²⁰

Obstetrical and Gynecological Procedures and Surgery

The peripheral nervous system can be injured in a variety of ways during pregnancy and delivery. Injury can occur at the level of the nerve roots, lumbosacral plexus, or individual peripheral nerves (Table 55-15).

The risk of injury to spinal cord or nerve roots from spinal or epidural anesthesia used for delivery is 0.1% or less. Various types of injury that have been described include epidural hematomas, chemical radiculitis or arachnoiditis, direct needle injury to the root, or spinal infarction secondary to hypotension.²²¹

Lumbosacral plexus injuries occur during labor or delivery and can be easily confused with a herniated disc. They occur in fetal-pelvic disproportion or in primiparous patients with large babies that necessitate midforceps delivery. The anterior division of the lumbosacral trunk (L4 or L5) is compressed by the fetal head or the obstetric forceps against the pelvic brim. These patients often complain of buttock or leg pain, which intensifies with uterine contractions. A footdrop or weakness of the tibialis anterior is the most common finding.²²²

A number of isolated nerve lesions may occur as a complication of obstetrical maneuvers. The obturator nerve may be injured when the patient is in the lithotomy position, because of angulation as the nerve leaves the obturator foramen. Clinically, the patient has weakness of adduction of the thigh and sensory loss over the medial thigh.

The femoral nerve is injured when the thighs are markedly flexed and abducted or the hips are abducted and externally rotated. Results of the injury include impaired extension of the knee, impaired flexion of the thigh, sensory loss over the anterior thigh, and loss of the patellar reflex.

The saphenous nerve can be injured by pressure from leg braces when the patient is in the lithotomy position. The

sciatic nerve can be injured when the patient is placed in stirrups on the obstetrical table or with a misplaced deep intramuscular injection. Clinically, the patient experiences sensory loss over the lateral leg and the whole foot, weakness of both dorsal and plantar flexion of the foot and of the extension of the knee, and loss of the ankle jerk. Isolated tibial injury is uncommon. The common peroneal is usually compressed at the head of the fibula from the leg braces with the patient in the lithotomy position.²²² Clinically, the patient has footdrop and inversion and sensory loss on the lateral aspect and the dorsum of the foot.

Nerve injury is an infrequent complication of gynecological surgery (see Table 55-15). The most frequently reported injury has been to the femoral nerve, followed by the sciatic and the obturator nerves.²²³ Stretch, compression, ligation, and transection are the most commonly reported intraoperative precipitators of symptoms, and postoperative scar formation may lead to entrapment symptoms at anatomical locations remote from the procedure.

Mechanisms of femoral neuropathy include self-retaining retractors, especially in thin patients with low transverse incisions and deep retractor blades; hyperflexion of the thigh; and control of bleeding deep in the pelvis and in the region of the psoas muscle. The clinical presentation is as described earlier.

Sciatic nerve injury can occur as a result of sacroiliac fossa bleeding, intramuscular injections, and the sacrospinus vaginal vault suspension procedure. Obturator nerve injury has been associated with pelvic surgery and specifically with pelvic lymphadenectomy.

Other less commonly encountered nerve injuries that may occur in association with gynecological surgery include the genitofemoral nerve, which may be injured during pelvic lymphadenectomy, and can result in numbness or tingling over the labia and the skin over the femoral triangle. The ilioinguinal and iliohypogastric nerves may be severed during an operation using a low transverse abdominal incision. The clinical syndrome consists of numbness or tingling over the suprapubic region, the upper medial thigh, and the anterior part of the labium majus. Finally, the lateral femoral cutaneous nerve may be injured during

TABLE 55-15

Neurological Complications of Obstetrical and Gynecological Procedures and Surgery

| SITE OF INJURY | MECHANISM | SYMPTOMS |
|--|--|---|
| Spinal cord and nerve roots | Spinal or epidural anesthesia (hematoma, chemical injury, infarction) | Myelopathy/radiculopathy |
| Lumbosacral plexus | Disporportion, large babies, midforceps use | Buttock/leg pain weakness: footdrop |
| Genitofemoral nerve | Pelvic surgery | Sensory loss: labia, femoral triangle |
| Ilioinguinal and upper-medial iliohypogastric nerves | Surgery with low transverse abdominal incision | Sensory loss: suprapubic area, thigh, anterior labial majus |
| Lateral femoral cutaneous | Inguinal lymphadenectomy | Sensory loss: anterior-lateral thigh |
| Pudendal nerve | Radical pelvic surgery | Sensory loss: clitoris, perineum, anus, incontinence |
| Obturator nerve | Lithotomy position, at the obturator foramen, pelvic surgery | Sensory loss: medial thigh, weakness: thigh adduction |
| Femoral nerve | Stirrups with thighs flexed and abducted and hip flexed and externally rotated, retractors | Sensory loss: anterior thigh, weakness: thigh flexion, reflex loss: patellar |
| Sciatic nerve | Stirrups, intramuscular injections, sacroiliac fossa bleeding | Sensory loss: lateral leg, foot weakness: foot flexion or extension, knee flexion, reflex loss: ankle |
| Common peroneal nerve | Lithotomy position, at the head of the fibula | Sensory loss: lateral and dorsum of the foot, weakness: footdrop and inversion |

an inguinal lymphadenectomy, and the pudendal nerve may be injured during radical pelvic surgery or during the performance of the sacrospinous vaginal vault suspension. Damage of the lateral femoral cutaneous nerve results in paresthesias over the lateral aspect of the front of the thigh as far as the knee, and damage of the pudendal nerve results in urinary and fecal incontinence and paresthesias of the clitoris, labia, perineum, and anus.

In contrast to brachial plexopathy, radiation-induced neural damage to the lumbosacral plexus is a rare complication. Although a few permanent lumbosacral lesions have been reported in patients treated with conventionally fractionated external beam, this syndrome is more often seen in patients treated with intracavitary irradiation for cervical or endometrial carcinoma.²²⁴

Careful surgical technique is probably the most important factor in prevention of the preceding complications. In addition, careful placement of the self-retaining retractor and careful positioning of the patient in stirrups is of paramount importance. With mild injuries, the prognosis for recovery is excellent, but recovery may be prolonged and incomplete if axonal degeneration has occurred. Recovery usually takes 4 weeks for the sensory function and 1 to 4 months for the motor function. Physical therapy, splinting or bracing to prevent contractures, and electrical stimulation are the usual treatment modalities used.

Critical Illness Polyneuropathy

The occurrence of muscle weakness in patients with sepsis and multiple organ failure managed in the ICU has been recognized with increasing frequency in the past 15 years. This weakness is due to an axonal polyneuropathy, otherwise called critical illness polyneuropathy. It must be differentiated from myopathy or disturbance of the neuromuscular junction that can also occur in the intensive care setting.²²⁵ Neither the cause nor the exact mechanism of critical illness polyneuropathy has been elucidated. Nutritional, toxic, metabolic, and vascular factors have all been proposed as likely causes, but none has been proved so far.²²⁵

The difficulty in examining critically ill patients may explain why this complication has only recently been recognized. The presence of encephalopathy or generalized edema can make the clinical diagnosis difficult to obtain. Predominantly proximal weakness can lead to quadriplegia. The facial muscles can be mildly weak, but the muscles of the eyes, tongue, and jaw are relatively spared.²²⁶ Deep tendon reflexes are partially preserved. Nevertheless, the signs of limb weakness and loss of previously elicited tendon reflexes are not present in all patients, even those who are subsequently shown by electrophysiological studies to have a moderately severe polyneuropathy.²²⁶

Electrophysiological studies demonstrate acute axonal damage to the peripheral nerves. Signs of primary demyelination, such as marked slowing of nerve conduction velocities, prolongation of distal latencies, dispersion of compound muscle action potentials, conduction block, and increased F-wave latencies, are absent even in severe cases of polyneuropathy.²²⁵ Parenchymatous axonal damage and marked neurogenic atrophy are constant features of nerve biopsy.

Before the recognition of critical illness polyneuropathy, these cases were usually misdiagnosed as acute demyelinating Guillain-Barré syndrome. The essentials for diagnosis of Guillain-Barré syndrome (e.g., absent reflexes, albuminocytological dissociation in the CSF, and evidence of demyelination in the electrophysiological studies), however, are not present in most critically ill patients with neuromuscular weaning failure. Furthermore, prolonged neuromuscular blockade following long-term treatment with muscle relaxant drugs, aminoglycoside antibiotics, neuromuscular-blocking agents in combination with high-dose corticosteroids for treatment of life-threatening status asthmaticus, and infectious, metabolic, or toxic myopathies or neuropathies should be included in the differential diagnosis of weakness and prolonged dependence on the ventilator.^{225,226}

Sepsis and multiple organ failure still has a high mortality rate, even in fully equipped ICUs. Clinical recovery from the neuropathy is rapid and nearly complete in those patients who survive, although it may appear to be incomplete on electrodiagnostic studies. Thus, neuropathy acquired during critical illness, although causing a delay in weaning from ventilatory support and hospital discharge, does not worsen long-term prognosis.²²⁵

- Abducens nerve. *See* Cranial nerve VI (abducens).
Abetalipoproteinemia, 637, 768–769
Abrodil, 460
Abscess(es)
 of brain, 947–949
 clinical features and disorders associated with, 948
 epidemiology and risk factors for, 947–948
 evaluation of, 948–949
 management of, 949
 pathogenesis and pathophysiology of, 948
 cerebrospinal fluid analysis in, 530t
 epidural, cranial and spinal, 950–952
 clinical features of, 951
 epidemiology and risk factors for, 950–951
 evaluation of, 951–952
 management of, 952
 pathogenesis and pathophysiology of, 951
Absence epilepsy, 1223
Absence seizures, 1217f, 1217–1218
Abulia, 35
 history of, 36–37
Academic achievement tests, 549
Acanthamoeba infections, 963, 964
Accessory nucleus, of cranial nerve XI, 232
Acetazolamide, for mountain sickness, 1207
Acetone intoxication
 occupations and job-related sources of exposure and, 867t–868t
 symptoms of, 877t
Acetylcholine
 basal ganglia and, 294
 motor system and, 260–261
 sleep and, 27t
Achondroplasia, 587
Acid maltase deficiency, 625–626, 626t
Acid-base status, of cerebrospinal fluid, 533
Acoustic reflex test, in cranial nerve VII assessment, 194
Acoustic schwannoma(s), 1068–1069
 clinical features and disorders associated with, 1068
 epidemiology and risk factors for, 1068
 evaluation of, 1068
 management of, 1069
 pathogenesis and pathophysiology of, 1068
Acquired immunodeficiency syndrome.
 See HIV/AIDS.
Acrocephalosyndactyly, 586, 586f
Acrocyanosis, 401
Acrodynia, 875
Acromegaly, 848
Actin, 245
Actinomycin D, neurological disorders due to, 1300–1301
Action tremors, 754–756, 755t
Acute disseminated encephalomyelitis (ADEM), 1129–1130
 clinical features and disorders associated with, 1129
 differential diagnosis of, 1129–1130
 epidemiology and risk factors for, 1129
 management, 1130
 pathogenesis and pathophysiology of, 1129
Acute inflammatory demyelinating polyradiculoneuropathy (AIDP), 283–284, 284t, 356, 1127–1142, 1138t. *See also* Guillain-Barré syndrome (GBS).
Acyclovir, 935t
 for Bell's palsy, 196
 for herpes simplex virus infections, 933–934
 for varicella zoster virus infections, 935
Adaptation, gait and balance and, 327
 impaired, 340–341
A-delta fibers, 364
Adenoma(s), 1070–1071
 clinical features and disorders associated with, 1070–1071, 1071t
 differential diagnosis of, 1071
 epidemiology and risk factors for, 1070
 evaluation of, 1071, 1071t
 management of, 1071
 pathogenesis and pathophysiology of, 1070
 prognosis and future perspectives on, 1071
Adie's pupil, 121, 154–155, 399
 evaluation of, 153t
Adie's syndrome, 152
Adrenal disorders, 845–848
Adrenergic disorders, pure, 398
Adrenergic neuropathy, pure, 398
Adrenoleukodystrophy, 626t, 634–635
Adriamycin, neurotoxicity of, 1298t, 1300–1301
Affect
 definition of, 35
 flattened, 35
 labile, 35
 pseudobulbar, 49
 Affective disorders. *See also* Bipolar disorder; Depression.
 in multiple sclerosis, 1108–1109
Age-associated memory impairment, 65
Aggression, 51–52
 history of, 37
 management goals for, 53
Agnosia
 in Alzheimer's dementia, 707
 associative, 722, 722t
 auditory, 211
 visual, 129–130
Agoraphobia, 51
Agraphia, 85t, 93
 left frontal (anterior), 93
 left parietotemporal (posterior), 93
 visuospatial, 93
AIDS. *See* HIV/AIDS.
AIDS-dementia complex, 726–727, 994.
 See also Cognitive impairment, HIV-related.
Akathisia, 304–305
 acute, neuroleptics and, 1287
Akinetic mutism, 35
Albendazole, for *Taenia solium* infections, 964
Alcohol, 910–915
 acute intoxication by, 911
 pharmacology of, 910
 stroke and, 1021
Alcoholic blackouts, 911
Alcoholic myopathy, 913–914
Alcoholic neuropathy, 914
Alcoholism
 nutritional deficiencies associated with, 897–910, 898t
 characteristics of, 899t
 copper deficiency myeloneuropathy as, 909
 historical background of, 897–898
 metabolic pathways and, 898f
 postgastroplasty polyneuropathy as, 909–910
 protein-energy malnutrition as, 908
 pyridoxine toxicity neuropathy as, 909
 Strachan's syndrome as, 909
 of vitamins, 898–907
 syndromes associated with, 911–915
 alcoholic dementia and cerebral atrophy as, 912

- Alcoholism (*Continued*)
 alcoholic myopathy as, 913–914
 alcoholic neuropathy as, 914
 cerebellar degeneration as, 913
 deficiency amblyopia as, 912–913
 fetal alcohol syndrome as, 915
 Marchiafava-Bignami disease as, 913
 movement disorders as, 914–915
 withdrawal syndromes as, 911–912
- Aldosteronism, 847
- Alexander's disease, 628t, 631
- Alexia
 with agraphia, 93
 assessment of, 85t
 frontal, 93
 without agraphia, 92–93
 assessment of, 85t
- Alfa-fetoprotein (AFP), neural tube defects and, 568–569
- Alice-in-Wonderland syndrome, 130
- Alkylating agents, neurological disorders due to, 1297–1298
- Allele-specific oligonucleotide (ASO) hybridization, 502t, 505
- Allodynia, 364
- Almitrine, sensory neuropathy due to, 345t
- Almotriptan, for migraine, 1252t
- Alper's disease, 665–666
 clinical features and disorders associated with, 665–666
 differential diagnosis of, 666
 epidemiology and risk factors for, 665
 evaluation of, 666
 management of, 666
 pathogenesis and pathophysiology of, 665
 prognosis and future perspectives on, 666
- Alpha motor neurons, 248–250, 248f–251f
- Alpha-gamma coactivation, 252, 252f
- Alprazolam, for insomnia, 1270t
- ALS. *See* Amyotrophic lateral sclerosis (ALS).
- Alternate cover test, in diplopia, 150–151
- Altitudinal hemianopia, 128
- Aluminum intoxication
 occupations and job-related sources of exposure and, 867t–868t
 symptoms of, 870t
- Alzheimer's dementia, 705–707, 706t
 definition of, 700
- Alzheimer's disease (AD), 700–711
 cerebrospinal fluid analysis in, 530t
 clinical features and disorders associated with, 704–707
 cranial nerve II dysfunction in, 121
 definition of, 700
 differential diagnosis of, 707–708
 electroencephalography in, 484
 epidemiology and risk factors for, 703, 704f
 evaluation of, 708
 management of, 708–710
 for abrupt decline, 709–710
 assisted living and skilled nursing facilities for, 710
 for behavioral disorders, 709
 driving cessation and, 710
 for intellectual decline, 709
 prevention and, 708–709
 for sleep-wake disturbances, 709
 weapon storage and, 710
 memory impairment and, 73, 74
 olfactory dysfunction in, 108
 pathogenesis and pathophysiology of, 700f, 700–701, 702f, 703
 positron-emission tomography in, 472–473
 prognosis and future perspectives on, 710–711
- Alzheimer's disease (AD) (*Continued*)
 single photon emission computed tomography in, 472–473
 trisomy 21 and, 701, 707
- Amanita* intoxication, 886t, 886–887
- Amantadine
 for Parkinson's disease, 740, 741t
 for spasticity, in multiple sclerosis, 1124
- Amaurosis fugax, 124–125
- Ambient state, observation of, in arousal assessment, 6
- Ambisome
 for *Aspergillus fumigatus* infections, 963
 for *Cryptococcus neoformans* infections, 961
 for Zygomycetes infections, 963
- Amblyopia, deficiency, 912–913
- Ambulatory sleep monitoring, 29
- Amebic infections, 963–964
- Amikacin
 for bacterial meningitis, 946, 946t
 neurotoxicity of, 1294t
- Aminoacidopathies, 641–659
 of later infancy, with recurrent metabolic crises, 651–652
 neonatal, 641–651
 screening programs for, 641–642, 642t
 progressive, of infancy and childhood, 652–659
- Aminoglycoside neurotoxicity, 1294, 1294t
 central, 1293t
 peripheral, 1293t
- 4-Aminopyridine, for heat sensitivity, in multiple sclerosis, 1124
- Amiodarone neurotoxicity, 1302t, 1303
- Amitriptyline
 actions of, 1288t
 for headache prophylaxis, 1253t
 for insomnia, 1270t
 for pain management, 378t
 for Parkinson's disease, 741t
- Amnesia, 74–75
 anterograde, 64

 basic principles and technique for, 487
 in cranial nerve V assessment, 172, 172t
 in cranial nerve VII assessment, 193
 in cranial nerve VIII assessment, 208, 209t
 in gait and balance assessment, 332
 normal findings on, 487, 488f
- Brain stem lesions
 proprioceptive and vibratory sense
 abnormalities due to, 346t
 sensory loss and, 358
- Brain stem motor tracts, 257–259,
 260f–262f
- Brain stem syndromes
 autonomic dysfunction secondary to, 399
 of cranial nerve V, 173, 176, 176f
 pain loss, 376
- Brain tumor(s). *See* Neoplastic disorders, cranial.
- Branching enzyme deficiency, 626, 626t, 627
- Breathing
 patterns of, in arousal assessment, 9–10, 10t
 with various levels of central nervous system
 dysfunction, 6t
- Breathing disorders, sleep-related, 31
 assessment of, 28t
 in neuromuscular disease, 1281–1282
- Bresolin's disease, 625, 626t
- Brief Smell Identification Test (B-SIT), 105
- Broca's aphasia, 88–89, 90f
 clinico-anatomical correlates of, 95t
- Broca's area, 80, 81, 81f
- Brody's disease, 821–822
 clinical features of, 821
 differential diagnosis of, 821
 epidemiology of, 821
 evaluation of, 822
 management of, 822
 pathogenesis and pathophysiology of, 821
 prognosis of, 822
- Bromocriptine
 for adenomas, 1071
 for Parkinson's disease, 741, 741t
- Brown-Séquard syndrome, 282, 282t, 1198
- Buerger's syndrome, 1165–1166
 clinical features and disorders associated
 with, 1166
 differential diagnosis of, 1166
 epidemiology and risk factors for, 1166
 evaluation of, 1166
 management of, 1166
 pathogenesis and pathophysiology of,
 1165–1166
 prognosis and future perspectives on, 1166
- Burners, 1204
- Burning hands syndrome, 1198
- Burst neurons, 144
- Busulfan, neurological disorders due to, 1298
- Butorphanol, for migraine, 1252t
- “Bystander” demyelination, 1105
- C
- C fibers, 364
- C syndrome, 586
- Cacosmia, 109
 definition of, 99
- CADASIL syndrome, 1250
- Caffeine, neurological disorders due to, 1304
- Caisson disease, 1207–1208
 clinical features and disorders associated
 with, 1208
 epidemiology and risk factors for, 1207–1208
 evaluation and management of, 1208
 pathogenesis and pathophysiology of, 1207
 prognosis and future perspectives on, 1208
- Calcification, intracranial, computed tomography
 in, 444–445, 446, 446f, 447f
- Calcium channelopathies, 815
- Calcium disorders, 833–835
- Calcium-channel blockers neurotoxicity,
 1302t, 1303
- California group virus encephalitis, 925

 HIV-related
 in adults, 994t, 994–1000
 clinical features and disorders associated with, 997–998
 differential diagnosis of, 998
 epidemiology and risk factors for, 995, 997
 evaluation of, 998–999, 999t
 management of, 999–1000
 pathogenesis and pathophysiology of, 994–995, 995t, 996f, 996t
 in AIDS-dementia complex, 726–727
 mild, 65
 in multiple sclerosis, 1108
 treatment of, 1124
- Cogwheel pursuit, 148
- Coital headache, 1260
- Cold pressor test, 394
- Cold water caloric stimulation, in vestibulo-ocular system examination, 149
- Colistin, peripheral neurotoxicity of, 1293t
- Collet-Sicard syndrome, 240
- Collier's sign, 160
- Colloid cyst(s), 1077
- Color perception, assessment of, 119
- Colorado tick fever virus infections, 925
- Coma
 alpha-pattern, electroencephalography in, 482
 definition of, 3
 after head injury, electroencephalography in, 482
 myxedema, cerebrospinal fluid analysis in, 530t
 in neonates, differential diagnosis of, 644t
 opioid overdose and, 892
 somatosensory evoked potentials in, 490
- Combined degeneration of spinal cord, subacute, cervical spondylosis vs., 599
- Commands, in language comprehension assessment, 82
- Common peroneal neuropathy, at fibular head, 609
- Communicating artery
 anterior, anatomy of, 409–410
 posterior, anatomy of, 410
- Complex regional pain syndrome (CRPS), 1205–1207
 clinical features and disorders associated with, 1206
 differential diagnosis of, 1206
 epidemiology and risk factors for, 1205–1206
 evaluation and management of, 1206
 pathogenesis and pathophysiology of, 1205
 prognosis and future perspectives on, 377, 401, 1206–1207
- Complex repetitive discharges, on electromyography, 491, 492f
- Compulsions, 36
- Computed tomography (CT), 441–447. *See also specific conditions.*
 abnormalities detectable on, 444–446
 with contrast enhancement, 445–446
 without contrast enhancement, 444f, 444–445, 445f
 in Alzheimer's disease, 708
 in apraxia assessment, 58
 basic principles and techniques for, 441–443, 442t, 443f
 of brain abscess, 948
 in cerebellar disorders, 318, 319f
 in cerebrovascular disease, 1019
 in consciousness assessment, 12
 in cranial nerve II assessment, 123
 in cranial nerve III assessment, 152
 in cranial nerve IV assessment, 152
 in cranial nerve VI assessment, 152
 in cranial nerve VII assessment, 192
 in HIV-related cognitive impairment, 998–999
 in intracerebral hemorrhage, 1040
 in mood, emotion, and thought assessment, 45
 in movement disorder examination, 299, 300t
 neurological applications of, 446–447
 in cranial disease, 446–447
 in spinal disease, 447
 in neurovascular examination, 417, 418, 418t
 normal findings on, 443–444
 in olfactory assessment, 106
 in pain and temperature sensation, 369
 in reflex assessment, 272, 273t–274t
 in speech and language assessment, 84
 in stroke, 1023
- Computed tomography angiography (CTA). *See also specific conditions.*
 in cranial nerve III assessment, 154
 in cranial nerve IV assessment, 154
 in cranial nerve VI assessment, 154
 in neurovascular examination, 419–420

- Concept formation
nonverbal, 550
verbal, 549–540
- Conceptual apraxia, 61
- Concussion. *See* Head injury.
- Conditioning, implicit memory and, 63
- Conduction aphasia, 90–91
clinico-anatomical correlates of, 95t
- Conduction apraxia, 60
- Conduction block, focal, on nerve conduction studies, 493
- Conduction slowing, focal, on nerve conduction studies, 493
- Conductive hearing loss, 210
- Cones (retinal), 114–115, 115f
- Confusion, assessment of, 12t
- Confusional arousals, 1279–1280
clinical features and disorders associated with, 1279
differential diagnosis of, 1279–1280
epidemiology and risk factors for, 1279
evaluation of, 1280
management of, 1280
pathogenesis and pathophysiology of, 1279
prognosis and future perspectives on, 1280
- Congenital rubella syndrome, 930–931
- Conjugate eye movements, 134
- Conjugate gaze, 133
paresis of, 134
- Conjugate gaze palsy syndromes, 159–160
- Connective tissue diseases, 1156, 1166–1174
mixed, 1172–1173
progressive systemic sclerosis as, 1171–1172
rheumatoid arthritis as, 1166–1167
Sjögren's syndrome as, 1173–1174
systemic lupus erythematosus as, 1167–1171
- Consciousness, definition of, 3
- Consciousness levels, 3–17
altered. *See also* Coma.
clinical syndromes of, 13–17
bilateral cortical dysfunction as, 13
brain death criteria and, 15–17, 16t
diencephalic dysfunction as, 13–14
herniation syndromes as, 14–15
medullary dysfunction as, 14
midbrain dysfunction as, 14
persistent vegetative state as, 5
pontine dysfunction as, 14
psychogenic unresponsiveness as, 17
syncope as, 13
electroencephalography in, 482
management goals for, 17, 17t–18t
anatomy of, 4–5
clinical history and, 2
definitions related to, 3–4
examination of, 5–13
associated medical findings in, 11
associated neurological findings in, 11
directed neurological examination in, 5–11
neurodiagnostic studies in, 11–13, 12t
historical background of, 3
- Constipation, in multiple sclerosis, 1108
- Construction
clinical situations for testing, 554
tests of, 553–554
- Content errors, in apraxia, 61
- Continuous positive airway pressure (CPAP), for obstructive sleep apnea, 1275
- Contraceptive agents, neurological disorders due to, 1306
- Contrast media, allergy to, pretreatment for, 442
- Controlled Oral Word Association Test, 551
- Conus medullaris syndrome, 1198
pain and temperature sensation in, 375, 375t
- Conversation, in language comprehension assessment, 82
- Coordination, 307–324
anatomy and physiology of, 308, 309t, 310t, 310–314, 311f
cerebellar afferents and, 310–312, 311f, 312f, 313
internal cerebellar structure and, 312f, 312–313
vascular cerebellar anatomy and, 314, 314f
definitions related to, 307–308
disorders of, 320–321, 322t–323t, 324, 324f
ataxia as. *See* Ataxia.
cerebellar speech as, 321
clinical history and, 308
clinico-anatomical correlates of, 310t
cognition and, 324
management goals for, 324
oculomotor, 321, 324
examination of, 314–322
associated medical findings in, 318
associated neurological findings in, 317–318
neurodiagnostic tests in, 318, 319t, 320
neurological, 314–317
cognitive function in, 317
oculomotor system in, 316
posture and gait in, 314–315
speech in, 316
voluntary motor acts in, 315f, 315–316
in gait and balance assessment, 331
historical background of, 307
- Copper deficiency myeloneuropathy, 909
- Copper metabolism disorders. *See* Wilson's disease.
- Cori-Forbes disease, 625, 626t
- Corneal hypesthesia, 178
- Corneal reflex, 170, 171f, 191
electrophysiological assessment of, latency of, 172–173, 174f
- Corneomandibular reflex, 171
- Coronary artery bypass graft surgery, neurological disorders due to, 1307–1308
central nervous system, 1307–1308
peripheral nervous system, 1308
- Corpus callosotomy, for epilepsy, 1241–1242
- Corpus callosum, agenesis of, 571–572, 572f
- Corsi Block Test, 546
- Cortical atrophy, posterior, 722, 722t
- Cortical blindness, 129
- Cortical deafness, 211
- Cortical development, disorders of, 575–576, 577f
- Cortical dysfunction
bilateral
assessment of, 12t
consciousness alteration and, 13
clinical findings in, 6t
- Cortical dysplasia, 578, 579
- Cortical pain syndrome, 376–377
- Cortical reflex myoclonus, 305
- Corticobasal degeneration, 727–729, 745
clinical features and disorders associated with, 727–728
differential diagnosis of, 728
epidemiology and risk factors for, 727
evaluation of, 728
management of, 728–729
pathogenesis and pathophysiology of, 727, 728f
- Corticobulbar tract, 257, 259f
- Corticospinal tract, 256–257, 257f–259f
lateral, 257
in multiple sclerosis, 1108
ventral, 257
- Corticosteroids. *See also specific corticosteroids.*
for intracranial pressure elevation, 536
for myasthenia gravis, 1175
for spinal metastases, 1092
- Cough headache, 1259–1260
- Cover-uncover test, in diplopia, 151, 151t
- Coxsackievirus infection(s)
clinical features and disorders associated with, 921–922
differential diagnosis of, 922
epidemiology and risk factors for, 919
management of, 922
pathogenesis and pathophysiology of, 919–921
prognosis and future perspectives on, 922
- C-polymodal nociceptors (CPNs), 364
sensitization of, 371, 373f, 374f
- Cranial diseases. *See also specific disorders.*
extra-axial, on magnetic resonance imaging, 449–450, 450f
intra-axial
computed tomography in, 446f, 446–447, 447f
on magnetic resonance imaging, 450–453, 451t, 451f–453f
neuroangiography in, 464–467
plain films in, 439–440
- Cranial epidural abscesses, 950–952
clinical features of, 951
epidemiology and risk factors for, 950–951
evaluation of, 951–952
management of, 952
pathogenesis and pathophysiology of, 951
- Cranial nerve disorders. *See also specific cranial nerves.*
computed tomography in, 446–447
in diabetes, 851–852
Lyme disease and, 958
- Cranial nerve function
in apraxia assessment, 58
in autonomic nervous system examination, 391
in cerebellar disorders, 317
in consciousness assessment, 11
in cranial nerve II assessment, 121
in cranial nerve III assessment, 152
in cranial nerve IV assessment, 152
in cranial nerve V assessment, 171
in cranial nerve VI assessment, 152
in cranial nerve VIII assessment, 207–208
in cranial nerve IX assessment, 223
in cranial nerve X assessment, 223
in cranial nerve XI examination, 237
in cranial nerve XII examination, 237
in gait and balance assessment, 331
in memory assessment, 70
in mood, emotion, and thought assessment, 44
in movement disorder examination, 298
in neurovascular examination, 414, 417
in olfactory assessment, 105–106
pain and temperature sensation and, 368
in reflex assessment, 270
in sensory loss, 355
in sleep disorders assessment, 27
in speech and language assessment, 84
- Cranial nerve I (olfactory), 99–110
anatomy of, 100–104, 101t
of central connections, 102
of neurochemical olfactory transduction process, 103–104
of secondary sensory neurons, 101–102, 103f
of sensory receptors and primary neurons, 100–101, 102f
definitions related to, 99–100
disorders of, 107–110, 108t
anosmia and hyposmia as, 107–109
bilateral, 99
clinical history and, 100
dissociated olfactory function syndromes as, 109–110

- Cranial nerve I (olfactory) (*Continued*)
 dysosmia as, 109
 hyperosmia as, 109
 management goals for, 110
 traumatic, 1193t
 unilateral, 99
 examination of, 104–107
 associated medical findings in, 106
 associated neurological findings in, 105–106
 neurodiagnostic tests in, 106–107
 neurological, 104–105
- Cranial nerve II (optic), 113–131
 anatomy of, 114t, 114–118, 116
 of eyes, 114
 of lateral geniculate nucleus, 117, 117f
 of optic chiasm, 114t, 116f, 116–117
 of optic nerve, 114t, 116
 of optic radiations, 114t, 117–118
 of optic tract, 114t, 117, 117f
 of retina, 114t, 114–116, 115f
 of striate cortex, 118
 of visual association area, 114t, 118
 assessment of, 122t
 definitions related to, 113
 disorders of
 cerebrospinal fluid analysis in, 531t
 clinical history and, 113
 clinico-anatomical correlates of, 114t
 in multiple sclerosis, 1107–1108, 1110
 optic neuritis as, 125
 optic neuropathy as, 172
 hereditary, Leber's, 669
 ischemic, 125–126
 retrobulbar, 125
 traumatic, 1193t
 visual evoked potentials in, 487
 examination of, 118–122
 ancillary ophthalmological techniques in, 120
 associated medical findings in, 121–122
 associated neurological findings in, 120–121
 fundoscopic examination in, 119–120, 120f
 of higher cortical visual function, 119
 neurodiagnostic tests in, 122t, 122–124
 neurological, 118–120
 of color perception, 119
 of visual acuity, 118–119
 visual field testing in, 119
 pupillary examination in, 119, 120f
 historical background of, 113
- Cranial nerve III (oculomotor)
 anatomy of, 136t, 137, 138–139, 139f, 140f
 definitions related to, 133–134, 134f
 disorders of
 clinical history and, 134–135, 137
 clinico-anatomical correlations of, 136t
 management goals for, 162
 palsy as, 156–157
 traumatic, 1193t
 examination of, 144–152
 associated medical findings in, 152
 associated neurological findings in, 152
 neurodiagnostic tests in, 152, 153t, 154
 neurological, 144–146, 146f
 historical background of, 133
- Cranial nerve IV (trochlear)
 anatomy of, 136t, 139, 140f
 definitions related to, 133–134, 134f
 disorders of
 clinical history and, 134–135, 137
 clinico-anatomical correlations of, 136t
 management goals for, 162
 palsy as, 157–158
 traumatic, 1193t
 examination of
 associated medical findings in, 152
 associated neurological findings in, 152
 neurodiagnostic tests in, 152, 153t, 154
 neurological, 144–145, 146–147
 historical background of, 133
- Cranial nerve IV (trochlear) (*Continued*)
 traumatic, 1193t
 examination of
 associated medical findings in, 152
 associated neurological findings in, 152
 neurodiagnostic tests in, 152, 153t, 154
 neurological, 144–145, 146
- historical background of, 133
- Cranial nerve V (trigeminal), 165–182
 anatomy of, 165–169, 166t, 167f
 of motor portion, 169
 pontine nucleus and lower motor nucleus and, 169
 supranuclear control and upper motor neurons and, 169
 of sensory portion, 166–169
 first-order neurons and, 166–168, 167f, 168t
 receptors and, 166
 second- and third-order sensory neurons and, 168–169
 definitions related to, 165
 disorders of, 173, 175t, 176–181
 clinical history and, 165
 gasserian ganglion syndromes as, 176–177
 lesions involving branches of cranial nerve V as, 177f, 177–179, 179f
 management goals for, 181–182
 nuclear (brain stem) syndromes as, 173, 176, 176f
 preganglionic syndromes as, 176
 supranuclear syndromes as, 173, 175f
 traumatic, 1193t
 trigeminal neuralgia as, 165, 179–181, 180f, 181f, 1262
 assessment of, 172t
 cerebrospinal fluid analysis in, 531t
 trigeminal neurilemmomas as, 1068–1069
 clinical features and disorders associated with, 1068
 epidemiology and risk factors for, 1068
 evaluation of, 1068
 management of, 1069
 pathogenesis and pathophysiology of, 1068
 examination of, 169–172
 associated neurological findings in, 171–172
 neurodiagnostic tests in, 172t, 172–173
 neurological, 169–171
 motor function and, 170, 171f
 reflexes and, 170–171, 171f
 sensory function and, 169–170, 170f
 first (ophthalmic) division of, 138
 historical background of, 165
 mandibular branch of, 165
 anatomy of, 166–167, 167f, 168t
 maxillary branch of, 165
 anatomy of, 166, 167f, 168t
 ophthalmic branch of, 165
 anatomy of, 166, 167f, 168t
- Cranial nerve VI (abducens)
 anatomy of, 136t, 139–140
 definitions related to, 133–134, 134f
 disorders of
 clinical history and, 134–135, 137
 clinico-anatomical correlations of, 136t
 management goals for, 162
 palsy as, 157–158
 traumatic, 1193t
 examination of
 associated medical findings in, 152
 associated neurological findings in, 152
 neurodiagnostic tests in, 152, 153t, 154
 neurological, 144–145, 146–147
 historical background of, 133
- Cranial nerve VII (facial), 185–197
 anatomy of, 186–190, 187t
 of lower motor neuron, 189–190
 cerebellopontine angle and, 187t, 189f, 189–190
 facial canal and, 187t, 190
 internal auditory meatus of temporal bone and, 187t, 190
 stylomastoid foramen and, 187t, 190
 of motor division, 186–188
 pontine nucleus and, 187t, 187–188, 188f
 upper motor neuron and, 186–187, 187t
 of nervus intermedius, 188–189, 189f
 gustatory nucleus of, 189
 parasympathetic nucleus of, 188
 sensory nucleus of, 188
 disorders of, 194, 195t, 196–197
 clinical history and, 185–186
 associated features and, 186
 extent of involvement and, 185, 186t
 precipitating elements and, 185–186
 temporal presentation and, 185
 Lyme disease and, 958
 medical management of goals for, 197
 overactivation syndromes as, 196
 hemifacial spasm as, 196
 myokymia as, 196
 paresis syndromes as, 194, 196
 central facial palsy as, 194
 nuclear/pontine lesions and, 194
 peripheral nerve lesions and, 194–196
 reinnervation syndromes as, 196–197
 crocodile tears as, 196
 gustatory sweating as, 197
 postparalytic movements and synkinesis as, 196
 traumatic, 1193t
 varicella zoster virus infections and, 934
 examination of, 190–192
 associated medical findings in, 192
 associated neurological findings in, 191–192
 neurodiagnostic tests in, 192–194, 193t
 neurological, 190–191
 motor, 190–191
 parasympathetic, 191
 of reflexes, 191
 sensory, 191
 historical background of, 185
 upper motor neuron and, 186–187, 187t
- Cranial nerve VIII (vestibulocochlear), 199–215
 anatomy of, 200–205, 201t
 of auditory system, 200–202
 first-order neuron and, 200–201, 202f
 fourth-order neuron and, 201–202, 203f
 second-order neuron and, 201, 203f
 third-order neuron and, 201
 vascular, 204–205, 205f
 of vestibular system, 202–204
 vestibular ganglion and nerve and, 203
 vestibular nuclei and, 203–204, 204f
 clinical history and, 199–200, 200t
 definitions related to, 199
 disorders of, 210–214, 211t
 clinico-anatomical correlates of, 201t
 management goals for, 214–215
 primarily involving hearing, 210–212
 primarily involving vestibular function, 212–214
 benign paroxysmal positional vertigo as, 212, 212f
 central vertigo as, 214, 214t
 cerebellopontine angle syndrome as, 213
 Ménière's disease as, 213–214

- Cranial nerve VIII (vestibulocochlear)
(*Continued*)
vestibular neuritis and other unilateral vestibulopathies as, 212–213, 213t
traumatic, 1194t
examination of, 205–208
associated medical findings in, 208
associated neurological findings in, 207–208
directed neurological examination and, 205–207, 207f
neurodiagnostic procedures for, 208–210, 209t, 210t
neurodiagnostic tests in, for neuroimaging, 208, 209t
historical background of, 199
- Cranial nerve IX (glossopharyngeal), 217–220
anatomy of, 218–220
of autonomic fibers, 220
of motor fibers, 218, 219f
of sensory fibers, 219–220
definitions related to, 217
disorders of, 219t
clinical history and, 217–218
clinical-anatomical correlations of, 219t
far distal peripheral lesions and, 227
glossopharyngeal neuralgia as, 227, 1263
management goals for, 227
middle peripheral lesions and, 226
nuclear lesions and, 226
proximal peripheral lesions and, 226
supranuclear lesions and, 224–226
traumatic, 1194t
examination of
associated neurological findings in, 223
neurodiagnostic tests in, 223–224, 224t
neurological, 222
historical background of, 217
- Cranial nerve X (vagus)
anatomy of, 220–222
of autonomic fibers, 221–222
of motor fibers, 220, 221f
of sensory fibers, 220–221
definitions related to, 217
disorders of
clinical history and, 217–218
clinical-anatomical correlations of, 219t
far distal peripheral lesions and, 227
management goals for, 227
middle peripheral lesions and, 226
nuclear lesions and, 226
proximal peripheral lesions and, 226
supranuclear lesions and, 224–226
traumatic, 1194t
examination of
associated neurological findings in, 223
neurodiagnostic tests in, 223–224, 224t
neurological, 222–223
historical background of, 217
- Cranial nerve XI (spinal accessory)
accessory portion of, 232
anatomy of, 232–234
disorders of, clinico-anatomical correlates of, 233t
of lower motor neuron and peripheral pathways, 232
of nucleus, 232, 234f
of upper motor neuron and supranuclear control, 233–234
definitions related to, 231
disorders of
clinical history and, 231–232, 232f
general management goals for, 240
traumatic, 1194t
examination of
associated neurological findings in, 237
neurodiagnostic tests in, 237–238, 238t
neurological, 236–237
historical background of, 231
- Cranial nerve XII (hypoglossal)
anatomy of, 234
of lower motor neuron and peripheral pathways, 234
of nucleus, 234
of upper motor neuron and supranuclear control, 234
definitions related to, 231
disorders of
clinical history and, 231–232, 232f

for myoclonus, 759t
- Valsalva maneuver
blood pressure response to, 394
heart rate response to, 393, 394f
- Vancomycin
for bacterial meningitis, 946t, 947
for brain abscess, 949
central neurotoxicity of, 1293t
for subdural empyema, 950, 951t
- Varicella zoster virus (VZV) infection(s), 934–935
clinical features and disorders associated with,
934–935
differential diagnosis of, 935
epidemiology and risk factors for, 934
management and prognosis of, 935, 935t
pathogenesis and pathophysiology of, 934
- Variola virus infection(s), 938–939
clinical features and disorders associated with,
939
diagnosis of, 939
epidemiology and risk factors for, 938–939
management of, 939
pathogenesis and pathophysiology of, 939
- Vascular dementia, 431, 431t, 715–716
- Vascular disorders. *See also specific disorders*.
brain biopsy and, 519–520, 520t
inflammatory, stroke and, 1034, 1035t–1036t
noninflammatory, stroke and, 1033
- Vascular dissection syndromes, 428–429
- Vascular lesions
intracranial, ultrasonography in, 469, 469f
in neck, ultrasonography in, 470, 470f, 471f
- Vascular malformations. *See also specific*
malformations.
intra-axial, on magnetic resonance
imaging, 453
of spinal cord, 426–427
- Vasculitis, 1155–1156, 1156f
with antiphospholipid antibodies, 1164–1165
clinical features and disorders associated
with, 1164–1165
differential diagnosis of, 1165
epidemiology and risk factors for, 1164
evaluation of, 1165
management of, 1165

- Vasculitis (*Continued*)
 pathogenesis and pathophysiology of, 1164
 prognosis and future perspectives on, 1165
 immune complex, 1155–1156
 infections and, 1156
 mononuclear-predominant, 1155
 neutrophil-predominant, 1155
- Vasomotor paralysis, 401
- Vasospasm, cerebral, with subarachnoid hemorrhage, 1043
- VDRL test, 956–957
- Vegetative state
 definition of, 3
 persistent, 15
- Vein of Galen tumor(s), 1075t
- Venezuelan encephalitis virus infections, 926
- Venlafaxine, for pain management, 378t
- Venous thrombosis, cerebrospinal fluid analysis in, 530t
- Venteroposteromedial nucleus (VPN), anatomy of, 168–169
- Ventral cranial nerve III fascicular syndrome, 423
- Ventricular metastases, 1085–1088
 clinical features of, 1085–1086, 1086t
 differential diagnosis of, 1086
 epidemiology and risk factors for, 1085, 1085t
 evaluation of, 1086, 1087f
 management of, 1086–1088
 pathogenesis and pathophysiology of, 1085
 prognosis and future perspectives on, 1088
- Ventricular system, 523–533
 anatomy of, 523–524, 524f, 525f
 physiology of, 524–528
 cerebrospinal fluid composition and, 525–526, 527t
 lumbar puncture and, 526–527, 527f
 secretion and absorption and, 524–525, 526f, 526t
- Ventriculoencephalitis, cytomegalovirus, 936
- Ventriculomegaly, fetal, 563–564
- Ventriculoperitoneal (VP) shunting, for hydrocephalus, 563
- Verapamil, for headache prophylaxis, 1253t
 of cluster headache, 1255t
- Verbal function. *See also* Speech; Speech and language.
 clinical situations for testing, 551
 tests of, 550–551
 individual, 551
- Vergence movements, 133
