Central Autonomic Network

The ANS, like the somatic nervous system, is organized in segmental levels. Neurons in the cerebral cortex, basal forebrain, hypothalamus, midbrain, pons, and medulla participate in autonomic control. Autonomic neurons are reciprocally interconnected by neurochemically complex pathways and constitute a functional unit referred to as the central autonomic network (CAN).^{3,4} The CAN integrates visceral, humoral, and environmental information to produce coordinated autonomic, neuroendocrine, and behavioral responses to external or internal stimuli. Within the CAN, there is segmental and regional specialization for the control of autonomic functions. A coordinated response is generated through interconnections among the amygdala and the neocortex, basal forebrain, ventral striatum, hypothalamus, and autonomic and somatic motor nuclei of the brain stem.³⁻⁵

Cerebral Cortex and Amygdala

The insular and medial prefrontal cortices (paralimbic areas) and nuclei of the amygdala are the higher centers involved in the processing of visceral information and the initiation of integrated autonomic responses. The insular cortex is the primary viscerosensory cortex and receives viscerotopically organized sensory information from visceral receptors, including arterial chemoreceptors and baroreceptors. Functional studies show activation of the human insular cortex in response to maneuvers that activate cardiovascular afferents.⁶ The insula and the anterior cingulate cortices are activated by nociceptive inputs and initiate autonomic responses associated with affective behavior.⁷ The amygdala receives exteroceptive and interoceptive information and provides it with emotional significance. The central nucleus of the amygdala projects to the hypothalamus, periaqueductal gray, and autonomic nuclei of the brain stem to integrate autonomic, endocrine, and motor responses to emotionally relevant stimuli.⁸

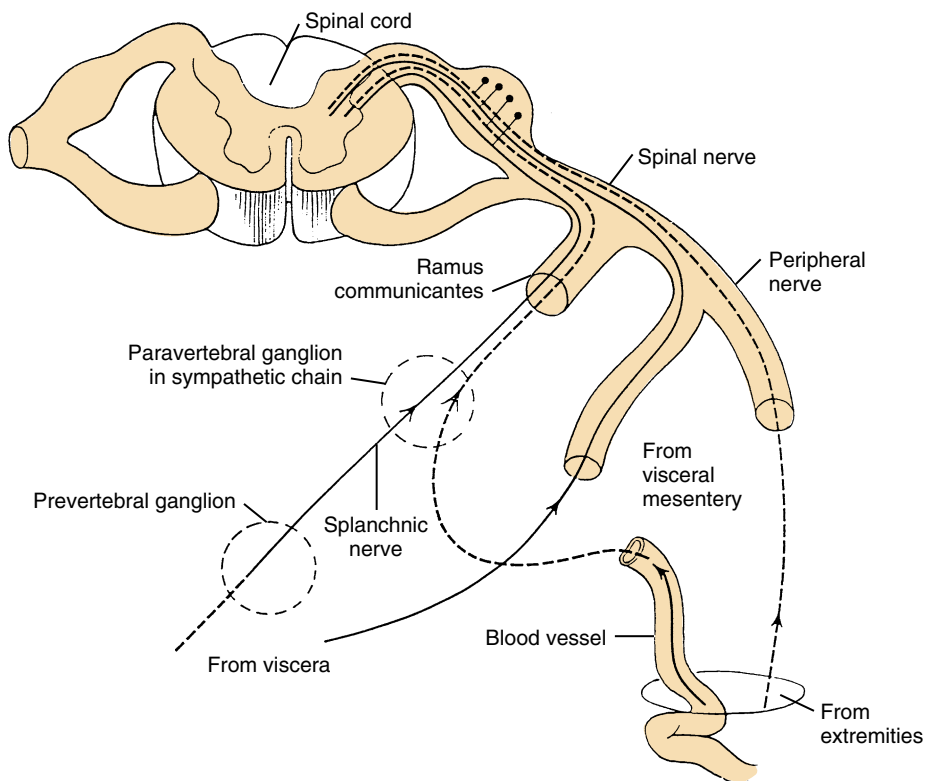

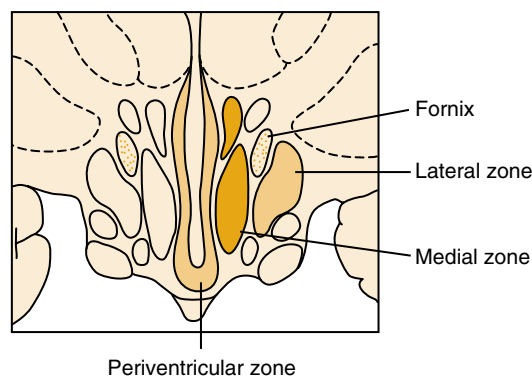

Figure 21-1. Organization of visceral and somatic afferents in the spinal cord. Hypothalamus

The hypothalamus integrates the autonomic and endocrine responses that are critical for homeostasis. It is functionally divided into three longitudinal zones: a *periventricular zone* involved in circadian rhythms and endocrine responses; a *medial zone* involved in the control of sexual function, osmoregulation, and thermoregulation; and a *lateral zone* involved in behavioral arousal (Fig. 21-2).⁹ All three zones project to the autonomic nuclei of the brain stem and spinal cord.

The paraventricular hypothalamic nucleus is the site of integrated autonomic and neuroendocrine responses to stress. It contains different subpopulations of “effector” neurons, including magnocellular neurons that secrete vasopressin, parvicellular neurons that produce corticotrophic-releasing hormone and other regulatory hormones that control pituitary function, and neurons that innervate all brain stem and spinal autonomic nuclei.¹⁰ The medial preoptic nucleus contains thermosensitive neurons that initiate autonomic, endocrine, and motor responses. Warm-sensitive neurons, excited by an increase in core temperature, initiate responses such as skin vasodilatation, sweating, and slow-wave sleep, which lead to heat loss. Cold-sensitive neurons initiate vasoconstriction and shivering. In humans, these thermoregulatory sudomotor and vasomotor pathways descend in the equatorial plane of the lateral column of the spinal cord.

The lateral hypothalamic area participates in arousal, motivated motor behavior, and autonomic control. Some neurons of this region synthesize orexin/hypocretin and project to cholinergic and monoaminergic regions of the

| Hypothalamic area | |

brain stem regulating rapid eye movement sleep. Dysfunction of this system has been implicated in the mechanism of narcolepsy.¹¹ These lateral hypothalamic neurons, as well as neurons in the ventromedial hypothalamus, including the arcuate nucleus, are the targets of leptin, a hormone secreted from adipose tissue in response to food intake. Leptin directly activates neurons of the arcuate nuclei to inhibit food intake and simultaneously inactivates neurons of the lateral hypothalamus that ordinarily increase food intake.¹² The hypothalamic autonomic pathways descend predominantly ipsilaterally in the dorsomedial and ventrolateral tegmentum of the brain stem.

Periaqueductal Gray Matter

The periaqueductal gray matter (PAG) of the midbrain is the site of integrated autonomic, behavioral, and antinociceptive stress responses. It is organized into separate columns that control specific patterns of response to stress.¹³ The lateral PAG mediates sympathoexcitation, opioid-independent analgesia, and motor responses consistent with the fight-or-flight reaction. The ventrolateral PAG produces sympathoinhibition, opioid-dependent analgesia, and motor inhibition. The PAG constitutes a critical relay station for the micturition reflex (see later discussion on the bladder).

Brain Stem

Neurons in the medulla are critical for the control of cardiovascular, respiratory, and gastrointestinal functions. The medullary nucleus of the solitary tract (NTS) is the first relay station for the arterial baroreceptors and chemoreceptors, as well as cardiopulmonary and gastrointestinal afferents.³ The NTS integrates multiple autonomic reflexes and projects to other central autonomic regions. Neurons in the reticular formation of the ventrolateral medulla are arranged in distinct groups that maintain cardiomotor, vasomotor, and respiratory functions. Neurons in the rostral ventrolateral medulla project directly to sympathetic

preganglionic neurons and maintain basal arterial blood pressure, whereas neurons in the ventral medulla are critical for respiratory rhythmogenesis. The nucleus ambiguus provides parasympathetic innervation to the heart.^{14,15}

These ventromedullary vasomotor, cardiomotor, and respiratory neurons form a network that is coordinated via interneurons of the medullary reticular formation.¹⁴ Together with the NTS, this network is involved not only in the generation of respiratory and cardiovascular rhythms but also in complex motor patterns such as vomiting, swallowing, sneezing, and coughing. The descending reticulospinal pathways for the automatic control of breathing and blood pressure, as well as those for sweating and micturition, run in the ventral half of the white matter of the lateral columns of the spinal cord (Fig. 21-3).

Efferent Autonomic Pathways

The autonomic output to effector organs consists of a two-neuron pathway with one synapse in the peripheral autonomic ganglia. The central neuron is called preganglionic, and the ganglionic neuron is called (illogically) postganglionic. Sympathetic preganglionic neurons are located in the intermediolateral cell column of the gray matter of the spinal cord at all thoracic and high lumbar levels (T1–L3) (thoracolumbar outflow) (Fig. 21-4A). Parasympathetic preganglionic neurons are located both in the brain stem and at the sacral (S2–S4) level of the spinal cord (craniosacral outflow) (Fig. 21-4B). Sympathetic and parasympathetic preganglionic axons emerge from the brain stem or spinal cord as small myelinated fibers, but postganglionic sympathetic and parasympathetic axons to the peripheral effector organs are unmyelinated.

Sympathetic Outflow

Preganglionic sympathetic neurons are organized into different functional units that control blood flow to the skin and muscles, secretion of sweat glands, skin hair follicles, systemic blood flow, as well as the function of viscera.

Figure 21-3. Basic circuitry of the medullary cardiorespiratory reflexes. Inputs from baroreceptors, cardiac receptors, chemoreceptors, and pulmonary receptors reach the central nervous system via branches of the glossopharyngeal (CN IX) and vagus (CN X) nerves. These afferents synapse on specific neuronal groups of the nucleus tractus solitarius (NTS), which is the first relay station for the cardiorespiratory reflexes. Neurons of the NTS project to the nucleus ambiguus (NA) and dorsal vagal nucleus, which provide vagal outputs to the heart and respiratory systems; to neurons of the ventral respiratory group (VRG) involved in generation of respiratory rhythm and control of spinal respiratory motor neurons; and to neurons of the rostral ventrolateral medulla (RVL), which provide sympathoexcitatory inputs to the preganglionic neurons of the spinal cord.

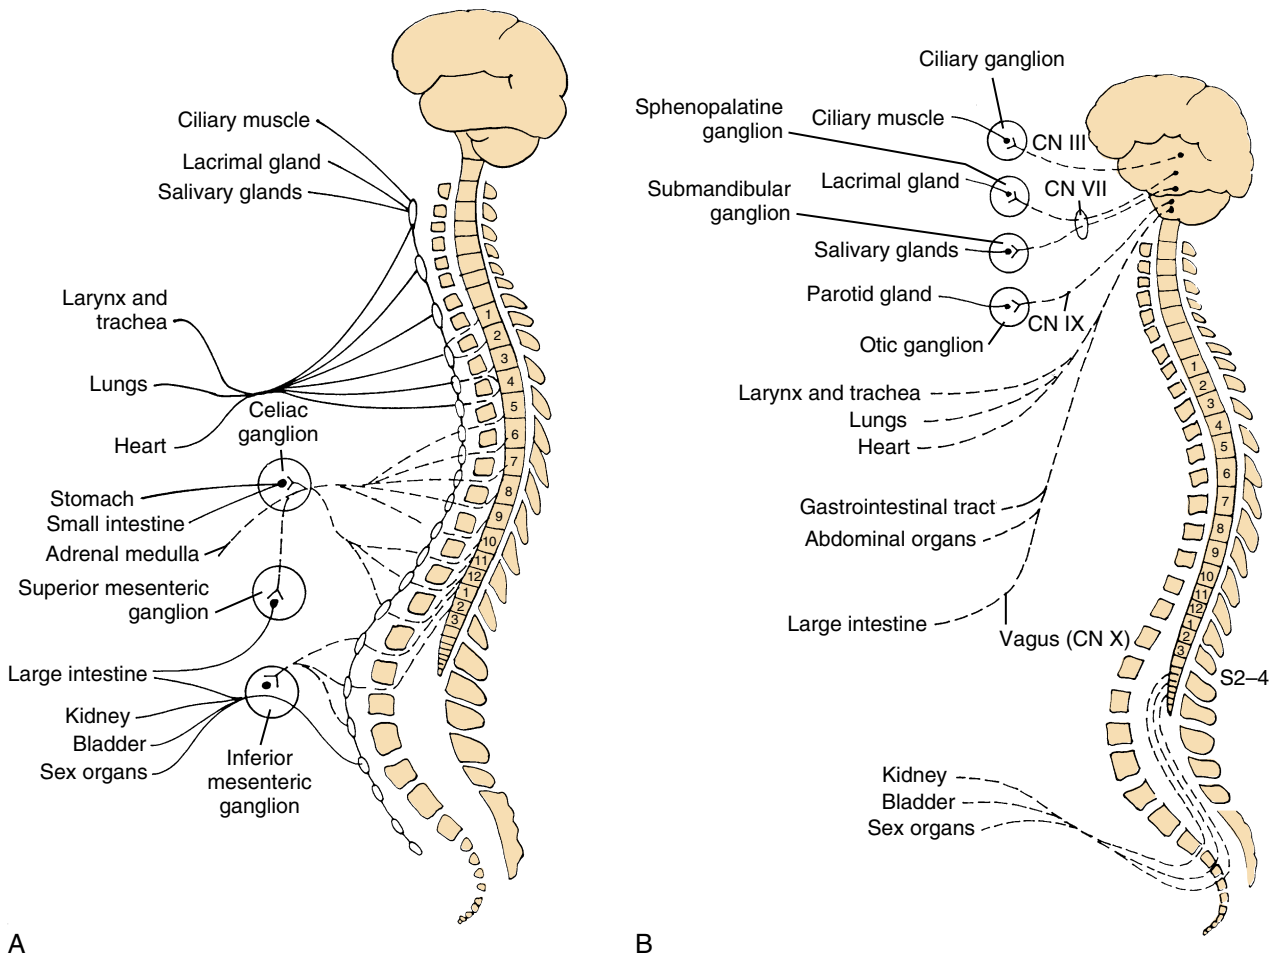

Figure 21-4. Sympathetic (A) and parasympathetic (B) divisions of the autonomic nervous system: efferent systems. (Modified from Noback C, Demarest R: *The Human Nervous System. Basic Principles of Neurobiology*. New York, McGraw-Hill, 1981, p 228.)

Preganglionic sympathetic neurons receive direct descending excitatory input from the paraventricular and lateral nuclei of the hypothalamus as well as the ventromedial and ventrolateral medulla. These pathways coordinate selective rather than massive patterns of sympathetic discharge by innervating different specific subsets of preganglionic sympathetic neurons. Selectivity is further refined by the release of different neurotransmitters.¹⁶

Preganglionic sympathetic axons exit through the ventral roots and pass through the white rami of the corresponding spinal nerve toward paravertebral or prevertebral ganglia (see following paragraphs). These axons have a segmental organization, but their distribution does not follow the dermatomal pattern of somatic nerves. Segments T1–T3 innervate the head and neck, T3–T6 the upper extremities and thoracic viscera, T7–T11 the abdominal viscera, and T12–L2 the lower extremities and pelvic and perineal organs.

Sympathetic ganglia are organized into two anatomical and functionally distinct groups: paravertebral and prevertebral ganglia. At the paravertebral ganglia (located at the sides of the spinal cord), preganglionic fibers may synapse on a postganglionic neuron at the same level or branch and run rostrally or caudally to synapse on a large number of postganglionic neurons at different levels. Preganglionic fibers also pass through the paravertebral ganglia without

synapsing to form the splanchnic nerves that innervate the prevertebral ganglia (located anterior to the spinal cord) or the adrenal medulla.

The paravertebral ganglia provide long unmyelinated axons to all sympathetically innervated tissues and organs except those in the abdomen, pelvis, and perineum. The superior cervical ganglion (T1–T2) provides pupilodilator and sudomotor fibers to the face. The stellate ganglion (T2–T6) innervates the upper limb through branches of the brachial plexus, and the lumbar sympathetic ganglia (T9–L1) innervate the lower limb through branches of the lumbosacral plexus. The postganglionic sympathetic fibers join the peripheral somatic nerve via the gray rami communicantes, and thus their distribution is similar to that of the corresponding somatic nerve. Sympathetic fibers in somatic nerves provide vasomotor, sudomotor, and pilomotor innervation to the extremities and trunk. The lower cervical and upper thoracic ganglia innervate the heart via the cardiac plexus and the tracheobronchial tree via the pulmonary plexus.

The prevertebral ganglia innervate the abdominal, pelvic, and perineal organs. Preganglionic fibers from T5–T12 levels are carried by the thoracic splanchnic nerves, which pierce the diaphragm and enter the abdomen to synapse on the celiac and superior mesenteric ganglia. These form the

celiac plexus, which innervates all abdominal viscera except the descending colon. Sympathetic activation produces splanchnic vasoconstriction, inhibition of secretion and motility of the gut, as well as secretion of epinephrine, renin, and glucagon. Preganglionic axons from L1–L3 levels, carried by the lumbar splanchnic nerves, synapse on the inferior mesenteric ganglion. The postganglionic axons innervate the descending colon, rectum, bladder, and genitalia via the hypogastric plexus. Sympathetic nerves inhibit muscle contractility of the bladder and bowel, thus allowing storage of urine and feces. These postganglionic neurons also produce the contraction of the vas deferens that is necessary for ejaculation.¹⁷

Parasympathetic Outflow

The cranial parasympathetic neurons are located in the general visceral efferent column of the midbrain, pons, and medulla. Their preganglionic axons travel in cranial nerves III, VII, IX, and X (see Chapters 9, 11, and 13). Parasympathetic outputs carried via cranial nerve III produce pupillary constriction and accommodation of the lens. Output carried via cranial nerves VII and IX stimulates lacrimal and salivary secretion. The vagus nerve (cranial nerve X) provides the most widespread brain stem parasympathetic output. Vagal preganglionic neurons are located in the dorsal motor nucleus, which controls respiratory and abdominal viscera, and in the region of the nucleus ambiguus, which innervates the heart. The vagus provides inputs to parasympathetic ganglia located in or near the target organs, and its main effects are cardioinhibitory, visceromotor, and secretomotor.

The sacral preganglionic parasympathetic neurons are located in the intermediolateral cell column at the S2–S4 levels of the spinal cord. Their axons pass through the ventral roots to the pelvic splanchnic nerves (*nervi erigentes*), which join the inferior hypogastric (pelvic) plexus. The sacral parasympathetic system is critical for defecation, micturition, and erection.¹⁷

Efferent Autonomic Neurotransmitters

Acetylcholine is the neurotransmitter of the sympathetic and parasympathetic preganglionic neurons. Acetylcholine produces fast excitation of ganglion neurons via nicotinic receptors. The main postganglionic sympathetic neurotransmitter is norepinephrine, which acts through α - and β -adrenergic receptors. The sympathetic innervation of the sweat glands is mediated by acetylcholine, acting via muscarinic receptors. The main postganglionic parasympathetic neurotransmitter is acetylcholine, which acts through different subtypes of muscarinic receptors. Postganglionic sympathetic terminals to the heart and smooth muscles also release adenosine triphosphate and neuropeptide Y, whereas postganglionic parasympathetic terminals may release vasoactive intestinal polypeptide or nitric oxide.

α -Adrenergic receptors mediate sympathetically induced pupillary dilatation (mydriasis), vasoconstriction, and contraction of the vas deferens and bladder and rectal internal sphincters. β Receptors mediate cardiac stimulation, vasodilation, bronchodilation, relaxation of the bladder, and endocrine-metabolic effects. Muscarinic receptors mediate

pupil constriction (miosis), salivary and lacrimal secretion, cardiac inhibition, bronchoconstriction, stimulation of motility and secretion in the gastrointestinal tract, evacuation of the bladder and rectum, and erection.

Afferent Autonomic Pathways

Visceral afferents transmit conscious sensations (e.g., gut distention and cardiac ischemia) and unconscious visceral sensations (e.g., blood pressure and chemical composition of the blood). Their most important function is to initiate autonomic reflexes at the local, ganglion, spinal, and supraspinal levels.¹⁸ Visceral receptors are innervated by small myelinated and unmyelinated fibers that have cell bodies in the dorsal root ganglia of the spinal or cranial nerves. Spinal visceral afferents are carried by thoracolumbar sympathetic and sacral parasympathetic nerve trunks. In the spinal cord, they branch extensively and synapse on viscerosomatic neurons in the dorsal horn and intermediate gray matter. These neurons receive convergent visceral and somatic inputs and are the substrate for referred pain (i.e., visceral pain referred to overlying or nearby somatic structures). Visceral sensation is carried primarily by the spinothalamic and spinoreticular pathways, which transmit visceral pain and sexual sensations. The dorsal columns may relay sensations related to micturition, defecation, and gastric distention. Viscerosensory inputs, after a relay in the thalamic nuclei, project to the insula and other cortical autonomic areas.¹⁸

Brain stem visceral afferents are carried by the vagus and glossopharyngeal nerves and have their cell bodies in the nodose and petrosal ganglia, respectively. Vagal afferents carry information from aortic, cardiac, pulmonary, and gastrointestinal receptors. Glossopharyngeal afferents carry signals from baroreceptors and chemoreceptors in the carotid sinus. These vagal and glossopharyngeal afferents synapse on neurons of the NTS. Taste and general visceral afferent information from the NTS is relayed, either directly or via the parabrachial nucleus, to the ventroposteromedial nucleus of the thalamus, which in turn projects to the insular cortex. Brain stem visceral afferents are important in complex automatic motor acts such as swallowing, vomiting, and coughing.

Autonomic Innervation of Specific Organs Cardiovascular System

The heart receives parasympathetic and sympathetic innervation. The cell bodies of the parasympathetic preganglionic neurons innervating the heart are located in the medulla (nucleus ambiguus and dorsal motor nucleus of the vagus).¹⁵

The axons of these neurons, which are part of the vagus nerve, join the cardiac neural plexus after entering the thorax to synapse with neurons in the intracardiac ganglia. From these ganglia, short postganglionic parasympathetic neurons emerge to innervate the myocardial tissue. Vagal innervation is particularly abundant in the nodes and the atrioventricular conduction system.

The heart draws its sympathetic innervation from neurons in the intermediolateral columns of the spinal cord at the

T1–T4 levels. Axons of these neurons synapse in superior, middle, and inferior (stellate) cervical ganglia, which are the origin of postganglionic sympathetic neurons that reach the heart in a mixed neural plexus along with preganglionic parasympathetic neurons. Sympathetic axons innervate the sinoatrial and atrioventricular nodes, the conduction system, and myocardial muscle fibers, most prominently in the ventricles. The arteries and veins of the systemic circulation are innervated primarily by the sympathetic system.

Postganglionic parasympathetic neurons release acetylcholine, which activates muscarinic receptors in the heart, causing a decrease in heart rate as well as reductions in the conduction, excitability, and contractility of myocardial cells. Postganglionic sympathetic axons release norepinephrine, which, primarily via β -adrenergic receptors, increases heart rate and the conduction, excitability, and contractility of the myocardium. Cardiac vagal neurons are activated through the baroreflex when arterial pressure increases and are inhibited during inspiration. Because acetylcholine acts quickly and is rapidly inactivated by cholinesterase, the vagus controls heart rate on a beat-to-beat basis.

Sympathetic outflow to the arteries, arterioles, and veins of the peripheral circulation produces vasoconstriction by activating α -adrenergic receptors. The presence of vasodilator cholinergic sympathetic fibers to skeletal muscle in humans is debatable. Sympathetic vasoconstrictor outflow to the blood vessels of skeletal muscle is strongly modulated by the baroreflex and is important for buffering acute changes in arterial pressure. Splanchnic vasoconstriction produced by sympathetic activation is critical for the maintenance of arterial pressure in the upright posture. Loss of splanchnic vasomotor outflow is the main mechanism causing orthostatic hypotension in autonomic failure.

Autonomic outflow to the heart and blood vessels is controlled on a moment-to-moment basis by a variety of reflexes, which are initiated by arterial baroreceptors and chemoreceptors and by several types of cardiac receptors. Of these reflexes, the one that has been best studied is the arterial baroreflex, which is a classic negative feedback mechanism that buffers fluctuations in arterial blood pressure. Afferent fibers in the vagus and glossopharyngeal nerves with cell bodies in the nodose and petrosal ganglia are sensitive to pressure or mechanical distention (i.e., baroreceptors). These neurons have arborizations that are distributed in the adventitial layer of the carotid sinus and the aortic arch, and their first synapse occurs in the NTS. Impulses from the NTS modify the activity of cardiac vagal motor neurons in the nucleus ambiguus and neurons in the ventrolateral medulla that control sympathetic outflow. When arterial pressure increases, afferent baroreceptor discharge in the NTS increases. This results in a rapid increase in cardiovagal efferent activity, which slows the heart, and in inhibition of sympathetic vasoconstrictor outflow, which causes vasodilatation. Conversely, when blood pressure falls, for example, when standing up, baroreceptors are “unloaded,” and their afferent discharge to the NTS decreases. This results in reflex sympathetic excitation and parasympathetic inhibition, which cause vasoconstriction and tachycardia.

Cardiovascular reflexes also control the release of vasopressin from the supraoptic and paraventricular hypothalamic nuclei. These neurons are tonically inhibited by baroreceptor input, and therefore a fall in arterial pressure elicits an increase in vasopressin release.¹⁹

Skin

Sympathetic innervation of the skin plays an important role in thermoregulation and the expression of emotional states. The sympathetic outflow to the skin includes cholinergic neurons innervating sweat glands (sudomotor neurons) and adrenergic neurons innervating blood vessels and hair follicles (vasoconstrictor and pilomotor neurons). Cutaneous vasomotor activity and sweating in the face is controlled by the T2–T3 segments of the spinal cord via the superior cervical ganglion. Postganglionic axons accompany branches of the internal carotid (for innervation of the forehead) and external carotid arteries (innervating the rest of the face) and follow branches of the trigeminal nerve. Sympathetic outflow produces vasoconstriction in the ears and lips but predominantly vasodilatation in the rest of the face. Fibers from the stellate ganglion (which receives innervation from T2–T6 preganglionic neurons) innervate the arm via branches of the brachial plexus. The lumbar sympathetic ganglia (which receive innervation from T9–L1 preganglionic neurons) innervate the lower limb via branches of the lumbosacral plexus. The trunk is innervated by the intercostal nerves.

Exposure to cold produces skin vasoconstriction (pallor) and piloerection (goose flesh) via α -adrenergic mechanisms; conversely, a warm environment elicits vasodilatation (redness and flushing) and sweating via muscarinic receptors. During certain emotional states (fear and anxiety) and hemodynamic stimuli (severe fall in arterial pressure), both vasoconstrictor and sudomotor outputs are activated simultaneously, producing a cold, clammy skin (“cold sweat”).

Gastrointestinal Tract

The dorsal nucleus of the vagus innervates the entire gastrointestinal tract with the exception of the proximal esophagus and the distal colon and rectum. The vagus produces increases in propulsive motility, relaxation of sphincters, and secretions of the exocrine and endocrine glands of the stomach, intestine, pancreas, and liver. Sympathetic outflow to the gastrointestinal tract, which arises from preganglionic neurons at the T1–L1 segments of the spinal cord and relays, via the splanchnic nerves, in the celiac and mesenteric ganglia, is involved in reflexes that decrease gut motility. Extrinsic vagal and sympathetic influences are relayed and integrated at the level of the enteric nervous system, located in the wall of the gut.

Bladder

The function of the bladder, rectum, and sexual organs is controlled by three outflows: sacral parasympathetic, lumbar sympathetic, and somatic. Control of the bladder serves as a paradigm for innervation of the other pelvic organs. The sacral parasympathetic (S2–S4) output to the bladder is carried via the pelvic nerves and is mediated by muscarinic

cholinergic receptors. These parasympathetic nerves promote bladder emptying (micturition) through activation of the detrusor muscle and relaxation of the bladder neck. The lumbar sympathetic (T11–L2) output is carried via the hypogastric nerves. The sympathetic nerves produce relaxation of the detrusor muscle by way of β receptors and contraction of the bladder neck by way of α receptors, thus favoring storage of urine. The sacral somatomotor output, which arises from motor neurons of the nucleus of Onuf (S2–S4) and is carried by the pudendal nerve, stimulates contraction of the external sphincter via nicotinic cholinergic receptors. Activation of these somatomotor nerves promotes storage of urine.¹⁷

In normal individuals, micturition involves a spino-pontospinal reflex that is initiated by bladder tension receptors and integrated in pontine micturition centers. This reflex coordinates the simultaneous activation of sacral parasympathetic autonomic neurons and inhibition of somatic sphincter motor neurons, thus allowing synergistic bladder contraction and sphincter relaxation during micturition.¹⁷

Interruption of the sacral parasympathetic outflow in patients with lesions of the conus or cauda equina results in a hypotonic areflexic bladder. In patients with spinal cord lesions, the suprasegmental pathway is interrupted, and micturition occurs through segmental spinospinal sacral reflexes, which are triggered by perineal or nociceptive stimulation. In this condition, bladder and sphincter contractions are not well coordinated, resulting in detrusor-sphincter dyssynergia. Cortical inputs are responsible for voluntary control of initiation and interruption of micturition. Lesions involving the medial aspects of the frontal lobes, including the anterior cingulate and paracentral gyri, result in involuntary but coordinated micturition, referred to as uninhibited bladder.

Other Organs

Autonomic innervation of the pupil (see Chapter 9) and the lacrimal and salivary glands (see Chapters 11 and 13) is reviewed in the chapters discussing the specific cranial nerves controlling these structures.

EXAMINATION OF THE AUTONOMIC NERVOUS SYSTEM

Directed Neurological Examination

The directed bedside neurological examination includes clinical observation and pharmacological testing with adrenergic and cholinergic agonists. Pharmacological tests can detect a decrease or increase in response of the effector organs due to denervation supersensitivity. Denervation supersensitivity is a manifestation of postganglionic, as opposed to preganglionic, neuronal autonomic failure.²⁰

Skin

The examiner may recognize sudomotor failure by noting a dryness of the skin and a lack of resistance to gentle stroking with the fingerpads or to a tuning fork run over the skin. Sudomotor failure may take the form of an iso-

lated generalized anhidrosis or a diffuse autonomic failure with other associated findings. A search should be made for localized increases in or the absence of sweating and for asymmetrical patterns of skin temperature or color. In patients with disturbances of autonomic innervation of the face, the physician may note gustatory sweating, flushing, and facial anhidrosis. Acral vasomotor changes that may be observed include acrocyanosis, pallor, mottling, livedo reticularis, or erythema.²¹ Skin temperature changes can be assessed by palpation. Other findings to be noted include atrophic skin changes, alopecia, hypertrichosis, nail thickening, skin decoloration or deformation, and Charcot's joints. Allodynia and hyperalgesia are components of a complex regional pain syndrome that in some cases may involve sympathetic mechanisms.

A bedside intradermal injection of pilocarpine can be used to assess the sweat glands; a supersensitive response to diluted pilocarpine indicates the presence of postganglionic sympathetic sudomotor denervation. Intradermal injection of histamine produces a "triple response" (erythema, flare, and wheal) through an axon reflex mediated by nociceptive C-afferent fibers. Loss of the histamine flare indicates severe loss or absence of nociceptive C axons, as in patients with familial dysautonomia or peripheral neuropathies affecting the sympathetic nerves.

Cardiovascular Reflexes

To assess cardiovascular autonomic function, blood pressure and heart rate should be measured while the patient is supine and after he or she has been standing for at least 3 minutes. In normal conditions, there is a 5- to 20-mmHg drop in systolic blood pressure on changing from the supine to the standing position, with no change or only a slight rise in diastolic pressure; heart rate increases 5 to 25 beats per minute²² (see section titled [Evaluation Guidelines](#) in this chapter). Orthostatic hypotension is defined as a reproducible fall of more than 20 mmHg in systolic pressure or of more than 10 mmHg in diastolic pressure within 3 minutes of adopting the erect position.²³ In patients with severe orthostatic intolerance, it is useful to monitor the length of time the patient can stand in place before he or she experiences symptoms. Severe orthostatic hypotension results in a "standing time" of less than 30 seconds. If orthostatic hypotension is not apparent, it is useful to ask the patient to squat several times and then repeat the blood pressure measurement. The presence of orthostatic hypotension without reflex tachycardia is evidence of sympathetic and cardiovagal failure. If a reflex tachycardia is present, hypovolemia should be excluded. However, the presence of tachycardia does not exclude an autonomic cause of orthostatic hypotension. An increase in heart rate of more than 30 beats per minute above the basal rate or more than 120 beats per minute on adopting the erect position, if associated with symptoms, is characteristic of the postural tachycardia syndrome. This syndrome is a heterogeneous disorder that has multiple possible causes.²⁴

Bladder

Clinical evaluation of bladder function includes assessment of the ability to control initiation or interruption of

micturition voluntarily and the integrity of the bladder and perianal sensation. Reflexes that are integrated at the level of the conus medullaris and are mediated by sensory and motor roots in the cauda equina should also be checked. The bulbocavernosus and anal reflexes are somatic reflexes that are integrated at the S2–S4 levels, and the scrotal and internal anal reflexes are autonomic reflexes that are integrated at the S2–S4 and T12–L2 levels, respectively. Palpation and percussion of the bladder can identify the presence of abnormal bladder distention. Measurement of post-void residual urine after catheterization is used to assess bladder function.

Pupil

Examination of the pupil is fully reviewed in the chapter on evaluation of cranial nerve III (see Chapter 9).

Lacrimal Glands

Reduced or absent tearing occurs with lesions that affect the parasympathetic innervation of these glands (see Chapter 11). Schirmer's test is a means of quantifying lacrimal gland secretion; it consists of application of a standard sterile filter paper strip over the lower eyelid border. The standard minimum for tear production is a length of wetness of this strip of 15 mm after 5 minutes (Video 24, Schirmer's Test).

Associated Neurological Findings

CEREBRAL. Assessment of mental status, particularly the function of the frontal lobe, is important because it allows detection of abnormalities involving memory or the higher cognitive processes, which may be associated with incontinence due to uninhibited neurogenic bladder.

CRANIAL NERVES. Examination of the optic and oculomotor nerves allows for the localization of lesions that produce asymmetrical pupils or absent pupillary responses to light. Because the pupilloconstrictor fibers are located peripherally in the oculomotor nerve, compressive (extrinsic) lesions such as aneurysms or an uncal herniation elicit unilateral mydriasis before extraocular motor paralysis. Intrinsic (vascular) lesions, such as the neuropathy resulting from diabetes, affect the central fascicles of the nerve and produce a “pupil-sparing” oculomotor palsy. There are some exceptions to this classic distinction. Examination of the function of the trochlear and abducens nerves and of facial sensation in the ophthalmic and maxillary distribution of the trigeminal nerve helps to localize lesions at the level of the cavernous sinus and orbit. A facial nerve palsy may be associated with the absence of lacrimation. Nystagmus, vertigo, and paralysis of the glossopharyngeal, vagus, and spinal accessory cranial nerves may occur in patients with lateral medullary infarctions that produce ipsilateral Horner's syndrome (Video 17, Horner's Syndrome). These features, which suggest lower brain stem dysfunction, may also accompany syringobulbia, which is associated with orthostatic hypotension, and Arnold-Chiari malformations, which produce syncope.²⁵ In patients with symmetrical polyneuropathies such as Guillain-Barré syndrome, facial diplegia and other cranial nerve pareses

can occur, especially in patients with the Miller-Fisher variant, which is often associated with autonomic instability.

MOTOR/REFLEXES/CEREBELLAR/GAIT. Autonomic dysfunction is a frequent accompaniment of central and peripheral motor syndromes. Muscle weakness in the distribution of a peripheral nerve or root may accompany hyperhidrosis or vasomotor changes resulting from nerve injury. Distal symmetrical motor weakness with loss of the deep tendon reflexes indicates a large-fiber peripheral polyneuropathy that can be seen in patients with peripheral demyelinating diseases such as Guillain-Barré syndrome and in those with certain toxic or drug reactions to agents such as vincristine. Proximal muscle weakness and areflexia occur in patients with prejunctional neuromuscular transmission defects that occur with cholinergic autonomic failure, such as botulism²⁶ and the Lambert-Eaton myasthenic syndrome.

Spastic paraparesis is frequently found in patients with neurogenic bladder and detrusor-sphincter dyssynergia (e.g., as in multiple sclerosis). Areflexia in the lower extremities, which is associated with loss of the anal and bulbocavernosus reflexes, indicates a lesion of the cauda equina that produces hypotonic bladder, bowel hypomotility, and sphincter incontinence. Extrapyramidal, pyramidal, cerebellar, and autonomic deficits in varying combinations are characteristic of multiple system atrophy (i.e., the Shy-Drager syndrome), a neurodegenerative disorder of unknown etiology. Autonomic failure may also accompany Parkinson's disease, with its associated resting tremor, bradykinesia, rigidity, and postural reflex impairment.

SENSORY. Distal, symmetrical loss of sensation to pinprick and temperature is typical of the small-fiber peripheral neuropathies associated with diffuse autonomic failure (e.g., diabetes and amyloidosis). Insensitivity to pain occurs in patients with some hereditary sensory and autonomic neuropathies, including familial dysautonomia (Riley-Day syndrome). Loss of the vibration and joint position sense occurs in paraneoplastic sensory ganglioneuronopathies and Sjögren's syndrome, both of which are commonly associated with autonomic failure. Hypesthesia and allodynia in a limb, associated with vasomotor and sudomotor changes, occur in patients with damage to a peripheral nerve (causalgia) or the poorly understood reflex sympathetic dystrophy.

Associated Medical Findings

Skin examination may reveal angiokeratomas in the trunk and lower limbs in patients with Fabry's disease, and the tongue may be enlarged in those with amyloidosis. The absence of fungiform papillae may also be demonstrated in children with familial dysautonomia (Riley-Day syndrome).

EVALUATION GUIDELINES (Table 21-1)

NEUROIMAGING. Magnetic resonance imaging (MRI) is useful for the evaluation of patients with focal or organ-specific autonomic syndromes. It can detect lesions that involve the frontal lobes (e.g., hydrocephalus) or the cervical, thoracic, or lumbar spine, producing different types of neurogenic bladder. It is also indicated for the

TABLE 21-1

Useful Studies in the Evaluation of Disorders of the Autonomic Nervous System

| SYNDROME | NEUROIMAGING | ELECTROPHYSIOLOGY | FLUID AND TISSUE ANALYSIS | NEUROPSYCHOLOGICAL TESTS | OTHER TESTS |
|---|--|---|---|---------------------------|---|
| Pandysautonomia | | | | | |

detection of hypothalamic lesions, lateral medullary infarctions, syringomyelia, or lesions in the cavernous sinus that produce Horner's syndrome. MRI of the neck is required when a diagnosis of paragangliomas arising from the carotid body or the vagus nerve is considered in patients with severe baroreflex failure. MRI of the abdomen can localize pheochromocytomas arising from chromaffin cells in the adrenal medulla or elsewhere in the abdomen, and imaging of the neck, chest, and pelvis should be used when pheochromocytomas are considered.

Neuroimaging has a low yield in the evaluation of patients with generalized autonomic failure, although it may show atrophy of the basal ganglia, pons, or cerebellum in patients with multiple system atrophy. In these patients, areas of hypointensity in the posterolateral putamen and a slitlike hyperintensity in the lateral putaminal border on T₂-weighted MRI images have been reported.²⁷

ELECTROPHYSIOLOGY. Electromyography (EMG) and nerve conduction velocities (NCVs) are useful in evaluating patients with peripheral neuropathy. However, the studies may be normal in conditions that selectively affect small nerve fibers. Small-fiber function may be assessed using quantitative sensory testing to determine the sensory

threshold for heat and cold sensation; these sensory modalities are mediated by the C- and A-delta nerve fibers. This technique measures the intensity of a stimulus necessary to evoke a specific sensation. EMG and NCVs are used to evaluate peripheral nerve injuries that may result in focal autonomic abnormalities. NCV studies may also be used to identify the cause of the predominantly cholinergic autonomic abnormalities that accompany the prejunctional disorders of neuromuscular transmission (e.g., botulism, the Lambert-Eaton myasthenic syndrome, and the autonomic abnormalities that accompany paraneoplastic sensory ganglioneuronopathy). Finally, EMG of the external anal sphincter may show denervation in patients with lesions of the conus or cauda equina and in patients with multiple system atrophy.

Electrodermal activity is generated by the sweat glands and overlying epidermis and mediated by supraspinal sites that include the orbitofrontal cortex, the posterior hypothalamus, the dorsal thalamus, and the ventrolateral reticular formation. This response, which occurs spontaneously and can be evoked by stimuli such as respiration, startle, mental stress, and electrical stimuli, is referred to as the sympathetic skin response or peripheral autonomic surface

potential. The sympathetic skin response is used in some EMG laboratories to assess sudomotor function. It consists of a slow change in the electrical potential of the skin of the palms and feet that depends on sweat production and is evoked reflexively by unexpected noise, deep inspiration, and electrical stimuli. Absence of the sympathetic skin response occurs in patients with autonomic failure, but it has limited specificity and no localizing value.

Microneurographic recordings of activity in sympathetic fibers innervating muscle and skin allow direct assessment of sympathetic vasoconstrictor and skin sudomotor outflows, respectively. However, because this technique is laborious, invasive, and requires considerable expertise as well as a very cooperative patient, it remains only a research tool.

Electroencephalography may show epileptiform activity in the temporolimbic areas, which may be associated with syncope or other paroxysmal autonomic phenomena. Sleep polysomnograms in patients with multiple system atrophy may allow the physician to make a diagnosis of sleep apnea or rapid eye movement sleep behavior disorder.

BODY FLUID AND TISSUE ANALYSIS. Blood tests useful in the evaluation of patients with autonomic failure include blood glucose and glycosylated hemoglobin (diabetes), protein immunoelectrophoresis and genetic tests for the transthyretin variant (amyloidosis), vitamin B₁₂ (pernicious anemia), erythrocyte sedimentation rate, anti-nuclear antibody (connective tissue diseases), extractable nuclear antigen (Sjögren's disease), anti-neuronal nuclear (anti-Hu) antibody, Purkinje cell cytoplasmic antibodies type 2 (PCA-2), antibodies to the neuron cytoplasmic protein, collapsin response-mediator protein-5 (CRMP-5) (paraneoplastic autonomic neuropathy), human immunodeficiency virus serology, and, in select cases, porphyrins (acute intermittent porphyria) or α -galactosidase (Fabry's disease). Some patients with acute or subacute autonomic neuropathy have antibodies against the α_3 subunit of the ganglionic nicotinic acetylcholine receptor, and autonomic dysfunction develops in rabbits that are immunized against the ganglionic acetylcholine receptor, suggesting that the antibodies are the cause of the disorder (autoimmune autonomic neuropathy).²⁸

Measurements of plasma cortisol in the morning and evening and, as previously mentioned, plasma catecholamines in the supine and standing positions may be helpful in the evaluation of patients with orthostatic hypotension.

CEREBROSPINAL FLUID. Cerebrospinal fluid examination may show albuminocytological dissociation with an elevated protein concentration and no pleocytosis in patients with Guillain-Barré syndrome and other acute pandysautonomias. Abdominal fat aspirate, rectal biopsy, or sural nerve biopsy should be considered in patients in whom amyloid neuropathy or Fabry's disease is suspected, and salivary or lacrimal gland biopsy should be done in patients in whom Sjögren's syndrome is suspected.

Special Autonomic Function Testing

Many laboratory tests are used to diagnose autonomic disorders, quantify autonomic function, and evaluate the efficacy of treatment. Disorders for which autonomic testing provides useful information include those involving generalized autonomic failure such as the Shy-Drager

syndrome, Parkinson's disease, and pure autonomic failure; suspected distal small-fiber and other peripheral neuropathies; orthostatic intolerance of uncertain etiology; syncope; localized autonomic disorders; unexplained autonomic symptoms or signs; and complex regional pain syndromes. The blood pressure and heart rate response to active standing, the passive head-up tilt test, and the Valsalva maneuver are the most commonly performed noninvasive tests used to assess reflex circulatory control.

Evaluation of Cardiac Vagal Innervation

HEART RATE RESPONSE TO DEEP BREATHING. Normally, heart rate varies from beat to beat, primarily due to changes in vagal activity. The most noticeable variation is that which is synchronous with the respiratory cycle (respiratory sinus arrhythmia). Heart rate increases during inspiration and decreases during expiration. The heart rate response to deep breathing is maximal at approximately six deep breaths per minute. Laboratory measures of heart rate variability include the peak-to-trough amplitude during a single breath, the standard deviation of the electrocardiogram R-R intervals during 1 minute, and other statistical measures such as the mean square successive difference, the expiratory-inspiratory ratio, and the mean circular resultant.^{29,30} The subject's age and the rate and depth of respiration influence heart rate variation in response to deep breathing. When these variables are taken into account, the maximum heart rate variation in response to deep breathing is the best noninvasive test for the assessment of cardiac vagal innervation.^{29,30}

HEART RATE RESPONSE TO VALSALVA MANEUVER. The Valsalva maneuver is typically performed by blowing through a mouthpiece connected to a mercury manometer for 15 or 20 seconds. The mercury column of the manometer is maintained at 40 mm. The normal cardiovascular response to a Valsalva maneuver has four phases (Fig. 21-5). Phase 1 consists of a transient rise in arterial pressure and an associated decrease in heart rate. In phase 2, the expiratory phase of the maneuver, there is a gradual decrease in blood pressure followed by a recovery. An increase in heart rate accompanies this phase. Phase 3 consists of a sudden brief decrease in blood pressure with an accompanying increase in heart rate that occurs with the cessation of straining. In phase 4, there is an increase in blood pressure above the resting value (the "overshoot") that is accompanied by a bradycardia. Phases 1 and 3 most likely reflect mechanical factors, whereas phases 2 and 4 are a consequence of sympathetic, vagal, and baroreflex interactions. The Valsalva ratio (i.e., the ratio between the tachycardia occurring during the maneuver and the postmaneuver bradycardia) provides an index of cardiac vagal function.³¹

HEART RATE RESPONSE TO POSTURAL CHANGE (THE "30:15 RATIO"). The heart rate changes that occur during the first 30 seconds of standing result mostly from modification of cardiovagal activity and are blocked by atropine (Fig. 21-6). Heart rate increases sharply on standing, peaking at approximately 12 seconds (approximately the 15th beat). It then becomes progressively slower until approximately 20 seconds after standing (so that the 13th R-R interval is usually the longest), and then it gradually rises again. This transient relative bradycardia is due to

Figure 21-5. Valsalva maneuver-induced changes in R-R intervals and blood pressure by Finapres recording in (A) a normal subject and (B) a patient with autonomic failure. reflex activation of efferent cardiac vagal fibers. These changes are reflected by the 30:15 ratio, which is calculated by dividing the longest R-R interval around the 13th beat by the shortest R-R interval around the 15th beat ($RR_{\max 30}/RR_{\min 15}$ ratio). In subjects with abnormal cardio-vagal function, the bradycardia is reduced or absent.³²⁻³⁴

Other tests of cardiovascular function include the carotid sinus massage, the cold face test (which assesses the trigeminovagal reflex), the atropine test,²² and power spectral analysis, which detects high-frequency oscillations of heart rate.³⁵

Evaluation of Cardiovascular Sympathetic Innervation

CARDIOVASCULAR RESPONSE TO POSTURAL CHANGE. Measurement of changes in blood pressure and heart rate induced by passive tilt or active standing is the most useful test of sympathetic function. During upright tilt to 60 degrees or more, normal subjects undergo a transient reduction in systolic, diastolic, and mean blood pressure, followed by a recovery within 1 minute. The heart rate also increases by 10 to 20 beats per minute. Patients with adrenergic failure have a marked reduction in systolic, diastolic, and pulse pressure with no recovery, and they have an inadequate compensatory tachycardia.^{22,36}

BLOOD PRESSURE RESPONSE TO VALSALVA MANEUVER. Beat-to-beat recordings of the blood pressure during a Valsalva maneuver may be used to measure cardiac adrenergic function. Sympathetic failure is characterized by a profound decrease of blood pressure in phase 2 and an absence of the blood pressure overshoot in phase 4 of the Valsalva maneuver.³¹

OTHER TESTS. Other tests used to assess sympathetic cardiovascular outflow include the hemodynamic response to physical or emotional perturbations such as immersion of a hand in cold water for 1 minute (cold pressor test), isometric exercise (e.g., the sustained handgrip maneuver), or emotional stress (e.g., mental arithmetic). In normal subjects, these maneuvers produce increases in diastolic pressure of more than 15 mmHg and in heart rate of more than 10 beats per minute.²² The venoarteriolar reflex is an axon reflex mediated by sympathetic C fibers. This reflex

TABLE 21-2

Differentiation of Preganglionic Versus Postganglionic Disorders

| | PREGANGLIONIC | POSTGANGLIONIC |
|---|----------------------------------|--|
| Pandysautonomia | Multiple system atrophy | Pure autonomic failure Small-fiber neuropathy |
| Plasma norepinephrine | Normal | Reduced |
| Norepinephrine response to standing | Abolished | Abolished |
| Norepinephrine response to edrophonium | Normal | Impaired |
| Blood pressure response to tyramine | Increased | No increase |
| Blood pressure response to norepinephrine | Increased, with normal threshold | Decreased threshold (denervation supersensitivity) |
| Vasopressin response to standing | Impaired | Normal or exaggerated |
| Thermoregulatory sweat responses | Impaired | Impaired |
| Cholinergic sudomotor axon reflex | Normal | Impaired |
| Horner's syndrome | | |
| Pupil response to phenylephrine | Dilated | No response |
| Pupil response to diluted alpha-agonist | No response | Dilated (supersensitivity) |
| Adie's pupil | | Constricts with diluted muscarinic agonist (denervation supersensitivity) |

is provoked by distention of the veins of a dependent limb that produces local arteriolar constriction; the reflex can be detected by a decrease in skin blood flow.²²

In research laboratories, other techniques used to evaluate autonomic circulatory control include the application of lower body negative pressure, which pools blood in the lower part of the body and elicits autonomic responses similar to those induced by standing up. The neck chamber device can also be used. This device modifies carotid artery transmural pressure and allows assessment of the carotid sinus baroreflexes. Finally, changes in heart rate in response to pressor or depressor drugs can be evaluated.²²

PLASMA CATECHOLAMINES. Circulating norepinephrine (NE) originates primarily in the sympathetic nerves innervating the blood vessels of muscles. Plasma NE constitutes approximately 10% of NE released into the synaptic cleft that escapes neuronal reuptake and “spills over” into the bloodstream. Patients with postganglionic autonomic disorders, such as pure autonomic failure or diabetic neuropathy, frequently have reduced plasma NE levels at rest in the supine position. In normal subjects, plasma NE levels double with the assumption of the upright posture. In contrast, this response is absent in patients with both pre- and postganglionic sympathetic failure.³⁶ Determination of plasma and urinary levels of NE metabolites, such as dihydroxyphenylglycol and normetanephrine, may also be useful for separating preganglionic from postganglionic causes of autonomic failure (Table 21-2).³⁷ In patients who lack dopamine β -hydroxylase, the enzyme that converts dopamine to NE, NE in plasma is virtually undetectable, whereas dopamine is high and increases further with maneuvers that increase sympathetic neural discharge.³⁸

Norepinephrine levels can be measured following an infusion of edrophonium, a cholinomimetic agent. This agent induces the release of NE by stimulating the sympathetic ganglia. NE levels can also be measured following the infusion of tyramine, an indirect sympathomimetic agent,

which releases NE from sympathetic terminals. The pressor response to an infusion of NE and other α -adrenergic agonists may be used to assess denervation supersensitivity and baroreflex function.

These pharmacological tests have been used to differentiate preganglionic from postganglionic causes of sympathetic failure. Postganglionic autonomic failure is characterized by decreased NE release and lack of a pressor response to edrophonium and tyramine. There is also a decreased threshold for the pressor effects of NE and other adrenergic agonists consistent with denervation hypersensitivity.²⁰

Evaluation of Sympathetic Cholinergic (Sudomotor) Innervation

Testing of the eccrine sweat glands can localize the site of sympathetic nervous system dysfunction in patients with autonomic failure. Thermoregulatory sweat testing is used to evaluate both the central and the peripheral sympathetic efferents, including the hypothalamus, the cervical and thoracic spinal cord, the peripheral autonomic nerves, and the sweat glands. This test, however, does not differentiate between preganglionic and postganglionic causes of anhidrosis. Postganglionic sudomotor function can be determined by measuring the sweat output after iontophoresis or intradermal injection of cholinergic agonists such as pilocarpine, nicotine, or methacholine. These agents either stimulate the sweat glands directly or affect a neighboring population of sweat glands via an axonal reflex. The site of a lesion can be established if the thermoregulatory sweat test is combined with a test measuring postganglionic sudomotor function. For example, an abnormal result of a thermoregulatory sweat test combined with normal postganglionic function indicates a preganglionic cause of anhidrosis. On the other hand, an abnormal thermoregulatory sweat test result in a patient with abnormal postganglionic function indicates a postganglionic cause of anhidrosis. Skin

potential recordings that measure skin conductance, skin resistance, or the sympathetic skin potential provide an alternative measure of sudomotor function. The following tests of sudomotor function may be performed.

THERMOREGULATORY SWEAT TEST. Thermoregulatory sweating is tested by raising the body temperature with an external heating source. This test evaluates the distribution of sweating by measuring the change in color of an indicator powder such as iodine with starch, quinizarin, or alizarin red in response to a rise in core body temperature.³⁹

QUANTITATIVE SUDOMOTOR AXON REFLEX TEST. The quantitative sudomotor axon reflex test (QSART) provides a quantitative measure of postganglionic sudomotor function. The sudomotor response measured by QSART is mediated by an “axon reflex” carried by unmyelinated postganglionic sympathetic cholinergic sudomotor fibers. This axon reflex can be elicited by iontophoresis of a cholinergic agonist.^{40,41}

SWEAT IMPRINT. A sweat imprint is formed by the secretion of active sweat glands into a plastic or silicone mold in response to iontophoresis of a cholinergic agonist. This test can be used to determine sweat gland density, sweat droplet size, and sweat volume per unit of area.

CLINICAL SYNDROMES INVOLVING THE AUTONOMIC NERVOUS SYSTEM (Table 21-3)

Clinical syndromes involving ANS dysfunction may be classified into those involving diffuse autonomic failure and pure cholinergic or adrenergic disorders (Table 21-4).

Diffuse Autonomic Failure (Pandysautonomia) Central (Preganglionic) Disorders

MULTIPLE SYSTEM ATROPHY. Multiple system atrophy (MSA; Shy-Drager syndrome) is a degenerative disorder of the CNS that affects the extrapyramidal, cerebellar, and autonomic neurons (see Chapter 34) (Video 234, Multiple System Atrophy, Cerebellar Type; Video 235, Multiple System Atrophy, Striatal-Nigral Degeneration). Autonomic dysfunction in patients with MSA is due to the loss of preganglionic neurons in the brain stem and spinal cord. Patients with MSA typically present with diffuse autonomic failure and parkinsonian, cerebellar, or pyramidal deficits in different combinations.⁴² Autonomic features include orthostatic intolerance, erectile dysfunction in

TABLE 21-3

Selected Etiologies Associated with Disorders of the Autonomic Nervous System

| ETIOLOGICAL CATEGORY | SELECTED ETIOLOGIES | CHAPTER |
|---|--|---------|
| Structural Disorders | | |
| Developmental structural disorders | Arnold-Chiari malformation Syringomyelia Normal pressure hydrocephalus | 28 |
| Hereditary and Degenerative Disorders | | |

| Pure adrenergic neuropathy |
| Dopamine β -hydroxylase deficiency |

males, bowel hypomotility, urinary incontinence due to denervation of the external urinary sphincter, and respiratory disturbances (sleep apnea and laryngeal stridor). There is usually a poor response to levodopa.⁴³ Pathologically, cell loss and gliosis in striatonigral, olivopontocerebellar, and autonomic neurons are evident, and intracytoplasmic oligodendroglial and neuronal inclusions are frequently present.

PARKINSON'S DISEASE. Autonomic dysfunction in patients with Parkinson's disease (see Chapter 34) is rarely as severe as that seen in patients with MSA (Video 62, Parkinsonian Gait). Autonomic failure frequently occurs late in the course of the illness and is often associated with levodopa and dopamine agonist therapy. In patients with Parkinson's disease, Lewy bodies are found not only in central but also in peripheral neurons, suggesting that autonomic dysfunction in this disorder may be caused by both preganglionic and postganglionic neuronal dysfunction.

Autonomic Ganglionic and Postganglionic Disorders

PURE AUTONOMIC FAILURE. Pure autonomic failure (PAF) is an idiopathic, sporadic, degenerative disorder of the autonomic nervous system of adult onset.⁴⁴ Unlike MSA

and Parkinson's disease, PAF has no motor manifestations. In patients with PAF, intracytoplasmic eosinophilic inclusion bodies with the histologic appearance of Lewy bodies, similar to those found in Parkinson's disease, are identified in neurons of the substantia nigra, locus ceruleus, thoracolumbar and sacral spinal cord, as well as sympathetic ganglia and postganglionic nerves.⁴⁵ The disorder is slowly progressive and has a better prognosis than MSA (see Table 21-2).

AUTONOMIC PERIPHERAL NEUROPATHIES AND NEUROPATHIES. Acute autonomic neuropathies with prominent sympathetic and parasympathetic involvement (i.e., acute pandysautonomia) occur in isolation or accompany the Guillain-Barré syndrome and acute paraneoplastic neuropathies. The protein level in the cerebrospinal fluid may be elevated, and the autonomic features may respond to intravenous immunoglobulin. Paraneoplastic dysautonomia may occur in association with carcinoma of the lung, pancreatic carcinoma, Hodgkin's disease, testicular cancer, and other neoplasms. Paraneoplastic gastrointestinal dysfunction with constipation and intestinal pseudo-obstruction has been reported in patients with small cell carcinoma of the lung and elevated titers of anti-Hu antibodies and in patients with autoimmune autonomic neuropathy with antibodies against the α_3 subunit of the ganglionic nicotinic receptor. In these cases, dysautonomia usually has a subacute (<3 months) clinical onset. Patients also have dry eyes and dry mouth, large pupils that react poorly to light and accommodation, and neurogenic bladder. Acute autonomic dysfunction may also be a feature of porphyria and of the neuropathies due to drugs (e.g., vincristine, taxol, and cisplatin), industrial toxins (e.g., thallium and acrylamide), marine toxins, and infections such as botulism and diphtheria.^{46,47}

Dysautonomia is a prominent feature of some chronic neuropathies affecting small-diameter unmyelinated fibers. Diabetes mellitus is the most common cause of autonomic neuropathy in the developed world. Typical features of diabetic autonomic neuropathy are orthostatic intolerance, impotence, voiding difficulties, gastroparesis, constipation alternating with diarrhea, and gustatory sweating. Patients with primary or familial amyloid neuropathy typically present with distal sensory symptoms, although the autonomic manifestations may be the presenting feature (see Chapter 37). Sensory neuronopathy with autonomic failure may be paraneoplastic, associated with Sjögren's syndrome (see Chapter 50), or may be idiopathic.⁴⁷

Hereditary sensory and autonomic neuropathies (HSANs) are characterized by prominent sensory loss and dysautonomia. Autonomic manifestations are mild in patients with HSAN type I and II but prominent in those with HSAN type III (Riley-Day syndrome, familial dysautonomia) (see Chapter 36). Familial dysautonomia is an autosomal recessive disorder that is seen primarily in Ashkenazi Jewish children. Its clinical features include insensitivity to pain and temperature, the absence of tears, hypoactive corneal and tendon reflexes, and the absence of fungiform papillae of the tongue. Patients with familial dysautonomia have poor suck and feeding responses, esophageal reflux with vomiting and aspiration, uncoordinated swallowing, episodic hyperhidrosis, vasomotor instability, postural hypotension, hypertensive crises, supersensitivity to cholinergic and adrenergic agents, and absent histamine flare.²⁸ Familial dysautonomia has a high

carrier frequency (1 in 27) in individuals of Ashkenazi, or Eastern European, Jewish extraction. Familial dysautonomia is caused by mutations in the gene *IKBKAP* on chromosome 9q. It is not known how the mutation in *IKBKAP* causes familial dysautonomia. It has been speculated that the familial dysautonomia mutations lead to inadequate development, poor differentiation, or limited survival of neuronal cells or that transcription and expression of other genes is impeded.⁴⁸ HSAN types IV and V, characterized by congenital insensitivity to pain and anhidrosis, have been linked to different mutations of the *trkA* gene encoding for the nerve growth factor receptor.⁴⁹

Fabry's disease is an X-linked recessive disorder caused by a deficiency of α -galactosidase A (see Chapter 30). Its manifestations include painful distal peripheral neuropathy; a truncal reddish-purple macular papular rash; angiectases of the skin, conjunctiva, nail bed, and oral mucosa; progressive renal disease; corneal opacities; and cerebrovascular accidents. The autonomic manifestations include hypohidrosis or anhidrosis, reduced saliva and tear formation, impaired histamine flare, and gastrointestinal dysmotility.⁴⁷ Enzyme replacement therapy with recombinant human α -galactosidase A improved small fiber function in one study.⁵⁰

Other hereditary autonomic neuropathies include the triple A (Allgrove) syndrome; Tangier disease, a sensory and autonomic neuropathy with arthropathy that is present in Navajo children; and multiple endocrine neoplasia type 2b.⁴⁶

Pure Cholinergic or Adrenergic Disorders

CHOLINERGIC DYSAUTONOMIAS. Acute or chronic cholinergic dysautonomias may occur in isolation or in patients with impaired neuromuscular transmission. In the Lambert-Eaton myasthenic syndrome (see Chapter 50) and in botulism (see Chapter 39), acetylcholine release from motor as well as autonomic neurons fails. Thus, neuromuscular and autonomic cholinergic neurotransmission is impaired, and muscle weakness, reflex loss, and autonomic failure result.²⁶

Chronic disorders that affect cholinergic function without neuromuscular impairment include Adie's syndrome; chronic idiopathic anhidrosis; Ross's syndrome (a combination of Adie's pupils and segmental anhidrosis); and Chagas' disease, a disease caused by *Trypanosoma cruzi* that affects the neurons of the parasympathetic ganglion and produces megaesophagus, megacolon, and cardiomyopathy (see Chapter 42).

PURE ADRENERGIC NEUROPATHY. Dopamine β -hydroxylase deficiency is a hereditary disease characterized by an inability to convert dopamine (DA) to NE. This disorder is characterized by severe orthostatic hypotension accompanied by ptosis, ejaculatory failure, nocturia, nasal congestion, and hyperextensible joints. Typically, the serum NE/DA ratio is 0.1 (normal, 10).³⁸

Autonomic Dysfunction Secondary to Focal Central Nervous System Disease

The autonomic nervous system syndrome may also be classified anatomically into telencephalic, diencephalic, brain stem, and spinal cord disorders (Table 21-5).

TABLE 21-5

Level-Specific Central Autonomic Nervous System Disorders

| | |
|---------------|---|
| Telencephalon | Stroke Temporolimbic seizures |
| Diencephalon | Wernicke's syndrome Episodic hyperhidrosis with hypothermia Paroxysmal autonomic hyperactivity Fatal familial insomnia Iatrogenic Neuroleptic malignant syndrome Serotonin syndrome |
| Brain stem | Tumors Vertebrobasilar disease Syringobulbia Arnold-Chiari type I malformation Inflammation (multiple sclerosis, poliomyelitis) |
| Spinal cord | Trauma Syringomyelia Multiple sclerosis Tetanus Stiff-person syndrome |

TELENCEPHALON SYNDROMES. Temporolimbic seizures may induce changes in heart rate, heart rhythm, and blood pressure. Cardiovascular manifestations of seizures include sinus tachycardia or bradyarrhythmias (including sinus arrest) with syncope. Seizure-induced ventricular tachycardia and fibrillation have been implicated in sudden death. Other autonomic manifestations of seizures include flushing, pallor, shivering, sweating, symmetrical or unilateral piloerection, visceral sensations, vomiting (ictus emeticus), and respiratory changes.^{4,51} Ischemic damage to the insula has been associated with cardiac arrhythmias and contralateral hyperhidrosis. When the cingulate and paracentral cortices are involved, urinary incontinence may occur because of uninhibited bladder contractions.

DIENCEPHALON SYNDROMES. Disorders affecting the hypothalamus may produce disturbances of thermoregulation, osmotic balance, endocrine function, and state of alertness.⁴ Chronic expanding lesions such as tumors or granulomas cause hypothermia, whereas acute lesions may cause hypothermia or hyperthermia. Wernicke's encephalopathy should be suspected in alcoholic and other malnourished patients presenting with unexplained hypothermia, particularly in the presence of disturbances of consciousness and oculomotor function (Video 229, Wernicke's Encephalopathy).⁴ Episodic hyperhidrosis with hypothermia may occur with no apparent cause,⁵² as a manifestation of agenesis of the corpus callosum and neighboring regions of the basal forebrain,⁵³ or during paroxysms of autonomic hyperactivity.

Although such paroxysmal autonomic hyperactivity in patients with brain tumors and other diseases of the diencephalon has been referred to as diencephalic seizures, this term is a misnomer. The electroencephalogram shows no ictal activity, and the episodes are refractory to antiepileptic drugs. Paroxysmal autonomic hyperactivity was first described in patients with tumors situated in the region of the third ventricle that caused hydrocephalus and abrupt increases in intracranial pressure. The majority of cases, however, are due to severe closed head injuries marked

by episodic increases in intracranial pressure and acute hydrocephalus following subarachnoid hemorrhage.⁴

Sympathetic hyperactivity also occurs in a transmissible spongiform encephalopathy characterized by severe atrophy of the anteroventral and dorsomedial nuclei of the thalamus (Video 50, Myoclonus in Creutzfeldt-Jakob Disease). This autosomal dominant prion disease presents with disruption of endocrine circadian rhythms, motor dysfunction, and progressive intractable insomnia—thus its name, familial fatal insomnia (see Chapter 43).⁵⁴

BRAIN STEM SYNDROMES. Cerebrovascular disease is the most common cause of dysautonomia associated with brain stem dysfunction. Transient ischemic attacks in the basilar artery territory may present with paroxysmal hypertension before any focal neurological deficit becomes apparent. Lateral medullary infarction (Wallenberg's syndrome) produces Horner's syndrome and, occasionally, more severe autonomic abnormalities, such as profound bradycardia, supine hypotension, or central hypoventilation.⁴

Other brain stem disorders associated with autonomic dysfunction include tumors, syringobulbia, Arnold-Chiari malformation type 1, multiple sclerosis, and poliomyelitis. Brain stem tumors may present with intractable vomiting, orthostatic hypotension, or paroxysmal hypertension. Syringobulbia may produce Horner's syndrome, orthostatic hypotension, cardiovagal dysfunction, lability of arterial pressure, and central hypoventilation.²⁵ Syncope, sleep apnea, and cardiorespiratory arrest have been reported in association with the Arnold-Chiari malformation type 1. Less common manifestations of brain stem dysfunction include hypertension due to involvement of the medullary reticular formation in poliomyelitis (see Chapter 41); autonomic hyperactivity, most likely due to disinhibition of preganglionic sympathetic and parasympathetic neurons in tetanus (see Chapter 39); and fulminant neurogenic pulmonary edema due to demyelination of the area surrounding the NTS in patients with multiple sclerosis (see Chapter 48).⁴

SPINAL CORD SYNDROMES. Traumatic spinal cord injury, particularly injury above the T5 level, is associated with severe and disabling cardiovascular, gastrointestinal, bladder, and sexual dysfunction. These patients have both supine and orthostatic hypotension and are at risk of developing bradycardia and cardiac arrest during tracheal suction or other maneuvers that activate the vagovagal reflexes. Vasopressin and the renin-angiotensin-aldosterone system have an enhanced role in maintenance of orthostatic arterial pressure in patients with spinal cord lesions. Lack of vasomotor and sudomotor thermoregulatory responses below the level of the lesion may lead to severe hypothermia or hyperthermia in response to changes in environmental temperature. Acute spinal injury or spinal shock produces a paralytic atonic bladder. The pattern of dysfunction seen in the chronic stages of disease, however, depends on the level of the lesion. Lesions above the sacral parasympathetic nucleus produce spastic bladder, commonly with detrusor-sphincter dyssynergia, whereas lesions of the conus medullaris produce a flaccid, areflexic bladder.

In patients with chronic tetraplegia with lesions at or above the T5 level, stimulation of the skin, muscle, or viscera innervated by segments below the lesion may result in a massive reflex activation of sympathetic and sacral

parasympathetic outflows, referred to as autonomic dysreflexia.⁵⁵ Stimuli that trigger autonomic dysreflexia arise primarily from the bladder, bowel, or skin. Vasodilation above the level of the lesion produces flushing of the face, chest, and upper arms and congestion of the nasopharyngeal mucosa. There may be excessive sweating above the anesthetic dermatome, piloerection, pallor in the abdomen and lower extremities, and pupillary dilatation. Severe hypertension is a prominent feature of autonomic dysreflexia and can result in hypertensive encephalopathy or intracranial, subarachnoid, or retinal hemorrhage. The combined parasympathetic and sympathetic stimulation may cause potentially dangerous supraventricular and ventricular arrhythmias.

Multiple sclerosis (MS) may affect autonomic pathways at the level of the spinal cord, brain stem, or diencephalon. Bladder, bowel, and sexual dysfunction are prominent autonomic manifestations of MS. The pathophysiological basis of the bladder dysfunction seen in patients with MS is detrusor hyper-reflexia and detrusor-sphincter dyssynergy. Subclinical abnormalities in cardiovascular sympathetic and parasympathetic function and abnormal thermoregulatory sweating detected by testing in the autonomic laboratory are common in patients with MS.

Syringomyelia produces partial interruption of sympathetic output pathways in the intermediolateral cell columns. Its autonomic manifestations include Horner's syndrome, sudomotor and vasomotor dysfunction, and trophic changes in the limbs, especially the hands.

Tetanus and the stiff-person syndrome may be associated with sympathetic hyperactivity due to lack of synaptic inhibition of preganglionic autonomic neurons. This results in hyperpyrexia, sweating, tachycardia, hypertension, tachypnea, and pupillary dilatation, usually associated with the muscle spasms (Video 238, Stiff-Person Syndrome).

Topographic or Organ-Specific Disorders (Table 21-6)

Pupils

ARGYLL ROBERTSON PUPILS. Argyll Robertson pupils are irregular and smaller than normal in darkness and demonstrate lack of the pupillary light reflex with preserved pupillary constriction during accommodation and convergence for near objects. These features, as in patients with large pupils with light-near dissociation, usually indicate a lesion in the rostral midbrain at the level of the posterior commissure.

ADIE'S PUPIL. These tonic pupils are large and irregular in shape, poorly reactive to light, and indicate a lesion of the ciliary ganglion or short ciliary nerves. On slit-lamp evaluation, regional palsies of the iris sphincter are visible. These pupils have a hypersensitive constrictor response to administration of diluted muscarinic agonists, such as a 2.5% solution of methylcholine chloride or a 0.1% solution of pilocarpine. Adie's pupils are tonic pupils associated with reduced or absent tendon reflexes.

HORNER'S SYNDROME. A unilateral small pupil is commonly due to underactivity of the ipsilateral sympathetic pathways. Miosis is commonly associated with ptosis (lid droop) due to sympathetic denervation of the tarsal muscle and facial anhidrosis (loss of sweating). This combination is known as Horner's syndrome. Oculosympathetic

Neurogenic Bladder

Spastic bladder with or without detrusor-sphincter dyssynergia
 Flaccid bladder

Gastrointestinal Dysmotility

Pseudo-obstruction

Sexual Dysfunction

Erectile dysfunction
 Ejaculation dysfunction

paralysis occurs ipsilaterally owing to (1) central lesions involving the hypothalamospinal pathways at the dorso-lateral brain stem tegmentum (e.g., a lateral medullary infarct), (2) preganglionic lesions (e.g., compression of the sympathetic chain by a tumor in the apex of the lung), or (3) postganglionic lesions at the level of the internal carotid plexus (e.g., lesions of the cavernous sinus). Postganglionic Horner's syndrome does not result in facial anhidrosis because pupilodilator and sudomotor axons follow separate paths along branches of the internal and external carotid arteries, respectively.

Local instillation of drugs that affect sympathetic neurotransmission in the pupil helps to localize the lesion causing oculosympathetic paralysis. Cocaine hydrochloride (5% to 10%), which prevents NE reuptake, will not dilate a pupil that is miotic because of a lesion anywhere in the sympathetic pathway. The responsible lesion can be further localized by hydroxyamphetamine hydrobromide (Paredrine 1%), which is an indirect sympathomimetic agent that releases norepinephrine from the synaptic terminals, thus eliciting pupillary dilatation in patients with preganglionic but not postganglionic Horner's syndrome. Phenylephrine hydrochloride (Neo-Synephrine) is a direct α agonist that, in a low concentration (1%), dilates the pupil only in patients with a postganglionic Horner's syndrome associated with denervation hypersensitivity of the pupil.

Facial Hyperhidrosis and Flushing

Facial flushing may result from the release of tonic sympathetic vasoconstriction, active sympathetic vasodilatation, increased parasympathetic activity via the greater petrosal nerve, and the release of vasoactive peptides. Gustatory sweating and flushing occur in the following conditions: idiopathic hemifacial hyperhidrosis associated with hypertrophy of the sweat glands; following bilateral cervicothoracic sympathectomy with reinnervation of the superior sympathetic ganglion by preganglionic sympathetic fibers destined for the sweat glands; after local damage to the autonomic fibers traveling with the peripheral branches of the trigeminal nerve (e.g., in parotid or submaxillary gland surgery or V3 zoster) with reinnervation of sweat glands and blood vessels by parasympathetic vasodilator fibers destined for the salivary glands; and accompanying peripheral neuropathies, most frequently diabetes mellitus.⁵⁶

Sympathetic failure may produce loss of sweating and flushing as manifestations of Horner's syndrome (Video 17, Horner's Syndrome). In contrast, the Poursfour du Petit syndrome consists of a dilated pupil with flushing and hyperhidrosis due to sympathetic hyperactivity. This syndrome is seen in patients with sympathetic nervous system lesions, frequently following injuries of the neck that damage the sympathetic plexus around the carotid artery. The harlequin syndrome consists of a sudden onset of flushing and sweating on one side of the face. This disorder may be due to lesions in the contralateral central or peripheral sympathetic nervous system pathways. Attacks of cluster headache may be accompanied by ipsilateral signs of parasympathetic hyperactivity (lacrimation and nasal discharge), sympathetic overactivity (forehead sweating), and ocular sympathetic paralysis (miosis and ptosis). The mechanisms producing these phenomena have no widely accepted explanation. Changes in both the sympathetic and the trigeminovascular pathways may be responsible for the autonomic features that accompany migraine and cluster headaches.⁵⁶

Vasomotor and Sudomotor Disorders of the Limbs

Hyperhidrosis may be generalized or localized. Localized hyperhidrosis is rare and may occur with injury to the spinal cord (e.g., in syringomyelia), peripheral nerves (e.g., with partial median or sciatic nerve injury), or eccrine sweat glands. Perilesional hyperhidrosis may surround an anhidrotic region produced by a lesion of the sympathetic ganglia or rami. The axillary eccrine sweat glands are activated by thermal stimuli, whereas the palmar and plantar glands are activated by emotional stimuli. Primary or essential hyperhidrosis affects the axillary, palmar, and plantar regions and may be familial. Available medical treatments, including systemic anticholinergics and β -blockers and topical agents such as aluminum antiperspirants and tap water iontophoresis, are largely ineffective. Surgical sympathectomy significantly reduces sweating but has frequent side effects, including pneumothorax, Horner's syndrome, and compensatory sweating in other areas of the body. Intradermal injections of botulinum toxin type A, which blocks the release of acetylcholine during nerve stimulation, have been reported to reduce excessive sweating in

patients with primary palmar hyperhidrosis.⁵⁷ Generalized hyperhidrosis may be secondary to infections, malignancies, or neuroendocrine disorders (e.g., pheochromocytoma, thyrotoxicosis, acromegaly, carcinoid, anxiety, hypotension, hypoglycemia, and cholinergic agents).⁵⁶

Vasomotor disorders in the limbs include Raynaud's phenomenon, acrocyanosis, livedo reticularis, vasomotor paralysis, and erythromelalgia. Raynaud's phenomenon is the episodic, bilateral, symmetrical change in skin color (pallor, followed by cyanosis and terminating in rubor after rewarming) that is provoked by cold or emotional stimuli. This response is due to episodic closure of the digital arteries. However, there is no consistent evidence of exaggerated sympathetic outflow to the skin. Raynaud's phenomenon may be associated with connective tissue disease (e.g., scleroderma, rheumatoid arthritis, and psoriasis), occupational trauma (e.g., the use of pneumatic hammers or chain saws producing vibration), the thoracic outlet syndrome, the carpal tunnel syndrome, or certain drugs (e.g., β -blockers, ergot alkaloids, methysergide, vinblastine, bleomycin, amphetamines, bromocriptine, and cyclosporine).⁵⁶

Acrocyanosis is a symmetrical distal blue discoloration, usually occurring below the wrists and ankles, that is due to arteriolar constriction and is aggravated by cold. In contrast, livedo reticularis is a vasomotor disorder that affects the extremities and the trunk and is due to vasospasm with obstruction of the perpendicular arterioles or stasis of blood in the superficial veins. It may be a benign disorder or may be associated with vasculitis, anti-phospholipid antibodies (Sneddon's syndrome), connective tissue disease, hyperviscosity syndrome, thrombocythemia, and drugs (e.g., amantadine, quinine, and quinidine).⁵⁶

Vasomotor paralysis may be seen in patients with lesions of the sympathetic pathways at the level of the spinal cord, preganglionic nerves, ganglia, or postganglionic nerves. Examples include surgical sympathectomy (e.g., for treatment of selective cases of hyperhidrosis, Raynaud's phenomenon, and reflex sympathetic dystrophy), trauma (e.g., carpal tunnel syndrome and ulnar nerve lesions), and tumor infiltration (e.g., Pancoast's tumor and malignant retroperitoneal disease).

Erythromelalgia is a painful acral erythematous condition that occurs with cutaneous warming and is associated with an intense burning sensation. It may occur in patients with small-fiber neuropathies. The mechanism may be activation of neurogenic flare by a polymodal C-nociceptor axon and release of vasodilator and algogenic neuropeptides such as substance P.²¹

Regional Pain Syndromes

Reflex sympathetic dystrophy (chronic regional pain syndrome type 1) is a pain syndrome defined as a continuous burning pain, hyperpathia (exaggerated response to painful stimuli), and allodynia (perception of an innocuous stimulus as painful) in a portion of an extremity. This disorder is associated with signs of sympathetic hypoactivity or hyperactivity and usually follows minor trauma that does not involve major nerves. Causalgia (chronic regional pain syndrome type 2) is a similar syndrome that occurs after partial injury of a nerve or one of its major branches. Vasomotor and sudomotor instability, manifestations of sympathetic hyperactivity or hypoactivity, are commonly seen.

Reflex sympathetic dystrophy is not a single pathological entity, but different central, peripheral, and psychogenic mechanisms may coexist in a particular case. Sympathetic blockade may be of benefit.²¹

Neurogenic Bladder

Disturbances at different levels of the bladder control system result in the development of neurogenic bladder. Neurogenic bladders can be subdivided into two types: the reflex or upper motor neuron type and the nonreflex or lower motor neuron type. The terms reflex and nonreflex denote the presence or absence, respectively, of bulbocavernosus and anal reflexes. The reflex type of neurogenic bladder includes the uninhibited bladder associated with lesions of the medial frontal region that results in urinary incontinence but not urinary retention because the detrusor-sphincter synergy is preserved. The automatic bladder results from lesions of the spinal cord that interrupt the pathway from the pontine micturition centers. An automatic bladder is associated with urgency, frequency, incontinence, and urinary retention that is due to detrusor-sphincter dyssynergia. The lower motor neuron type of neurogenic bladder, such as that occurring with lesions of the cauda equina or peripheral nerves, is characterized by incomplete bladder emptying, urinary retention, and overflow incontinence.¹³

GENERAL MANAGEMENT GOALS

Orthostatic Hypotension

Management of orthostatic hypotension requires patient education to avoid factors that precipitate a decrease in blood pressure. Patients should be made aware of the hypotensive effects of certain drugs, large meals, environmental temperature increases, and physical activities. Other instructions include institution of a high-fiber diet to lessen straining resulting from constipation and the use of physical maneuvers that help to increase postural tolerance. These maneuvers include crossing the legs, lowering the head in a stooped position, bending forward, and placing a foot on a chair or squatting. Some patients may be helped by sleeping with the head of the bed elevated 15 to 30 cm (the reverse Trendelenburg position) to avoid supine hypertension and decrease nocturnal natriuresis and volume depletion. This maneuver alone may reduce postural hypotension in the morning. To reduce postprandial hypotension, patients should eat smaller, low-carbohydrate meals more frequently and drink strong coffee. Finally, custom-fitted elasticized garments (a Jobst or Barton-Carey leotard) may reduce venous pooling in the legs.

Pharmacological interventions are directed toward increasing intravascular volume and peripheral vascular resistance without markedly increasing supine hypertension. Volume expansion can be achieved by ensuring adequate hydration (2–2.5 L of fluid per day) and increasing sodium intake (150–250 mEq, or 10–20 g).

Fludrocortisone is the drug most frequently used for the treatment of orthostatic hypotension in patients with autonomic failure. Even at low doses, it expands blood volume by its mineralocorticoid action. The initial dose is 0.1 mg PO QD; this is increased slowly in 0.1-mg increments at

1- or 2-week intervals. Few patients require more than 0.4 mg. Side effects include volume expansion, congestive heart failure, supine hypertension, and hypokalemia.

The next line of therapy entails the use of vasoconstricting sympathomimetic agents. Several types are available. Indirect sympathomimetic drugs, such as ephedrine and methylphenidate (Ritalin), release NE both centrally and peripherally and therefore may produce tachycardia, anxiety, and tremor. Direct α agonists, such as phenylephrine, may be helpful but have erratic gastrointestinal absorption, a short duration of action, and an increased risk of super-sensitive hypertensive responses and tachyphylaxis; phenylpropanolamine, previously frequently used to treat this disorder, increases the risk of intracerebral hemorrhage, particularly in women.⁵⁸ Midodrine, a prodrug metabolized in the liver to desglymidodrine, is a potent α_1 -adrenergic agonist that acts on both the arteries and the veins. This agent is well absorbed following oral administration and does not cross the blood-brain barrier.⁵⁹ All sympathomimetic agents may produce supine hypertension and should not be used at night.

Dihydroxyphenylserine is a synthetic amino acid that is decarboxylated by L-amino acid decarboxylase to norepinephrine, thus bypassing the dopamine β -hydroxylase step of catecholamine synthesis. It is therefore the agent of choice for the treatment of hypotension in patients with inherited dopamine β -hydroxylase deficiency. It is also effective in patients with multiple system atrophy and autoimmune autonomic neuropathy.^{60,61}

Recombinant epoietin alfa (25–75 U/kg SC two or three times weekly) corrects the mild anemia frequently seen in patients with severe autonomic failure and may increase blood pressure and orthostatic tolerance.⁶² Other agents that may be of benefit in the treatment of orthostatic hypotension include ergotamine tartrate, dihydroergotamine, monoamine oxidase inhibitors, yohimbine, and nonsteroidal anti-inflammatory agents. It is unclear whether any of these agents are effective.

Severe supine hypertension, particularly at night, is a troublesome feature of this disorder that may be prevented by sleeping in the reverse Trendelenburg position, avoiding vasoconstrictor drugs in late afternoon, and eating a small carbohydrate-rich snack or drinking alcohol before bedtime. If needed, a short-acting vasodilator agent (e.g., nifedipine 10 mg PO) may also be used at night.

Neurogenic Bladder

DETRUSOR HYPER-REFLEXIA WITHOUT OUTLET OBSTRUCTION. In patients with detrusor hyper-reflexia without outlet obstruction, the treatment most frequently given is an anticholinergic drug such as oxybutynin, tolterodine, propantheline, or dicyclomine. Timed voiding and moderate fluid restriction are helpful in reducing frequency, urgency, and urge incontinence. DDAVP may also be useful in patients with significant incontinence and nocturia. In patients with severe spasticity, both intrathecal baclofen infusion and dorsal rhizotomy may be effective. Augmentation cystoplasty has a place in the treatment of patients with MS and refractory detrusor hyper-reflexia.

DETRUSOR HYPER-REFLEXIA WITH OUTLET OBSTRUCTION. Treatment of patients with detrusor

hyper-reflexia and detrusor-sphincter dyssynergia is more difficult, and these patients are at higher risk of sustaining upper urinary tract damage. α -1 Antagonists such as phenoxybenzamine or prazosin may decrease bladder-outlet sphincter tone. Dantrolene, baclofen, or benzodiazepines may reduce the tone of the striated external sphincter. The most useful method is the combined use of anticholinergics and intermittent self-catheterization. Surgical external sphincterotomy or diversion procedures are treatments of last resort.

DETRUSOR AREFLEXIA OR POOR BLADDER CONTRACTILITY. Bethanechol hydrochloride is a muscarinic agonist that has a relatively selective action on the urinary bladder and may be effective in treating patients with chronic detrusor atony or hypotonia. Other options include the use of adrenergic antagonists, prostaglandins, and narcotic antagonists, but their efficacy is unproved. The simplest and most effective form of management in patients with hypotonic bladder and detrusor areflexia is intermittent self-catheterization. Patients who are unable to perform intermittent self-catheterization because of motor difficulties may require an indwelling catheter or suprapubic diversion. Women may benefit from using the Credé maneuver. In patients with conus or cauda equina lesions, α -adrenergic agonists (e.g., ephedrine or phenylpropanolamine) may be used to increase bladder outlet resistance.

Sexual Dysfunction

Treatment of organic impotence includes treatment of secondary psychological problems and reducing or eliminating aggravating factors, such as poor sleep, chronic pain, malnutrition, alcohol use, and some medications. Yohimbine can be used orally to increase penile arterial vasodilatation and enhance relaxation of the cavernous trabeculae. Direct injection of papaverine (direct smooth muscle relaxant), phentolamine, or prostaglandin E₁ into the corpora cavernosa may be effective but poses the risks of priapism and scarring of the tunica albuginea. Sildenafil is now the drug of choice in the treatment of male erectile dysfunction of various etiologies. By inhibiting phosphodiesterase type 5, the enzyme within the corpus cavernosum responsible for breakdown of cyclic guanine monophosphate (cGMP), sildenafil increases vasodilatation and enhances penile erection. Nitric oxide is the principal neurochemical for penile erection. Within the trabecular myocyte (corpus cavernosum), nitric oxide activates a soluble guanylyl cyclase that elevates intracellular levels of cGMP. This, in turn, stimulates the activities of cGMP-dependent protein kinases, which then phosphorylate certain proteins and ion channels, resulting in smooth muscle relaxation (and erection). During the return to the flaccid state, cGMP is hydrolyzed to GMP by the highly specific cGMP-binding phosphodiesterase type 5 (PDE-5). Sildenafil is a specific PDE-5 inhibitor that prevents the hydrolysis of cGMP, thereby augmenting penile smooth muscle relaxation and erection. A vacuum device may also be used to enhance corporal filling.⁶³

Gastrointestinal Dysmotility

The principles of management of any gastrointestinal motility disorder include restoration of hydration and nutrition by the oral, enteral, or parenteral route; suppression of

bacterial overgrowth; use of prokinetic agents or stimulant laxatives; and resection of localized disease.

BOWEL HYPOMOTILITY. The first line of treatment of bowel hypomotility is to increase dietary fiber as well as water intake and exercise. Psyllium or methylcellulose with a concomitant increase in fluid intake may be used to further increase stool bulk. Some caution is required in diabetic patients, in whom high fiber may pose a risk of distention, cramping, and potential bezoar formation in the presence of gastroparesis. If these measures are ineffective, stool softeners (e.g., docusate sodium) or lubricants (e.g., mineral oil) together with an osmotic agent (e.g., milk of magnesia or lactulose) may be used. Glycerine suppositories or sodium phosphate enemas promote fluid retention in the rectum and thus stimulate evacuation. Contact cathartics such as diphenylmethane derivatives (e.g., phenolphthalein and bisacodyl) or anthraquinones (e.g., senna and cascara) should be used sparingly because these agents may damage the myenteric plexus, producing a "cathartic bowel."

This regimen can be used in conjunction with the prokinetic agents, which include the following: metoclopramide, which has antiemetic effects due to blockade of central dopaminergic D₂ receptors and indirect prokinetic effects through cholinergic mechanisms; domperidone, a peripheral D₂ receptor antagonist; and cisapride, which increases the release of acetylcholine from neurons of the myenteric plexus but has been associated with an increase in ventricular tachyarrhythmias and is no longer generally available. Newly available selective agonists of the serotonin 4 receptor such as tegaserod are effective prokinetic agents and improve symptoms of constipation. Because these agents do not inhibit cardiac K currents, they are devoid of the arrhythmogenic danger of cisapride; erythromycin, which mimics the prokinetic actions of motilin, a gastrointestinal polypeptide, and misoprostol, a synthetic prostaglandin E₁ analogue are also prokinetic agents. Patients who do not respond to medical therapy may require colonic surgery.

BOWEL HYPERMOTILITY. Diarrhea may result from bacterial overgrowth in patients with intestinal hypomotility. A trial with tetracycline or metronidazole is generally conducted in patients with unexplained chronic diarrhea, particularly if steatorrhea is present. Prokinetic agents may paradoxically improve diarrhea in this situation. If these measures fail, synthetic opioid agonists, such as loperamide or diphenoxylate, can be used. Opioid agonists decrease peristalsis and increase rectal sphincter tone. Clonidine, an α_2 agonist, has been used to treat diarrhea associated with diabetic dysautonomia.

Idiopathic fecal incontinence may be associated with delayed conduction in the pudendal nerves and denervation changes in the sphincter muscles. High-fiber bulking agents may be beneficial because semiformal stools are easier to control than liquid feces. Fecal disimpaction is indicated in some patients. Daily tap water enemas aid in clearing the residue from the rectum between evacuations and may improve continence. Biofeedback may be successful in some cases. Patients who undergo surgical sphincter repair may gain some continence for solid stool, although the presence of pudendal neuropathy is associated with a poor outcome. Other surgical treatments include colostomy, artificial anal sphincters, and creation of a neosphincter with muscle grafts.

HISTORY AND DEFINITIONS

The modern study of neurovascular function owes much of its success to important, early contributors to the field. Some of the earliest drawings of the cerebral circulation were done in the 1500s by Andreas Vesalius.¹ Gabriel Fallopius provided a detailed description of the cerebral vasculature, including a description of what was later called the circle of Willis.¹ Thomas Willis was the first to describe the function of the circle that bears his name.¹ Vascular anatomy was transformed into physiology through the work of William Harvey in the early 1600s.¹ The most important early advances in the study of “apoplexy” were a result of meticulous studies of the cerebral blood vessels of patients with apoplexy by Johann Jakob Wepfer.² The actual demonstration that the paralysis was on the side opposite the brain lesion in “apoplexy” was through the work of Domenico Mistichelli, and François Bayle was among the first to relate atherosclerosis in cerebral arteries to “apoplexy.”²

The classical definition of a transient ischemic attack (TIA) is an episode of focal, nonconvulsive neurological dysfunction caused by a reversible interference of the blood supply to an area of the retina or brain that lasts less than 24 hours. A working group has proposed redefining TIA as “a brief episode of neurological dysfunction caused by focal brain or retinal ischemia, with clinical symptoms typically lasting less than 1 hour, and without evidence of acute infarction.”³ The episodes are sudden and often are unprovoked. They reach a maximum intensity almost immediately. TIAs are not benign events, and they should be considered as warning signs of an impending stroke.

A completed (established) stroke is the preferred term to describe an acute episode of focal brain ischemia that lasts longer than 24 hours. Most completed strokes reach a maximal neurological deficit within an hour of onset.

Older terms that have been used in the past include apoplexy (literally meaning “struck with violence” or “being thunderstruck”) and cerebrovascular accident. Both of these terms imply a random, unpredictable, or uncertain nature to these events, which often is not the case.

Stroke in evolution or progressive stroke describes a temporal profile in which the neurological deficit occurs in a stepwise or progressive pattern. In the carotid artery distribution, there is usually little likelihood of progression after 24 hours. In the vertebrobasilar distribution, progression may continue for up to 72 hours.⁴ There are numerous causes to consider (Table 22-1) when there is “progression” of an ischemic event.

Stroke may be divided into ischemic infarctions, which may be bland or hemorrhagic, and hemorrhages, including intracerebral hemorrhages and subarachnoid hemorrhages. Ischemic infarctions can be due to intrinsic vascular occlusion (thrombus) or an occlusion from intravascular material that originates elsewhere, such as heart or other vessels (embolism).

Common focal sites of cerebrovascular atherosclerosis include the proximal common carotid artery, the origin of the internal carotid artery, the carotid siphon, and the proximal middle cerebral and vertebral arteries. The aortic arch has been recognized as a source for atheroembolism.

Small arteries are also susceptible to atherosclerotic changes. Examples of these small arteries are the lenticulostriate arteries, thalamoperforating arteries, the basilar paramedian penetrating arteries, and the medullary arteries. These arteries supply the deep cerebral white matter. The most frequent sites of lacunar infarcts are the putamen, basis pontis, thalamus, posterior limb of the internal capsule, and caudate nucleus. They may also occur in the anterior limb of the internal capsule, subcortical cerebral white matter, and cerebellar white matter.

TABLE 22-1

Causes of Neurological Worsening after an Ischemic Event

| |
|--|
| Thrombus propagation |
| Occlusion of a stenotic artery due to thrombus |
| Recurrent embolism |
| Hemorrhagic transformation |
| Failure of collateral blood supply |
| Hypoperfusion due to systemic hypotension |
| Hypovolemia or decreased cardiac output |
| Hypoxia |
| Cerebral edema |
| Herniation |
| Seizures |
| Medication effects |
| Medical conditions such as pneumonia, pulmonary embolus, myocardial ischemia, congestive heart failure, electrolyte disturbances, or urosepsis |

Overall, embolism accounts for between 15% and 30% of strokes.⁵⁻⁷ Emboli that cause brain ischemia may arise from the heart, the aorta, the venous system in combination with a transcardiac defect, or from other intracerebral or extracerebral arteries (artery-to-artery embolism).

Diffuse perfusion deficits may lead to brain ischemia and may occur with severe hypotensive crises due to sepsis, anaphylaxis, acute blood loss, pharmacological alterations, cardiac surgery, and other acute medical crises. These situations may lead to infarctions, typically in the borderzone regions (watershed areas) between the anterior, middle, and posterior cerebral arteries.

Hemorrhages may be subarachnoid, intraparenchymal, or a combination of both. Intraparenchymal hemorrhages are the result of bleeding from an arterial source directly into the brain. Subarachnoid hemorrhages are the result of bleeding into the subarachnoid spaces.

Another distinction needs to be made between hematomas within the brain parenchyma, which are referred to as intracerebral, and those outside the brain parenchyma, which are referred to as extracerebral. Examples of extracerebral hematomas are subdural and epidural hematomas.

CLINICAL HISTORY

One of the first questions to address in the history is whether the problem involves neurovascular dysfunction. The clinical hallmark of many forms of neurovascular dysfunction is an acute focal change in neurological status. Therefore, an event that has an indistinct onset or course may not involve the neurovascular system. There are two exceptions to consider. One is the indistinct time of onset of symptoms in an individual who awakens with the neurological dysfunction. The other is a stuttering or waxing or waning course that can be seen in some patients with cerebral arterial thrombosis. In most instances of neurovascular dysfunction, the neurological deficit is maximum from its onset, with the involved body parts being simultaneously affected. The diagnosis of neurovascular dysfunction is weakened if there is a series of events in which neurological deficits accumulate or if there is a march of symptoms from one area to another. Focal seizures can

usually be differentiated by obtaining a history of associated involuntary motor activity and a march of symptoms. A gradual onset of symptoms with accumulation of deficits over time would suggest the possibility of a space-occupying lesion. It would be distinctly unusual for neurovascular dysfunction to present with positive neurological phenomena such as visual hallucinations or scintillating visual symptoms. Fleeting positive visual phenomenon would be more consistent with migraine. Isolated vertigo may be more consistent with a labyrinthine disorder. Hypoglycemia should be considered in the diabetic patient with transient paresis or aphasia, particularly if there is associated altered consciousness or confusion.

Specific details need to be sought in the history to adequately evaluate the possible underlying type and mechanism of neurovascular dysfunction. It is important to review any cerebrovascular risk factors with the patient, including a history of cardiac disorders, hypertension, hematological abnormalities, hyperlipidemia, diabetes, tobacco use, alcohol or drug use, migraine, oral contraceptive use, and a personal history or family history of TIA or stroke. Information should be obtained about use of medications such as oral anticoagulants or antiplatelet agents and the use of illicit drugs. Patients may have other medical illnesses associated with stroke, including connective tissue diseases, malignancies, and hypercoagulable states. Rarely, a preceding or concurrent infection may predispose to stroke. A history of recent trauma should be sought in patients with symptoms of carotid or vertebral dissection. A history of posterior circulation symptoms with arm exercise may suggest a subclavian steal syndrome.

It is often difficult to differentiate an ischemic infarction from a hemorrhage. Some historical features that suggest a hemorrhage would be an altered level of consciousness or a seizure at the onset, vomiting, or a severe headache. However, onset headaches can also be present in 17% of patients with ischemic infarction.⁸ A carotid dissection may present with pain involving the neck, ipsilateral head, or the periorbital region.

Although it is difficult to distinguish cardiogenic stroke from other causes based on the neurological profile, historical features that may suggest a cardioembolic cause are an abrupt onset with a maximum deficit at the onset, a history of infarctions in more than one vascular territory, or systemic emboli to the limbs or other organs.

Patients noting monocular visual loss or having complaints of a speech disorder suggestive of aphasia most likely have carotid distribution ischemia. Complaints of binocular visual loss, vertigo, balance difficulties, gait instability, bilateral or alternating weakness or altered sensation, swallowing difficulties, or diplopia suggest ischemia in the vertebrobasilar distribution. Etiologies other than vertebrobasilar ischemia should be considered with isolated vertigo, diplopia, or dysarthria. Localization of the neurovascular dysfunction to the cortical or subcortical region may be possible based on historical features. Patients with complaints of any degree of altered consciousness may have cortical or combined subcortical and cortical ischemia. Loss of vision in one field or forced eye deviation usually implies a cortical or combined cortical and subcortical localization. A history of weakness or sensory loss affecting the face, arm, and leg equally usually

implies a subcortical or brain stem localization. Complaints of severe dysarthria are often indicative of a subcortical or combined cortical and subcortical infarction.

ANATOMY OF THE NEUROVASCULAR SYSTEM

Extracranial Arterial System

Heart, Aorta, Common Carotid, Subclavian, Innominate Arteries

The ascending aorta arises from the left ventricle. The aortic arch gives rise to several important branches. The first branch of the aorta is normally the innominate artery, which is also referred to as the brachiocephalic trunk. Shortly after its origin, the innominate artery divides into the right subclavian and right common carotid arteries. The right vertebral artery arises from the right subclavian artery, courses posteromedially, and then enters the foramen transversarium of C6. The right common carotid artery bifurcates into the internal and external carotid arteries in the midcervical region, usually at C3 or C4, approximately 3 cm below the angle of the mandible. However, the bifurcation may be as rostral as C1 or as caudal as T2.

The next branch of the aorta is the left common carotid artery, which bifurcates into the internal and external carotid arteries at the same level as the right common carotid artery (Fig. 22-1). The last branch of the aortic arch is

the left subclavian artery. The left vertebral artery is the first branch of the left subclavian artery. This branch usually arises from the superior portion of the artery and then courses cephalad to enter the foramen transversarium of C6. It is reported that the left vertebral artery is as large as or larger in caliber than the right vertebral artery in approximately 75% of cases.⁹

External Carotid Artery and Branches

The external carotid artery arises from the common carotid artery in the midcervical region. The proximal portion of this artery lies anteromedial to the internal carotid artery, but as it ascends, it courses posteromedially to supply structures of the face. The external carotid artery has nine major branches (Fig. 22-2). Several of these branches, particularly the maxillary artery and its branches, the ascending pharyngeal artery, and the facial artery, can be important sources of collateral blood flow in the event of internal carotid artery occlusion. The order in which these branches arise and the selected important structures they supply are as follows:

1. Superior thyroid artery, which supplies the larynx and portions of the thyroid.
2. Ascending pharyngeal artery, which supplies portions of the meninges, middle ear, lower cranial nerves, and the upper cervical nerves.

Figure 22-1. Branches of the aortic arch. (Copyright 1996 by Indiana University Medical Illustration Department.)

Figure 22-2. Major branches of the external carotid artery. (Copyright 1996 by Indiana University Medical Illustration Department.)

3. Lingual artery, which supplies the tongue and pharynx.
4. Facial artery, which supplies the face, palate, and pharynx.
5. Occipital artery, which supplies musculocutaneous structures of the scalp and neck.
6. Posterior auricular artery, which supplies the scalp, tympanic cavity, pinna, and the parotid gland.
7. Maxillary artery, which is the larger terminal branch that has three major portions, each with its own branches. The most important branches to remember are the middle meningeal artery, which can be lacerated in head trauma and produce an epidural hematoma, and the anterior deep temporal artery, which can be a source of collateral blood flow through the ophthalmic artery when the internal carotid artery is occluded.
8. Transverse facial artery, which with the facial artery supplies the buccal area.
9. Superficial temporal artery, which is the smaller terminal branch that supplies the anterior two-thirds of the scalp and portions of the face.

Vertebral Extracranial Portion and Anterior Spinal Artery

The vertebral artery is divided into four segments.¹⁰ The first or V1 segment is the portion from its origin at the subclavian artery to its entry into the costotransverse foramen of C6 or C5. The second or V2 segment travels between C6 and C2, entirely within the transverse foramina. The third or V3 segment takes a tortuous course between C2

to the suboccipital triangle between the atlas and the occiput, where it is covered by the atlanto-occipital membrane. The fourth or V4 segment is the intracranial portion, after it has pierced the dura mater to enter the foramen magnum to join the opposite vertebral artery at the medullopontine level.

The anterior spinal artery is formed by the anastomosis of the two branches of the vertebral arteries. This artery extends from the olivary nucleus to the conus medullaris and supplies the ventral surface of the medulla and the anterior two-thirds of the spinal cord.

Intracranial Arterial System: Circle of Willis Internal Carotid Artery and Branches (Ophthalmic and Anterior Choroidal)

The internal carotid artery (ICA) can be conceptually divided into three main segments: cervical, petrosal, and intracranial. The cervical portion extends from the carotid bifurcation to the base of the skull. This segment has no branches. The petrosal segment begins after the artery enters the base of the skull and travels through the carotid canal in the petrous portion of the temporal bone. The artery then crosses the foramen lacerum and enters the cavernous sinus. The intracranial portion begins distal to the petrosal segment and proximal to the anterior clinoid process. At this point, the presellar and juxtaseilar portions of the ICA are distinguished. The juxtaseilar portion lies within the cavernous sinus and is closely associated with

Figure 22-3. Lateral internal carotid artery angiogram, arterial phase. 1, Internal carotid artery; 2, ophthalmic artery; 3, anterior cerebral artery; 4, orbitofrontal branch; 5, frontopolar branch; 6, callosomarginal branch; 7, pericallosal branch; 8, middle cerebral artery branches. (Courtesy of Karen S. Caldemeyer, MD.)

cranial nerves III, IV, VI, and the ophthalmic and maxillary divisions of cranial nerve V. Meningohypophyseal branches arise from the presellar and juxtaseilar portions to supply the meninges and the posterior lobe of the hypophysis. The ICA pierces the dura mater medial to the anterior clinoid process to become supraclinoid.

The first major branch of the ICA, the ophthalmic artery, arises at the level of the anterior clinoid process (Fig. 22-3). After initially running intracranially, this artery traverses the optic canal and then goes to the orbit. The most important of the ocular branches is the central retinal artery. Numerous anastomotic channels between the internal and external carotid arteries ultimately involve the ophthalmic artery.

After giving rise to the ophthalmic artery, the ICA gives rise to the posterior communicating artery (PCoA) and then the anterior choroidal artery (AChA). The AChA has a proximal or cisternal segment that courses posteromedially below the optic tract and medial to the uncus of the temporal lobe. The artery then turns laterally and passes through the crural cistern and around the cerebral peduncle to enter the choroidal fissure of the temporal lobe.¹¹ The distal or plexal segment of the AChA starts at the choroidal fissure and goes posteriorly in a cleft of the temporal horn. The AChA may terminate near the lateral geniculate body or extend around the pulvinar of the thalamus.¹² There is a rich anastomotic relationship between the AChA and the lateral posterior choroidal, posterior communicating, and posterior cerebral arteries. Therefore, the regions supplied by the AChA and its branches can be extensive but also variable. Possible regions supplied by this artery include the choroid plexus of the temporal horn, the amygdaloid nucleus, the piriform cortex and uncus of the temporal lobe, the hippocampus and dentate gyri, the lateral geniculate

Figure 22-4. Anterior posterior internal carotid artery arteriogram, arterial phase. 1, Internal carotid artery; 2, anterior cerebral artery; 3, middle cerebral artery; 4, medial lenticulostriate arteries. (Courtesy of Karen S. Caldemeyer, MD.)

body, the optic tract and the origin of the optic radiations, the genu and inferior and medial parts of the posterior limb of the internal capsule, the medial globus pallidus, the tail of the caudate nucleus, and the upper brain stem. After giving off the AChA, the ICA bifurcates to form the anterior cerebral and middle cerebral arteries (Fig. 22-4; see also Fig. 22-3).

Circle of Willis

The circle of Willis is an arterial anastomosis at the base of the brain that connects the internal carotid and vertebrobasilar arterial systems. The circle surrounds the ventral surface of the diencephalon adjacent to the optic nerves and tracts. The anterior portion of the circle of Willis consists of the two internal carotid arteries, the anterior cerebral arteries, and the anterior communicating artery. The posterior portion of the circle consists of the proximal portions of the posterior cerebral arteries and the two posterior communicating arteries (Fig. 22-5).

Anterior Cerebral and Anterior Communicating Artery

The anterior cerebral artery (ACA) arises below the anterior perforated substance and runs anteromedially to the interhemispheric fissure, where it joins the opposite ACA by way of the anterior communicating artery (ACoA). The ACA supplies the medial surface of the cerebrum and the upper border of the frontal and parietal lobes.¹²

The ACA is often divided into A1 and A2 segments. The A1 segment is the horizontal, proximal portion that extends from the origin of the ACA to its union with the contralateral ACA by way of the ACoA. The A2 segment is the portion of the ACA that is distal to the ACoA. It runs superiorly into the interhemispheric fissure, coursing around the genu

Figure 22-5. Selective computed tomographic angiogram of the circle of Willis.

of the corpus callosum. It has an important relationship anatomically to two other midline structures, lying above the optic chiasm and the pituitary gland.

The ACA gives rise to medial lenticulostriate, pericallosal, and hemispheric branches (see Fig. 22-4). The medial lenticulostriate branches include basal branches, which supply the dorsal aspect of the optic chiasm and hypothalamus, and the medial striate artery (recurrent artery of Heubner), which supplies the anteroinferior limb of the internal capsule and the anterior aspects of the putamen and caudate nuclei. The callosal branches arise from the pericallosal artery, which is that portion of the ACA distal to the ACoA. Some reserve the term pericallosal artery for the segment beyond the origin of the callosomarginal artery. The ACA and the pericallosal arteries also supply the septum pellucidum and the fornix. The hemispheric branches supply the medial surface of the hemisphere and include the orbitofrontal, frontopolar, internal frontal (anterior, middle, and posterior), paracentral, and internal parietal (superior and inferior) branches.

Middle Cerebral Artery and Its Branches

The middle cerebral artery (MCA), the largest branch of the ICA, arises below the medial part of the anterior perforated substance. It supplies most of the lateral surface of the cerebral hemisphere, including the lateral frontal, parietal, and temporal lobes; insula; claustrum; and extreme capsule.¹³

The MCA is divided into proximal, sylvian, and distal segments. The posterior-superior aspect of the proximal segment gives rise to the lenticulostriate arteries that supply the corona radiata, external capsule, claustrum, putamen, part of the globus pallidus, body of the caudate nucleus, and superior portion of the anterior and posterior limbs

of the internal capsule. Other branches that may arise from the horizontal segment are the orbitofrontal and the anterior temporal arteries, but there are many variations. The sylvian segment includes all of the branches on the insula of Reil and in the sylvian fissure. After the takeoff of the anterior temporal artery, the main trunk of the MCA usually bifurcates into two branches—a superior and inferior division. Less common patterns include a trifurcation into superior, middle, and inferior divisions and a ramification pattern into four or more trunks. One branch gives rise to the anterior or proximal group of arteries, and the other branch gives rise to the posterior or distal group. The anterior group includes the orbitofrontal, precentral, central, and anterior parietal arteries. The posterior group includes the posterior parietal, posterior temporal, and the angular or terminal arteries.

Posterior Communicating Artery

The PCoA arises from the posteromedial aspect of the intracranial ICA and runs caudally and medially above the oculomotor nerve to join the posterior cerebral artery. The two PCoAs from each side provide a connection between the carotid and vertebrobasilar systems. The PCoAs supply the anterior and medial portions of the thalamus and also the walls of the third ventricle.

Posterior Cerebral Artery and Branches

The posterior cerebral arteries (PCAs) usually arise as the terminal bifurcation of the basilar artery ventral to the midbrain (Fig. 22-6). Approximately 15% to 22% of people have a fetal (embryonic) origin of the PCA from the ICA.^{14,15} The PCA supplies the occipital lobes, inferomedial portions of the temporal lobes, midbrain, thalamus, and deep structures including the choroid plexus and ependyma of the third and lateral ventricles. The first branches are the small thalamoperforating arteries that penetrate and supply the midbrain, thalamus, and lateral geniculate body. The next branches are the medial and lateral posterior choroidal arteries that supply the posterior portion of the thalamus and the choroid plexus. An anterior division of the PCA gives rise to the inferior temporal arteries (hippocampal, anterior, middle, posterior, and common temporal arteries) that supply the inferior portions of the temporal lobes. A posterior division includes the two terminal branches of the PCA; the parieto-occipital artery, which supplies part of the cuneus and precuneus, the superior occipital gyrus, and, occasionally, the precentral and superior parietal lobule; and the calcarine artery, which supplies the visual cortex, inferior cuneus, and part of the lingual gyrus. The splenic arteries may arise directly from the PCA or from the parieto-occipital artery.

Vertebral System

Vertebral Arteries

The vertebral arteries (VAs) normally arise as the first branches of the subclavian artery (see Fig. 22-1). They course superiorly and medially to enter the transverse foramen of C6. The VAs course vertically through the

Figure 22-6. Anterior posterior vertebral angiogram. 1, Vertebral artery; 2, posterior inferior cerebellar artery; 3, anterior inferior cerebellar artery; 4, basilar artery; 5, superior cerebellar artery; 6, posterior cerebral artery. (Courtesy of Karen S. Caldemeyer, MD.)

transverse foramen of C3–C6 and then turn superolaterally to pass through the C2 foramen. After the arteries pass through the foramen of the atlas, they curve around the atlanto-occipital joint and lie in a horizontal groove along the posterior arch of C1. The VAs then curve cephalad to enter the skull through the foramen magnum.

Basilar Artery

The basilar artery is formed by the union of the two vertebral arteries, which takes place at the lower border of the ventral pons (see Fig. 22-6). It continues superiorly to terminate in the interpeduncular cistern by dividing into the PCAs. The branches of the basilar artery can be divided into paramedian arteries, short circumferential arteries, and long circumferential arteries. The paramedian vessels are four to six in number, and they penetrate into the pontine parenchyma to supply the medial basal pons. The short circumferential arteries enter the brachium pontis to supply the ventrolateral basis pontis. The long circumferential arteries include the superior cerebellar artery (SCA), anterior inferior cerebellar artery (AICA), and the internal auditory artery.

Long Circumferential Arteries (PICA, AICA, SCA)

The arterial supply to the cerebellum includes the posterior inferior cerebellar artery (PICA), AICA, and SCA. PICA is the largest branch of the vertebral artery (Fig. 22-7; see also Fig. 22-6). PICA encircles the medulla to supply the lateral medulla. The distal portion of PICA then bifurcates into a medial trunk that supplies the vermis and the adjacent cerebellar hemisphere and a lateral trunk that supplies the cortical surface of the tonsil and cerebellar hemisphere.

AICA most often arises directly from the basilar artery (see Figs. 22-6 and 22-7). Rarely, it may arise from the vertebral artery. In its normal course, it runs across the pons, enters the cerebellopontine angle cistern, and then forms a tight loop before running over the cerebellum. AICA supplies the lateral tegmentum of the lower two-thirds of the pons and the ventrolateral cerebellum. The internal auditory artery arises from AICA to supply the auditory and facial nerves.

SCA arises from the basilar artery near its terminal bifurcation (see Figs. 22-6 and 22-7). It courses posterolaterally in the perimesencephalic cistern to circle the brain stem in the region between the pons and the mesencephalon. SCA supplies the superolateral cerebellar hemispheres, the superior cerebellar peduncle, the dentate nucleus, and part of the middle cerebellar peduncle.

Vascular Supply to the Spinal Cord

Extraspinal System (Extramedullary Arteries)

The anterior spinal artery arises from the anastomosis of two branches from the intracranial vertebral arteries. It travels in the anterior sulcus of the spinal cord and extends from the level of the olivary nucleus to the conus medullaris. It supplies the ventral surface of the medulla and the anterior two-thirds of the spinal cord. The artery is continuous in the upper cervical region. However, in the

Figure 22-7. Lateral vertebral. 1, V3 segment of the vertebral artery; 2, V4 segment of the vertebral artery; 3, posterior meningeal artery; 4, posterior inferior cerebellar artery; 5, basilar artery; 6, anterior inferior cerebellar artery; 7, superior cerebellar artery; 8, posterior cerebral artery. (Courtesy of Karen S. Caldemeyer, MD.)

segments inferior to the upper cervical region, it consists of anastomosing branches from the anterior radicular arteries.

The two posterior spinal arteries most commonly arise from the vertebral arteries. However, in some instances, they arise from PICA. There are contributions from numerous posterior radicular arteries that form an anastomotic network on the posterior surface of the spinal cord.¹⁶ These arteries supply the posterior one-third of the spinal cord. The anterior and posterior spinal arteries join in an anastomotic loop at the conus medullaris.¹⁷

The different regions of the spinal cord receive an unevenly distributed blood supply. The upper cervicothoracic region between C1 and T2 is richly vascularized by the anterior spinal artery in the most superior segments and radicular arteries in the lower cervical and upper thoracic segments. The artery of the cervical enlargement is the most important of these radicular arteries. There are a number of radiculomedullary arteries that feed the posterior spinal arteries. The intermediate or midthoracic portion of the cord between T3 and T8 is poorly vascularized by intercostal arteries. There is a single radiculomedullary artery between T6 and T8. There are a limited number of segmental feeders to the posterior spinal arteries. In the lower or thoracolumbosacral region, there is again a rich vascular supply through the radiculomedullary branches of the intercostal and lumbar arteries. One important artery is the great anterior radicular artery of Adamkiewicz (artery of the lumbar enlargement). There are numerous posterior radicular arteries at this level. An understanding of these variations is important in spinal cord vascular syndromes, particularly with hypoperfusion of the spinal cord due to hypertension.

Intraspinal System (Intramedullary Arteries)

Branches of the anterior and posterior spinal arteries form a vascular plexus or peripheral vasocorona that encircles the cord. There are also sulcal arteries arising from the anterior spinal system that travel in the anterior median fissure of the cord and then branch and penetrate the cord. There are fewer sulcal arteries in the midthoracic region, which may contribute to the susceptibility of this region to ischemia. The branches of this plexus supply a major portion of the white matter and the dorsal horns of the gray matter. The arterial supply of the gray matter is richer than that of the white matter. The gray matter, except the dorsal horns, is supplied by the largest branches of the anterior spinal artery called the sulcocommissural arteries. The dorsal horns and the funiculi are supplied by paired posterior spinal arteries, posterior medullary feeders, and perforating pial branches.

Venous System

The venous system of the spinal cord generally parallels the arterial supply. An exception is the presence of a single median posterior spinal vein, compared to the paired posterior spinal arteries. The anterior spinal vein receives contributions from the sulcal and circumferential veins. The territories of the veins closely parallel the arterial supply, except for the broader boundaries of the anterior spinal vein.

Arterial Structure

Arteries are classified into three categories based on their size and histological features. The large or elastic arteries, such as the aorta and its major branches, have three layers: the tunica intima, the tunica media, and the tunica adventitia. In large arteries, the intima is a smooth layer of thin endothelial cells on a basement membrane; the media is the muscular layer that is rich in elastic tissue; and the adventitia is a layer of connective tissue with elastic fibers, nerve fibers, and the vasa vasorum. With aging, the elastic fibers of the media in large vessels become less resilient. This causes less expansion with blood pressure elevations and predisposes to tortuosity. The medium or muscular arteries also consist of three layers. The distinguishing features of muscular arteries are the internal elastic lamina that forms the outer limit of the intima and the external elastic membrane that forms the outer layer of the media and is more defined than in large arteries. The adventitial layer in muscular arteries contains more nerves than this layer in large vessels due to their role in autonomic control. Arteriosclerosis and atheromatosis are most characteristic of the large and medium-sized vessels. Medial calcific sclerosis can affect medium-sized arteries. Finally, small arteries are characterized by a progressive loss of the three layers such that arterioles have no identifiable layers. The extracranial cerebral arteries have the usual structure of elastic or muscular arteries. However, intracranial arteries differ because they have no external elastic lamina and there is no vasa vasorum.¹⁸

Blood-Brain Barrier

The microcirculation of the brain is unique because of the blood-brain barrier (BBB). This barrier to free metabolic exchange keeps a homeostatic environment around neurons. There are actually two parts to the BBB, including the BBB and the blood-cerebrospinal fluid (CSF) barrier.¹⁹ The BBB consists of capillary endothelial cells that are joined at tight junctions devoid of fenestrae. There is very little pinocytosis occurring, and passage of substances depends on their affinity for lipids and the presence of carrier proteins. The blood-CSF barrier consists of the periventricular region, including the choroid plexus, median eminence, and the area postrema. In these locations, there is active pinocytosis that allows small molecules into the subependymal interstitial space. Cerebral edema occurs when there is an increase in water content in the brain. Cerebral infarctions, hemorrhages, and contusions cause vasogenic edema as a result of leakage of water and plasma directly into the central nervous system due to damaged capillary endothelial cells that have lost their BBB function.

Venous Supply of the Brain

The venous system of the head and neck is extensive. Emphasis is made here only to those vessels that are relevant to cerebrovascular syndromes (Fig. 22-8).

The blood from the brain is drained by the cerebral veins, which empty into dural sinuses that are primarily drained by the internal jugular veins. The extracranial draining veins of the neck consist of the external jugular vein, the internal jugular vein, and the vertebral vein.

Figure 22-8. Major veins of the cerebral venous system. (Copyright 1996 by Indiana University Medical Illustration Department.)

The venous drainage of the brain and meninges can be divided into the diploic veins, the meningeal veins, the dural sinuses, and the cerebral veins. The diploic veins run between the tables of bone of the skull to drain the diploë. These vessels communicate extensively with the extracranial venous system, the meningeal veins, and the dural sinuses. The meningeal veins are epidural vessels that supply drainage for the falx cerebri, the tentorium, and the cranial dura mater. The major dural sinuses include the superior and inferior sagittal sinuses, the cavernous and intracavernous sinuses, the superior and inferior petrosal sinuses, the occipital sinus, and the straight, transverse, and sigmoid sinuses.²⁰

The dural sinuses that are most often affected by thrombosis are the superior sagittal sinus (SSS), the lateral sinuses (LS), and the cavernous sinuses (CS). The SSS originates near the crista galli, where it communicates with the facial and nasal veins.²¹ It courses posteriorly in the midline along the falx cerebri and then courses backward toward the occipital protuberance, where it joins the lateral and straight sinuses to form the torcular Herophili. The SSS drains a major portion of the cortex. Due to its connection with the diploic veins that drain the scalp through the emissary veins, the SSS can be affected by infections or contusions of the face and scalp.

The LS course from the torcular Herophili to the jugular bulbs. They have a transverse portion that lies in the

attached border of the tentorium and a sigmoid portion that runs on the mastoid process. Due to the latter anatomical configuration, this sinus can be affected by mastoiditis and otitis media. The drainage territory of the LS includes the cerebellum, brain stem, and the posterior portion of the cerebral hemisphere.

The CS are paired venous structures that lie next to the sphenoid bone. There are several important structures that lie in the region of the CS, including cranial nerves (CNs) III, IV, V₁, and V₂ in the lateral wall, and CN VI and the carotid artery with its sympathetic plexus in the central portion of the sinus. The CS drain blood from the orbits and the anterior portion of the base of the brain. They drain via the superior and inferior petrosal sinuses into the internal jugular veins.

The three important groups of veins that drain blood from the brain are the superficial cerebral veins, the deep cerebral veins, and the veins of the posterior fossa. The superficial cerebral veins lie along the cortical sulci. These vessels drain the cerebral cortex and portions of the white matter. The frontal, parietal, and occipital cortical veins drain into the SSS, whereas the middle cerebral veins drain into the LS. The middle cerebral veins run along the sylvian fissure to drain the opercular region. These veins are unique because they have no muscular layers or valves, which enables them to dilate and reverse the direction of blood flow if a sinus into which they drain is occluded.

The deep cerebral veins, including the internal cerebral and basal veins, drain blood from the deep white matter of the cerebral hemispheres and the basal ganglia. These veins join to form the great vein of Galen, which subsequently drains into the straight sinus. The veins of the posterior fossa are divided into three major systems. The superior group drains into the galenic system. The anterior group drains the anterior cerebellum, pons, and medulla. The posterior group drains into the torcular Herophili and adjacent dural sinuses. They supply the cerebellar tonsils and the posteroinferior cerebellar hemispheres.

EXAMINATION OF THE NEUROVASCULAR SYSTEM

Directed Neurological Examination

The carotid artery should be palpated gently for the presence and the intensity of the impulse. The artery should be auscultated for a bruit. However, a bruit is not always indicative of carotid artery stenosis. In addition, the absence of a bruit does not rule out carotid stenosis. A vertebral artery bruit can be auscultated over the posterior upper cervical region. The temporal region, the orbits, and the mastoid region are good locations to auscultate cranial bruits, as in the case of arteriovenous malformations or aneurysms. Attention should be paid to the scalp, looking for prominence or tenderness of the superficial temporal artery that may be seen with temporal arteritis. Bounding pulsation of the superficial temporal or the supraorbital arteries may be seen with internal carotid occlusive disease owing to increased collateral flow through the external carotid artery. Necrosis of the scalp can be seen with temporal arteritis.

Attention should be paid to the ocular globe, looking for scleral injection, dilated ocular and orbital vessels, pulsating exophthalmos, chemosis, or ophthalmoplegia that can be seen with carotid-cavernous fistulas. A dilated fundoscopic examination can demonstrate the ocular manifestations of carotid vascular disease, including hypoperfusion or venous stasis retinopathy, anterior ischemic optic neuropathy, retinal infarctions, and rubeosis iridis. There may be evidence of microemboli such as bright orange-yellow, refractile, or Hollenhorst plaques; white platelet-fibrin intra-arterial plugs; or gray-white nonrefractile calcific emboli.

A careful auscultation of the heart should focus on the detection of structural lesions or rhythm disturbances. The aorta and peripheral pulses should be palpated and auscultated to provide clues to underlying peripheral atherosclerosis.

Associated Neurological Findings

CEREBRAL. Patients with ischemic stroke or intracerebral hemorrhage may have a number of varied cortical deficits (Table 22-2). Patients should be evaluated for disturbances in attention, emotion, memory, language, and speech. Examination of higher cortical functions may be difficult acutely, but serial examinations are often helpful to detect the type and extent of cognitive disturbances.

A basic mental status examination should be performed, evaluating orientation, object recall, calculations, reading, writing, and comprehension. Patients should be examined for disturbances in spatial relationships including anosognosia, spatial disorientation, hemispacial neglect, constructional

apraxia, and other apraxias that are seen with nondominant hemisphere lesions (Video 40, Apraxia). Finger agnosia and right-left disorientation are seen with dominant hemispheric lesions. The typical deficits seen with the various stroke syndromes are detailed in Table 22-2.

Detailed classification of aphasia subtypes is helpful in localizing the area of stroke (Video 96, Conduction Aphasia). There are typical findings with regard to fluency, comprehension, repetition, and naming with lesions in different locations (see Chapter 6).

CRANIAL NERVES. Visual acuity should be checked with correction to evaluate for a decrement that can be seen with retinal vascular lesions. A dilated fundoscopic examination may show evidence of retinal emboli. Visual fields examination may show a homonymous hemianopia that can be seen with MCA or PCA territory stroke or with PCA occlusion secondary to basilar artery disease. Bilateral homonymous hemianopia results in cortical blindness and is most often due to simultaneous or successive PCA occlusions.

Vertical eye movements are impaired with midbrain infarctions. Examination of CN III may disclose an oculomotor paresis that can be seen with the midbrain syndromes, an aneurysm at the junction of the internal carotid and posterior communicating arteries, an aneurysm of the ICA in the cavernous sinus, or with uncal herniation. Horizontal eye movements are impaired with pontine infarctions. CN IV may be affected by midbrain infarction or hemorrhage. CN VI may be affected by pontine infarction or hemorrhage (Video 1, Cranial Nerve VI Palsy), carotid aneurysms or carotid-cavernous fistulas within the cavernous sinus, or compressive lesions within the prepontine cistern such as with fusiform basilar artery aneurysms. Pupillary responses may be helpful in localization of the vascular lesion. Pinpoint pupils that are reactive are seen with pontine tegmental lesions. Fascicular or peripheral III nerve lesions seen with compression due to aneurysms and herniation produce an ipsilateral dilated and unresponsive pupil. Lesions in the midbrain tegmentum produce midposition, irregular, and corectopic pupils (noncentered). Lesions in the midbrain tectum produce midposition and unreactive pupils, often with spontaneous hippus.

Horner's syndrome (Video 17, Horner's Syndrome) may be seen with disruption of the descending oculosympathetic system in lateral medullary infarctions (Wallenberg's syndrome), infarctions in the territories of the superior cerebellar or anterior inferior cerebellar arteries, or mesencephalic hemorrhages. Cervical carotid dissection or occlusion can be associated with postganglionic Horner's syndrome.

An internuclear ophthalmoplegia (INO) (Video 19, Internuclear Ophthalmoplegia), characterized by adduction weakness on the side of the medial longitudinal fasciculus lesion and monocular nystagmus of the abducting eye, can be seen with brain stem infarctions. The INO may be unilateral or bilateral.

CN IV may be affected with midbrain infarction or hemorrhage. CN V may be affected with vascular disease of the pons or medulla or in the cavernous sinus. Dysfunction of CN VII can be manifested as a central facial palsy due to supranuclear corticobulbar lesions that cause a contralateral paresis of the lower portion of the face, with relative sparing of upper facial function (Video 2, Central CN VII Paresis).

TABLE 22-2

Clinico-anatomical Correlation of Disorders of Neurovascular Function

| ANATOMICAL SITE OF DAMAGE | NEUROVASCULAR | CEREBRAL | CRANIAL NERVES | MOTOR/REFLEXES/ CEREBELLAR/GAIT | SENSORY | AUTONOMIC NERVOUS SYSTEM |
|--|---|---|---|--|---|--|
| Diffuse Ischemia—Hypoperfusion | | | | | | |
| Cerebral | Usually normal | Confusion, somnolence | Lower altitudinal defect; saccade/pursuit defects | Bibrachial weakness | Bibrachial sensory loss | Orthostatic hypotension |
| Spinal cord | Usually normal | Normal | Normal | Paralysis below lesion | Sensory loss below lesion | Orthostatic hypotension, bladder/ bowel incontinence |
| Extracranial steal syndrome | Decreased radial pulse in affected arm | Normal | Transient CN dysfunction | Transient uni- or bilateral quadriparesis | Transient sensory loss, body not face | Decreased blood pressure in affected arm |
| TIA | | | | | | |
| Carotid | Carotid bruit, decreased carotid pulse, atherosclerosis | Transient aphasia and dysarthria | Ipsilateral amaurosis fugax, contralateral HH | Transient contralateral weakness or clumsiness | Transient bilateral sensory loss | Cardiac arrhythmia, hypertension |
| Vertebrobasilar | Vertebral or basilar bruit | Normal | Transient CN findings—diplopia, dysarthria | Transient bilateral weakness or clumsiness | Transient bilateral sensory loss | Cardiac arrhythmia, hypertension |
| Focal Ischemia Carotid System | | | | | | |
| Carotid | Carotid pulse diminished or absent | Depressed consciousness, global aphasia | Retinal emboli, contralateral HH, conjugate eye deviation | Weakness contralateral face, arm, leg | Contralateral hemisensory loss face, arm, leg | Cardiac arrhythmia, hypertension |
| Middle cerebral | Possible bruit mid/ upper cervical area | Aphasia (left), apraxia (right) | Contralateral HH | Weakness contralateral face, arm greater than leg | Contralateral hemisensory loss face, arm, greater than leg | Cardiac arrhythmia, hypertension |
| Anterior cerebral | Possible bruit mid/ upper cervical area | Emotional lability, aphasia (left), apraxia (right) | Conjugate eye deviation | Weakness contralateral leg more weak than face, arm | Contralateral hemisensory loss, leg more involved than face and arm | Cardiac arrhythmia, hypertension |
| Anterior choroidal | Possible cervical bruit, atherosclerosis | Affect changes, hemineglect | Contralateral HH | Weakness contralateral face, arm, leg | Contralateral hemisensory loss face, arm, leg | Cardiac arrhythmia, hypertension |
| Small vessel (lacunar infarction) | Usually normal | Dementia (multiple lacunar strokes) | Usually normal (except for CN VII) | Paralysis, if present, usually involves face, arm, leg | Sensory loss, if present involves face, arm, leg | Hypertension |
| Anatomical Site of damage | Neurovascular | Cerebral | Cranial Nerves | Motor/Reflexes/ Cerebellar/ Gait | Sensory | Autonomic Nervous System |
| Focal Ischemia Vertebrobasilar System | | | | | | |
| Posterior inferior cerebellar | Possible vertebral bruit | Normal | Ipsilateral weak palate, Horner's syndrome, decreased p/t ipsilateral face | Ipsilateral limb ataxia | Decreased p/t contralateral body | Cardiac arrhythmia, hypertension |
| Anterior inferior cerebellar | Normal | Normal | Ipsilateral deafness, ipsilateral facial weakness, decreased sensation ipsilateral face | Ipsilateral limb ataxia | Decreased p/t contralateral body | Cardiac arrhythmia, hypertension |

Continued

TABLE 22-2

Clinico-anatomical Correlation of Disorders of Neurovascular Function—cont'd

| ANATOMICAL SITE OF DAMAGE | NEUROVASCULAR | CEREBRAL | CRANIAL NERVES | MOTOR/REFLEXES/CEREBELLAR/GAIT | SENSORY | AUTONOMIC NERVOUS SYSTEM |
|---|--|--|---|---|---|--|
| Focal Ischemia Vertebrbasilar System—continued | | | | | | |
| Superior cerebellar | Normal | Normal | Nystagmus, ipsilateral deafness, diplopia (CN IV) | Ipsilateral limb ataxia | Decreased all sensory modalities contralateral body | Cardiac arrhythmia, hypertension |
| Posterior cerebral | Possible vertebral bruit | Visual agnosia, visual neglect, dyslexia | Contralateral HH, cortical blindness, Balint's syndrome | Usually normal, possible chorea or ballism | Normal unless thalamic pain | Cardiac arrhythmia, hypertension |
| Medial midbrain basilar | Usually normal | Normal | Internuclear ophthalmoplegia, CN III paresis | Contralateral body weakness, ataxia | Normal | Cardiac arrhythmia, hypertension |
| Medial pontine basilar | Usually normal | Normal | Internuclear ophthalmoplegia, CN6 paresis or conjugate eye deviation to side of lesion | Contralateral body weakness, bilateral lesions cause quadraparesis and "locked-in" syndrome | Normal, may have decreased position and vibration contralateral body | Cardiac arrhythmia, hypertension |
| Medial medullary | Usually normal | Normal | CN XII: dysarthria, may have upbeat nystagmus | Contralateral body weakness, ataxia | Decreased position and vibration contralateral body | Cardiac arrhythmia, hypertension |
| Transient global amnesia | Normal | Loss of memory for recent events, cannot learn new information | Normal | Normal | Normal | Normal |
| Hemorrhage | | | | | | |
| Subarachnoid | Possible cranial bruits | Variable depressed level of consciousness | CN III paresis if internal carotid posterior communicating artery aneurysm Fundus: subhyaloid hemorrhages | Normal, unless intraparenchymal extension or secondary vasospasm | Normal, unless intraparenchymal extension or secondary vasospasm | Hypertension, cardiac arrhythmia |
| Intracranial hematoma | Possible cranial bruits | Depressed level of consciousness | Depends on location: brain stem-CN findings prominent; cortical/subcortical-HH; thalamic-conjugate downward deviation | Hemi- or quadriplegia | Cannot assess well if comatose. If thalamus or parietal lobe affected, hemisensory loss contralateral | Hypertension |
| Extracranial hematoma | Normal | Normal or depressed level of consciousness | Normal, possible CN VI palsy from increased intracranial pressure | Varying degree of hemiparesis | Varying degree of hemisensory loss | Normal or Cushing's triad if increased intracranial pressure |
| Vascular Anomalies | | | | | | |
| Intracranial steal | Cranial bruits | May have cognitive deficits | Transient visual deficits | Transient hemiparesis | Transient hemisensory deficits | Normal |
| Vessel dissection | Diminished carotid, superficial temporal, or supraorbital pulses | Normal unless infarction occurs | CN XII lesions, other CN (II, III, V, XI) may be involved; Horner's syndrome | Variable hemiparesis | Variable hemisensory loss | |
| Vascular fistula | Orbital bruit, ocular pulsation | Normal | Variable visual loss and restriction of eye movements and chemosis | Normal | Normal | Normal |
| Spinal Cord Ischemia | | | | | | |
| Anterior spinal artery | Aortic pulsation or aortic dissection | Normal | Normal | Flaccid paraplegia or quadriplegia below lesion | Loss of pain and temperature below lesion | Hypotension |
| Posterior spinal artery | Normal | Normal | Normal | Loss of reflexes below lesion | Loss of position and vibration below lesion | Hypotension |

HH, homonymous hemianopia; p/t, pain/temperature sensation.

This type of involvement is commonly seen with cortical or subcortical cerebral hemorrhage or ischemia. A peripheral type facial nerve palsy with paralysis of the upper and lower facial muscles can be seen with pontine lesions.

Acute hearing loss can occur with AICA infarctions. Vascular lesions of the auditory cortex do not lead to complete deafness, even if the lesions are bilateral. Pure word deafness can occur with unilateral or bilateral temporal lesions affecting Heschl's gyri. Due to the binaural representation of the ascending auditory tracts above the level of the cochlear nuclei, lesions of the brain stem involving the auditory pathways do not cause deafness.

Dysfunction of CN IX and CN X with vascular lesions is manifested by dysphagia and an altered gag response. Bilateral supranuclear corticobulbar lesions, as can occur with bilateral infarctions, can result in severe dysphagia as well as other pseudobulbar signs (Video 10, Dysarthria). Lateral medullary infarctions affect CN IX and CN X function due to involvement of the nucleus ambiguus and cause hoarseness, hiccups, dysphagia, and paralysis of the pharynx, palate, and vocal cords.

Lesions of CN XII can be assessed by observing the tongue at rest and with protrusion. With supranuclear lesions due to infarction or hemorrhage, the tongue will deviate toward the side of the hemiplegia. This nerve can also be affected in its intramedullary course due to infarction or hemorrhage. The medial medullary syndrome can cause paresis of the tongue, with the tongue protruding away from the hemiplegia.

MOTOR/REFLEXES/CEREBELLAR/GAIT. The motor deficits with cerebrovascular disease can vary from a mild limb drift to hemiplegia (Video 4, Pronator Drift). The different clinical syndromes have different patterns of motor deficits, and the extent of weakness varies (see Table 22-2). The presence of bilateral or crossed weakness may suggest vertebrobasilar circulation ischemia, particularly in the presence of other signs of vertebrobasilar ischemia. Weakness of the face and arm more than the leg usually indicates MCA ischemia. Involvement of the face, arm, and leg equally can be seen with capsular or pontine ischemia. Prominent weakness of the leg may be seen with ACA ischemia (Video 11, Hemiplegic Gait). In spinal cord vascular lesions, there is paralysis below the level of the lesion if the anterior spinal artery is involved.

It is also important to evaluate tone since hypotonia may be seen with cerebellar lesions and varying degrees of hypertonicity can be seen with cerebral infarcts or hemorrhages or with brain stem compression. Paratonia (gegenhalten phenomenon) is present often with frontal infarction or hemorrhage.

Asymmetry of the muscle stretch reflexes or a unilateral extensor toe sign or Hoffman response may be the only indication of corticospinal tract dysfunction (Video 80, Hyper-reflexia). There may be "primitive" reflexes, such as a grasp or snout reflex with extensive frontal lesions.

Ataxia or dystaxia of the limbs, trunk, or gait is seen with cerebellar lesions. The gait may be wide based, with impaired tandem gait. Asynergia, dysdiadochokinesia, and dysmetria may be present (Video 9, Dysmetria). The presence of truncal ataxia and titubation suggests a lesion in the midline cerebellum.

SENSORY. Tactile sensory loss may be seen with many of the stroke syndromes (see Table 22-2). Patients can be tested for graphesthesia and stereognosis. Lesions of the postcentral gyrus in the parietal lobe can cause contralateral sensory loss with astereognosis, impaired position sense, and impaired tactile sensation greater than to pain, temperature, and vibration. There may be extinction to double simultaneous tactile stimulation. Hemisensory deficits can occur with thalamic infarctions in the territory of the thalamogeniculate arteries, which supply the somatosensory nuclei. There are crossed sensory findings with lateral medullary infarctions.

In spinal cord vascular lesions, there is loss of pain and temperature sensation below the level of the infarction if the anterior spinal artery is involved. Loss of position, vibration, and light touch sensation below the level of the lesion is seen with infarction of the posterior spinal artery.

AUTONOMIC NERVOUS SYSTEM. Other autonomic testing is usually normal with disturbance of neurovascular function. With the anterior spinal artery syndrome, there is loss of bowel, bladder, and sexual function due to dysfunction of autonomic pathways.

Orthostatic blood pressure and pulse will provide information on ambient autonomic function and reflex response to gravitational changes. In cases in which vascular abnormalities in the neck are suspected (e.g., subclavian steal syndrome), left versus right blood pressure and pulse comparisons are useful.

EVALUATION GUIDELINES

The goals of the diagnostic evaluation are to establish the diagnosis of ischemic or hemorrhagic cerebrovascular disease as a cause of the patient's symptoms and to determine the underlying cause of the event. Early diagnosis and management in the first few hours after stroke are critical. Since proper management begins with an accurate diagnosis, it is paramount to differentiate between cerebral infarction and hemorrhage. The tests that may assist with diagnosis are detailed in Table 22-3. There are a number of potential etiologies of cerebral infarction and hemorrhage that need to be considered (Tables 22-3 and 22-4; see Chapter 45).

NEUROIMAGING. In patients with suspected ischemic stroke, an unenhanced computed tomogram (CT) of the brain is usually the first test performed due to its availability and the rapid production of images. It can readily differentiate between infarction and hemorrhage. In addition, other disorders that mimic acute cerebrovascular disease can be excluded, including tumors, abscesses, and subdural hematomas. Intravenous contrast-enhanced CT is needed only when these diagnoses are a consideration. Thin CT cuts through the posterior fossa should be done if posterior fossa pathology is suspected. Magnetic resonance imaging (MRI) has some benefits over CT due to its more accurate and earlier diagnosis of infarction, especially for smaller strokes, while showing equivalent accuracy in determining when hemorrhage is present. MRI is more sensitive than CT for other types of brain disease, such as brain tumor, that might mimic a stroke. Diffusion-weighted MRI (DWI), a technique sensitive to the Brownian motion of water molecules, is very sensitive and relatively specific

TABLE 22-3

Useful Tests in the Evaluation of Disorders of Neurovascular Function

| SYNDROME | NEUROIMAGING: MRI/CT | ELECTROPHYSIOLOGY | FLUID AND TISSUE ANALYSIS | NEUROPSYCHOLOGICAL TESTS | OTHER TESTS |
|-----------------------------------|---|---|--|---|--|
| Ischemia | | | | | |
| Diffuse hypoperfusion Cerebral | Uni- or bilateral infarcts in “watershed” areas | EEG: diffuse slowing | NA | Depressed LOC | None |
| Spinal cord | Infarct in thoracic “watershed” areas | SSEP delay | NA | Normal | None |
| Extracranial steal syndrome | Normal unless infarct occurs | EEG usually normal | NA | NA | None |
| TIA | | | | | |
| Focal ischemia Large vessel | Infarct in involved region | Polymorphic delta waves over region | Lab tests* | Variable depending on site | Chest x-ray, ECG, NV tests [†] |
| Small vessel (lacunae) | Small infarcts subcortex and brain stem | Normal | Lab tests* | Variable depending on site | Chest x-ray, ECG, NV tests [†] |
| Hemorrhage | | | | | |
| Subarachnoid | Blood subarachnoid space, MR angiogram may visualize aneurysm | Varying degrees of diffuse slowing | CSF: RBCs/ xanthochromia | Depressed LOC dependent on extent of bleeding, hydrocephalus, and vasospasm | Cerebral angiography to show aneurysm |
| Intracranial hematoma | Intraparenchymal blood | EEG: polymorphic slow waves over region | Decreased CSF cystatin C (cerebral amyloid angiopathy) | Variable depressed LOC depending on site | Biopsy of hematoma site may reveal tumor cells or cerebral amyloid angiopathy |
| Extracranial hematomas | Extradural or subdural defects | EEG: attenuated background over hematoma | NA | Variable degrees of depressed consciousness | Cerebral angiogram: avascular mass |
| Vascular Anomalies | | | | | |
| Intracranial steals | MRI/CT: vascular mass | EEG: slow waves in contralateral hemisphere | Normal | Variable cognitive effects depending on site of AVM | AVM on cerebral angiogram |
| Vessel dissection | Cerebral or brain stem infarct | EEG: polymorphic slow waves over ipsilateral hemisphere | Normal | Aphasia in carotid dissection | Dissection seen on angiogram |
| Fistula | MRI/CT: dilated vascular structure, esp. cavernous sinus | Normal | NA | Normal | Cerebral or MR angiogram; dilated vascular channels |
| Spinal cord ischemia | MRI: infarction of cord | SSEP: normal (anterior spinal artery) or prolonged (posterior spinal artery) | NA | NA | Spine x-rays, aortic ultrasound, TEE, angiography useful in aortic dissection |

*Lab tests = standard battery of tests of neurovascular evaluation; includes CBC with differential, platelet count, ESR, PT, PTT, plasma glucose, BUN, creatinine, lipid analysis, luteic serology, urinalysis. More detailed testing for hematological abnormalities are added as indicated.

[†]NV tests = noninvasive diagnostic procedures are carotid and vertebral duplex, 2-D echocardiography, or TEE. These are useful in evaluating a cerebrovascular lesion. Cerebral angiography is invasive and therefore used only in selected instances.

AVM, arteriovenous malformation; CT, computed tomography scan; EEG, electroencephalography; LOC, level of consciousness; MRI, magnetic resonance imaging; NA, not applicable; SSEP, somatosensory evoked potentials; TEE, transesophageal echocardiography.

in detecting acute ischemic stroke. DWI findings have shown high levels of diagnostic accuracy; however, studies have demonstrated that small brain stem lacunar infarctions may escape detection with this technique.²¹ MRI perfusion imaging in combination with DWI has been increasingly used in the management algorithm of ischemic stroke with thrombolytic agents.

In patients with suspected intracerebral hemorrhage, CT is the most effective initial test to accurately identify the location, site, direction of extension, and type of an acute intracerebral hemorrhage. The presence and degree

of hydrocephalus, ventricular shift or compression, and edema can be assessed. Although MRI is not often used acutely, it is an important diagnostic tool later for identifying whether vascular malformations or tumors are present.

Carotid Doppler ultrasonography is used as a noninvasive means of evaluating for stenosis or occlusion of the common and proximal portions of the internal and external carotid arteries. Transcranial Doppler ultrasound is a technique that allows identification of alteration in direction or velocity of flow in the basal intracranial arteries. This test can be helpful in subarachnoid hemorrhage to evaluate for vasospasm.

TABLE 22-4

Selected Etiologies Associated with Neurovascular Disorders

| ETIOLOGICAL CATEGORY | SELECTED SPECIFIC ETIOLOGIES | CHAPTER |
|--|---|---------|
| Structural Disorders | | |
| Developmental structural disorders | Saccular aneurysms Arteriovenous malformations | 28 |
| Hereditary and Degenerative Disorders | | |
| Storage diseases: Lipidoses, glycogen disorders, and leukodystrophies | Fabry's disease | 30 |
| Amino/organic acidopathies, mitochondrial enzyme defects, and other metabolic errors | MELAS Menke's disease | 31 |
| Chromosomal abnormalities and neurocutaneous disorders | Rendu-Osler-Weber, Ehlers-Danlos type IV | 32 |
| Movement disorders | Sydenham's chorea | 34 |
| Hereditary nondegenerative neuromuscular disease | Inherited disease producing accelerated atherosclerosis Inherited nonatherosclerotic vasculopathies | 37 |
| Acquired Metabolic and Nutritional Disorders | | |
| Endogenous metabolic disorders | Acquired prothrombotic states | 38 |
| Exogenous acquired metabolic disorders of the nervous system: Toxins and illicit drugs | Heroin, cocaine, phencyclidine, phenylpropanolamine, amphetamines, methanol intoxication | 39 |
| Nutritional deficiencies and syndromes associated with alcoholism | Binge alcohol intoxication | 40 |
| Infectious Disorders | | |
| Viral infections | Herpes zoster arteritis | 41 |
| Nonviral infections | Meningovascular syphilis, meningitis (bacterial, tuberculosis), fungal infections, sarcoidosis | 42 |
| HIV and AIDS | Bleeding diatheses, opportunistic infection | 44 |
| Neurovascular Disorders | | |
| | Arterial hypertension Atherosclerotic vasculopathy Embolic cardiac diseases, valvular heart disease, arrhythmias, intracardiac defects, cyanotic congenital heart disease, atrial myxoma, infective endocarditis Hemoglobinopathies Vascular anomalies (e.g., aneurysms, AVMs) Nonatherosclerotic vasculopathies Cerebral venous thrombosis | 45 |
| Neoplastic Disorders | | |
| Primary neurological tumors | Intracranial hemorrhage into tumor | 46 |

Magnetic resonance angiography (MRA) may be used to produce very detailed two- and three-dimensional images of the blood vessels using MRI technology. MRA can be particularly useful in cases of hemodynamically consequential extracranial internal carotid artery stenosis, in cases of suspected cervicocephalic arterial dissection, in imaging the major intracranial arteries in the region of the circle of Willis, and in cases of intracranial venous

occlusive disease. Limitations of MRA include a tendency to overestimate the degree of arterial stenosis; difficulties in assessing tandem arterial lesions, intracranial vasculitis, and arterial ulcerations; and difficulty in the assessment of very slow flow.

Computed tomographic angiography (CTA) is rapidly emerging as an alternative to MRA for imaging both the extracranial and the intracranial circulation, but it requires

the administration of intravenous iodinated contrast and has additional limitations, including a considerable amount of time required for processing the acquired data.

Catheter cerebral angiography is indicated in patients who are possible candidates for carotid endarterectomy, angioplasty/stenting, and cerebral vasculitis; patients suspected of harboring tandem lesions; and patients with cervicocephalic arterial dissections with suboptimal MRA or CTA studies or contraindications for MRA or CTA. Cerebral angiography plays an important role in the evaluation of selected patients with intracerebral hemorrhage. Angiography is of importance when there is reason to suspect an aneurysm, arteriovenous malformation (AVM), vasculitis, or moyamoya disease (Video 216, Moyamoya Stroke). Angiography is performed in patients who have an atypical location for hypertensive hemorrhage or in the young patient without hypertension.

In patients with spinal cord ischemia, a spinal MRI may show an area of infarction or hemorrhage or a vascular malformation.

BODY FLUID AND TISSUE ANALYSIS. A basic workup that should be performed in all patients with ischemic stroke includes a complete blood count with differential and platelet count, erythrocyte sedimentation rate, prothrombin time with international normalized ratio, activated partial thromboplastin time, plasma glucose level, blood urea nitrogen, serum creatinine, lipid analysis, luetic serology, and urinalysis (see Table 22-3).

A basic evaluation that should be performed in all patients with intracerebral hemorrhage includes a complete blood count with differential and platelet count, prothrombin time with partial thromboplastin time, erythrocyte sedimentation rate, plasma glucose, serum alkaline phosphatase, serum aspartate aminotransferase, serum calcium, blood urea nitrogen, serum creatinine, and urinalysis. Additional paraclinical evaluation is listed in Table 22-3.

CEREBROSPINAL FLUID. There is almost no indication for a lumbar puncture in patients suspected of having ischemic stroke or intracerebral hemorrhage. Rarely, patients suspected of having infection as a cause of stroke may need CSF analysis. In patients with intracerebral hemorrhage or a large hemispheric stroke, a lumbar puncture can be dangerous because of sudden intracranial compartmental shifts with resultant herniation. Patients with suspected subarachnoid hemorrhage with a CT scan that does not reveal hemorrhage should undergo a lumbar puncture. There is no need to perform a lumbar puncture if the CT scan shows subarachnoid blood.

NEUROPSYCHOLOGICAL TESTS. Depression occurs in 30% to 50% of stroke patients within 2 years of the initial event.²² Poststroke depression produces physical, emotional, and cognitive symptomatology and may have a major impact on the recovery of these patients. Approximately 40% to 50% will display depressive symptomatology in the first month after stroke. Approximately half of the patients meet criteria for major depression. The other half have minor depressive symptoms. A particularly interesting finding, not corroborated by all investigators, has been that depression is most common with strokes involving the frontal lobe and head of the caudate nucleus, particularly with lesions close to the frontal pole. Depression is more common with lesions affecting the left dorsolateral frontal lobe in comparison with the right frontal pole. One possible explanation for this neuroanatomical

correlation is that such lesions may interrupt noradrenergic and serotonergic pathways. Both nortriptyline and citalopram have shown efficacy in the treatment of poststroke depression.²³ Persuading patients to comply with treatment requires a detailed explanation of the potential unwanted effects of the medications. The selection of the antidepressant is based on the side effect profile of the medication and the clinical characteristics of the patient.

Other neuropsychiatric problems that can occur after stroke include mania, anxiety, bipolar affective disorders, and psychosis. Another problem that can develop is a pseudobulbar affect or emotional incontinence that may be due to bilateral infarctions.

OTHER TESTS. Other tests that should be performed in all patients with ischemic stroke include chest roentgenography and electrocardiography. Cardiac investigations to determine whether emboli have a cardiac source are advised in selected circumstances. Two-dimensional echocardiography in older patients with ischemic stroke is often limited to those with clinical clues of heart disease. Two-dimensional echocardiography should be considered in all patients younger than 45 years with otherwise unexplained ischemic stroke. Transesophageal echocardiography should be used in selected individuals, particularly for the evaluation of mitral and aortic prosthetic valves or vegetations; whenever there is a need for better visualization of the left atrial appendage or interatrial septum; or when a right-to-left shunt or debris from atherosclerosis of the aortic arch is suspected.

CLINICAL SYNDROMES

There are a number of syndromes that result from ischemia or hemorrhage involving the central nervous system. Table 22-2 details typical clinical features, whereas Table 22-3 details tests that assist in the diagnosis of the syndromes. Causes of stroke are discussed in Chapter 45.

Diffuse Hypoperfusion Syndromes (Cerebral and Spinal Cord)

As discussed in the section on arterial anatomy, the mid-thoracic spinal cord is a border zone or watershed area that is susceptible to ischemia due to the unequal blood supply in this region. In situations of systemic hypoperfusion, there can be a spinal cord infarction. Conditions such as an aortic dissection can also cause a global decrease in spinal cord perfusion that results in gray matter infarction with relative sparing of the white matter tracts.

There can be border zone or watershed infarctions in the brain between the major arterial circulations. These conditions may occur with severe hypotension or in association with cardiac surgery. There are several described syndromes.²⁴

If there is ischemia in the border zone territory of the anterior, middle, and posterior cerebral arteries, there may be bilateral parieto-occipital infarcts. There can be a variety of visual defects, including lower altitudinal visual field defects, optic ataxia, cortical blindness, disorders of ocular pursuit, and abnormalities in judging size, distance, and movement. If there is ischemia between the territories of the anterior and middle cerebral arteries bilaterally, a syndrome of bibrachial sensorimotor impairment can occur. Initially, there is weakness of the entire upper limbs, but

later the weakness may be confined to the forearms and hands. Saccadic eye movements may be impaired due to involvement of the frontal eye fields. In ischemia to the border zone regions between the middle and posterior cerebral arteries, there can be bilateral parietotemporal infarctions. Patients have cortical blindness initially that may improve. However, there are a number of defects in higher cortical function that persist, including dyslexia, dysgraphia, dyscalculia, and memory defects.

Extracranial Steal Syndromes from Disease of the Aortic Branches

Occlusive disease in the subclavian arteries or the innominate artery can give rise to extracranial steal syndromes. The most defined syndrome is the subclavian steal syndrome. In this condition, occlusive disease in the proximal subclavian artery can lead to a siphoning of blood away from the brain by a reversal of flow down the vertebral artery on the affected side to the ischemic limb. The pulse and blood pressure are diminished in the affected limb. The symptoms may include headache, vertebrobasilar ischemia, and limb claudication, often precipitated by exercise. A bruit may be heard over the subclavian artery. The limb may become cyanotic if it is held above the level of the heart. It should be noted that a majority of people with subclavian steal detected by noninvasive techniques have no neurological symptoms.²⁵

Transient Ischemic Attacks

A TIA is a transient episode of focal neurological or retinal dysfunction secondary to impaired blood supply in a vascular territory. Clinical signs typical of TIAs in the carotid and vertebrobasilar territories are outlined in Table 22-2. It should be noted that transient vertigo, diplopia, dysarthria, or dysphagia in isolation is insufficient to establish a diagnosis of vertebrobasilar TIAs. In addition, isolated drop attacks in which the patient falls to the ground, maintains consciousness, and then arises without a deficit are seldom due to vertebrobasilar ischemia. The annual risk of stroke after a TIA is 3% or 4% per year. However, the risk of a subsequent stroke is at least three times greater for individuals who have had a TIA than in those individuals who have not had a TIA.²⁶

Amaurosis fugax may be described as a sudden onset of a “fog,” “haze,” “scum,” “curtain,” “shade,” “blur,” “cloud,” or “mist.” A curtain or shade pattern with the loss of vision moving superiorly to inferiorly is described only by 15% to 20% of patients.^{27,28} Less commonly, there can be a concentric visual loss presumed to be due to marginal perfusion causing diminished blood flow to the retina. The visual loss is sudden in onset, often brief in duration, and painless in nature. The length of visual loss is usually 1 to 5 minutes and rarely lasts more than 30 minutes. Positive phenomena such as scintillation, fortification spectra, or flashing lights are rarely indicative of amaurosis fugax. After an episode of amaurosis fugax, the vision is usually fully restored, although some patients may have permanent visual loss due to a retinal infarction (see Table 22-2).²⁸

In amaurosis fugax, it is key to evaluate for ICA stenosis with a carotid duplex ultrasound and to exclude temporal arteritis or a cardiac abnormality as a cause.

Carotid System Stroke Syndromes

Internal Carotid Artery Occlusion

Occlusion of the ICA can produce symptoms and signs of infarction in either the ACA or the MCA territories (or both), as described later. PCA territory infarctions can be seen with ICA occlusion if a fetal origin of the PCA is present. The sole feature that distinguishes the MCA syndrome from a carotid artery syndrome is the presence of amaurosis fugax.^{29,30} Infarctions are often large, involving multiple lobes. Cerebral edema may be a life-threatening concern. The carotid pulse may be absent ipsilaterally. Horner’s syndrome may be present due to oculosympathetic involvement along the carotid artery.

Middle Cerebral Artery Syndrome

An MCA infarction is one of the most common manifestations of cerebrovascular disease (Fig. 22-9). The clinical picture with an MCA infarction is varied and depends on whether the site of the occlusion is in the stem, the superior division, the inferior division, or the lenticulostriate branches and whether there is good collateral blood flow.

When the stem of the MCA is occluded, there is usually a resultant large infarction with contralateral hemiplegia,

Figure 22-9. CT of a large acute right middle cerebral artery territory infarction. (Courtesy of Karen S. Caldemeyer, MD.)

conjugate eye deviation toward the side of the infarct, hemianesthesia, and homonymous hemianopia. There is associated global aphasia if the dominant hemisphere is involved and hemineglect with nondominant hemispherical lesions. The difference between an upper division MCA infarction and an MCA stem lesion is that the hemiparesis usually affects the face and arm more than the leg with upper division infarction. Broca's aphasia is more common in upper division infarcts due to preferential involvement of the anterior branches of the upper division in occlusions. With lower division MCA syndromes, a Wernicke-type aphasia is seen with dominant hemisphere infarction, and behavioral disturbances are seen with nondominant infarction. A homonymous hemianopia may be present. A lenticulostriate branch occlusion may cause a lacunar infarction with involvement of the internal capsule producing a syndrome of pure motor hemiparesis. These described syndromes are variable and are dependent on the presence of collaterals and whether edema is present.³¹⁻³³

Alexia with agraphia may occur with left angular gyrus involvement. Gerstmann's syndrome, which consists of finger agnosia, acalculia, right-left disorientation, and agraphia, may be seen with dominant hemisphere parietal lesions. The perisylvian aphasias seen with dominant hemispherical infarctions may be of the Broca, Wernicke, conduction, or global type, depending on the site and extent of involvement (Video 96, Conduction Aphasia). Anosognosia most commonly is associated with right hemispheric strokes. Nondominant infarction may cause inattention, neglect, denial, apraxia (Video 40, Apraxia), impaired prosody, and, rarely, acute confusion and agitated delirium.³⁴ A contralateral homonymous hemianopia or contralateral inferior quadrantanopia can occur with infarctions in either hemisphere.

Anterior Cerebral Artery Syndrome

ACA territory infarctions are uncommon. They can be seen in patients with vasospasm after subarachnoid hemorrhage due to ACA or ACoA aneurysms. Excluding these causes, less than 3% of acute cerebral infarcts occur in the ACA territory.³⁵⁻³⁷ The characteristics of ACA infarction vary according to the site of involvement and the extent of collateral blood flow.³⁸ Contralateral weakness involving primarily the lower extremity and, to a lesser extent, the arm is characteristic of infarction in the territory of the hemispheric branches of the ACA (see Table 22-2). Other characteristics include abulia, akinetic mutism (with bilateral mesiofrontal damage), impaired memory or emotional disturbances, transcortical motor aphasia (with dominant hemispheric lesions), deviation of the head and eyes toward the lesion, paratonia (gegenhalten), discriminative and proprioceptive sensory loss (primarily in the lower extremity), and sphincter incontinence (see Table 22-2).

An anterior disconnection syndrome with left arm apraxia due to involvement of the anterior corpus callosum can be seen. Pericallosal branch involvement can cause apraxia, agraphia, and tactile anomia of the left hand. Infarction of the basal branches of the ACA can cause memory disorders, anxiety, and agitation.

Infarction in the territory of the medial lenticulostriate artery (artery of Heubner) causes more pronounced weakness of the face and arm without sensory loss due to this artery's supply of portions of the anterior limb of the internal capsule.

Anterior Choroidal Artery Syndrome

The AChA syndrome is often characterized by hemiparesis as a result of involvement of the posterior limb of the internal capsule, hemisensory loss due to involvement of the posterolateral nucleus of the thalamus or thalamocortical fibers, and hemianopia secondary to involvement of the lateral geniculate body or the geniculocalcarine tract.^{39,40} (see Table 22-2). The visual field defect that is seen with AChA infarcts is characterized by a homonymous defect in the superior and inferior visual fields that spares the horizontal meridian.⁴¹ In a small number of patients, there may be left spatial hemineglect with right hemispheric infarctions and a mild language disorder with left hemispheric infarctions.^{40,42} With bilateral infarctions in the AChA territory, there can be pseudobulbar mutism and a variety of other features, including facial diplegia, hemiparesis, hemisensory loss, lethargy, neglect, and affect changes.⁴³

Lacunar Stroke Syndromes

Although there are more than 20 described lacunar syndromes, the 4 that have been best described will be addressed here. These syndromes have been described with ischemic lacunar infarctions as well as with discrete hemorrhages (Video 215, Cadasil Stroke).⁴⁴

Pure motor hemiparesis is characterized by a unilateral motor deficit involving the face, the arm, and, to a lesser extent, the leg. There may be a mild dysarthria. There is no associated aphasia, apraxia, or agnosia. In addition, there is no sensory, visual, or higher cortical dysfunction. This syndrome may be secondary to a lacunar infarction in the posterior limb of the internal capsule, corona radiata, basis pontis, cerebral peduncle, or the medullary pyramid.⁴⁵ However, an ischemic cortical lesion may also cause a pure motor hemiparesis.⁴⁴

Pure sensory stroke (pure hemisensory or paresthetic stroke) is characterized by unilateral numbness, paresthesias, and a hemisensory deficit involving the face, arm, trunk, and leg. Subjective complaints may be out of proportion to objective findings. Lacunae in the ventroposterolateral nucleus of the thalamus may cause this syndrome. However, pure sensory stroke can also be due to ischemic infarctions in the corona radiata or in the parietal cortex.⁴⁴

Ataxic hemiparesis (homolateral ataxia and crural paresis) is characterized by weakness that is more prominent in the lower extremity in association with ipsilateral arm and leg incoordination. Involvement of the face is uncommon. Dysarthria is usually not present. There may be an extensor plantar response. Lacunae in the posterior limb of the internal capsule, basis pontis, red nucleus, or in the thalamocapsular region can cause this syndrome.^{44,46}

The dysarthria-clumsy hand syndrome is characterized by supranuclear facial weakness, tongue deviation, dysphagia,

dysarthria, impaired fine motor control of the hand, and an extensor plantar response. There is no sensory deficit. Lacunae in the basis pontis, at the junction of the upper one-third and lower two-thirds of the pons, or in the genu of the internal capsule may cause this syndrome.⁴⁴

Vertebrobasilar Stroke Syndromes

The circumferential vessels perfuse the lateral brain stem, and the perforant vessels directly from the large basilar or vertebral arteries perfuse the midline structures. Whereas obstruction of the circumferential arteries gives rise to standard syndromes, there is great variability in the perforant vessels, and therefore several syndromes are described. As a rule, midline syndromes affect the pyramidal system, consciousness, and midline cranial nerves (extraocular muscles), whereas lateral syndromes affect the cerebellum, sensation, and the lateral cranial nerves. There are additional overlap syndromes when vessels perfuse areas in between.

Posterior Inferior Cerebellar Artery Syndrome

The areas of the cerebellum supplied by the PICA are variable. There are several different patterns of PICA territory cerebellar infarctions (Video 95, Brain Stem Infarction). Typical clinical findings are detailed in Table 22-2. If the medial branch territory is affected, involving the vermis and vestibulocerebellum, the clinical findings include prominent vertigo, ataxia, and nystagmus. If the lateral cerebellar hemisphere is involved, patients can have vertigo, gait ataxia, limb dysmetria and ataxia, nausea, vomiting, conjugate or dysconjugate gaze palsies, miosis, and dysarthria. If the infarction is large, there may be altered consciousness or confusion. Hydrocephalus or herniation may develop. There is also a syndrome of combined dorsolateral medullary and cerebellar infarction that may be due to a vertebral artery occlusion or a medial PICA occlusion.⁴⁷ Although a PICA occlusion can be the cause of Wallenberg's (lateral medullary) syndrome, this syndrome is more often due to an intracranial vertebral artery occlusion (Fig. 22-10).⁴⁸

Anterior Inferior Cerebellar Artery Syndrome

The AICA syndrome causes a ventral cerebellar infarction that has a characteristic clinical picture^{49,50} (see Table 22-2). The signs and symptoms that are seen include vertigo, nausea, vomiting, and nystagmus due to involvement of the vestibular nuclei. There may be ipsilateral facial hypalgesia and thermoanesthesia and corneal hypesthesia due to involvement of the trigeminal spinal nucleus and tract. There is ipsilateral deafness and facial paralysis due to involvement of the lateral pontomedullary tegmentum. Ipsilateral Horner's syndrome is present due to compromise of the descending oculosympathetic fibers (Video 17, Horner's Syndrome). There is contralateral trunk and extremity hypalgesia and thermoanesthesia due to involvement of the lateral spinothalamic tract. Finally, there is ipsilateral ataxia and asynergia due to involvement of the cerebellar peduncle and cerebellum.

Superior Cerebellary Artery Syndrome

Infarction in the territory of the SCA produces a dorsal cerebellar syndrome that may also involve the lateral superior pons⁵¹ (see Table 22-2). Vertigo may be present, although it is less common with SCA infarcts than with the other cerebellar syndromes. Nystagmus is present due to involvement of the medial longitudinal fasciculus and the cerebellar pathways. Ipsilateral Horner's syndrome is seen due to involvement of the descending sympathetic tract. Ipsilateral ataxia and asynergia and gait ataxia are noted due to involvement of the superior cerebellar peduncle, brachium pontis, the superior cerebellar hemisphere, and the dentate nucleus. There is an intention tremor due to involvement of the dentate nucleus and superior cerebellar peduncle. Choreiform dyskinesias may be present ipsilaterally. Contralaterally, there is hearing loss due to lateral lemniscus disruption and trunk and extremity hypalgesia and thermoanesthesia due to spinothalamic tract involvement. A contralateral fourth nerve palsy may be present due to involvement of the midbrain tectum. The diagnostic findings are detailed in Table 22-3.

Midline Basilar Artery Syndromes: Midbrain

It should be emphasized that there is great variability in the arterial blood supply to the brain stem. The syndromes that are described may be oversimplified, and several variations are possible.

WEBER'S SYNDROME. Weber's syndrome (ventral cranial nerve III fascicular syndrome) is due to infarction in the distribution of the penetrating branches of the PCA affecting the cerebral peduncle, especially medially with damage to the fascicle of CN III and the pyramidal fibers. The resultant clinical findings are contralateral hemiplegia of the face, arm, and leg due to corticospinal and corticobulbar tract involvement and ipsilateral oculomotor paresis, including a dilated pupil. A slight variation of this syndrome is the midbrain syndrome of Foville, in which the supranuclear fibers for horizontal gaze are interrupted in the medial peduncle, causing a conjugate gaze palsy to the opposite side.

BENEDIKT'S SYNDROME. Benedikt's syndrome is caused by a lesion affecting the mesencephalic tegmentum in its ventral portion, with involvement of the red nucleus, brachium conjunctivum, and the fascicle of CN III. This syndrome is due to infarction in the distribution of the penetrating branches of the PCA to the midbrain. The clinical manifestations are ipsilateral oculomotor paresis, usually with pupillary dilation and contralateral involuntary movements, including intention tremor, hemiathetosis, and hemichorea.

CLAUDE'S SYNDROME. Claude's syndrome is caused by lesions that are more dorsally placed in the midbrain tegmentum than with Benedikt's syndrome. There is injury to the dorsal red nucleus that results in more prominent cerebellar signs without the involuntary movements. There is oculomotor paresis.

NOTHNAGEL'S SYNDROME. Nothnagel's syndrome is characterized by an ipsilateral oculomotor palsy with contralateral cerebellar ataxia. Infarctions in the distribution of the penetrating branches of the PCA to the midbrain are the cause of this syndrome.

Figure 22-10. Forty-seven-year-old man involved in a motor vehicle accident presenting with lateral medullary syndrome due to a vertebral artery dissection. **A**, T2-weighted image shows hyperintensity in the right posterior lateral medulla (*arrow*). **B**, Axial T1-weighted image shows lack of flow void in the right vertebral artery (*left arrow*). Notice the normal flow void in the left vertebral artery (*right arrow*). **C**, Time-of-flight magnetic resonance arteriogram shows no flow in the right vertebral artery. (Courtesy of Karen S. Caldemeyer, MD.)

PARINAUD'S SYNDROME. Parinaud's (dorsal rostral midbrain) syndrome can result from infarctions in the midbrain territory of the PCA penetrating branches. This syndrome is characterized by supranuclear paralysis of eye elevation, defective convergence, convergence-retraction nystagmus, light-near dissociation, lid retraction (Collier's sign), and skew deviation.

TOP OF THE BASILAR SYNDROME. Top of the basilar syndrome is due to infarction of the midbrain, thalamus, and portions of the temporal and occipital lobes.^{52,53} It is due to occlusive vascular disease, often embolic in nature,

of the rostral basilar artery. The following signs may be present:

1. Behavioral abnormalities, including somnolence, peduncular hallucinosis (see Chapter 3), memory disturbances, and agitated delirium.
2. Ocular findings, including unilateral or bilateral paralysis of upward or downward gaze, disordered convergence, pseudoabducens palsy, convergence-retraction nystagmus, abnormalities of abduction, Collier's sign (elevation and retraction of the upper eyelids), skew

deviation, and oscillatory eye movements. Visual defects that may be present include hemianopia, cortical blindness, and Balint's syndrome (see Chapter 8).

3. Pupillary abnormalities, including small and reactive pupils, large or midposition and fixed pupils, corectopia, and, occasionally, oval pupils.
4. Motor and sensory deficits.

Midline Vertebrobasilar Syndromes: Pons

Although there are many named pontine syndromes, the most beneficial categorization is based on neuroanatomical divisions.

LOCKED-IN SYNDROME. Locked-in syndrome (deafferented state) is the result of bilateral ventral pontine lesions that produce quadriplegia, aphonia, and impairment of the horizontal eye movements in some patients. Wakefulness is maintained due to sparing of the reticular formation. Patients can move their eyes vertically and can blink because the supranuclear ocular motor pathways lie more dorsally (see Chapter 1). In some patients, there is a "herald" hemiparesis that makes the lesion appear to be cortical in nature. However, within a few hours, there is progression to bilateral hemiplegia and CN findings associated with the locked-in syndrome.⁵⁴

MEDIAL INFERIOR PONTINE SYNDROME. This syndrome is due to occlusion of a paramedian branch of the basilar artery. There is ipsilateral paralysis of conjugate gaze to the side of the lesion, abducens palsy, nystagmus, and ataxia. Contralateral to the lesion, there is hemibody impairment of tactile and proprioceptive sensation and paralysis of the face, arm, and leg.

MEDIAL MIDPONTINE SYNDROME. Medial midpontine syndrome is due to ischemia of the medial midpontine region from occlusion of the paramedian branch of the midbasilar artery. It can lead to ipsilateral limb ataxia. Contralateral to the lesion, there is eye deviation and paralysis of the face, arm, and leg. Although there are predominant motor symptoms, there can be variable impaired touch and proprioception.

Lateral and Combined Vertebrobasilar Syndromes

LATERAL MIDPONTINE SYNDROME. Occlusion of the paramedian branch of the midbasilar artery can lead to ipsilateral impaired sensory and motor function of the trigeminal nerve with limb ataxia.

TOTAL UNILATERAL INFERIOR PONTINE SYNDROME. An occlusion of the AICA can lead in some circumstances to a combination of the symptoms and signs seen with the lateral and medial pontine syndromes.

LATERAL PONTOMEDULLARY SYNDROME. This syndrome can be seen with occlusion of the vertebral artery. The manifestations seen are a combination of the medial and lateral inferior pontine syndromes.

LATERAL MEDULLARY SYNDROME (WALLENBERG'S SYNDROME). The lateral medullary syndrome is most often due to occlusion of the vertebral artery. Less commonly, it is due to occlusion of the PICA. This syndrome produces an ipsilateral Horner syndrome; loss of pain and temperature sensation of the face; weakness of the palate, pharynx, and vocal cords; and cerebellar ataxia.

Contralateral to the lesion, there is hemibody loss of pain and temperature sensation.

TOTAL UNILATERAL MEDULLARY SYNDROME. Occlusion of the vertebral artery can lead to a combination of medial and lateral medullary syndromes.

Midline Vertebrobasilar Syndrome: Medulla

This syndrome is less common than the lateral medullary syndrome. It may be due to occlusion of the vertebral artery, a branch of the vertebral artery, or the lower basilar artery. The findings with this syndrome include an ipsilateral lower motor neuron paralysis of the tongue and contralateral paralysis of the arm and leg. In addition, there is contralateral hemibody loss of tactile, vibratory, and position sense.

Thalamic Infarction

The main arterial supply to the thalamus arises from the PCoAs and the perimesencephalic segment of the PCA. Localization of the arterial territory responsible for a thalamic infarction often can be determined from clinical findings. Thalamic infarctions typically involve one of the four major vascular regions: posterolateral, anterior, paramedian, and dorsal.

Posterolateral thalamic infarctions result from occlusion of the thalamogeniculate branches arising from the P2 segment of the PCA. Three common clinical syndromes may occur: pure sensory stroke, sensorimotor stroke, and the thalamic syndrome of Dejerine-Roussy. Findings in Dejerine-Roussy syndrome contralateral to the involved thalamus may include hemianesthesia, transient slight hemiparesis, hemiataxia, choreoathetoid movements, athetoid posture, paroxysmal pain, and homonymous hemianopia (often due to simultaneous medial occipital infarction).

Anterior thalamic infarction results from occlusion of the polar or tuberothalamic artery. Findings may include predominant neurobehavioral disturbances such as abulia, apathy, disorientation, lack of insight, and personality changes. There may also be facial paresis for emotional movement, contralateral hemiparesis and visual field defects, dysphagia with left-sided lesions, and hemineglect and impaired visuospatial processing with right-sided lesions.

Infarctions in the territory of the paramedian artery may also involve the paramedian region of the midbrain. Occlusion of the top of the basilar artery can cause this syndrome. Findings may include transient loss of consciousness or somnolence, behavioral changes, recent memory loss with anterograde and retrograde components, disorders of vertical gaze and convergence, contralateral hemiataxia, asterixis or motor weakness, and delayed action tremor in the contralateral limbs.

Dorsal thalamic infarction results from occlusion of the posterior choroidal arteries. These infarctions are characterized by the presence of homonymous hemianopia or homonymous horizontal sectoranopia. There may also be an asymmetrical optokinetic response and hemibody (face and arm) hypesthesia. Involvement of the pulvinar may account for thalamic aphasia.

Posterior Cerebral Artery Syndrome

The signs and symptoms seen with PCA territory infarctions are variable, depending on the site of the occlusion

and the availability of collateral blood flow. Unilateral infarctions in the distribution of the hemispherical branches of the PCA may produce a contralateral homonymous hemianopia. This is due to infarction of the striate cortex, the optic radiations, or the lateral geniculate body. There is partial or complete macular sparing if the infarction does not reach the occipital pole. The visual field defect may be limited to a quadrantanopia. A superior quadrantanopia is caused by infarction of the striate cortex inferior to the calcarine fissure or the inferior optic radiations in the temporo-occipital lobes. An inferior quadrantanopia is the result of an infarction of the striate cortex superior to the calcarine fissure or the superior optic radiations in the parieto-occipital lobes (see Chapter 8).

There may be more complex visual changes, including formed or unformed visual hallucinations (“release hallucinations”), visual and color agnosias, and prosopagnosia (agnosia for familiar faces).⁵⁵ Finally, there can be some alteration of sensation with PCA hemispherical infarctions, including paresthesias and altered position, pain, and temperature sensations.

Infarction in the distribution of the callosal branches of the PCA involving the left occipital region and the splenium of the corpus callosum produces alexia without agraphia (Video 97, Dyslexia).⁵⁶ In this syndrome, patients can write, speak, and spell normally. However, they are unable to read words and sentences. Naming of letters and numbers may be intact. However, there can be inability to name colors, objects, and photographs.⁵⁷ Right hemispheric PCA territory infarctions may cause contralateral visual field neglect. Amnesia may be present with PCA infarctions that involve the left medial temporal lobe or when there are bilateral mesiotemporal infarctions. In addition, an agitated delirium may occur with bilateral penetrating mesiotemporal infarctions. Large infarctions of the left posterior temporal artery territory may produce an anomia or transcortical sensory aphasia (see Chapter 6).⁵⁸

Infarctions in the distribution of the penetrating branches of the PCA to the thalamus can cause aphasia if the left pulvinar is involved, akinetic mutism, global amnesia, and/or Dejerine-Roussy syndrome. In the latter syndrome, the patient has contralateral sensory loss to all modalities, severe dysesthesias on the involved side (thalamic pain), vasomotor disturbances, transient contralateral hemiparesis, and choreoathetoid or ballistic movements. There are also a number of syndromes that can result from infarctions in the distribution of the penetrating branches of the PCA to the midbrain that were previously discussed with the midbrain syndromes. Bilateral infarctions in the distribution of the hemispheric branches of the PCAs may cause bilateral homonymous hemianopia. With bilateral occipital or occipitoparietal infarctions, one can have cortical blindness, often with denial or unawareness of blindness (Anton’s syndrome). Another syndrome—Balint’s syndrome—may be seen with bilateral occipital or parieto-occipital infarctions. The characteristics of this syndrome include optic ataxia, psychic paralysis of fixation with inability to look to the peripheral field, and disturbance of visual attention.

Transient Global Amnesia Syndrome

Transient global amnesia (TGA) is an episode of total amnesia that lasts little more than 24 hours. Patients classically ask many questions repeatedly. During the episode, there are no visual, motor, sensory, or brain stem abnormalities. After the episode, the individual has no recall for the events during the period of TGA, but there are no other cognitive residuals. The mechanism of TGA is not known. Theories advanced suggest either medial temporal lobe seizure activity or a vascular phenomenon, such as PCA territory ischemia involving the medial temporal lobes bilaterally. There seems to be an association with strenuous exertion, sexual intercourse, and emotional stress.⁵⁹

Spinal Cord Stroke Syndromes

Anterior Spinal Artery Syndrome

The anterior spinal artery syndrome is characterized by an abrupt onset of flaccid paraplegia or tetraplegia below the level of the lesion due to bilateral corticospinal tract damage. There is thermoanesthesia and analgesia below the level of the lesion due to compromise of the spinothalamic tracts bilaterally. Position, vibration, and light touch are spared due to preservation of the dorsal columns, which are supplied by the posterior spinal arteries. Bowel and bladder function is impaired. There may be associated radicular or “girdle” pain.

These infarctions most commonly occur in the “watershed” areas or boundary zones where the distal branches of the major arterial systems of the cord anastomose, between the T1 and T4 segments and at the L1 segment. Common etiologies of arterial spinal cord infarction are detailed in Table 22-3.

Posterior Spinal Artery Syndrome

The posterior spinal artery syndrome is uncommon, probably due to the presence of numerous posterior radicular arteries and the reversal of flow that is possible at the conus medullaris if there is compromise of the artery of Adamkiewicz. The characteristics of this syndrome are loss of proprioception and vibration sense below the level of the lesion and loss of segmental reflexes. The common etiologies are listed in Table 22-3.

Spinal Cord Vascular Malformations

Spinal cord vascular malformations are a heterogeneous group of disorders of the spinal vasculature that may affect the spinal cord parenchyma directly or indirectly. They can be classified as AVMs, arteriovenous fistulas (AVFs), cavernous malformations, and complex vascular malformations.

AVMs are classified as extradural-intradural AVMs (juvenile AVM or metameric AVMs in old nomenclature) and intramedullary AVMs (classic AVM or glomus type in old nomenclature).⁶⁰ Both types of AVMs can affect the spinal cord through compression, vascular steal, and hemorrhage.

AVFs are classified as either extradural or intradural. The extradural AVFs consist of a direct connection between an extradural artery and vein. This leads to development of a high-flow fistula that causes epidural venous

engorgement, intradural venous hypertension, and shunting of arterial blood into the venous system, with resultant vascular steal from the spinal cord.⁶⁰ Intradural dorsal AVFs are the most common type of spinal AVF and are usually in the thoracic region. The primary pathophysiology of these malformations is through venous hypertension. Intradural ventral AVFs originate directly from the anterior spinal artery and have a direct fistula to an enlarged venous network with no intervening capillary system. This produces rapid blood flow through these fistulas, which can produce aneurysms and venous hypertension.^{60,61}

Cavernous malformations of the spinal cord consist of a mass of thin-walled, sinusoidal vessels, which have no recognizable intervening neural parenchyma. Most of these malformations are intramedullary. These lesions are associated with diapedesis and hemorrhage.

Two syndromes that involve complex vascular malformations bear special attention. Cobb syndrome (metameric angiomasia or cutaneomeningospinal angiomasia) is a rare noninherited disorder characterized by the combination of a vascular skin nevus and an associated AVM in the spinal canal at the same metamere (somite). Osler-Weber-Rendu syndrome, also known as hereditary hemorrhagic telangiectasia, is an autosomal dominant disorder identified typically by the triad of telangiectasia, recurrent epistaxis, and a positive family history for the disorder. Patients may have multiple mucocutaneous and visceral vascular malformations. The major cause of morbidity and mortality due to this disorder lies in the presence of visceral AVMs and the associated hemorrhage that may accompany them. Primary involvement of the spinal cord by vascular malformations occurs rarely.

Subarachnoid Hemorrhage Syndrome

Aneurysmal subarachnoid hemorrhage (SAH) syndrome accounts for 6% to 8% of all strokes, affecting approximately 28,000 individuals each year in the United States.

The most common cause of spontaneous SAH is a ruptured intracranial saccular aneurysm (Fig. 22-11). In addition, SAH may be due to many other causes that are outlined in Tables 22-3 and 22-4.

The clinical presentation of SAH is usually an abrupt onset of a severe headache, photophobia, nausea, vomiting, meningismus, and, often, unconsciousness and other neurological deficits (see Table 22-2). In some instances, a premonitory headache, representing a sentinel bleed, may occur days to weeks before the presenting hemorrhage. Misdiagnosis of SAH occurs in up to 25% of cases.⁶² A ruptured aneurysm should be suspected in patients complaining of “sudden onset of the worst headache of my life,” later onset of migraine headache with no family history of migraine, a change in the headache pattern in a known migraineur, severe localized and persistent headache, and severe “vascular” headaches that are refractory to conventional therapy.

Neurological signs are detailed in Table 22-2. Meningismus with nuchal rigidity and Kernig’s sign is present in two-thirds of patients. A dilated ophthalmologic examination may show papilledema or hemorrhages (see Table 22-2). Ptosis or diplopia due to oculomotor nerve palsy can be seen with internal carotid-posterior communicating artery aneurysms, distal basilar aneurysm, or uncal herniation. Other neurological findings depend on the location of the aneurysm.

Clinical deterioration after SAH may be due to multiple causes, including seizures, electrolyte disturbances such as hyponatremia, cerebral vasospasm, rebleeding, hydrocephalus, and development of medical complications such as pneumonia, hypotension, electrolyte abnormalities, and cardiac arrhythmias. Diagnosis and treatment of these disorders are detailed in Part 3 of this book.

Syndromes of Extracranial Hematomas

Subdural Hematoma

Subdural hematomas can be acute, subacute, or chronic. Acute subdural hematomas occur within 24 to 48 hours

Figure 22-11. A, Nonenhanced axial CT shows subarachnoid hemorrhage in the left sylvian fissure and adjacent intraparenchymal hemorrhage in the temporal lobe. B, Anterior posterior left common carotid arteriogram shows a lobulated left middle cerebral artery trifurcation aneurysm. (Courtesy of Karen S. Caldemeyer, MD.)

Figure 22-12. Nonenhanced axial CT shows a lens-shaped frontal density consistent with an acute epidural hematoma.

after an injury. They can be secondary to arterial or venous bleeding into the subdural space. The usual cause is a blow to the head by falling or being struck. The neurological symptoms depend on the area of the brain involved. There can be rapidly evolving focal signs that produce aphasia, memory disturbances, hemiparesis and hemisensory deficits, and altered consciousness. Signs of increased intracranial pressure may be present. Diagnosis is made by CT scan. Chronic subdural hematomas present at weeks to months after the injury. Patients presenting with this type of hematoma include the elderly with cerebral atrophy, patients with epilepsy, patients with alcohol dependence, and people with coagulation defects. These hematomas may become quite large without producing symptoms. The neurological findings may vary from no or minimal deficit to focal neurological symptoms that may be transient or progressive. In some, there may be florid symptoms of increased intracranial pressure with headaches, nausea, vomiting, and papilledema. There may be accompanying seizures. Diagnosis of a chronic subdural hematoma may require a CT scan without and with contrast due to the possibility of isodensity of the hematoma with the surrounding brain at some point in its evolution (see Chapter 23).

Epidural Hematoma

The most important type of epidural hematoma to be acquainted with is the acute epidural hematoma usually due to arterial bleeding from damage to the middle meningeal artery. Patients with this condition may have a history of trauma with a lucid interval followed by rapid development of focal neurological signs and deterioration in consciousness. The deterioration is due to high-pressure arterial bleeding with increased intracranial pressure. Like subdural hematomas, epidural hematomas can present

subacutely or chronically, with the same time frame and similar symptoms. A CT scan classically shows a lens-shaped density that does not follow sulcal margins (Fig. 22-12). Skull x-rays may show an associated skull fracture. Prompt diagnosis is important because a craniotomy with evacuation of the clot is often needed.

Intracranial Steal Syndromes

In some patients with AVMs that are large and are fed by both deep and superficial vessels, there has been some anecdotal clinical support for intracerebral steal. The theory is that the presence of low-resistance shunt vessels compromises blood and nutrient flow to adjacent areas of the brain supplied by the same blood vessels, causing transient or permanent damage to neurons.⁶³ The clinical reports, although limited in number, report that these patients with AVMs have a variety of focal neurological deficits, cognitive deficits, visual deficits, and seizures that recover after the AVM is excised. In most patients, the neurological deficits are confined to the area of the brain supplied by the AVM. However, there have been reports of electroencephalogram abnormalities in the hemisphere contralateral to the AVM and lower cerebral blood flow in the contralateral hemisphere that may support relative areas of ischemia.⁶⁴ More documentation of this syndrome in large numbers of patients is needed.

Vascular Dissection Syndromes

Dissections of arteries develop when there is blood extravasated within the medial or subintimal layers of the arterial wall with resultant compromise of the arterial lumen and development of a pseudoaneurysm. Vascular dissections can be associated with blunt trauma, penetrating

trauma, or even trivial trauma. There are a number of associated conditions, including fibromuscular dysplasia, Marfan's syndrome, Ehlers-Danlos type IV syndrome, atherosclerosis, pronounced vessel tortuosity, moyamoya, cystic medial degeneration, pharyngeal infections, α_1 -antitrypsin deficiency, and luetic arteritis. However, dissections may occur spontaneously. Cervicocephalic arterial dissections may present with ischemic stroke due to arterial occlusion or secondary embolization. The vessel that is most commonly involved is the extracranial carotid artery between C2 and the base of the skull. The vertebrobasilar system, intracranial carotid, and middle cerebral arteries are less frequently involved.⁶⁵ Patients may present with symptoms of transient retinal ischemia, hemispheric or posterior fossa ischemia, cerebral infarction, or subarachnoid hemorrhage. Pain along the forehead, eye, face, or neck may be present with carotid dissections. Vertebral dissections can cause pain in the occiput and neck. Other associated symptoms may include Horner's syndrome, audible bruits, and pulsatile tinnitus. Other cranial nerves that may be involved include CN II, III, V, and VII through XII.⁶⁶ Diagnosis requires a high level of clinical suspicion that is confirmed with typical arteriographic signs (see Chapters 45 and 50).

Carotid-Cavernous Fistula

A carotid-cavernous fistula is an abnormal communication between the carotid artery and the veins of the cavernous sinus, creating a high-pressure, high-flow system. There is often a history of trauma. Patients may present with an audible bruit and progressive pulsatile proptosis with chemosis, restricted eye movement, and progressive visual loss in late stages (see Table 22-2). The diagnosis is made by cerebral angiography, but a CT scan with contrast, MRI, or MRA may show the lesion (see Table 22-3 and Chapter 23).

Cerebral Venous Thrombosis

Intracranial venous occlusive disease is significantly less common than arterial disease. The symptoms can be nonspecific. The symptoms that are present depend on the venous structure that is affected, the extent and rapidity of thrombosis, and the extent of venous collaterals. Common symptoms include headache, nausea, vomiting, altered consciousness, and seizures. Examination may show papilledema, meningismus, and subtle focal neurological deficits (see Table 22-2). Possible findings on CT and MRI are presented in Table 22-3. Diagnosis may be made with magnetic resonance venography or conventional or digital intravenous angiography (Fig. 22-13).

Syndromes of Intracerebral Hemorrhage

There are general features of the clinical syndrome of intracerebral hemorrhage that may help to characterize it. Historical features include a presentation that is maximum at the onset in one-third of patients and gradual with smooth progression over 30 minutes in two-thirds of patients. Interestingly, most hemorrhages occur during activity rather than during sleep.^{67,68}

A headache is present in approximately half of patients. Nausea and vomiting are present in more than 50% of patients. The level of consciousness may be variable. Seizures rarely occur at the onset. There is usually no history of any prodromal attacks. There is often a history of arterial hypertension. On examination, meningeal irritation can be seen if the bleeding extends to the subarachnoid space. Retinal hemorrhages may be present on funduscopic examination (see Table 22-2). There are a number of potential etiologies of intracerebral hemorrhage (see Table 22-3).

The various forms of intracerebral hemorrhage have distinctive clinical presentations that are dependent on the location, size, direction of spread, and the rate of development of the bleeding⁶⁴ (see Table 22-2). The results of testing are detailed in Table 22-3.

Putaminal Hemorrhage

A putaminal hemorrhage is the most common form of intracranial hemorrhage because the putamen is the most common site involved with hypertensive intracranial hemorrhage. Hemorrhages in this location may be confined to the putamen, or they may enlarge to involve the internal capsule, corona radiata, centrum semiovale, temporal lobe, or intraventricular system. The classic presentation with putaminal hemorrhages that are large involves rapidly progressing contralateral hemiparesis or hemiplegia with less severe contralateral hemisensory loss.⁶⁹ Rarely, with a small hematoma, there can be a pure motor hemiparesis.⁷⁰ There is a conjugate horizontal gaze palsy, with the eyes conjugately deviated toward the side of the hematoma. Homonymous hemianopia is present. A dominant hemisphere putaminal hemorrhage produces associated global aphasia, whereas a nondominant lesion results in hemi-inattention with apraxia, left visual neglect, and constructional apraxia.⁷¹ Occasionally, patients with a nondominant putaminal hemorrhage have allesthesia, in which a noxious stimulus on the side of the hemisensory disturbance is perceived on the opposite normal side in the corresponding area.⁷² Pupillary size is normal unless there is associated uncal herniation.

Lobar Hemorrhage

This type of hemorrhage refers to bleeding occurring within the subcortical white matter. Underlying structural lesions are more common than arterial hypertension as a cause. The clinical presentation can resemble that of an embolic cerebral infarction. There are characteristic findings with hemorrhages in different locations.⁷³ With frontal lobe hemorrhages, characteristic findings are abulia, contralateral hemiparesis, and a conjugate gaze palsy toward the side of the hemorrhage. Parietal lobe hemorrhages may cause contralateral hemisensory loss, neglect of the contralateral visual field, mild hemiparesis, and, occasionally, a hemianopia or anosognosia. A temporal lobe hemorrhage may present with variable degrees of visual field deficit or, occasionally, agitated delirium. With dominant temporal lobe hemorrhages, there can be a Wernicke aphasia. If there is an extension into the dominant parietal lobe, there can be conduction or global aphasia. A hemorrhage in the occipital lobe may cause a contralateral homonymous hemianopia and ipsilateral orbital pain.^{73,74}

Figure 22-13. A 35-year-old woman who was 2 weeks postpartum presented with 24 to 48 hours of nausea, visual hallucinations, headache, and a seizure. **A**, Coronal T1-weighted image shows the absence of a flow void in the superior sagittal sinus (*white arrow*) and decreases signal in the left parietal region with associated shift of the midline structures. Findings were consistent with a superior sagittal sinus thrombosis and an acute left parietal cerebral infarction. **B**, Digital subtraction angiography in the venous phase, with frontal and lateral views, shows lack of filling of the superior sagittal sinus consistent with superior sagittal sinus occlusion (*black arrow*).

Thalamic Hemorrhage

The usual cause of thalamic hemorrhages is hypertension. However, an underlying structural lesion, such as a vascular malformation or tumor, is another consideration. Thalamic hemorrhages may be confined to the thalamus or may extend laterally to involve the internal capsule, inferomedially to compress the subthalamus and midbrain, or medially to involve the third ventricle. Classic signs of a thalamic hemorrhage include a hemisensory deficit with a lesser degree of hemiparesis. Ocular findings may include convergence-retraction nystagmus, impairment of vertical gaze, pupillary light-near dissociation, downward-inward deviation of the eyes (depression-convergence syndrome), unilateral or bilateral pseudo-sixth nerve paresis, skew deviation and conjugate gaze palsy to the side of the lesion (“wrong-way eyes”), and a conjugate horizontal gaze palsy.

If the hemorrhage is located in the posterior thalamus, there can be distinctive features.⁷⁵

Pontine Hemorrhage

The signs and symptoms of pontine hematomas depend on size, location, and the presence or absence of ventricular involvement or hydrocephalus. Primary pontine hematomas are usually symmetrically placed at the junction of the basis pontis and tegmentum. Large pontine hematomas cause coma, decerebrate rigidity, quadriplegia, centrally positioned eyes with absent oculocephalic and oculo-vestibular reflexes, and pinpoint reactive pupils. Ocular bobbing, characterized by rapid conjugate downward movements of the eyes followed by a slow upward drive to primary position, may be present. Hyperthermia and respiratory

abnormalities may be present. Partial damage to the lateral basis pontis may cause pure motor hemiparesis. Lateral pontine tegmentum hemorrhage may cause ipsilateral conjugate gaze paresis, ipsilateral internuclear ophthalmoplegia, the “one-and-a-half” syndrome, and ocular bobbing (see Chapter 9). Lateral tegmental hemorrhages may cause ipsilateral hemiataxia with contralateral hemiparesis and hemisensory deficits.

Cerebellar Hemorrhage

The signs present with cerebellar hematomas depend on their location and size and whether there is associated brain stem compression or hydrocephalus. The most common location for a cerebellar hemorrhage is in the region of the dentate nucleus. The vermis is less frequently involved. The most frequently observed findings are truncal or limb ataxia, ipsilateral gaze palsy, and small reactive pupils. Other ocular findings may include skew deviation, gaze-paretic nystagmus, or ocular bobbing. Other cranial nerve findings may include ipsilateral peripheral facial weakness and ipsilateral absence of the corneal reflex. Dysarthria is often present.

Caudate Hemorrhage

Caudate hemorrhages can cause headache, nausea, vomiting, meningismus, confusion, and decreased short-term memory.⁷⁶ Findings that are variably present include a transient contralateral conjugate gaze paresis, contralateral hemiparesis, transient hemisensory deficits, and, rarely, ipsilateral Horner’s syndrome.

Vascular Dementia Syndrome

Vascular dementia is the second most common cause of dementia in the United States and Western Europe, and it is the most frequent cause of dementia in Japan, Russia, and other Eastern countries. It is defined as a global decline in intellectual functioning, without a change in the level of consciousness, that is produced by cerebrovascular disease. A number of conditions are classified under the category of vascular dementia (Table 22-5). The pathological substrates that can produce vascular dementia are extensive. Any lesion in the brain rostral to the upper brain stem can potentially affect cognition. Cerebrovascular disease

TABLE 22-5

Vascular Dementias

TABLE 22-6

DSM-IV Diagnostic Criteria for Vascular Dementia

- A. The development of multiple cognitive deficits manifested by both
 1. memory impairment (impaired ability to learn new information or to recall previously learned information)
 2. one (or more) of the following cognitive disturbances:
 - a. aphasia
 - b. apraxia
 - c. agnosia
 - d. disturbance in executive functioning
- B. The cognitive deficits in criteria A1 and A2 each cause significant impairment in social or occupational functioning and represent a significant decline from a previous level of functioning
- C. Focal neurological signs and symptoms
- D. The deficits do not occur exclusively during the course of a delirium

can affect cognition by destroying the neural components (cortical areas) of the networks or their connections (white matter and subcortical relay centers).⁷⁷ The size and location of the region affected by cerebrovascular disease are important in delineating the clinical manifestations. The diagnostic criteria for vascular dementia are listed in Table 22-6.⁷⁸

GENERAL MANAGEMENT GOALS

Rapid diagnosis of stroke and initiation of treatment are important to maximize recovery and to prevent recurrence of stroke (see Chapter 45). If patients present to the emergency department within less than 180 minutes of the onset of stroke symptoms, they may be candidates for intravenous tissue plasminogen activator treatment if criteria are met. For acute ischemic stroke, the dose is 0.9 mg/kg intravenously (not to exceed 90 mg, with 10% of the dose administered as an initial bolus over 1 minute). Patients with an acute stroke should be admitted to the hospital for emergency evaluation and treatment, preferably in a stroke unit or intensive care unit where close medical and nursing observation is available. A multidisciplinary approach with referral to specialists with expertise in stroke is beneficial. Care should focus not only on the treatment of the stroke but also on the prevention of complications.

Patients should be thoroughly investigated in an attempt to determine the likely etiology of the stroke. Appropriate therapy should be instituted to reduce the likelihood of a recurrent stroke. Choices for therapy that are available include fibrinolytic agents; antiplatelet therapies such as aspirin, clopidogrel, ticlopidine, or aspirin in combination with modified-release dipyridamole; anticoagulation with heparin acutely followed by warfarin (usually reserved for a cardiac etiology of stroke); and carotid endarterectomy (in appropriate situations). The choice of treatment needs to be made on a case-by-case basis and is influenced by a number of variables. The most important factors are the time interval from stroke, the severity of the neurological impairments, the results of the baseline brain imaging studies, and the cause of the stroke.⁷⁹

In the patient with an intracranial hemorrhage, hemostatic defects should be sought and corrected, if present. Offending drugs such as warfarin and heparin and thrombolytic therapy should be stopped and, in appropriate

situations reversed immediately. Neurosurgical consultation and intervention may be indicated in patients with large cerebellar infarctions; in patients with large, nondominant hemispheric ischemic infarctions with deterioration and herniation; and in selected patients with accessible, large lobar hemorrhages, when there is a progressive course. Patients with cerebellar hemorrhages should have an immediate neurosurgical consultation. Further guidelines for specific therapy are detailed in Chapter 45.

Frequent neurological checks are vital to early recognition of neurological changes associated with herniation, recurrent or progressive stroke, recurrent hemorrhage or vasospasm in the patient with subarachnoid hemorrhage, and seizures. Cerebral edema with resultant herniation is the leading cause of death in the first week after an ischemic or hemorrhagic stroke.⁸⁰ Cerebral edema caused by ischemia overlaps both cytotoxic and vasogenic forms.

In patients with stroke, the blood pressure should be monitored frequently or even continuously for the first 48 to 72 hours. It is not unusual for the blood pressure to be transiently elevated after a stroke. Within a few days, the blood pressure may return to prestroke levels. Whether transient elevations should be treated is controversial.^{81,82} It is important not to overtreat the blood pressure and cause hypotension. The most important objective is to maintain adequate cerebral blood flow in the presence of impaired autoregulation.

Cardiac monitoring is recommended for the first 24 to 48 hours after stroke due to the high frequency of cardiac dysfunction associated with stroke. In approximately 3% of cases, concomitant cerebral and myocardial ischemia can occur. A variety of cardiac arrhythmias can occur after ischemic or hemorrhagic stroke and SAH, including tall P waves, longer or shorter PR and QT intervals, ST segment elevation or depression, peaked or inverted T waves, U waves, sinus bradycardia, wandering atrial pacemaker, paroxysmal atrial pacemaker, nodal bradycardia, atrioventricular block, premature atrial or ventricular contractions, atrial fibrillation and flutter, and atrioventricular dissociation. These abnormalities have generally been attributed to increased circulating levels of catecholamines. If ischemic electrocardiographic changes occur, serial creatine kinase and lactate dehydrogenase isoenzymes are indicated. Ventricular wall motion abnormalities have been demonstrated by echocardiography in patients with aneurysmal SAH. Patients with SAH often have microscopic changes consistent with subendocardial necrosis at postmortem.

Prevention of pulmonary complications is necessary in the bedridden patient or in the patient with impaired oropharyngeal function. Management of the airway and maintenance of adequate oxygenation and ventilation should be accomplished immediately. Ventilatory assistance is indicated if there are signs of respiratory depression, a Glasgow Coma Scale less than or equal to 8, or raised intracranial pressure and herniation. Pneumonia is the most common cause of non-neurological death in the first 2 to 4 weeks after a stroke.⁸³ The mortality rate from pneumonia is as high as 15% to 25%. It is important to place a temporary enteral feeding tube if there is evidence of oropharyngeal dysfunction to avoid aspiration. Good pulmonary toilet is needed, including chest physical therapy, frequent turning, and volumetrics.

Lower extremity deep venous thrombosis (DVT) in the hemiparetic limb is a common occurrence if DVT prophylaxis is not initiated. If there are no contraindications, low-dose subcutaneous unfractionated heparin or low-molecular-weight heparin should be instituted. Aspirin may also be effective in patients with contraindications to anticoagulation. Support stockings are of unproven value. If heparin is contraindicated, as in the patient with intracranial hemorrhage, intermittent pneumatic compression stockings are recommended.

The patient's nutritional status and fluid requirements should be assessed. Patients with a large ischemic stroke may need fluid restriction during the first few days. In patients with intracranial hemorrhage, one should try to maintain euvolemia. In patients with SAH, strict fluid restrictions should be avoided due to the possible risk of increasing cerebral ischemia in patients developing vasospasm. The patient's swallowing function should be assessed before intake of fluid or food is initiated. Patients who have significant oropharyngeal dysfunction will require parenteral or tube feeding.

Indwelling catheters should be placed only if absolutely necessary and should be removed at the earliest possible time to avoid urosepsis. The chronic use of an indwelling catheter should be limited to patients with incontinence or urinary retention that is refractory to other treatments.

The development of pressure sores occurs in approximately 15% of patients after a stroke.⁸⁴ Steps to avoid this complication include frequent inspection of the skin, routine skin cleansing, frequent turning, use of special mattresses and protective dressings, maintaining adequate nutritional status, and trying to improve the patient's mobility as soon as possible after stroke.

One of the most common causes of injury to the patient with a stroke is falling. Assessments of the risk for falling should be made at regular intervals during the acute hospitalization. Measures should be instituted to minimize the risk of falls. Rehabilitation plays an important role in recovery in patients who are good candidates for intensive therapies.

Mortality is highest within the first 30 days after stroke and remains elevated to different degrees depending on the presenting stroke syndrome, stroke subtype, and other comorbidities.⁸⁵ The risk for recurrent stroke is greatest within the first 30 days. Only approximately half of those surviving a stroke are independent 6 months after a stroke, and the quality of life is decreased.⁸⁵

Imaging of the nervous system encompasses a wide variety of modalities that have undergone rapid evolution in the past few decades. Although still employed, plain film analysis of the skull and spine is not routine in the initial investigation of patients with neurological signs and symptoms. Computed tomography (CT), developed in the 1970s, remains a common radiographic technique, particularly for the acutely traumatized patient. Magnetic resonance imaging (MRI), which came into widespread clinical usage in the 1980s, has supplanted CT for evaluation of many suspected pathological processes of the brain and spine. Depending on availability, MRI is often the initial study ordered, particularly in an outpatient setting. MRI continues to be a rapidly evolving field, encompassing techniques such as magnetic resonance angiography (MRA) and spectroscopy. Myelography, intro-

duced in the early 1900s, has been replaced to varying degrees by MRI owing to the noninvasive nature of the latter. Myelography is still regarded as useful in visualizing the intradural nerve roots and is performed in selected cases, particularly when MRI is contraindicated. Throughout the century, myelography has evolved into a much safer examination owing to development of contrast agents with dramatically reduced neurotoxicity. Angiography, introduced in 1927, remains the gold standard for evaluation of neurovascular disease. Interventional neuroradiology, also known as endovascular surgical neuroradiology, a field that has evolved in the past two decades, offers patients therapy through catheter-based angiographic techniques. Ultrasonography is most useful for evaluating the neonatal brain and spine and extracranial vascular disease. Transcranial Doppler studies are useful in selected patients for assessing intracranial vascular disease. Ultrasonography has also been used in the operative setting. Positron emission tomography and single-photon emission computed tomography are nuclear medicine techniques that offer physiological information (Table 23-1).

AVM, arteriovenous malformation

The PA view demonstrates the frontal and ethmoidal sinuses, frontal bones, nasal cavity, superior orbital rims, and mandible. The following are demonstrated on the lateral view: the frontal, parietal, temporal, and occipital bones; the sella turcica; the orbital roofs; the mastoid region; and the lateral aspect of the facial bones. The Towne view shows the zygomatic arches, the foramen magnum, the occipital bone, and the mastoid region. The base view demonstrates the basal structures of the skull. To evaluate the facial bones and sinuses, the occipitomeatal (Waters) view is often used. However, CT imaging has largely supplanted the use of plain films, particularly in the evaluation of the “specialty regions” (i.e., the paranasal sinuses, orbits, temporal bones, and sella).

Conventional radiographic examination of the spine plays a critical role in the initial evaluation of the trauma patient. Because the cervical cord is prone to damage from unnecessary manipulation, the initial radiographic examination is usually limited to two or three projections that provide the optimal amount of clinically pertinent information. Plain film examination of the spine is also an invaluable tool in the screening of patients for degenerative, inflammatory, and neoplastic conditions and serves as an excellent imaging modality by alerting the physician to the presence and degree of abnormalities. Of all the spine

examinations involving radiation, plain film radiography gives the lowest dose, averaging 0.2 rad to the ovaries for a four-view lumbar examination. The testicular dose is 10% to 50% of the ovarian dose.

Normal Findings

The skull varies considerably in shape and consists of a superior portion, the vault, and an inferior portion, the base. Along the base lie the orbits, sella turcica, and the temporal bones. The skull bones are composed of outer and inner tables of compact bone separated by the diploic space containing bone marrow. The inner table contains grooves for vascular structures such as the middle meningeal artery branches, and care should be taken not to confuse these for linear fractures. Pacchionian depressions house arachnoid granulations that are related to venous lacunae communicating with the superior sagittal sinus. From the midline they commonly extend 2.5 to 3.0 cm, and any inner table depression beyond that distance should be considered suspicious, possibly an inner table erosion secondary to a neoplasm.¹ Beyond age 3, the cranial sutures appear similar to those of adults, and portions undergo actual closure at variable ages. Normal intracranial calcifications involve the dura, pineal gland, habenular commissure, choroid plexus, arachnoid

granulations, and basal ganglia. The latter can be seen in hypothyroidism and pseudohypothyroidism but are most often physiological.

For the spine, the lateral view is the single most useful projection because it can demonstrate most post-traumatic lesions of the cervical spine.² The lateral projection clearly demonstrates the vertebral bodies, apophyseal joints, anterior arch of the atlas, atlanto-odontoid distance, odontoid process, spinous processes, and disc spaces. A mandatory requirement is the demonstration of the C7 vertebral body. The four smooth contour lines of the normal cervical spine are apparent on the lateral view and should be evaluated to exclude interruption or angulation. The lines include the anterior and posterior vertebral lines, the spinolaminar line (defines the posterior margin of the spinal canal), and the posterior spinous line. Evaluation of the prevertebral soft tissues can also be performed because the retropharyngeal and retrotracheal spaces are adequately demonstrated and may be pathologically widened in traumatic or nontraumatic conditions.

The anterior projection demonstrates the C3–C7 vertebral bodies, intervertebral disc spaces, lateral masses, uncinat processes, uncovertebral (Luschka) joints, and the spinous processes that, superimposed upon the bodies, resemble teardrops. To provide adequate visualization of C1 and C2, a variant of the AP projection is often obtained, termed the *open-mouth* or *odontoid view*. The atlanto-occipital and atlantoaxial joints, odontoid process, and lateral masses of C1 and C2 are effectively demonstrated.

The oblique view of the cervical spine demonstrates the neural foramina and facet alignment. Neural canal stenosis typically occurs secondary to degenerative spur formation arising from the uncinat processes anteriorly or from the respective facet joints posteriorly. Pathological foraminal widening can be associated with neurofibromas as seen in cases of neurofibromatosis. Rarely, vascular masses of the spine, particularly those associated with the vertebral artery, can be expansile and mimic benign neural tumors. In cases of spine trauma, the oblique view can be helpful in delineating fracture dislocations of the articular processes, particularly in cases of perched or jumped facet injuries. The oblique view of the lumbar spine is the single most useful view in evaluating for suspected spondylolytic defects through the pars interarticularis.

Types of Detectable Abnormalities

With the advent and marked success of both CT and MRI, the clinical utility of skull and spine radiography has declined. However, it remains useful in the detection and diagnosis of fractures, abnormal calcifications, developmental anomalies, and osteolytic or osteoblastic disorders. Degenerative spinal conditions and osteophytic changes are still commonly evaluated with spine films.

Neurological Applications in Diagnosis and Treatment Generalized Diseases

METABOLIC AND SYSTEMIC DISEASES. Renal osteodystrophy, hyperparathyroidism, and acromegaly represent some of the metabolic and endocrine disturbances to which

the skull responds. However, the importance of radiographic findings has decreased with the routine laboratory determination of certain diseases. The skull characteristically demonstrates mottling of the vault, manifesting a “salt and pepper” appearance. Occasionally, cystlike lesions, or brown tumors, may occur. The findings in renal osteodystrophy are identical to those of primary hyperparathyroidism. Findings in acromegaly include thickening of the calvarium and expansion of the supraorbital ridge and frontal sinus, but the clinical manifestations and hormonal assay are more sensitive and objective determinations of disease severity.

Cranial Diseases

NEOPLASMS AND DESTRUCTIVE LESIONS. Skull radiography remains valuable in the evaluation of destructive lesions and metabolic abnormalities. By far the most common neoplastic involvement of the skull is secondary to metastasis or invasion from adjacent neoplasm. Metastatic carcinoma, multiple myeloma, and lymphoma usually present as lucent or lytic lesions and represent the most common malignancies affecting the calvarium. Breast carcinoma commonly manifests as large and variable-sized lucencies. In males, prostate carcinoma is the most common cause of osteoblastic metastasis. There is little to differentiate osteomyelitis from neoplasm radiographically, but, fortunately, osteomyelitis of the calvarium is rare in North America and many other areas of the world.

STRUCTURAL AND DEVELOPMENTAL ABNORMALITIES. Several acquired abnormalities can be demonstrated by plain films. Fibrous dysplasia classically features sclerosis, lucency, and thinning and bulging of the inner table. This entity can be confused with Paget’s disease but is encountered in a younger age group and often ceases to grow at approximately the third decade of life. The classic calvarial presentation of eosinophilic granuloma is that of a sharply circumscribed lucency involving the diploë and inner and outer tables, similar in appearance to that of a destructive lesion. Indeed, the differential considerations are metastatic neoplasm, infection, and recent surgical repair. Hemangiomas of the calvarium usually have an unmistakable “Aunt Minnie” appearance on plain film. These lesions are typically discrete, predominantly lucent areas with a reticular or “spoke wheel” trabecular bony configuration. Furthermore, a prominent diploic vascular channel is frequently identified entering the lesion; this may represent an enlarged draining venous channel. The initial or lytic phase of Paget’s disease results in areas of sharply demarcated lucency termed *osteoporosis circumscripta*. Subsequent stages demonstrate enlarged, coarsened trabeculae; thickening of the cortex; and nonhomogeneous patchy densities referred to as a “cotton wool” appearance. Paget’s disease can be confused with other entities, but the patient’s age, blood chemistry, and involvement of other bones aid in the formulation of an appropriate differential diagnosis.

Developmental alterations can also be demonstrated on radiographic examination of the skull. Sutural abnormalities such as premature closure (craniosynostosis) or widening (from increased intracranial pressure seen in aqueductal atresia and Dandy-Walker syndrome) can be identified. Decreased size of one-half of the cranium along

with the compensatory, ipsilateral skull thickening are key findings in the Dyke-Davidoff syndrome of cerebral hemiatrophy secondary to intrauterine and perinatal internal carotid artery infarction (Video 243, Hemiatrophy). Childhood anemias and sickle cell disease classically demonstrate generalized skull thickness or density. Decreased thickness and density can be seen in osteogenesis imperfecta. Defects in bone can occur with cranial myelomeningoceles, dermal sinuses, and epidermoids.

TRAUMA. Skull radiography is generally not indicated for cranial trauma because many patients with a skull fracture have no neurological sequelae and many with severe intracranial abnormalities have no associated skull fractures. Patients with significant cranial injury or post-traumatic neurological symptoms should be evaluated by CT. There are two situations in which the skull fracture poses a clinical threat. The depressed fracture and fracture associated with a penetrating injury are of great concern. However, the symptoms associated with such injuries will invariably direct the clinician to use CT for evaluation. Plain films are valuable in demonstrating facial fractures, which often occur in recognizable patterns. Cortical disruption and displacement of osseous fragments represent direct signs of fracture. Indirect signs include paranasal sinus opacification or air-fluid levels, orbital emphysema, and soft tissue prominence. One side of the facial skeleton should always be compared with the other, and asymmetrical radiodensities should be regarded as suspicious findings.

Spinal Diseases

SPINAL FRACTURES AND POST-TRAUMATIC SPINAL DESTABILIZATION. Most unstable of all cervical spine injuries, the flexion teardrop fracture can be identified on the lateral view.³ This fracture, characterized by anterior avulsion of a teardrop-shaped fragment by disruption of the anterior longitudinal ligament as well as fracture of the posterior elements and posterior displacement of the involved vertebrae, should be distinguished from the stable extension teardrop fracture. Although also demonstrating an anteriorly displaced fragment, this injury shows no subluxation, and the spinolaminar and posterior vertebral lines are preserved. The lateral view can also effectively demonstrate unilateral or bilateral locked facets (unstable), dens fractures (type 2 unstable), the stable clay-shoveler (fracture of the C6/C7 spinous process), and simple wedge fractures.

Symmetrical and bilateral fractures involving the anterior and posterior arches of C1 characterize the unstable Jefferson fracture, best demonstrated on the open-mouth odontoid view. Odontoid fractures, with emphasis being placed on transverse fracture through the base (type 2, unstable), can often be diagnosed on this view even though detail of an injury is often lacking. The AP view affords identification of fractures involving the bodies of C3–C7 as well as abnormalities of the intervertebral disc spaces and uncovertebral joints.

Familiarization with the radiological findings that indicate instability is imperative in evaluation of the trauma patient.⁴ These findings include displacement of the vertebrae, disruption of the posterior vertebral body line, and widening of the apophyseal joints. Widening and elongation

of the vertebral canal with evidence of increased interpedicular distance also indicates instability. The single presence of any of these findings represents enough radiological proof to assume instability. The same principles for determining the stability of a cervical spine injury apply to those of the thoracolumbar spine.

The AP and lateral views comprise the standard radiographic projections for evaluating traumatic thoracic spine injuries. For lumbar spine evaluation, AP, lateral (including a view of L5–S1), and oblique views are traditionally obtained. By using the same general principles mentioned previously, burst fractures, fracture/dislocations, and distraction fractures can be identified. The Chance, or “seat belt” fracture, is an injury at the thoracolumbar junction that can be stable or unstable, depending on the extent and severity. Fracture/dislocations are notoriously unstable.

DEGENERATIVE AND INFLAMMATORY BONE DISEASE. Osteoarthritis, degenerative disc disease, spondylosis deformans, and diffuse idiopathic skeletal hyperostosis represent degenerative conditions that involve the spine and will frequently coexist in the same patient. The anatomical site of degenerative change determines the type of degenerative disease.⁵

Degenerative changes involving the synovial joints (atlantoaxial, costovertebral, apophyseal, and sacroiliac) produce osteoarthritis of these structures. The defining radiological features are identical to other synovial joints and include joint space narrowing, subchondral sclerosis and cyst formation, and osteophyte formation. The mid- and lower cervical and lumbar spine frequently demonstrate apophyseal joint degenerative changes. Involvement of the apophyseal joints often discloses gas within the joint, termed the *vacuum phenomenon*. This is virtually pathognomonic for an advanced degenerative process. Oblique views can be valuable in demonstrating posterior osteophytes, which may encroach on the neural canal sac. Frequently, however, CT is required to demonstrate such findings.

Degenerative disc disease is secondary to degenerative changes within the intervertebral disc and may also manifest the vacuum phenomenon in long-standing degenerated discs.⁶ Disc space narrowing and marginal osteophytosis of the adjacent vertebral bodies are also prominent features of this entity. Degenerative spondylolisthesis can be seen in patients with degenerative disc disease and apophyseal joint arthritis (Fig. 23-1; Video 237, Foot Drop).

Abnormalities of the annulus fibrosus can promote anterior and anterolateral disc herniation leading to the formation of anterior and lateral osteophytes, a process termed *spondylosis deformans*. Indeed, the primary radiological feature of this entity is extensive osteophytosis, and, unlike degenerative disc disease, the disc spaces are relatively well preserved.

Diffuse idiopathic skeletal hyperostosis demonstrates extensive osteophytosis without significant sclerosis or intervertebral disc space narrowing. Flowing ossification is characteristically seen along the anterior aspect of the vertebral bodies, stretching across the disc space. The findings are secondary to ossification involving the ligaments, entheses, and fibrous articulations. The radiological characteristics are best demonstrated on the lateral view.

The offending bacterial organism of the infectious spondylitis can be varied, with staphylococci, streptococci,

Figure 23-1. Cervical spondylosis. **A**, Lateral x-ray of cervical spine demonstrates chronic degenerative disc disease from C3-C4 through C6-C7 with varying degrees of disc space narrowing and associated endplate spur formation at each level. **B**, Right anterior oblique x-ray of cervical spine demonstrates multilevel neural canal stenosis from C3-C4 through C6-C7 secondary to chronic degenerative spur formation arising from the uncinate processes.

Escherichia coli, *Proteus*, and *Pseudomonas* being the most common. Bacterial spread is usually by the hematogenous route, being common in immunocompromised individuals and intravenous drug abusers, but it may also be iatrogenic, occurring after spinal surgery, lumbar puncture, or complicating diagnostic discography. The most common location is the lumbar region, and the lesion is detected on plain radiographs by loss of disc space stature along with rarefaction of the adjacent endplates. If untreated, significant vertebral body involvement may lead to collapse of the vertebral body, resulting in wedge deformities, focal kyphosis, and/or scoliosis. The inflammatory process may extend beyond the confines of the vertebral body into the paraspinal soft tissues or posteriorly into the epidural space of the central canal with abscess formation and thecal sac compression. CT and MRI allow excellent visualization of the extent of these inflammatory processes, which cannot be adequately assessed with plain film radiography.

The most common location for spinal tuberculosis is the lower thoracic and upper lumbar regions. The granulomatous process usually begins in the anterior third of the vertebral bodies and spreads along the spinal axis beneath the paraspinal ligaments. The intervertebral disc space in tuberculous spondylitis remains relatively intact for a longer period of time than in pyogenic infections. In untreated chronic cases of spinal tuberculosis, paraspinal, paravertebral, and psoas abscesses frequently occur. The psoas abscess may calcify.

NEOPLASMS. By far the most common extradural malignancy of the spine is the metastatic lesion. Although

breast and prostate cancer are known for their osteoblastic or sclerotic lesions, most metastases are osteolytic. Spine metastases can involve all vertebral levels but most commonly affect the lower thoracic and lumbar spine.

The most common plain film finding is pedicle destruction, even though in adults the initial site of involvement is typically the vertebral body. Pathological compression fractures, multiple lytic vertebral body lesions, and paraspinal soft tissue masses are other common expressions of metastatic neoplasms. A discriminating eye can sometimes detect an indistinct posterior vertebral body margin, a clue to epidural metastatic disease. However, MRI is a highly sensitive imaging study that can portray epidural and paraspinal soft tissue involvement as well as cord compression. Breast, lung, and prostate cancer are commonly associated with epidural spinal cord compression. Other common adult metastatic primary lesions include renal cell carcinoma, melanoma, lymphoma, multiple myeloma, and sarcoma.

COMPUTED TOMOGRAPHY

Basic Principles and Techniques

The advent of computed tomography was one of the most exciting developments in the history of neuroimaging. For the first time, direct visualization of the brain became possible. Although MRI has surpassed CT in displaying neuroanatomy and pathology, CT remains a mainstay for several

reasons. Wider availability and lower costs of CT are considerations in today's managed care environment. CT is easier to perform in the setting of acute trauma and in the ventilated patient. Owing to the speed with which CT images can be obtained, high-quality studies are more feasible in the patient unable to cooperate for examination. Patients with implanted devices, such as cardiac pacemakers, spinal stimulators, aneurysm clips, and other surgical implants, as well as patients harboring ferromagnetic foreign bodies, are not MRI candidates.⁷ Disadvantages of CT include the potential need for iodinated contrast material to visualize vessels and many intracranial pathological processes, artifacts related to beam hardening (which particularly limits evaluation of posterior fossa structures) or the presence of metallic foreign bodies, and difficulty in obtaining imaging planes other than the axial. The latter particularly limits evaluation of the spine.

CT is a technique in which a tightly collimated x-ray beam is directed through the patient. The patient is placed in the CT gantry, and the x-ray beam travels in a circular path around the patient. Detectors 180 degrees opposite the beam measure x-ray attenuation, or removal of the photons from the beam. The x-ray beam is collimated in a range from 1 to 10 mm, depending on the size of the structure being examined. The patient is moved by the same increment as the slice thickness for contiguous images of the area of interest. The signal from the radiation detector must be digitized by means of an analogue-to-digital converter so that the image can be constructed using a computer algorithm. Images are reconstructed by convention; air is seen as black and bone as white. Air is the tissue with the least attenuation of x-rays and on the Hounsfield scale (named after Godfrey N. Hounsfield, the inventor of CT) is arbitrarily designated as -1000. Bone, the greatest attenuator, is designated as +1000, with water as 0. Table 23-2 lists the approximate Hounsfield units for anatomical tissues encountered on head CT, in order from dark to bright. Resolution of small structures is a function of pixel size, determined by field of view (typically 23 cm for a routine head) and matrix size (typically 512).⁸

A recent technological advance is the development of helical CT, which requires a new system or updated hardware and software to perform. Helical CT differs from conventional CT in that the patient is moved continuously through the x-ray beam, dramatically shortening scanning times. There is some loss of resolution with this technique

as scanning times decrease, such that in routine brain imaging, helical scanning is not employed. Helical scanning is useful when a rapid collection of data is necessary, such as in the traumatized or uncooperative patient. Helical scanning has made CT angiography possible because rapid collection of images is needed after a bolus of contrast medium is injected.⁹ The latest advance in CT imaging is the coupling of helical technology with multislice imaging, allowing for extremely rapid and detailed simultaneous multislice acquisitions.

The typical radiation dose for a head CT is 40 to 60 milligray (mGy). There are a number of factors influencing dose, such as voltage (kVp), current (mA), scan time (seconds), field of view, rotation angle, filtration, collimation and section thickness, and spacing. The dose distribution also depends on the size, shape, tissue density, and elemental composition of the patient.¹⁰

Morbidity of CT is mainly that of reactions to intravenous contrast medium administration. Today, nonionic contrast medium is available with significant reduction in the number and severity of adverse reactions. Lower cost has allowed CT use to become more routine. Patient conditions in which only nonionic contrast medium should be administered include prior reaction to iodinated contrast medium, asthma, multiple allergies, cardiac disease, and pulmonary hypertension.¹¹

Patients with allergic histories can also be given a steroid pretreatment consisting of prednisone, 50 mg, orally 13, 7, and 1 hour before dye injection with diphenhydramine (Benadryl), 50 mg, 1 hour before if desired.¹² In this patient population, it is preferable to avoid contrast medium-enhanced CT if possible, with MRI providing an excellent alternative. If MRI is contraindicated, and the patient has a history of laryngospasm or hypotension with previous use of contrast medium, an anesthesiologist should be present during the contrast medium administration. Acute renal failure is an absolute contraindication to the administration of contrast medium. Renal insufficiency should be regarded as a relative contraindication, and again MRI is recommended as the study of choice. Patients on dialysis can be imaged safely with contrast medium, preferably with dialysis planned soon after the study.

CT can be used to guide stereotactic brain biopsy, a technique that is especially helpful for tissue diagnosis of small or deep-seated lesions. Stereotactic radiation therapy, stereotactic craniotomy, brachytherapy, and management of brain stem lesions can also be planned from CT images. For most stereotactic procedures, the patient is placed in a device such as a Brown-Robert-Wells head ring. CT scanning is performed, and the lesion of interest is targeted using the head ring as an external reference. A computer transforms the two-dimensional coordinates of rods fixed in the head ring and the targeted lesion into three-dimensional space so that the trajectory of the biopsy needle can be planned.¹³ Frameless stereotactic techniques have also been developed.

The standard head CT is performed with the gantry angled parallel to the orbitomental line obtaining images in the axial plane. Five-millimeter sections are obtained through the posterior fossa to ensure adequate visualization of the fourth ventricle with 10-mm sections through the supratentorial space. Thinner sections (1–3 mm) are

TABLE 23-2

Appearances of Tissues on Computed Tomography

| Bone | 1000 | White (↑↑↑) |

↓↓↓, marked hypoattenuation; ↓↓, moderate hypoattenuation; ↓, mild hypoattenuation; —, isoattenuation (to brain); ↑↑, moderate hyperattenuation; ↑↑↑, marked hyperattenuation.

employed for detailed examination of small anatomical regions, such as the temporal bone, sella, orbits, and paranasal sinuses. Direct coronal imaging is essential for evaluation of these structures and may be used to visualize lesions in the tentorial region or at the vertex. Coronal imaging requires repositioning the patient in the gantry with the neck hyperextended either supine or prone. Gantry angulation can help reduce the degree of cervical extension but often is insufficient alone for direct coronal imaging. Patients with cervical spine disease, airway obstruction, or obesity also may not be able to tolerate positioning for coronal imaging, and intubated patients cannot be placed in this position.

Filming of head CT images is done at narrow windows (60–80 HU) to accentuate the minor difference in Hounsfield units between white and gray matter, with white matter being slightly lower in attenuation. In cases of trauma, metastatic disease, bone infection, or neoplasm, bone windows (2000–4000 HU) should be obtained to evaluate for fracture, bone destruction, or hyperostosis associated with meningiomas. Bone windows are also useful in the detection of intracranial air and can separate air and fat density. At these windows, the brain is not seen. A bone algorithm, a computer reconstruction technique, can also be employed and is particularly useful in evaluating small or thin bones, such as the ossicles in the middle ear, the facial bones, and the skull base. Acquisitions in bone algorithm alone give detailed bone information, but the images cannot be filmed at brain windows because they will be unsatisfactory. Subdural windows (150–200 HU) are necessary to identify acute subdural hematomas, which blend in with the calvarium on routine brain images (Fig. 23-2).

Normal Findings

A normal unenhanced head CT scan shows midline position of the third and fourth ventricles and the septum pellucidum/

fornix positioned between the lateral ventricles. The bodies of the lateral ventricles need not be symmetrical. Mild differences in the sizes of the frontal, temporal, and occipital horns are common. There should be density discrimination between the white matter (centrum semiovale, corona radiata, internal capsule, and brachium pontis) and gray matter. No focal white matter low densities should be seen in young or middle-age patients. Patients older than 65 years may show mild periventricular hypodensities as part of the normal aging process. Ventricular and subarachnoid space size is variable between individuals. In general, the ventricles and subarachnoid spaces are small in younger patients and increase in size with increasing age. In an older patient, the ventricles should not be dilated out of proportion to the subarachnoid space size.

Normally calcified structures are the pineal gland and the glomus of the choroid plexus in the trigone of the lateral ventricle. Calcification may be seen throughout the choroid plexus, including the temporal horns and the outlets of the fourth ventricle. Occasionally, the habenula (directly anterior to the pineal gland) may show calcification. The arteries of older patients are not uncommonly calcified. Calcification of the globus pallidus can be physiological and becomes more prominent with advancing age. Calcification in dural structures, including the walls of venous sinuses, is seen as a normal variant. Excessive calcifications of vascular or dural structures may indicate an underlying pathological process.

Arteries and veins show normal enhancement owing to the higher attenuation of blood containing iodinated contrast material. Lack of a blood-brain barrier and the tight junctions between endothelial cells allow enhancement of the dural structures (falx and tentorium) and pituitary gland. The choroid plexus in the ventricular system usually shows mild to moderate enhancement owing to its vascular nature. This enhancement can be prominent in the outlets of the fourth ventricle, simulating a vascular lesion.

Figure 23-2. Twenty-three-year-old man status post motor vehicle accident. **A**, An acute frontal subdural hematoma causes compression of the left lateral ventricle, but it is difficult to see at routine brain windows (60). **B**, At subdural windows (150), the hematoma is identified subjacent to the calvarium.

In evaluation of spine CT, the intervertebral disc is seen as having a higher density than that of the contents of the spinal canal. The spinal canal has relatively low attenuation owing to the presence of cerebrospinal fluid (CSF), particularly in the lumbar region. The nerve roots of the cauda equina may be visualized in the posterior portion of the thecal sac. Roots in the cervical and thoracic subarachnoid space cannot be visualized unless intrathecal contrast medium is present. The intervertebral foramina contain mostly fat, which outlines the dorsal root ganglion and is best appreciated in the lumbar region. In the cervical region, soft tissue density of the nerve root is seen in the inferior neural foramen, whereas in the lumbar spine the root is seen in the superior aspect of the foramen. The osseous structures should be smooth, with no encroachment upon the central canal, neural foramina, or lateral recesses. Linear lucencies representing veins may be seen in the vertebral bodies and are corticated, distinguishing them from fracture lines. The basivertebral venous plexus exits the vertebral body midway between the superior and inferior endplates and has a dorsal calcified cap that should not be mistaken for an osteophyte. The ligamenta flava are visualized particularly well in the lumbar spine but should not indent the thecal sac.¹⁴

Types of Detectable Abnormalities

Computed Tomography without Contrast Medium Enhancement

CT is an excellent study to evaluate for acute intracranial hemorrhage, particularly in the subarachnoid space (Fig. 23-3). Acute hemorrhage is detected as high attenuation owing to clot retraction with separation of the high-density erythrocytes from lower-density plasma. Unclotted, active bleeding may be detected in either epidural or subdural hemorrhages as a relative lucency, commonly referred to as the “swirl sign.”

Edema is identified as low attenuation owing to the presence of increased water content. Cytotoxic edema associated with infarct or diffuse anoxia is seen as low density in the gray matter, representing abnormal accumulation of intracellular water (Fig. 23-4). Vasogenic edema is the abnormal accumulation of extracellular water in the white matter, seen as “fingers” or “fronds” of low attenuation following white matter tracts.

CT is valuable in detecting mass effect including subfalcine, descending transtentorial (uncal), ascending transtentorial, and transsphenoidal herniations (see Chapter 1). Cerebellar tonsillar herniation is infrequently detected and can be missed secondary to beam hardening artifact at the level of the foramen magnum.

Evaluation of ventricular size can be done by CT. Enlargement of the temporal horns out of proportion to the lateral ventricular bodies is helpful in recognizing early hydrocephalus. Hydrocephalus with marked dilatation of the ventricles and relative effacement of sulci is typical of more advanced cases. CT can be helpful to follow ventricular size after shunting (Video 54, Normal Pressure Hydrocephalus).

CT is very useful for detecting intracranial calcifications, such as those seen in congenital infections, vascular

Figure 23-3. Middle-aged woman presenting with what she reported as the worst headache of her life and third nerve palsy. Acute subarachnoid hemorrhage is present in left-sided basal cisterns secondary to rupture of a posterior communicating artery aneurysm. Central lucency represents the aneurysm.

Figure 23-4. Thirty-four-year-old woman status post cardiorespiratory arrest and resuscitation. CT shows severe diffuse cerebral (cytotoxic) edema with loss of white-gray matter differentiation and compression of ventricles and subarachnoid spaces secondary to anoxia.

lesions, metabolic disease, and neurocutaneous disorders. The location and distribution of calcifications is key in differentiating these various causes. The identification of calcification in a neoplasm aids in differential diagnosis.

Although congenital brain malformations can be seen on CT, MRI is the modality of choice owing to direct multiplanar imaging with visualization of structures such as the corpus callosum and improved sensitivity for migrational abnormalities. CT is complementary in the evaluation of encephaloceles and meningocele in regard to identifying bone defects.

CT is preferred for evaluating acute fractures of the calvarium, skull base, and spine. Fractures are identified as lucencies without sclerotic margins. These features aid in differentiating fractures from vascular grooves or sutures. In the spine, CT can uniquely demonstrate bone impingement on the central canal, implying possible spinal cord injury. Epidural hematomas are occasionally but not consistently identified in the spine (Fig. 23-5). Again, the spinal cord is typically not directly visualized without the use of intrathecal contrast medium.

CT and MRI provide complementary information about neoplasms of the vertebrae, particularly in the case of spine hemangioma (Fig. 23-6). Infection of the spine is better evaluated by MRI, although CT can provide very useful information regarding bone destruction and paravertebral soft tissue involvement.

Many pathological processes of the extracranial head and neck can be identified by CT. High-resolution thin-section CT is the test of choice for evaluation of the paranasal sinuses and middle ear structures owing to its exquisite bone detail highlighted by air. CT affords better evaluation of the paranasal sinuses, although the intracranial extent of neoplasm or infection is best evaluated by MRI. CT and MRI can both be used for the evaluation of the orbits, with the orbital fat providing excellent contrast for the optic nerve and extraocular muscles with either technique. CT provides information about calcification, which may be seen in tumors, drusen, and vascular lesions.

Figure 23-6. Fifty-five-year-old man with asymptomatic mass lesion identified on chest x-ray. CT myelogram reveals hyperdense spiculated lesion of the T7 vertebral body with soft tissue components in the paraspinal and epidural space consistent with hemangioma.

Computed Tomography with Contrast Medium Enhancement

In general, it is preferable to perform neuroimaging with MRI than to perform CT with contrast medium enhancement. MRI is more sensitive to subtle changes in tissue signal and is superior to CT in initial as well as follow-up evaluation of enhancing lesions, such as neoplasms, infection, and vascular lesions. MRI affords evaluation of masses in multiple planes and is especially useful in surgical or stereotactic irradiation planning. Meningeal disease is better evaluated by MRI and can be missed on CT owing

Figure 23-5. Twenty-three-year-old man status post motor vehicle accident. **A**, Bone windows from a lumbar CT reveal a burst fracture of L2. **B**, Soft tissue window demonstrates an anterior epidural hematoma at the L1 level.

to volume averaging with the skull coupled with the normal bright enhancement of the meninges.

Contrast medium-enhanced CT is useful in patients who cannot undergo MRI and when MRI is not readily available. Contrast medium aids in the detection of intracranial lesions that may otherwise be poorly delineated or invisible on unenhanced CT. Patterns of enhancement can be helpful in the differential diagnosis of intracranial masses.

CT is not as sensitive in the detection of white matter and neurodegenerative disorders as MRI and should not be used as the primary imaging modality. If MRI is contraindicated, CT may identify white matter lesions secondary to demyelination or dysmyelination, and contrast medium enhancement is occasionally useful in differential diagnosis.

Neurological Applications in Diagnosis and Treatment

CT is useful in detecting structural abnormalities causing multifocal, focal, or subcortical cerebral dysfunction. Evaluation of the brain stem is generally limited to the mid-brain and upper pons. CT has limited usefulness in the evaluation of the spinal cord and nerve roots. CT is not useful in the evaluation of neuromuscular disease.

Cranial Diseases

INTRA-AXIAL DISORDERS. CT can often identify lesions responsible for cerebral dysfunction and is ordered in the acutely ill neurological patient with a history of trauma, stroke, “worst headache” of life, anticoagulation or bleeding diathesis, or seizure. In any case of suspected acute intracranial hemorrhage, intravenous contrast medium should not be immediately administered because contrast medium enhancement and acute extravascular blood have similar attenuation characteristics. Likewise, evaluation for infarction should be performed without contrast medium enhancement to exclude hemorrhage and also because subacute infarction may show mild enhancement such that it is indistinguishable from normal cortex. Where available, perfusion CT imaging can be obtained in acute stroke patients to assess the extent of ischemic brain. Typical unenhanced scans performed within the first 24 hours of clinical symptomatology of infarct may not reveal any detectable abnormality. Early signs of middle cerebral artery infarct include hyperdensity of the artery (thrombus and embolus), loss of differentiation of insular cortex (insular ribbon sign), and obscuration of the lentiform nuclei from adjacent capsular white matter structures due to edema, as well as effacement of the sylvian fissure and sulci. Should urgent angiography be necessary in acutely ill patients, caution should be taken when interpreting CT imaging studies performed over the next 24 hours because residual intravascular contrast can be present, particularly in patients with renal insufficiency or failure.

Differential diagnosis of enhancing lesions includes primary brain neoplasm, metastasis, abscess, infarct, demyelinating disease, resolving hematoma, and vascular malformation. Abscesses, metastases, and high-grade primary neoplasms incite prominent vasogenic edema, whereas other enhancing lesions usually show less edema. Demyelinating disease shows ring or solid enhancement in the acute stage, commonly in a periventricular location. Resolving

hematomas show ring enhancement 1 or 2 weeks after hemorrhage at the margin of the hematoma bed. Arteriovenous malformations demonstrate enlargement of feeding arteries and draining veins with central dense enhancement representing the “nidus.” Cavemous angiomas show enhancement in a solid pattern and are often hyperdense without contrast medium owing to calcification. CT can detect venous angiomas utilizing contrast medium due to lack of any quantifying features other than the enhancing aberrant vein.

Intracranial calcifications are seen in a variety of disease processes. Arteriovenous malformations, aneurysms, and cavernous angiomas all may contain calcifications. Of the neurocutaneous disorders, tuberous sclerosis and Sturge-Weber syndrome show characteristic patterns. Patients with tuberous sclerosis demonstrate calcifications that are mainly periventricular in location (Fig. 23-7). Patients with Sturge-Weber syndrome show a gyriform pattern of calcification seen in the posterior temporal, parietal, and occipital cortex. Patients with neurofibromatosis may also demonstrate parenchymal calcifications in the basal ganglia and elsewhere. Excessive basal ganglia calcifications are seen in many metabolic disorders usually related to calcium metabolism. Neoplasms that calcify include gliomas (particularly oligodendrogliomas), meningiomas (Fig. 23-8), ependymomas, craniopharyngiomas, and choroid plexus papillomas. The most common acquired intracranial infection to demonstrate intracranial calcification is cysticercosis.

CT plays a complementary role to MRI in evaluation of patients with cranial nerve palsies (Video 43, Tongue Fasciculations). CT excels in evaluation of the bony skull base and can detect pathological processes such as tumor,

Figure 23-7. One-year-old male with tuberous sclerosis. CT without contrast reveals periventricular calcifications, the largest at the left foramen of Monro.

Figure 23-8. Sixty-year-old woman with right parasagittal meningioma. Without contrast, the lesion is hyperdense and contains calcifications. Low-density white matter represents vasogenic edema.

infection, and primary bone lesions as they encroach upon, enlarge, or destroy foramina. Because all the cranial nerves have a close relationship to the skull base, bone detail thin-section scanning should be obtained in all patients with these palsies. Of the cranial nerves, only the optic nerve can be directly visualized by CT. Patients with monocular visual loss may demonstrate enhancement and/or enlargement of the optic nerve.

Spinal Disease

MRI is generally the test of choice for evaluating upper or lower motor neuron disease localized to the spinal cord, spinal roots, or plexi. In particular, CT should not be used as a primary imaging modality in suspected spinal cord compression because soft tissue lesions such as abscesses, hematomas, and sometimes disc herniations may be missed. CT serves a complementary role in defining bone lesions causing spinal cord compression once the level of interest has been identified by MRI or myelography, predominantly if MRI is contraindicated. Metastatic disease, discogenic disease with osteophyte formation and calcification of disc material/ligaments, infection, and primary bone tumors or metabolic lesions are examples of pathological processes in which CT can add or supplement information to MRI. CT can visualize nerve roots surrounded by low-attenuation fat particularly in the lumbar neural foramen and is useful in evaluating bone encroachment on the neural foramina from endplate osteophyte formation, facet degeneration, or unciniate process osteophytes of the cervical spine. CT myelography can visualize nerve roots and the spinal cord in the thecal sac and is particularly useful in the patient who cannot undergo MRI.

MAGNETIC RESONANCE IMAGING

Basic Principles and Techniques

Gorter is given credit for the origin of the concept of nuclear magnetic resonance (NMR) in 1936.¹⁵ Work was continued by Purcell and Block in the mid-1940s with their Nobel Prize-winning discovery of the magnetic resonance phenomenon. Experimentation was limited to very small quantities of materials that were contained within a vacuum chamber. In the late 1960s, Jackson reported NMR experiments on animal tissues. Damadian, in 1972, was the first to describe whole-body NMR for medical diagnosis. Soon after, in 1973, Lauterbur theorized using magnetic field gradients to create a position-dependent NMR signal. The first MR images of detailed human anatomy were produced by Aberdeen in 1976. The widespread clinical use of MRI began approximately in 1980 and continues to grow at an exponential pace.

NMR is the science that forms the basis for MRI. Abundant water molecules within the human body contain hydrogen protons that act as microscopic magnets. When the human body is placed into a static main magnetic field, approximately 50% of the magnets align parallel to this main magnetic field. The remainder aligns in an antiparallel fashion. These magnets cancel each other out, although approximately 1 in 1 million bar magnets is not canceled out and creates the basis of a tiny magnetic net vector. These microscopic magnets form the basis of the intrinsic signal that is used to generate clinical images. These net magnetic vectors align with the axis of the main magnet and rotate at a specific frequency known as the Larmor frequency. A second type of magnetic field, known as the gradient field, is used to augment the main magnetic field and allow for anatomical localization of the specific spinning protons. Finally, there is a third type of magnetic field known as a resonance frequency field and referred to as a radiofrequency (RF) pulse. This RF pulse is a very low amplitude that oscillates near the Larmor frequency (63.87 MHz for a 1.5-Tesla [T] MR image). When the RF pulse is applied, the spinning protons become excited and flip their orientation to a predetermined flip angle, which is usually 90 degrees for a spin-echo technique. When the RF field is turned off, these excited spinning protons convert to a relaxed state, releasing energy. This energy can be measured with head, body, or surface coils and forms the basis for image formation.

The intrinsic high tissue contrast medium for MRI is one of the major strengths of this modality. Whereas CT uses differences in x-ray attenuation coefficients of two adjacent tissues, the MR signal is intrinsic and is generated by changing the proton spins in response to an external RF pulse. The different macromolecular characteristics of the intercellular and extracellular protons within the water molecules determine the intrinsic MR signal that is displayed for diagnostic interpretation. The macromolecular spin magnetization returns to its equilibrium state through a process defined by two relatively independent relaxation times, referred to as T1 and T2.

After a 90-degree RF pulse, the proton magnetization net vector rotates from the axis of the main magnet (Z axis, longitudinal magnetization) to the transverse plane (X and Y axes, transverse magnetization). When the RF pulse

TABLE 23-3

 —, Intermediate signal intensity; ↑, small increase; ↑↑, bright; ↓, small decrease; ↓↓, dark.

ends, the longitudinal magnetization recovers toward 100% in an exponential manner. The time it takes for the proton to recover 63% of its longitudinal magnetization is referred to as *T1* or *spin-lattice relaxation*. In a similar fashion, when the RF pulse ends, the transverse magnetization is 100% and decays toward zero. The time it takes the proton to lose 63% of its transverse magnetization is termed *T2* or *spin-spin relaxation time*. The energy signal formed during this decay process is referred to as free induction decay. This signal is intrinsically weak. It is enhanced by the addition of a second 180-degree RF pulse, which follows the first 90-degree RF pulse. This second RF pulse refocuses the protons and creates a spin-echo signal. The time from the 90-degree pulse to the spin-echo signal is termed the *TE*. This process is repeated, and the repetition time between the 90-degree pulses is called *TR*.

Images can be created that have relative T1 weighting (T1W) or T2 weighting (T2W) by varying the TR and TE. A T1-weighted image has a TR less than 1000 msec and a TE less than 50 msec. A T2-weighted image has a TR greater than 2000 msec and a TE greater than 60 msec. An intermediate so-called proton density weighing has a TR greater than 2000 msec and a TE less than 40 msec.

Normal Findings

There are basic MR signal patterns of normal tissues in the brain. These patterns are shown in [Table 23-3](#).

Types of Detectable Abnormalities

The MR signal characteristics of a lesion on T1- and T2-weighted sequences enable the differential diagnosis of any particular brain abnormality to be narrowed. A summary of signal characteristics is shown in [Table 23-4](#). There are specific and nonspecific patterns of MR signal regarding normal and abnormal tissues. The most specific patterns are seen with respect to CSF, fat, bone, and stages of intracranial hemorrhage.

CSF has decreased signal on T1-weighted images, intermediate signal on proton density, and increased signal on T2-weighted images. When evaluating a cystic lesion, one must determine if the lesion follows CSF signal characteristics on all pulse sequences. If the lesion does not, it is considered atypical. Lesions that follow CSF signal typically represent arachnoid cysts or dilated CSF spaces as seen in Virchow-Robin spaces or secondary to encephalomalacia. Complicated fluid may show increased signal on both T1- and T2-weighted sequences. These abnormalities suggest the presence of proteinaceous or complex hemorrhagic fluid and may harbor malignancy.

Fat has increased signal on T1-weighted images and decreased signal on T2-weighted images. Lesions that follow this pattern most commonly represent fat, as seen in congenital lipomas and teratogenic tumors. Confirmation of a fatty lesion can be obtained with a fat saturation RF pulse sequence.

Each stage of hemoglobin molecular breakdown has its own peculiar imaging signature based on the MR signal. That is, the stages of hemorrhage, whether acute, subacute,

or chronic, generate unique changes that are uniquely shown only by MRI. These signals range from nearly isointense to hypointense signal, as seen in acute hemorrhages, to increased signal seen on both T1- and T2-weighted images observed in late subacute or chronic hemorrhages.^{16,17} The identification of hemosiderin typifies chronic cerebral hemorrhage. The signal patterns of brain hemorrhage are summarized in Table 23-5.

MR signal patterns are recognizable with common diseases such as cerebral edema, neoplasm, abscess, infarcts, or demyelinating processes. These entities demonstrate a nonspecific pattern of decreased signal on T1-weighted images and increased signal on proton density and T2-weighted images. Therefore, to obtain a differential diagnosis with a high degree of accuracy, this information is linked with anatomical location, morphology, and a degree of contrast medium enhancement. These, with good clinical history, all help in arriving at a correct differential diagnosis.

Neurological Applications in Diagnosis and Treatment

In general, owing to high tissue contrast between tissues and multiplanar imaging, MRI is the study of choice to evaluate all lesions in the brain and spine. CT, however, is more sensitive than MRI for the evaluation of calcifications and subtle fractures, and it remains pivotal in the diagnosis of acute subarachnoid hemorrhage. Additionally, MRI cannot be performed in patients who have intraorbital foreign bodies, pacemakers, or non-MRI-compatible implants, such as artificial heart valves, vascular clips, cochlear implants, or ventilators. When approaching a lesion that is seen on an MRI of the brain, the specific location of the lesion must be identified. If one begins superficially and moves inward toward the deeper spaces of the brain, the first important space is the extracalvarial soft tissues, consisting of skin, muscle, and facial structures. The bony calvarium is next composed of the outer table, bone marrow within the diploic space, and inner table. The next space to consider is the extra-axial leptomeningeal structures, which include the epidural, subdural, and subarachnoid spaces. The layer beneath the subarachnoid space is the pia mater, which is closely adherent to the gray matter cortical ribbon. Deep to the pial layer lie the intra-axial structures. These structures include the cortical gray matter, the underlying white matter, the deeper basal ganglionic structures, and the brain stem as well as the ventricular system. On routine MRI of the brain, there are additional structures to examine, including the orbits, paranasal sinuses, temporal bone, and skull base.

Calvarial-Related Lesions

Bone abnormalities include primary and secondary masses. Metastatic lesions and rare primary tumors such as osteogenic sarcomas or giant cell tumors can affect the calvarium. Additional secondary neoplastic processes that can involve the diploic (marrow) space include leukemia and lymphoma. Benign neoplastic processes include neurofibroma in a patient with neurofibromatosis (type I), soft tissue fibromas, and dermoid and epidermoid tumors. These can affect the skull, resulting in bony deformities, or can directly involve the calvarium. Hemangiomas can be seen as enhancing, expansile masses originating within the diploic space.

Inflammatory lesions within the extracalvarial soft tissues typically include benign processes such as sebaceous cysts or cellulitis. Primary calvarial inflammatory lesions include osteomyelitis or an infected postoperative bone flap.

Bony lesions and congenital fibro-osseous lesions such as fibrous dysplasia or Paget's disease are common calvarial abnormalities. A common bone marrow disorder is conversion from fatty marrow to hematopoietic marrow in patients with anemia. Primary loss of normal hematopoietic elements with conversion to dense fibrous matrix can be seen in myelofibrosis.

Cranial Diseases

EXTRA-AXIAL SPACE LESIONS. Congenital tumors of epidermal and mesodermal origin that arise from the skull base and cerebellopontine angle are typically epidermoid tumors. These tumors are usually eccentric and are locally invasive. Congenital tumors that contain all three embryonic layers are termed dermoid tumors. These tumors tend to occur in the midline at the skull base and within the suprasellar cistern. More aggressive neoplasms to consider include ependymomas, which arise from ependymal cells most commonly within the fourth ventricle or cerebellopontine angle (Video 201, Cranial Nerve VII Anatomy). Secondary neoplastic involvement of the pachymeninges includes lymphoma, metastasis from lung or breast, or possibly an adenocarcinoma from an unknown primary tumor. These lesions may present as a single metastatic focus or can result in diffuse carcinomatosis.¹⁸

The most common dural-based tumor is the meningioma, which represents a primary neoplasm of the dura (Fig. 23-9). These tumors commonly involve the dural convexities but may also involve the falx, cerebellar tentorium, and skull base. Rarely, these tumors present as intraventricular masses

Figure 23-9. Olfactory groove meningioma. **A**, Axial T2-weighted image shows a mass attached to the anterior falx (dural extension). Note relative low signal on T2-weighted image and surrounding signal edema. **B**, Coronal T1-weighted image after contrast shows homogeneous enhancement of the dural-based extra-axial mass.

or masses involving the foramen magnum. Meningiomas typically enhance densely with contrast material and can display a signature “dural tail” representing contiguous involvement of the dura beyond seemingly defined tumor margins.

Inflammatory processes such as epidural empyema from an adjacent sinus infection may occur. Subdural effusions have been described in children with systemic *Haemophilus influenzae* infections. The most common inflammatory process to consider is a meningitis, which may be of viral, fungal, or bacterial origin.

An important pattern of abnormality is diffuse pachymeningeal thickening with homogeneous enhancement following an intravenous injection of contrast agent (gadolinium). The differential diagnosis includes carcinomatosis, sarcoidosis, meningitis, or a more recently described entity referred to as central CSF hypotensive pachymeningitis.¹⁹ The exact cause of this last entity is not well understood, but it is believed to be related to either a CSF leak or an abnormal CSF metabolic process.¹⁶ One of the more common extra-axial lesions is a post-traumatic epidural or subdural hematoma.²⁰ These lesions are occasionally imaged primarily by MR, but more frequently they are imaged as an adjunct to CT scanning. MRI can be helpful in clarifying the involved extra-axial space and its secondary effects, as well as evaluating the hemorrhage age or chronicity. Lesions within the subarachnoid space that follow CSF signal on all pulse sequences and demonstrate mass effect represent congenital or post-traumatic (acquired) arachnoid cysts.

INTRA-AXIAL SPACE LESIONS. Small focal lesions at the gray matter/white matter junction, which demonstrate mass effect, surrounding edema, and contrast medium enhancement, most commonly represent metastatic lesions. Large enhancing masslike lesions that involve both the gray matter and the white matter and that do not follow a wedgelike distribution typically represent primary brain gliomas. Low-grade (I and II) gliomas typically do not enhance, whereas higher-grade gliomas (III and IV) usually

do. A low-grade neoplastic process must also be considered if there is a focal, nonenhancing enlargement of the gray matter cortex that continues to have mass effect over a 3- or 4-week interval. This lack of change will help differentiate a low-grade glioma from a cortical infarct.

Peripheral cortical inflammatory processes secondary to meningitis may lead to cerebritis or, consequently, a focal abscess. Viral inflammatory processes of the cortex and subcortical white matter may occur and are most commonly secondary to a herpesvirus infection. Multifocal enhancing lesions in the gray matter/white matter junction, brain stem, and cerebellum may represent multifocal abscesses in the appropriate clinical setting (Fig. 23-10).

The differentiation of intracranial cystic lesions is often difficult using conventional MRI sequences. Both cystic gliomas and cerebral abscesses appear as rim enhancing lesions with increased signal on T2-weighted images and decreased signal on T1-weighted images. Apparent diffusion coefficient (ADC) maps and diffusion weighted imaging (DWI) have been found to aid in distinguishing between these lesions (Table 23-6). The ADC map is a measurement of the random motion of water molecules. As cells swell in cytotoxic edema, there is restricted diffusion of the intracellular water molecules, which results in a low ADC value. In contrast, the extracellular water of vasogenic edema demonstrates increased diffusion and a higher ADC value. DWI is a rapidly acquired image based on the ADC values in which restricted diffusion appears as high signal intensity.

In a study of 63 cystic lesions, Bukte and colleagues²¹ found that all pyogenic abscesses were hyperintense on DWI, whereas all cystic gliomas were hypointense on DWI. The authors proposed that the cellular and proteinaceous organization of an abscess restricts water motion. The cystic or necrotic center of brain tumors is similar to serous fluid in which water can freely diffuse, resulting in low signal on DWI. Of 11 metastatic lesions studied, 8 were hypointense and 3 were hyperintense on DWI. Thus,

Figure 23-10. Cysticercosis. **A**, Axial T2-weighted image shows two parietal lobe lesions with up signal. **B**, Coronal T1-weighted image after contrast shows small ring-enhancing lesions.

TABLE 23-6

Differentiating Intracranial Cystic Lesions with Diffusion Weighted Imaging (DWI) and Apparent Diffusion Coefficient (ADC) Maps

| LESION | DWI SIGNAL | ADC SIGNAL |
|----------------|------------|------------|
| Acute stroke | Increased | Decreased |
| Abscess | Increased | Decreased |
| Cystic glioma | Decreased | Increased |
| Epidermoid | Increased | Isointense |
| Arachnoid cyst | Decreased | Increased |

rarely, metastatic lesions may simulate imaging characteristics of abscesses. DWI has also been found to be useful in distinguishing epidermoid cysts from arachnoid cysts, both of which have imaging characteristics similar to CSF on CT and conventional MRI. Epidermoids are typically hyperintense on DWI, whereas arachnoid cysts are hypointense.

A wedge-shaped lesion that involves both white and gray matter and follows a vascular distribution usually represents an infarction from cerebrovascular disease (Video 215, Cadasil Stroke). Acute infarctions may become evident on routine T2W spin-echo images within 12 to 24 hours of onset. The most sensitive pulse sequence is a water diffusion coefficient weighted technique.²² This pulse sequence can detect an infarct within the first few minutes of onset. MR perfusion imaging can further be helpful in differentiating a devascularized brain territory (Fig. 23-11), and an appropriate mismatch between diffusion and perfusion imaging can help guide appropriate neurointervention. Peripheral vascular venous occlusions of the superior sagittal sinus or adjacent cortical draining veins may lead to a cortical or a cortical/subcortical venous infarction.

Lesions that primarily involve the white matter are most commonly secondary to small vessel occlusive disease or a

Figure 23-11. DWI demonstrating abnormal decreased signal in the left middle cerebral artery distribution.

demyelinating process. Small rounded infarctions less than 1 cm within the deep white matter, basal ganglion, cerebellum, or brain stem in an adult older than 50 years of age most commonly represent lacunar infarctions. Also in this population, tiny lesions within the periventricular white matter are usually secondary to small vessel ischemic disease. Demyelinating lesions secondary to multiple sclerosis may mimic this appearance but typically are present in

Figure 23-12. Acute disseminated encephalomyelitis. Axial T2-weighted image shows multiple white matter lesions.

younger adults. Lesions of multiple sclerosis may present as early as the second decade as rounded or ovoid lesions in the periventricular deep white matter. Ovoid lesions that are perpendicular to the long axis of the body of the lateral ventricles represent demyelination within perivascular spaces termed *Dawson's fingers*. Additional lesions can present in the corpus callosum, brain stem, and spinal cord. In children younger than age 10 years, periventricular white matter lesions and basal ganglionic, brain stem, or cerebellar lesions may represent an acute disseminated encephalomyelitis, typically secondary to a postviral or postvaccine autoimmune process (Fig. 23-12).

Multiple sclerosis and acute disseminated encephalomyelitis are the most common acquired leukoencephalopathies (Video 12, Dysdiadochokinesis). Another leukoencephalopathy to consider is human immunodeficiency virus encephalopathy, which is a diffuse process. Multifocal lesions with minimal mass effect and no abnormal contrast medium enhancement in an immunocompromised patient may represent progressive multifocal leukoencephalopathy. Postradiation and/or postchemotherapeutic leukoencephalopathy should be considered (Video 113, Pontine Myelinolysis). There are a wide variety of congenital dysmyelinating disorders, the most common of which are metachromatic leukodystrophy, adrenoleukodystrophy, and Canavan's disease. All of these dysmyelinating diseases represent congenital enzymatic defects.

MRI is an effective noninvasive means of localizing focal epileptogenic lesions (Video 78, Frontal Lobe Complex-Partial Seizure). Identification of such lesions (i.e., structural abnormality such as tumor or arteriovenous malformation) with noninvasive neuroimaging improves postsurgical outcomes. In the case of temporal lobe epilepsy, a seizure-free postsurgical outcome is 82% with concordant MRI lesions compared to 56% with no corroborative MRI finding.²³ The literature suggests improved presurgical evaluation of patients with focal epilepsy when studied on a phased array 3T MRI magnet and interpreted by an experienced neuroradiologist.²⁴

Diffusion tensor imaging (DTI) is an evolving new noninvasive technique that assesses changes in the micromolecular environment of cerebral tissues. DTI is under investigation for its role in the workup of temporal lobe surgery. DTI has been described to characterize abnormal tissue within the hippocampal formation of patients with temporal lobe epilepsy that, in some cases, did not have any structural abnormality on high-resolution MRI.²⁵⁻²⁷ See Figure 23-13 for an example of abnormal DTI in the hippocampal formation.

Within the deeper basal ganglionic structures, brain stem, or cerebellum, the most common lesions are focal infarctions and demyelination. Much less common lesions include focal encephalitis or gliomas. Focal mass lesions within the brain stem or cerebellum may occur within an older adult and most commonly represent metastasis.

Figure 23-13. A, Coronal T2 sequence through the anterior hippocampal formation without abnormality. B, Directionally encoded color with increased trace-D and fractional anisotropy depicted by decreased blue pitch in the right hippocampal formation (arrow) in a patient with seizures.

Figure 23-14. Brain stem glioma. Midline sagittal T1-weighted image shows a focal enlargement of the pons with decreased signal.

A primarily cystic lesion with an enhancing mural nodule within the cerebellum in a child represents a pilocystic astrocytoma. In a young adult, a similar-appearing lesion most likely represents a hemangioblastoma, which may be a manifestation of von Hippel-Lindau disease. A focal expansile lesion within the brain stem most commonly in the pons in a young child typically represents a brain stem glioma (Fig. 23-14). In a child, the primary differential diagnosis for a posterior fossa mass includes, in decreasing frequency, a primitive neuroectodermal tumor (medulloblastoma), brain stem glioma, cerebellar pilocystic astrocytoma, and ependymoma.

Vascular malformations are most commonly found within the intra-axial space, although they may be present solely within an extra-axial space. These lesions represent a spectrum from benign cavernous angiomas, which have a low bleeding potential, to arteriovenous malformations that carry a bleeding potential of 2% to 4% per year.²⁸ Cavernous angiomas have characteristic appearances of lobulated blood-filled channels with a rim of hemosiderin. Arteriovenous malformations have serpiginous tangles of flow voids with adjacent feeding arteries and draining veins. Dural malformations may be difficult to detect by MRI alone due to an inherent lack of brain parenchymal involvement.²²

Primary neoplasms, although uncommon, do occur. These tumors include choroid plexus papilloma or carcinoma; central neurocytomas, which are characteristically attached to the septum pellucidum (Fig. 23-15); interventricular meningiomas; and ependymomas. Colloid cysts typically originate within the region of the roof of the anterior portion of the third ventricle and are usually benign. Occasionally, these cysts may cause acute hydrocephalus and, rarely, death in a young adult from brain herniation.

Figure 23-15. Central neurocytoma. Axial post-contrast T1-weighted image shows a heterogeneously enhancing, rounded intraventricular mass within the anterior portion of the lateral ventricle.

FUNCTIONAL MAGNETIC RESONANCE IMAGING

Functional magnetic resonance imaging (fMRI), based on blood oxygenation level-dependent (BOLD) imaging²⁹ of the brain, provides functional data of cerebral activation during any given task (e.g., motor, visual, and cognitive). This method allows for a quantitative nonclinical method for assessing changes in cerebral function as related to cerebral activities (i.e., performance of physical or cognitive tasks). The BOLD fMRI technique allows for detection of minute changes in cerebral oxygenation. In fMRI, examining the signal intensity differences in an imaging voxel between the presence and absence of a stimulus identifies areas that are receiving increased blood flow, which is used as a marker for increased functional activity. This methodology has been widely used and has shown promising results for fMRI studies of various pathways of the brain, including the language, memory, and visual pathways (Fig. 23-16). See Figure 23-17 for fMRI of a patient with right parietal high-grade glioma during left finger-to-thumb hand squeezing.³⁰⁻³²

CEREBROSPINAL FLUID FLOW—PHASE CONTRAST IMAGING

Physiological CSF flow information can be obtained using a proton phase-sensitive (phase contrast [PC]) technique.

Figure 23-16. Frontal and lateral three-dimensional fMRI rendering of functional activity in the occipital lobe secondary to a visual stimulus.

Figure 23-17. A, Axial FLAIR sequence demonstrating right parietal high-grade glioma with surrounding vasogenic edema. B, fMRI sequence showing activation of the right sensorimotor strip, which is displaced by glioma. C, Sagittal fMRI demonstrating superior and anterior displacement of the right sensorimotor strip.

Moving tissue such as CSF causes shifting of the phase of the spinning protons. The phase shifting can be measured and qualitative direction of flow and quantitative flow velocity can be measured using a PC technique. CSF flow is a dynamic process that moves in a to-and-fro motion. The flow of CSF through the aqueduct of Sylvius, basal cisterns, and foramen magnum normally changes direction two or three times per second, with a net slow flow in the superior to inferior direction. Cardiac gating can be performed with the PC technique, and flow information can be determined at selected intervals during the cardiac cycle. This flow information can be displayed in a cine loop, demonstrating the temporal and spatial changes of CSF flow. There are several clinical indications for CSF flow PC imaging, including characterizing partial versus complete aqueductal stenosis; determining the patency of an internal ventriculostomy (endoscopic osteotomy in the floor of the third ventricle to bypass an aqueductal obstruc-

tion); characterizing increased CSF velocity in normal pressure hydrocephalus; and characterizing the CSF flow around the basal cisterns and cervicomedullary junction in Chiari I malformation.

MAGNETIC RESONANCE IMAGING OF THE SPINE

Since the mid-1980s, MRI of the spine has attained acceptance as the premier modality in the evaluation of spine diseases. MRI is eloquent in the evaluation of both benign and malignant spinal processes and is further unique in its inherent noninvasive ability to image the spinal cord and surrounding structures. Structures such as CSF, dura, and adjacent ligaments are routinely seen and evaluated. The utility of spine MRI can be discussed in terms of the three classic categories of spine disease: extradural, intradural-extramedullary, and intramedullary processes.

A frequent cause of epidural disease is intervertebral disc pathology. MRI can uniquely image the intervertebral disc directly, without the use of contrast material. Disc integrity can be assessed in terms of degeneration, abnormal disc bulges, or herniations (Video 237, Foot Drop). High-resolution T2-weighted images of the disc can diagnose annular and circumferential tears that previously required injection of contrast material (i.e., CT discography). Any effect on spinal contents, either the spinal cord or existing nerves in the cervical and thoracic regions, or nerve impingement on either the cauda equina or existing nerve roots in the lumbar region can be assessed. Additionally, inherent signal aberrations within the intervertebral discs can also be analyzed for primary intrinsic disc abnormalities, such as infectious discitis and associated vertebral osteomyelitis.

Although MRI is inherently poor for showing dense, cortical bone, it is extremely useful in the evaluation of infiltrative bone marrow diseases. Both degenerative and malignant bone marrow changes can be detected and categorized based on MR signal patterns. Benign processes such as post-traumatic bone edema, fatty bone marrow infiltration, or benign neoplasms such as primary vertebral hemangiomas can be readily distinguished from carcinomatous changes (i.e., vertebral plasmacytoma or frank metastatic disease with or without vertebral destruction or paravertebral soft tissue involvement). MRI is also useful in the analysis of degenerative spondylosis and complications of spondyloarthropathies as well as in the evaluation of benign or malignant spinal canal or foraminal stenosis. MRI is pivotal in the emergency evaluation of post-traumatic spinal cord compression.

Infrequently, intradural extramedullary masses present for evaluation. In the cervical and thoracic regions, meningiomas, neuromas, and arachnoid cysts predominate, whereas in the lumbar spine, schwannomas, ependymomas, or, rarely, intradural disc herniations are more common. Occasionally, intradural extramedullary metastases are encountered that may stud the spinal cord and meninges with metastatic deposits.

MRI is uniquely sensitive in detecting the presence of intramedullary spinal cord diseases. Common primary intramedullary neoplasms that can be elucidated include astrocytoma, ependymoma, and spinal cord hemangioblastoma. Contrast medium-enhanced MRI can help differentiate spinal cord edema, as seen in these entities, from the primary tumoral masses. Other causes of abnormal signal within the spinal cord include inflammatory or demyelinating diseases such as acute disseminating encephalomyelitis, transverse myelitis, and multiple sclerosis. The evaluation of spinal cord edema secondary to trauma, either from chronic discogenic disease or in situations of acute complex fracture injuries, is essential, particularly in national trauma centers.

MAGNETIC RESONANCE ANGIOGRAPHY

Basic Principles and Techniques

MRI techniques have been developed to image the flowing blood. MRA and magnetic resonance venography (MRV)

are used to study the flow in various vessels and have proved to be robust in routine clinical examination of vascular diseases. In this section, the basic principles of MRA and the major clinical uses are discussed.

There are two major MRA techniques that are used in MRI that exploit either the longitudinal spin magnetization or the transverse spin magnetization of the protons in blood to visualize flowing blood. They are the time-of-flight (TOF) technique, which utilizes the inflow-outflow of the moving spins within the selected imaging volume to image the blood flow, and the PC technique, which utilizes the flow-induced phase variations of the MRA signal caused by the motion of the blood. These MRA techniques by convention depict the blood flow as bright in contrast to the dark surrounding stationary tissues. The MRA data are postprocessed with a maximum intensity projection (MIP) algorithm and may be displayed in multiple angiographic projections and angulations.

Normal Findings

The TOF method uses the longitudinal magnetization, such that the blood flowing into the selected volume during the RF excitation period is fully relaxed, whereas the magnetization from the stationary tissue is saturated, and hence the signal from the blood is brighter compared to that of the stationary tissue. This phenomenon was first described in a nonimaging context by Singer.³³ After RF excitation, the longitudinal magnetization recovers exponentially with time constant T1 and is typically much longer than with T2W. In a volume of stationary tissue and flowing blood, during every TR interval, the magnetization recovers incompletely throughout the volume, acquiring T1W that suppresses particularly the signals with longer T1. This is referred to as saturation. The degree of T1W depends on the solution of the Bloch equation, which is a function of TR, T1, and the excitation flip angle α . Usually, a TR of 30 to 100 msec and flip angles of 10 to 60 degrees are used. These imaging parameters can be optimized for maximum suppression of the stationary tissues and better flow visualization.

In TOF imaging, faster flow through a vessel lumen running perpendicularly through the slice partially or completely exits the slice in the interval between the 90- and 180-degree excitation pulses.³⁴ Consequently, the 180-degree pulse fails to invert the nuclei, and the signal is diminished. However, with slow flow, washout of the spins between the 90-degree and the 180-degree pulses is minimal. The previously excited outgoing slice is replaced during the TR interval by the inflow of fully magnetized spins from outside the volume, giving a brighter signal than the one acquired from stationary tissue. This phenomenon is generally referred to as entry phenomenon or flow-related enhancement. Furthermore, the heavy T1W associated with these short TR sequences suppresses stationary tissue, an important contributor to the contrast between the stationary and the flowing signal. Therefore, the TOF method primarily uses these flow-related enhancement phenomena to image the blood vessels.

Two major techniques exist in TOF MRA: two-dimensional TOF (2D TOF) and three-dimensional TOF (3D TOF) imaging techniques. Two-dimensional TOF is advantageous

Figure 23-18. Carotid bifurcation of a patient with arteriosclerosis. **A**, Digital subtraction arteriogram shows mild stenosis in proximal carotid bulb (*short arrow*), moderate to marked stenosis in external carotid artery (*open arrow*), and marked stenosis (approximately 85%) in distal bulb/proximal internal carotid artery (*long, thin arrow*). Contrast medium collection probably represents ulceration (*large arrowhead*). Ascending pharyngeal artery (*small arrowhead*). **B**, Axial two-dimensional TOF (surface coil). Accurate demonstration of moderate to marked stenosis in external carotid artery (*open arrow*). Small elongation of mild stenosis in proximal bulb (*arrow*). Slight exaggeration of marked stenosis (to approximately 90%) in distal bulb/proximal internal carotid artery (*long, thin arrow*). Signal is lost within the proximal portion of this stenosis. Ulceration (*large arrowhead*) and ascending pharyngeal artery (*small arrowhead*) are identified. (From Faro SH, Vinitski S, Ortega HV, et al: Carotid magnetic resonance angiography: Improved image quality with dual 3-inch surface coils. *Neuroradiology* 1996;38:403-408.)

because of its sensitivity to slow flow rates, minimal saturation effects for normal flow velocities, and short acquisition times (5–7 minutes). Although widely used, the technique has a few limitations. The appearance of the moving blood varies when the imaging plane is not perpendicular to the slice select direction. Owing to the in-plane flow, the blood vessels that run parallel to the imaging plane experience multiple RF pulses and eventually become saturated. Hence, the portion of the vessel traversing the imaging plane may exhibit some reduction in signal intensity and appear artifactually narrowed or even discontinued. Preliminary work with 2D TOF and magnetization transfer (MT) in the carotid artery bifurcation has shown an improved signal-to-noise ratio (SNR) and greater sharpness of vessel margins.³⁵ The 3D TOF MRA technique offers a number of advantages over its 2D counterpart. The 3D volume acquisition techniques offer superior SNR and high spatial resolution and are sensitive to fast and intermediate flow. The other major advantage of this technique is that the acquisition can be made in thin slices, thereby reducing voxel size and hence decreasing intravoxel dephasing of the moving blood. The use of surface coil along with small

imaging voxels has been shown to significantly improve SNR and vessel conspicuity in normal and diseased carotid arteries.³⁶ Three-dimensional TOF is relatively insensitive to slow flow and is effective only for relatively small 3D volumes because blood is saturated by multiple RF pulses while traversing the slab. MRA using 3D TOF with MT has been widely used in routine clinical imaging of the circle of Willis owing to their excellent stationary tissue suppression capabilities.³⁷ Preliminary work with 3D TOF acquired with dual 20- and 60-degree flip angles demonstrates improved SNR and vessel definition.³⁸ Contrast-enhanced 3D TOF imaging has further enhanced detail to near angiographic quality.

In contrast to TOF, the PC angiography technique uses the flow-induced phase variations of the MRA signal caused by the motion of the blood. These phase shifts induced by blood flow can be selectively modulated using bipolar flow-encoding gradients and, therefore, images of flow can be generated. With this strategy, two sets of data are acquired under identical conditions, except that the polarity of the bipolar flow-encoding gradients is alternated during data acquisition. This modulates the velocity-

induced phase shift for spins having macroscopic motion (flowing blood) and has no effect on stationary spins. MRA projections are created by subtracting one data set from another, removing the signal from stationary tissues, and retaining the signal from the flow. Moreover, the phase shift of the image can also be used to obtain a phase map of the image. This phase map is usually displayed in gray scale and indicates the regions where flow has occurred.

The two most popular methods image the slab volume either with sequential time-averaged 2D slices³⁹ or with simultaneous acquisition of 3D volume slabs⁴⁰ and are generally referred to as 2D or 3D phase contrast angiography. The 2D PC angiograms, like 2D TOF, are obtained as sequential individual slices. In 3D PC MRA, the data are collected in three dimensions. This has several advantages over the 2D PC technique, such as isotropic voxels, reduction in phase variations, and flexibility in cross-sectional presentation of the feature of interest. However, the overall imaging time is much higher compared with the 2D technique. In the past few years, cine PC MRA, a variant of 2D PC MRA in which cardiac gating is used to generate images at different points within the cardiac cycle, has become widely used. This method has been used to analyze temporal flow of blood in carotid arteries in the neck⁴¹ and flow of CSF in the brain.⁴²

Neurological Applications in Diagnosis and Treatment Extracranial Disease

CAROTID BIFURCATION LESIONS. One of the primary uses of MRA is the evaluation of the lesions in the carotid artery bifurcation. Atherosclerotic lesions within the carotid bulb and proximal internal carotid artery are major factors contributing to the development of cerebrovascular ischemia. The appropriate treatment of patients with asymptomatic and symptomatic carotid stenosis remains controversial. The North American Symptomatic Carotid Endarterectomy Trial⁴³ and the European Carotid Surgery Trial⁴⁴ demonstrated that patients with transient ischemic attacks or nondisabling stroke ipsilateral to a carotid stenosis of 70% or more have been found to have a significant incidence of further strokes. In a group of patients with asymptomatic carotid stenosis of 50% or more, Hobson and associates and the Veterans Affairs Cooperative Study Group showed that carotid endarterectomy reduced the overall incidence of ipsilateral neurological events in this population.⁴⁵ Although the exact degree of carotid stenosis that would affect patient management (i.e., medical or surgical) has not been definitely determined, these studies have set the current trends. Noninvasive techniques that accurately measure the degree of carotid stenosis will continue to be a very important part in the workup of these patients. Figure 23-18 shows an example of an MRA of a complex stenosis.

The use of gadolinium bolus 2D and 3D TOF MRA leads to greater detection of carotid bifurcation stenosis. Additionally, gadolinium-enhanced MRA has added to the diagnosis of stenosis of the origins of the great arteries. Figure 23-19 demonstrates gadolinium-enhanced MRA of the great arteries and carotid bifurcations.

Atherosclerotic disease is most prevalent at arterial bifurcations and usually involves the carotid bulb of the

Figure 23-19. Gadolinium-enhanced TOF MRA demonstrating normal origins of the great arteries and carotid bifurcations A, AP view. B, Oblique view.

internal carotid artery. The development of plaque and stenosis at the carotid bulb is believed to be related to the anatomy of the carotid bifurcation and associated complex hemodynamic forces that cause microscopic intimal injury and subsequent initiation of the atherosclerotic cascade. The complex flow (vortices, separation of flow streams, and slow flow) within the carotid bifurcation is well demonstrated using computer simulation based on images obtained by digital subtraction angiography (DSA) and MRA.³³

Complex flow is one of the major causes of intravoxel dephasing, which leads to signal loss in MRA. An example of MRA signal loss distal to a carotid stenosis is shown in Figure 23-20. Comparison is made with DSA and computer simulation of temporal blood in this vessel. DSA remains the gold standard to characterize carotid bifurcation disease; however, numerous investigations have shown that noninvasive MRA has the potential to replace DSA as a screening test and obviate the need for diagnostic carotid angiography.^{46,47}

Intracranial Disease

LESIONS IN THE CIRCLE OF WILLIS. The primary uses of circle of Willis MRA are to screen for the presence of unruptured aneurysms that came to medical attention due to incidental discovery by MRI and to assess for the presence of intracranial atherosclerotic disease. The use of MRA as a noninvasive screening test to identify congenital berry aneurysms before rupture in groups at risk (e.g., adult polycystic kidney disease and family history of aneurysm) would also be desirable. Several studies have shown that the sensitivity

Figure 23-20. Carotid bifurcation of patient with atherosclerotic disease. **A**, Selected digital subtraction arteriogram of carotid artery bifurcation showing a mild to moderate (approximately 33%) stenosis in the proximal internal carotid artery. **B**, Axial two-dimensional TOF (surface coil) shows a smooth, approximately 50% stenosis in the proximal internal carotid artery. Exaggeration of the degree and length of stenosis is present. **C** and **D**, Color simulation of vascular flow pattern in the carotid bifurcation in this patient during the acceleration phase of systole. (From Faro SH, Vinitzki S, Ortega HV, et al: Carotid magnetic resonance angiography: Improved image quality with dual 3-inch surface coils. *Neuroradiology* 1996;38:403–408.)

Figure 23-21. A, DSA image shows a well-defined 5- or 6-mm anterior communicating artery aneurysm with distal tip. B, Three-dimensional TOF MRA accurately shows the aneurysm.

Figure 23-22. A, MRV shows loss of flow-related signal in the proximal and distal and straight sinuses (SS) and superior sagittal sinus (SSS) in a patient with dehydration and dural sinus thrombosis. B, Follow-up MRV showed reconstitution of the SSS and SS.

of MRA to detect congenital aneurysms 5 mm or larger is approximately 90%.⁴⁸⁻⁵⁰ Figure 23-21 shows an aneurysm detected with MRA. Aneurysms smaller than 5 mm do rupture, although the incidence is reduced. MRA is considered an accurate noninvasive screening test for patients at risk for aneurysms. Conventional DSA, however, remains the gold standard for preoperative planning as well as for the assessment of ruptured aneurysms resulting in subarachnoid hemorrhage. Nevertheless, MRA frequently may have a complementary role in the assessment of patients suffering subarachnoid hemorrhage when DSA is inconclusive.

OTHER APPLICATIONS. Vascular malformations, either pial (intramedullary) or dural (extramedullary), may be detected with MRA. Serpiginous flow patterns and voids, either within or extrinsic to the spinal cord, can suggest specific diagnoses. Even the presence of unexplained spinal cord edema may suggest angiodysgenic myelomalacia (Foix-Alajouanine syndrome) in the presence of an underlying vascular malformation. Intravenous contrast medium administration in MRI of the spine further aids in the delineation of spinal cord tumors and has proved helpful in the evaluation of the postoperative spine, particularly in the differentiation between nonenhancing recurrent disc herniation and enhancing postoperative scar.

MAGNETIC RESONANCE VENOGRAPHY

The MR method to examine the cerebral venous system including the dural sinuses is MRV. A 2D TOF technique is used, which has the advantage of increased sensitivity to slower-flowing vessels and generally a larger region of coverage in comparison to 3D TOF techniques. Two-dimensional TOF is a slice-by-slice technique, and flow-related signal is maximized when a flowing vessel is perpendicular to the imaging slice. Patients are primarily scanned in the coronal plane using a slice thickness of 1.5 to 2 mm. Coronal imaging maximizes flow in the superior sagittal sinus (SSS) and transverse sinuses. Decreased flow may occur in the distal SSS due to in-plane dephasing artifact (flowing vessel is parallel to the imaging slice). An additional axial 2D TOF MRV through the region of the distal SSS may be used to decrease dephasing artifact. Note that the transverse sinus may be congenitally small (most commonly the left) and may mimic a thrombosed vessel. Examination of the raw data prior to the MIP postprocessing will demonstrate the congenitally attenuated vessel. Patients with the diagnosis of thrombosis of the SSS or transverse sinuses can be assessed and followed with serial MRV studies (Fig. 23-22).

MYELOGRAPHY

Basic Principles and Techniques

Myelography has its “roots” in the early 1900s when subarachnoid injections of air were performed to localize spinal cord tumors. This technique of pneumomyelography was eventually supplanted by the subarachnoid injection of an iodized poppy seed oil, Lipiodol, the myelographic medium of choice during the 1930s. Lipiodol had its disadvantages, including a very high viscosity, its immiscibility with CSF (thereby making it difficult to perform satisfactory diagnostic studies as well as remove on completion of the study), and its irritating nature to the leptomeninges. In 1940, Pantopaque was introduced. This oil-based contrast agent was less viscous and less irritating to the leptomeninges than Lipiodol. Its lower specific gravity allowed it to flow more freely in the subarachnoid space with fewer tendencies to form large irregular globules; accordingly, removal on completion of the study was easier to perform than its predecessor. Pantopaque became the contrast medium of choice in the United States until the late 1970s, although it was still far from being an ideal subarachnoid contrast agent. Its relative immiscibility in CSF resulted in its inability to enter nerve root sleeves, thereby making it difficult to evaluate far posterolateral disc abnormalities. A 20-gauge spinal needle or larger was required during Pantopaque insertion and removal, and the use of this relatively large-sized needle commonly resulted in spinal headaches from CSF leakage at the puncture site. Furthermore, Pantopaque was still difficult to remove in entirety after completion of the study. When left behind, Pantopaque was absorbed slowly at the rate of approximately 1 mL/year and could further produce local changes of arachnoiditis.

In the early 1930s, experimental studies were carried out with Abrodil, a water-soluble organic iodine compound widely used in the Scandinavian countries for lumbar myelography. Abrodil never achieved popularity in the United States as a result of its marked hypertonicity in comparison to CSF, which produced significant irritation to the leptomeninges and neural elements. Water-soluble myelography was revitalized in the United States during the early 1970s with the introduction of Conray and Dimer-X, salts of iodinated acids. These compounds, like Abrodil, caused significant neurotoxic effects, including meningeal and radicular irritation, as a result of their hypertonicity.

As a result of ongoing investigations, metrizamide was marketed as a synthetic nonionic water-soluble contrast medium that had a much lower osmolality than the salts of iodinated acids. This contrast agent provided safe examination of the entire spinal column without significant neurotoxicity.

In recent years, in an attempt to further reduce the incidence of serious side effects, other nonionic water-soluble contrast agents, such as Isovue and Omnipaque, have been synthesized and are now in wide use. In many institutions, iopamidol (Isovue) is used for subarachnoid injections. In the concentration used for lumbar myelography (200 mg iodine/mL), iopamidol is only mildly hyperosmolar compared with CSF (413 vs. 301 mOsm/kg H₂O) and has dramatically fewer neurotoxic side effects than the salts of

iodinated acids. Iopamidol is rapidly excreted in the kidneys, with undetectable plasma levels at 48 hours in the absence of renal dysfunction. The most common adverse reactions are headache, nausea, vomiting, and transient worsening of neck, back, or leg symptomatology. Hypotensive collapse and shock are rare, with only isolated reports found in the literature. The usual recommended adult dose range for iopamidol when performing myelographic procedures is 2000 to 3000 mg iodine. This is equivalent to 10 to 15 mL Isovue-M200, which is used for lumbar myelography, and to 10 mL maximum Isovue-M300, which is used for cervical myelography. Modern myelographic studies are approached via lumbar injection of contrast material, and virtually all patients have a postmyelogram CT evaluation to supplement the conventional diagnostic myelographic imaging procedure.

Before a myelogram is performed, certain information should be obtained from all patients. In those individuals with a prior history of dye allergy, bronchial asthma, hay fever, and food allergies, premedication with corticosteroids and antihistamines is indicated to prevent or minimize possible allergic reactions. Patients should also be well hydrated before and after the myelographic procedure. Dehydration may contribute to acute renal failure in patients with a history of diabetes, advanced vascular disease, or preexisting renal disease. Knowledge as to current prescription and nonprescription medications as well as underlying disease states is extremely important. Specifically, elective studies should not be performed on patients who are receiving oral or intravenous anticoagulants, and the use of aspirin should be discontinued for approximately 48 hours before the myelographic procedure. Drugs that lower the seizure threshold, such as monoamine oxidase inhibitors, tricyclic antidepressants, and central nervous system stimulants, should be withheld for 48 hours before and after the myelographic procedure. Prior to myelography, serum creatinine, blood urea nitrogen, and coagulation profile including prothrombin time, partial thromboplastin time, and platelet counts may be obtained to assess procedure risk, particularly in the elderly population.

During lumbar myelography, a 22-gauge spinal needle is inserted either in the midline between the spinous processes or slightly off midline through the rhomboid fossa at the level of L2-L3 or L3-L4. This puncture site is preferred over the L4-L5 and L5-S1 levels because of the higher incidence of herniated discs and spinal stenosis at these lower levels. Alternatively, if premyelography imaging studies or certain clinical information is available, the puncture site can be performed at these lower lumbar levels when significant disease is known to exist at the level of L2-L3. The lumbar injection should be performed slowly over a period of 1 or 2 minutes to avoid excessive mixing with CSF and subsequent loss of contrast medium as well as premature cephalad dispersion.

In most instances, cervical myelography can be adequately performed by means of a lumbar puncture with subsequent fluoroscopic guidance of a more concentrated dose of contrast medium into the cervical region by gravity. Alternatively, a lateral C1-C2 puncture can be performed with the needle placement in the posterior third of the spinal canal between the C1-C2 neural arches. Intracranial entry of a

bolus of contrast medium should be avoided because this could possibly lead to acute neurotoxic effects.

Meticulous radiographic technique is essential to obtain quality diagnostic examinations. Low voltage (KVp) with optimal milliamperes-seconds (mas) maximizes contrast detail. Air gaps should also be eliminated to reduce scatter and increase edge sharpness. In both the lumbar and the cervical regions, AP, lateral, shallow, and steep oblique views should be obtained with the addition of AP and lateral views of the conus during lumbar myelography. For thoracic myelography, AP and lateral views are routinely filmed.

Postmyelography CT of abnormal lumbar disc levels should be performed in the prone position. Imaging can be deferred for up to 4 hours to reduce the degree of contrast within the desired area to be studied. Before obtaining the postmyelogram CT scan, the patient should be helped to roll over several times to thoroughly mix the contrast medium and avoid pooling in dependent portions of the spinal canal.

Routine postprocedure orders include keeping the patient's head elevated 30 to 45 degrees for 12 to 24 hours with close neurological monitoring. Oral fluids should be encouraged and diet prescribed as tolerated. All movements should be monitored by hospital personnel and performed slowly with the patient's head maintained in an upright position.

Normal Findings

Routinely, with either cervical or lumbar myelography, there is symmetrical filling of the nerve root sleeves without evidence of nerve root displacement or nerve root sleeve truncation. The size and direction of the spinal roots vary at different levels. The largest roots are the lower lumbar and upper sacral roots, which innervate the lower extremities. Accordingly, the roots of the lower four cervical and first thoracic nerves are also large owing to their upper extremity innervation. The upper cervical and remaining thoracic nerve roots are rather small in comparison, and the lower sacral and coccygeal nerve roots are the smallest. Discrepancies in length and direction of spinal nerve roots are secondary to the spinal cord being much shorter than the vertebral canal. In the cervical region, the relatively short nerve root traverses the lower portion of its respective neural canal in a horizontal direction. The thoracic nerve roots are directed obliquely downward, with the length and degree of obliquity increasing from the upper to the lower thoracic levels. Because the spinal cord ends at approximately L1, the lumbar, sacral, and coccygeal nerve roots descend in a nearly parallel course, with the length of the roots increasing successively from above downward. This group of nerve roots below the level of termination of the cord is termed the *cauda equina*. The thecal sac should have a smooth contour without evidence of narrowing or mass effect from extradural abnormalities. There should be smooth tapering of the distal thecal sac at a variable distance below the L5-S1 disc space to a smooth "pencil point" appearance. The silhouette of the cervical and thoracic cord as well as the appearance and position of the conus should be closely scrutinized for intramedullary expansile lesions.

Types of Detectable Abnormalities

The use of water-soluble intrathecal contrast medium has markedly decreased during the past 10 to 15 years with the introduction of CT and, more recently, MRI. Before these more advanced imaging tools, water-soluble myelography was the gold standard in evaluating patients with back pain and had the ability to evaluate spinal stenosis, disc bulges and herniations, other extradural impressions on the thecal sac, spinal cord enlargement, and various inflammatory conditions. However, intrathecal contrast medium enhancement still lacked sensitivity in evaluating lateral disc herniations and specificity in determining the exact cause for extradural impressions on the thecal sac and cord enlargement. With the use of CT and MRI, it is now possible to further define the factors contributing to spinal stenosis and to offer a much more exact and detailed differential diagnosis for the etiology of intramedullary lesions. With this added preciseness has come the general acceptance of these imaging modalities over myelography by other physicians not formally trained in radiological sciences.

Certain situations still warrant the use of water-soluble myelography. In extremely obese patients, in whom image resolution is significantly degraded on both CT and MRI studies, myelography in conjunction with postmyelography CT of abnormal levels still plays an important role in the diagnosis of spinal disease. Likewise, in patients with marked claustrophobia, in patients in whom MRI is contraindicated (e.g., those patients with intracerebral aneurysm clips, pacemakers, transcutaneous electrical nerve stimulation units, or orbital metallic foreign bodies), or in patients with postoperative metallic internal fixation devices, myelography and postmyelography CT remain the imaging studies of choice. In our experience, myelography, in conjunction with postmyelography CT, is as sensitive in the evaluation of subtle cases of arachnoiditis as MRI.

Neurological Applications in Diagnosis and Treatment Extradural Spinal Lesions

The most common disorder seen while performing myelography is the extradural defect. Ventral extradural defects at the level of the disc space are caused by a variety of conditions, including disc bulges, disc herniations, posterior endplate spur formation, epidural hematomas, inflammatory processes, and epidural tumor, with or without associated adjacent bone involvement. Anterolateral extradural defects at the level of the disc space are routinely caused by posterolateral disc herniations, which will also result in nerve root displacement or nerve root sleeve truncation and the classic double-density sign seen on a lateral radiograph with the patient in the prone position (Fig. 23-23). Posterior and posterolateral extradural defects at or near the level of the disc space are usually the result of chronic degenerative changes of the posterior elements, including hypertrophic facet disease, ligamentum flavum hypertrophy, and the occasional synovial cyst arising from a markedly degenerated facet joint. Less common causes include metastatic disease to the posterior elements in association with a posterior epidural tumor component. An anterior or anterolateral extradural defect not limited to the disc space level could be the result of a migrated free disc fragment, epidural hematoma,

Figure 23-23. **A**, Prone cross-table lateral view of lumbar myelogram. Prominent ventral impressions upon the contrast column are present at L3-L4 and L4-L5. Much milder ventral impressions are seen at L2-L3 and L5-S1. A so-called double-density sign consistent with an eccentric posterior disc herniation is present at L3-L4 and L4-L5. **B**, Prone left anterior oblique view of lumbar myelogram. Left-sided filling defects are present at L3-L4 and L4-L5 secondary to eccentric posterior disc herniations at both levels. **C**, Axial CT scans at and just below L3-L4 disc space demonstrate moderate-sized broad-based central and left-sided posterior disc herniation extending into left lateral recess. This eccentric posterior disc herniation would account for the double-density sign seen in part A.

inflammatory process, or metastasis. Far lateral disc herniations within the lateral aspect of the neural canal that extend beyond filling of the nerve root sleeve are radiographically silent on myelography. Similarly, a significant percentage of disc bulges and herniations at the L5-S1 level are nondescript using conventional myelography owing to the rather prominent anterior epidural space at this level that allows for posterior extension of disc material without associated thecal sac compression or nerve root displacement (Video 237, Foot Drop).

Intramedullary Spinal Lesions

Intramedullary lesions causing enlargement of the spinal cord or conus with concomitant narrowing of the adjacent subarachnoid space include primary cord neoplasms such as ependymomas, astrocytomas, and hemangioblastomas; metastases; inflammatory conditions such as sarcoidosis and abscess formation; cord hematomas and infarcts; vascular malformations; and congenital lipomas, dermoids, and epidermoids. Although these groups of lesions will most certainly cause widening of the silhouette of the cord

or conus, the intrinsic pathology and extent of these intramedullary lesions are far better imaged with MRI.

Intradural Extramedullary Spinal Lesions

Intradural extramedullary lesions, such as meningiomas and the majority of neurofibromas, can be adequately studied with myelography followed by CT. Whereas the intrinsic characteristics of these lesions are best evaluated with MRI, myelography and postmyelography CT still play an important role in the presurgical evaluation of these lesions. Subtle cases of arachnoiditis or the determination of the level of a dural tear in a postoperative pseudomeningocele is as adequately visualized with myelography and postmyelography CT as with MRI (Fig. 23-24). Myelography and postmyelography CT are excellent diagnostic tools in evaluating patients with brachial plexus traction injuries presenting with nerve root sleeve tears and nerve root avulsion injuries. The communication of intradural and extradural arachnoid cysts, sacral cysts, and Tarlov cysts with the subarachnoid space can be accurately evaluated with myelography and postmyelography CT.

Figure 23-24. Adhesive arachnoiditis. **A**, Anteroposterior view of lumbar myelogram. The thecal sac below the level of the L2-L3 disc space is narrowed and featureless with central clumping of distal nerve roots giving the appearance of a pseudocord. Note the absence of posterior elements at L3 and L4 secondary to prior decompressive laminectomy surgery. A small amount of contrast has inadvertently been injected into L2-L3 disc space during lumbar puncture. **B**, Postmyelogram CT scan through the L3-L4 disc space. Central clumping of lumbosacral nerve roots with “pseudocord” appearance is once again noted. Large bilobed pseudomeningocele protruding through laminectomy defect into deep and superficial soft tissues represents postoperative complication secondary to dural tear with continued CSF leak.

NEUROANGIOGRAPHY

Basic Principles and Techniques

Diagnostic neuroangiography is the study of the central nervous blood vessels and related cervicocerebral vasculature using radiographs obtained during the simultaneous injection of intravascular contrast media. Cerebral angiography was first introduced by Moniz in 1927 and remains today a vital tool in the neuroradiological evaluation of cerebrovascular diseases. Although neuroangiography had been historically used to evaluate many types of central nervous system diseases, CT and MRI have largely supplanted diagnostic angiography in the primary evaluation of central nervous system diseases.⁵¹ Furthermore, state-of-the-art CT and MRI offer advanced vascular imaging capabilities, yielding excellent “angiographic” types of information. Nevertheless, diagnostic neuroangiography remains the gold standard in the evaluation of vascular diseases related to the head, neck, and spine, and it also provides a platform for neurointerventional procedures.

The goal of neuroangiography is to define and outline the cerebral vasculature for both diagnostic and potentially therapeutic purposes. Typical cerebral angiography is performed using the femoral arterial approach to gain access to the cerebrovascular arterial tree. Alternatively, in selected cases, the axillary, brachial, or direct cervical approaches may be used as necessary. After access, nonselective catheterization of the aortic arch or selective catheterizations of the cervical arteries (specifically, the carotid or vertebral arteries) can be performed. Contrast medium is injected through the catheter with simultaneous radiographic filming of appropriate vascular territories such that diagnostic images of the cerebral vasculature are obtained. Current microcatheter technology also permits superselective angiographic analysis of smaller branch vessels of the brain for both diagnosis and management of intracranial diseases.

Conventional film-screen technology in modern cerebral angiography has largely been replaced by digital subtraction technology. State-of-the-art digital suites now image with a 1024² matrix resolution, providing exquisite vascular detail. In addition, digital angiography allows rapid image acquisition, instantaneous review, and pixel shifting capabilities, providing vascular resolution unsurpassed by conventional filming. For these reasons, conventional film-screen angiography is rapidly becoming outmoded, and most new, dedicated neuroangiographic suites are constructed solely with digital angiographic capabilities.

Normal Findings

Neuroangiography is used today primarily as a diagnostic modality in the evaluation of patients with vascular diseases of the central nervous system. Typical four-vessel cerebral angiography includes selective catheterizations of both internal carotid and vertebral arteries with angiographic filming in the AP, lateral, or oblique planes as needed. Additionally, imaging of the aortic arch as well as the cervical carotid and vertebral arteries may be necessary in the evaluation of many patients suffering cerebrovascular disease. Angiographic filming is acquired during the arterial, capillary, and venous phases because each

phase reveals important vascular information. For example, the arterial phase is critical in the evaluation of entities such as cerebral aneurysms, cervical or intracranial arterial stenosis, or arterial occlusions. In contrast, the capillary and venous phases may reveal important data regarding vascular malformations, tumor neovascularity, venous stenoses, or venous thrombi. The measurement of the intracranial transit time of contrast material may further provide insight regarding focal or diffuse central nervous system abnormalities. Therefore, all phases of the angiographic study can provide important information regarding the overall health of the central nervous system. Yet, angiography maintains flexibility in that studies may be tailored to answer specific clinical questions.

Risks of neuroangiography are generally related to the complexity of the angiographic procedure, with an estimated 1% overall incidence of neurological deficit and a 0.5% incidence of persistent deficit.⁵² Risks include local bleeding or arterial injuries secondary to vascular access. The intra-arterial positioning of an angiographic catheter within the arterial tree carries a risk of injury to the intimal lining of the arterial wall, particularly in patients with pre-existing atherosclerosis. This, coupled with the intra-arterial injection of contrast media, presents a risk of arterial dissection or stroke due to distal embolization. Lastly, there are potential risks associated with the use of iodinated contrast material, including allergic reactions and systemic organ effects such as renal damage. In preparing to study a patient with an allergic history, the current recommendation is 50 mg of prednisone orally 13, 7, and 1 hour prior to the procedure. Diphenhydramine 50 mg orally may also be administered 1 hour prior to the procedure.

Types of Detectable Abnormalities

Angiography may be useful in detecting vascular lesions causing focal or bilateral cerebral dysfunctions, subcortical dysfunctions, or brain stem or spinal cord abnormalities. Abnormal size and contour of the appropriate vessel lumen, abnormal distribution of vessels, and abnormal sequences of vascularization (early or late) can be seen. Additionally, displacement of vessels by extrinsic lesions can be detected along with endovascularization from tumors. In the following section, angiography is discussed in relationship to diagnosis and management of patients with ischemic brain disease, intracranial aneurysms, vascular malformations, and neoplasms. Although intracranial masses and their mass effects classically distort the cerebral vasculature, the primary diagnosis of intracranial masses has shifted to CT and MRI and is not addressed in this section. Angiography is not currently useful in the evaluation of peripheral nervous system or neuromuscular diseases.

Neurological Applications in Diagnosis and Treatment

Cranial Lesions

ISCHEMIC CEREBROVASCULAR DISEASE. Diagnostic angiography in ischemic brain disease allows evaluation of the cerebral circulation from the aortic arch level to the terminal intracranial vessels.⁵³ This provides a thorough evaluation for vascular lesions potentially causing stroke.

Figure 23-25. Arteritis. **A**, Anteroposterior right vertebral angiogram demonstrating diffuse beading of the posterior cerebral arteries. **B**, Lateral view.

Lesions most commonly diagnosed are atherosclerotic in origin. However, stenosis may be secondary to other entities, such as fibromuscular dysplasia, dissection, intimal hyperplasia, or radiation-induced vasculopathy. Cerebral angiography is also useful in evaluating patients with suspected vasculopathies. Angiography can uniquely identify abnormal regions of arterial narrowing or beading as seen in extracranial or intracranial arteritis (Fig. 23-25; Video 95, Brain Stem Infarction; Video 216, Moya Moya Stroke).

A primary goal in cerebrovascular disease therapy is stroke prevention. Hemodynamically significant stenosis carries an increased stroke risk, particularly when involving the carotid artery. Angiography remains key in detecting both extracranial and intracranial disease and allows precise

characterization of inner plaque contour, including assessment of ulceration and stenosis measurement.

Traditionally, surgical treatments such as carotid endarterectomy have been the treatment of choice in the correction of cervical or intracranial stenosis.⁵⁴ A growing literature now supports the use of endovascular techniques as an alternative in controlling cerebrovascular disease.⁵⁵ The use of stent-supported percutaneous transluminal angioplasty (PTA) in the treatment of subclavian, vertebral, or even carotid territory stenosis is growing.⁵⁶ Advancing stent technology has further added to the success of cervical carotid PTA. Cervical carotid PTA trials are ongoing, many of which include the use of distal embolization protection devices (i.e., umbrellas and balloons) (Fig. 23-26). These

Figure 23-26. Carotid stent. **A**, Right common carotid arteriogram demonstrating high-grade internal carotid stenosis at the level of the cervical bifurcation. **B**, Introduction of filter wire providing distal protection. **C**, Post-stent supported angioplasty. No residual internal carotid artery stenosis remains.

techniques will undoubtedly challenge carotid endarterectomy as the treatment method of choice for cervical carotid stenosis.⁵⁷⁻⁶¹ Furthermore, intracranial PTA is now technically feasible in both the carotid and the vertebral territories. Combination therapy may also be considered for tandem lesions.

Stroke literature now supports prompt neurointervention with thrombolytics in patients who generally present with major cerebral arterial occlusive disease within 6 hours of acute neurological symptoms. In these cases, angiography precisely localizes sites of arterial occlusion and accesses collateral vasculature. Microcatheter delivery of thrombolytic agents directly into the occlusive thrombus can potentially reestablish normal arterial flow. This treatment has the potential to avert an impending stroke or significantly reduce the overall extent of cerebral infarction.

Brain infarction or hemorrhage occasionally may result secondary to venous occlusive disease. CT or MRI ordinarily establish the identification of venous thrombus. Angiography or cerebral venography may be necessary when the diagnosis is obscure. Angiography can demonstrate absence of flow within a dural sinus or identify intraluminal filling defects. When necessary, a thrombosed dural sinus can be treated with direct microcatheter delivery of thrombolytics, balloon angioplasty, or thrombectomy devices, resulting in clot lysis. The treatment goal here is to reduce vascular congestion and reestablish normal venous outflow.

ANEURYSMS AND VASCULAR MALFORMATIONS.

Cerebral angiography remains the gold standard in the evaluation of patients suffering from subarachnoid hemorrhage. A complete angiographic evaluation of all cerebral arteries, particularly the circle of Willis bifurcations, is mandatory (Fig. 23-27A). Generally, in cases of suspected brain aneurysm, all cerebral vessels are studied because of the frequency of multiple aneurysms. Standard four-vessel angiography detects aneurysms in 85% of patients who

present with subarachnoid hemorrhage. If initial angiography is negative, repeat angiography is generally indicated in 10 to 14 days, increasing aneurysm detection rate by approximately 5%. Many neurosurgical centers favor prompt neurosurgical or endovascular intervention in cases of acute subarachnoid hemorrhage. This is in an effort to eliminate the incidence of aneurysm rebleeding and sudden death. In addition to standard neurosurgical clipping, various detachable coil devices are now approved for intracranial aneurysm therapy in the United States, offering an endovascular alternative for treatment of intracranial aneurysms⁶² (Fig. 23-27B).

The treatment algorithm of intracranial aneurysms is largely dependent on the age of the patient, location of parent vessel, and the specific aneurysm characteristics (i.e., size, morphology, and neck size) at initial diagnostic angiography. Traditionally, broad-necked aneurysms have been managed with neurosurgical clipping, whereas posterior circulation aneurysms seem more amenable to endovascular coiling. The advent of the Neuroform stent, a microcatheter-delivered nitinol stent, allows for endovascular management of intracranial aneurysms with wide necks greater than 4 mm or a dome-to-neck ratio less than 2 when the parent vessel is greater than 2 mm but less than 4.5 mm.⁶³⁻⁶⁶

Cerebral angiography is pivotal in the evaluation of central nervous system vascular malformations, particularly arteriovenous malformations (AVMs). Although MRI is highly sensitive in detecting central nervous system malformations, precise vascular mapping of AVMs remains essential. Angiography uniquely shows detailed information regarding the angioarchitecture of AVMs (i.e., feeding arteries, nidus, and draining veins) (Fig. 23-28). Also, additional risks for AVM rupture, such as associated feeding arterial pedicle aneurysms or venous stenosis, can be identified. Treatment options, such as surgical resection, endovascular

Figure 23-27. Aneurysm. **A**, Left internal carotid arteriogram demonstrating giant, lobulated internal carotid bifurcation aneurysm. **B**, Appearance following successful GDC coiling.

Figure 23-28. Vertebral angiogram demonstrating a deep left hemispheric arteriovenous malformation fed by the posterior choroidal artery with deep venous drainage.

embolization, radiotherapy, or a combination, remain dependent on precise angiographic characterization.

NEOPLASM. The assessment of neovascularity may be warranted in the evaluation of selected intracranial tumors, particularly when surgical resection is planned. Embolization procedures in these types of cases are not intended to be curative. Rather, embolization is used to reduce blood loss at surgery and help lower overall perioperative surgical morbidity. Intracranially, embolization is most commonly applied to bulky extra-axial tumors such as meningiomas to facilitate surgical resection. Cervical angiography and embolization may be helpful in managing the abnormal vascularity associated with head and neck tumors. These techniques can be useful in patients with paragangliomas of the head and neck, metastatic nodal disease from thyroid or kidney, and Castleman's disease. In these types of cases, the angiographic tumor blush can be quite intense and presurgical embolization can be very helpful.

Spinal Vascular Lesions

Spinal angiography remains key in the analysis of vascular disorders of the spine. Vascular malformations of the spinal cord lead to serious spinal cord morbidity and paralysis. The treatment plan frequently depends on angiographic delineation of these malformations. Angiography delineates the intramedullary or extramedullary location of the AVM nidus, the feeding arteries including their relationship to the artery of Adamkiewicz, and venous drainage (Fig. 23-29).

Neovascularity secondary to spinal cord tumors can be demonstrated angiographically, providing complementary information to CT and MRI. In selected cases, spinal embolization can also be a useful adjunct.⁶⁷ For example,

Figure 23-29. Right vertebral angiogram demonstrating a spinal arteriovenous malformation fed mainly by a vertebral muscular branch vessel. An aneurysm is present on the arterial feeder (arrow).

vertebral hemangiomas, aneurysmal bone cysts, giant cell tumors, or metastatic disease of the spine can demonstrate intense vertebral neovascularity. Preoperative embolization can be valuable to attaining a successful surgical resection.

ULTRASONOGRAPHY

Diagnostic ultrasonography (US) uses sound waves above the audible level to generate diagnostic medical images. US operates on the principles of sound propagation; therefore, the patient is not exposed to ionizing radiation. US has various imaging applications, with specific uses in neurological disorders. It is readily available in hospitals or outpatient imaging facilities, and it typically is less costly than other, comparable diagnostic imaging modalities. Routinely, images are obtained in real time, within a gray scale format. US uses a variety of transducers, which are available for different applications. Diagnostic US can be coupled with Doppler devices, with or without color, allowing flow measurements in vascular structures, such as commonly employed for carotid artery studies.

Basic Principles and Techniques

Ultrasonography depends on the presence of sonographic "windows," which allow sound wave propagation and detection of echo signals. These signals form the basic

sonographic units for image generation. Therefore, as a general rule, US is indicated when visualization of the target object is not blocked by intervening bone or air, such as calvarium or bowel gas. This limitation does not completely negate the use of US in the evaluation of adult brain disorders, as discussed later. The usefulness of US as an imaging tool in pediatrics is particularly appealing owing to its inherent lack of ionizing radiation.

Carotid US consists of gray scale imaging to assess location and extent of plaque and Doppler to measure flow velocities and degree of stenosis. Color may be added to the Doppler to improve visualization of the flow lumen and optimize the Doppler angle.⁶⁸ The term *carotid duplex* represents the union of these entities.^{69,70} Measurements of peak systolic velocity and end diastolic velocity are made in the distal common carotid artery, carotid bulb, and cervical internal carotid artery. Color information enhances the ability of carotid duplex in the identification of maximal flow velocity points and is also useful in allowing precise transducer placement in patients when high-flow jets are encountered.⁷¹

The bony calvarium severely inhibits sound propagation, which has limited the ability of US to directly image the brain in adults. However, research led to the development of transducers capable of measuring intracranial flow velocities of key vascular structures despite the presence of intervening bone. This technology resulted in the development of transcranial Doppler (TCD), the study of the intracranial arteries using the spectral analysis of blood flow velocity. The technique generally employs a 2-MHz pulsed Doppler transducer. Vessel identification is based on the cranial window utilized, transducer position, and depth of sample volume. The direction and velocity of blood flow are recorded, noting the relationship to the terminal internal carotid and response to common carotid artery compression.^{72,73} Unfortunately, TCD may be limited by the thickness of the calvarium, which simply may not allow the measurement of intracranial Doppler signals.

Normal Findings

Direct brain imaging in the pediatric age group is possible owing to the presence of large fontanelles, which normally remain open until age 6 to 9 months and thereby provide adequate windows to extensively image the brain. Routine imaging consists of a series of coronal and sagittal images typically obtained through the anterior fontanelle. Additional views can be obtained through other windows as necessary. Details regarding cerebrum and cerebellum are routinely seen and include views of the cerebral hemispheres, the deep ganglionic structures, thalami, ventricles, and posterior fossa.

Carotid imaging is typically performed with either a 5- or a 7-MHz linear array transducer maintaining a duplex Doppler angle between 30 and 60 degrees and a sample size of 2 to 4 mm. Transverse and longitudinal images of the cervical carotid artery are routinely obtained that provide anatomical detail regarding the cervical carotid bifurcations. Normal flow velocities in the carotid arteries range between 60 and 100 cm/sec. The cervical vertebral arteries can also be evaluated, but this examination is inherently limited owing to the bony spine. The goal of vertebral

artery US is to identify stenotic or occlusive disease or retrograde flow such as seen in subclavian steal syndrome. Representative images can be obtained with Doppler waveforms recording the presence and direction of flow.

Types of Detectable Abnormalities

In infants and very young children, brain structures can be visualized and congenital anomalies thereby detected. Differences in transduction by tissue, fluid, and blood permit a differentiation of hydrocephalus, cysts, and hemorrhage. Various tumors and vascular disorders, especially vascular malformations, can also be detected with US. In newborns up to 6 months of age, spinal cord lesions can also be detected with US because the posterior elements are membranous rather than bony. In adults, US is used primarily for evaluation of vascular lesions of the head and neck, specifically stenosis, obstruction, and dissection.

Neurological Applications in Diagnosis and Treatment Cranial Lesions

INTRACRANIAL HEMORRHAGE AND PREMATURE INFANTS. Due to advances in neonatology, increasing numbers of infants are evaluated for neurological disorders secondary to prematurity. This coupled with primary neurological diseases has led to wide use of US as a leading diagnostic imaging tool in the neurological evaluation of children.⁷⁴ Regions of the brain hemorrhage can be readily diagnosed and graded, typically on a scale of 1 to 4 (Table 23-7). Hemorrhages can range in size from a small, solitary petechial hemorrhage to multiple large parenchymal hemorrhages with associated ventricular changes. Noninvasive follow-up imaging of these hemorrhages can be repeated as necessary without concern for radiation exposure. Small, germinal matrix hemorrhages, common in premature infants, carry the best long-term neurological prognosis (Fig. 23-30). In contrast, intraventricular hemorrhages may be seen in premature infants, representing a higher-grade hemorrhage. Larger parenchymal hemorrhages represent the more severe spectrum of premature brain injury and typically result in long-term neurological deficits. Hydrocephalus may complicate brain hemorrhage, which can be readily diagnosed and followed with US.

CONGENITAL AND ACQUIRED NEONATAL DISORDERS. US can provide useful information regarding other intracranial pediatric abnormalities, particularly in the newborn period. For example, congenital abnormalities

TABLE 23-7

Grades of Intracranial Hemorrhage

| GRADE | DESCRIPTION |
|-------|--|
| 1 | Subependymal hemorrhage into one or both germinal matrices |
| 2 | Germinal matrix hemorrhage with intraventricular extension, no hydrocephalus |
| 3 | Germinal matrix hemorrhage with intraventricular extension and hydrocephalus |
| 4 | Germinal matrix hemorrhage with intraparenchymal extension |

Figure 23-30. Cranial ultrasound of infant demonstrating left germinal matrix hemorrhage (arrow).

such as Chiari malformations, agenesis of the corpus callosum, anencephaly, aqueductal stenosis, holoprosencephaly, and encephaloceles can be evaluated. Congenital pediatric neoplasms that occur in the first year of life such as choroid plexus papilloma and carcinoma, gliomas, primitive neuroectodermal tumors, and vascular disorders (e.g., the vein of Galen malformation) can be elucidated. Infectious diseases of the brain may result in abnormal intracranial fluid collections, complicating meningitis or encephalitis.

US can be useful in providing guidance for needle aspirations of these collections.

Limitations of US include decreased detection rates of convexity lesions, such as extra-axial hemorrhages or masses (i.e., subarachnoid hemorrhage). Periventricular leukomalacia or the effects of perinatal asphyxia can be imaged but can also be challenging to recognize. As necessary, US information can be supplemented by other imaging tests, such as CT or MRI, to improve detection of conditions not recognized by US.

Intracranial Vascular Lesions

The indications for TCD continue to evolve but primarily focus on stroke prevention. TCD is useful in inferring the presence of intracranial stenosis or occlusions of major intracranial arteries and may further document routes of collateral circulation. One important role for TCD is for screening and follow-up of intracranial vasospasm complicating subarachnoid hemorrhage. Vasospasm typically peaks on days 3 through 7 after subarachnoid hemorrhage. TCD is useful in screening these patients for the onset of vasospasm, before clinical symptomatology (Fig. 23-31). This allows for early treatment planning, before the patient becomes symptomatic. TCD can be useful intraoperatively, for example, providing continuous intraoperative recording of the middle cerebral artery during carotid endarterectomy, and, therefore, can help identify patients needing an indwelling shunt. Other developing indications of TCD include screening patients for intracranial stenosis that complicates sickle cell disease, identification of flow disturbances in migraine, and identification of AVMs. In the latter instance, the nidus of AVMs can be analyzed showing routes of supply and drainage and may further show flow reductions in AVMs after interventions. Lastly, TCD may be useful in accessing venous diseases such as sagittal sinus thrombosis and may play a future role in brain death determination.

Figure 23-31. Transcranial Doppler image of the left middle cerebral artery showing elevated flow velocities in the left middle cerebral artery status post subarachnoid hemorrhage consistent with vasospasm.

Vascular Lesions in the Neck

The prevalence of stroke in the United States has led to the development of screening modalities aimed at recognition and correction of stroke risk factors. Increasingly, atherosclerotic disease involving the cervical carotid and vertebral arteries is recognized for its inherent risk in stroke. The Asymptomatic Carotid Atherosclerosis Study demonstrated benefit in ipsilateral stroke reduction with carotid endarterectomy for patients with asymptomatic stenoses of extracranial carotid artery greater than or equal to 60%.⁷⁵ The North American Symptomatic Carotid Endarterectomy Trial demonstrated strong benefit with carotid endarterectomy in symptomatic patients with ipsilateral carotid stenosis greater than or equal to 70%.⁷⁶ Therefore, because the majority of strokes are currently believed to be embolic in etiology, carotid screening becomes justified. The presence of significant stenosis of the carotid bifurcation is now generally accepted as an indication for intervention in both asymptomatic and symptomatic patients.

US of the cervical vasculature has several key advantages compared with other imaging modalities as a screening study.⁷⁷⁻⁷⁹ These include patient comfort, lack of procedure risk, and high sensitivity and specificity in detecting cervical stenosis. Information regarding surface contour and internal characteristics of plaque can be routinely obtained. US limitations include operator dependency and possible error, field of view limitations (thorax inferiorly and the mandible superiorly), technical problems related to vessel tortuosity, and kinking, dense calcifications, and the potential to miss a trickle of blood in cases of high-grade, 99% stenosis. The latter in particular continues to justify the need for additional imaging studies in cases of suspected complete carotid occlusion and in cases in which information beyond the US field of view is needed. Indications for cervical US include

evaluation of cervical bruit, transient ischemic attack, and stroke. Figure 23-32 provides an example of a severe cervical carotid bifurcation plaque with angiographic correlation. US is also useful in following progression of atherosclerosis in cases of known plaque or in detecting other cervical pathologies, such as arterial dissection (Fig. 23-33).

At many institutions, carotid stenosis is graded based on a sliding scale developed by Bluth and colleagues.⁸⁰ Mild carotid stenosis results in broadening of the normal ultrasonic spectral waveform with mild elevation of peak systolic velocity (PSV) due to turbulent flow from small plaques. In contrast, higher degrees of stenosis result in higher flow velocities, which can be seen in both systole and diastole. Generally, PSV greater than 130 cm/sec indicates moderate stenosis, whereas PSV greater than 250 cm/sec indicates severe stenosis. Systolic and diastolic ratios between the stenotic internal carotid artery and the common carotid artery are also calculated and, if increased, may further indicate regions of carotid narrowing. Ratio analysis can aid in identifying false-positive and false-negative results in conditions such as systemic hypertension. Routinely, all high-flow jets are also recorded. A point can be reached at which flow velocities can diminish. These areas can further define abnormal regions of critical carotid stenosis.

Pediatric Spinal Lesions

Imaging of spinal abnormalities is useful in children up to 3 to 6 months of age because the posterior elements are membranous not bony. Beyond this age, these elements calcify and generally US would then need to be complemented with another imaging modality. Early evaluation and differentiation of neural tube defects, such as lipomas, meningoceles, myelomeningoceles, and tethered spinal cord, is possible. US can evaluate the subcutaneous structures and allow for

Figure 23-32. A, Cervical duplex ultrasound showing acoustical shadowing secondary to calcified atherosclerotic plaque. B, Corresponding carotid angiogram confirming stenosis.

Figure 23-33. A, Ultrasound of right internal carotid demonstrating flap consistent with arterial dissection (*arrows*). B, Diagnostic right internal carotid angiogram confirming arterial dissection (*curved arrow*).

recognition of abnormal spinal canal development, including spinal cord abnormalities. Even in older children, the presence of abnormal skull dimples, pores, or hair tufts can be evaluated for underlying spinal dysraphism. Rarely, US can be useful in evaluating spinal neoplasm or syrinx development.

POSITRON EMISSION TOMOGRAPHY AND SINGLE-PHOTON EMISSION COMPUTED TOMOGRAPHY

Basic Principles and Techniques

Kuhl and Edwards⁸¹ pioneered the original work of radionuclide emission tomography in 1963. This research demonstrated the initial use of radionuclide tracers to create axial reconstructed images. It became apparent that the relative low resolution of this technique was a limitation as research began to focus on the functional imaging capabilities of this technique. Early work with CT in the early 1970s demonstrated the correlation between focal lesions in the brain and lesions demonstrated by radionuclide emission tomography. Single-photon emission computed tomography (SPECT) imaging uses radionuclides that release gamma radiation. Gamma cameras detect the radiation released in 360 degrees and create multiplanar re-formations. In the early 1980s, iodine-based radionuclides were initially used to determine symmetrical brain function. The uptake and distribution of such radionuclides within the brain is believed to be proportional to blood flow.⁸² Major breakthroughs occurred in the late 1980s with the introduction of

technetium-99m-labeled compounds, the most common of which was hexamethylpropylene amineoxime (HMPAO).

A second major technique that investigates functional and, to a lesser degree, anatomical details within the brain is positron emission tomography (PET). This procedure uses positron-emitting radionuclides. This is in distinction to SPECT imaging, which uses gamma emitters. Positron-emitting particles decay by releasing two annihilation radiation particles into opposite directions that are separated by 180 degrees. Data are postprocessed and reformatted into multiple planes. Sokoloff et al, in 1977, described the use of the radionuclide ¹⁴C-deoxyglucose.⁸³ This was a major advancement in functional imaging of the brain that enabled the measurement of glucose uptake and metabolism. Soon after, the most commonly used PET agent, ¹⁸F-deoxyglucose (FDG), was introduced. The development of ligands associated with specific neurochemical receptors or other proteins has broadened the use of PET and SPECT to include a growing number of degenerative or biochemical disorders.

Normal Findings

Radionuclides are evenly distributed into the brain parenchyma for both PET and SPECT scanning. The calvarium and ventricles represent photopenic regions. The brain images can be displayed in axial, coronal, or sagittal projections. Under normal conditions, when a subject performs a motor, language, visual, or other sensory task, ¹⁸F-deoxyglucose PET scans will identify increased glucose metabolism in the involved cortical region.

Types of Detectable Abnormalities

SPECT and PET imaging have shown comparable detection of diseased states. In chronic pathological states, the cerebral blood flow demonstrated by SPECT correlates to abnormal metabolic activity that is shown by PET imaging. Unfortunately, PET imaging requires cyclotron-produced nucleotides. This, as well as cost, has limited PET to major research facilities. SPECT imaging is more accessible owing to advances in stability of radionucleotides and in computer technology. These factors have led to a significant increase in the resolution of the SPECT images. Both PET and SPECT can detect generalized hypometabolism in anoxia, degenerative disease, trauma, and aging or a focal hypometabolism. Hypermetabolism due to increased blood flow can be imaged as seen in tumors, infections, or seizure foci. In degenerative illnesses with neurotransmitter defects (e.g., Parkinson's disease and Huntington's disease), focal deficits can be detected, although these applications remain largely in the research realm (Video 18, Limb Chorea; Video 62, Parkinsonian Gait).

Neurological Applications in Diagnosis and Treatment Cerebrovascular Disease

Cerebrovascular disease is the third leading cause of death in the United States. The ability to rapidly diagnose acute stroke has both therapeutic and prognostic value. Acute intra-arterial thrombolysis of a recently formed thrombus is a new pioneering procedure that may significantly decrease the morbidity and mortality of cerebrovascular disease. PET is able to demonstrate a rise in regional oxygen extraction fraction indicating an evolving stroke. These changes are often demonstrated earlier and show more extensive tissue damage than what is predicted by CT or MRI. However, work with diffusion-weighted MRI suggests that this may be the most sensitive imaging study for acute stroke.⁸⁴ In patients with reversible ischemic injury, there is a decrease in regional cerebral blood flow that is termed *misery perfusion*. These patients would have a false-positive PET and SPECT scan. Areas of chronic infarction generally demonstrate decreased regional cerebral blood flow and oxygen and glucose metabolism. SPECT imaging can identify areas of decreased blood flow in patients with acute infarcts not detectable by CT.

A diagnostic test to identify high-risk patients who would benefit from surgical intervention of an arteriosclerotic lesion within the carotid bifurcation can also be of great value. A pharmacological stress test with acetazolamide, which causes cerebrovascular dilatation and increased regional cerebral blood flow, has been investigated.⁸⁵ Others have investigated the prognostic value of the ratio of regional cerebral blood flow to regional cerebral blood volume.⁸⁶ The regional cerebral blood volume can be determined with technetium-99m-labeled red blood cells. As the regional cerebral blood flow decreases, the regional cerebral blood volume increases to maintain perfusion. This procedure has been described as an indicator of cerebral perfusion reserve, thus defining a patient's risk for infarction. SPECT and PET have also demonstrated "luxury perfusion," which represents the areas of subacute stroke that receive increased blood flow in relation to the nonaffected brain. This is most

likely due to an increase in an aerobic metabolism in the region of infarction. SPECT has also demonstrated hypoperfusion of the contralateral cerebellum in patients with cortical strokes termed *crossed cerebellar diaschisis*. This is believed to be secondary to disruption of the corticopontine tracts uniquely seen by SPECT.

Brain Tumors

The majority of tumor investigation imaging has been with PET. FDG is the primary positron emitter used today. In general, high-grade neoplasms demonstrate increased metabolism, whereas low-grade neoplasms demonstrate relatively decreased activity. There has been high correlation between metabolic activity determined by PET and histological grade of the neoplasm.⁸⁷ One of the many uses of PET scanning is to distinguish tumor recurrence from radiation necrosis. Focal areas of decreased metabolic activity help diagnose areas of radiation necrosis, whereas tumor recurrence shows increased metabolic activity. PET remains one of the most sensitive tests to differentiate between these two entities.

SPECT has a more limited role in the evaluation of brain tumors. Some enthusiasm has been displayed with the use of SPECT to differentiate a lymphoma from toxoplasmosis in immunocompromised patients. Imaging with thallium-labeled gamma emitters demonstrates increased activity within lymphomas and decreased activity within toxoplasmosis⁸⁸ (Fig. 23-34).

Dementia

Within the past decade, there has been much excitement about the use of PET and SPECT to evaluate dementia. Alzheimer's disease is the most common cause of dementia in the United States. There have been numerous studies that have described decreased regional glucose metabolism in healthy older subjects within the frontal, parietal, and temporal lobe regions.⁸⁹ Current PET normalizes regional values using internal standards such as the cerebellum or calcarine fissure region. Characteristic patterns of decreased regional glucose metabolism within the parietal and temporal lobes have been described in patients with Alzheimer's disease.⁹⁰ In these patients, there is relative preservation of the calcarine fissure region, sensory motor region, cerebellum, and basal ganglion region. Decreased metabolic rates for oxygen have also been reported in the same regions that demonstrate areas of decreased glucose metabolism in patients with Alzheimer's disease.⁹¹ Patients with progressive Parkinson's disease have a similar pattern to that seen in patients with Alzheimer's disease. Multiple-infarct dementia occurs after multiple lacunar infarctions. PET can therefore demonstrate the corresponding multifocal regions of decreased glucose metabolism⁹² that typify the focal lesions demonstrated by CT or MRI. Significant decreases in glucose metabolism within the frontal and temporal lobes have been described in patients with Pick's disease, which can be detected by PET.⁹³ Patients with Huntington's chorea, a disorder of the extrapyramidal system, have shown a decrease in glucose metabolism within the caudate nuclei (Video 15, Facial Chorea).⁹⁴

Figure 23-34. A 30-year-old HIV-positive male presents with mental status changes. **A**, MR (post-contrast T1-weighted image) demonstrates a focal mass-like lesion with ring enhancement within the right frontoparietal area. The primary differential diagnosis is between lymphoma and toxoplasmosis. **B**, Thallium SPECT scan shows abnormal increased uptake representing a primary CNS lymphoma.

These findings may present before atrophy of the caudate nuclei is demonstrated by CT or MRI.

Decreased regional cerebral blood flow demonstrated with SPECT has shown a similar pattern of decreased glucose metabolism in comparison to PET. Most investigators believe that SPECT is a test of equal sensitivity to characterize dementia.

Cerebral Trauma

In severe head trauma, there is a strong association between a diffuse axonal injury and decreased brain metabolism. It has been demonstrated that diffuse and focal areas of decreased metabolism can recover over time. Correlations have been found between post-traumatic decreases in glucose metabolism identified by PET and decreased regional cerebral blood flow identified with SPECT. Focal lesions identified on CT demonstrate a larger area of abnormal regional cerebral blood flow by SPECT.⁹⁵ A goal of SPECT research in head trauma has been to use this method to characterize prognosis of focal lesions as well as cases of more widespread diffuse axonal injury (Video 242, Post-Traumatic Dystonia).

Seizure Disorders

SPECT and PET have been investigated as complementary noninvasive studies for localization of seizure foci. CT, MRI, and electroencephalography (EEG) are the primary noninvasive methods used to localize an epileptic focus but do not always identify a lesion (Video 78, Frontal Lobe Complex-Partial Seizure). These patients may require invasive placement of depth electrodes to definitively elucidate a seizure focus. SPECT has been helpful in demonstrating regional decreased cerebral blood flow within a seizure focus between seizures and increased regional cerebral blood flow ictally. PET studies have also shown decreased metabolism between seizures within a seizure focus and increased metabolic activity ictally. In both SPECT and PET, up to approximately 80% of patients who demonstrated a focal EEG abnormality also demonstrated an associated perfusion or metabolic activity defect within the same region.²⁵ The rapid availability of cyclotron-produced nucleotides is, again, a limiting factor for the use of PET for

the ictal stage.²⁶ HMPAO is the SPECT radionucleotide of choice. This tracer is taken up by the brain during the first vascular pass and does not redistribute after the first few minutes. Imaging can then be obtained up to 3 or 4 hours after the seizure ictus. There is an additional increased sensitivity if an ictal SPECT scan can be obtained. Research suggests that a more stable SPECT imaging agent, ethyl cystinate dimer, which is chemically more stable than HMPAO, has the potential to become the radionucleotide of choice.

Degenerative Disorders: Parkinson's Disease and Huntington's Disease

PET can use a number of ligands other than glucose, and these applications are of particular interest in neurological disorders involving neurotransmitter abnormalities. Parkinson's disease and Huntington's disease are the prototypical examples (see Chapter 34) of such conditions, but dystonias and other movement disorders have also been studied with PET (Video 65, Dystonic Gait).²⁷ To study the activity of the nigrostriatal dopaminergic system, fluorodopa (a derivative of levodopa) is typically used. Receptor agonists can be used to study postsynaptic function of the same system. Although these ligand "probes" remain research tools, increasing experience may lead to their use in regular clinical neurological practice. In animal models of Parkinson's disease, there is a good correlation between fluorodopa uptake and striatal dopamine content. An even higher correlation exists between uptake and the number of dopamine cells in the substantia nigra zona compacta, an area specifically affected by Parkinson's disease. In patients with severe clinical disability from Parkinson's, fluorodopa scans show lower uptake than those of patients with mild disease (Video 62, Parkinsonian Gait). Possible future applications include its potential use in patients with tremors in whom the diagnosis of Parkinson's disease is clinically unclear. Such scans may also prove useful in monitoring the success of such therapies as tissue transplants. In Huntington's disease, most PET attention has focused on its putative utility in preclinical detection and the monitoring of clinical disease progression (Video 63, Choreic Gait).

ELECTROENCEPHALOGRAPHY

Basic Principles and Technique

Electroencephalography is a noninvasive technique in which the electrical activity of the brain is recorded from the scalp to evaluate the function of the brain. It is thus complementary, rather than an alternative, to neuroimaging techniques. The differences in voltage between electrodes placed in different regions of the scalp are recorded and amplified. The polarity, frequency, amplitude, distribution, and changes with time of this activity are then studied to determine whether the findings are normal or abnormal and whether they suggest any particular type of underlying pathological process.

Electrodes are placed on the scalp based on standardized, internationally agreed locations (the 10–20 system).¹ The potential difference between pairs of scalp electrodes (bipolar derivation) or between individual scalp electrodes and a common reference point such as the linked ears (referential derivation) is then recorded as the electroencephalogram (EEG) on moving paper or viewed on the screen of an oscilloscope. Recordings are made simultaneously from pairs of electrodes in an organized sequence or pattern termed a *montage*, which is generally either longitudinal or transverse in orientation.² In longitudinal montages, recordings are made from electrodes in a sagittal plane; in bipolar derivations, recordings are between linked pairs of electrodes, whereas in referential derivations, the

recordings are between each electrode and the reference point. In transverse montages, recordings are made from electrodes in a straight coronal plane. The recordings are then displayed in anterior-to-posterior or left-to-right sequences.

For recording purposes, the input from each pair of electrodes (or from active and reference electrodes) is connected to the two inputs of a differential amplifier in such a way that the input from the active electrode is connected to input one and from the reference electrode (or, with bipolar recordings, from the more posterior or right-sided electrode) to input two. The recording arrangement is such that an upward deflection indicates either increased negativity at the electrode connected to input one or increased positivity at input two.

In recording the EEG, an attempt is generally made to activate abnormalities by hyperventilation for approximately 3 minutes and also by photic stimulation at flash rates up to 20 Hz. Other common activating procedures include sleep during the recording procedure and sleep deprivation on the night before the examination.²

It is sometimes necessary to monitor the EEG for several days in patients with episodic behavioral disturbances to record during some of the episodes and determine whether they have electrocerebral accompaniments such as occur with epileptic seizures. This can either be undertaken in a long-term video EEG monitoring unit in the hospital or, in some instances, by recording the EEG with an ambulatory

cassette EEG system. The latter approach can be undertaken in the home setting and does not require continuous supervision by specialized personnel. Tapes last for 24 hours and can generally be reviewed in less than 1 hour.³

The traditional method of EEG interpretation depends on visual analysis, which is subjective and very time intensive. Quantitative or automated (computerized) techniques for analysis are being developed but are not yet in widespread use for routine purposes.

It is important to distinguish between cerebral activity and artifactual discharges of biological or nonbiological origin. Bioelectric artifacts include ocular, cardiac, respiratory, movement, muscle, and sweat artifacts. These various artifacts have characteristic appearances that facilitate their recognition. Artifacts may also arise from the equipment or electrodes and especially from variation in electrode impedance. Other artifacts may arise from the environment in which the recording is made, such as from other electrical equipment, intravenous infusion lines, and static electricity generated by nylon clothing.

The electrocerebral activity recorded from the scalp consists not of action potentials but of the summated synaptic potentials from large numbers of cortical neurons. It thus reflects the summated excitatory and inhibitory postsynaptic cortical potentials. This activity is markedly attenuated by the skull and scalp and is therefore considerably greater when recorded from the cortical surface.

Normal EEG Activity

The cerebral activity recorded at electroencephalography is generally rhythmic; that is, it consists of regularly recurring waveforms of similar duration and morphology. It is widely believed that the rhythmicity is imposed on the cerebral cortex by a thalamic pacemaker.⁴

Activity recorded in the human EEG is characterized by its frequency. In normal adults, a posteriorly predominant 8- to 12-Hz rhythm is present and is attenuated by eye opening; this is designated the alpha rhythm (Fig. 24-1). Faster-frequency activity, or beta activity, is also present to a variable extent, has a generalized distribution, and is enhanced by certain medications such as benzodiazepines. Activity slower than 8 Hz is designated as theta (4–7 Hz) or delta (<4 Hz) activity. Such slow activity is a normal feature of certain stages of sleep but is generally not present in awake, alert adults.

Abnormal EEG Activity

The pathophysiology of abnormal EEG activity is multifactorial and difficult to clarify. Increased excitability of the cerebral cortex probably accounts for cortical spike activity. More generalized spike-wave bursts probably depend on thalamocortical projections. The delta activity recorded in certain pathological circumstances probably reflects lesions involving predominantly the cerebral white matter. When subcortical nuclei are involved, either alone or in association with pathology affecting the cerebral cortex, paroxysmal slow activity is seen and may include spike discharges.⁵

Slow activity sometimes occurs with a localized distribution and varies in rhythm, rate, and amplitude with time.

Figure 24-1. A posteriorly predominant 9-Hz alpha rhythm is present when the eyes are closed and is attenuated by eye opening in the EEG of this normal subject. Electrode placements in this and succeeding figures are as follows: Fp, frontopolar; F, frontal; C, central; P, parietal; O, occipital; T, temporal; A, earlobe; Sp, sphenoid. Right-sided placements are indicated by even numbers, left-sided placements by odd numbers, and midline placements by Z.

Such a focal polymorphic slow-wave disturbance, when present continuously, suggests an underlying structural lesion involving the cerebral white matter (Fig. 24-2) but provides no clue as to its nature. Transient polymorphic slow-wave activity is suggestive of either migraine or a postictal state after a partial (focal) seizure.

Intermittent rhythmical slow activity may occur with a frontal emphasis in adults or an occipital emphasis in children and is a nonspecific finding that has been described in a variety of settings, including metabolic disturbances, hydrocephalus, and diencephalic lesions.

A diffusely slowed record during wakefulness is nonspecifically abnormal but is seen most commonly in patients with diffuse encephalopathic processes such as a metabolic disturbance or encephalitic disorder (Fig. 24-3). It may also reflect long-standing diffuse cerebral dysfunction such as occurs in patients with a perinatal static encephalopathy.

Focal attenuation of EEG activity reflects destructive disease of the cerebral cortex, whereas more diffuse attenuation may result from severe encephalopathic processes and occurs also in certain degenerative disorders such as Huntington's disease. Electrocerbral silence or

Figure 24-2. EEG showing a focal polymorphic slow-wave disturbance in a patient with a right frontal glioma.

inactivity, in recordings made under conditions to enhance the presence of any underlying low-voltage EEG activity, is suggestive of neocortical brain death but may also occur in patients who are hypothermic or have taken an overdose of drugs that depress the central nervous system (CNS) (Fig. 24-4).⁶ In some instances, the EEG consists of bursts of mixed-frequency activity occurring on a relatively quiescent background. This so-called burst-suppression pattern may occur with any severe encephalopathy, such as after severe cerebral anoxia or after head trauma, after overdose of CNS depressant drugs, and with anesthesia.

Epileptiform discharges consist of abnormal paroxysmal events containing sharp waves or spike discharges, at least in part. A spike discharge is a potential having a sharp contour and a duration of less than 80 msec, whereas a sharp wave has a duration of between 80 and 200 msec. They may occur without any clinical correlates or significance but are found interictally with a greater incidence than normal in patients with epilepsy.

Periodic lateralized epileptiform discharges are lateralized epileptiform discharges that occur with a regular periodicity. They occur in association with acute hemispheric pathology such as an infarct or rapidly expanding tumor,^{7,8} typically in obtunded patients with a focal neurological deficit and often recurrent seizures, and are commonly replaced after several weeks by a continuous polymorphic slow-wave disturbance.

Repetitive complexes consisting of slow waves, sharp activity, or both occur with a regular periodicity and generalized distribution in various disorders. Such periodic complexes are especially characteristic of certain infective disorders of the brain but may also occur after severe cerebral anoxia, head injury, or generalized seizures; with deep anesthesia; and in cerebral lipidosis.

Certain EEG patterns are worthy of mention because they are frequently regarded as abnormal when, in fact, they are simply normal variants of no pathological significance. Such patterns include 14- and 6-Hz positive spikes,

Figure 24-3. Diffusely slowed EEG in an obtunded patient with a metabolic encephalopathy.

small sharp spikes (sometimes referred to as benign epileptiform transients of sleep), wicket spikes, 6-Hz spike-wave activity, and rhythmical temporal bursts of sharpened theta activity, all of which occur most commonly during drowsiness or light sleep.²

Clinical Uses of the EEG

The EEG is useful in the evaluation of patients with several types of neurological disorders, including seizures,

encephalopathy, and focal cerebral abnormalities. It also provides an ancillary aid to the diagnosis of brain death and may suggest certain specific neurological diagnoses when characteristic EEG findings are recorded in patients with clinical disorders of uncertain nature.

Epilepsy

The EEG is important in the evaluation of patients with known or suspected epilepsy. The interictal occurrence of epileptiform activity in a patient with an episodic behavioral disorder that may represent seizure activity increases markedly the probability of epilepsy.⁹ In patients with epilepsy, the EEG findings help to classify the seizure disorder, often permitting a distinction between seizure types when this cannot be made clinically. For example, the EEG findings permit typical absence seizures to be distinguished from complex partial seizures and generalized seizures to be distinguished from partial seizures having rapid secondary generalization (Fig. 24-5; Video 74, Secondary Generalized Seizure; Video 248, Complex-Partial Seizures with Automatisms). Such findings therefore suggest the appropriate anticonvulsant drug for treating individual patients and provide a guide to prognosis. A guide to prognosis is also provided by the background EEG activity; a slowed background implies a poorer prognosis than otherwise. In addition, the EEG permits certain epileptic syndromes with specific prognostic implications to be recognized. For example, benign rolandic epilepsy of childhood

Figure 24-4. Electrocerebral silence in the EEG of a brain-dead patient following attempted resuscitation after cardiopulmonary arrest.

Figure 24-5. EEG in a woman with complex partial seizures, showing focal spike discharges in the right central region.

has a characteristic interictal EEG pattern (rolandic spikes) and a good prognosis, whereas anterior temporal spike discharges are typically associated with complex partial seizures and imply a poorer outcome.

When surgery is under consideration for the treatment of medically intractable seizures, the EEG has a major role in localizing seizure foci, provided that actual seizures can be recorded. This generally requires admission to a hospital, where the EEG can be recorded continuously while patients are video monitored.

The interictal EEG findings may suggest certain characteristic seizure disorders. *Hypsarrhythmia* refers to a pattern characterized by high-voltage, irregular slow activity with superimposed multifocal spike discharges. It is typically found in children with infantile spasms, although some children with infantile spasms do not have this EEG pattern and it is sometimes found in patients without infantile spasms.¹⁰ Generalized spike-wave activity suggests primary generalized epilepsy when it occurs interictally at 3 Hz and is bilaterally symmetrical and bisynchronous (Fig. 24-6) and Lennox-Gastaut syndrome when it is at 1 to 2 Hz and irregular in frequency and morphology. Polyspike-wave activity occurs with myoclonic epilepsy, including juvenile myoclonic epilepsy of Janz.

The ictal EEG recorded during a tonic-clonic convulsion is always abnormal, but the findings may be obscured by muscle and movement artifact (Video 77, Clonic Seizure). A transient attenuation of ongoing electrocerebral activity

or the development of low-voltage fast activity heralds the onset of the seizure (Fig. 24-7), followed by the appearance of rhythmic, repetitive activity at approximately 10 Hz that gradually becomes intermixed with increasing amounts of slow activity until the record is characterized by spike-wave activity as the tonic phase of the seizure is succeeded by the clonic phase. This is followed in turn by a transient attenuation of the background EEG and then by irregular slow activity before the EEG reverts to its preictal appearance. During tonic seizures, the EEG shows generalized, repetitive spike activity or an attenuation of the ongoing background activity. During a typical absence attack, by contrast, the EEG is characterized by 3-Hz spike-wave activity, and during myoclonic seizures it is characterized by polyspike-wave activity at 4 to 5 Hz. The EEG may show no ictal accompaniments during simple partial seizures, and this should not be taken to imply that the seizures are nonorganic in origin. In other patients with such seizures and in those with complex partial seizures, the EEG shows rhythmic, organized, localized discharges (Fig. 24-8) with or without spike activity that may become more generalized as the seizure proceeds and may be followed postictally by a transient flattening of the traces and then by polymorphic slow activity with a localized or generalized distribution.

During tonic-clonic (major motor or grand mal) status epilepticus, the EEG shows repeated electrographic seizures. The EEG is not required for diagnostic purposes,

Figure 24-6. Burst of generalized 3- or 4-Hz spike-wave activity occurring interictally in a patient with primary generalized epilepsy.

however, except when patients have been paralyzed pharmacologically to facilitate management; when coma has been induced to control refractory status, the EEG has an important role in monitoring the level of anesthesia. In patients with nonconvulsive status epilepticus, the basis for the abnormal mental status can only be recognized by the EEG finding of continuous, generalized spike-wave activity (so-called spike-wave stupor) or repeated partial seizures. This underscores the importance of obtaining an EEG in any patient with a change in mental status of uncertain basis.

Focal Cerebral Pathology

With the advent of new imaging techniques, the role of the EEG in screening patients for suspected focal intracranial pathological processes has declined, except in developing countries. In fact, the EEG detects disturbances of function, whereas imaging procedures detect structural abnormalities so that the two approaches are complementary, not alternatives. EEG abnormalities are sometimes generalized in patients with focal intracranial pathology, detracting from the value of the technique in localizing the lesion but emphasizing its importance in reflecting the extent of functional impairment. Thus, generalized slowing of the EEG commonly reflects a disturbance in the level of consciousness. Even when focal abnormalities are present, they generally provide no indication as to the nature of the underlying pathology. They typically consist of a localized slow-wave disturbance (see Fig. 24-2) or an attenuation of

background electrocerebral activity, sometimes accompanied by focal spikes or sharp waves.

Abnormal States of Consciousness

The EEG is an important means of investigating patients with a disturbance of consciousness. It may suggest the cause of the abnormal mental state, helps to determine the depth of coma, and provides a guide to prognosis. Moreover, the EEG is an important means of distinguishing between unconscious states and neurological disorders simulating unconsciousness, such as the locked-in syndrome, in which the EEG is normal or shows only minor nonspecific changes.

In patients with a disturbance of consciousness due to diffuse cerebral dysfunction, the EEG typically shows generalized slowing (see Fig. 24-3) without focal or lateralizing features. In some metabolic encephalopathies, triphasic waves are conspicuous, but these are a nonspecific finding. When epileptiform discharges or electrographic seizures are found in the EEG, they suggest that a postictal state or status epilepticus is responsible for the obtundation.

In coma after head injury, the EEG is likely to be diffusely slowed, but focal abnormalities (slowing, spike discharges, or an attenuation of activity) may be superimposed. These localized abnormalities may relate to hematoma or cerebral contusion, ischemia, or edema.

Alpha-pattern coma designates coma associated with alpha-frequency activity in the EEG. The alpha-frequency activity is usually widespread in distribution and nonreactive to external stimuli. It is found most commonly after pontine strokes and occasionally with a drug overdose. Alpha-pattern coma was originally thought to imply a poor prognosis, but the outlook relates more to the cause of the coma than to the presence of alpha-frequency activity in the EEG.^{11,12}

In some comatose patients, the EEG shows a burst-suppression pattern, indicating a severe encephalopathic process such as an anoxic encephalopathy. The finding of electrocerebral silence indicates that irreversible brain damage and neocortical brain death have occurred. A similar finding may also relate to hypothermia or the presence of CNS depressant drugs, however, and these conditions must always be excluded before prognostic implications are ascribed to the EEG changes.

Other Applications

In patients with encephalitis or meningoencephalitis, the EEG typically shows diffuse slowing without any specific features. However, characteristic abnormalities are found in certain infectious disorders of the brain. In herpes simplex encephalitis, periodic lateralized complexes may occur over one or both temporal regions, usually repeating once every 1 to 4 seconds (Fig. 24-9).¹³ These discharges may take up to 2 weeks to develop, and their absence does not exclude the diagnosis. Their presence provides strong support for it, however, and their bilateral occurrence implies a poorer prognosis for survival than otherwise. In subacute sclerosing panencephalitis, generalized periodic complexes are seen, often lasting for up to 3 seconds

Figure 24-7. EEG recorded at the onset of a generalized clonic-tonic-clonic seizure, showing the development of bisynchronous low-voltage generalized fast activity that then becomes intermixed with increasing amounts of slow activity as the seizure continues.

Figure 24-8. Repetitive focal spike activity arising in the right anteromesial temporal region (right sphenoidal electrode at Sp2) at the onset of a complex partial seizure in a patient with epilepsy.

Figure 24-9. Repetitive complexes occurring in the right temporal region of a child with herpes simplex encephalitis.

and with an interval of 3 to 15 seconds between complexes. A similar pattern is sometimes observed in patients who have taken phencyclidine.¹⁴ In Creutzfeldt-Jakob disease (Fig. 24-10), periodic complexes are typically triphasic in configuration and occur at a rate of approximately 1 Hz. Their occurrence in patients with a rapidly progressive dementia strongly supports the diagnosis.^{15,16}

The EEG findings are of little relevance to the diagnosis of migraine. They are usually normal, but focal or generalized slow activity may be found, especially during or immediately after migrainous attacks. Epileptiform transients are also encountered in some patients.

Figure 24-10. EEG of a patient with Creutzfeldt-Jakob disease showing periodic complexes that often have a triphasic configuration.

Abnormalities may be found in demented patients and consist usually of a nonspecific loss of the alpha rhythm and the presence of excessive slow activity. Focal slowing may also occur, especially in Alzheimer's disease. A normal EEG in no way excludes a diagnosis of dementia, but a diffusely abnormal record supports a diagnosis of dementia as opposed to pseudodementia. The EEG findings may suggest the cause of the dementia, such as in Creutzfeldt-Jakob disease or subacute sclerosing panencephalitis, or when a focal structural lesion is present (Video 50, Myoclonus in Creutzfeldt-Jakob Disease).

The EEG findings after head trauma reflect the severity of injury and level of consciousness. They do not improve the ability to predict which patients are likely to develop post-traumatic epilepsy.

POLYSOMNOGRAPHY

Basic Principles and Technique

Disorders of sleep are common and often respond well to treatment. Polysomnography is important in diagnosing and characterizing such disorders. It involves recording the EEG on two or a few channels to characterize the stage of sleep while recordings are also made of eye movements, mentalis muscle activity (chin electromyogram), electrocardiogram, respiration, and oxygen saturation. Respiratory movements are recorded by measurement of airflow through the nasal passages and the mouth using thermistors and by recording thoracoabdominal excursions with surface electrodes. Oxygen saturation is measured using an ear oximeter. A microphone can be taped to the face to record snoring.

Normal Polysomnographic Findings

The EEG shows a characteristic sequence of events during sleep. During drowsiness (stage 1 sleep), the alpha rhythm is attenuated and the background consists of mixed frequencies. Rolling eye movements are characteristic. During stage

2 sleep, the background EEG consists of diffuse theta and slower activity superimposed on which are vertex sharp waves, sleep spindles (bursts of 12- to 14-Hz activity that occur bilaterally in the central regions), and K complexes (high-voltage slow-wave complexes). During slow-wave (stages 3 and 4) sleep, high-voltage theta and slower activity is present, with activity at 2 Hz or less being present for up to 50% of the time in stage 3 sleep and for more than this in stage 4 sleep. Tonic activity is present in the mentalis muscle during these stages of sleep. During rapid eye movement (REM) sleep, the EEG resembles that of stage 1 sleep, but rapid eye movements occur in all directions and tonic muscle activity is either absent or markedly reduced.

Sleep goes through these various stages sequentially from stage 1 to stage 4 and then back to stage 2 over approximately 90 minutes, following which REM sleep occurs. Such sleep cycles usually occur approximately three or four times each night, with the amount of REM sleep increasing in later cycles.

Abnormal Findings and Clinical Uses of Polysomnography

Polysomnography is important in the investigation of patients with excessive daytime somnolence, disorders of initiating and maintaining sleep, disorders of the sleep-wake cycle, and disorders associated with certain sleep stages (parasomnias).

It is important in confirming the existence of insomnia and characterizing its nature by determining, for example, whether it is associated with nocturnal myoclonus or periodic leg movements. Some patients complain of insomnia but, in fact, have a normal amount of sleep. Patients with complaints of excessive daytime somnolence may have sleep apnea, which can be diagnosed by polysomnography. Apnea is defined in this context as the cessation of airflow

at the mouth and nostrils for at least 10 seconds, whereas hypopnea refers to a reduction in respiratory airflow to one-third of its basal value, with an associated reduction of abdominal and thoracic respiratory movements and a decline in oxygen saturation. The number of respiratory irregularities per hour of sleep can be calculated by dividing the number of apneic and hypopneic episodes by the total sleep time in minutes and multiplying the result by 60. A value of 5 or less is regarded as within the normal range.¹⁷ Polysomnography further indicates whether sleep apnea syndrome relates to a central disturbance, an obstructive disturbance in the oropharynx (Fig. 24-11), or a mixed disorder. Sleep apnea is dangerous because various cardiac abnormalities may occur during the apneic episodes, sometimes resulting in death. Polysomnography permits the severity of the syndrome and the presence of cardiac abnormalities to be determined, thereby indicating the need for prompt therapeutic intervention.

Another important cause of excessive daytime sleepiness is narcolepsy, which is diagnosed by the multiple sleep latency test. This quantifies the time required to fall asleep and allows the recognition of abnormally short latencies for going into REM sleep.^{18,19} Patients are monitored for five periods of 20 minutes at intervals of 2 hours, during which they are allowed to fall asleep; between these periods, they are kept awake and alert. A mean daily score of less than 5 minutes indicates a pathological level of daytime sleepiness. The number of sleep-onset REM periods (with REM sleep occurring within 15 minutes of sleep onset) is determined. Normally, REM sleep does not occur during these periods; two sleep-onset REM episodes strongly support a diagnosis of narcolepsy. The sensitivity and specificity of the test, however, are not clearly defined.²⁰

Certain complex behavioral disorders may disrupt sleep. These parasomnias are best characterized also by polysomnography (Video 241, REM Behavioral Disorder;

Figure 24-11. Polysomnogram of a patient with obstructive sleep apnea. An obstructive apneic episode is seen during REM sleep and is characterized by cessation of airflow associated with oxygen desaturation, accompanied by attempted respiratory movements of the thoracic and abdominal musculature.

Video 251, Periodic Leg Movements). They tend to occur particularly during slow-wave sleep, and precise diagnosis facilitates appropriate treatment. In other patients, seizures may occur during sleep and these can be recognized by the study. Further discussion of sleep disorders is provided in Chapter 54.

OVERVIEW OF EVOKED POTENTIALS

Stimulation of certain sensory systems leads to the generation of cerebral potentials that can be recorded over the scalp with surface electrodes. The latency and morphology of these evoked potentials depend on the eliciting stimulus. Evoked potentials are generally of low voltage and are intermixed with background EEG activity. For this reason, they are not easily seen without computer averaging of a number of responses so that signals that are time locked to the stimulus are enhanced, whereas other electrocerebral activity is averaged out.

Evoked potential recordings provide a means of detecting lesions in the afferent pathways under study. They assess the functional integrity of these pathways, whereas imaging techniques such as magnetic resonance imaging evaluate their anatomical basis. Thus, evoked potential studies sometimes reveal abnormalities missed by magnetic resonance imaging and vice versa. The findings may be important for diagnostic purposes, in following the course of certain neurological disorders, or for determining the extent of pathological involvement.²¹ In patients with known pathological processes involving the CNS, evoked potential studies help to detect and localize lesions. Subclinical abnormalities may be detected in a variety of disorders, and multifocal abnormalities occur not only in multiple sclerosis but also in a variety of different settings. The electrophysiological findings must therefore be interpreted in the clinical context in which they are obtained. Evoked potential studies are also helpful in the evaluation of ill-defined complaints to categorize more precisely the functional integrity of any afferent pathways that may be responsible for the symptoms in question.²¹

The clinical utility of the various evoked potential studies in widespread use depends on the context in which they are obtained. Although some investigators have attempted to localize lesions on the basis of the electrophysiological findings, precise localization by this approach may not be possible. The generators of many of the recorded components are not known with confidence, and some components may have multiple generators.

Evoked potentials have been used to monitor neural structures at risk during surgical procedures, such as correction of scoliosis, in an attempt to minimize or prevent neurological damage. When an evoked potential abnormality occurs during the surgical procedure, it is hoped that alteration or reversal of the procedure may prevent or minimize damage. However, the utility of intraoperative monitoring is not well established in most circumstances. Moreover, even if an electrophysiological change occurs intraoperatively, it sometimes remains unclear whether this simply predicts an adverse outcome rather than actually permitting that outcome to be prevented if the surgical technique is modified. Nevertheless, in limited contexts,

it is clear that intraoperative monitoring is beneficial. During posterior fossa surgery, for example, recordings of brain stem auditory evoked potentials are helpful in monitoring the status of the eighth cranial nerve to prevent its damage, and stimulation of the seventh cranial nerve aids in identifying this nerve and ensuring its functional continuity. Similarly, somatosensory evoked potential studies to monitor spinal cord function seem to reduce the morbidity associated with the surgical correction of scoliosis.

VISUAL EVOKED POTENTIALS

Basic Principles and Technique

Monocular stimulation generates a cerebral response that is best recorded over the occipital region. Either a flash or a pattern that occurs without change in background luminance can be used to elicit the response. Responses to approximately 100 stimuli are generally averaged to obtain robust and unambiguous potentials. For pattern stimulation, the seated subject looks at the center of a television screen on which is displayed a checkerboard pattern of white and black squares. The pattern reverses at approximately 1 Hz so that the white squares become black, and vice versa, without change in total luminance. The size of the checks is usually between 15 and 50 minutes of arc at the subject's eye, and the entire pattern should subtend at least 10 degrees of visual angle. Pattern-reversal stimuli generate robust responses and have a higher yield of abnormalities than flash stimuli. Small checks (15–30 minutes) preferentially activate the macular region and are the most widely used stimulus.

Normal VEP Findings

The typical visual evoked potential (VEP) elicited by a pattern-reversal stimulus is a negative-positive-negative complex that is recorded maximally in the midoccipital region with reference to either the midfrontal region or the linked ears.²² The positivity is the most conspicuous and consistent of these potentials and has a latency to its peak of approximately 100 msec (Fig. 24-12). It is therefore called the P100 response, and it is to this component that attention is directed.

In analyzing the VEP, the latency of the P100 response is measured after stimulation of each eye and then the interocular difference in latency is determined. These values are compared with normal values obtained using an identical stimulation and recording technique. This is important because certain physical attributes of the stimulus (e.g., its contrast or the check size) normally influence the response latency. The amplitude of the response and the latency of the preceding and succeeding negativities (the N75 and N145, respectively) are of uncertain clinical utility, but absence of the P100 is abnormal.

Abnormal Findings and Clinical Uses of the VEP

Visual evoked potentials are useful in evaluating the function of the anterior visual pathways. They are not useful in evaluating lesions posterior to the optic chiasm.

Figure 24-12. Visual evoked potential elicited by 50-minute checks and recorded between the midoccipital and midfrontal regions with monocular stimulation in a normal subject (A) and a patient with a past history of optic neuritis (B). Two trials are superimposed to show the replicability of the findings. The P100 response in part B is prolonged to 146 msec.

In patients with an acute optic or retrobulbar neuritis, the P100 response is initially lost; with time, it recovers and is then found to have a markedly prolonged latency that generally persists indefinitely (see Fig. 24-12),^{23,24} even if apparently complete clinical recovery occurs. The VEP is therefore an important means of evaluating patients with suspected optic neuritis and may be delayed even when magnetic resonance imaging of the optic nerve is normal.²⁴ Abnormalities may relate to either recent or long-standing pathological processes. The VEP may be abnormal in patients without a past history of optic neuritis, thereby providing evidence of subclinical involvement of the optic nerve. For this reason, it is useful to record the VEP in such patients when multiple sclerosis is a diagnostic possibility.²⁵

Other disorders may also lead to VEP abnormalities. In particular, ocular pathology (e.g., refractive error, inability to focus on the pattern stimulus, or glaucoma) may be responsible. Compressive, ischemic, toxic, or nutritional optic neuropathies may also produce VEP changes, and abnormalities occur in Leber's hereditary optic atrophy (Video 200, Afferent Pupillary Defect).^{26,27} Compressive lesions of the optic nerve typically lead to VEPs that are markedly abnormal in shape as well as delayed in latency²⁸; in ischemic or toxic neuropathies, the response is usually markedly attenuated in amplitude without being delayed significantly.²⁶ The findings, however, have to be interpreted in the clinical context in which they were obtained.

The VEP findings are of little help in the evaluation of lesions posterior to the optic chiasm. It has been suggested that VEPs can be used to evaluate the visual fields, but the approach is time-consuming, requires the close cooperation and attention of patients, and is no better or even less sensitive than standard tests of perimetry.^{29,30} In patients with cortical blindness, the VEP may be normal or abnormal; the presence of a normal response should therefore not lead, in itself, to a diagnosis of nonorganic visual loss.³¹

The pattern-elicited VEP can be used to measure refractive error or detect amblyopia in preverbal children who are unable to cooperate for behavioral testing.³² For refractive purposes, the VEP is recorded while different lenses are placed in front of the eye to determine the lens with which the VEP to small (15-minute) checks is of largest amplitude and shortest latency; this lens will be the optimal one for the patient. By an analogous approach, the interocular difference in size of the VEP elicited by small checks is important as a means of detecting unilateral amblyopia at an early age, when recovery may still be possible.

BRAIN STEM AUDITORY EVOKED POTENTIALS

Basic Principles and Technique

Potentials generated in the auditory nerve and in different regions of the auditory pathways in the brain stem can be recorded at the vertex of the head after auditory stimulation.³³ These brain stem auditory evoked potentials (BAEPs) occur within 10 msec of the stimulus, which for clinical purposes is a monaural click. This is usually set at approximately 65 dB above the patient's hearing threshold and is delivered through earphones while the opposite ear is masked by white (i.e., mixed-frequency) noise. The attention of the subject is not required. Because the BAEP is of very low voltage, between 1000 and 2000 responses are generally recorded so that the BAEP can be extracted by averaging from the background noise.

Normal BAEP Findings

The BAEP consists of a series of up to seven components (identified by Roman numerals) that occur within 10 msec of the click stimulus and are generated in different regions of the peripheral and central auditory pathways. Wave I and the early part of wave II represent the auditory nerve action potential. Wave III probably arises in the region of the superior olive, whereas waves IV and V arise in the midbrain and inferior colliculus. Waves VI and VII are of uncertain origin and, because of their inconsistency in normal subjects, are of little clinical utility.

The most consistent components are waves I, III, and V, and it is to these that attention is directed when BAEPs are evaluated for clinical purposes. The absolute latency of these components, the intervals between them (the so-called interpeak latencies), and the amplitude of wave V relative to wave I are assessed. Interside differences in interpeak latency are also measured and may reveal minor abnormalities. Figure 24-13 illustrates a normal response.

Abnormal Findings and Clinical Uses of the BAEP

The BAEP is an important means of evaluating function of the eighth cranial nerve and the central auditory pathways in the brain stem.

In infants, young children, and adults who are unable to cooperate for behavioral testing, BAEPs can be used to evaluate hearing.³⁴ The wave V component of the response is generated by auditory stimuli that are too weak to generate

Figure 24-13. Brain stem auditory potential elicited by monaural stimulation at 75 dB SL and recorded with an ipsilateral mastoid reference in a normal subject (A) and a patient with a structural lesion involving the upper pons (B). Two trials are superimposed to show the replicability of the findings. It can be seen that waves IV and V are markedly attenuated in the response recorded in part B.

other components. As a screening test of hearing, then, the electrophysiological threshold for eliciting wave V is determined. An impairment of auditory acuity is suggested if a stimulus intensity greater than 40 dB is required. BAEPs provide a sensitive screening test for acoustic neuromas or other lesions in the cerebellopontine angle involving the eighth cranial nerve. Indeed, the BAEP findings may be abnormal at a time when imaging studies show no definite abnormality.

The BAEP is also useful in assessing the integrity of the brain stem (see Fig. 24-13). Although the auditory pathways have a bilateral course, a unilaterally abnormal BAEP nevertheless suggests an ipsilateral, structural brain stem lesion. The presence of normal BAEPs in comatose patients suggests either that the coma is due to bihemispheric disease or that it relates to metabolic or toxic factors; abnormal BAEPs in this context imply brain stem pathology and a poorer prognosis than otherwise. When coma is due to brain stem pathology, the BAEP findings help in localizing the lesion: Alteration of wave V suggests midbrain dysfunction, and alteration of waves I to III indicates a lesion in the lower brain stem.³⁵ In patients with brain death, the BAEP should be absent apart from wave I and the early part of wave II, which are generated peripherally. In many patients with suspected brain death, however, all BAEP components, including wave I, are absent, and it is then not possible to exclude other causes (e.g., technical factors or deafness) for the absent response.³⁶

BAEPs have been used to detect subclinical brain stem pathology in patients with suspected multiple sclerosis.^{37,38} However, the yield in this circumstance is less than with the visual or somatosensory evoked potentials, possibly because the auditory pathway is relatively short or is more likely to be spared.

SOMATOSENSORY EVOKED POTENTIALS

Basic Principles and Technique

Stimulation of a mixed nerve or its sensory branch leads to a response that can be recorded from the nerve more proximally or distally (the sensory nerve action potential), as well as over the spine and scalp. The scalp response is small and obscured by the ongoing EEG, and for this reason it is often necessary to average up to 2000 responses after stimulation of a nerve in the arm or 4000 responses with stimulation of a nerve in the leg, depending on the amount of background noise, to obtain well-defined responses.

The somatosensory evoked potential (SEP) depends on the functional integrity of the fast-conducting large-diameter group IA muscle afferent fibers and group II cutaneous afferent fibers and on the posterior columns of the cord, although some fibers may follow a different, extralaminar pathway. It is elicited for clinical purposes by an electrical stimulus that is sufficient to produce a slight muscle twitch when a mixed nerve is stimulated or to generate a sensory nerve action potential that is approximately 50% of maximum. It is generally well tolerated, even when applied with a repetition rate of approximately 3 to 5 Hz. SEPs can also be elicited by cutaneous nerve or dermatomal stimulation, but the role of these approaches, especially in the evaluation of suspected radiculopathies, is uncertain. SEPs are best recorded with surface electrodes. Over the scalp, either a bipolar derivation (both recording electrodes placed on the scalp) or a referential derivation (involving a noncephalic reference electrode) may be used.

Normal SEP Findings

SEP components are defined by polarity and latency. With stimulation of a nerve in the arm, recording between the contralateral "hand area" of scalp and contralateral Erb's point (i.e., in a referential derivation) demonstrates a P9 potential that reflects activity at or just beyond the brachial plexus. A P13-P14 potential reflects postsynaptic activity in the medial lemniscus, and an N20 component is generated in the primary somatosensory cortex (Fig. 24-14). A variety of other potentials may also be detected but are clinically less helpful and are not discussed further. With stimulation of the tibial nerve at the ankle, a P38 response is recorded over the scalp in the midline and represents activation of the primary somatosensory cortex (Fig. 24-15). Recordings over the cervical spine after stimulation of the nerve in the arm reveal an N13/P13, whereas stimulation of a leg nerve elicits a negative peak over the cauda equina and lumbar spine.

The presence or absence of these obligate components of the response and their latency and interpeak latency are recorded. Amplitude measurements may also be made, but abnormalities should not be based solely on amplitude criteria, except when an obligate response is absent. The absolute latency of individual components, but not the interpeak latency, varies with limb length.

As with the BAEP, it has generally been assumed that different components of the SEP reflect sequential activation of neural generators. However, potentials can be generated by a change in the physical characteristic of the

Figure 24-14. Median-elicited somatosensory evoked potential elicited in **A**, a normal subject by right-sided stimulation, and **B**, a patient with multiple sclerosis by left-sided stimulation. Two trials are superimposed to show the replicability of the findings. In the responses recorded in the patient, an Erb's point (EP) potential is present but responses over the cervical spine and scalp are absent. CV5, fifth cervical spine; i, ipsilateral; c, contralateral; other abbreviations as in previous figures.

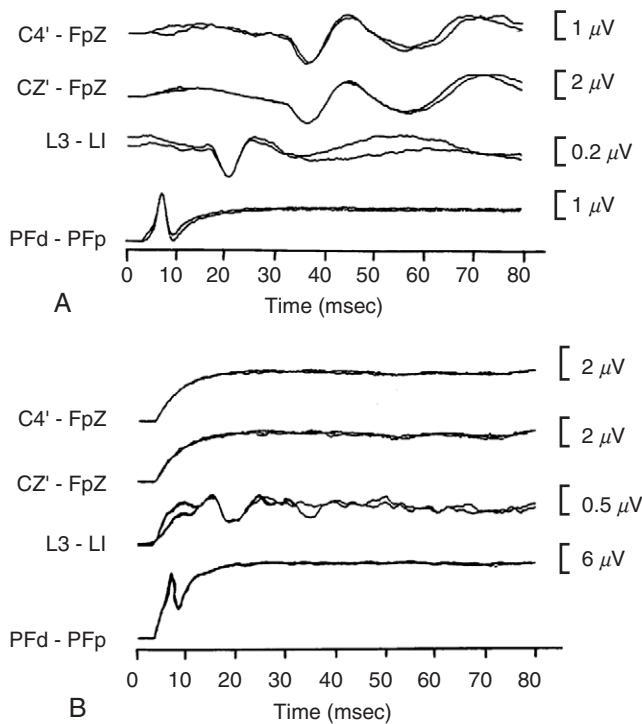

Figure 24-15. Responses recorded over the popliteal fossa and also over the spine and scalp to stimulation of the left tibial nerve at the ankle. Two trials are superimposed to show the replicability of the findings. **A** shows the finding in a normal subject, and **B** shows the response in a patient with multiple sclerosis. No response is present over the scalp in the patient. PF, popliteal fossa; L1, first lumbar spine; L3, third lumbar spine; d, distal; p, proximal; other abbreviations as in previous figures.

volume conductor as, for example, when an impulse passes from the arm to the axilla.^{39,40}

Abnormal Findings and Clinical Uses of the SEP

Somatosensory evoked potentials are helpful in detecting and localizing lesions of the somatosensory pathways within the CNS but provide no indication about the nature of the underlying pathological processes. They are of little value in evaluating the peripheral nervous system, except when there is concern about the functional integrity of nerves that are not easily accessible for conventional nerve conduction studies.⁴¹ SEPs have been used to evaluate patients with suspected radiculopathies. Abnormalities would not be expected in the SEP obtained by a stimulation of a polysegmental nerve trunk in patients with isolated root lesions, and cutaneous nerve or dermatomal stimulation has given conflicting results and should therefore be regarded as investigational.⁴²

In patients with multiple sclerosis, SEP abnormalities may indicate the presence of subclinical lesions, thereby helping to establish the diagnosis.⁴³ The presence of such abnormalities may also suggest that vague sensory complaints have an organic basis when this is difficult to determine clinically. The SEP is abnormal in approximately 80% of patients with multiple sclerosis (see Figs. 24-14 and 24-15), but SEP abnormalities are found in only approximately 30% of patients when this is merely a diagnostic possibility. The yield is greater in SEPs elicited by stimulation of a nerve in the legs than the arms and is more likely when there are pyramidal signs in the stimulated

limb or legs.⁴⁴ The most common abnormality found in patients with multiple sclerosis is loss or marked attenuation of the cervical response after stimulation of the median or ulnar nerve, and there may be an increase in central conduction time.⁴⁵ Subclinical SEP abnormalities may also indicate sensory involvement in patients with hereditary spinocerebellar degenerations, hereditary spastic paraplegia, AIDS, and a deficiency of vitamin B₁₂ or vitamin E, and they are therefore not pathognomonic of multiple sclerosis (Video 207, Spinal Cerebellar Atrophy III).^{43,46}

SEPs may indicate involvement of the central somatosensory pathways by other disorders at the spinal, brain stem, or thalamic levels. In patients with unilateral lesions of the cerebral hemisphere, the SEPs are often normal unless there is a clinical sensory disturbance, when they may be lost or markedly attenuated.

The SEP has been used to provide a prognostic guide in comatose patients.^{36,43,47-49} In particular, loss bilaterally of the N20 response after stimulation of the median nerve is commonly associated with a fatal outcome or development of a persistent vegetative state. In patients with unilateral loss of the N20, the outcome is more variable; with bilaterally preserved N20 responses, approximately 50% of comatose patients regain useful function, 25% remain in a vegetative state, and the remainder die. Based on several other studies, it seems reasonable to conclude that patients with absent cortical SEPs bilaterally are unlikely to recover cognition, but the presence of normal SEPs does not predict that useful recovery will necessarily follow. The bilateral absence of all responses later than the N13-N14 response is supportive of brain death, when this is diagnosed by clinical criteria.³⁶

After spinal injury, the SEP findings vary over the scalp after stimulation of a leg nerve, depending on the timing of the examination and the severity of the lesion. The absence of any cortical response in the acute stage after cord injury should not be taken to imply that the lesion is complete or that recovery will fail to occur. Preserved responses or their early return, however, indicate a better prognosis, although the degree of functional recovery varies.

SEPs have been used intraoperatively to monitor cord function, but it is not clear how useful they are in this context. This approach, however, is helpful in reducing the morbidity of scoliosis surgery.

MOTOR EVOKED POTENTIALS

Magnetic stimulation of the brain and spine elicits so-called motor evoked potentials (MEPs). This technique is usually well tolerated by patients and poses no immediate safety hazards. The latency of the motor responses can be measured, and central conduction time can be estimated by comparing the latency of the responses elicited by cerebral and spinal stimulation. Abnormalities have been described in patients with a variety of central disorders, including multiple sclerosis, amyotrophic lateral sclerosis, stroke, and certain degenerative disorders.⁵⁰ However, the clinical utility of these techniques is unclear.

ELECTROMYOGRAPHY

Basic Principles and Technique

Electrical activity can be recorded by a needle electrode placed within muscle. The potentials are amplified, displayed on an oscilloscope screen, and fed through a loudspeaker so they can be monitored by ear. Several different types of needle electrodes are in common use, but the most popular is the concentric needle electrode. This consists of a fine silver or platinum wire, insulated except at its tip, that is contained within a pointed steel shaft; the potential difference between the outer shaft and inner wire is recorded.

The electrical activity recorded from muscle—that is, the electromyogram (EMG)—provides a guide to the pathological site in patients with disease of the motor units. Pathological processes can be localized to the neural, muscle, or junctional components of the motor units. In neuro-pathic diseases, the pattern of affected muscles also permits a lesion to be localized to the spinal cord, nerve roots, limb plexuses, or peripheral nerves. However, the EMG findings are not pathognomonic of specific diseases and do not in themselves provide a definitive diagnosis.

Normal EMG Activity

When a needle electrode is inserted into a muscle, a brief burst of activity occurs for 2 to 3 seconds or less. Once this insertion activity has settled, spontaneous activity is not present in normal muscle except in the endplate region, where endplate “noise” can be recorded and corresponds to the nonpropagated miniature endplate potentials generated by the spontaneous release of acetylcholine at the neuromuscular junctions.

When slight voluntary contraction is initiated, a few of the motor units within the muscle are activated and initially fire irregularly and at a low rate. With increasing effort, they fire more rapidly; at a certain firing rate, additional units are recruited. With further effort, so many units are active that individual potentials cannot clearly be distinguished, leading to a complete “interference pattern” on the trace of the oscilloscope (Fig. 24-16).

Individual motor unit action potentials are usually biphasic or triphasic in configuration, but up to 10% to 15% are polyphasic (i.e., they have five or more phases). They normally have a duration of between 2 and 15 msec and an amplitude of between 300 μ V and 3 mV (Fig. 24-17; Video 6, Normal Motor Unit Potentials).

Abnormal EMG Activity

Insertion activity is increased in neuropathic and certain myopathic or myotonic disorders and in myositis. Abnormal spontaneous activity is present in various neuromuscular diseases. *Fibrillation potentials* (Fig. 24-18) are biphasic or triphasic discharges with a positive onset except in the endplate region; they have an amplitude of approximately 300 μ V, have a duration of up to 5 msec, fire up to 20 times per second, and represent action potentials generated in single muscle fibers. They usually fire rhythmically, and this probably reflects oscillations of the

Figure 24-16. Motor unit activity during increasing voluntary effort. The number of units activated increases with the force of contraction, and eventually (bottom trace) individual potentials can no longer be recognized. In accordance with conventions, an upward deflection in this and subsequent figures indicates that the active electrode is negative with respect to the reference one. (From Aminoff MJ: Electromyography in Clinical Practice, 3rd ed. New York, Churchill Livingstone, 1998.)

resting membrane potential of skeletal muscle fibers.⁵¹ *Positive sharp waves* (Fig. 24-19) may be found in association with them and consist of an initial positive deflection followed by a slow deflection in the negative direction. Although similar in size to fibrillation potentials, they often last for 10 msec or more and may discharge at rates up to 100 per second. Fibrillation potentials and positive sharp waves are found in conditions with increased muscle fiber irritability. They occur in denervated muscle but may not appear until 3 or 4 weeks after an acute neuropathic lesion. They are also found in patients with inflammatory disorders of muscle, occasionally in patients with muscular dystrophies, after muscle trauma, in patients with certain metabolic disorders (e.g., acid maltase deficiency), and in association with botulism.

In patients with chronic partial denervation, as well as with certain of the muscular dystrophies or inflammatory disorders of muscle, *complex repetitive discharges* are found (Video 99, Gower's Sign). These have a high discharge frequency, but their amplitude and frequency remain constant (Fig. 24-20). They appear to arise in the muscle and are probably initiated by a fibrillating muscle fiber that then depolarizes adjacent fibers by ephaptic transmission.⁵² In contrast, in the *myotonic discharges*

Figure 24-17. Motor unit action potentials. A, Normal potential. B, Long-duration polyphasic potential (shown twice). C, Short-duration, low-amplitude, polyphasic potential. (From Aminoff MJ: Electromyography in Clinical Practice, 3rd ed. New York, Churchill Livingstone, 1998.)

(Fig. 24-21) that characterize certain myotonic disorders with delayed relaxation after voluntary contraction, high-frequency trains of action potentials occur spontaneously, wax and wane in amplitude and frequency, and relate to a disorder of the muscle fiber membrane.

Fasciculation potentials have the dimensions of motor unit action potentials and represent the spontaneous activation of all the muscle fibers in individual units. They produce a sudden dull thump over the loudspeaker. They are found most often with disease of the anterior horn cells but may also occur with other neuropathic disorders, occasionally with certain myopathic disorders (as in thyrotoxicosis), and sometimes as an isolated phenomenon without pathological significance. Studies in patients with diverse lower motor neuron lesions have revealed that they may arise at multiple sites along motor axons or the cell bodies of diseased motor neurons,⁵³ but in most instances they originate at the distal extremity of the axon.⁵⁴ Myokymic discharges, in which motor unit action potentials discharge spontaneously in characteristic patterns, are discussed later in this section.

The motor unit action potentials may show characteristic abnormalities in various diseases of the motor units. In *myopathies*, the number of muscle fibers in individual motor units is reduced (Video 38, Facial Myopathy and Ophthalmoplegia). In consequence, the mean duration and amplitude of the motor unit action potentials is reduced (see Fig. 24-17) and the incidence of polyphasic potentials is increased. Moreover, because the individual units

generate less tension than normal, an increased number is recruited for any given degree of voluntary activity. In contrast, in *neuropathic disorders*, the number of motor units—but not their content of muscle fibers—is reduced; indeed, if denervated muscle fibers have been reinnervated by sprouting from the axon terminals of surviving units, the number of fibers per unit may actually be increased (Video 218, Ulnar Neuropathy, Wartenberg Sign). In consequence, motor unit action potentials may be longer in duration and larger in amplitude than normal, with an increased incidence of polyphasic potentials, indicating that reinnervation has occurred (see Fig. 24-17). During mild voluntary activity, there is an increase in the rates at which individual units begin firing and at which they fire before additional units are recruited; during maximal effort, the interference pattern is reduced.

In disorders with *abnormal neuromuscular transmission*, such as myasthenia gravis, motor unit action potentials vary in amplitude and area during continued activity and, in addition, there is an excess of small, short-duration

potentials in affected muscle (Video 226, Myasthenia Gravis: Edrophonium). The variability of the potentials reflects the reduced safety factor for neuromuscular transmission, as a consequence of which there is variation in the number of muscle fibers firing with each discharge of the unit. Single-fiber electromyography is a technique in which action potentials are recorded from two or more muscle fibers belonging to the same motor unit by means of a special electrode, and the temporal variability (or jitter) between the two action potentials at consecutive discharges is measured.⁵⁵ This jitter reflects variation in neuromuscular transmission time in the two motor endplates involved. An increased jitter is therefore to be expected in patients with diseases of neuromuscular transmission, and impulse blocking may also occur.

Myokymic discharges consist of a spontaneously occurring grouped pattern of firing of motor units; double, triple, or multiple discharges occur, followed by a period of silence and then by another grouped discharge. They may

occur in patients with radiation-induced plexopathy or myelopathy and occasionally with chronic radiculopathies or entrapment neuropathies, Guillain-Barré syndrome, multiple sclerosis, or gold intoxication; they may also be found in facial muscles in patients with brain stem gliomas (Video 221, Miller Fisher Syndrome).^{56,57}

NERVE CONDUCTION STUDIES

Basic Principles and Technique

Needle electromyography is generally performed in conjunction with nerve conduction studies, which may be undertaken to determine the functional integrity of the peripheral nerves. For motor conduction studies, the nerve is stimulated at two or more points along its course while the electrical response is recorded of one of the muscles supplied by it. Electrical stimuli are preferred and must be of sufficient intensity to excite all of the fibers in the nerve. The muscle response is recorded by surface or subcutaneous needle electrodes, with the active electrode being placed over the endplate region and the reference electrode over the muscle tendon. The response recorded in this way is called the compound muscle action potential (CMAP), or M wave, and represents the sum of the electrical activity of all of the activated muscle fibers within the pickup region of the recording electrode. The shape, size, and latency of the response obtained by stimulating the nerve at different sites are compared. By measuring the distance between stimulation sites and the difference in latency of the responses elicited by stimulation at these sites, the conduction velocity can be determined for the fastest conducting fibers along the intervening segments of the nerve (Fig. 24-22). In the arms, the normal range of maximal motor conduction velocity is between 50 and 70 m/sec, whereas in the legs the corresponding velocities are between 40 and 60 m/sec.

Sensory nerve conduction studies involve stimulating a sensory nerve either orthodromically or antidromically and recording the response at another point along the course of that same nerve. The calculated conduction velocity is the same, but the response is larger with antidromic stimulation. Responses can also be recorded from a purely sensory nerve

after stimulation of the parent nerve trunk from which it originates, or vice versa.

In patients with *focal conduction block* involving an individual nerve, the CMAP elicited by stimulating the nerve above the site of the lesion is reduced in amplitude compared with more distal stimulation and in severe cases is completely lost. Sensory nerve action potentials are also small or unrecordable when the lesion is located between stimulation and recording sites. With *focal conduction slowing* (but not block), the size of the CMAP is reduced as the distance increases between the stimulating and recording electrodes. Motor and sensory conduction velocities are slowed across the region of the nerve encompassing the lesion, and sensory nerve action potentials may be markedly attenuated or unrecordable because of dispersion. *Axon-loss lesions* are characterized by an attenuated muscle response, by reduced or absent sensory nerve action potentials, and by electromyographic signs of denervation in the affected muscle. Motor or sensory conduction velocity is normal or reduced only minimally, when it can be recorded.

Clinical Uses of Nerve Conduction Studies

Motor conduction studies are helpful in indicating that weakness is due to pathology of the peripheral nerves rather than other parts of the motor unit. Sensory conduction studies may indicate that sensory symptoms are due to an impairment of peripheral nerve function or, when normal, to a lesion proximal to the dorsal root ganglia. Motor and sensory conduction studies are important in determining the presence and extent of a peripheral neuropathy, distinguishing between a polyneuropathy and mononeuropathy multiplex, recognizing the selective involvement of motor or sensory fibers, and following the course of peripheral nerve disease. The nature of the abnormalities found on motor or sensory conduction studies may suggest the type of underlying pathology and, in particular, whether this is primarily axonal loss or segmental demyelination.⁵⁸ Nerve conduction studies are also important as a means of recognizing subclinical polyneuropathies and in detecting and localizing a focal lesion involving individual nerves (Video 217, Anterior Interosseous Neuropathy, Pinch Sign).

Figure 24-22. Arrangement for measuring motor conduction velocity in the forearm segment of the median nerve. The nerve is stimulated distally (A) and proximally (B), and the evoked potentials are recorded from the abductor pollicis brevis muscle. (Ground electrode not shown.) Maximal motor conduction velocity (m/sec) between the proximal and distal sites of stimulation is calculated by dividing the distance between these sites by the difference in latency of the responses. (From Aminoff MJ: Electromyography in Clinical Practice, 3rd ed. New York, Churchill Livingstone, 1998.)

Focal nerve lesions may result from injury or compression at sites of entrapment of the nerve by neighboring anatomical structures. Common entrapment neuropathies include compression of the median nerve at the wrist (carpal tunnel syndrome); the ulnar nerve at the elbow, cubital tunnel, or Guyon's canal; and the peroneal nerve at the head of the fibula (Video 219, Ulnar Neuropathy, Froment Sign; Video 237, Foot Drop). Electrophysiological studies are very important in localizing the lesion in such disorders and also in excluding the possibility of a subclinical polyneuropathy manifest primarily by the entrapment neuropathy. The findings depend on the duration and severity of nerve damage, the rapidity of its evolution, and the underlying disorder.⁵⁹

F-RESPONSE AND H-REFLEX STUDIES

Basic Principles and Technique

F responses are evoked from muscle as the result of antidromic activation of motor neurons by a peripheral electrical stimulus. The stimulus should be of greater intensity than is required to elicit a maximal CMAP and may not always elicit an F response. F responses are small (usually <5%) compared with the CMAP (Fig. 24-23), and their latency and amplitude vary considerably even when the stimulating and recording arrangements remain constant, presumably because different anterior horn cells are activated antidromically. Various parameters of F waves can be measured, but the most popular is the minimum latency of 10 or more responses.

The H reflex, named after Hoffmann, who first described it, can be recorded easily only from the gastrocnemius-soleus muscle in the legs and the flexor carpi radialis muscle in the forearm in response to stimulation of the nerve to these muscles. The stimulus required to elicit the response is lower in intensity than is necessary to elicit CMAPs of maximal size (see Fig. 24-23). The afferent pathway subserving the H reflex consists of spindle afferent (Ia) fibers, and the efferent arc is via the alpha motor axons. The H reflex is not easily obtained from other muscles except in infants or patients with pyramidal lesions, limiting its clinical utility.

Normal Findings

The latency of the H reflex or F response depends on a subject's height or limb length, and normal values must therefore be obtained with this in mind to permit appropriate evaluation of the results from patients. It may also be helpful to compare interside differences in latency of the responses in individual patients; for H and F responses from the soleus muscle, or the F responses from the intrinsic hand muscles, this is normally less than 2 msec.⁶⁰

Abnormal Findings and Clinical Uses of F-Response and H-Reflex Studies

F-response and H-reflex studies are sometimes useful in the evaluation of patients with peripheral neuropathies, particularly when the pathological process is so proximal that conventional nerve conduction studies fail to reveal

Figure 24-23. Diagrammatic representation of the relationship between the direct (M) response, F response, and H reflex and the intensity of the eliciting stimulus. With low-intensity stimulation of the tibial nerve, an H reflex is elicited from the soleus muscle. As the intensity of stimulation increases, the H reflex declines and a small M wave is seen. With a higher stimulus intensity, the H reflex disappears and the M wave increases in size until it is maximal. Following the maximal M wave, a small F response is sometimes seen. (From Aminoff MJ: *Electromyography in Clinical Practice*, 3rd ed. New York, Churchill Livingstone, 1998.)

any abnormalities. A prolongation of the minimum F-response latency may occur in patients having polyneuropathies with involvement of motor fibers, sometimes when conventional nerve conduction studies are normal. Abnormalities are sometimes encountered with radiculopathies, but these patients generally have abnormalities on needle electromyography so that the added F-response abnormality does not influence management. H-reflex abnormalities (lost or delayed responses) may also be found in patients with polyneuropathies or with a lesion anywhere along the pathways subserving the reflex.

BLINK REFLEX

Basic Principles and Technique

The blink reflex is a polysynaptic reflex that is most conveniently recorded from surface electrodes placed over the

orbicularis oculi muscle after electrical stimulation of the supraorbital nerve (Fig. 24-24). The afferent arc of the reflex is subserved by the trigeminal nerve, and the efferent arc is subserved by the facial nerve.

Normal Findings

The response is characterized by a short-latency (approximately 10 msec) ipsilateral response that is designated R1, followed by a more asynchronous, bilateral response having a latency of 28 to 30 msec that is designated R2 (Fig. 24-25).

Abnormal Findings and Clinical Uses of the Blink Reflex

The blink reflex may be helpful in revealing the presence of a subtle trigeminal or facial nerve lesion. Ipsilateral trigeminal nerve lesions lead to responses that are either lost or have a prolonged latency bilaterally. A unilateral facial nerve lesion, by contrast, leads to a delayed or absent response on the affected side regardless of which side is stimulated.

The blink reflex may be abnormal with polyneuropathies, thereby indicating the extent of the disorder. Abnormalities may also occur with tumors in the cerebellopontine angle involving either or both nerves or the brain stem and with brain stem lesions involving the central pathways subserving the reflex, such as in multiple sclerosis, sometimes in the absence of clinical evidence of brain stem involvement (Video 201, Cranial Nerve VII Anatomy).

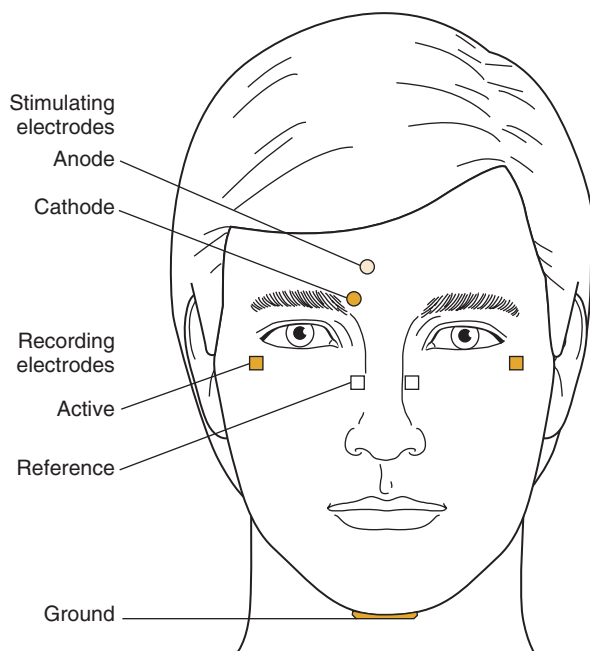

Figure 24-24. Arrangements for eliciting the blink reflex. (From Aminoff MJ: *Electromyography in Clinical Practice*, 3rd ed. New York, Churchill Livingstone, 1998.)

Figure 24-25. The blink reflex elicited by electrical stimulation of the right supraorbital nerve in a normal adult. Two separate responses are shown. The R1 component of the response is present only on the side that is stimulated, whereas R2 is present bilaterally. (From Aminoff MJ: *Electromyography in Clinical Practice*, 3rd ed. New York, Churchill Livingstone, 1998.)

REPETITIVE NERVE STIMULATION

Basic Principles and Technique

Electrophysiological techniques are important in the evaluation of neuromuscular transmission. The amount of acetylcholine released by a nerve impulse—and thus the size of the endplate potential—is influenced by preceding activity in the junctional region. This normally is of little consequence because the amount of acetylcholine released far exceeds that required to generate endplate potentials above the threshold for activating muscle fiber action potentials. Reduction in this safety factor, however, may alter the number of muscle fibers activated by an impulse and thus the size of the CMAP elicited by a supramaximal stimulus to the motor nerve. The size of the electrical response evoked in muscle by two or more supramaximal stimuli, or by a single stimulus applied after a 30-second period of maximal voluntary activity or tetanic stimulation, therefore reflects the efficacy of neuromuscular transmission.

Normal Findings

There is normally no change in size of the responses to paired or repetitive shocks delivered to the motor nerve at rates of up to 10 Hz or in the response to single shocks delivered before and after maximum voluntary activity or tetanic stimulation.

Abnormal Findings and Clinical Uses of Repetitive Nerve Stimulation

Repetitive nerve stimulation is a useful technique for evaluating neuromuscular transmission. In diseases in which such transmission is impaired, the muscle response to

repetitive nerve stimulation may show abnormal alterations in size or area. In myasthenia gravis, a progressive decrement in the response may occur with repetitive stimulation (especially at 2 to 3 Hz), or an initial decrement may be followed by a leveling off of the response at a reduced size (Video 225, Myasthenia Gravis). Abnormalities are more likely to be found in proximal rather than distal limb muscles and in facial rather than limb muscles. Normal findings do not exclude the diagnosis. In contrast, in patients with Lambert-Eaton myasthenic syndrome or botulism, the response to a single stimulus is abnormally small and stimulation at a slow rate leads to a further reduction in response size; with rapid rates of stimulation, a progressive increase in size of the response occurs.

Specific Indications

For the variety of applications it offers, clinical laboratory testing for neurological disease has undergone revolutionary change in recent years. Diagnostic capabilities for metabolic diseases, for rapid detection of infection, and for determining genetic risk factors are only a few examples of recent developments in testing capabilities. Results from the clinical laboratory are the only way to evaluate for certain neurological disorders. Laboratory tests have become an expensive part of the medical enterprise, but often they can provide the most cost-effective means for answering diagnostic questions.

Abnormalities detected by laboratory testing are not always attributable to a particular neurological disorder. Clinicians sometimes need to apply a process of decision-tree logic to derive useful information from laboratory results. Another limit of abnormal test results is that they do not always point to the mechanism of disease. The latter point was well known to a 19th-century founder of clinical laboratory medicine, Claude Bernard, who made the analogy that “as familiar as we might become with the structure of a mill, there is still much to learn before we would know the craft of a miller.” The imprint of disease on the tissues and fluid compartments of the body provides an important but sometimes imperfect tool for solving clinical problems and guiding therapy. False-positive and false-negative findings, other sources of artifactual results, multimodal distributions of normal values, and the constant evolution of new information all are reasons that clinicians need to maintain a broad base of knowledge concerning laboratory medicine.

Certain screening laboratory studies, including complete blood counts, electrolytes, and tests of renal and hepatic function, are commonly used in the evaluation of many neurological conditions. Other studies such as drug and toxicological screens (see Chapter 39) as well as nutritional (see Chapter 40), coagulation (see Chapter 45), immunological (see Chapter 50), and enzymatic studies (see Chapters 30 and 31) may be useful in specific clinical settings and are covered in their respective chapters in Part Three of this textbook. This chapter focuses on the proper use of genetic studies and primary neurological tissue (muscle, nerve, and brain) in the diagnosis of neurological disease.

GENETIC STUDIES

The pace of discovery of genes responsible for hereditary neurological diseases has been escalating over recent years. The sheer number of genetically defined disorders already is too large to permit comprehensive coverage of the molecular diagnosis of these disorders in a single chapter. In addition, there will be no doubt that some of the information presented here will be superseded or rendered obsolete as scientific advances occur. Rather, the necessary background information needed to understand key concepts and discoveries will be presented, along with some general guidelines to enable the reader to select the most efficient and beneficial approach (which may be to refer the patient to a geneticist) to the diagnosis and counseling of a patient suspected of having a genetic neurological condition.

In order to fully appreciate the current findings and to rationally approach the investigation of a patient suspected of having a genetic disorder, it is essential to understand some basic principles of genetics and molecular biology.

The Human Genome

All biological activities depend directly or indirectly on the proteins that lie within cells. The totality of genetic information for an organism is referred to as the genome. The human genome is divided among 23 pairs of chromosomes; females have two X chromosomes and 22 pairs of autosomes (nonsex chromosomes) and males have an X and a Y chromosome in addition to the 22 pairs of autosomes. Genetic information is contained in the linear sequence of nucleotides, or bases, in deoxyribonucleic acid (DNA). Each chromosome is a single enormous molecule of linear DNA associated with a complex assortment of proteins that play structural and regulatory as well as enzymatic roles during DNA replication and gene expression. The autosomes are numbered according to their sizes and contain over 200 million bases in chromosome 1 to about 50 million bases in chromosome 22.

With the completion of the human genome sequencing project, it has been found that the human genome has about 30,000 genes. They range in size from about 100 bases for

genes for structural ribonucleic acids (RNAs) to about 2.5 million bases for the largest known gene, dystrophin. Gene expression is the sequence of processes from messenger RNA (mRNA) synthesis, or transcription, to protein synthesis, or translation. Gene transcription is a complex process and begins with the regulated initiation of transcription from a transcription initiation site. This initiation process is of fundamental importance and is mediated by proteins termed transcription factors. A primary transcript is synthesized down the length of the entire gene from the 5' to the 3' end. The information in most genes is broken up into discontinuous pieces termed *exons*, which are separated by *introns*, or intervening sequences. These introns are removed from the primary transcript through splicing. Most spliced products then have a string of adenosine bases added to their 3' ends. This spliced and polyadenylated product is the mRNA, which is then transported to the cytoplasm of the cell and serves as a template for the synthesis of protein.

An individual gene, therefore, is the composite not only of the sequences that code for protein, but also the introns, the transcribed but not translated regions at the 5' and at the 3' ends of the mRNA, and sequences that regulate the transcription initiation, termination, and splicing processes. Regulatory sequences can flank the transcription initiation and termination sites or even lie within introns or exons (Fig. 25-1).

The sequence of bases in an mRNA encodes the amino acid sequence of the protein for a gene. Nucleotide information is interpreted in groups of three bases, termed codons. With four nucleotide bases, there are 64 possible codons. Four codons are particularly important. AUG encodes methionine,

which is always the first amino acid of the primary translation product (which may be cleaved to make a mature protein product). The codons UAG, UGA, and UAA are stop codons. Mutations that cause disease can be as subtle as the substitution of one nucleotide base for another. The consequences of point mutations demonstrate the great variety of effects that result from an alteration in a gene and illustrate most of the key problems that result from mutations. The results of such a mutation depend critically on the location of the mutation within the gene as well as on the particular bases that are involved. If the mutation lies within the coding region (also known as the open reading frame), the result could be the substitution of one amino acid for another. Some point mutations result in no change of the amino acid and are termed *silent mutations*. Other protein coding region mutations can result in the conversion of an amino acid encoding codon into a termination or stop codon. A mutation affecting an initiation codon would prevent translation unless another AUG codon was present elsewhere. Point mutations can occur outside the coding region. Consequences include obliteration or creation of splice sites, destruction or creation of transcription initiation or termination sites, or of regulatory sites.

Mutations can also result from deletions or insertions, that range in size from one to thousands of nucleotides. When an insertion or deletion lying within the coding region for a protein involves a number of bases that is not a multiple of 3, then the coding frame is disrupted, resulting in a protein sequence that diverges from the normal sequence from that point on, unless a second mutation restores the proper reading frame.

Figure 25-1. Eukaryotic gene expression. The initial step in gene expression is the transcription of the primary RNA transcript. The intervening regions, or introns, that separate the exons that contain the protein coding regions are removed from the primary transcript by splicing. The spliced transcript is modified at its 5' and 3' ends (not shown), and the mature mRNA is then transported out of the nucleus and into the cytoplasm, where it serves as the template for translation, the process of decoding the RNA sequence into protein using the ribosomes and transfer RNA (tRNA) molecules that both "read" the genetic code words, or codons, and provide a single amino acid that is added to the growing polypeptide chain. (Adapted from Griffiths AJF, Miller JH, Suzuki DT, Lewontin RC, Gelbart WM: An Introduction to Genetic Analysis 6.0. New York, WH Freeman, 1996.)

TABLE 25-1

Trinucleotide and Pentanucleotide Repeat Disorders

| DISORDER | GENE | CHROMOSOME | REPEAT UNIT | NORMAL REPEAT NUMBER (RANGE/PATHOLOGICAL RANGE) | OTHER MUTATIONS |
|------------------------------------|------------------------|------------|-------------|---|--|
| Huntington disease | Huntingtin | 4p16.3 | CAG | 15–20/39–~100 | |
| X-linked spinal and bulbar atrophy | Androgen receptor | Xq11 | CAG | 15–20/40–~100 | |
| SCA1 | Ataxin-1 (ATX1) | 6p23 | CAG | –6–36/39–83 | |
| SCA2 | Ataxin-2 (ATX2) | 12q24 | CAG | 15–31/34–400 | |
| Machado-Joseph/SCA3 | MJD | 14q24.3 | CAG | 12–40/55–86 | |
| SCA6 | CACNL1A4 | 19p13 | CAG | 4–16/20–33 | Other mutations cause episodic ataxia or hemiplegic migraine |
| SCA7 | Ataxin-7 | 3p21.1–p12 | CAG | 4–19/37–>300 | |
| SCA8 | Ataxin-8 | 13q21 | CTA/CTG | 15–50/80–250 | Some with very large repeats do not have ataxia |
| SCA10 | Ataxin-10 | 22q13 | ATTCT | 10–22/800–4500 | |
| SCA12 | Protein phosphatase 2A | 5q31 | CAG | 6–26/66–78 | |
| SCA17 | TATA binding protein | 6q27 | CAG | 30 | |
| DRPLA | DRPLA | 12p13 | CAG | 3–36/49–~88 | |
| Myotonic dystrophy | Myotonin | 19q13.2 | CTG | 5–27/50–thousands | |
| Fragile-X | FMR 1 | Xq28.3 | CCG | 6–54, premutation 56–200/~200–thousands | ILE367ASN,1BP DEL, ACT125CT, FS159TEACT125CT, FS159TER,IVS1, G-T, –1 AND G-A, +1 |

DRPLA, dentatorubropallidolusian atrophy; SCA, spinocerebellar ataxia.

A recently recognized but important category of mutations, properly considered a subtype of insertion, is the trinucleotide repeat expansion mutations (Table 25-1). These mutations are characterized by an elongation of a gene region characterized by repeats of a three-nucleotide sequence. The precise sequence varies among these disorders as does the scale of expansions. There are some general distinctions that can be drawn, however, to characterize all these repeat expansion mutations. When the trinucleotide, or triplet, repeat unit lies outside the coding region, the expansions can reach a very large size. The mutations that cause fragile-X mental retardation syndrome (FMR1) are expansions of a region involving the trinucleotide CCG that lies in the 5' untranslated but transcribed portion of the gene (Video 254, Fragile X). Normally, there are about 5 to 50 CCG repeats in this region, but affected individuals can have hundreds or even thousands of such repeats. Expansions of over several hundred triplet repeats have been found in patients with myotonic dystrophy (Steinert's disease), in which the repeat unit CTG is normally present in 5 to 27 copies and lies in the 3' untranslated region of the myotonin gene (Video 99, Gower's Sign). The Friedreich ataxia triplet repeat mutation is due to expansion of a GAA repeat that has a normal length of 7 to 22 repeats and that lies in the seventeenth intron of a gene believed to be a phosphoinositol kinase gene. Patients can have several hundred copies of the triplet. Interestingly, point mutations in the FMR1 and Friedreich ataxia genes can also cause mental retardation and Friedreich ataxia, respectively (Video 37, Friedreich Ataxia).

The other type of triplet repeat mutations involves repeats of the nucleotide bases CAG, which encode the amino acid glutamine, and lie within the coding domains

of their respective genes. Not only is the repeat unit the same for these disorders, but also the scale of the repeat expansion is quite similar: The length of the normal repeat is approximately 20, whereas affected individuals have 40 or more repeats. To date, all of the mutations of this type described are of special importance to neurologists, as the major syndromes affect the brain, spinal cord, or muscles.

Mutations affecting mitochondrial DNA cause a wide variety of clinical neuromuscular syndromes and can affect any part of the central and peripheral nervous systems, the muscles, and other organs. Mutations may arise sporadically, such that there is no family history of disease, or may be transmitted via maternal inheritance with up to 100% of a mother's offspring receiving the genetic defect. This unique phenomenon arises because all mitochondria are inherited from the ovum. Another special feature of mitochondrial inheritance arises from the fact that mixtures of normal and abnormal mitochondria can exist not only within a single cell, but also in different tissues. *Homo-plasmy* refers to the state of having uniformly normal or abnormal mitochondria in a tissue, while *heteroplasm* refers to the state of having a mixture of normal and abnormal mitochondria in a tissue. Typically over 90% of the mitochondria need to be abnormal before abnormal clinical symptoms and signs are apparent. It is important to recognize that some disorders, such as Kearns-Sayre syndrome (KSS), may cause abnormal mitochondria to develop in some tissues, such as ocular muscles, but not in others, such as peripheral blood leukocytes. In such a situation (which is common in the case of KSS), molecular testing for the deletions of the mitochondrial genome may not be detected in blood samples but may be present in other tissues, such as muscle (Video 38, Facial Myopathy and Ophthalmoplegia).

Testing Methods (Table 25-2)

High-Resolution Karyotype

The lowest resolution genetic test is the karyotype analysis. In this test, a sample of cells (e.g., blood leukocytes or amniotic fluid cells) are grown in tissue culture medium in the presence of mitotic inhibitors that arrest cells at metaphase. The cells are then “squashed” to spread the chromosomes on the microscope slide. The chromosomes can then be stained to reveal a pattern of bands along the length of the chromosome arms. This form of testing is able to assess whether the cells have the normal number of chromosomes and can determine whether interchanges of chromosome arms between chromosomes (i.e., translocations) have occurred. Depending on their size, this analytic method can also detect some deletions or duplications

of chromosomal regions. A typical high-resolution test can detect deletions of approximately 10 million base pairs or more. Smaller deletions or duplications (submicroscopic deletions) will not be seen, such as the duplication found in most patients with Charcot-Marie-Tooth disease IA (CMTIA) (Fig. 25-2; Video 34, Charcot-Marie-Tooth Disease).

Fluorescent in situ Hybridization (FISH)

FISH analysis is a useful method for determining deletions or duplications of specific chromosomal regions. The technique involves staining chromosomes by hybridization with a nucleic acid probe that has been covalently labeled with a fluorescent molecule that can be visualized with a conventional fluorescence microscope. Typical probes

TABLE 25-2

Molecular Testing Methods

| METHOD | DISEASE EXAMPLES | LIMITATIONS OF TESTING | COMMENTS |
|---------------------------------|---|--|---|
| Karyotype | Complex phenotypes (contiguous gene syndromes, aneuploidies, [e.g., Down's syndrome]); balanced translocation | Will not detect chromosomal anomalies smaller than approximately 5 megabases; may miss small balanced translocations | |
| FISH | Pelizaeus-Merzbacher disease (PMD), Charcot-Marie-Tooth disease IA | Will not detect point mutations | May need to use point mutation testing (e.g., ASO, direct sequencing) if negative |
| Allele-specific oligonucleotide | Canavan disease, cystic fibrosis, factor V Leiden, MELAS, MERRF, NARP | Examines only the more common point mutations; will not detect any other mutations | May need to perform SSCP or direct sequencing if negative; will not detect large gene duplications/deletions |
| Trinucleotide repeat expansion | HD, SCA1, 2, 3, 6, 7, 8, 10, 12, 17, FRDA, muscular dystrophy, DRPLA, FMR | Will miss other mutations, e.g., episodic ataxia-2, FRDA caused by point mutations in the frataxin gene; may not detect large expansions | May need to do Southern blot if only single allele (repeat length) is detected, which can appear to be the case with huge expansions; will not detect large deletions or duplications |
| PCR/RFLP | PMD; many other diseases | Will miss mutations outside of region(s) amplified by PCR | |
| Direct sequencing | Numerous | Will miss large duplications/deletions; will miss mutations in regions not amplified in the PCR (e.g., intronic mutations, regulatory region mutations); may not be able to reliably distinguish pathological mutations from polymorphisms | Labor and time intensive; expensive |
| SSCP; heteroduplex analysis | PMD; others | Will miss large deletions/duplications, mutations outside of PCR-amplified region(s) | Often used as screening test; may miss up to 20% of point mutations within the amplified region(s) |
| Linkage | Neurofibromatosis, Duchenne muscular dystrophy, many others | Laborious; requires multiple family members, including normal as well as affected individuals | Appropriate for diseases where gene has not yet been identified but has been localized to a particular chromosomal region; can be used for nondisclosing linkage analysis, e.g., determining whether a child of a clinically normal parent is at risk for developing HD, but where the parent does not wish to find out if she/he definitely has inherited HD |
| PCR/gel electrophoresis | Duchenne muscular dystrophy | Will miss point mutations and mutations outside of PCR-amplified segment(s) | Most appropriate for conditions resulting frequently from intragenic deletions; may detect duplications/deletions |
| Premature protein truncation | Neurofibromatosis 1 | Will miss missense and other small mutations, duplications | Depends on RNA expression of the gene; useful when significant proportion of mutations result in frameshift or nonsense changes; will not detect about 30% to 40% of NF1 mutations; may not be reliable for prenatal testing |

ASO, allele-specific oligonucleotide; DRPLA, dentatorubropallidolusian atrophy; FISH, fluorescent in situ hybridization; FMR, fragile-X mental retardation; HD, Huntington's disease; NF1, neurofibromatosis I, PCR, polymerase chain reaction; RFLP, restriction fragment length polymerization; SCA, spinocerebellar ataxia; SSAP, single-strand confirmation polymorphism.

Figure 25-2. Fluorescent in situ hybridization (FISH) of metaphase chromosomes. The right side of the photomicrograph shows the original distribution of chromosomes from a single cell whose nucleus has been ruptured to release the chromosomes, which are stained with a red fluorescent probe to a gene on chromosome 11. The images of the chromosomes on the right side of the figure have been excised and organized on the left side of the figure to easily examine each pair of chromosomes from this karyotypically normal male. (Adapted from Griffiths AJF, Miller JH, Suzuki DT, Lewontin RC, Gelbart WM: *An Introduction to Genetic Analysis* 6.0. New York, WH Freeman, 1996.)

range from a few thousand bases to tens of thousands of bases in length. In addition to staining chromosomal spreads prepared as described previously for conventional karyotype analysis, the method can also be used to stain chromosomes in interphase, or nonmitotic, cells, which has the advantage that the DNA is not tightly wound into densely packed chromatin, so that relatively closely spaced fluorescent markers can be resolved microscopically. Examples of this technique include detection of the 1.5 million base duplication in CMT1A, and detection of the submicroscopic deletions responsible for the Smith-Magenis, or for the Prader-Willi/Angelman syndromes. This method is very valuable in basic research as a straightforward method for localizing genes to specific chromosomal regions.

Chromosomal Microarray Analysis

With the advent of the complete sequencing of the human genome and ability to analyze many genes simultaneously using arrays of nucleic acids immobilized on glass microscope slides, it has become easier, and with greater sensitivity, to identify microdeletions, microduplications and more complex chromosomal rearrangements. Although methodologic variations are possible, the general approach is to isolate genomic DNA from the patient and label it with a fluorochrome (fluorescent dye, e.g., that emits green fluorescence), mix it with an equivalent amount of control DNA that has been labeled with a fluorochrome that emits another color (e.g., red) and hybridize it onto glass microscope slides (microarrays) (Fig. 25-3). These slides can be made with small DNA spots that are from well-characterized regions of the genome. Because current technology allows tens of thousands of spots to be placed on a single slide, a large number of chromosomal regions can be surveyed. With probes from chromosomal regions spaced about 100,000 base pairs apart, the entire human genome can be screened for deletions and duplications with a microarray containing about 30,000 spots.

Single Gene Mutation Screening

Mutation detection specificity and sensitivity concerns apply to molecular diagnostic testing as well as to conventional biochemical testing. It is important to understand the nature(s) of mutations that are known to occur in a gene in question as well as to understand the range of potential mutations that can occur for any gene. The type or types of mutations that can cause a genetic disease determine how comprehensive or sensitive a screening test is. The trinucleotide repeat disorders represent a group of genetic diseases that can be screened easily and with great sensitivity, because the mutations are of a single type and occur in a single region of respective genes. On the other hand, disorders such as X-linked Charcot-Marie-Tooth disease (gap junction $\beta 1$ [GJB1] gene) or myotonia congenita (skeletal muscle chloride channel) are more difficult to diagnose through molecular genetic testing, because different families affected by the disease will often have unique, or private, mutations such as single base changes or small insertions or deletions (Video 34, Charcot-Marie-Tooth Disease). With large genes, the molecular detection of mutations can be quite daunting, to the point that, while technically feasible, particularly with relatively rare disorders, there may not be commercial laboratories willing to develop screening tests. By virtue of the natures of their mutations, however, some genetic disorders can be detected by relatively convenient tests even when they are caused by private mutations. Although the dystrophin gene, responsible for Duchenne and Becker muscular dystrophies, is an extremely large gene with many exons, mutations tend to be fairly sizable (tens or hundreds of bases) deletions in most cases. Because particular gene regions are “hot spots” for these deletions, polymerase chain reaction (PCR) simultaneous amplification (so-called multiplex PCR) of the dystrophin gene regions that are most often deleted can detect mutations in about 75% of cases. Neurofibromatosis 1 (NF1) is another example of a

Figure 25-3. Chromosomal microarray analysis. Genomic DNA is isolated from a patient (typically peripheral blood leukocytes) and labeled with a fluorescent dye (green in this example). An equal amount of genomic DNA from a normal person is labeled with a different dye (red in this example). The two labeled DNA specimens are mixed together and hybridized to a microscope slide onto which small amounts of DNA from known genes or chromosomal regions are spotted. After the unhybridized DNA is washed off, the slide is analyzed in a fluorescent microscope (or similar apparatus). Where equivalent amounts of patient and control DNA have hybridized to a spot, a yellow color is seen, whereas if there is a duplication (or greater increase) of a chromosomal region, a green spot will be seen. In contrast, if the patient has a deletion of a chromosomal region, a red spot will be seen. This approach is useful for other applications, such as analysis of tumor specimens, where complex combinations of duplications and deletions may occur affecting multiple chromosomes at the same time.

genetic disorder affecting a large gene caused by many private mutations. The majority of mutations lead to premature termination of protein synthesis of the neurofibromin protein. Because the neurofibromin gene is expressed in white blood cells, the premature protein truncation test can screen leukocyte RNA for the neurofibromin mRNA that can be specifically amplified and then used as a template for *in vitro* protein synthesis. After electrophoresis

of the neurofibromin generated synthetically and detection by antibody on Western blot, mutations can be reliably inferred if the immunoreactive neurofibromin is a smaller size than the normal protein. The premature protein truncation assay is now commercially available and is reported to detect mutations in the NF1 gene in about 70% of individuals who fulfill the clinical criteria for NF1. When mutations are not found in a clinically affected individual, mutation detection then becomes more problematic. Currently there is no commercial laboratory that offers testing for mutations in the remaining 30% of NF1 individuals. When the clinical situation merits an intensive search for mutations in a gene, it is hoped that future advances in genetic screening and sequencing technology will facilitate mutation identification.

A description of some of the most common techniques in current use illuminate the available dimensions of molecular biological diagnostics.

Polymerase Chain Amplification

Polymerase chain amplification is a critical technique that is central to many detection tests. Even though it does not enable direct mutation detection in all cases, it enables the generation of large amounts of DNA for testing applications. Routine PCR is limited to the amplification of specific small (up to several hundred base pairs in length) regions of a single gene that are bracketed by a pair of opposing DNA primers that define the origins and directions of DNA synthesis of a target gene (Fig. 25-4).

Because each strand of the double helix can be used as a template for DNA synthesis, for each repetitive cycle of DNA denaturation, primer annealing, and DNA synthesis, there is a doubling in the number of amplified DNA regions. Thus, a several billionfold amplification of a gene region is readily achievable from even a minute amount of DNA. As mentioned, PCR is the basis for detecting trinucleotide repeat expansion mutations and for detecting deletions of the dystrophin gene. PCR is also used to amplify segments of a gene suspected of having a mutation. The PCR products are then used in a variety of assays that can screen for mutations.

Single-Strand Conformation Polymorphism (SSCP) Analysis

This modification of PCR technology has the capability of detecting single base mutations and is a very valuable means of screening for small mutations. PCR products, generally a few hundred bases in length, when denatured and subjected to electrophoresis will usually show measurable differences in electrophoretic migration, due to the differences in conformation of the dissociated single strands of DNA. Mutations in a gene may further alter the electrophoretic migration of dissociated DNA strands which have been PCR amplified. This is the basis of SSCP analysis. SSCP when properly designed can detect about 80% or even more of point mutations (mutations as small as a single base difference) within the region amplified. If needed for precise definition of the mutation, direct sequencing of the PCR product can be done.

Allele-specific Oligonucleotide (ASO) Hybridization

This method is primarily used to detect specific point mutations. Certain diseases are caused by a common mutation that recurs spontaneously or by an inherited mutation that is responsible for most occurrences of the disease. An example of the former is achondroplasia, which is acquired by spontaneous mutation of the fibroblast growth factor receptor 3 gene. For unknown reasons, a specific base substitution occurs spontaneously in this disorder. An example of a disorder with a specific point mutation in most affected individuals is sickle cell anemia, wherein individuals with the affected allele inherited it from a common ancestor. With properly designed oligonucleotides, single-stranded DNA probes of about 20 bases in length, it is possible to detect specifically either the normal or mutant gene variant by hybridization of the probes to PCR-amplified DNA segments.

Direct Gene Sequencing

The definitive method for point mutation detection is to sequence the gene directly. For large genes such as the NF1 gene or the dystrophin gene, such a direct screen would be impractical with current technology. For some genes, however, this technique is the method of choice. For example, the entire prion protein gene coding region conveniently lies within a single exon that can be amplified by PCR with a single pair of primers. Current methods can now readily scan the entire coding sequence of the gene in cases of suspected hereditary prion mutations. Other genes, such as the proteolipid protein gene that is mutated in Pelizaeus-Merzbacher disease, with relatively short and few exons, are also amenable to direct sequencing for mutation screening.

Southern Blot Hybridization

There are several neurogenetic syndromes that are caused by increased or decreased numbers of otherwise normal genes. CMT1A and Pelizaeus-Merzbacher disease are most often caused by duplications of the peripheral myelin protein-22 (PMP22) and proteolipid protein genes, respectively. Hereditary neuropathy with predisposition to pressure palsies is due to a loss of one copy of the PMP22 gene. These alterations in gene number or dosage had actually been overlooked previously. The most straightforward method

Figure 25-4. Polymerase chain reaction (PCR). Short, synthetic, single-stranded DNA primers that hybridize to opposing strands of the target DNA are typically spaced a few hundred to a few thousand bases apart (A) and are allowed to anneal to thermally denatured DNA (B). C, DNA polymerase, typically isolated from thermophilic bacteria, is allowed to synthesize the complementary DNA, beginning from the primer. D, The newly synthesized DNA products are thermally denatured, then cooled to allow the primers to anneal again, and the DNA polymerase reaction again allowed to proceed. Step D is repeated, typically about 30 times, to exponentially amplify the product strands, which after round 3 of the reaction preferentially amplifies the short double-stranded DNA product whose termini are defined by the two primers. A typical 30-cycle PCR theoretically can amplify a single DNA molecule over 200 million times. (Adapted from Griffiths AJF, Miller JH, Suzuki DT, Lewontin RC, Gelbart WM: An Introduction to Genetic Analysis 6.0. New York, WH Freeman, 1996.)

of detecting these changes is to examine the signal intensities of the altered gene region compared to the level of a gene region lying outside the duplicated or deleted region. These differences can be overlooked unless specifically sought. The originally used method relied on the standard Southern blot technique (named after its inventor). For this technique, genomic DNA, usually isolated from peripheral leukocytes, is digested with an appropriate restriction endonuclease, subjected to electrophoresis through agarose gels, and

transferred to nylon membranes for hybridization to labeled gene probes. For dosage analysis, a gene probe that spans the junction of the normal and dose-altered genomic region is hybridized to the filter. If a restriction enzyme site exists that separates the normal from altered copy number regions, then the probe will hybridize to a normal level to a DNA restriction fragment in the normal copy region. If the copy number for the gene is increased or decreased, the signal intensity will be altered (Fig. 25-5).

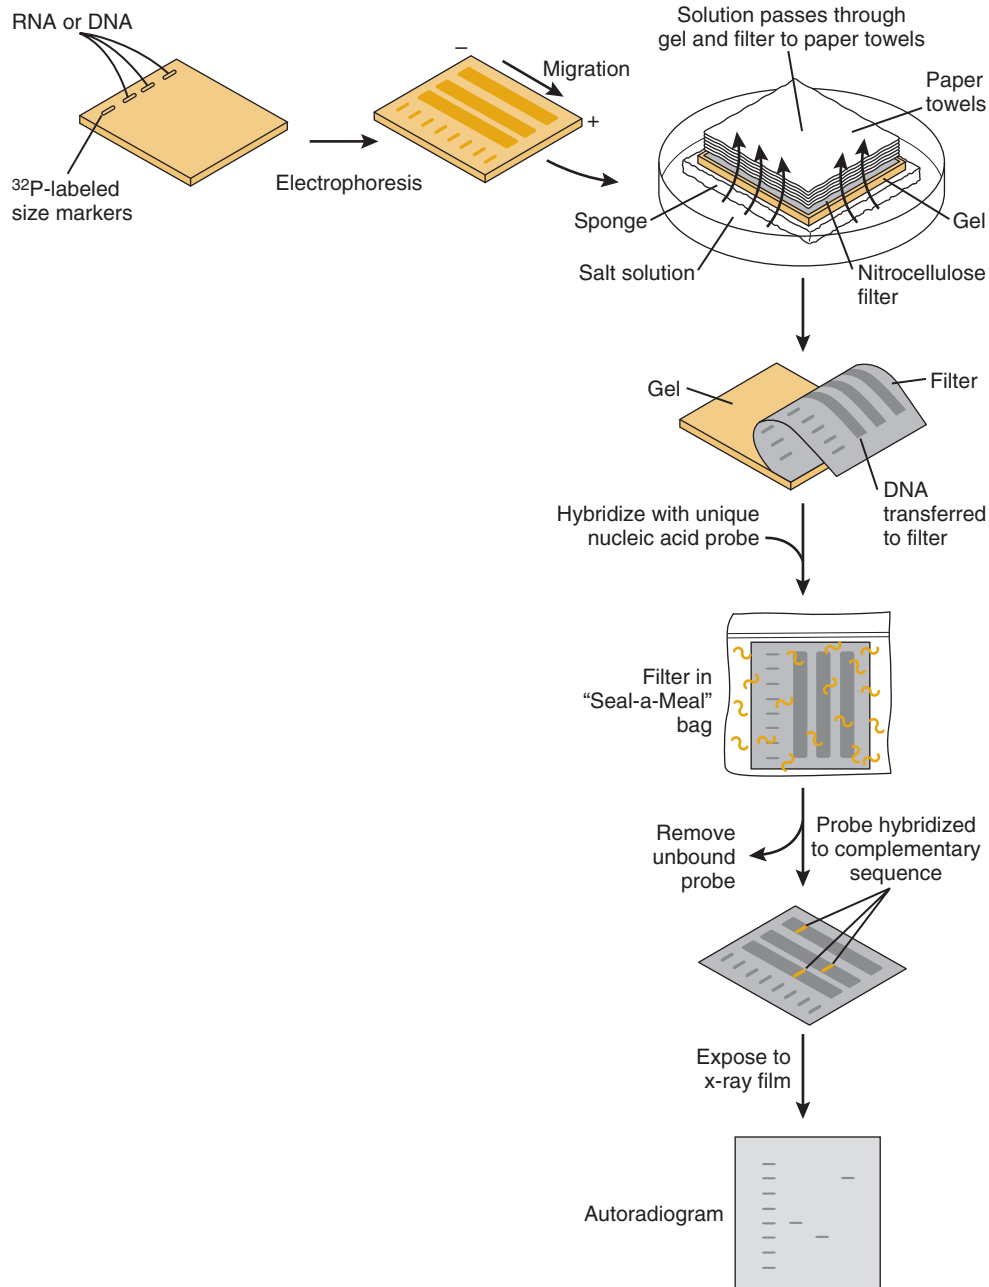

Figure 25-5. Southern blot. DNA fragments, typically after a restriction digest or after PCR, are electrophoretically separated on agarose gels, which sieve the fragments according to size (smaller fragments migrate more quickly). The DNA fragments are transferred, in this case by capillary transfer, to a sheet of nitrocellulose (nylon is also used) under conditions that also denature the DNA into single-stranded molecules that can be recognized by appropriate complementary probes. The nitrocellulose filter is then hybridized with a labeled (usually radioactively tagged) single-stranded probe that sticks to the specific target. The hybridized filter is then exposed to x-ray film and the signals revealed by developing the film. (Adapted from Griffiths AJF, Miller JH, Suzuki DT, Lewontin RC, Gelbart WM: *An Introduction to Genetic Analysis* 6.0. New York, WH Freeman, 1996.)

Restriction Fragment Length Polymorphism (RFLP) Analysis

By chance, mutations that alter the sequence of a gene may create or abolish a sequence cleavable by bacterial proteins called restriction endonucleases. These enzymes cut double-stranded DNA wherever a specific short, usually 4 to 10 base, sequence occurs. The discovery of these enzymes was key to the advances in recombinant DNA technology and modern molecular analysis. When a restriction site is created or abolished, the pattern of DNA fragments generated by the appropriate enzyme is also changed. Because restriction analysis is technically easy to perform, it is a preferred method when informative (Fig. 25-6).

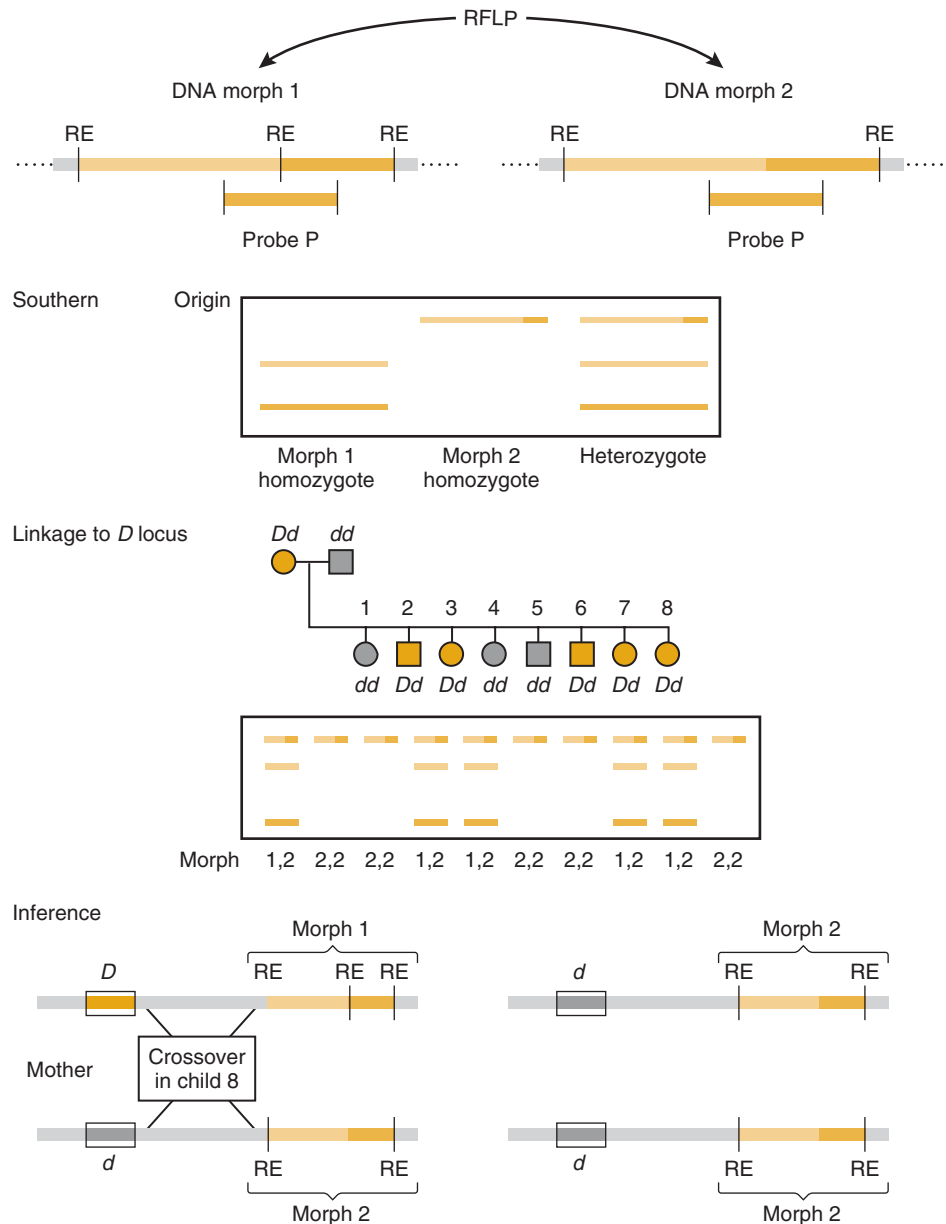

Methods of gene hunting that rely on RFLP analysis take advantage not only of restriction site variation within the

gene itself, but also site variations that lie outside but nearby the gene in question. For example, prior to the discovery of the Huntington's disease (HD) gene, RFLP analysis was the mainstay of genetic diagnosis of presymptomatic individuals (Video 15, Facial Chorea; Video 16, Luria Testing). Nearby restriction site variations outside the HD gene could be used to mark the abnormal chromosome with high (over 95%) reliability, even though these restriction site polymorphisms were not the cause of the disease.

Limitations of Testing

It is important to recognize that the sensitivity of genetic testing varies from one clinical condition to the next, and that it is important to apply testing in the appropriate

Figure 25-6. A, Detection of a restriction fragment length polymorphism (RFLP). A probe (P) hybridizes to a genomic region that straddles a region that contains a polymorphic restriction endonuclease site (the middle one on "morph 1"). The morph 1 region is digested into two fragments of different size that both hybridize to the probe, whereas the morph 2 region is digested such that only a single fragment (whose size happens to be the sum of the sizes of the two fragments in morph 1) is detected. The lower part of the figure is a Southern blot of an agarose gel showing the patterns of hybridization that result. B, Inheritance of an RFLP in a hypothetical family with an autosomal dominant disease (gene symbolized as "D," with normal allele indicated as "d"). Note that the polymorphic restriction site is near but not within the d gene. On most of the chromosomes with the mutant D gene, there is an extra restriction endonuclease site (RE, as in A), so that most of the affected family members have a pattern of three bands, a large band corresponding to the normal allele, and the two smaller bands resulting from the additional restriction site. Individual 8, however, although affected, has the restriction pattern of a normal person due to a recombination, schematized in the lower part of the figure. Such "recombinants" are extremely useful in mapping the location of, and eventually finding, new disease genes. (Adapted from Griffiths AJF, Miller JH, Suzuki DT, Lewontin RC, Gelbart, WM: An Introduction to Genetic Analysis 6.0. New York, WH Freeman, 1996.)

context. The molecular test for HD is very sensitive and specific, but there are other clinical conditions that can present not only with adult onset chorea, but also may even have an autosomal dominant pattern of inheritance. For example, spinocerebellar ataxia 1 and dentatorubropallidoluysian atrophy have autosomal dominant patterns of inheritance but are caused by triplet repeat expansions of unique genes distinct from huntingtin, the gene affected in HD. Therefore, a negative HD test only has value in an asymptomatic person if the genetic test is positive in a clinically affected blood relative. The diagnosis of NF1 is best established clinically, because the search for gene mutations is currently too laborious to be practical in most cases. The premature protein truncation test is the most sensitive molecular test for this disease but only detects abnormalities in about 70% of cases.

In cases in which the gene product, generally a protein, is well characterized functionally, it is usually more effective to screen for abnormalities by functional testing. For example, the lysosomal storage diseases are caused by defective enzymes that can be assayed directly. Thus, the most effective screening test is a direct assay of enzyme function or of substrates or breakdown products of the enzyme in question in a specimen such as serum, urine, or, in certain circumstances, cells, such as fibroblasts obtained by skin biopsy. The category of mitochondrial diseases presents special complicating factors in making a diagnosis, because the diseases due to mtDNA mutations are not reflected in the genomic DNA and the proportion of mutant mitochondria can vary tremendously from tissue to tissue. For example, the blood leukocyte mitochondrial assays may be normal in patients with KSS, necessitating muscle biopsy in many cases to find the DNA deletions that make the diagnosis.

As the number of testable genetic conditions grows, it is anticipated that the approach to diagnostic evaluation will become more complicated and more expensive. For the inherited ataxias alone, there are at least 20 different disease-causing genes. For the most part, these disorders cannot be reliably distinguished solely through clinical history and evaluation, and genetic testing is the only reliable method to differentiate them. Guidelines for rational and cost-efficient testing will need to be developed, perhaps by developing panels of tests for the most common genetic

causes, and secondary panels for the rarer causes. Geographic and ethnic factors, as well as clinical features, when appropriate, may help narrow the number and sequence of tests that need to be done to establish the diagnosis.

Although genetic testing may be somewhat expensive, once a diagnosis is established, no further testing is needed, and testing for other affected relatives can be focused with precision. Furthermore, genetic diagnosis is essential for rational family planning using prenatal and preimplantation genetic testing. In the future, molecularly confirmed diagnoses will be essential to identify those individuals who are appropriate for disease-specific treatments for these disorders.

Ethics of Testing

Particularly for genetic testing, where molecular test results not only provide diagnostic information, but can also predict the onset of disease in many cases, it is important to advise patients on potential implications of genetic information in regard to their economic and social well-being, their own health, and the health of relatives. Adverse genetic risk information potentially could affect an individual's employment and insurance status. Confidentiality must be maintained according to the patient's wishes in virtually all situations.

Need for Counseling

It is very important to ensure that counseling be included as part of a program of genetic testing. The diagnostic and therapeutic team should include a geneticist and genetic counselor to provide understandable information to the patient and family, thereby enabling them to comprehend maximally the direct and more subtle implications of genetic disease. Especially for presymptomatic and prenatal testing for hereditary diseases, it is often necessary to have several counseling sessions in order for the patient to decide on which avenue to proceed. In many cases, and not just limited to presymptomatic testing for HD, psychological evaluations and counseling should be an integral part of the testing process before, during, and after molecular test results are disclosed (Table 25-3).

MUSCLE ENZYMES AND BIOPSY

Forearm Exercise Testing

Muscle fibers develop tension and shorten, thereby producing movement. These processes, including contraction and relaxation, are coordinated by the nervous system and are energy-requiring. Skeletal muscle meets its energy demands by converting chemical energy into mechanical energy. One feature unique to skeletal muscle compared with other tissues is the energy requirement difference between its resting and fully active states, a value that can approach two to three orders of magnitude.¹ When the metabolic energy demands of active muscle cannot be met by the available energy sources, muscle fatigue and dysfunction occur. In such settings, when abnormalities of muscle biochemistry are responsible for the decreased energy supply, the term *metabolic myopathies* is applied (Video 13, Myopathic Gait). For diagnostic purposes, these disorders can be divided into two groups: (1) exercise-induced (dynamic) myopathies, in which symptoms such as weakness, cramping, myalgias, and stiffness appear during exercise; and (2) stable, or slowly progressive (static), myopathies (Tables 25-4 and 25-5).² Muscle energy metabolism may be assessed through exercise testing. The results of these studies may refine the differential diagnosis and reduce the cost of the microscopic analysis. Additionally, when the microscopic evaluation is unrevealing, provocative exercise testing may confirm the presence of a metabolic defect. Common types of exercise testing include forearm (grip) exercise that primarily provides information about the integrity of glycolytic metabolism; incremental bicycle ergometry that yields information about the integrity of aerobic metabolism; and ³¹P magnetic resonance spectroscopy that provides information about the intracellular

metabolites of energy metabolism (i.e., adenosine triphosphate [ATP], inorganic phosphate, and phosphocreatine). Because exercise testing is an important part of the investigation of muscle disease, particularly with disorders of skeletal muscle energy metabolism, it is essential that physicians understand skeletal muscle energy metabolism.

Skeletal Muscle Energy Metabolism

Although muscle contraction is ATP-consuming, the ATP content of a contracting muscle changes little during a sustained contraction. Interestingly, muscle ATP stores are incapable of sustaining a muscle contraction for more than a single second. Phosphocreatine, a high-energy compound with an intramuscular concentration approximately four- to fivefold that of ATP, permits rapid ATP regeneration through the rephosphorylation of adenosine diphosphate (ADP). This reaction is catalyzed by creatine kinase, an enzyme found in large quantities in skeletal muscle tissue. Nevertheless, this anaerobic energy source is depleted in less than a minute, and even when combined, these two sources of readily available energy are incapable of maintaining high-intensity exercise. For this reason, skeletal muscle tissue must rely on other energy sources when sustained exertion is necessary.

In the nonfasting individual, the energy requirements of skeletal muscle are met by the metabolism of either carbohydrate (e.g., glycogen, glucose) or lipid (e.g., free fatty acids). The principal source of carbohydrate for skeletal muscle metabolism is intracellular glycogen, which is formed from blood glucose, via glycogenesis, and stored within the myocyte. When energy is required, glycogen is hydrolyzed to glucose (glycogenolysis) and then to pyruvate (glycolysis). In addition to pyruvate, glycolysis also generates ATP and nicotinamide adenine dinucleotide hydrogen (NADH) (reduced form of nicotinamide adenine dinucleotide [NAD⁺]). Under aerobic conditions, pyruvate is subsequently metabolized to acetyl-CoA. The latter compound enters the Krebs' (tricarboxylic acid) cycle, yielding further molecules of ATP and NADH, as well as flavin adenine dinucleotide hydrogen (FADH₂). The reducing equivalents generated by glycolysis and the Krebs' cycle (i.e., the NADH and FADH₂) enter the electron transport

system, a chain of enzymes located on the inner mitochondrial membrane, and are oxidized. The energy released from their oxidation is used to drive the phosphorylation of ADP to ATP. The maximum derivable energy from the aerobic metabolism of one molecule of glucose is 38 molecules of ATP. Conversely, under anaerobic conditions, because pyruvate is converted to lactate and the generated reducing equivalents cannot be metabolized by the electron transport system, only four molecules of ATP are generated from one molecule of glucose. Hence, the metabolism of carbohydrate is much more energy-efficient in the presence of oxygen (i.e., aerobic metabolism) than in its absence (i.e., anaerobic metabolism). The skeletal muscle fatigue (i.e., the inability to maintain high-intensity exertion for more than several minutes) associated with anaerobic glycolysis results from end-product accumulation (ADP, inorganic phosphorus, hydrogen ion), not from a lack of oxygen.¹ Although blood glucose can be used directly, most carbohydrate energy is derived from glycogen. Unlike carbohydrate storage, which is primarily intramuscular, lipid storage is primarily extramuscular. For this reason, the primary source of lipids during skeletal muscle metabolism is plasma free fatty acids; the lipid present within the myocyte contributes to a much lesser extent. Because the rate of free fatty acid mobilization is slow, the contribution of lipid metabolism during initial energy generation is limited. In addition, although carbohydrate can undergo both aerobic and anaerobic metabolism, lipid can only be metabolized aerobically and consequently cannot be utilized during anaerobic conditions.

As expected, the exact ratio of carbohydrate and lipid utilized for muscle energy metabolism, a topic summarized in an editorial by Layzer,³ reflects many variables, including the intensity of exertion and its duration, the blood concentration of free fatty acids and oxygen, the amount of blood flow to the muscle, the muscle glycogen concentration, and the muscle's capacity for oxidative metabolism. At rest and during light exercise, skeletal muscle tissue metabolism is aerobic, and consequently it aerobically metabolizes free fatty acids for its energy. As the degree of intensity increases, the supply of lipid-derived energy becomes unable to keep pace with the energy requirement. For this reason, a greater proportion of energy must be contributed by carbohydrate. In general, enough glycogen is available to work intensively for 3 to 4 hours.⁴ Should effort continue after the glycogen supply is depleted, the slower rate of lipid metabolism immediately diminishes the magnitude of the ongoing effort. At maximum intensity (e.g., sprinting at full speed), skeletal muscle energy is supplied through anaerobic glycolysis. Initially, the readily available energy substrates are exhausted (i.e., ATP and phosphocreatine), and aerobic glycolysis begins. Although simultaneous changes enhance oxidative metabolism (i.e., increased blood flow to muscle, increased oxygen uptake), they are insufficient to meet the energy demands of maximum exertion. Thus, anaerobic glycolysis occurs and pyruvate is converted to lactate. As lactate accumulates, oxygen debt increases, a term that refers to the additional oxygen required, during recovery, to oxidize the accumulated lactate. Again, this level of exertion can be maintained only for several minutes.⁵ Through aerobic exercise train-

ing, athletes enhance their muscles' capacity for oxidative (aerobic) metabolism. Thus, during submaximal efforts, the blend of substrate used contains a greater percentage of lipid and, for this reason, less glycogen. As a result, the glycogen supply lasts longer, as does the individual's endurance.

Technique

Forearm exercise testing can be performed in a number of ways. Traditionally, the patient was asked to repetitively squeeze a handheld ergometer while a blood pressure cuff was maintained above systolic pressure. The blood pressure cuff, by inducing ischemia, ensures that oxidative phosphorylation cannot occur. A simple technique for evaluating lactate production in response to ischemic forearm exercise was described by Munsat in 1970.⁶ In that report, rested and fasting individuals squeezed a handheld ergometer, with a workload of 4 to 7 kg-m, at 60 Hz for 1 minute. (Alternative methods are to sustain 1.5-second contractions that are separated by 0.5-second rest periods for 1 full minute⁷ or squeezing a hand dynamometer to 50% of maximum grip strength until exhaustion—usually about 10 minutes.²) Although the serum lactate concentrations vary significantly among the studied individuals (the standard deviation approximated 60% of the mean), their *relative change* (rather than their absolute change) is fairly constant for a given individual. The serum lactate concentration peaks within 5 minutes (within 3 minutes for 90% of the tested individuals) of work cessation at a value that is three- to fivefold greater than the initial resting value. Because ischemic work induces pain, it is fortunate that the best correlation between the degree of serum lactate rise and the total work performed occurs when the exercise period is limited to 1 minute, a period of ischemic exercise that most individuals can tolerate. The relationship of forearm work and lactate production without ischemia was also evaluated and appears to produce comparable results, provided the workload exceeds 6 to 7 kg-m. In other words, the work intensity must be sufficiently strenuous to exceed the individual's aerobic threshold, thereby inducing anaerobic energy metabolism. This technique avoids the use of blood pressure cuff-induced ischemia, which may be hazardous to patients with glycolytic defects (may cause severe muscle necrosis).^{2,7}

Regardless of the technique used, the anaerobic condition blocks oxidative phosphorylation, thereby ensuring dependence on anaerobic glycolysis. Pre-exercise and post-exercise (1, 2, 4, 6, and 10 minutes) venous lactate and ammonia levels are determined from venous blood samples collected from a catheter placed in an antecubital vein proximal to the deep veins of the forearm (e.g., the median vein). A three-way stopcock can be connected; blood samples are obtained from the side port and a slow infusion of normal saline maintains catheter patency. Normally, the lactate value rises three- to fivefold (resting level is ~ 1 mmol/L) within 1 to 2 minutes, whereas the ammonia value rises two- to tenfold within 2 to 5 minutes of exercise.^{1,2,5} In the presence of a metabolic disorder, however, different metabolite patterns may be observed: With a *defect in glycolysis*, ammonia elevation occurs, but lactate elevation is diminished or does not occur. With *myoadenylate deaminase deficiency*, lactate elevation occurs, but

elevation of ammonia does not. In the setting of *mitochondrial disorders*, lactate elevation is excessive, and with *poor effort*, neither lactate nor ammonia concentrations increase. As expected, with *disorders of lipid metabolism*, the metabolite profile is normal. Although the major source of blood lactate is muscle, the blood lactate concentration rises with anxiety, hyperventilation, muscular activity, and food intake, and, therefore, the patient should be relaxed, still, and in a fasting state.⁶

Muscle Biopsy

The decision to proceed with a muscle biopsy is made after a thorough medical and neurological history, physical and neurological examination, laboratory evaluation, and electromyogram (EMG) study, thereby permitting the formulation of a preliminary diagnosis and, hence, dictating the studies required of the muscle biopsy specimen. The history characterizes the weakness (e.g., its rate of onset, distribution, time course, precipitants [e.g., exercise-induced], associated symptoms, and family pedigree). The examination quantifies the weakness and identifies any associated features (e.g., myotonia). The laboratory assessment (e.g., serum creatine kinase, urine myoglobin) screens for abnormalities of the blood and urine, while EMG provides information typically not obtainable in other ways, including (1) identification of a nonmyopathic disorder (e.g., motor neuron disease, neuromuscular junction defect), thereby avoiding an unnecessary muscle biopsy; (2) characterization of the myopathy (e.g., its distribution, its associated electrical features [e.g., fibrillation potentials]), thereby further defining the diagnostic possibilities; and (3) identification of the best muscle for biopsy. As expected, the information obtained from the muscle biopsy specimen is related to the underlying disorder, as well as its severity and rate of progression. When the patient is free of muscle weakness, the muscle biopsy is unlikely to show any significant changes. Other important variables influencing the yield of the muscle biopsy include (1) the particular muscle biopsied; (2) the way in which the muscle biopsy specimen is processed; and (3) the particular studies performed on the specimen. Consequently, this subsection includes a discussion of these important variables. Most important, it is necessary for the clinician, the person performing the biopsy, the pathologist, and when indicated, the referring pathology laboratory to carefully plan their approach to the evaluation of the muscle specimen.

Muscle Selection and Technique

Myopathic processes do not affect all skeletal muscles equally. Therefore, a risk of sampling error among muscle biopsy specimens is always present. For this reason, it is paramount to select the muscle that will most likely yield the desired information. Important clinical and electrodiagnostic data to consider in making this determination include (1) the degree of involvement of the muscle; (2) the rapidity of onset of the disease process; (3) the muscle's history; (4) the pathological familiarity of the muscle; (5) the accessibility of the muscle; and (6) the EMG examination findings. A clinically unaffected muscle should be avoided, because it may not be involved pathologically.

A severely affected muscle is also avoided, since it may show only end-stage features (e.g., atrophy, fat, and fibrosis) rather than the distinguishing features of a specific disorder. Although a moderately affected muscle should be sought in patients with a slowly progressive disorder, a more severely affected muscle may provide the greatest diagnostic yield in individuals with a more acute disorder. The chosen muscle additionally should neither be involved with another disease process (e.g., radiculopathy) nor have suffered a recent (i.e., within 1 month) injection or needle electrode examination (i.e., EMG). The needle electrode examination should generally be performed on only one side of the body (and this should be clearly labeled in the chart) and is used to help in the identification of a muscle meeting sampling criteria so that the homologous muscle in the contralateral extremity may be sampled.

In general, the most frequently biopsied upper extremity muscles are the deltoid and biceps brachii, and the most frequently biopsied lower extremity muscles are one of the quadriceps (e.g., vastus lateralis) because the range of normal for these muscles is well defined. Although the gastrocnemius is frequently cited as a useful muscle, it should be avoided because of its type 1 muscle fiber predominance, increased connective tissue, greater susceptibility to random pathological changes, and pennate nature.⁷ The problem with pennate muscles (i.e., muscles in which the tendon insertion extends throughout the muscle) is that inadvertent sampling near the myotendinous junction can occur. This region tends to have more central nucleation, muscle fiber size variability, and split muscle fibers. As expected, the muscle chosen must be easily accessible.

The technique of muscle biopsy is usually not difficult in the hands of an experienced individual. The skin and subcutaneous tissues are anesthetized (e.g., 2% Xylocaine [lidocaine]), while carefully avoiding muscle infiltration. A small incision is then placed in the belly region (i.e., away from the myotendinous junction) along the long axis of the muscle and is extended only to the fascia. In most cases, three specimens are collected: (1) an unclamped specimen for histochemistry (the most important piece); (2) a clamped specimen for electron microscopy; and (3) a clamped specimen for histopathology. A fourth specimen can be obtained and frozen in the event further studies are deemed necessary.

The specimen for histochemistry should be 2 to 3 cm in length and about as thick as a pencil. It should be handled gently by its ends using tweezers and placed in a cool, normal saline-moistened piece of gauze to prevent drying out (soaked gauze may interfere with freezing and produce artifacts). The gauze-wrapped muscle specimen is then placed in a screw-cap vial for later freezing. The specimen should be rapidly transported to the pathology laboratory; otherwise it may lose its enzymatic activity. Many techniques exist for the preparation of the frozen specimen. Typically, it is gently immersed in a Pyrex beaker containing 2 inches of liquid nitrogen-cooled isopentane (-140°C to -155°C), frozen for roughly 30 seconds, and then removed and immediately placed in a previously cooled specimen container (e.g., another screw-cap vial). When the specimen is sent to an outside reference laboratory, the specimen container should be placed in an insulated shipping container filled with dry ice.

The specimen for electron microscopy can be slightly smaller and should be gently raised (e.g., with Metzenbaum scissors) just high enough to permit the placement of a muscle clamp. The clamp is then locked and the muscle specimen cut just *outside* the clamped sites. Clamping helps avoid contraction artifact. A less cumbersome technique involves the suturing of the muscle tissue specimen (e.g., with 3–0 silk) to a piece of tongue depressor before excising it (i.e., it is sutured in situ). Once removed, the muscle specimen is then placed in a 4% buffered glutaraldehyde fixative (or Karnovsky's fixative).

The specimen for histopathology is obtained similar to that for electron microscopy, with the exception that it is fixed in formalin. The fixed specimens should be shipped separately from the frozen specimen. It is important to include the patient's name, the sampled muscle, the procurement time, and a brief note detailing the clinical presentation and workup findings to date, as well as a list of pending studies. Importantly, when specialized studies are planned (e.g., mitochondrial DNA studies), larger tissue specimens may be necessary. For this reason, the reference laboratory should be contacted before performing the muscle biopsy so that the required amount of tissue is procured. Since any delay in the initial freezing can result in enzyme activity reduction, whenever a biochemical analysis is planned (e.g., phosphofructokinase), the muscle specimen should be flash-frozen at the time of its procurement. It can be stored in liquid nitrogen or in a freezer (–130°C) and packed in dry ice if it is to be shipped to an outside laboratory.

The indications for an open biopsy, as opposed to a needle biopsy, are unsettled. There are two major advantages of open biopsies—a larger specimen can be obtained and the specimen can be fixed at its in situ length, thereby preventing contraction artifact. The two major advantages of a needle biopsy are the limited scarring and the ability to sample multiple sites (in either the same or different muscles) in a single session. Disadvantages of this technique include the smaller specimen size and greater orientation difficulty. In general, the experience of the person performing the biopsy and the expertise of the laboratory personnel dictate which technique is utilized.

Diagnostic Staining Methods

OVERVIEW. A brief overview of pertinent neuromuscular anatomy and physiology, including muscle fiber types, is a necessary preface to a discussion of the various stains and reactions. Skeletal muscles are composed of muscle fibers and connective tissue elements termed endomysium, perimysium, and epimysium. Epimysium surrounds the muscle belly and also lies between fascicles. Fascicles are surrounded by perimysium and are composed of groups of muscle fibers that are individually surrounded by endomysium. Small arteries, arterioles, veins, and nerve twigs are contained within the perimysium. Unlike the epimysium, which may contain adipose tissue, the perimysium of adults is usually devoid of adipocytes. Muscle fibers are cylindrical, polygonal (in adult cross sections), multinucleated syncytia derived from myoblast fusion. The muscle cytoplasm is termed sarcoplasm, and the muscle membrane is termed sarcolemma. Muscle nuclei (roughly

five per fiber in cross section) are located just below the sarcolemma (up to 3% may be more centrally placed). Satellite cells are located subjacent to the sarcolemma and are covered by the basement membrane, which surrounds the entire muscle fiber. These function as a reserve cell population. Each muscle fiber contains hundreds of myofibrils that are composed of repeating subunits, termed sarcomeres, containing the contractile elements (e.g., actin, myosin). Tubular extensions of the sarcolemma, termed T-tubules, extend transversely into the muscle fiber between the myofibrils. These structures permit the passage of electrical activity into the depths of the muscle fiber, thereby ensuring a maximal contraction. A second intermyofibrillar system of tubules is the sarcoplasmic reticulum, which is oriented parallel to the myofibrils (i.e., perpendicular to the T-tubules). The ends of these tubules are dilated into cisternae. The T-tubules are surrounded on both sides by the terminal cisternae of the sarcoplasmic reticulum. The nearness of these structures permits the electrical activity traversing the T-tubules to induce calcium release from the sarcoplasmic reticulum, thereby initiating muscle contraction. These tubular structures, as well as the aqueous sarcoplasm and mitochondria, are collectively termed the intermyofibrillar network.

There are two major types of muscle fibers, type 1 and type 2, each with different histochemical and physiological properties that give them specificity for certain activities. Type 1 fibers contain more oxidative enzymes, mitochondria, capillaries, and myoglobin and are hence best suited for aerobic metabolism and nonfatiguing activities (e.g., standing still). Type 2 fibers contain fewer mitochondria, and more abundant glycogen and glycolytic enzymes and are best suited for anaerobic metabolism and, consequently, those activities requiring maximal energy outputs (e.g., bench-pressing). Type 2 fibers are further subdivided into types 2A, 2B, and 2C. The type 2A fibers are more oxidative in nature than the type 2B fibers; type 2C fibers are present in fetal muscle, as well as regenerating muscle. Individual human skeletal muscles are composed of both muscle fiber types. The functional unit of movement is the motor unit, which consists of all the muscle fibers innervated by the same lower motor neuron. Its size, like that of the muscle fiber is dependent on the particular muscle. Although different types of muscle fibers compose an individual human skeletal muscle, the muscle fibers of a given motor unit are all identical in type (since this determination is made by the innervating lower motor neuron). The muscle fibers of a given motor unit normally are randomly distributed among the muscle fibers of other motor units. Although the relative abundance of fiber types among different muscles varies, the proportion of muscle fiber types observed in adults is as follows: type 1 (30% to 40%), type 2A (20% to 30%), and type 2B (40% to 50%). Thus, there are roughly twice as many type 2 fibers as type 1 fibers, whereas in children, the ratio of type 1 fibers to type 2 fibers is nearly 1.⁸ Type 1 fiber predominance is present when more than 55% of the fibers are type 1, whereas type 2 fiber predominance occurs when more than 80% of the muscle fibers are type 2.⁹ The mean diameter of powerful muscles is 85 to 90 μm , as opposed to weaker, more distal muscles that have a mean diameter of 20 μm .⁹ The muscle fiber type also influences

diameter. In general, the diameter of type 1 fibers is less than or equal to that of type 2 fibers. Regarding gender, male type 1 fibers are equal to those of females, whereas male type 2 fibers are larger than those of females, a reflection of hormonal influences.⁹

FROZEN SPECIMEN. This, the most important specimen, is utilized for a variety of histochemical stains and reactions, some of which are listed in Table 25-6. The hematoxylin and eosin stain is useful for characterizing the general morphology (e.g., myocytes, nuclei, connective tissue, blood vessels, nerves) of the skeletal muscle specimen. The hematoxylin component identifies cell nuclei, and hence nuclear position, and muscle cross-striations; the eosin portion counterstains the cytoplasm reddish pink. Connective tissue appears darker with eosin staining. The modified Gomori trichrome stain colors nuclei and mitochondria red and myocytes blue-green. This stain is useful in identifying ragged-red fibers. The periodic acid-Schiff stain causes glycogen to appear purple. This stain readily identifies glycogen storage disorders, as well as capillaries. Oil red O stains lipid orange. Its utility, like that of the Sudan black stain, is in the identification of lipid storage disorders. Nicotinamide adenine dinucleotide dehydrogenase-tetrazolium reductase (NADH-TR) is an oxidative enzyme reaction that, like other reactions of this type, reflects the concentration of mitochondria within myocytes. This reaction colors myocytes purple-gray. By highlighting the sarcoplasmic reticulum, T-tubules, and mitochondria (i.e., the intermyofibrillar network), this reaction causes the sarcoplasm to take on a granular appearance. Although oxidative enzyme

reactions differentiate the different muscle fiber types (i.e., type 1 > 2A > 2B), these reactions should not be used for fiber typing because atrophied type 2 fibers appear darker (i.e., appear like type 1 fibers). Succinate dehydrogenase, a Krebs' cycle enzyme, selectively stains mitochondria, as does cytochrome-c oxidase, a respiratory chain enzyme. Thus, unlike NADH-TR, the tubular elements are not highlighted. These two reactions can be used to determine whether intermyofibrillar aggregates are mitochondrial or tubular elements. The myofibrillar ATPase reaction is the most accurate method of muscle fiber typing.⁹ The color characteristics are determined by the preincubation pH. In short, acidic pHs (e.g., 4.3, 4.6) cause type 1 fibers to appear darker than type 2 fibers, whereas alkaline pHs (e.g., 9.4) cause the type 2 fibers to appear darker. When preincubated at pH 4.3, the type 2A and 2B fibers are lighter than the type 2C fibers, which are intermediate in intensity; at pH 4.6, the type 2A fibers are lighter than the type 2B and 2C fibers, which are intermediate in intensity. Thus, preincubation at pH 4.3 permits the 2C fibers to manifest. Acid phosphatase, a lysosomal enzyme, facilitates the identification of degeneration (since necrotic fibers have increased lysosome content), inflammatory cells, and lysosomal storage disorders (e.g., acid maltase deficiency). Acid phosphatase is stained red, whereas the background is green. The alkaline phosphatase reaction stains regenerating fibers black, as well as normal capillary basement membranes; the background is yellow. Nonspecific esterase highlights endplates, lysosomes, and macrophages. It also identifies recently (i.e., within 6 months) denervated muscle fibers. The denervation-induced atrophy causes these fibers to appear smaller and darker. Sulfonated alcian blue stains amyloid "sea foam" green; it stains mast cells red. The alkaline Congo red stain causes amyloid to appear red, and when viewed under polarized light, an apple green birefringence is observed.

These stains and reactions, on transverse section, permit the shape, diameter, and intermyofibrillar pattern of the myocyte, as well as the arrangement and proportion of muscle fiber types, to be determined. Adult muscle fibers appear polygonal, and their cross-sectional diameters vary, depending on the specific skeletal muscle. Within a given section, they are somewhat uniform. The intermyofibrillar pattern is best demonstrated with the histochemical reactions for oxidative enzymes and should appear uniform. Two examples of the histopathological features that disrupt the intermyofibrillar network include target fibers and central cores. Since the muscle fiber types of different motor units are interspersed, normal muscle shows a checkerboard pattern of light and dark fibers. This same reaction permits the recognition of fiber type disproportion and those disorders confined predominantly to one muscle fiber type (e.g., atrophy, cytoarchitectural abnormalities). When atrophy is identified, it should be further characterized as to muscle fiber type involved. When atrophy is due to a chronic denervating disease, the checkerboard pattern of type 1 and type 2 fibers is altered by collateral sprout-related reinnervation. Thus, the adjacent atrophied myocytes are of the same histochemical fiber type. Conversely, when atrophy is due to disuse, the checkerboard arrangement of muscle fiber types is maintained because collateral sprouting does not occur. Certain cytoarchitectural

TABLE 25-6

Selected Stains and Reactions and Their Usefulness in Evaluating Skeletal Muscle

| STAINS/REACTIONS | USEFULNESS |
|---------------------------|---|
| Stains | |
| Hematoxylin and eosin | Hematoxylin: nuclei, cross-striations (purple) Eosin: cytoplasm (red), connective tissue (darker red) |
| Modified Gomori trichrome | Nuclei, mitochondria, T-tubules, sarcoplasmic reticulum (red); myocytes (blue-green) |
| Periodic acid-Schiff | Glycogen (purple; type 1 > 2; glycogen storage disorders) |
| Oil red O | Lipid (orange; type 1 > 2; lipid storage disorders) |
| Reactions | |
| NADH-TR | T-tubules, sarcoplasmic reticulum, mitochondria Type 1 (dark); type 2A (intermediate); type 2B (light) |
| Succinate dehydrogenase | Krebs' cycle enzyme; selectively stains for mitochondria |
| Cytochrome-c oxidase | Respiratory chain enzyme (orange-brown; type 1 > 2) |
| ATPase (pH 4.3) | Type 1 (dark); type 2 (light) |
| ATPase (pH 4.6) | Type 1 (dark); type 2A (light); type 2B (intermediate) |
| ATPase (pH 9.4) | Type 1 (light); type 2 (dark) |
| Acid phosphatase | Degeneration (stains red; background fir green) |
| Alkaline phosphatase | Regeneration (stains black; background yellow) |
| Nonspecific esterase | Acetylcholinesterase (yellow-red; type 1 > 2) |

TABLE 25-7

Preferential Fiber Type Involvement**Preferential Atrophy**

Type 1 fibers: Myotonic dystrophy (prominent), nemaline myopathy, centronuclear myopathy, congenital fiber type disproportion
 Type 2 (especially 2B) fibers: Disuse, corticosteroid excess (exogenous, endogenous)*

Cytoarchitectural Abnormalities

Type 1 fibers: Target fibers, central cores (central core disease), rod bodies (nemaline myopathy), mitochondrial abnormalities
 Type 2 fibers: Tubular aggregates

*Type 2 fiber atrophy, especially if limited to type 2B fibers, is a nonspecific finding most frequently indicating disuse.

abnormalities are more pronounced in one muscle fiber type (Table 25-7).

Target fibers are a cardinal feature of neurogenic disorders and are composed of three “rings”: (1) a central light-staining ring; (2) an intermediate dark-staining ring; and (3) a peripheral normal-staining ring. They are most predominant among type 1 muscle fibers. With central core disease, the NADH-TR reaction produces central unreactive zones, termed central cores, among affected myocytes. Thus, these structures are composed of two rings: a central ring of absent staining surrounded by a normally staining periphery. Again, type 1 fibers are mainly affected. Rod bodies (nemaline myopathy), which originate from Z disc material, appear reddish purple in the modified Gomori trichrome stain. Because a small number of muscle fibers in muscular dystrophy and polymyositis have been noted to contain these structures,⁹ a diagnosis of nemaline myopathy requires the presence of numerous rod bodies in many muscle fibers. As previously noted, the modified Gomori trichrome stain is also useful in the identification of mitochondria and the tubular system of muscle. This stain readily identifies subsarcolemmal collections of mitochondria, termed ragged-red fibers, as well as sarcoplasmic reticulum–derived collections, termed tubular aggregates. Both of these abnormalities stain red. Because tubular aggregates are also highlighted by the NADH-TR reaction, but not by the succinate dehydrogenase reaction, they are easily differentiated from mitochondrial aggregates. Although these structures are frequently seen with hyperkalemic periodic paralysis, they are not diagnostically specific for this condition. Rimmed vacuoles have blue margins with hematoxylin and eosin and red margins with the modified Gomori trichrome stain. They are seen in association with inclusion body myopathy, oculopharyngeal muscular dystrophy, distal myopathy, and denervated muscle.

Regarding the two other specimens, the glutaraldehyde-fixed specimen is embedded in plastic for electron microscopy (discussed later in the chapter), whereas the formalin-fixed specimen is embedded in paraffin for light microscopy. Paraffin sections, which are routinely stained with hematoxylin and eosin (viewed in polarized light) and trichrome (viewed in bright field optics), can serve several purposes.¹⁰ Longitudinally oriented sections permit the identification of cross-striation loss, inflammatory infiltrates, and blood vessel wall changes and can also serve as backup material.

SPECIALIZED STUDIES. Immunocytochemical techniques utilize commercially prepared antibodies to identify absent or abnormal proteins (e.g., dystrophin, laminin, complement cascade components) and to characterize cell types (e.g., lymphocyte subclasses), among other functions. For example, antibodies against dystrophin can confirm the diagnosis of Duchenne muscular dystrophy when blood tests are uninformative; antibodies against cell markers can demonstrate immune deposits distinctive of dermatomyositis; and antibodies against the membrane attack complex can identify cells targeted for destruction by the immune system. Enzyme histochemistry permits the biochemical analysis of muscle homogenates for specific enzymes (e.g., phosphofructokinase), and electron microscopy is available when ultrastructural examination of the tissue specimen (e.g., diagnosis of congenital myopathies, inclusion body myopathy, mitochondrial inclusions, tubular aggregates) is required. Western blot analysis is useful in the detection of the protein deficits associated with some of the dystrophies, and DNA studies are helpful in the diagnosis of certain hereditary diseases.

Some histopathological changes are pathognomonic of a particular disorder. In general, the more specialized the study, the more likely its results will have pathognomonic significance (e.g., immunocytochemical studies [dystrophin], electron microscopy [inclusion body myopathy, congenital myopathies with pathognomonic ultrastructural features], and enzyme histochemistry studies for specific enzymes). In addition, certain morphological features, such as atrophy, are indicative of an underlying muscle disorder. For example, perifascicular atrophy, in which the muscle fibers near the edges of the fascicle are atrophied, is the hallmark of dermatomyositis, whereas panfascicular atrophy is indicative of Werdnig-Hoffmann disease.

Myopathic and Neurogenic Changes

The histopathological features observed in skeletal muscle biopsies can be subdivided into two pathological processes—those due to interruption of innervation (i.e., neurogenic changes) and those due to dysfunction of the muscle fiber itself (i.e., myopathic changes). Because nerve and muscle pathophysiology dictate the observed changes, a brief overview of this topic initiates this subsection. As previously discussed, the functional unit of movement is the motor unit. This structure consists of a single lower motor neuron, its peripherally directed axon, and all of the muscle fibers it innervates. With lower motor neuron and motor axon disorders, because the affected axons undergo wallerian degeneration, the muscle fibers of an entire motor unit are denervated. Denervated muscle fibers undergo several changes, including downregulation of contractile element synthesis and contractile element resorption, both of which permit their survival, albeit in an atrophied state. If these muscle fibers are not reinnervated within approximately 20 months, they will be replaced by connective tissue. With incomplete nerve lesions, the uninvolved motor axons can sprout collaterals to the denervated muscle fibers, thereby “adopting” them. This process increases the number of muscle fibers innervated by the adopting lower motor neuron. With myopathic disorders, random muscle fiber loss occurs,

rather than loss of whole motor unit territories. However, collateral sprouting may still occur with a myopathy. When a portion of a muscle fiber is degenerated (i.e., segmental necrosis), the muscle fiber functions as two separate fibers, the portion with the motor endplate (i.e., the innervated fiber) and the portion without it (i.e., the denervated fiber). Because the regenerative capacity of muscle is considerable, the denervated portion can be adopted by collateral sprouting. Also, precursor cells (satellite cells) proliferate and fuse with each other to regenerate the destroyed portion of the muscle. Muscle fibers that are not reinnervated undergo degeneration, a process associated with extensive collagen deposition and fatty infiltration.

HISTOLOGICAL FEATURES ASSOCIATED WITH NEUROPATHIC PROCESSES. Histological features associated with neuropathic processes include angular atrophic fibers, group atrophy, fiber type grouping, target fibers, nuclear bags, and the presence of minimal interstitial fibrosis.⁸ Of these features, the most typical attribute is atrophy, a process resulting in the appearance of small angulated (in cross section) muscle fibers, not selective for fiber types, scattered throughout the specimen. The atrophy also causes the intensity of staining to increase; thus, the denervated fibers appear darker (e.g., nonspecific esterase). Normally, the intermixing of muscle fiber types produces a random checkerboard pattern when skeletal muscle tissue is stained using fiber type-specific techniques. Because collateral sprouting increases the number of muscle fibers innervated by the adopting lower motor neurons and, as previously discussed, converts them to its own histochemical type, fiber type grouping occurs. For this reason the normal checkerboard staining pattern of muscle fibers diminishes. As denervation continues, assuming reinnervation keeps pace, larger and larger groups of contiguous fibers of the same histochemical type are observed (the *sine qua non* of reinnervation). Atrophy of these groups produces grouped atrophy, the hallmark of chronic denervation. The extreme version of grouped atrophy is panfascicular atrophy, a feature indicative of Werdnig-Hoffmann disease. Fiber type grouping must be distinguished from fiber type predominance.

HISTOLOGICAL FEATURES ASSOCIATED WITH MYOPATHIC PROCESSES. Primary disorders of muscle may affect solely the sarcolemma, a single region (segment) of the muscle fiber, or the entire muscle fiber. Thus, the histological features observed vary with the particular myopathic process. Features considered to be indicative of a myopathic process include rounded fibers, central nucleation, muscle fiber size variability, fiber splitting, segmental necrosis, muscle fiber necrosis (degeneration), cellular inflammation, myophagocytosis, regeneration (i.e., basophilic fibers), an increase in connective tissue elements, and structural abnormalities (e.g., vacuoles [glycogen, lipid], ragged-red fibers [mitochondrial myopathies], granulomas [sarcoid], and microorganisms [toxoplasmosis, trichinosis], as well as those structural changes associated with various congenital myopathies [e.g., rod bodies, central cores]).⁸ Centrally located nuclei may be observed in up to 3% of normal muscle tissue specimens, but when present in a higher percentage, this indicates an underlying myopathy. This finding is especially prominent in the muscle fibers of patients with myotonic dystrophy (see Chapter 36). In fact,

when internal nuclei appear in most of the muscle fibers of the sample, this diagnosis is strongly implicated. However, when a *single* central or paracentral nucleus appears in essentially every myocyte, the diagnosis of centronuclear myopathy is indicated. The combination of atrophy and hypertrophy contributes to the wide variability of muscle fiber size. Because muscle fiber splitting normally occurs near myotendinous junctions, muscle biopsies from this region may appear myopathic, and, consequently, sampling in this region is discouraged. When viewed in cross section, connective tissue septae, often with adjacent nuclei, are seen traversing the affected (i.e., split) muscle fibers. When muscle fiber necrosis destroys only a portion of the myocyte, the term *segmental necrosis* is applied. In this situation, proliferating satellite cells may regenerate the destroyed segment, thereby reinnervating the portion lacking a motor endplate. Features of regeneration include basophilic sarcoplasm (due to the rich ribonucleic acid content) and large nuclei with prominent nucleoli. However, when reinnervation occurs by collateral sprouting, small foci of fiber type grouping may be observed. Hence, small patches of fiber type grouping should not be considered synonymous with a neuropathic process. Inflammatory cell collections may have a perivascular distribution (e.g., collagen vascular disorder, dermatomyositis) or be most pronounced intracellularly (e.g., facioscapulohumeral dystrophy). With dystrophic myopathies, the thin connective tissue layers separating individual muscle fibers thicken and the muscle fibers may undergo considerable fibrosis. Regarding disease tempo, muscle fiber necrosis, basophilia, and myophagocytosis are features typical of an active myopathic process, whereas muscle fiber splitting is more characteristic of a chronic myopathy.¹¹

NERVE TISSUE

Biopsy of the peripheral nerve has somewhat limited use. It is generally performed in suspected neuromuscular diseases in order to aid in the distinction between segmental demyelination and axonal degeneration, particularly when the clinical evaluation, laboratory studies, and electrophysiological examinations are nondiagnostic or contradictory. Nerve biopsy may also be useful in the diagnosis of a number of specific disorders with characteristic findings that may involve a peripheral nerve such as amyloidosis, vasculitis, sarcoidosis, and some neoplasms.¹² Diagnostic nerve biopsy is generally restricted to a relatively expendable sensory nerve such as the sural, although portions of peripheral motor nerve twigs may be available for examination as part of muscle biopsy. Because of the limited amount of nervous system tissue available for examination and the relatively limited repertoire of pathological findings, peripheral nerve biopsy has a high chance of being noninformative unless the procedure is performed to answer a specific question in the context of the other clinical and electrophysiological findings.

Nerve Selection and Techniques

Biopsy of peripheral nerve is usually completed either as a full-thickness nerve biopsy (i.e., a complete transection of

the nerve to remove a segment) or as a fascicular biopsy (i.e., a longitudinal dissection of the nerve to remove segments of only one or several fascicles), sparing at least a portion of the nerve. Full-thickness nerve biopsy is considered technically easier to perform and is preferable when the pathological evaluation should include both nerve fibers and surrounding connective tissue and vascular structures. Fascicular nerve biopsy usually produces a smaller deficit and is favored when larger nerves are biopsied.

The choice of peripheral nerve biopsy site is limited by the potential deficits arising from nerve transection. The most common sites are the sural nerve or the superficial peroneal nerve, both subcutaneous sensory nerves in the lower extremity. In occasional cases, the superficial radial nerve in the upper extremity or the greater auricular nerve is also sampled. As noted earlier, concomitant biopsy of skeletal muscle to include small intramuscular nerve twigs may supplement the examination of the peripheral nervous system. Peripheral nerve biopsy may also be combined with skin biopsy, removing an ellipse of overlying skin, when morphological or tissue culture examination of skin is desired for diagnosis of metabolic or degenerative disease.

The sample amount is varied and should be judged, on the one hand, by the amount of tissue needed for the proposed studies and, on the other hand, by the fact that deficits arising from transection of the nerve during biopsy will not necessarily be increased by removing the extra centimeter or two that transforms a nondiagnostic biopsy into a useful diagnostic tool. For most purposes, a 2- to 3-cm segment of full-thickness nerve or fascicles is adequate to provide tissue for standard light and electron microscopic examination, including preparation of teased nerve fibers and frozen section.

Testing Methods

The usual morphological techniques for examination of peripheral nerve include standard light microscopy and electron microscopy, supplemented by morphometric studies, examination of teased nerve fibers, and examination of frozen sections when special studies such as immunohistochemistry are needed (Table 25-8).¹³ For light and electron microscopy and teased nerve studies, specimens are usually fixed in glutaraldehyde solution. Cross sections

are standard and useful for morphometric studies. Longitudinal sections are also useful for demonstrating some pathological findings, including focal processes such as vasculitis that may be irregularly distributed along the length of the nerve and missed in a given cross section. For light microscopic examination, resin-embedded sections stained with dyes such as toluidine blue give good morphological resolution. The same tissues can be subsequently processed for electron microscopy. Formalin-fixed or glutaraldehyde-fixed paraffin-embedded tissues and frozen sections give less resolution but generally permit examination of larger expanses of tissue and may be useful for some special stains, including some immunohistochemical procedures. Teased nerve fiber preparations, involving the dissection of single nerve fibers from fascicles of fixed nerve, are used for examination of sequential internodes of myelin along the fiber and are essential for proper assessment of various conditions involving axonal degeneration, regeneration, segmental demyelination, and remyelination. Morphometric procedures allow for the scoring of abnormalities.

BRAIN AND MENINGEAL TISSUE

In the earlier part of this century, diagnostic brain biopsy was often considered a technique of last resort. The development of improved imaging techniques such as computed tomography (CT) and magnetic resonance imaging (MRI) now permits a high degree of definition of lesions, including both anatomical localization and pathological characteristics. Concomitant developments in neurosurgical techniques, including stereotactic or computer-guided neurosurgery, microsurgical techniques, and intraoperative neurosurgery such as electrocorticography, now permit access to brain tissue with relatively little morbidity, even in vulnerable areas such as motor cortex, the diencephalon, and the brain stem.¹⁴⁻¹⁶

Diagnostic biopsy of a brain lesion, possibly followed by resection, is now essential in the diagnosis and management of most primary brain tumors and often plays a role in the management of metastatic disease as well. Diagnostic brain biopsy may also play a role in the management of other mass lesions of a non-neoplastic nature, such as distinguishing between reactive and neoplastic mass lesions. Diagnostic brain biopsy currently also has a more limited use in certain forms of infectious, degenerative, or metabolic diseases that affect the brain. In some of these disease categories, the need to sample brain tissue has been lessened because of the development of improved imaging studies and other ancillary diagnostic techniques. Recent rapid developments in genetics and molecular diagnosis may further supplant the need to obtain central nervous tissues in some circumstances but may also create as yet unforeseen needs for brain tissue. In addition, brain tissue resection is part of the management of some forms of chronic intractable epilepsy.

Despite the improvements in neurosurgical and other clinical practice, removal of nonregenerating brain tissue is still accompanied by risk of permanent neurological deficit. Additional risks of intraoperative complications such as hemorrhage, cerebral infarction, or infection and of

TABLE 25-8

Morphological Examination of Peripheral Nerve

| TECHNIQUE | FIXATION | USE |
|----------------------------------|------------------------------------|--|
| Routine light microscopy | Formalin, paraffin | Survey (vasculitis, amyloidosis) |
| | Glutaraldehyde, paraffin, or resin | Survey |
| Frozen specimen light microscopy | None | Special stains (immunohistochemistry, metachromasia) |
| Teased nerve examination | Glutaraldehyde, osmium | Myelin internodes |
| Electron microscopy | Glutaraldehyde, osmium, resin | Fine structure |

postoperative complications such as scarring with formation of an epileptic focus must also be considered. The decision to remove brain tissue must be balanced between the attendant risks and the utility of a tissue diagnosis.¹⁷

Tissue Selection and Techniques

Diagnostic brain biopsy is usually performed as stereotactic biopsy or open craniotomy.¹⁶ Stereotactic brain biopsy, using CT or MRI guidance, is usually completed by the aspiration of tissue through a needle inserted into the area of the lesion. Although this technique is particularly useful in cases in which the lesion is small, deep-seated, or located in a sensitive area such as the motor cortex or deep nuclei, the amount of tissue removed is small and may hinder diagnosis. The procurement of multiple biopsies along the needle trajectory, however, may provide a more complete picture of the pathological process. For accessible lesions, open craniotomy permits the intraoperative assessment of pathological processes by direct observation and may be performed when biopsy and resection are contemplated. This procedure may also be considered when maintenance of the anatomic relationship of the biopsy specimen is desired. Stereotactic localization techniques can also be applied to open craniotomy procedures and are sometimes useful in planning and monitoring resections.

The choice of biopsy site depends on the suspected diagnosis.¹⁸ In the setting of a structural or mass lesion (brain tumor), whether neoplastic or non-neoplastic, tissue from the area of imaging abnormality is the obvious choice, although the pathological lesion and the imaged lesion may not be equivalent. Infiltrating gliomas, for example, may extend well beyond the area of contrast enhancement seen on imaging studies, and occasional lesions that appear discrete on imaging studies such as MRI may be remarkably ill-defined and elusive in the operating room or in the pathology laboratory. In the case of a mass lesion, the amount and pattern of sampling should also be guided by the suspected diagnosis. The amount of tissue sufficient for diagnosis cannot be predicted and often depends on the nature of the disease process. A few cells from a cerebrospinal fluid or needle aspiration of tissue may be sufficient in the diagnosis of metastatic carcinoma or lymphoma, whereas even post-mortem examination of the entire brain may be inadequate to establish a precise diagnosis in some degenerative or metabolic diseases.^{19,20} Direct communication between the clinician and the pathologist prior to the surgical procedure is the best method of ensuring that tissue sampling is appropriate.

Intraoperative evaluation of tissue samples by frozen section or other preparation has several roles. Frozen sections may provide a specific diagnosis in some cases, but in many situations a definitive diagnosis can be made only after evaluation of all tissue specimens and with adjunctive studies. Frozen sections are sometimes used to guide resection of a mass lesion. In many cases, particularly in primary biopsies of undefined lesions, frozen section is most useful in the assessment of whether the tissue sample appears adequate to answer the clinical question. It also is useful in the selection and processing of the tissue for other pertinent studies, even if a precise diagnosis cannot be rendered intraoperatively.²¹

In the case of large tumors, abscesses, or other reactive lesions, the abnormal brain region may be heterogeneous. Sampling of central areas of complete tissue necrosis in tumors or abscesses may not yield diagnostic tissue. The relationship of the lesioned tissue to the adjacent brain is often important in assessing the nature of the pathological process, for example, demonstrating the infiltrating border in gliomas, the presence of residual or recurrent tumor in radiation necrosis, or the boundary between demyelinated or necrotic brain and normal brain. Microorganisms are often present at the expanding edge of infectious lesions but absent in the necrotic center. Stereotactic biopsy offers the advantage of obtaining multiple samples along a single needle trajectory and is useful in evaluating heterogeneous lesions such as gliomas, in which different areas of the tumor may show different degrees of malignancy, as well as in reactive lesions.

Intraoperative monitoring of brain function by techniques such as electrocorticography is useful in guiding sampling or resections in sensitive areas such as the motor strip. These techniques are also essential in mapping epileptic foci and can be used in conjunction with conventional imaging studies and special studies such as positron-emission tomography.

In the absence of a mass lesion or defined area on imaging studies, noneloquent areas of the cerebrum are generally selected. The type of tissue sampled (e.g., gray or white brain matter, leptomeninges) should also be guided by the suspected diagnosis. The most useful specimen should be large enough to allow for the proper orientation by the pathologist and to be divided into pieces adequate for special studies (see later in the chapter). For degenerative or metabolic diseases, infectious diseases (viral encephalitis), and diffuse disorders (cerebral vasculitides), a wedge of brain tissue consisting of cerebral cortex, overlying leptomeninges, and underlying white matter provides the most useful tissue sample and should be large enough to provide material for ancillary studies (e.g., biochemical analysis, electron microscopy).

Testing Methods

Morphological techniques include cytological studies (the evaluation of individual cells in fluids) and histological studies (the evaluation of cells in their tissue context). The latter involve light microscopy with routine and special stains, electron microscopy, histochemistry, and immunohistochemistry. Typical methods of fixation and staining for each technique are summarized in Table 25-9. Ancillary studies that supplement the armamentarium of morphological techniques include microbiology (e.g., bacterial, viral, fungal cultures), cytogenetics (e.g., karyotype analysis), molecular genetics (e.g., polymerized chain reaction), and biochemical analyses.

The choice of morphological and ancillary techniques depends on the nature of the lesion and the available material. Although most pathological diagnoses are made on sections of formalin-fixed paraffin-embedded tissues stained with hematoxylin and eosin or a comparable general tissue stain, some diagnoses require other stains to be used on the paraffin-embedded tissues or even other methods of tissue handling and fixation (freezing, glutaraldehyde fixation,

TABLE 25-9

Diagnostic Brain Biopsies: Common Tissue Techniques

| EVALUATION | BIOPSY TECHNIQUE | FIXATIVE | STAINING |
|---|--------------------------------------|---------------------------------|---|
| Cytological | Imprint/touch Smear/squash | Alcohol | Rapid hematoxylin and eosin, Diff-Quik, Papanicolaou |
| Routine histological | Frozen section Paraffin section | Alcohol Formalin, B5 | Rapid hematoxylin and eosin, metachrome B, special staining |
| Special histological: histochemistry, immunohisto-chemistry | Frozen section Frozen or paraffin | None Variable | Enzymes, biochemical reactions Monoclonal or polyclonal antibodies |
| Electron microscopy | Thick section Thin section | Glutaraldehyde/OsO ₄ | Toluidine blue Lead citrate/uranyl acetate |

and plastic embedding for electron microscopy; submission of unfixated tissues in special handling media for cytogenetic or microbiological studies). Before fixation, tissue should be divided and processed appropriately for these studies. Consideration of the expected diagnosis, obtained from the preoperative workup or from intraoperative frozen section, is essential in the planning and optimal handling of the diagnostic brain biopsy. Familiarity with a particular institution’s manual of laboratory procedures that list recommendations for handling tissues for specific tests and communication with the neurosurgeon and pathologist in advance of the biopsy procedure are necessary to avoid inappropriate handling of valuable specimens.

Specific Indications

Categories of central nervous system (CNS) disease amenable to diagnosis by brain biopsy or mimicking types of disease normally presenting as neurosurgical conditions are summarized in Table 25-10. This disorder can be grouped into conditions that present with mass lesions, focal or multifocal nonmass lesion abnormalities, and diffuse abnormalities. Mass lesions include most neoplasms and neoplastic or non-neoplastic cysts, some forms of infection (abscesses, cerebritis, tuberculomas, some encephalitides), specific vascular disorders (hemorrhages, early

infarcts), malformations or developmental lesions (hamartomas, some migrational abnormalities), and a variety of miscellaneous conditions (e.g., sarcoidosis, acute multiple sclerosis, and adrenoleukodystrophy) (Video 252, Neonatal Adrenoleukodystrophy). Conditions that produce imaging study abnormalities that are not necessarily mass lesions include some neoplasms (infiltrating gliomas, gliomatosis, lymphomas), cerebrovascular disorders (vasculitides, vasculopathies), infections (viral encephalitis, progressive multifocal leukoencephalopathy, CNS syphilis), degenerative diseases (Creutzfeldt-Jakob disease, and other dementias), inflammatory and immunological disorders (acute disseminated encephalomyelitis, limbic encephalitis, Rasmussen’s encephalitis), developmental and malformative disorders (cortical migrational disorders and dysplasias), toxic and metabolic disorders (leukodystrophies, central pontine myelinolysis, mitochondrial encephalopathies), and some forms of epilepsy (mesial temporal sclerosis, malformations). Finally, some conditions show either no imaging study abnormalities or show only atrophy without focal findings, for example, degenerative diseases (Alzheimer’s disease, Parkinson’s disease), toxic and metabolic diseases (hepatic encephalopathy, many storage diseases), and most cases of idiopathic epilepsy.

Mass Lesions (Table 25-11)

TUMORS. The differential diagnosis of a mass lesion presumed to be neoplastic can be limited by considering the age of the patient and the location of the tumor.

TABLE 25-10

Brain and Meningeal Biopsy Diagnoses

| CATEGORY | EXAMPLES |
|---------------------------|---|
| Neoplasms | Gliomas, metastatic tumors, CNS lymphoma |
| Infections (inflammatory) | HIV encephalitis, opportunistic infections (toxoplasma, cytomegalovirus, herpes simplex, <i>Cryptococcus</i>), bacterial abscess, cysticercosis, tuberculosis, sarcoidosis |
| Degenerative diseases | Creutzfeldt-Jakob disease, Alzheimer’s disease, Pick’s disease |
| Vascular diseases | Vasculitis, amyloid angiopathy, vascular malformations, CADASIL |
| Epilepsy | Mesial temporal sclerosis, dysplasias and malformations, Rasmussen’s encephalitis |
| Metabolic diseases | Leukodystrophies, storage diseases, mitochondrial diseases |

CADASIL, cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy; CNS, central nervous system; HIV, human immunodeficiency virus.

TABLE 25-11

Differential Diagnosis of Space-Occupying Central Nervous System Lesions

| CATEGORY | SPECIFIC LESIONS |
|-----------------|---|
| Neoplasms | Intra-axial: gliomas, metastatic tumors, lymphoma Extra-axial: meningiomas, nerve sheath tumors |
| Infections | Abscesses (bacterial, fungal, parasitic), granulomas (tuberculosis, sarcoidosis), necrotizing lesions (toxoplasma, some focal viral encephalitides) |
| Cerebrovascular | Hemorrhages, acute infarctions |
| Demyelinating | Acute multiple sclerosis, adrenoleukodystrophy |
| Cysts | Metastatic neoplasms, primary neoplasms (gliomas), primary developmental disorders (arachnoid, neuroepithelial, colloid, enterogenous) |

TABLE 25-12

Differential Diagnosis of Neoplastic Central Nervous System Tumors

| AGE | CEREBRAL HEMISPHERES | DIENCEPHALON | POSTERIOR FOSSA | CEREBRAL MENINGES | SPINAL CORD |
|-----------|--|--|--|--|--|
| Adulthood | Astrocytoma, glioblastoma, oligodendroglioma, ependymoma, metastatic tumor, lymphoma | Astrocytoma, glioblastoma, colloid cyst, pituitary adenoma | Metastatic tumor, hemangioblastoma | Meningioma, CN VIII schwannoma, metastatic carcinoma, lymphoma | Meningioma, nerve sheath tumors, astrocytoma |
| Childhood | Astrocytoma, ependymoma, choroid plexus tumor, primitive neuroectodermal tumor | Germ cell tumors, craniopharyngioma | Medulloblastoma, ependymoma, cerebellar pilocytic astrocytomas, brain stem astrocytoma, choroid plexus tumor | Leukemia, lymphoma | Nerve sheath tumors, astrocytoma |

CN, cranial nerve.

Table 25-12 lists examples of tumors encountered in certain nervous system locations in the pediatric and adult age groups. Diagnostic biopsy is usually directed toward the mass lesion. As noted earlier, the possibilities of tissue heterogeneity and central necrosis should be taken into account by adequate sampling of different areas, including the interface between tumor and adjacent brain. A preliminary intraoperative assessment by frozen section is useful to gauge the adequacy of the specimen for diagnosis and to predict how tissues should be handled for ancillary studies. Neoplasms that may present without evidence of a mass lesion and mimic other forms of neurological disease include neoplasms disseminated in the subarachnoid space (metastatic carcinoma, glioma, lymphoma), infiltrating gliomas (low-grade astrocytomas, oligodendrogliomas, or gliomatosis cerebri), and some forms of mixed neuronal and glial neoplasms (dysembryoplastic neuroepithelial tumor) and lymphomas. Non-neoplastic mass lesions such as infections can be suspected on intraoperative frozen section evaluation, and appropriate ancillary studies can be done.

RADIATION NECROSIS. Following therapeutic radiation therapy for intracerebral neoplasms, the distinction between recurrent neoplasm and radiation necrosis is often difficult. Diagnostic brain biopsy is often useful in demonstrating residual or recurrent neoplasm and may show the coagulative tissue necrosis and vasculopathic changes characteristic of radiation necrosis in adjacent brain parenchyma, with or without evident tumor. Diagnostic brain biopsy can be performed as part of the therapeutic removal of necrotic tissue as well.

NON-NEOPLASTIC CYSTS. Diagnostic biopsy of a cyst wall can be performed as part of cyst fenestration or drainage and may be useful in distinguishing between neoplastic and non-neoplastic cystic mass lesions.

INFECTIONS. Infectious diseases of the CNS are diagnosed by a variety of means, including assessment of clinical history, standard laboratory studies, serological and microbiological evaluation of blood and cerebrospinal fluid, and imaging studies. Diagnostic brain biopsy plays a limited role in this setting. In the case of mass lesions or focal brain lesions, diagnostic brain biopsy may be useful in distinguishing between neoplasms and infections. Diagnostic brain biopsy evaluated by morphological and microbiological studies (including molecular biological techniques) may also be useful in identifying an organism that has failed to be diagnosed by blood or cerebrospinal

fluid studies. Diagnostic brain biopsy is also performed when a suspected infectious lesion fails to respond to a trial of antimicrobial therapy. Diagnostic brain biopsy is also performed in some patients with human immunodeficiency virus (HIV) infection and certain CNS complications. The spectrum of possible infectious complications in these patients is large and varied. Common CNS infections include toxoplasma cerebritis, cryptococcal and other fungal infections of the meninges or brain parenchyma, herpes simplex and cytomegalovirus encephalitis, and progressive multifocal leukoencephalopathy (JC virus). Although these infections often present with characteristic clinical and imaging features, a considerable overlap among these infections and primary CNS lymphoma can occur. In HIV patients who fail a trial of antimicrobial agents for a suspected infection, diagnostic brain biopsy may also be useful.

Degenerative Diseases

Many degenerative diseases are characterized by neuronal loss and gliosis in various brain structures without distinctive features. Diagnosis by brain biopsy remains inconclusive in many cases. In patients with a rapidly progressive dementia, a distinction can be made between Creutzfeldt-Jakob disease and degenerative disorders by the presence of spongiform changes or prion proteins in the former. In addition, the demonstration of senile plaques and neurofibrillary tangles in a random biopsy of cerebral cortex, while suggestive of Alzheimer's disease, does not exclude the possibility of other forms of neurodegenerative disease or the presence of other concomitant disease (Video 51, Parkinsonism in Alzheimer's Disease). Because of the variability of distribution of the pathological changes in most degenerative disorders, random biopsies may be nondiagnostic. For adequate evaluation, a piece of cerebral cortex with overlying leptomeninges and underlying white matter that can be oriented is desirable. Tissue should be considered potentially infectious, and precautions for Creutzfeldt-Jakob disease should be taken according to local institutional guidelines. The tissue should be fixed and reserved for possible electron microscopy or other studies (Video 50, Myoclonus in Creutzfeldt-Jakob Disease).

Vascular Diseases (Table 25-13)

Surgical resection of tissue is occasionally performed in the setting of cerebrovascular disease. Diagnostic brain or

TABLE 25-13

Tissue Diagnoses in Cerebrovascular Disease

| DISEASE | TISSUE DIAGNOSIS |
|--|--|
| Vasculitis | Primary CNS vasculitis, CNS involvement in systemic vasculitis, infectious vasculitis |
| Vascular malformations | Arteriovenous malformation, cavernous angioma, venous angioma |
| Vasculopathies and diseases presenting as intracranial hemorrhages | Amyloid angiopathy, hypertensive vasculopathy, vasculitis, primary or metastatic neoplasms, infections |
| Cerebrovascular diseases mimicking mass lesions | Recent infarction |

CNS, central nervous system.

meningeal tissue biopsy is usually performed when CNS vasculitis is suspected. Resection of brain tissue is usually performed for the diagnosis and treatment of vascular malformations. Symptomatic treatment of acute cerebrovascular diseases, usually hemorrhages and traumatic lesions, by evacuation of hematoma with removal of damaged brain tissue, may provide histological evidence of specific etiologies such as amyloid angiopathy, hypertensive vasculopathy, or cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) (Video 215, CADASIL Stroke). CADASIL can be diagnosed in some cases by ultrastructural examination of small blood vessels on skin punch biopsy. Some cases of cerebrovascular disease, such as infarcts, present as mass lesions and may be clinically mistaken for neoplasms.

Metabolic Diseases

Diagnosis of metabolic and storage disorders by brain biopsy has been superseded in many conditions by biochemical and molecular genetic analysis of more readily obtainable non-CNS cells and tissues. In cases in which metabolic or storage disease involving the CNS is suspected but no metabolic defect can be identified by other means, random biopsy of cerebral cortex and white matter may provide either positive or useful negative information. Reserved frozen or properly fixed tissues may prove useful later when subsequent clinical clues or testing techniques become available.

Epilepsy

Some patients with intractable epilepsy may benefit from surgical resection of brain tissue (see Chapter 52). In patients with complex partial seizures originating in the temporal lobe, temporal lobectomy with partial hippocampectomy may be beneficial (Video 78, Frontal Lobe Complex-Partial Seizure). Examination of medial temporal lobe structures may disclose evidence of neuronal loss and gliosis in the hippocampus, amygdala, or adjacent gray matter structures (mesial temporal sclerosis). In occasional cases, other pathological findings (neoplasm, vascular malformation, cicatrix)

may account for an epileptogenic focus. In some patients with intractable epilepsy with focal abnormalities demonstrated by electrophysiological, conventional neuroimaging modalities, or physiological imaging modalities such as positron-emission tomography scanning, removal of the focus is indicated. Pathological findings may include cortical migrational abnormalities, dysplasias, vascular malformations, glial scars, neoplasms, or focal infections. More widespread resections such as lobectomy or even hemispherectomy are occasionally performed with patients with established neurological deficits and more extensive malformations or with progressive lesions such as Rasmussen's encephalitis. Despite the finding of a focal lesion on one or more studies, no specific pathology is found in a large percentage of cases.

HISTORY

The cerebrospinal fluid (CSF) has served as an aid to the diagnosis and treatment of a variety of central nervous system (CNS) disorders for more than 100 years. In 1891, Quinke first developed the technique of spinal puncture and introduced it into clinical practice.¹ He was the first to use a needle with a stylet to measure opening and closing pressures and to pioneer the measurement of CSF glucose, protein, and cell counts. Much of the CSF literature in the early part of the 20th century dealt with changes related to bacterial meningitis and neurosyphilis.²

The notion that elevated intracranial pressure (ICP) can occur began in 1783 when Alexander Monroe posited that the skull is a closed container and its contents are nearly incomprehensible. These concepts were expanded in 1824 by George Kellie, who proposed that the volume of the blood within the brain was constant. In 1846, Burrows suggested that the volume of blood within the brain could only change in a reciprocal manner with the CSF and brain parenchyma. This concept formed the foundation of the Monroe-Kellie hypothesis, and modern theories of pressure-volume relationships still refer to this hypothesis. Early anatomists hypothesized that the choroid plexus was the source of CSF because of its location within the ventricles. This hypothesis was substantiated by Dandy and Blackfan³ and then by Harvey Cushing,⁴ who observed oozing of fluid from the choroid plexus during neurosurgery. Later, Ames provided definitive proof that the majority of intraventricular CSF was produced by the choroid plexus.^{5,6}

CEREBROSPINAL FLUID AND THE VENTRICULAR SYSTEM

Anatomy

The choroid plexus produces the majority of the CSF in addition to smaller amounts secreted by the ependyma and the perivascular spaces. The choroid plexus is derived embryologically from the neural epithelium and is composed of two layers, including a specialized ependymal cell

layer composed of the epithelial lining of the ventricular system and a highly vascularized pia mater layer. This bilayered structure, known as the choroidal epithelium, is folded into microvilli and forms a brush border on which cilia are present on the apical surfaces of some of these cells (Fig. 26-1). The choroidal epithelium with accompanying blood vessels and interstitial connective tissue collectively form the choroid plexus.

The choroidal epithelium shares many characteristics with the blood-brain barrier. The concept of a blood-brain barrier was first considered in the 19th century when Paul Ehrlich injected dye into the blood of animals and noted that all the organs except the brain were stained. Later, in 1913, Edwin Goldmann injected dye into the CSF compartment and found that the brain was stained but no dye appeared in the blood. From these findings, the hypothesis that the brain was separated from blood and that the brain capillaries provide this barrier was proposed. When electron microscopy became available, it was revealed that capillary endothelial cells rest on a basement membrane and form a tube joined by continuous tight junctions with the merging of the outer leaflets of two adjoining cells. This barrier is involved in protecting the brain from substances in the blood, selectively transporting desired blood constituents, and metabolizing or modifying substances transported between compartments.

The properties of brain endothelial cells that differentiate them from systemic capillaries include complex tight junctions between individual capillary endothelial cells, which provide a high electrical resistance. These junctions are formed through the merging of the outer leaflets of two adjoining cells. Second, little bulk flow of molecules occurs through these cells because of the paucity of pinocytotic vesicles and fenestrae. These two features protect the brain from various neurotoxic agents that may be present in the blood. Only substances that can cross biological membranes owing to their lipophilic character may diffuse unrestricted across the blood-brain barrier. Specific carrier systems, however, do exist in the brain endothelial cells and allow for the controlled exchange of substances between the system blood and the nervous system. These include facilitated diffusion in the case of the glucose transporter and adenosine

Figure 26-1. Diagram of choroidal epithelium demonstrating the ependymal microvilli and cilia forming a brush border into the ventricular lumen. (From Page RB, Leure-dePree AE: Ependymal alterations in hydrocephalus. In Wood JH [ed]: *Neurobiology of Cerebrospinal Fluid*. New York, Plenum Press, 1983, p 802.)

triphosphate (ATP)–dependent active transport mechanisms. Third, in addition to the endothelial cells, pericytes, perivascular microglia, and astrocytes contribute to the barrier. Pericytes are contractile adventitial cells and serve as the counterpart to the smooth muscle of large systemic vessels. Whereas evidence exists to suggest that these cells are necessary for the growth and integrity of the capillary endothelial cells and cellular transport, their exact function is unknown. Perivascular microglial cells are derived from bone marrow and most likely migrate to the brain. In proximity to the capillary endothelial cells, these microglial cells most likely serve as phagocytes. Finally, astrocytic endfeet are also closely associated with capillary endothelial cells and are separated from the cell plasma membrane by only the basal lamina. The astrocytes and their associated processes may be involved in the induction of the blood-brain barrier.

The choroid plexus is found in the walls of the lateral ventricles, and this structure is continuous with choroid plexus in the roof of the third ventricle. Additionally, the fourth ventricle contains a T-shaped choroid plexus that projects into the cavity from the roof. Whereas the choroid plexus of the lateral ventricles receives its arterial supply from the anterior and posterior choroidal arteries, the third ventricular choroid plexus is supplied by branches of the posterior cerebral artery. The posterior inferior cerebellar artery supplies the choroid plexus of the fourth ventricle.

After the CSF is secreted by the choroid plexus, it circulates throughout the ventricular system and the subarachnoid space that surrounds the brain and spinal cord (Fig. 26-2). The anatomy of the ventricular system allows for movement of CSF in and around all the major structures of the brain. The lateral ventricles are located within the cerebral hemispheres and communicate with the third ventricle via the foramina of Monroe. The third ventricle

Figure 26-2. The ventricular system. This diagram demonstrates the flow of cerebrospinal fluid from the choroid plexus to the arachnoid villi. (From Fishman RA: *Cerebrospinal fluid in diseases of the nervous system*. In Fishman RA [ed]: *Cerebrospinal Fluid in Diseases of the Nervous System*, 2nd ed. Philadelphia, WB Saunders, 1992, p 8.)

lies caudal to the lateral ventricles and is a midline structure within the diencephalon. At its caudal end, the third ventricle is connected by the aqueduct of Sylvius to the fourth ventricle, which is situated between the brain stem and cerebellum. Cerebrospinal fluid then flows into the basal cisterns and subarachnoid space by the lateral foramina of Luschka and the medial foramen of Magendie. From these cisterns, the CSF flows throughout the subarachnoid space and over the hemispheric convexities and around the spinal cord.

CSF is reabsorbed into the venous system by numerous microscopic arachnoid villi and larger but less common arachnoid granulations. The granulations have a collagenous trabecular core with associated channels and a cap of arachnoid cells on the apex. Villi and granulations represent outpouchings of the arachnoid membrane that penetrate gaps in the dura and protrude within the venous sinuses (Fig. 26-3). Arachnoid villi are also present at various levels of the spinal cord and surrounding spinal nerve roots.

Physiology

Secretion and Absorption

It is estimated that the average adult ventricular system and subarachnoid space contain between 90 and 150 mL of CSF with nearly 80% being present in the ventricles. The production of CSF occurs at a rate of about 500 mL/day

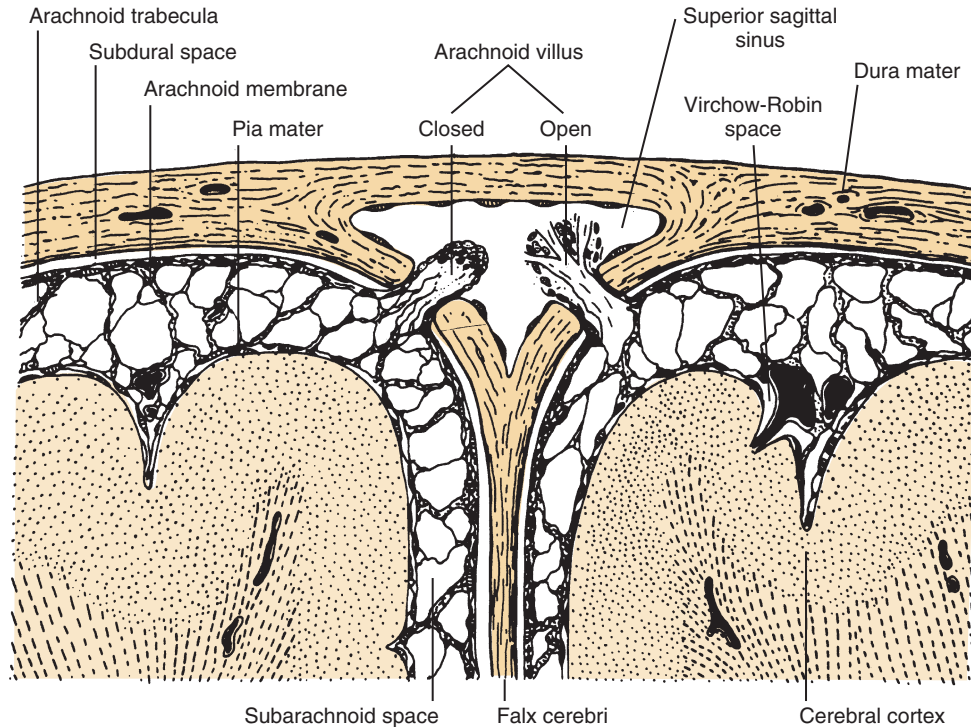

Figure 26-3. The arachnoid villi with outpouchings into the superior sagittal sinus. (From Wood K: Physiology, pharmacology and dynamics of cerebrospinal fluid. In Wood JH [ed]: Neurobiology of Cerebrospinal Fluid. New York, Plenum Press, 1980, pp 1–16.)

(20 mL/hour), and the entire amount of CSF is replenished five times a day. The secretion of CSF by the choroid plexus is linked to the hydrostatic pressure within the plexus capillaries that moves water and electrolytes into the interstitial space and subsequently into the choroidal epithelium (Fig. 26-4).⁷ Water and ions are then transferred into the ventricular cavity by either traversing the tight apical junctions or the plasma membrane of the apical villus. Because the secretion of CSF is associated with the transport of sodium, ion pumps are involved in this transfer, and the movement of sodium is linked to the membrane-bound enzyme sodium-potassium-activated ATPase that has been identified on the brush border and intercellular clefts.⁸ In addition to the sodium-potassium ion exchange at the apical surface, basolateral sodium-hydrogen antiports and apical and basal chloride-bicarbonate antiports are also present in the choroidal epithelium (Fig. 26-5). Typically, a net secretion of sodium, chloride, and bicarbonate occurs from the plasma to the CSF, yet ion exchanges can occur in either direction and depend on the relative levels of various ions in the cells and the CSF.

The exact mechanisms regulating the action of these ion pumps and the permeability of the choroidal epithelium is incompletely understood, yet a strong correlation exists between the rate of sodium exchange and the rate of spinal fluid formation.⁹ The rate of sodium exchange is, in turn, partially regulated by the permeability of bicarbonate, and the enzyme carbonic anhydrase is important in this relationship. This enzyme is present in the cytosol of the choroidal epithelium and catalyzes the formation of carbonic acid from water and carbon dioxide.^{10,11} Carbonic acid then freely dissociates to bicarbonate and a hydrogen ion that

are available to participate in their respective ion pumps. Investigators have demonstrated that a carbonic anhydrase inhibitor such as acetazolamide can reduce CSF sodium exchange by 50% to 100%¹⁰ and can reduce CSF production significantly.¹¹ Other factors may influence the rate of CSF formation (Table 26-1), although most findings are based on animal studies and the results cannot necessarily be extended to human physiology.

Because CSF production is in equilibrium with absorption, approximately 0.35 mL of CSF are absorbed every minute. This rate is the bulk flow of fluid and does not represent the absorption of individual constituents such as ions and proteins. These latter CSF components are exchanged at individual rates that depend on the rate of fluid absorption, the degree of active transport of the solute from the CSF, and the amount of solute diffusion into the parenchyma of the brain and brain capillaries.⁷ The process in which fluid and other molecules move across the villi and granulations to enter the venous system is not entirely understood, but possible mechanisms include direct flow through a tubular system,¹² the use of giant vacuoles,¹³ pinocytosis, and extracellular transport.¹⁴

Composition

In addition to the major ions, CSF contains oxygen, sugars (e.g., glucose, fructose, polyols), lactate, proteins (e.g., albumin, globulins), amino acids, urea, ammonia, creatinine, lipids, neurotransmitters and their metabolites, hormones (e.g., insulin, gastrin), and vitamins. Whereas the regulation of many CSF constituents is unknown, some are transported into the CSF by facilitated diffusion using a proteolipid

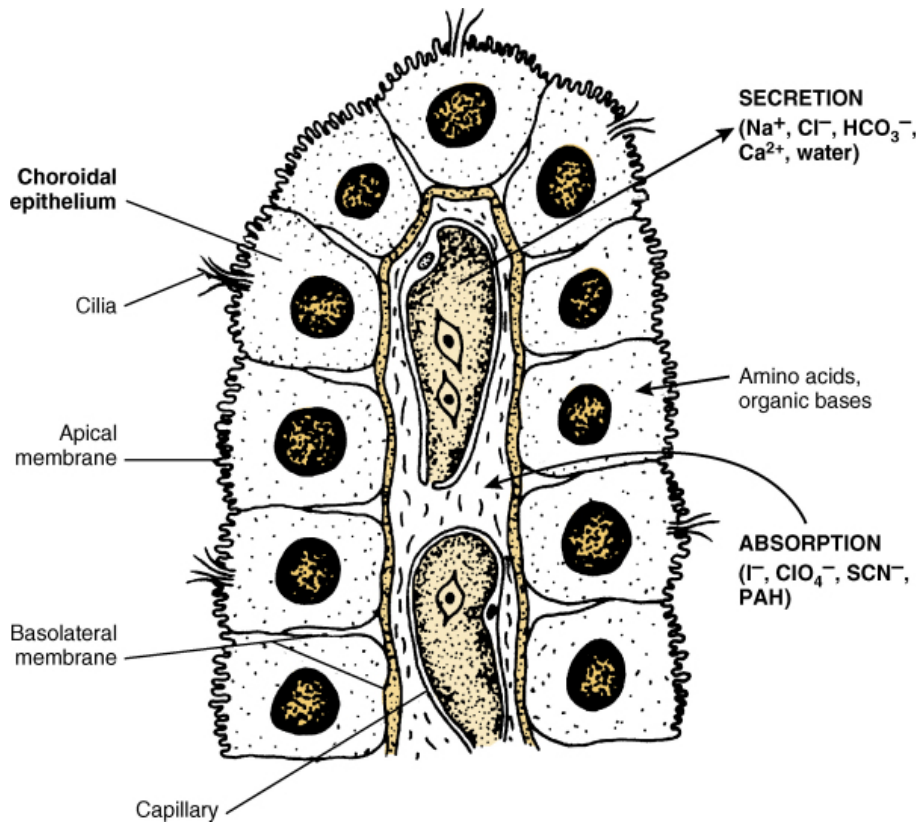

Figure 26-4. Diagrammatic representation of the choroid plexus with respect to the relationship of a variety of ions and small molecules. (From Wright EM: Transport processes in the formation of the cerebrospinal fluid. *Rev Physiol Biochem Pharmacol* 1978;83:1–34.)

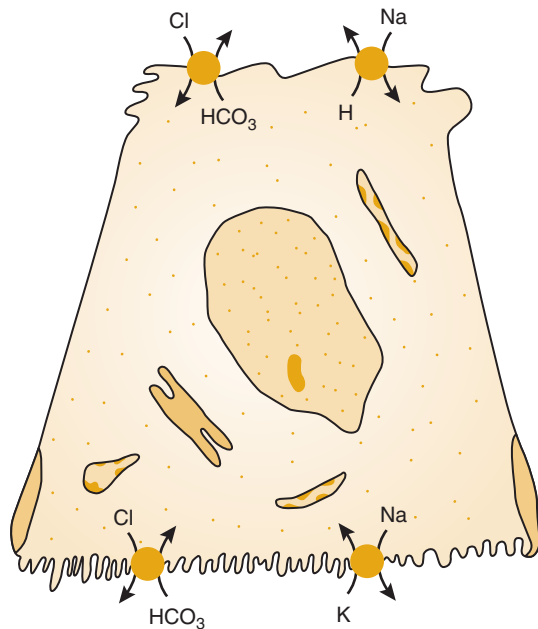

Figure 26-5. Demonstration of the sodium/hydrogen ion, sodium/potassium, and chloride/bicarbonate pumps in a choroid epithelium cell. (Modified from Johansen CE, Parandoosh Z, Smith OR: Cl = HCO₃ exchange in choroid plexus: Analysis by the DMO method for cell pH. *Am J Physiol* 1985;249:478.)

carrier (e.g., glucose). In general, CSF glucose concentration is about 60% of the serum. CSF concentrations of sodium, chloride, and magnesium are the same or greater than those in the serum; however, potassium, calcium, and glucose concentrations are lower (Table 26-2).

TABLE 26-1

Factors That May Influence the Formation of Cerebrospinal Fluid (CSF)

| AGENT | EFFECT ON CSF PRODUCTION | PRESUMED MECHANISM |
|----------------------------|--------------------------|---|
| Cholera toxin | Increases | Stimulates adenosine monophosphate |
| Alpha-adrenergic drugs | Increases | Stimulates adenylate cyclase |
| Hyperosmolality | Decreases | Alteration in ionic concentrations |
| Hypothermia | Decreases | Unknown |
| Furosemide | Decreases | Inhibition of the sodium-potassium-chloride co-transport system |
| Dopamine (D1) antagonists | Decreases | Unknown |
| Vasopressin | Decreases | Reduces choroidal blood flow |
| Atrial natriuretic hormone | Decreases | Modulates cyclic GMP activity |
| Acetazolamide | Decreases | Inhibition of carbonic anhydrase |
| Ouabain | Decreases | Inhibition of sodium-potassium ATPase |

ATPase, adenosine triphosphate; GMP, guanosine monophosphate.

Acquisition

The technique of the lumbar puncture (LP), or spinal tap, was first developed by Quinke in 1891 and has likely changed little since that time (Video 111, Lumbar Puncture). Before performing an LP to obtain CSF, a patient’s coagulation profile should be checked. If the results of these studies demonstrate a thrombocytopenic (platelet count less than 20,000/μL) or a prolonged prothrombin time or

TABLE 26-2

Normal Cerebrospinal Fluid (CSF) Constituents

| SUBSTANCE | PLASMA | CSF |
|-----------------------------|--------|------------------|
| Sodium (mEq/L) | 140.0 | 144.0 |
| Potassium (mm/L) | 4.6 | 2.9 |
| Magnesium (mEq/L) | 1.6 | 2.2 |
| Calcium (mg/dL) | 8.9 | 4.6 |
| Chloride (mEq/L) | 99.0 | 113.0 |
| Bicarbonate (mm/L) | 26.8 | 23.3 |
| Inorganic phosphate (mg/dL) | 4.7 | 3.4 |
| Protein (g/dL) | 6.8 | 0.028 (28 mg/dL) |
| Glucose (mg/dL) | 110.0 | 50 to 80 |
| Osmolality | 0.3 | 0.29 |
| pH | 7.4 | 7.3 |
| Pco ₂ (mmHg) | 41.1 | 50.5 |

Adapted from Wood K: Physiology, pharmacology and dynamics of cerebrospinal fluid. In Wood JH (ed): Neurobiology of Cerebrospinal Fluid, Vol. 1. New York, Plenum Press, 1980, p 87.

partial thromboplastin time, these abnormalities should be corrected before the LP.¹⁵ An imaging study of the brain should be obtained prior to LP in any patient with an altered level of consciousness, a seizure or a focal examination, papilledema, or in immunocompromised patients. In adults, the LP is best performed with the patient in the lateral decubitus position with the head and spine parallel to the floor. This positioning is particularly important for the accurate measurement of the opening and closing pressures. After positioning the patient, certain landmarks should be palpated, beginning with the iliac crest. An imaginary line that runs between the crests will intersect approximately the L3-L4 interspace. Once this area is located, the spinal processes of L3 and L4 should be palpated and between them the interspace may be felt. This procedure is easily accomplished in thin patients but may be difficult in obese or edematous individuals.

When the landmarks are located, the patient should pull the knees into the chest and assume the so-called fetal position. This maneuver helps widen the vertebral interspace. The clinician should appropriately prepare the skin surface using a sterilizing agent and then place the sterile draping. One to two percent lidocaine should be injected intradermally and then is infiltrated into the deeper tissues. Once the patient is anesthetized, a spinal needle with a stylet should be inserted into the skin toward the interspace. Some debate exists as to the optimum gauge of spinal needle that should be used. Although fewer post-LP headaches occur when finer-gauge needles are used,¹⁶ it is more difficult to remove CSF and accurately measure pressures. A 20- or 22-gauge needle is generally used. In order to reduce the risk of post-LP headache, the needle should be advanced with the bevel parallel to the long axis of the spine,¹⁷ which will prevent the transection of the fibers of the longitudinal ligament. Instead, this technique causes the separation of these fibers. Alternatively, an atraumatic needle may be used. A randomized, controlled trial of atraumatic versus standard needles demonstrated that the use of atraumatic needles significantly reduced the risk of post-LP headache (25% absolute risk reduction). There was, however, a slight increase in the number of LP attempts when using an atraumatic needle.¹⁸ When the needle reaches the longitudinal ligament,

there will be a slight increase in resistance, yet with continued advancement a sudden decrease in the amount of resistance will occur. When this is felt, the needle has passed through the longitudinal ligament and has entered the subarachnoid space (Fig. 26-6). At this point, the removal of the stylet results in the flow of CSF. If no fluid flows, the stylet should be replaced and the needle should be rotated 90 degrees so that the bevel is oriented cephalad. The needle may need to be further adjusted or reinserted if the CSF fails to flow from the needle. Each time the needle is reinserted, the stylet should be replaced.

When the CSF begins to flow, a manometer may be attached to the hub of the spinal needle, which allows the CSF to flow into the manometer tube. This maneuver should be done immediately in order to avoid spuriously low opening pressure readings. Often some fluid has already been removed. The CSF should be allowed to rise into the tube until a steady state is reached. Coughing, talking, or performing the Valsalva maneuver can falsely elevate the pressure reading. It may also be helpful to allow the patient to come out of the fetal position to reduce the amount of intra-abdominal pressure, which may affect opening pressure measurements. A normal opening pressure ranges from 10 to 20 cm H₂O (approximately equivalent to 5 to 15 mmHg). Following the measurement of the opening pressure, the CSF can be collected for analysis.

When acquiring the CSF, the clinician should number the tubes and maintain this order during the CSF collection.

Figure 26-6. Diagram demonstrating the passage of the spinal needle through the fibers of the longitudinal ligament and into the subarachnoid space.

After the CSF fluid is collected, the manometer should be reconnected and a closing pressure should be measured. This value is usually less than the opening pressure; however, the range of closing pressure values depends on the amount of CSF removed. A low opening pressure may indicate a CSF leak or a spinal subarachnoid obstruction, which does not allow for communication of the lumbar space with the cranium. Disorders that elevate the opening pressure (greater than 20 cm H₂O) are numerous, including mass-occupying lesions and diffuse cerebral inflammatory or toxic processes. The closing pressure is used to assess the pressure reduction after an LP, particularly in cases of therapeutic lumbar puncture. Before withdrawing the spinal needle, the stylet should not be reinserted, to lessen the likelihood of contamination. It is not necessary for the patient to lie supine for any specific amount of time after the LP, because controlled studies have clearly demonstrated that position does not reduce the risk of a post-LP headache.¹⁹

The LP may also be performed in the sitting position, or CSF may be collected with cisternal or lateral cervical punctures under fluoroscopic guidance. The advantages of performing the LP in a sitting position are threefold: (1) the midline is much easier to determine; (2) some patients find that tightly flexing the hips while sitting is more comfortable than the fetal position; and (3) gravity can assist the flow of the CSF in cases of low CSF pressures. This technique is essentially the same as that of the lateral decubitus position, but the patient is upright. The patient should be asked to sit on the edge of the bed or examination table and lean forward as far as possible. This position is best accomplished with the patient leaning forward on a table that is slightly higher than the bed. With the physician standing behind the patient, the iliac crests are palpated, and at the intersection of these structures and in the midline lies the L3-L4 interspace. This area is prepped, draped, and anesthetized similarly to the earlier description. Again, the needle is inserted with the bevel facing laterally so as not to tear the fibers of the longitudinal ligament. The angle of insertion is upward in this position, toward the umbilicus. In this position, neither opening or closing pressures can be accurately determined. In order to obtain the pressure readings, the patient may be moved to the lateral decubitus position once the spinal needle is in the subarachnoid space.

Other than the L3-L4 interspace, several other lumbar levels may be used to perform the LP including L4-L5 and L5-S1. More rostral levels should not be attempted because spinal cord trauma may occur. If anatomical restrictions exist, such as occurs in severe spinal spondylosis, previous spinal surgery with fusion, or morbid obesity, and impedes the acquisition of CSF levels, an attempt should be made to obtain CSF under fluoroscopic guidance. If this procedure is unsuccessful, CSF may be obtained through a cisternal or lateral cervical puncture. These procedures should be performed by an experienced clinician under radiographical guidance. A cisternal puncture is performed by placing the spinal needle in the cisterna magna and carries the risk of brain stem or upper cervical cord damage. A lateral cervical puncture involves the insertion of the spinal needle in the C1-C2 interspace from a posterolateral approach and also has the risk of damage to the cervical cord.

When an asymmetrical CNS process or an increase in ICP is suspected, a computed tomography (CT) or magnetic resonance imaging scan (MRI) should be obtained prior to an LP. If a mass lesion is found, the LP should be delayed. On the other hand, diffuse cerebral processes that predictably elevate the opening pressure, such as pseudotumor cerebri²⁰ and some forms of encephalitis or meningitis,²¹ may be benefited by frequent LPs to lower ICP.

Whereas LP is considered a standard, safe diagnostic intervention, headache is a common sequel, occurring in approximately 30% of cases. In the 2000 American Academy of Neurology practice guidelines, the following factors were identified to reduce the risk of post-LP headaches: (1) small needle sizes, (2) assurance that bevel direction is parallel to dural fibers, and (3) replacement of the stylet before the needle is withdrawn. There was no established evidence that recumbency after the procedure or increased fluid intake influenced the frequency or severity of post-LP headache. In 2005 the American Academy of Neurology published an addendum to the assessment on prevention of post-LP headache supporting the use of an atraumatic needle over the traditional cutting needle for diagnostic LP. However, the use of an atraumatic needle is technically more challenging than the use of a cutting needle and may not be ideal for emergent situations, patients with a high body mass index, or when the practitioner is less experienced.

Normal and Pathological Findings (Tables 26-2 to 26-4)

The general appearance of CSF is clear and colorless, because it is more than 99% water. Color of CSF is observed only in pathological circumstances. Whereas the term xanthochromia means yellow color, it has been used for the presence of other colors as well. Because of this practice, the actual color of the CSF should be stated and a gradation of its magnitude (from 1+ to 4+) should be noted. A yellowish tinge can be found with any cause of a markedly increased protein (greater than 200 mg per 100 mL). A yellow or pink color is found when hemoglobin has been released into the CSF from prior bleeding and sufficient time has passed for its breakdown to bilirubin and other pigments. Oxyhemoglobin is red but becomes pink or yellow when diluted. The concentration of oxyhemoglobin is maximal within the first 36 hours and disappears by 14 days. Bilirubin is yellow and is first detected in the CSF 10 hours after subarachnoid bleeding. Its concentration is maximal at 2 days and may persist for up to a month. Other causes for coloration of CSF include an elevated systemic bilirubin from liver disease; a brownish or gray coloration in the presence of CNS melanoma; and a greenish tinge related to leukemic meningeal infiltration.

Fluid that is obviously blood-tinged or bloody indicates a traumatic tap or the presence of a subarachnoid hemorrhage. In traumatic taps, the CSF usually clears as sequential amounts are collected and is unlikely to have a pink- or yellow-tinged supernatant. The CSF may occasionally clot if the ratio of blood to CSF is high. Bloody CSF from subarachnoid hemorrhage does not clear with sequentially collected tubes and may demonstrate xanthochromia if the

*Results on fluids removed at first lumbar puncture are used in most instances.

†Increase of protein usually due to presence of admixed serum.

From Fishman RA: Cerebrospinal fluid in diseases of the nervous system. In Fishman RA (ed): Cerebrospinal Fluid in Diseases of the Nervous System, 2nd ed. Philadelphia, WB Saunders, 1992, p 431.

bleeding occurred over 2 to 4 hours before the LP. If the CSF is acquired over 12 hours after the onset of subarachnoid hemorrhage, virtually all patients' CSF will demonstrate xanthochromia.²²

Whenever the viscosity of CSF is increased, the most likely explanation is a marked increase of protein content. If sufficient fibrin is present, the free flow of CSF can be impaired and spontaneous clotting of the CSF can occur (Froin's syndrome). Turbidity detected in CSF when a collection tube is twirled in the beam of a bright light is indicative of the presence of at least 200 or more leukocytes per microliter. Turbidity may also be caused by the presence of microscopic fat globules that have traveled to the brain as emboli. The presence of erythrocytes will impart turbidity up to a concentration of 400 cells/ μ L, above which there will be pink coloration from their hemoglobin content.

Six common CSF studies include the cell count and differential, Gram stain and culture, blood glucose, and protein concentrations and direct observation for color and character.

Cell Counts

CSF cell counts (red blood cell [RBC] count and white blood cell [WBC] count) with differentials should be performed on every specimen. Typically, the CSF contains no RBCs/ μ L and 0 to 1 WBCs/ μ L. Cook and Brooks²³ reported that the normal CSF WBC count in 11 patients

was $0.826 + 0.733$ cells/ μ L with differentials of approximately 66% lymphocytes, 33% monocytes, and 1% polymorphonuclear cells. Fishman has also noted that the normal CSF should contain no more than five lymphocytes or mononuclear cells per microliter, and counts greater than 6 cells/ μ L are abnormal. A traumatic LP causes elevations of RBCs and WBCs, but these elevations are differentiated from subarachnoid hemorrhage because the former elevations are high in the first tube but clear in the later tubes. To determine whether an elevated CSF WBC count is due to blood from a traumatic tap or other causes, an expected ratio can be used. If the elevated WBC count is due to blood in the CSF, 1 WBC/ μ L for every 700 RBC/ μ L is found. If the WBC count exceeds this ratio, its origin must be accounted for from other causes such as infection or inflammation.

Glucose

As noted in Table 26-2, the CSF glucose concentration is normally 60% of the plasma glucose concentration, and under nonpathological conditions, this ratio changes proportionately in response to a rising or falling plasma glucose event with a 4-hour lag time. This linear ratio of CSF to plasma glucose concentration decreases as the plasma glucose exceeds 500 mg/dL. The reason for this decrease is unclear, but it may reflect the saturation of the carrier-mediated transport of glucose at high plasma

TABLE 26-4

Selected Disorders and Associated CSF Studies

| DOMAIN | DISORDER | USEFUL CSF STUDIES | EXPECTED RESULTS | COMMENTS |
|--|--------------------------------------|---|---|---|
| Cerebral Dysfunction | | | | |

concentrations.⁷ As a result, it is important to obtain a concomitant serum glucose level at the time of the CSF sample. Although an elevated CSF glucose level (hyperglycorrhachia) results from an elevated plasma glucose level, a decreased CSF glucose concentration (hypoglycorrhachia) may be due to a variety of causes including hypoglycemia. The other etiologies include bacterial meningitis^{24,25} (including typical bacteria, tuberculosis, and neurosyphilis), fungal meningitis, certain viral meningitides (mumps),²⁶ subarachnoid hemorrhage,²⁷ carcinomatous meningitis, chemical meningitis, and meningitis resulting from parasitic organisms (cysticercosis, trichinosis, amebiasis). If 0.4 is used as the lower limit of the normal CSF to serum glucose ratio, values below 0.4 have a sensitivity of 80% to 91% and a specificity of 96% to 98% for bacterial meningitis versus aseptic meningitis (inflammatory cells without evidence of a common bacterial pathogen).^{28,29} The CSF glucose value often returns to normal before other CSF determinations (such as protein or lactate), and some investigators have suggested serial determinations to guide treatment decisions.²⁵ The CSF glucose level may take several weeks to return to normal despite the normalization of the protein concentration and cell count.³⁰

Protein

The majority of CSF protein is derived from the serum, and the CSF/serum albumin ratio is approximately 1:200. This ratio implies that the entry rate of protein from the serum to the CSF is approximately 200 times less than its exit rate.⁷ The CSF protein concentration varies at different levels of the neuroaxis and generally increases from the cephalad to caudal levels. Elevation in lumbar CSF protein is a nonspecific but sensitive indicator of CNS disease.⁷ Table 26-3 illustrates the various disorders that can cause an elevation in the CSF protein level.²³ A very high CSF protein concentration (greater than 500 mg/dL) is an infrequent finding but can occur with bacterial meningitis, subarachnoid hemorrhage, or spinal-subarachnoid block. When a significant amount of blood is present in the CSF (e.g., subarachnoid hemorrhage), a correction for the total protein concentration should be calculated. The presence of 1000 RBCs in the CSF results in the increase of protein by 1 mg/dL. A spinal-subarachnoid block can cause Froin's syndrome and is usually the result of a spinal cord tumor and can cause very significant elevations in CSF protein (greater than 1000 mg/dL).²³ Protein concentrations of 100 mg/dL or greater have sensitivity and specificity for bacterial meningitis of 82% and 98%, respectively, as compared with aseptic meningitis,³¹ and if the concentration is 200 mg/dL, the sensitivity is 86% and the specificity is 100%.²⁸ A lower than normal CSF protein level may occur in young children (6 months to 2 years of age), in patients with pseudotumor cerebri, and in patients with unintended loss of CSF from frequent LPs, a lumbar drain, or a lumbar dural CSF leak.

Certain proteins arise within the intrathecal compartment. Among these are immunoglobulins produced by CNS lymphocytes, transthyretin (produced by choroid plexus), and various structural proteins found in brain tissue (including glial fibrillary acidic, tau, and myelin basic proteins). The last group of proteins and transthyretin are found only in trace amounts, whereas immunoglobulins

$$\text{IgG index} = \frac{\text{Immunoglobulins}_{\text{CSF}}/\text{immunoglobulins}_{\text{serum}}}{\text{Albumin}_{\text{CSF}}/\text{albumin}_{\text{serum}}}$$

Figure 26-7. Formula for the determination of cerebrospinal fluid immunoglobulin. (From Fishman RA: Cerebrospinal fluid in diseases of the nervous system. In Fishman RA [ed]: Cerebrospinal Fluid in Diseases of the Nervous System, 2nd ed. Philadelphia, WB Saunders, 1992, p 431.)

compose a substantial fraction of normal CSF (5% to 12%). Electrophoretic techniques can be used to define the gamma globulins as a heterogeneous group of proteins. Because serum IgG comprises nearly 20% of the total serum protein, a variety of formulas have been used to correct the CSF IgG level for the contribution derived from the blood in order to determine the CNS (Fig. 26-7). Contamination of the CSF with blood may significantly elevate the IgG index and the IgG synthesis rate.

The electrophoretic separation of CSF proteins can be accomplished through the use of agarose gel and by the staining of the bands that are produced. Within the gamma region, three patterns of bands may be observed including one clone (monoclonal), many clones (polyclonal), and a few bands (three to five bands, or oligoclonal bands).⁷ Each band represents a homogeneous protein that is secreted by a single clone of plasma cells.

Oligoclonal bands (OCBs) are present in the CSF when three to five bands are seen on gel electrophoresis. This finding implies that a single clonal population of plasma cells is responsible for each band. More than one OCB rarely occurs in normal CSF. A serum sample should also be obtained simultaneously with the acquisition of the CSF to determine whether the OCBs are unique to the CSF. Oligoclonal bands are present in 83% to 94% of patients with multiple sclerosis, 100% of patients with subacute sclerosing panencephalitis, 25% to 50% of patients with other inflammatory CNS disorders (CNS lupus, neurosarcoidosis, cysticercosis, Behçet's disease, and viral, fungal, and bacterial infections), as well as most with some brain tumors and Guillain-Barré syndrome. Because OCBs are present in such varied conditions, their presence offers little to a specific diagnosis.

Gram Staining

Examining the CSF with Gram stain is useful to diagnose bacterial meningitis.²⁴ A Ziehl-Neelsen acid-fast stain should also be performed if tuberculous meningitis is a diagnostic possibility. CSF cultures should be done in the setting in which an infectious process is suspected. Bacteria that commonly cause meningitis are routinely cultured on standard preparations. *Mycobacterium* can also be cultured, yet several weeks (or more) may be required to grow these organisms. Viral cultures may be ordered; however, the yield is generally low. Fungal cultures should be performed in clinical settings of suspected chronic meningitis.

Specialized Tests

In addition to these routine studies, various specialized tests may also be useful in specific clinical settings.

The measurement of the CSF acid-base status is not normally part of the routine evaluation of this body fluid.

In experimental studies, normal subjects have a CSF pH that is slightly lower than the pH of arterial blood and a P_{CO_2} that is higher. In contrast, bicarbonate levels are generally equal. Comparisons between CSF obtained through cisternal and lumbar punctures reveal that the pH is typically lower and P_{CO_2} higher in lumbar CSF. Again, bicarbonate levels are not significantly different. The variations between the cisternal and lumbar CSF samples may reflect differences in rates of local metabolism relative to clearance rates,³² and the clinical measurement of the lumbar CSF pH may be an unreliable indicator of the metabolic state of the CNS.

Because the concentration of CSF lactate is dependent on CNS glycolysis,³³ the measurement of this agent may be helpful in the diagnosis of bacterial meningitis. This concentration of lactate increases proportionally to the number of inflammatory cells in the CSF.³⁴ A lactate concentration of 4.2 mmol/L accurately predicted 24 out of 25 cases of bacterial meningitis, whereas no patients with presumed viral meningitis had a lactate level that exceeded this value. Unlike the glucose concentration, CSF lactate levels typically remain elevated for a significant time after appropriate therapy is initiated.²⁵ This finding may be helpful in the diagnosis of bacterial meningitis when antibiotics had been given before the acquisition of CSF. The CSF lactic acid level can also be useful for differentiation of bacterial meningitis from a nonbacterial meningeal syndrome following neurosurgical procedures.³⁵ Increased lactate may also result from a cerebral hemorrhage, malignant hypertension, hepatic encephalopathy, diabetes mellitus, and hypoglycemic coma.³⁶

Perhaps an even better marker for bacterial meningitis is the measurement of CSF concentrations of C-reactive protein (CRP). In a meta-analysis of studies published from 1981 through 1995, Gerdes and colleagues analyzed 24 studies examining the use of CSF concentrations of CRP for the diagnosis of bacterial meningitis.³⁷ These studies were heterogeneous in design, with some involving children only, some adults and children, and some adults only, some using quantitative and some qualitative measures of CRP. Although most of these studies were small, some enrolled large numbers of patients (250–478) and most compared patients with bacterial versus viral meningitis. Gerdes and colleagues found that the sensitivity ranged from 18% to 100% and the specificity ranged from 75% to 100%. In spite of these wide-ranging values and varying methods, the odds ratio was quite high at 241 (95% CI: 59–980) for diagnosing bacterial meningitis.

The measurement of CSF glutamine can be a helpful test in diagnosing patients with confusion in the setting of hepatic encephalopathy. Glutamine is formed by the combination of ammonia, which is toxic to the CNS, and alpha-ketoglutarate in the brain. This process helps protect the CNS from the effects of ammonia. Normally, the CSF concentration of ammonia is less than one half of arterial levels, but may increase dramatically in patients with hepatic failure.⁷ Although a correlation exists between increased levels of ammonia and glutamine and the severity of encephalopathy, technical difficulties exist that hamper the ability to use these indices in acute settings.⁷

Various biogenic amines (and their metabolites) may be measured within the CSF, including dopamine (homovanillic acid [HVA]), serotonin (5-hydroxyindoleacetic acid [5-

HIAA]), and norepinephrine (3-methoxy-4-hydroxyphenylglycol [MHPG]). Significant ventricular to lumbar gradients exist for HVA and 5-HIAA, although MHPG levels are nearly equivalent. Decreased lumbar CSF levels of HVA and 5-HIAA have been reported in patients with parkinsonism and Alzheimer's disease. Whereas decreased HVA levels have also been documented in the ventricular CSF of patients with dystonia, cerebral palsy, multiple sclerosis, and posthypoxic states, no significant differences in 5-HIAA levels are apparent. Biogenic amine levels have also been studied in psychiatric patients, and whereas normal HVA levels are present in the lumbar CSF of patients with schizophrenia, decreased 5-HIAA concentrations are present in depressed subjects. Increased lumbar CSF MHPG levels have been identified in patients with cerebral infarction and hemorrhage. Animal studies further reveal that changes in biogenic amine levels in the CSF parallel CNS changes; however, delays in the clearance of these metabolites from the CSF complicate the interpretation of the values obtained. Because of these physiological constraints and the nonspecific nature of changes in biogenic amine levels, their measurement remains a research tool and has little clinical applicability.

Tumor cells can also be found in the CSF and occur in association with neoplasms of the brain or meninges. The cytopathological identification of these cells requires the acquisition of large volumes of CSF (more than 20 mL) and the sample should be brought immediately to the laboratory to minimize cell lysis and morphological changes. Serial LPs may be necessary to obtain positive cytological results. In a study of the usefulness of CSF cytology and autopsy, Glass and co-workers reported that 26% of patients with metastatic brain tumors had positive CSF cytological findings.³⁸ In another study, the cytological examination of the CSF identified metastatic involvement of the meninges in 70% of cases.³⁹ The detection of other CSF markers may be useful for the diagnosis of primary or metastatic malignancies including astroprotein (glioblastoma), carcinoembryonic antigen (carcinomas), β -2-microglobulin (lymphoblastic leukemia and lymphoma), α -fetoprotein (germ cell tumors), chorionic gonadotropin (choriocarcinoma and testicular tumors), and ferritin (carcinomas).⁴⁰

Finally, it is possible to measure a wide variety of enzymes in the CSF, although few are clinically important and most are not routinely obtained. An elevated lactate dehydrogenase (LDH) may occur in bacterial meningitis⁴¹ and cortical versus lacunar strokes.⁴² Elevated levels of CSF creatinine kinase-BB are also present in a wide variety of conditions that cause parenchymal damage. Lysozyme levels are increased in processes similar to those previously mentioned, whereas adenosine deaminase (ADA) elevations can occur in tuberculous meningitis.³⁹ Though some authors have found that increased ADA levels are sensitive for tuberculous meningitis, it appears ADA has limited utility in the diagnosis in HIV infected individuals due to a high false positive rate in this patient population.⁴³

INTRACRANIAL PRESSURE

Basic Principles

Intracranial hypertension may result from a wide variety of surgical and medical conditions. The association between

elevated ICP and the potential for devastating brain stem herniation has been recognized for centuries. Because the skull is essentially a closed container, its contents have only limited compressibility. The intracranial contents are composed of three compartments: (1) the brain and interstitial fluid, take up approximately 80% of the intracranial space; (2) intravascular blood, which accounts for 10% of intracranial space; and (3) the CSF (in the ventricles and subarachnoid space), which makes up the final 10%. In order to maintain physiological ICP, an increase in volume of one compartment must lead to a compensatory decrease in the volume of another compartment. As an example, diffuse cerebral edema causes an increase in the parenchymal and interstitial compartment that necessitates a compensatory decrease in the amount of blood or CSF (or both) in the intracranial space. Similarly, an increase in the CSF compartment (hydrocephalus) must lead to a decrease in the parenchymal or blood compartments.

The body is able to regulate and modify the diameter of brain arterial vasculature to maintain a relatively constant amount of blood flow over a range of systemic blood pressures that vary among patients (Fig. 26-8). This regulatory mechanism, termed autoregulation, allows the brain to regulate the flow of blood to meet its metabolic needs. Under normal conditions, the cerebral blood flow ranges between 50 and 60 mL per 100 g brain per minute (approximately 700 to 850 mL blood per minute for the whole brain)⁷ and accounts for about 20% of the total cardiac output. In patients with chronic hypertension, the graph is shifted to the right (see Fig. 26-8). The cerebral vasculature is innervated by cholinergic-, noradrenergic-, and neuropeptide-containing neurons; however, it is unlikely that these neurotransmitters contribute significantly to autoregulation, although they certainly contribute to cerebral blood flow. The control of autoregulation more likely arises from the intrinsic sensitivity of the vascular smooth muscle cells to tension across the vessel wall. Additionally, hydrogen ions also have effects on the vessels, and increases in their concentration result in dilatation. The precise role of the

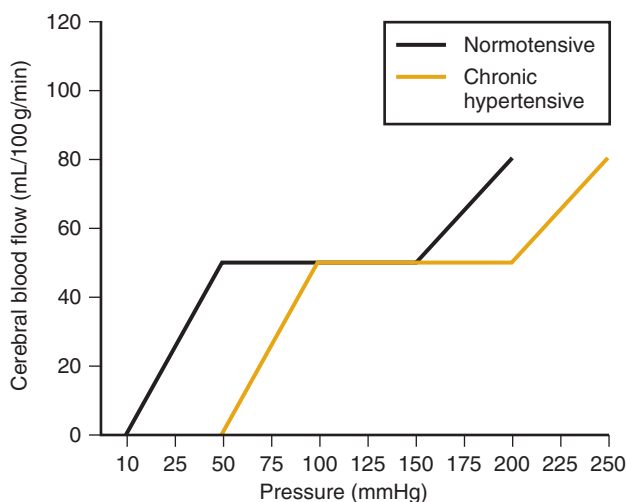

Figure 26-8. This graph illustrates the approximate mean arterial pressures in which the brain is able to autoregulate blood flow (flat portion of graph). The line in color illustrates the shift to the right in a person with chronic hypertension.

mechanisms involved in cerebral vasculature autoregulation under all conditions remains unclear.

Many of the diseases or syndromes that increase ICP do so by causing cerebral edema (Table 26-5). The pathophysiology of cerebral edema is based on one (or more) of three causes (Table 26-6). In vasogenic edema, an increase in capillary permeability occurs through the widening of tight junctions and increases in pinocytotic vesicles at the level of the blood-brain barrier. Because a disruption of the blood-brain barrier occurs with this disorder, MRI and CT studies administered with contrast typically demonstrate brain parenchymal enhancement. In cytotoxic edema, a swelling of the neurons, glia, and endothelial cells of the brain is present. Cytotoxic edema occurs in the setting of a decreased energy supply to brain cells (i.e., hypoxia) or osmotic disequilibrium (i.e., dialysis disequilibrium). The third type of cerebral edema occurs with hydrocephalus and results in an increase in interstitial fluid in the periventricular region. Through this mechanism, hydrocephalus raises ICP by increasing CSF volume and causing periventricular cerebral edema.

ICP Monitoring

Recording the ICP was initially performed through LPs in the 1890s by Quinke. Although the opening pressure is routinely measured at the time spinal taps are performed, this technique is not appropriate for long-term ICP monitoring.

Because clinical signs of elevated ICP, such as the Cushing response (systemic hypertension, bradycardia, and irregular respirations),⁴⁴ are usually a late finding and may never even

TABLE 26-6

Types of Cerebral Edema

| TYPE OF EDEMA | PATHOGENESIS | LOCATION | EDEMA FLUID | ECF VOLUME | SYNDROMES |
|---------------|----------------------------------|---|---|------------|---|
| Vasogenic | Increased capillary permeability | White matter | Plasma filtrate | Increased | Tumor, abscess, infarction, hemorrhage, lead encephalopathy, ischemia, meningitis |
| Cytotoxic | Cellular swelling | Gray and white matter | Intracellular H ₂ O and sodium | Decreased | Hypoxia, ↓ osmolality, ischemia, meningitis, Reye's syndrome |
| Hydrocephalus | Increased intraventricular fluid | Ventricular, periventricular white matter | Cerebrospinal fluid | Increased | Communicating and noncommunicating hydrocephalus |

Adapted from Fishman RA: Cerebrospinal Fluid in Diseases of the Nervous System. Philadelphia, WB Saunders, 1992.

occur,⁴⁵ it is important to directly measure ICP with an invasive device in appropriate settings. Furthermore, because increases in ICP may result in a decrease in cerebral perfusion pressure (CPP) if autoregulation fails, early intervention can be hastened by the direct measurement of ICP. Normal ICP ranges from approximately 10 to 20 cm H₂O (or about 5 to 15 mmHg). CPP is calculated by subtracting the ICP from the mean arterial pressure (MAP) (CPP = MAP – ICP). Cerebral vasculature autoregulation cannot maintain appropriate cerebral blood flow and perfusion at CPP levels below 50 mmHg. Long-term ICP monitoring was initiated in the 1950s and 1960s with the introduction of ventricular catheterization. This procedure involves insertion of a sterile catheter into the lateral ventricle that is guided by either skull-based landmarks or through stereotactic placement. Once within the ventricle, CSF may be drained and the ICP can be monitored. The latter may be completed by either direct visualization of the height of the CSF column generated outside the body or through its measurement by an external transducer. Possible complications of the ventricular catheter include subdural, epidural, or intracerebral hematomas and infection. A risk of so-called upward herniation exists if an infratentorial mass is present and CSF is quickly removed from the supratentorial lateral ventricles. Other systems for the measurement of ICP do not involve direct entry into the ventricles. Collectively, these devices are termed intracranial bolts, although this is a misnomer, and historically, they consist of hollow screws that are inserted through the skull and extend into the subarachnoid space. After the placement of these devices, tubing filled with sterile saline is attached to the bolt and a pressure monitor. True bolts are rarely used today, yet multiple systems are available that may use a hollow screw-like device. These devices usually use a pressure transducer or a fiberoptic cable inserted through the hollow bolt that directly measures the pressure within the subdural or subarachnoid space or in the brain parenchyma. Compared with the ventriculostomy, the risk of hemorrhage and ventriculitis is lower with this procedure.

After the ICP monitoring device is inserted, a waveform may be generated. Because the ICP varies with both respirations and the cardiac cycle, positive deflections of 2 to 10 mm H₂O can be observed in a patient who is not receiving positive-pressure ventilation immediately after systole and during exhalation. Maneuvers to test the function of the ICP monitor include asking patients to increase their intrathoracic pressure (by using the Valsalva technique), which causes an increase in the ICP. Alternatively,

a modified Queckenstedt test may be performed in which the jugular veins are lightly compressed. Because this maneuver causes a decrease in the venous drainage from the brain, an increase in the ICP occurs, and if the intracranial compliance is low, this is rapidly observed. Neither of these tests should be performed in patients with critically elevated ICP. In these patients, evidence for plateau waves (acute elevations in ICP [600 to 1300 mm H₂O] that last 5 to 20 minutes and then return to baseline) may be present. These waves may represent an autoregulatory response to insufficient cerebral blood flow (secondary to elevated ICP) that produces vasodilatation, an increased cerebral blood flow, and, in turn, further elevations of the ICP.⁴⁶ Because of the presumed underlying pathophysiology, the presence of plateau waves suggests a poor prognosis.

The clinical conditions for performing ICP monitoring or ventricular drainage are limited. In severe head trauma with diffuse intracerebral edema, ICP monitoring may aid in guiding therapeutic interventions; however, no randomized, controlled studies exist to determine if ICP monitoring affects long-term outcome. Other conditions that may require ICP monitoring to guide interventions include large intracranial hemorrhages or strokes, encephalitis or bacterial meningitis, acute and fulminant hepatic encephalopathy, intracranial tumors, and Reye's syndrome. In patients with normal pressure hydrocephalus, transient elevations in ICP (similar to plateau waves) may be present during rapid eye movement sleep, and documentation of these waves may aid in determining which patients could improve with shunting.

Treatment of Increased Intracranial Pressure

The treatment of increased ICP involves a few standard procedures (Table 26-7). Perhaps the easiest method for decreasing ICP is proper positioning of the patient and the avoidance of situations that can increase intrathoracic pressure. Placing the patient in an upright (or close to upright) position will lower ICP by promoting an increase in venous flow and will avoid compression of the jugular veins. Additionally, if high pressures associated with positive-pressure ventilation are managed, increases in ICP can be reduced. The control of pain and agitation with pharmacologic agents is also important. Sedative medications can also lower ICP by reducing cerebral metabolic rate of oxygen consumption and cerebral blood flow. The administration of intravenous mannitol or hyperventilation

TABLE 26-7

Treatment Options for Elevated Intracranial Pressure (ICP)

| TREATMENT | DOSE | ADVANTAGES | LIMITATIONS |
|---------------------------------|--|---------------------------------------|---|
| Hypocarbica by hyperventilation | Pco ₂ 25 to 33 mmHg RR 10 to 16/min | Immediate onset, well tolerated | Hypotension, barotrauma, duration usually hours or less |
| Osmotic | Mannitol 0.5 to 1 g/kg | Rapid onset, titratable, predictable | Hypotension, hypokalemia, duration hours or days |
| Barbiturates | Pentobarbital 1.5 mg/kg | Mutes BP and respiratory fluctuations | Hypotension, fixed pupils (small), duration days |
| Hemicraniectomy | Timing critical | Large sustained ICP reduction | Surgical risk, tissue herniation through wound |

BP, blood pressure; RR, respiratory rate.

can quickly lower ICP in most patients, yet both procedures have possible adverse side effects and are not long lasting. Mannitol treatment may lead to dehydration or electrolyte imbalance as a result of its potent osmotic diuretic effect. The beneficial effects of hyperventilation are believed to be short lived because the body quickly compensates for the induced respiratory alkalosis by producing a metabolic acidosis. However the effects of hyperventilation may be more prolonged in the injured brain than commonly realized. Theoretically, overhyperventilation may lead to significant vasoconstriction with associated cerebral ischemia. Though hyperventilation can lead to decreased cerebral oxygenation and neurochemical parameters that suggest ischemia, some controversy exists as to whether outcome is negatively affected. One prospective trial did show worse outcome associated with prolonged hyperventilation within the first few days following severe traumatic brain injury (TBI).⁴⁷ It is best to avoid significant hyperventilation unless brain stem herniation is evident. Corticosteroids are best used to treat increased ICP in the setting of vasogenic edema (see Table 26-5) such as occurs with brain tumors or abscesses and have little value in the setting of a patient with a stroke or head trauma. The management of blood pressure is also important in patients with an elevated ICP, because although lowering the systemic blood pressure can lower ICP, it may also lower CPP. Beta-blockers or mixed beta- and alpha-blockers provide the best antihypertensive effects without causing significant cerebral vasodilatation that can lead to elevated ICP. Finally, in rare cases of hydrocephalus, direct drainage of CSF by ventriculostomy may be extremely useful.

Normal-Pressure Hydrocephalus

PATHOGENESIS AND PATHOPHYSIOLOGY. Normal-pressure hydrocephalus (NPH) is the result of an imbalance between production and resorption of the CSF, usually around the brain convexities. Whereas there is full communication between the ventricles and the subarachnoid space (communicating hydrocephalus), the communication between the subarachnoid space and the arachnoid villi and granulations is not intact, so fluid is not transferred efficiently to the superior sagittal sinus. Subarachnoid hemorrhage, meningitis, head trauma, and elevated levels of CSF protein all cause thickening of the arachnoid or obstruction of the subarachnoid space. A relatively large number of patients do not have an identifiable cause for hydrocephalus, and, pathophysiologically, their lesion best

fits with reduced resorption of CSF, based on studies of increased resistance to CSF outflow.⁴⁸ Less frequently, intracranial tumors, stenosis of the aqueduct of Sylvius, and arachnoid cysts (causes mainly discussed in the previous section) can cause NPH due to obstruction within the ventricular system, and normal pressure is maintained as a result of apparent compensations.

In spite of its name, it appears that intracranial pressure in NPH is not always normal. Physiological experiments suggest that a transient elevation of pressure may increase ventricular size and a new fluid balance is reached with normal pressure but with a higher force, based on Pascal's law of pressure in fluids. Other mechanisms may include abnormal ventricular distensibility, increased CSF pulse amplitude, and increased transmante pressure gradients between the intraventricular and subdural spaces that lead to expansion of the ventricles.

EPIDEMIOLOGY AND RISK FACTORS. NPH has its highest prevalence in the late middle-aged and elderly groups, and is rare in patients younger than 60 years of age. On the other hand, neonates, infants, children, adolescents, and young adults can develop primary or secondary NPH. It accounts for 5% of patients with dementia in the older age group, but its prevalence in the general population is unknown.

CLINICAL FINDINGS AND ASSOCIATED DISORDERS. The triad of progressive dementia, gait disturbance, and urinary incontinence was originally described by Adams and colleagues.⁴⁹ In most instances, gait disturbance is the first sign, followed by dementia, and, later, urinary dysfunction. The gait is slow, unsteady, and wide-based (Video 54, Normal-Pressure Hydrocephalus). Steps are usually short, and patients have difficulty picking their feet off the ground to ambulate (so-called magnetic gait). Turning is difficult and takes several steps. On examination, there is bradykinesia, and the legs may be spastic with increased reflexes. Patients may have difficulty in handwriting and dressing, and may appear to be mildly parkinsonian, but their tremor, if present, is usually postural, not resting. One particular feature is the discrepancy between leg function during walking and simulated walking when sitting. Patients can usually move their legs well and imitate walking while in a chair, but they become awkward and severely impaired as soon as they attempt to walk. This dyspraxia for gait eliminates a pyramidal lesion.

Cognitive decline is clinically multidimensional and involves impaired attention, poor memory, and poor executive function.⁵⁰ Apathy and bradyphrenia are common, whereas aphasia and upper extremity limb dyspraxia are uncommon.

Neuroanatomically, the gait dysfunction and urinary impairment are believed to relate to the stretched fibers innervating the legs and sphincters that project through the vicinity of the frontal horns of the ventricular system. Compromised microcirculation due to increased intraparenchymal pressure may contribute to the cognitive impairment. Positron-emission tomography (PET) data suggest that glucose utilization defects are widespread in NPH and involve subcortical and cortical regions.

EVALUATION AND DIFFERENTIAL DIAGNOSIS. Because the clinical picture of NPH is not specific, especially in the younger patient, several diagnostic tests play a crucial diagnostic role. CT or MRI scans are important to establish the presence of hydrocephalus. The diagnosis of NPH is supported when the anterior ventricular horns measure greater than 30% of the diameter of the cranial cavity and the inferior horns are wider than 2 mm. On T₂-weighted MRI, increased signal in the periventricular areas occurs due to presumed transependymal exudation of CSF. Other findings can suggest alternate diagnoses: for example, a normal-sized fourth ventricle with dilated third and lateral ventricles usually indicates aqueductal stenosis.

Clinically, dementing illnesses of all types must be differentiated from NPH. Alzheimer's disease is not associated with marked gait dysfunction, and a patient with multi-infarct dementia or Binswanger's disease may have a similar clinical presentation to a patient with NPH but has MRI signs of multiple strokes. In younger patients, in whom the classic clinical triad may not be met, the differential diagnosis is wider.

A lumbar puncture usually reveals normal CSF pressure. Furthermore, removal of 20 to 50 mL of CSF may cause clinical improvement in cognitive and gait dysfunction supporting the diagnosis of NPH. Intermittent pressure B-waves detected by intracranial monitoring devices suggest decreased brain compliance and NPH. Radioisotope cisternography is used most often but is not particularly specific. Whereas in normal subjects isotope injected intrathecally can be seen around the brain convexity within 48 hours, reflux into the ventricles and stasis beyond 48 hours are often seen with NPH. However, this finding has relatively low predictive accuracy in the diagnosis of NPH and the response to therapy by shunting procedures.⁵¹

MANAGEMENT AND PROGNOSIS. The primary treatment is large-volume lumbar puncture and eventual ventricular shunting. However, selection of patients for shunting is controversial; most reports agree that dementia of less than 2 years' duration and typical gait and urinary dysfunction should be considered for shunting as long as there is no evidence for a multi-infarct state on MRI scans. Medical management can include acetazolamide or digoxin to decrease CSF production. The rate of complications of CSF-diverting procedures is approximately 30%, with 5% being serious with long-term sequelae.⁵² Subdural hematomas, intracranial infections, stroke, and failure of the shunt are the major complications. The proportion of patients who experience long-term benefit from this treatment range from 25% to 80%.

SYNDROMES OF ALTERED CSF DYNAMICS. Several syndromes occur when the normal production or flow of CSF is altered. Those syndromes related to obstruction of the ventricular system, either the foramen leaving the

lateral ventricles or the third or fourth ventricle cause "obstructive hydrocephalus," discussed primarily in Chapter 1 because altered level of consciousness is the usual overriding symptom. Another condition, normal pressure hydrocephalus, as a syndrome, is discussed in this chapter and further details are available in various Chapters in Part Three dealing with specific etiologies associated with this clinical picture.

HISTORY AND DEFINITIONS

Neuropsychology is the subspecialty of psychology that studies brain–behavior relationships. Neuropsychology is a diverse field that includes experimental neuropsychology, the study of brain–behavior relationships in nonhumans; cognitive neuropsychology, the study of normal cognition in humans; behavioral neuropsychology, the blending of behavioral theory and neuropsychological principles; and clinical neuropsychology, the study of brain–behavior relationships in humans. When a physician requests neuropsychological testing for a patient, a clinical neuropsychologist will likely provide the assessment.

In most states, clinical neuropsychologists are licensed as clinical psychologists and have specialized training (both pre- and postdoctoral) in neuropsychology. The major role of clinical neuropsychologists is the assessment of cognitive function in individuals with known or suspected brain damage. Cognitive functions may be conceptualized as those processes by which an individual perceives both external and internal stimuli; selects pertinent stimuli and inhibits nonpertinent stimuli; records, retains, and recalls information; forms associations between stimuli and manipulates information in the pursuit of a goal; and outputs information through the expression of overt behavior. Clinical neuropsychology is based on the premise that assessments of these overt behaviors provide information about the functional integrity of the central nervous system.

The development of the science of neuropsychology is found in the works of Gall,¹ Broca,² James,³ Watson,⁴ Lashley,⁵ Goldstein,⁶ Halstead,⁷ and Luria.⁸ Early theories of the relationship between neurological functioning and cognition proposed independent modules of function, demonstrated most clearly by the phrenologist Gall. According to this theory, specific brain regions, reflected by bumps on the skull, were associated with specific behavior. With the advances in localization of function, in part owing to patient case studies, Broca refined our understanding of language processing, specifically within the realm of expressive language functions. James' and Watson's contributions to the principles of psychology in general, and

neuropsychology specifically, led to an increased sensitivity to the need for empirical data to support theories of cognitive function, and the application of the scientific method to psychological studies. The work of Lashley and Goldstein led to a better understanding of the relationship between brain localization and behavior in neurologically healthy and neurologically damaged individuals. Halstead and Luria, through differing methods, clearly demonstrated that the assessment of overt behaviors could be used to identify brain damage with accuracy.

Although current understanding of the relationship between neuroanatomical structures and behavior rejects the skull-based tenets of phrenology, discovery of the neuroanatomical substrates of cognitive function remains a major goal of neuropsychology. It is hypothesized that cognitive function depends on both localized areas of specific functions as well as recursive connections between multiple brain areas that contribute, in toto, to cognition. In order to understand such a complex system, neuropsychology is a composite field of study integrating various disciplines including psychology, neurology, clinical neurosciences, psychiatry, statistics, and physiology.

The role of clinical neuropsychology is to elucidate the effects of brain damage on behavior, and to be able to account for the influences of other factors such as genetic, developmental, emotional, and experiential contributions on cognitive functioning. In order to accomplish this goal, neuropsychologists assess patients' cognitive function using behavioral tests. Two main approaches to neuropsychological assessment are typically used by clinicians: the quantitative approach, typified by standardized assessment techniques and comparison of individual performance measures against normative expectations, and the qualitative approach typified by in-depth analysis of individual performance characteristics using relatively standardized measures to elicit pathognomonic signs. Although these two approaches developed semi-independently, current practices in clinical neuropsychology incorporate aspects of both.⁹ Not only do neuropsychologists use both quantitative and qualitative approaches to testing, they also test cognitive function in a multidimensional manner. For example, the

assessment of verbal memory, a form of cognition, may be assessed by simply asking patients to remember a list of words. This approach to testing is inadequate by itself, however, because verbal memory is more complex than simply remembering lists of words. Therefore, assessment of verbal memory entails testing memory for lists of words, pairs of words, sentences, and short stories, using both immediate recall, delayed recall, and recognition paradigms. Such an assessment strategy provides enough data to analyze fully specific deficits in cognitive abilities that may be shared by multiple processes and allows for a finer discrimination of abilities and impairments.

The complexity and depth of knowledge about brain-behavior relationships are reflected in the vast number of volumes devoted to their description. This chapter provides an overview of adult clinical neuropsychology with the aim of assisting practitioners in the use and interpretation of neuropsychological data.

OVERVIEW OF TESTING

Purposes of Neuropsychological Examination

With the advent of modern structural imaging techniques such as computed tomographic (CT) imaging and magnetic resonance imaging (MRI), and even newer functional imaging techniques such as positron emission tomography (PET) and functional magnetic resonance imaging (fMRI), the use of neuropsychological assessments to identify the location and type of CNS lesion has waned.⁶⁻⁸ However, because they identify and quantify both cognitive strengths and deficits, neuropsychological assessments are widely used in current neurological practice.⁹ Indeed, the Therapeutics and Technology Assessment Subcommittee of the American Academy of Neurology rated neuropsychological assessments as an established adjunct to neurological examinations.¹⁰

Traditionally, neuropsychological assessment can be thought of as either diagnostic or descriptive. With regard to diagnostics, neuropsychological testing is commonly used to diagnose a variety of difficulties or pathologies. For example, neuropsychologists are often asked to diagnose conditions such as mental retardation, specific learning disabilities, mild cognitive impairment, or dementia. Clinical neuropsychologists are also frequently referred patients in which there is a question of differential diagnosis. In such cases, the neuropsychological testing is tailored to rule out one of two possible diagnoses, or to differentiate psychiatric from neurological difficulties. For example, depression and disorders of memory can share common clinical features: problems with attention and concentration, short-term memory difficulties, or deficits in working memory and processing speed. Thus, determining what specific brain functions are compromised, as well as which cognitive functions are intact, can help differentiate between two disorders. Separating which difficulties are attributable to a major depressive episode from those which are attributable to a true memory impairment or dementia is useful not only for diagnostic purposes, but is also critical for the implementation of appropriate treatment options and long-term prognosis.

Neuropsychological testing can also be used for descriptive purposes. Examination questions that are descriptive in nature inquire into the specific characteristics of the patient's condition, and the test battery is tailored to answer questions concerning relative cognitive strengths and weaknesses of a particular patient. The value of the test battery depends upon two psychometric characteristics: sensitivity and specificity. While the sensitivity of a test refers to the probability of correctly classifying an individual as abnormal who is performing abnormally with regard to a specific function or functions, the specificity of a test is the probability of classifying a normally functioning person as normal. In general, it is essential to know the specificity of a given test score cut-off, and to acquire as much information as possible about that cut-off's resulting sensitivity to various types of disorders. For example, the Mini-Mental Status Examination uses a cut-off of 24 out of 30 as a marker for impairment. This cut-off appears to be sensitive and specific with regard to cognitive dysfunction in aging populations. Once baseline data has been established for a patient, repeated testing sessions can then be used to document deterioration or improvement of cognition and the relative rates of change between functions for the individual patient.

Referrals generally fall into the diagnostic or descriptive category, although the referral source may not be specifically asked questions pertaining to specific diagnoses or inquire about the descriptive nature of a patient's deficits. Most referrals for neuropsychological assessments, however, are generally made within one of five specific domains: patient care, rehabilitation, educational planning, forensic issues, and treatment outcome analyses.

Patient Care

The largest number of referrals for neuropsychological assessments involve issues of patient care. Neuropsychological examinations are particularly informative for conditions in which neuroimaging results and other laboratory findings are not informative. For example, testing is often requested to assess the CNS effects of toxic exposure, mild head injury, dementing conditions, and in differentiating psychiatric conditions from neurological illnesses. Neuropsychological data can provide valuable information for the identification of these processes as well as the extent of resultant CNS damage.

Neuropsychological examinations may also be used to characterize the patient's current levels of cognitive and emotional functioning in association with a known or suspected CNS process. Often these data are used to monitor changes in the patient's neuropsychological status across repeated examinations,¹¹ so the effect of various treatment interventions on cognitive abilities can be assessed. Additionally, since neuropsychological assessments provide detailed information on both intact and impaired abilities, these assessments are useful for providing medical staff and family caregivers information on the patient's strengths as well as deficits. This information is particularly helpful in coordinating efforts to help the patient and family adjust to a given condition and make appropriate plans.

A newer application of neuropsychological examinations to neurological care is the use of screening examinations.

In contrast to a full neuropsychological examination, which typically requires from 3 to 12 hours of testing, screening examinations usually require less than 1 hour. A typical screening examination tests functioning in attention, orientation, short-term and long-term memory, expressive and receptive language abilities, abstract reasoning, and intelligence. Although these shorter examinations do not give the depth of information that a full neuropsychological examination provides, they still offer basic information on the integrity of each of these abilities.¹² The data from screening examinations are particularly helpful in identifying patients in need of full examinations.

Another purpose of neuropsychological assessment in patient care situations is to assist in the differentiation of psychiatric from neurological illnesses. Often a patient presents with a neurological complaint that does not clearly follow accepted pathophysiological principles. The presentation may be as obvious as functional blindness, but can be as subtle as memory loss owing to severe depression. Neuropsychologists are able to use their training in clinical psychology as well as their knowledge of neurological systems to aid in identifying these conditions.

Rehabilitation

With the increase in cognitive rehabilitative programs for patients with CNS damage, neuropsychologists help to identify patients who can benefit from such efforts, document cognitive abilities in need of rehabilitation, provide goals for therapy, develop individual rehabilitation plans, and track the efficacy of rehabilitative interventions. Neuropsychological assessments are particularly well suited to address these issues and are a cost-effective addition to rehabilitative efforts.¹³

Educational Planning

As with other psychological assessments, neuropsychological assessments can provide important information for educational planning, especially for children. Documentation of basic intellectual abilities helps determine appropriate classroom placement (e.g., enriched environment, special education) for school-age children. Such tests also aid in the identification of children with severe intellectual deficits, such as mental retardation. Differences between intellectual ability and academic achievement are used in the identification of specific learning disabilities. In neurological conditions such as Gilles de la Tourette's syndrome, neuropsychological assessments can be an integral component to individual educational plans by identifying strengths and weaknesses in academic abilities, as well as indicating co-morbid conditions such as attention deficit disorder, hyperactivity, and obsessive-compulsive behaviors.

Forensic Issues

Neuropsychological assessments are used to document the presence and extent of cognitive impairments following accidents or injury. Levels of present functioning can be compared with estimates of premorbid functioning to assign a monetary value to present and future lost abilities.

Treatment Outcomes Research

Neuropsychologists are trained in research designs and methods. With this knowledge they are able to assist in the design, implementation, and analysis of clinical research projects. They are often asked to apply their knowledge of cognitive assessment to suggest outcome measures, which may include standard neuropsychological tests or experimental measures. One example of this is quality of life measures, which are the increasing focus of clinical drug trials and neurosurgical interventions in neurological illness.

Integration with Neurological Examination

Neuropsychological assessments are ancillary to the typical neurological examination, and establish better precision of the type and extent of cognitive and behavioral deficits found on bedside testing. To accomplish this goal, neuropsychological tests need to be standardized, valid, and reliable, and need to make meaningful comparisons of patient-derived data to normative performance.

Standardization of neuropsychological testing procedures allows for the comparison of performance across time and across individuals. Because the interpretation of neuropsychological tests requires consistent assessment methods, neuropsychological tests are standardized to testing environment, presentation of instructions, presentation of testing stimuli, seeking clarification of response from the patient, scoring procedures, and interpretative methods. Standard testing methods provide all patients with an equal opportunity to perform the required task.

Another important aspect to neuropsychological assessment is the use of reliable and valid tests. Reliability refers to the degree to which a given test score represents differences in the behavior of interest as opposed to error. Reliability measures include the degree to which a test provides consistent scores across different time points (test-retest reliability); the degree to which a test provides consistent scores across different examiners (inter-rater reliability); the degree to which the test is internally consistent (split-half reliability); and the degree to which a test provides consistent score across alternate forms of the test (alternate-form reliability).¹⁴ A valid test is one that measures what it is purported to measure. This aspect of test development and utilization depends upon many factors. Validity measures include the degree to which the items of the test cover the relevant domain of interest but not other domains (content validity); the degree to which the test agrees with either a gold standard of the domain of interest or another test designed to measure the same domain (concurrent validity); the degree to which a test does not agree with another test designed to measure a different domain (discriminant validity); and the degree to which a test measures the theoretical construct under study (e.g., intelligence) (construct validity).

The relationship between reliability and validity is statistically constrained. Validity scores cannot exceed the square of reliability scores. Thus, a test can be highly reliable but invalid, but a test can never be valid and unreliable. One way to increase reliability of a given test is the use of the preceding standardized testing methods. If the manner in which a test is administered varies across examiners or

across testing sessions, extraneous error is introduced, which lowers reliability and validity.

The ability to make meaningful comparisons of an individual patient's performance to normative expectations is constrained by how test performance is interpreted. Neuropsychological assessments are usually requested to identify and quantify some form of cognitive impairment. Thus, neuropsychological tests are designed to assess deficits in performance.¹⁵ In order to assess impairments, there must be some knowledge of normal expectancies of performance. Thus, testing results must have a referent for comparison, either individual comparisons or normative comparison groups.

Individual comparisons of test performance are the most obvious method for identification of deficits. In individual comparisons previous data from a patient are used to compare with present performance. Thus, if a patient demonstrated above-average performance on a test of verbal memory prior to developing herpes simplex encephalitis, but performed at the below-average range of performance on the same test following the illness, one could conclude that a decline in verbal memory had occurred. In reality such a situation rarely occurs because neuropsychological data are usually not available from the period prior to disease or trauma. Even when such data are available there are other possible explanations for the decline in performance. If for any reason the scoring on the first or second examination is incorrect, scores are artificially inflated or minimized. Again, standardization of testing methods and concerted efforts to eliminate testing bias help to reduce this occurrence.

A second referent for neuropsychological test performance interpretation is the population-based comparison. This method is most frequently used in neuropsychological assessment and involves the comparison of individual patients' test scores to norms that detail performance on the measure of interest by a standardization sample. A relative ranking of the individual's score can then be determined according to the performance of the normative sample. A norm is constructed by sampling a large number of individuals, called the standardization sample, on the measure of interest. The standardization sample should be representative of the population of interest. Thus, if one wishes to develop norms for adult performance on a measure of general intelligence, the standardization sample must include individuals from all relevant age ranges, gender distributions, and educational strata. The norms provided for the Wechsler Adult Intelligence Scale—Third Edition (WAIS-III)¹⁶ are an example of such a procedure and the norms of WAIS-III performance are reflective of this population.

Random sampling is required for the development of most norms, because a random sample, stratified for pertinent variables is one of the assumptions of a normal distribution. Sampling theory states that large, random samples of test scores will approach a normal distribution as the sample size approaches infinity. The characteristics of a normal distribution are particularly well suited to norm development (Fig. 27-1). In a normal distribution the measures of central tendency (mean, median, mode) are unitary and the dispersion of scores (standard deviation) on either side of mean is symmetrical. The shape of a normal distribution

Figure 27-1. The normal distribution is approached when many scores of a given test are collected from a random sample. This distribution is symmetrically shaped with common measures of central tendency (mean, median, mode) and equal variance on either side. The percentages of cases falling within each standard deviation are presented between the dashed lines. The ranking of any single score may be represented by standard deviation units, z score units, or percentile ranking. sd, standard deviation.

has been called a bell-shaped curve because it peaks in the middle and trails off as you approach either tail. The characteristics of a normal distribution allow the ranking of average performance. Approximately 68% of all cases (or WAIS-III scores in our example) fall within one standard deviation of the mean, and approximately 95% of all cases fall within two standard deviations of the mean. This characteristic allows for a meaningful comparison of an individual's score to the standardization sample. Therefore, one can express an individual's performance in terms of standard deviations away from the mean of the standardization sample; z scores, which represent the individual's score minus the mean of the standardization sample divided by the standard deviation of the standardization sample; or a percentile ranking based on the standardization sample. In most neuropsychological assessments, one of these methods for ranking an individual's performance will be reported.

Comparison of an individual's performance to these norms then provides a meaningful yardstick to identify strengths and weaknesses. If someone is performing above the mean of the standardization sample, that performance is above average for the population. Such a comparison scheme is very helpful in tracking patients' abilities and disabilities. It does, however, raise the question of whether lower than average performance really equals impaired performance. Since the standardization sample assumes normal distributional properties, the probability of occurrence of any score can be calculated. In most clinical neuropsychological assessments, performance is defined as impaired when the probability of obtaining a score that low or lower in the standardization sample is less than 5%. This corresponds to the standard level of significance used in most statistical analyses.

Because the standardization sample is used to interpret individual test performance, an important consideration in all neuropsychological assessments is the adequacy of the sample. Even with well-normed tests such as the WAIS-R, care needs to be exercised when comparing specific individuals with the standardization sample. For example, the standardization sample for the WAIS-III has adequate representation of individuals up to the age of 89, but does not provide any normative information for individuals over the age of 89. Thus, if the performance on a 92-year-old patient on the WAIS-III is compared with this standardization sample, the results may not truly reflect the performance of all 92-year-old persons.

Many other tests used in neuropsychological assessments have much more limited standardization samples, and as such may be subject to erroneous interpretations. The interpretation of many neuropsychological tests is based on standardization samples of less than 100 scores. Heaton and colleagues¹⁷ have attempted to generate better norms for many commonly used neuropsychological tests. Their efforts have surely led to improved interpretative methods. However, even this effort suffers from a lack of generalizability to the populations of interest. This is because the standardization samples they used were not randomly selected but rather were composed of volunteers from limited geographic regions. Therefore, it is important for the consumer of neuropsychological assessment results to be aware of how the interpretations are made and the norms used in those interpretations.

Hierarchy of Testing Functions

A given cognitive function is usually composed of multiple discrete functions. Memory performance is affected not only by the ability to recognize and recall stimuli but also by the ability to perceive, process, and store those stimuli, and, finally, to reproduce them in an observable fashion. Most neuropsychologists approach patient assessment using a general hierarchy of functions involved in cognition.

The primary components of this hierarchy are the perception of stimuli, ability to attend to the stimuli, and the ability to generate some form of response. In consideration of these issues, one of the first cognitive functions to be tested in almost all examination formats is level of consciousness (see Chapter 1). If a patient is comatose there is little need to conduct neuropsychological testing. Testing of sensory systems (usually visual, auditory, tactile, and proprioceptive) is also conducted to ensure adequate stimuli processing. Finally, in order to assess a patient, a competent effector system that enables a response must be present. Therefore, testing of basic motor, vocal, and praxis abilities is conducted. If deficits are noted in any of these basic abilities, the neuropsychologist uses that information in the interpretation of other cognitive tests to increase or decrease confidence in those results. Once these three levels of abilities have been tested, testing of higher cognitive functions (e.g., intelligence, reasoning, language) can begin.

Testing Batteries versus Individualized Testing

There are two basic approaches to testing methods in neuropsychological assessments: the use of comprehensive testing batteries or the use of individualized testing. Each approach has its strengths and weaknesses, and most neuropsychologists use a combination of these two approaches to capitalize on the strengths and minimize the weaknesses.

The Battery Approach

Neuropsychological testing batteries provide a structured approach to the assessment of cognitive function. Although there are many neuropsychological testing batteries, two batteries are most commonly used: the Halstead-Reitan Battery¹⁸ and the Luria-Nebraska Neuropsychological Battery.¹⁹ The Halstead-Reitan Battery is a collection of tests that Halstead found to discriminate normal individuals from patients with organic brain disease. The core of the Halstead-Reitan Battery includes six tests developed by the authors (measuring abstract reasoning, tactile performance, tactile/visual-spatial memory, rhythm perception and memory, speech-sound perception, and primary motor speed) and seven tests developed by other individuals (measuring intelligence, psychomotor speed, sequencing abilities, language function, sensory function, grip strength, and personality functioning). The entire battery requires at least 6 hours for administration, not including scoring and interpretation, so testing often requires multiple visits. The original standardization sample for the development of the Halstead-Reitan Battery norms was inadequate; new norms have been generated using a larger and perhaps more representative standardization sample.¹⁷ The Halstead-Reitan Battery appears to

be adequate in discriminating brain-damaged individuals from neurologically healthy individuals, but is not sensitive to mild cognitive impairment or to precise localization. Despite these limitations, the Halstead-Reitan Battery is the most commonly used neuropsychological assessment battery.

The Luria-Nebraska Neuropsychological Battery¹⁹ developed out of the extensive investigations of behavioral neurology conducted by the Russian neurologist Luria and the work of Christensen,²⁰ who brought Luria's theories and methods of neuropsychological testing to America. The battery uses selected Luria test items that best discriminate brain-damaged patients from neurologically healthy individuals. It consists of 269 individual items that are scored on a zero (no impairment) to 2 (impairment) scale (Video 16, Luria Testing). The test items are simple and complex commands and problems, such as motor commands and arithmetic. The 269 items are composed of 11 clinical/ability scales measuring motor abilities, rhythm sense and reproduction, tactile abilities, visual abilities, receptive speech, expressive speech, writing, reading, arithmetic abilities, memory function, and intelligence. Three additional scales provide information as to the presence of pathognomonic signs, left hemisphere damage, and right hemisphere damage. Administration of the Luria-Nebraska Neuropsychological Battery is approximately 2 to 3 hours (substantially less than the Halstead-Reitan Battery).

Although authors of the Luria-Nebraska Neuropsychological Battery have published numerous articles in support of its reliability and validity, other investigators have not been able to replicate these results.²¹ The inadequate validity and reliability of the Luria-Nebraska Neuropsychological Battery are owing primarily to the lack of any theoretical model used in its development. Whereas the strength of Luria's original work was his ability to generate hypotheses about brain-behavior relationships and methods to tests these hypotheses, the developers of the Luria-Nebraska Neuropsychological Battery were unable to emulate this strength.

Individualized Testing Approach

The main advantage to the battery approach is that it allows for the collection of massive amounts of information on the status of cognitive functioning in a highly standardized manner. This advantage is contrasted with numerous disadvantages: the time required for a complete assessment is often excessive and fatigues the patient; the batteries often include assessment measures that are not necessary for a given patient, and, conversely, the batteries do not provide comprehensive assessments of all cognitive functions. By recognizing these limitations, most neuropsychologists use an individualized approach to testing.

An individualized approach allows the neuropsychologist to use pertinent information to guide test selection. For example, if neuropsychological assessment is requested for a patient with diagnosed Alzheimer's disease, the neuropsychologist knows that trying to complete a Halstead-Reitan Battery would not only be unfair to the patient but would also provide little useful information. Instead, the examiner may choose to use a number of shorter tests with

lower performance ranges to allow for extremely low scores. Using this approach, the neuropsychologist chooses tests (either from existing batteries or tests designed to assess specific deficits) that assess cognitive functions relevant to a given patient. Thus, examination time is shortened, and the specificity of the testing results is increased. Inevitably, however, the selection of tests introduces a certain bias, and some domains of good or bad function may be missed.

Neuropsychologists have a vast array of tests from which to choose when using the individualized approach. More than 700 tests of cognitive functioning are available, assessing such complex functions as intelligence and such basic functions as primary motor speed. Although a detailed description of all of these neuropsychological tests is well beyond the scope of this chapter, the next section provides a brief description of the most commonly used tests and their role in assessing specific cognitive domains. This review is limited to the most commonly used tests in neuropsychological assessments of adults.

NEUROPSYCHOLOGICAL TESTS

Orientation, Attention, and Vigilance

Impairments in orientation, attention, and vigilance are common sequelae to brain damage, and regardless of the localization of brain pathology, these abilities are often compromised. When a patient is disoriented and unable to attend to ongoing events, there is usually severe pathology (Video 21, Disinhibition). In addition, inability to attend to ongoing stimuli makes the interpretation of neuropsychological tests of higher cognitive functions, such as intelligence or memory, difficult. Therefore, the assessment of orientation, attention, and vigilance is an integral part of all neuropsychological assessments and usually is performed first.

Orientation Tests: Personal, Temporal, and Spatial

Standard bedside mental status examinations always assess orientation to person, time, and place. Usually this information is gathered from interviewing the patient in an open manner, and is not part of a standardized test. Many tests of cognitive function include questions assessing orientation, although they may not provide selective scores for orientation. Specific tests with orientation questions, or tests designed to assess orientation, are listed here.

MINI-MENTAL STATE EXAMINATION (MMSE).²² The MMSE includes questions that assess orientation to time ("What is today's date?" "Month?" "Day of the week?" "Year?") and orientation to place ("Where are you now?" "What state are you in?" "County?" "City?" "What is the name of this place?"). Each item is scored as pass or fail. Although the orientation section of the MMSE does not provide a separate score, a failure of two or more items is reflective of impaired performance.

WECHSLER MEMORY SCALE-THIRD EDITION (WAIS-III).²³ Although the majority of this test's items assess memory function, there is a subtest, Information and Orientation, that assesses orientation to person, place,

or time. Failure of two or more items is considered impaired.

TEMPORAL ORIENTATION TEST (TOT).²⁴ The TOT is designed to assess specifically orientation to time. The questions include knowledge of current hour and minutes, date, day of the week, month, and year. Errors are assigned negative scores depending on the amount of disorientation. The error score is subtracted from 100 and any score less than 95 is reflective of impaired performance.

MONEY ROAD MAP TEST (MRMT).²⁵ The MRMT assesses the ability of the patient to identify left and right directions at different orientations. The patient views a map on which the examiner traces a route. At each turn, the patient has to identify whether the examiner made a left or right turn. In order to perform this test correctly, patients must be able to reorient mentally to the perspective of the examiner and to different orientations of the route. If a patient makes more than 10 errors (out of 32 turns) his or her performance is considered impaired.

FINGER LOCALIZATION TEST.²⁶ This test of personal orientation requires the patient to identify which finger has been stimulated by the examiner under visual guidance, and in the absence of visual input. A variant of this test is found in the Halstead-Reitan Battery, which assigns numbers to each finger of each hand, and requires the patient to identify which hand and which finger number has been stimulated in the absence of visual input.

LEFT-RIGHT ORIENTATION TEST.²⁷ This test of left-right orientation requires the patient to display lateralized body parts (e.g., “show me your left hand”), identify laterality of the examiner’s body (e.g., “point to my left hand”), and touch lateralized body parts of the examiner (e.g., “touch my left hand”). In order to perform this task correctly, the patient must be able to reverse personal orientation when confronted with identifying laterality of the examiner. The normative data for this test are very limited, but a cut-off score of four errors is suggestive of impaired left-right orientation.

Mental Status Tests

Mental status tests are used to assess overall level of cognitive functioning. These tests are brief to administer and not very comprehensive. They tend to include a few questions on orientation, attention, memory, language, and sometimes praxis. Although mental status testing provides basic information on the integrity of most cognitive functions, the tests tend to lack sensitivity to detect mild cognitive impairment. In addition, most tests of mental status do not have normative data, so the effects of various demographic variables (e.g., age, gender, education) are unknown. Despite these limitations, the tests provide useful information, and some form of mental status testing should be a part of all neuropsychological assessments.

MINI-MENTAL STATE EXAMINATION (MMSE).²² In addition to the preceding orientation questions, the MMSE includes items assessing registration of information, recall of three words, attention and sequencing abilities (serial sevens, or spell world backward), naming, repetition, following spoken commands, writing, and copying. The test provides a general summary of cognitive function, but does not assess any cognitive domain in depth. The maximum

score for the MMSE is 30, and a cut-off score of 24 is considered to indicate impaired performance (Video 260, Memory Testing).

Although the MMSE is the most commonly used mental status test, it has a number of problems. First, one must accept the basic limitation of any screening examination. Since the test has a limited number of questions, adequate testing of cognitive function is not possible. Practically, however, the MMSE score is used as an indicator of intact or impaired performance. The cut-off score of 24 is associated with relatively high false-negative rates (test indicates absence of impairment when impairment is present) and relatively high false-positive rates (test indicates impairment when no impairment is present). Additionally, MMSE score is affected by education, race, and gender. Despite these limitations, the MMSE provides a “quick-and-dirty” assessment of overall cognitive function, and in most contexts a score of 22 or lower is considered an accurate mark of clinically significant cognitive impairment.

MENTAL STATUS QUESTIONNAIRE (MSQ).²⁸ The MSQ is composed of items assessing orientation to time and place and ability to name the current and past presidents of the United States. The maximum score of the MSQ is 10 errors, and individuals making more than 2 errors are considered moderately impaired. This cut-off score suffers from the same limitations as the MMSE.

SHORT-PORTABLE MENTAL STATUS QUESTIONNAIRE (SPMSQ).²⁹ The advantage of the SPMSQ over the MMSE and MSQ is that normative data have been gathered to aid in interpreting performance. This represents a major advantage to the SPMSQ. However, the test still suffers from problems with false-positives and false-negatives (particularly in patients with mild cognitive impairment).

Tests of Attention and Vigilance

Testing attention involves assessment of the ability to attend to stimuli, the ability to focus attention on selected stimuli, and ability to inhibit attention to inappropriate stimuli. Tests of vigilance also require the active updating of information in an ongoing display requiring attention. All of these abilities are essential to intact cognitive function. Information on attention and vigilance should be reported in all neuropsychological assessments.

SIMPLE REACTION TIME (SRT). SRT tasks require the patient to respond, as quickly as possible, to a stimulus. The time the patient takes to respond (RT) is usually measured in milliseconds. Slowed RT is one of the most sensitive measures of impaired cognitive functioning, but individual data are difficult to interpret owing to the large inter- and intra-patient variability.

CHOICE REACTION TIME (CRT). There are many measures of CRT, but all follow a basic paradigm: the patient is required to respond to one stimulus but to not respond to another. An example of this is the Continuous Performance Test, in which the patient is asked to respond, as quickly as possible, to a rare stimulus that is embedded in a stream of ongoing similar stimuli. These tests assess the patient’s ability to maintain attention and vigilance for the target stimulus and the ability to inhibit responses to the nontarget stimuli. Individual differences are difficult to interpret owing to large inter- and inpatient variability.

SPAN TESTS. Tests of span capacity are a more standard form of assessing attention and vigilance than reaction time measures. In addition to assessing attention, span tests also require some form of short-term memory. However, forward span tests (see following discussion) are thought to be more reflective of attentional abilities. When backward span (repeating a sequence heard in the reverse order of presentation) is used, different cognitive processes are required, including working (or short-term) memory, so that the test is no longer a pure measure of attention.

The most commonly used span measures are the Digit Span tests from the WAIS-III and the Wechsler Memory Scale-Third Edition (WMS-III).²³ In these tests, patients listen to random sequences of numbers presented in increasing length, and immediately repeat each sequence. Two trials at each span length are presented, and maximum span is the number of digits the patient can correctly repeat on at least one trial. Average performance on this measure is considered to be between five and nine digits.³⁰ Another type of span test is the Letter-Number Sequencing subtest of the WAIS-III and WMS-III. Similar to the Digit Span subtest, the Letter-Number Sequencing subtest requires the patient to repeat back a sequence of letters and numbers. However, during this subtest, the patient must now manipulate the letters and numbers by first repeating back all the numbers in numerical order, and then all the letters in alphabetical order. Both digit and letter span are measures of verbal ability. A nonverbal span measure is the Corsi Block Test.³¹ In this test the patient is presented with an array of nine blocks arranged in a random order. The examiner touches blocks in sequences of increasing length. The patient is required to reproduce the sequence at each length. As in the Digit Span test, two trials are given at each sequence length and maximum span is the number of blocks the patient taps in the correct order on at least one trial. Average performance on this test is similar to digit span. The Spatial Span subtest of the WMS-III is an equivalent test to the Corsi Block Test, and has good standardization and normative data.

ATTENTION/CONCENTRATION SUBTESTS OF THE WMS-III. Two subtests of the WMS-III (discussed following) that assess attention and concentration are the Letter-Number Sequencing subtest and the Spatial Span subtest. Together these subtests form the composite measure of Working Memory. One major advantage to the use of these measures is that they have good normative information (see WMS-III description later) and can be converted to age-adjusted standard scores with a mean of 100 and a standard score of 15. The use of these standard scores allows for comparisons across many different neuropsychological tests (e.g., WAIS-III).

PACED AUDITORY SERIAL ADDITION TEST (PASAT).³² The PASAT is a test requiring attention and vigilance. In this test, the patient listens to a tape recording of digits presented one at a time. The task for the patient is to add each number to the one immediately preceding it. For example, the recording might present the numbers 1, 7, 5, 4. The patient adds the first two numbers ($1 + 7$) and responds with the number 8. The patient then adds the second two numbers ($7 + 5$) and responds with the number 12. The patient then adds the third two numbers ($5 + 4$) and responds with the number 9. This continues for a total of

61 numbers presented in a random order. The test can be given at different rates of presentation ranging from a slow rate of one number every 2.4 seconds to the fastest rate of one number every 1.2 seconds. This test assesses attention and vigilance because the patient is required to not only attend to the relevant stimuli (numbers) but also be vigilant to changes in the ongoing presentation. This is an extremely sensitive measure of vigilance. However, the test also involves working or short-term memory because the patient must “hold” in short-term memory the preceding number while formulating a response. Although this is a sensitive test, the norms for interpretation are limited.

DIGIT SYMBOL.¹⁶ This subtest of the WAIS-III presents the patient with a row of numbers one through nine, each paired with nonsense symbols (e.g., inverted T). Below this key are empty boxes with numbers above each box. The patient is required to transcribe the symbol corresponding to the number above the box as quickly as possible. This measure requires focused attention and switching behavior between the key and the target boxes. One advantage of this test is the extensive WAIS-III norms available on performance expectations. This test also requires motoric speed and may not be appropriate for patients with marked motor impairment. A variant of this test is available that requires a verbal response only, thus decreasing motoric demands.³³

SYMBOL SEARCH.¹⁶ This subtest of the WAIS-III presents the patient with two target symbols (nonsense symbols) and an array of additional symbols (nonsense symbols). The patient is required to respond yes if the array of additional symbols contains one or more of the target symbols, and respond no if the array of additional symbols does not contain one or more of the target symbols. Again, one advantage of this test is the extensive WAIS-III norms available on performance expectations. This test also requires motoric speed, and thus, should not be used with patients who have motor impairments.

TRAIL MAKING TEST.³⁴ There are two forms to this test: Trail Making Tests A and B. Trail Making Test A provides an assessment of complex attention. This test requires the patient to connect randomly positioned numbered circles in numeric order as quickly as possible. Form B presents the patient with numbered circles and circles with letters. The patient is required to connect the circles in numeric and alphabetic order as quickly as possible, alternating between numbers and letters. Both Forms A and B require focused attention for successful performance. In addition, Form B requires the patient to switch cognitive sets between numbers and letters. Both forms of the Trail Making Test are highly dependent upon motoric speed, and may not be appropriate for patients with marked motor impairment (e.g., Parkinson’s disease).

CANCELLATION TESTS. Another useful test of attention and vigilance is that which requires the patient to seek a selected stimulus out of a background of similar stimuli. One such measure is the Letter Cancellation Test,³⁵ in which the patient is required to cancel selected letters, designs, or words from a background of nontarget letters, designs, or words. Another cancellation test is the Visual Search and Attention Test (VSAT).³⁶ Here, the patient is required to cancel out either a letter or symbol of varying colors. Because cancellation tasks are timed measures

requiring motoric responses, they may not be appropriate for patients who have marked motor impairment.

Clinical Situations for Testing Orientation, Attention, and Vigilance

Neuropsychological data on orientation, attention, and vigilance abilities are useful in defining dysfunction in all levels of neurological functioning. Such tests are particularly useful in cases of toxic and metabolic abnormalities (see Chapters 38 and 39), which affect level of consciousness (see Chapter 1), sleep/wake cycles (see Chapter 2), and memory functioning (see Chapter 5). In addition, attentional testing is essential for patients who evidence neglect or dyspraxia (see Chapter 4). Useful information on patients with psychiatric presentations is also provided when attention is assessed (see Chapters 1 and 3). When requesting neuropsychological assessment of orientation, attention, and vigilance, it is important to request testing on all aspects of attention and vigilance including simple attention, focused attention, and set-shifting.

Intellectual Abilities

Intelligence is considered to be the culmination of cognitive abilities. The testing of intelligence involves assessments of attention, reasoning, memory, language, perception, and construction. Intelligence tests should provide an overview of cognitive function integrity. Most tests of intelligence do not adequately assess all cognitive abilities, however.

Intelligence Quotients

These tests are the current gold standard in intelligence testing and include the WAIS-III.^{16,36,37} Each Wechsler test is used for different age ranges: the WPPSI-R test is for ages 3 years to 7 years and 3 months; the WISC-III test is for ages 0006 years to 16 years 11 months; and the WAIS-III test is for ages 16 years to 74 years 11 months. Because the different Wechsler tests are similar in construction, interpretation, and psychometric concerns (standardization, norms, reliability), only the WAIS-III will be discussed.

In keeping with the idea that intelligence is the culmination of cognitive function, the WAIS-III is composed of different subtests, each assessing different cognitive functions (Table 27-1). Because of this composition, the various subtests are listed under different subheadings in this chapter. In addition, since the WAIS-III assesses many different cognitive functions, it is often the framework for neuropsychological assessment, and provides an overview of the integrity of cognitive abilities. Results for subtest performance often guide further (and more extensive) testing of selected functions.

The WAIS-III provides three summary measures: Verbal IQ, Performance IQ, and Full Scale IQ. The IQ score represents an age-adjusted scaling of an individual's intellectual performance. This provides a standard measure that can be compared across individual patients or within a given patient over chronological age. Due to the extensive norms for the WAIS-III (see preceding discussion) these measures may be generalized to the population of the United States.

TABLE 27-1

Subtests of the Wechsler Adult Intelligence Scale-Third Edition and Cognitive Functions They Assess

| SUBTESTS | COGNITIVE FUNCTION ASSESSED |
|--|--|
| Verbal Scales (Verbal IQ) | |
| Vocabulary | Vocabulary knowledge Semantic memory |
| Similarities | Reasoning, problem solving, concept formation Executive function |
| Arithmetic | Attention/concentration Executive function Processing speed Calculations |
| Digit Span | Attention/concentration Short-term memory |
| Information | General fund of information |
| Comprehension | Reasoning, problem solving, concept formation Executive function |
| Performance Scales (Performance IQ) | |
| Picture Completion | Reasoning, problem solving, concept formation Executive function |
| Digit Symbol | Attention/concentration Executive function (sequencing) Motor function Processing speed |
| Block Design | Construction Praxis Spatial reasoning Motor function Processing speed |
| Matrix Reasoning | Visual-spatial processing Abstract reasoning |
| Picture Arrangement | Reasoning, problem solving, concept formation Executive function (sequencing) |

The Wechsler tests have been translated into many different languages, and adequate norms exist for most of these modifications. The characteristics of the standardization sample of IQ scores (Verbal, Performance, and Full Scale) are a mean performance of 100, with a standard deviation of 15. In addition, individual subtest performance can be converted to standard scores with associated variability. Thus, the clinician is able to classify individual performance for both summary IQ measures and individual subtest performance against these values and provide a relative ranking of performance.

The summary IQ scores are extremely useful in educational settings. Although these scores are useful, care needs to be exercised in their use. Because IQ scores represent the culmination of cognitive abilities, they are extremely susceptible to brain damage.¹⁵ The presence of a potentially reversible impairment in one of the basic elements of cognitive function (e.g., attention/vigilance) will provide artificially low IQ performance. Therefore, IQ scores need to be interpreted in the context of a complete neuropsychological examination.

One particularly difficult issue in intellectual performance is the diagnosis of profound intellectual impairments, or mental retardation. First, this diagnosis has major consequences for an individual. Once assigned with the label of mental retardate, educational and occupational opportunities are limited. The individual is guided away

from mainstream educational settings and provided with specialized training. Second, there are no universally accepted diagnostic criteria for mental retardation. The usual criterion is IQ performance greater than two standard deviations below the mean (e.g., an IQ score of less than 70 on the WAIS-III). Because the performance level for mental retardation is so low, however, statistical reliability of the standardization sample is also low. As seen in [Figure 27-1](#), as the scores decrease (or increase) toward the tail of the distribution, the number of sample scores drops dramatically. The representativeness of cases at these extreme levels is limited and hence it is problematic to generalize the results to the population of interest. Because of these issues, it is incumbent on the examiner to base the diagnosis of mental retardation on multiple assessments of intellectual performance and not on a single measure.

The use of IQ scores in neuropsychological assessments is limited to providing a basic measure of cognitive functional integrity. Comparison of Verbal IQ performance to Performance IQ performance has been suggested to provide an assessment of dominant (verbal) and nondominant (performance) hemispheric function. Actuarial studies of this Verbal IQ/Performance IQ comparison, however, have not supported its use in this capacity.³⁸ Verbal IQ measures do provide some indication of dominant hemispheric integrity, but Performance IQ measures do not reliably indicate nondominant hemispheric integrity. This lack of reliability is due to basic differences between verbal and performance measures. Whereas most subscales comprising Verbal IQ are not timed, all Performance IQ subscales are. This difference adversely affects the Performance IQ scores of individuals with compromised motor and cognitive speed (e.g., patients with basal ganglia damage). In addition, there are basic differences in sensitivity to brain damage between verbal and performance subscales. The subtests of Verbal IQ tend to require overlearned abilities such as vocabulary knowledge and general information. These abilities are, in general, less affected by brain damage. The subtests of Performance IQ tend to require novel abilities, such as reproducing visual patterns using colored blocks. These abilities are, in general, more affected by brain damage. This difference between overlearned and novel abilities is evident in aging, and reflected in the performance of the standardization sample.

In contrast to the use of summary IQ scores for neuropsychological assessment, the analysis of subscale performance is very useful. As shown in [Table 27-1](#), each subscale assesses specific (and overlapping) cognitive abilities. The pattern of performance on the subtests can provide useful information in forming hypotheses as to possible impairment in various cognitive abilities. These hypotheses can then be tested with additional, more focused, assessments. The use of subscale performance patterns has resulted in various interpretative methods for specific neuropsychological use.

Premorbid Estimates of Intellectual Function

In order to provide useful information on general cognitive functioning, current measures of intelligence need to be compared with premorbid level of functioning. Because neuropsychological testing results are typically not available

for the period prior to neurological trauma, neuropsychologists are forced to estimate premorbid abilities.³⁹ There are three basic approaches to estimation of premorbid intellectual functioning: estimates derived from life-history variables believed to be correlated with measures of cognitive functioning (e.g., years of education); measures of best current cognitive functioning, or “present abilities,” which are used to estimate a minimum level of premorbid functioning; and comparison of an individual’s test results to population-based estimates of normal performance (norm-based comparisons as discussed previously). Each of these approaches has associated error that needs to be considered in the interpretation of neuropsychological testing data.

The first method, estimates based on life-history variables, offers a potential wealth of information that is thought to be related to the cognitive performance. Estimates derived from life-history variables may include basic demographic information such as age, education, and gender but may also include information from developmental history, medical history, occupational history, and academic history. The application of these data to an estimate of premorbid functioning can be accomplished in either qualitative or quantitative methods. The qualitative approach allows the examiner to form a “best-guess” of premorbid functioning.³⁹ For example, the estimated premorbid functioning for an individual with a normal developmental history, outstanding academic history, a college degree, and an occupational attainment of CEO of a major corporation would be higher than an individual with a normal developmental history, poor academic history, a high school diploma, and an occupational attainment of sales clerk. Although this information may be helpful, it does not provide an actual estimate of premorbid functioning.

The quantitative approach to the use of life-history information typically uses demographic information such as age, education, and gender to provide an estimate of the range of premorbid test scores for a given individual.^{40,41} This approach is useful because specific ranges of test scores may be generated to be compared with current scores, but typically does not take full advantage of nonquantifiable information such as developmental and medical history.

The second method of estimating premorbid cognitive abilities, the “present abilities” approach, uses current test scores to provide a lower-bound estimate of prior functioning. The theory underlying this approach is that neurological damage does not affect all cognitive abilities equally and that an individual’s highest test score on current testing is most likely to reflect intact performance. Therefore, that highest test score can be used to provide an estimate of overall premorbid cognitive functioning. For example, if an individual is scoring at the below average range of performance on tests of verbal memory, verbal comprehension, and verbal fluency but is performing at the average range on a test of visual-spatial skills and nonverbal reasoning, the examiner may assume that the individual was performing at least at the average range on all measures. Of course, this estimate is only meant to provide an interpretative guide, as other explanations for a given pattern of intact and impaired performance are possible.

A more standardized method than the “present abilities” approach for estimating premorbid IQ is found in tests such as the Wechsler Test of Adult Reading (WATAR)⁴² and its

variants. These tests rely on current performance of reading ability or vocabulary knowledge to estimate premorbid abilities. Both reading ability (particularly reading of phonically irregular words such as *debt*) and vocabulary knowledge tend to be less affected by brain damage than other cognitive abilities. By using these abilities to estimate premorbid IQ, the examiner is able to get an estimate of a lower-bound to previous IQ.⁴³

All of these approaches to premorbid IQ estimation are subject to many caveats. First, the range of scores provided by the quantitative approaches is limited. With these measures, it is not possible to get very high or very low IQ estimates. Second, these approaches overestimate low IQ performance and underestimate high IQ performance. Third, each approach is associated with differing levels of statistical error, usually measured as the standard error of estimate. For example, the quantitative approaches have standard errors ranging between 2.6 and 16 points. Since the standard deviation of IQ is 15 points, these estimates can at best provide a range of possible scores equal to or greater than one standard deviation. Therefore, extreme care needs to be applied to the use of these estimates. Most neuropsychologists will use a combination of quantitative and qualitative approaches to the estimation of premorbid IQ.

Other Intelligence Tests

The Wechsler scales are not the only method for the assessment of intellectual abilities. Due to space limitations we cannot list all tests of intelligence. However, other tests of intellectual abilities tend to follow two different assessment methods: tests of verbal abilities and tests of nonverbal abstraction. The first method, testing of verbal abilities, is represented by tests such as the Peabody Picture Vocabulary Test–Revised (discussed in the section on Perception and Construction Abilities), in which patients are asked to choose which of four pictures best identifies a spoken word. This method is based on the high correlation between vocabulary knowledge and IQ.⁴⁴ The second method, tests of nonverbal abstraction, is represented by the Raven’s Progressive Matrices Test (discussed in the section on Reasoning and Problem Solving Through Concept Formation), in which patients must abstract general principles and rules from patterns. This method tends to correlate well with the Full Scale IQ from the Wechsler scales.

Tests of Academic Achievement

Tests of academic achievement typically assess standard academic skills such as reading, writing, arithmetic skills, and spelling. The scores derived from these measures provide important information on neuropsychological and educational abilities. They allow comparisons of an individual patient’s educational development to normative expectations. They also help identify specific areas in need of remediation. Finally, academic achievement tests provide important information in the diagnosing of specific learning disabilities. The presence of learning disabilities is suggested when there is a large discrepancy between measures of intellectual ability and measures of academic achievement. Additional testing is required to formally

assign a diagnosis of learning disabilities. The most commonly used tests of academic achievement are the Peabody Individual Achievement Test–Revised (PIAT-R)⁴⁵ and the Wide Range Achievement Test–Third Edition (WRAT-III).⁴⁶ Both of these tests assess reading, arithmetic, and spelling. The PIAT-R has additional scales assessing the patient’s fund of general information and reading recognition. Both tests provide information as to an individual patient’s academic achievement in terms of grade level, standard score, and standing.

Clinical Situations for Tests of Intellectual Abilities

Intellectual assessment is very important for patients presenting with impairments of higher cognitive functioning such as memory, language, and reasoning. Because these higher cognitive functions are highly correlated with intelligence, intelligence assessment allows the examiner to interpret scores of memory, language, and reasoning performance in light of basic intellectual abilities. Intellectual assessments are not particularly helpful in patients with disturbances in level of consciousness (see Chapter 1), disrupted sleep/wake cycles (see Chapter 2), or neglect and dyspraxia (see Chapter 4). Additionally, the comparison of intellectual abilities and academic achievement is helpful in identifying patients who may have learning disabilities. In children with developmental or neurodegenerative disorders affecting the cortex or subcortex (see Chapters 28 and 34) and those with chromosome alterations, enzyme defects, or storage abnormalities (see Chapters 30–32), these assessments help in tailoring educational efforts and expectations. When intelligence testing is requested, the referring physician should ask for a reporting of subscale performance as well as summary IQ scores.

Reasoning and Problem Solving through Concept Formation

Reasoning and problem solving are highly related to intellectual functioning. Similar to intellectual function, these abilities tend to be impaired following damage to the CNS. Specific location of injury appears to be less important to reasoning impairments, as does the presence of CNS disturbance. Impairments in reasoning and problem solving result in difficulties in all areas of daily functioning. Patients may not be able to form generalizations from a given situation and interpret events concretely. Tests of reasoning and conceptualization usually assess verbal or nonverbal abilities.

Tests of Verbal Reasoning and Concept Formation

COMPREHENSION.¹⁶ This subtest of the WAIS-III is a test of verbal conceptualization. Patients are required to answer questions or interpret proverbs that require problem solving (e.g., “What does ‘a rolling stone gathers no moss’ mean?”). Scoring is based on partial credit on most items for concrete responses and full credit on responses reflecting abstraction of general principles. One advantage of this test is the extensive WAIS-III norms available on performance expectations.

SIMILARITIES.¹⁶ This subtest of the WAIS-III requires the patient to identify the common elements between seemingly uncommon stimuli. The test begins with simple problems (e.g., “How are an orange and banana alike?”), and progress to more difficult problems (e.g., “How are praise and punishment alike?”). Scoring awards full credit for complete abstractions, partial credit for concrete responses, and no credit for incorrect responses. One advantage of this test is the extensive normative data from the WAIS-III standardization sample.

ARITHMETIC.¹⁶ This subtest of the WAIS-III presents the patient with progressively more difficult arithmetic word problems. The test is timed so the patient must attempt to complete each problem as quickly as possible. In addition, bonus points are given for some of the difficult problems when the patient responds very quickly. Since this test is a subtest of the WAIS-III, it benefits from extensive normative data.

Tests of Nonverbal Reasoning and Concept Formation

CATEGORY TEST.¹⁸ The Category Test is part of the Halstead-Reitan Battery and tests visual concept formation. In this test, patients see slides with four stimuli and are required to identify the concept presented on each slide. The principle remains the same in each of six different sets of slides, but changes between sets. A final set of slides presents pictures viewed in previous sets as a test of memory for the solution. This test can be very frustrating for patient and examiner alike, but is one of the more sensitive measures in the Halstead-Reitan Battery.

RAVEN'S PROGRESSIVE MATRICES.⁴⁷ These tests (Colored Progressive Matrices, Standard Progressive Matrices, and Advanced Progressive Matrices) measure visual concept formation and problem solving. Patients are presented with multiple designs that are linked by a common conceptual pattern. The final design is missing, and the patient must choose which of six to eight alternative final designs is correct. The range of abilities this test assesses is very large, from the concrete to extremely abstract. Extensive normative data are available for British norms, and adequate norms are available for U.S. norms.

WISCONSIN CARD SORTING TEST (WCST).⁴⁸ This test of visual concept formation adds cognitive set-shifting to concept formation. Patients are presented with four “target” cards with simple colored designs that can be sorted by three concepts. The patients match probe cards with identical colored design to the target cards according to whatever concept they generate. The only feedback to the patient after each trial is whether his or her response is correct. The order of sorting concept is fixed, but unbeknownst to the patient, changes after a set number of correct responses. Thus, patients must be able to switch the concept they were using for the previous trials.

Clinical Situations for Tests of Reasoning and Problem Solving through Concept Formation

Because reasoning and problem-solving abilities are closely associated with intellectual functioning, testing should be requested in those situations that require intelligence testing.

Verbal Function

Disturbances in language function are one of the most noticeable impairments in cognitive abilities. They can be the result of generalized cognitive deterioration, as in dementing conditions (see Chapter 33), or confusional states (see Chapters 38–40 and 55). Likewise, they may be due to specific lesions, as in transcortical aphasia (see Chapter 6) or psychiatric conditions (see Chapter 3), as in psychotic word salad or neologisms. Most assessments of verbal function include testing of expressive abilities (spontaneous speech, naming, repetition of words and phrases, writing) and receptive abilities (comprehension of speech, comprehension of written material).

Aphasia Batteries (see Chapter 6)

BOSTON DIAGNOSTIC APHASIA EXAMINATION (BDAE).⁴⁹ This battery is a comprehensive assessment of verbal function. It provides information on 12 areas of language abilities using 34 subscales (Video 96, Conduction Aphasia). Assessments include verbal comprehension, written comprehension, writing to dictation, naming, articulation, spontaneous speech, repetition, reading, following simple and complex commands, speech fluency, and prosody. The test provides an overall severity rating score and a profile of subtest performance. This test is very useful in providing a comprehensive assessment of verbal function, but because of the number of items, testing time is quite long. Therefore, this battery is mostly used for specific diagnosis and rehabilitative planning of aphasic patients. Because of scoring and normative information, separate subtests can be given independently for a more focused (and shorter) examination of specific areas of verbal function.

MULTILINGUAL APHASIA EXAMINATION (MAE).⁵⁰ This test is similar to the BDAE in that it provides a comprehensive assessment of language function. The administration time is shorter, however. MAE tests were taken from the Neurosensory Center Comprehensive Examination for Aphasia. An advantage to the MAE is that alternate forms are provided, so repeated testing can be conducted without contamination of practice effects. Subtests of the MAE can also be given independently of the complete battery.

NEUROSENSORY CENTER COMPREHENSIVE EXAMINATION FOR APHASIA (NCCEA).⁵¹ This battery provides detailed assessments of reading, writing, articulation, visual abilities, and tactile abilities. The battery has 20 subtests measuring visual naming, description of use of objects, tactile naming, digit repetition forward and backward, sentence construction, identification of objects, oral reading for single words and sentences, visual naming of objects, written naming of objects, writing to dictation, writing from copy, and articulation. In addition, four “control tests” are provided. These tests are given if the patient makes errors on the tactile naming, visual naming, or reading tests. Extensive norms are provided for each subtest, so they may be used independently. Administration time is usually under 2 hours, which makes this battery practical in everyday clinical use.

Aphasia Screening Tests

Because most aphasia batteries require extensive time for administration, screening measures have been developed.

These screening tests have variable reliability, sensitivity, and specificity to language impairments.

APHASIA SCREENING TEST.¹⁸ This test is part of the Halstead-Reitan Battery and is composed of 32 items testing reading, articulation, spelling, repetition, naming, calculations, and construction. Administration time is brief (approximately 15 to 30 minutes). Each ability is tested with one or two items, so the range of abilities is not great. In addition, studies of the diagnostic utility of this test have been disappointing.⁵²

TOKEN TEST.⁵³ This test is extremely sensitive to impairments in verbal functions. It does not provide specific information as to type of verbal disturbance, however. The patient is presented with tokens of different shapes (i.e., circles, squares, triangles), sizes, and colors. The patient is required to perform certain acts with the tokens, such as point to selected tokens, touch them, pick them up, and place one token on top of another. Administration and scoring are very simple and the testing time is brief (approximately 15 minutes). Because this test requires comprehension of detailed information, it is sensitive to patients with disturbances of attention and vigilance. This test is particularly useful in identifying the presence of verbal function disturbances and whether additional, more detailed testing is required.

Individual Tests of Verbal Skills

The most commonly used individual tests of verbal skills come from the previously discussed batteries. Because of the common use of these individual tests, a few are presented here:

NAMING TEST.⁵⁰ This test comes from the MAE. Patients are required to name common and uncommon objects depicted in line drawings.

BOSTON NAMING TEST.⁵⁴ This naming test is not part of any battery, but is often added to the BDAE. Patients are required to name 60 objects depicted in line drawings. The objects range from simple and common objects such as a tree to complex and uncommon objects such as an abacus. If a patient is unable to name an object, he or she is given a phonemic cue and a semantic cue.

CONTROLLED ORAL WORD ASSOCIATION TEST.⁵⁰ This test measures verbal fluency and comes from the MAE. Patients are required to generate as many words as possible, as quickly as possible, to a given letter. Proper nouns, numbers, and the plural form of a produced word are not allowed. The patient is given three 1-minute trials using three different letters. A variant of this test also requires the patient to generate exemplars from different categories (e.g., four-legged animals, things found in a grocery store, parts of a building).

SENTENCE REPETITION.⁵⁰ This test is part of the MAE and requires the patient to repeat spoken sentences. The first item is simple, composed of three syllables, and the last item is complex, composed of 24 syllables. In addition to testing repetition, this test assesses verbal memory.

Clinical Situations for Tests of Verbal Function

Assessment of language function is necessary for all neuropsychological examinations. Not only do these tests provide

information about verbal function, they also assess basic skills needed to complete other neuropsychological tests. Usually, requests for administration of aphasia batteries are limited to patients with documented verbal impairments (Video 97, Dyslexia). Screening tests or individual tests of naming, comprehension, verbal fluency, repetition, reading, and writing should be requested for all referrals. In the assessment of patients with vascular disease (see Chapters 22 and 45), cortical developmental (see Chapter 28), or degenerative processes (see Chapters 31–35), language testing can help in identifying deficits and tracking verbal decline or improvement.

Memory (see Chapters 5 and 33)

The ability to record, retain, and reproduce information constitutes memory functioning. Memory is not a unitary phenomenon, however. There are different forms of memory (Table 27-2) including memory requiring awareness (explicit memory) as well as memory that occurs in the absence of awareness (implicit memory; see Chapter 5). All standard clinical assessments of memory test explicit memory. Even within explicit memory there are different forms. Semantic memory represents the ability to learn information about the world in general. Episodic memory represents memories that are tied to specific episodes. For example, the knowledge that a bicycle has two wheels, pedals, a seat, and handlebars represents semantic memory; it is not possible to identify when this information was acquired. The memory of the first time one rode a bicycle is an example of episodic memory; the events surrounding that first ride are part of the memory trace. Most clinical neuropsychological tests of memory test a combination of semantic and episodic explicit memory. There are many different memory tests, both batteries and tests of single abilities.

Specific Memory Tests

WECHSLER MEMORY SCALE—THIRD EDITION (WMS-III).²³ The WMS-III is a memory assessment battery composed of 17 subtests (Table 27-3). The 17 subtests include

1. Information/Orientation—assessing general personal information and orientation to person, place, and time;
2. Logical Memory I—assessing recall of orally presented stories;

TABLE 27-2

Wechsler Memory Scale—Third Edition, Primary and Optional Indexes

| PRIMARY INDEXES | OPTIONAL INDEXES |
|-----------------------------------|------------------------------|
| Auditory Presentation | |
| Logical Memory I and II | Information and Orientation |
| Verbal Paired Associates I and II | World Lists I and II |
| | Mental Control |
| Letter-Number Sequencing | Digit Span |
| Visual Presentation | |
| Faces I and II | Visual Reproduction I and II |
| Family Pictures I and II | |
| Spatial Span | |

TABLE 27-3

Subtests of the Wechsler Memory Scale—Third Edition That Form the Primary Indexes and the Memory Functions They Assess

| INDEXES AND SUBTESTS | COGNITIVE FUNCTION ASSESSED |
|--|--|
| Auditory Immediate Index | |
| Logical Memory I | Verbal long-term memory Verbal learning |
| Verbal Paired Associates I | Verbal long-term memory Verbal learning |
| Visual Immediate Index | |
| Faces I | Nonverbal long-term memory Nonverbal learning |
| Family Pictures I | Nonverbal long-term memory Nonverbal learning |
| Immediate Memory Index | |
| Logical Memory I | |
| Verbal Paired Associates I | |
| Faces I | |
| Family Pictures I | |
| Auditory Delayed Index | |
| Logical Memory II | Verbal delayed memory Verbal learning |
| Verbal Paired Associates II | Verbal delayed memory Verbal learning |
| Visual Delayed Index | |
| Faces II | Nonverbal delayed memory Nonverbal learning |
| Family Pictures II | Nonverbal delayed memory Nonverbal learning |
| Auditory Recognition Delayed Index | |
| Logical Memory II Recognition | Recognition of verbal information |
| Verbal Paired Associates II Recognition | Recognition of verbal information |
| General Memory | |
| Logical Memory II | |
| Verbal Paired Associates II | |
| Faces II | |
| Family Pictures II | |
| Working Memory | |
| Letter–Number Sequencing | Auditory processing Attention/concentration Executive function |
| Spatial Span | Visual–spatial processing Attention/concentration Executive function |

3. Faces I—assessing ability to recognize visually presented target faces from distracter faces;
4. Verbal Paired Associates I—assessing recall memory for orally presented word pairs that have been previously learned;
5. Family Pictures I—assessing recall of visually presented family scenes involving four family members;
6. Word Lists I—assessing recall of an orally presented list of words;
7. Visual Reproduction—assessing ability to reproduce difficult-to-verbalize designs after a brief exposure;

8. Letter–Number Sequencing—assessing ability to manipulate and recall letters and numbers;
9. Spatial Span—assessing ability to reproduce increasingly longer spatially separated sequences of forward and backward taps on blocks;
10. Mental Control—assessing speeded performance for reciting the alphabet, counting forward and backward, days of the week forward and backward, months of the year forward and backward, counting by 6s while stating days of the week in order;
11. Digit Span—assessing forward and backward digit span;
12. Logical Memory II—assessing ability to recall information from the stories in Logical Memory I after a 30-minute delay, as well as assessing recognition of information from stories;
13. Faces II—assessing ability to recognize visually presented target faces from Faces I after a 30-minute delay;
14. Verbal Paired Associates II—assessing ability to recall associations from Verbal Paired Associates I after a 30-minute delay, as well as assessing recognition of word pairs;
15. Family Pictures II—assessing recall of visually presented family scenes from Family Pictures I;
16. Word Lists II—assessing recall of the orally presented list of words from Word List I after a 30-minute delay;
17. Visual Reproduction II—assessing ability to recall the designs presented in Visual Reproduction I after a 30-minute delay, as well as specific sub-subtests to assess recognition of correct figures from nontarget figures, copying of figures to assess visual perception abilities, and a subtest to analyze discrimination abilities.

Ten of these subtests contribute to eight indices, namely the Auditory Immediate Index (Logical Memory I and Verbal Paired Associates I), Visual Immediate Index (Faces I and Family Pictures I), Immediate Memory Index (Logical Memory I, Verbal Paired Associates I, Faces I, and Family Pictures I), Auditory Delayed Index (Logical Memory II and Verbal Paired Associates II), Visual Delayed Index (Faces II and Family Pictures II), Auditory Recognition Delayed Index (Logical Memory II Recognition and Verbal Paired Associates II Recognition), General Memory Index (Logical Memory II, Verbal Paired Associates II, Faces II, and Family Pictures II), and Working Memory Index (Letter–Number Sequencing and Spatial Span). The standardization sample for the WMS-III follows the same method as that used in the WAIS-III (although with a smaller standardization sample size), so good normative data are provided for each subtest as well as the index scores.

KEY AUDITORY VERBAL LEARNING TEST (RAVLT).⁵⁵ This test of verbal memory presents the patient with multiple trials of learning a list of 10 words. Following each presentation of the study list, the patient is asked to recall as many words as possible. Following the fifth repetition of this study list, a new study list is introduced followed by a recall trial. Following this recall, the patient is asked to recall as many of the words from the first list as possible. Finally, a recognition test is given if delayed recall is

defective. This test provides information on immediate verbal memory, rate of learning, occurrence of retroactive and proactive interference, delayed recall, and recognition.

CALIFORNIA VERBAL LEARNING TEST-II (CVLT-II).⁵⁶ This variant of the RAVLT increases the number of words on each list to 16 and uses words belonging to one of four categories of “shopping list” items. The testing procedure is also modified to provide a cued recall where the categories are provided to the patient to aid recall. Additionally, both a short delay and long delay recall and cued-recall component has been added to the testing procedures.

REY-OSTERRIETH COMPLEX FIGURE.⁵⁷ In this non-verbal test of memory, patients are presented with a difficult-to-verbalize complex line drawing. They are first asked to copy the figure, with no mention of being required to remember the design for later recall. After a brief delay (approximately 3 minutes) the patient is asked to reproduce the design. Delayed memory is tested again in 30 minutes. One potential difficulty with this test is that most of the elements that make up the complex design can be assigned a verbal label (e.g., a square on top of a triangle with a flag on top), so some verbal memory contamination can occur. This difficulty is common to most nonverbal tests of cognitive abilities.

Clinical Situations for Memory Tests

Because memory is a basic ability of higher cognitive function, some assessment of memory ability should be conducted for most patients. Memory assessment is particularly important for patients with suspected dementing illnesses (see Chapter 33), toxic and metabolic conditions (see Chapters 38, 39, and 55), and possible depression (see Chapter 3). When requesting memory assessment, information on form of memory tested should be provided (Video 260, Memory Testing).

Perception and Construction Abilities

The ability to perceive stimuli is one of the basic requirements for the assessment of cognitive function. Therefore, tests of visual, auditory, and tactile perception are common in neuropsychological assessments. Certain alterations in perception, such as neglect, are diagnostically informative.

Visual Perception and Construction

Tests of visual perception typically assess color perception, object recognition, visual organizational abilities, visual scanning, and differentiation of figure from ground. Most neuropsychological assessments will assess color perception informally. The Color Vision Screening Inventory⁵⁸ is occasionally used by examiners, however. This test provides a screening measure of color blindness.

PEABODY PICTURE VOCABULARY TEST-REVISED.⁵⁹ This test is discussed in the section on Tests of Verbal Function; it can be used to assess ability to visually recognize objects.

BENTON FACIAL RECOGNITION TEST.⁶⁰ This test of visual object recognition uses faces as stimuli. Patients are presented with a target face on one page and six faces

on the adjacent page. One of the six faces matches the target face. The test progresses in difficulty from easy (a duplicate of the target face is presented in the six faces) to hard (the matching face differs from the target face in orientation and lighting). Since both the target and matching face are seen together, memory requirements are minimized.

JUDGMENT OF LINE ORIENTATION (JLO).⁶¹ This test assesses ability to match lines of different orientation to target lines. Difficulty increases on this test by varying the length of the matching lines. Since both target and matching lines are seen together, memory requirements are minimized.

HOOPER VISUAL ORGANIZATION TEST (HVOT).⁶² This test presents the patient with 30 easily recognized objects that have been decomposed into parts and randomized. The patient is required to identify each object. Successful performance on this test requires the patient to mentally reorganize the decomposed images into the complete shape. There have been a number of normative studies of performance on the HVOT, but none is fully adequate.

PICTURE ARRANGEMENT.¹⁶ This subtest of the WAIS-III requires the patient to rearrange a series of pictures that, when placed in the correct order, tell a story. One advantage of this test is the extensive normative data generated for the WAIS-III.

LETTER CANCELLATION TEST.³⁵ This visual scanning test is discussed in the section on Tests of Attention and Vigilance. When systematic errors occur on this test, such that the patient completes only one side of the page, the possibility of visual neglect is raised.

LINE BISECTION TEST.⁶³ This test presents the patient with lines drawn in different locations on a page. The patient is required to draw a perpendicular line through the lines on the page. Visual scanning is required to locate all the lines on the page. As with the cancellation tests, if systematic errors occur, where the patient does not bisect the line on one side of the page, the possibility of visual neglect is raised.

EMBEDDED FIGURES TEST.⁶⁴ This test differentiates figure from ground and consists of 16 line drawings of figures on one page, and a complex figure that contains the target figure and overlapping figures. The patient is required to trace the target figure in the complex figure. Scoring is on a pass-fail basis, with extra credit given for fast performance.

REY-OSTERRIETH COMPLEX FIGURE.⁵⁷ This test of visual construction is discussed in the section on Memory. Information on visual construction can be found from performance on the copy portion of this test.

CLOCK DRAWING TEST.⁶⁵ This test of visual construction in which the patient is required to draw a clock with all the numbers and “set” the clock at 20 minutes to four o’clock. Clock drawing has been a part of bedside mental status testing for a long time, but scoring had been somewhat arbitrary. The addition of explicit scoring criteria has improved interpretation.

DEVELOPMENTAL TEST OF VISUAL-MOTOR INTEGRATION (VMI).⁶⁶ This visual construction test was originally developed for the assessment of children. It is also useful in assessing adult visual constructional abilities, however. The patient is required to copy 24 geometric designs ranging from simple (a single line) to complex.

Adequate norms for children exist for this test, and its range of performance can be extended to adults.

THREE-DIMENSIONAL BLOCK CONSTRUCTION.⁶⁷

This test assesses constructional abilities in three dimensions. Patients are presented with 29 blocks of different shapes in a prearranged order. A model is shown to the patient, who is told to use some or all of the blocks to recreate the model. In all, three models are presented to the patient. A maximum of 5 minutes is allowed to complete each model. Adequate norms exist for this test.

Auditory Perception

Auditory perception is tested for acuity, perception of organized sounds, and rhythms.

SENSORY EXAMINATION.¹⁸ This test is part of the Halstead-Reitan Battery and assesses auditory perception to single and simultaneous stimulations. The examiner stands behind the patient and gently rubs two fingers together next to each ear. This tests auditory perceptual problems in each ear, and also the presence of extinction to double-simultaneous stimulation.

SPEECH-SOUND PERCEPTION TEST.¹⁸ This test is part of the Halstead-Reitan Battery. Patients listen to 60 nonsense syllables on a tape and must choose among four options of printed versions of the sounds. One problem with this test is that individuals who have high-frequency hearing loss tend to perform poorly.

SEASHORE RHYTHM TEST.¹⁸ This test is part of the Halstead-Reitan Battery. Patients listen to two sets of tape-recorded rhythms and are required to judge whether the rhythms are the same or different. The test includes easy items with a few beats and complex items with many beats. Because the patient must remember the first rhythm and must attend rapidly to changing stimuli, this test also measures memory and attention.

Tactile Abilities

Testing of tactile abilities in most neuropsychological assessments is limited to the hands. This information is particularly important for assessing the effects of tactile deficits on test performance.

SENSORY EXAMINATION.¹⁸ This test is part of the Halstead-Reitan Battery. The tactile ability assessment includes Fingertip Number Writing, where the examiner traces a number on each finger and asks the patient to report the number without visual guidance, and Tactile Finger Recognition (discussed in the section on Tests of Attention and Vigilance), where the patient must identify which finger has been touched by the examiner without visual guidance.

FACE-HAND TEST.^{18,68} This is a test of single and simultaneous stimuli on either side of the patient's hand, face, or both. Information from this test is helpful in identifying the presence of tactile inattention.

TACTILE FORM PERCEPTION.⁶⁹ This test requires the patient to recognize geometric forms placed in one hand hidden from view, and identify a drawing of the object in a multiple-choice format. Adequate norms are provided for this test. A variant of this test is found in the Halstead-Reitan Battery, which uses three-dimensional forms and

requests verbal responses as opposed to multiple-choice responses.

Clinical Situations for Tests of Perception and Construction Abilities

Assessment of perception and construction abilities is very important, not only to aid in diagnosis of inattention (neglect) and constructional apraxia, but also to assess the competency of basic skills required for adequate testing. Most of the tests presented also can assess attention and vigilance. Testing is appropriate for all patients except perhaps for those with alterations in level of consciousness (see Chapter 1) or dementia (see Chapter 33).

Executive Function and Motor Performance

Executive Function

Traditionally, executive functions have been ascribed to the frontal lobes. They involve the ability to assess ongoing stimuli for relevance to specific goals, the formation of goals, planning action to achieve goals, ability to evaluate plans for efficacy, and executing plans. According to this description, executive functions involve many processes associated with reasoning and intellectual performance. Indeed, the Digit Symbol subtest of the WAIS-R (discussed in the section on Tests of Attention and Vigilance), Category Test, Wisconsin Card Sorting Test, Raven's Progressive Matrices (all discussed in the section on Tests of Reasoning and Problem Solving Through Concept Formation), Rey-Osterrieth Complex Figure (discussed in the section on Memory), and tests of visual scanning (discussed in the section on Perception and Construction Abilities) can all be used to assess executive function. Following is a list of a few additional tests.

PORTEUS MAZES.⁷⁰ This test of planning requires the patient to trace a path through progressive difficult mazes without entering any blind alleys. Scoring is based on number of errors (entering a blind alley) and on time to complete the mazes. Both of these measures have been found to be sensitive to patients with frontal-lobe damage.

DESIGN FLUENCY.⁷¹ This test of mental flexibility requires the patient to create as many designs as possible that are not objects or shapes in 5 minutes. Next, the patient is required to make as many designs as possible using only four lines (straight or curved) in 4 minutes. Adequate norms exist for this test.

STROOP WORD-COLOR INTERFERENCE TEST.⁷²

This test of inhibition has three trials. The first trial requires the patient to read the color names printed in black ink as quickly as possible. On the second trial, the patient is required to name the color of colored dots as quickly as possible. The third trial requires the patient to name the color of ink of color name words. The color name does not match the color of the ink. Forty-five seconds are allowed for completion of each trial. Scores for each trial indicate the number of correct responses. An interference score can be generated that quantifies the patient's ability to inhibit the inappropriate response of reading the color name as opposed to the color of ink used to print the name in the third trial.

Motor Performance Tests

Assessment of motor performance is particularly helpful in identifying integrity of each hemisphere and subtle motor performance. Tests of motor performance include simple motor speed, strength, and complex motor/dexterity abilities.

FINGER TAPPING TEST.⁷³ This is a test of primary motor speed of the index finger of each hand. Patients tap a finger as quickly as possible for five consecutive 10-second trials. Because fatigue may affect performance, a rest period is given between each trial. Large differences between left and right finger speed may reflect lateralized hemispheric dysfunction. Adequate norms are available for this test.

HAND DYNAMOMETER.¹⁸ This test measures grip strength in each hand. Patients are given three trials with each hand, the first considered practice. Large differences between left and right grip strength may reflect lateralized hemispheric dysfunction. Adequate norms are available for this test.

PURDUE PEGBOARD TEST.⁷⁴ This test of finger dexterity requires patients to place pegs in vertically arranged holes. They perform the task using each hand separately and then using both hands. Each trial last 30 seconds. Large differences between left and right performance in comparison to performance using both hands may reflect lateralized hemispheric dysfunction. Adequate norms are available for this test.

Clinical Situations for Tests of Executive Function and Motor Performance

Assessment of executive function is very important for patients presenting with impairments of higher cognitive functioning such as memory, language, and reasoning. Because these higher-cognitive functions are highly correlated with planning, inhibition of inappropriate responses, and goal execution, executive function assessment also aids the examiner in interpretation of tests assessing memory, language, intelligence, and reasoning performance. Assessment of executive function is also helpful in patients with disturbances in level of consciousness (see Chapter 1), disrupted sleep/wake cycles (see Chapter 2), and neglect and dyspraxia (see Chapter 4).

Emotional Functioning

Most assessments of emotional functioning are conducted during the interview with the patient. This information can be gathered in a standardized or nonstandardized format. Tests of emotional functioning ought to be used to generate hypotheses as to the presence of dysfunction with follow-up of these hypotheses occurring during the interview (see Chapter 3). There are two general formats to tests of emotional functioning: objective tests and projective tests. Only objective tests will be presented in this section.

Specific Tests

MINNESOTA MULTIPHASIC PERSONALITY INVENTORY-2 (MMPI-2).⁷⁵ This self-report test is an objective measure of personality function composed of 567 true-false questions. The questions were chosen based on their ability

to differentiate emotionally impaired individuals from non-impaired individuals. The MMPI-2 has 10 clinical scales and 4 validity scales. Profiles of the clinical scales can suggest the presence of many different emotional disorders, ranging from mild depression to psychotic conditions (Video 22, Delusional Thinking). This test has acceptable norms, although the standardization sample was limited in racial diversity. Care needs to be exercised in the interpretation of the MMPI-2 when applied to patients with brain damage, because many of the symptoms elicited by MMPI-2 questions are common to neurological patients.

BECK DEPRESSION INVENTORY SECOND EDITION.⁷⁶ This objective self-report measure assesses the presence of depressive symptoms experienced by the patient within the past week. It is composed of 21 questions. Each question is scored on a 4-point scale ranging from no impairment (0) to severe impairment (3). The maximum score is 63; a cut-off score indicative of mild depressive symptoms is greater than 10 and for severe depressive symptoms is greater than 30. One problem with the use of the Beck Depression Inventory with brain-damaged patients is that many of the items reflect somatic concerns and social changes associated with neurological damage.

GERIATRIC DEPRESSION SCALE.⁷⁷ This objective self-report measure of depression was designed for use in elderly patients. The test consists of 30 yes or no questions. A cut-off score of 13 is recommended as an indication of depression.

Clinical Situations for Tests of Emotional Functioning

The assessment of emotional functioning is important for three reasons. First, emotional disturbance often follows or accompanies CNS damage. Examples include cerebrovascular disease (see Chapters 22 and 45), neurodegenerative disorders (see Chapters 33–36), and metabolic, nutritional, and drug-induced encephalopathies (see Chapters 38–40). Not only do patients face adjustments to physical function, they also often must make social adjustments that can affect emotional functioning. Second, emotional disturbances can affect cognitive functioning. Although the diagnosis of pseudodementia, or dementia related to depression, does not appear to be real dementia, severe depression can cause impairments in attention, vigilance, and motivation, which may affect performance on memory tests. Third, assessment of emotional functioning is required to differentiate functional from neurological disorders.

PRACTICAL ISSUES

In order to serve the patient best, neuropsychological assessments need to be a cooperative effort between the neuropsychologist and the referring neurologist. The neurologist needs to be as specific as possible when formulating the referral questions. Any pertinent patient information, such as current and past medical status, current medications, brief description on the history of the present illness, and a brief review of physical and neurological examination results should also be provided. This information helps guide the neuropsychologist in the selection of testing materials and approach to the patient. If testing is to be

conducted in the hospital, the patient's schedule needs to include blocks of time when no other clinical tests are scheduled (e.g., radiology, discharge planning) so that the patient may be tested without interruptions and when maximally alert and attentive. The neuropsychologist needs to communicate with the neurologist before testing to discuss the assessment plan, including which cognitive abilities will be tested, the approximate length of testing, and when the neurologist can expect the written report. After the assessment is completed, but before submitting the written report, the neuropsychologist generally contacts the neurologist to provide preliminary feedback. The written report, delivered shortly thereafter, should be brief but complete, including a listing of the tests administered, some form of score report, usually a percentile or standard score for each test, a summary of the findings, and an interpretation of these findings. The brevity of the report depends on the nature of the referral and the questions the neurologist has posed.

This chapter reviews the major structural malformations and associated problems related to the central nervous system (CNS) and surrounding structures. Hydrocephalus, although not a specific structural disorder, is discussed in the first section because of the importance and frequency with which hydrocephalus occurs in many of the disorders that follow in the chapter. Furthermore, the evaluation and diagnosis of hydrocephalus play a pivotal role in clinical management of many malformations. Following hydrocephalus, disorders of development are discussed according to the approximate timing of the pathogenesis. Because the developmental timing for many disorders is not known or is only speculative, disorders have also been grouped into major categories.

HYDROCEPHALUS

Hydrocephalus is one of the most common manifestations of developmental disorders. A fundamental understanding of the principles, evaluation, and management of congenital and neonatal hydrocephalus is essential for physicians involved in the care of infants with developmental structural disorders of the CNS. Hydrocephalus, in the strictest definition, denotes an increased volume of cerebrospinal fluid (CSF) within the skull, most frequently in the ventricles. Unfortunately, the use of various definitions in a wide variety of clinical presentations and pathological abnormalities has resulted in confusion surrounding the definition and meaning of the term *hydrocephalus*. In this chapter, hydrocephalus is defined as an increase in the volume of CSF within the ventricular system independent of the actual head circumference. Entities such as “normal pressure hydrocephalus” will not be discussed as they are generally not considered malformations and occur mainly in an adult population.

PATHOGENESIS AND PATHOPHYSIOLOGY. In contrast with normal CSF physiology discussed in Chapter 26, hydrocephalus is the result of a disturbance in normal CSF fluid dynamics. Two terms frequently used when dis-

cussing hydrocephalus are obstructive (noncommunicating) and nonobstructive (communicating) hydrocephalus. These terms were first coined by Harvey Cushing to describe the results of injection of air (pneumoencephalography) into the subarachnoid space or dye into the ventricles. If the air was found to move into the ventricles or the dye out to the subarachnoid space, the cause of the hydrocephalus was considered nonobstructive. If no communication between the spaces was found, the cause of the hydrocephalus was considered obstructive. These terms were used to help define the pathophysiological mechanisms underlying the hydrocephalus. While conceptually appealing, Adams and Victor¹ challenged the value of this distinction, pointing out that increased pressure leading to hydrocephalus is virtually always a result of blockage,² whether along the pathway of CSF flow or at the site of resorption. Overproduction of CSF, as reported in rare cases of choroid plexus papillomas, is not likely to represent a common, if even plausible, cause of hydrocephalus. Thus, the entities included in this section, with the exception of the destructive lesions, will be discussed, when known, in reference to where the blockage occurs (Table 28-1).

Hydrocephalus associated with congenital malformations and disruptions often is associated with flattened gyri and reduced sulci. If hydrocephalus develops in utero, the cerebral hemispheres may show an abnormal gyral pattern characterized by multiple complex small gyri. This abnormal gyration has been called microgyria, polygyria, or stenogyria. It is important to distinguish this gyral abnormality from polymicrogyria. The primary basis for distinction relies on the abnormal cortical lamination in polymicrogyria and the normal cortical cytoarchitecture in hydrocephalus related to gyral abnormalities. Although a six-layer neocortex is recognized in polygyria, neuronal populations may be significantly reduced. It is equally important to remember that true polymicrogyria and hydrocephalus may coexist in certain malformations.

When hydrocephalus occurs as a function of increasing intracranial CSF fluid volume, intracranial pressure will begin to increase as well. In an attempt to relieve the increased intracranial pressure the head circumference will

TABLE 28-1

Overview of the Differential Diagnosis of Congenital Hydrocephalus

| ETIOLOGY | SPECIFIC CAUSES* | MECHANISM OF HYDROCEPHALUS |
|----------------------------|----------------------------------|--|
| Tumors | Most types, benign and malignant | Blockage of CSF pathway |
| Malformations | Many | |
| | Chiari II | Unknown |
| | Dandy-Walker | Unknown |
| | Aqueductal anomalies | Obstruction of CSF flow at the level of the cerebral aqueduct |
| | Forking/stenosis | |
| | X-linked hydrocephalus | |
| Infectious/post-infectious | Abscess | Obstruction by a mass lesion |
| | Meningitis/ventriculitis | Obstruction of CSF resorption and/or obstruction due to fusion of ventricular wall |
| | Congenital infections | |
| | Cytomegalovirus | Adhesions and fusion of ventricular wall |
| | Toxoplasmosis | Ex vacuo and/or mass lesion |
| Vascular/hemorrhagic | Vascular malformation | Mass lesion of post-hemorrhage |
| | Post-hemorrhagic | |
| | Germinal matrix origin | Intraventricular blood obstructs CSF flow |
| | Choroid plexus origin | |
| Destructive | Hydranecephaly | Ex vacuo |
| Secondary | Porencephaly | Ex vacuo |
| | Perinatal leukomalacia | Ex vacuo |

*The entities listed are only a partial list and are not meant to reflect a complete differential diagnosis.

begin increasing by widening of the sutures. Although the cranial sutures have begun fusion by 2 years of age, they can often be “split” open if the intracranial pressure rises prior to the age of complete skull ossification (8 to 10 years). At the same time the fontanelles, if still open, will become tense and bulging. The majority of conditions that are discussed in this chapter result in hydrocephalus prior to fusion of the cranial sutures; thus, an enlarging head occurs concurrently with the hydrocephalus.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Signs and symptoms of postnatal hydrocephalus depend on the expandability of the skull. As outlined earlier, prior to fusion of the sutures the skull is able to expand, resulting in an enlarged head circumference and tense fontanelles. In addition to the finding of a tense or bulging fontanelle, the separation of sutures can give rise to the so-called “cracked pot” sound on percussion of the skull. The scalp veins may be prominent, especially frontally. The absolute head circumference measured at only one time point cannot be used as a strict diagnostic guide; instead, it is important to follow the trajectory of the head circumference plot over a brief period of time. Any upward crossing of percentiles over a few weeks is potentially relevant and requires urgent investigation. Clinical signs and symptoms may be minimal or completely absent.³ When present, irritability, frequent crying, unexplained vomiting (especially in the morning), and persistent or increasing headaches may all signal hydrocephalus. Alternatively, as a result of chronically increased intracranial pressure there may be developmental delay, disinterest in the environment with a “dull” affect, endocrine dysfunction, unsteady gait, and increased tone in the legs.⁴ In the newborn period bradyarrhythmia and apneic spells may be the only clinical sign of overt hydrocephalus.

Ophthalmological signs often occur early and are important to recognize. Disturbances of extraocular movements include a supranuclear upgaze paresis, giving rise to the

“setting sun phenomenon” in infants. In this condition, the eyes appear driven downward and the white of the sclera is seen above the iris. This phenomenon is probably related to aqueductal distention with compression of periaqueductal structures, or by pressure on the quadrigeminal plate by a dilated third ventricular subpineal recess. Unilateral or bilateral abducens and trochlear paresis can also occur. Swelling of the optic nerve head (papilledema) occurs in hydrocephalus before closure of the sutures only with very rapidly progressive hydrocephalus. On the other hand, chronic and long-standing hydrocephalus can lead to optic atrophy, resulting in papilledema no longer being apparent. In neonatal hydrocephalus stretching of the optic radiations and cortices can also result in a picture of cortical blindness. Another unusual neurological manifestation of hydrocephalus is the so called “bobble-head-doll” syndrome, in which the patient shows rhythmical to-and-fro movements of the head in the upright position. It is related to obstructive lesions in and around the aqueduct as well as to cystic lesions of the third ventricle, but its pathophysiology is unknown.

Long-standing untreated hydrocephalus has been associated with a neuropsychological profile referred to as the “cocktail-party syndrome.”⁵ Characteristic manifestations include a fluent and profuse speech that lacks content and is pragmatically deficient. Chronic hydrocephalus may also result in precocious puberty. Earlier detection, primarily as a result of improved imaging of the central nervous system, along with advances in treatment and management have resulted in these manifestations of chronic hydrocephalus being relatively rare.

The special case, a hereditary form of hydrocephalus, occurs in familial aqueductal stenosis, most frequently inherited as an X-linked trait. Mutations in the gene for L1-CAM, a neuronal surface glycoprotein implicated in migration and fasciculation of neuronal cells,⁶ have been identified in one subtype (linked to chromosome Xq28). How mutations in this molecule lead to aqueductal stenosis

is unclear. The condition should be considered in diagnosing both infants and children with hydrocephalus because, in the case of Xq28-linked familial aqueductal stenosis, in about 50% of affected males, mental retardation, spastic paraparesis, and adducted thumbs may not become apparent until later in life.

DIFFERENTIAL DIAGNOSIS. Hydrocephalus does not necessarily mean an enlarged head, although an enlarged or enlarging head often is the presenting feature. The converse is also not necessarily true; an enlarged head (macrocephaly) is not equivalent to hydrocephalus. Several metabolic disorders, hamartomas, and other genetic conditions can be associated with macrocephaly independent of hydrocephalus.⁷ If the brain itself is enlarged without a significant component of hydrocephalus, the term megalencephaly is appropriately applied. Examples include neurofibromatosis type I, several of the overgrowth syndromes such as Sotos syndrome, Alexander's disease, metabolic disorders such as Canavan's disease, several of the gangliosidoses, and glutaricaciduria type I. Malformations and disruptions with enlarged ventricles but without CSF flow obstruction have to be differentiated by careful imaging. Holoprosencephaly and hydranencephaly provide examples. In the newborn, congenital infections, especially toxoplasmosis, must be considered as well as the possibility of preceding intracerebral hemorrhage potentially causing aqueductal stenosis as well as diminished CSF absorption. Space-occupying lesions around the midbrain, tectum, and pineal region must also be excluded by appropriate imaging studies.

EVALUATION. The diagnosis of hydrocephalus relies on the application of neuroimaging techniques combined with the clinical features outlined in the beginning of this section.⁸ Plain radiographs of the skull may show an irregular, shallow scalloping of the inner bone table. Although hydrocephalus will be obvious on computed tomography (CT) or cranial ultrasound, precise anatomical definition of the blockage level is best investigated by magnetic resonance imaging (MRI). Assessment of the cerebral aqueduct in the sagittal plane, including evaluation of a flow void through the aqueduct, is also possible via this technique. On CT or MRI, CSF driven transependymally into the periventricular white matter may be apparent as low attenuation on CT or high signal on T₂-weighted MRI sequences.

Evaluation must take into account whether the cranial sutures are open or closed. The ventricular size with an expandable skull versus a fixed volume skull can be dramatically different even with an equal increase in intraventricular pressure. In the case of open sutures, even moderate rises of pressure can expand the ventricles enormously and the surrounding brain may appear compressed to a thin band. A dramatic reconstitution of the cerebral mantle may be seen after shunting, sometimes with reversal of some preexisting neurological deficits, in particular impaired visual function. On the other hand, in the fixed volume skull, even enormously elevated intraventricular pressures may give rise to only moderate expansion of ventricular size, especially with "communicating" hydrocephalus. "Arrested" or inactive hydrocephalus with apparently normal pressure measurements may pose a special problem for management decisions, as spot-check measurements of CSF pressure by lumbar puncture may not accurately reflect

chronic CSF dynamics. Longer, continuous monitoring of intracranial pressure using a subdural or epidural device has been advocated for such cases. These investigations are not without risk for the patient and are not universally recommended. Meticulous attention to clinical details in order to decide whether the hydrocephalus is symptomatic should guide treatment decisions.

Early prenatal detection of hydrocephalus is possible, but it should be kept in mind that hydrocephalus may develop only after 16 to 18 weeks' gestation. Of paramount importance is the detection of additional CNS and extracerebral malformations, as these may heavily influence the prognosis and management decisions.

MANAGEMENT AND PROGNOSIS. Shunting of the CSF from the ventricles is the mainstay of therapy for hydrocephalus.⁹ The predominant shunt systems currently in use are ventriculoperitoneal shunting (VP) devices with pressure-controlled valves placed under the scalp close to the burr hole. The major complications associated with VP shunt treatment involve mechanical problems, shunt-related infections, and functional problems. Signs of increased intracranial pressure with headache, lethargy, and vomiting will be apparent in most of the situations in which shunting is impaired. Functional overshunting can also occur, albeit less frequently. Headache again is the most common clinical symptom, but in contrast to the headache associated with increased intracranial pressure, headache resulting from overshunting tends to be relieved in the recumbent position. Shunt infections are a serious complication and are most often caused by *Staphylococcus aureus*. Unexplained fever, which can sometimes be low-grade, is seen, and chronic or frank meningitis usually is the presenting feature. Treatment is with penicillinase-resistant antibiotics, but culturing the pathogen for determination of drug susceptibility should be attempted in all cases. Replacement of all hardware is frequently necessary. Abdominal complications of VP shunting include peritonitis, perforation of an abdominal organ, peritoneal cysts, and the development of hydroceles in boys. Seizures, especially during the first year after shunting, occur in approximately 5.5% of patients. The incidence of developing seizures declines after the first year. In the Xq28-linked familial aqueductal stenosis VP shunting is indicated as well. Importantly, the development of mental retardation and spastic paraparesis appears to be independent from the ventricular dilatation per se and does not improve with the treatment.

Under certain circumstances such as neonatal post-hemorrhagic hydrocephalus, in which some patients may show resolution of the hydrocephalus without more permanent intervention, temporizing measures may be useful. Daily lumbar punctures removing substantial amounts of CSF have been used, but this treatment still requires more systematic clinical evaluation. Pharmacological intervention consists of a combination of high-dose acetazolamide with furosemide, which can reduce CSF production considerably. Careful monitoring for the development of nephrocalcinosis (particularly problematic in premature infants treated with this combination of drugs) and electrolyte imbalances is essential. The management of neonatal posthemorrhagic hydrocephalus is rather complex and beyond the scope of this chapter.¹⁰

The detection of a fetal ventriculomegaly by ultrasound has created a new problem in the management of

hydrocephalus that requires insight into the natural history of fetal ventriculomegaly.^{11,12} The prognosis is strongly influenced by the coexistence of major neural and extra-neural abnormalities. In one large series,¹² 50% of detected cases died in utero or the pregnancy was electively terminated, mainly because of the detection of major additional anomalies. Of the remaining 50% only a small percentage of cases were found to develop progressive ventriculomegaly in utero on follow-up investigations. These infants were shunted immediately after delivery and had relatively good outcomes. In an even smaller percentage, the ventriculomegaly resolved, also with a favorable outcome. Of the majority that were stable in utero, a little more than half remained stable postnatally and their ultimate prognosis was dependent on the presence of additional associated anomalies and malfunctions. The other group developed postnatal progression of the hydrocephalus requiring shunting. The outcome was good in the infants without additional anomalies. This pattern also holds true for hydrocephalus detected at birth.¹³ Given the importance of additional anomalies for the ultimate prognosis, once fetal ventriculomegaly is identified, a complete workup should be conducted at an experienced center. Currently no definite benefit to intrauterine shunting has been demonstrated.

NEURAL TUBE DEFECTS

Defects in formation of the neural tube account for 0.001% to 1% of all human malformations, depending on the reference population, making this group of disorders among the most common major malformations. Neural tube closure defects are also among the oldest recorded malformations. For example, a mummy from ancient Egypt, investigated by Etienne Geoffroy Saint-Hilaire, was determined to have anencephaly. A curious observation in the 16th century of a child with a froglike head and face, now believed to represent anencephaly, was born to a woman who had a frog placed on her hand during a febrile illness and represents the first indication that neural tube closure defects may result from environmental factors.¹⁴ This example of “maternal impression,” a theory widely postulated for many centuries as the cause of some congenital anomalies, including the “Elephant Man,” is noteworthy because of the now recognized association of maternal hyperthermia and neural tube closure defects.¹⁵

PATHOGENESIS AND PATHOPHYSIOLOGY. The prevailing theory on the pathogenesis of neural tube defects is that they result from a failure of the neural folds to come together to form the neural tube as opposed to splaying open of a closed neural tube. Experimental models and studies in humans have supported this contention. Although monoallelic disorders are occasionally associated with neural tube closure defects,¹⁶ most data implicate a multifactorial etiology for the occurrence of neural tube closure defects. Neural tube closure defects are common in animals, including mice, in which mutant strains have been invaluable in identifying many genes important for neural tube closure. Strain differences in the susceptibility to neural tube closure defects have been recognized, consistent with the multifactorial model. Similarly, environmental

factors have been identified that result in neural tube closure defects. Recent data also indicate that at least in the cranial region, neural tube closure occurs not in a single continuous closure, but at multiple sites and in a coordinated pattern. Each defined site may be under the control of different genes and be susceptible to different environmental factors (Fig. 28-1).^{17,18}

Given that several of the known environmental risk factors can be controlled, it is important to appreciate the embryonic timing of neural tube closure and therefore the gestational age at which these defects are believed to arise. Closure of the neural folds begins on approximately day 20 after fertilization and is complete by approximately day 28. This is approximately 1 to 2 weeks beyond the time a woman is expecting her normal menstrual cycle. Thus, during this critical time of development for the nervous system, a woman is frequently still unaware that she is pregnant. As a result, preventive measures have to be already in place before conception.

EPIDEMIOLOGY AND RISK FACTORS. The past decades have witnessed an overall decline in the incidence of neural tube closure defects, although the etiology for this decline remains elusive. Epidemiological and experimental investigations into potential environmental risk factors, particularly in Wales and Ireland, have failed to identify an obvious single source. Several environmental factors have been linked to neural tube closure defects including maternal diabetes, maternal hyperthermia, and some anticonvulsants (valproic acid and carbamazepine in particular)¹⁹; however, the elimination of some of these minor risk factors is not sufficient to explain the overall declining incidence.²⁰ Recently, vitamin supplementation, particularly folate, has been linked to a reduced risk for having a second child with a neural tube closure defect.^{21,22} Preliminary data indicate that similar supplementation may also reduce the risk for all mothers.²³ The mechanisms by which vitamin supplementation prevents neural tube closure defects are poorly understood, but recent genetic evidence suggests that certain polymorphisms in folate metabolizing enzymes (MTHFR, MTHFD1) confer a higher risk for neural tube defects, providing a basis for the effectiveness of folate replacement therapy.²⁴

As alluded to already, it is likely that many factors play roles in the causation of neural tube closure defects, and the actual etiology is more often than not multifactorial. Additional genetic factors certainly play an important role in at least conferring a predisposition to having a child with a neural tube closure defect. These genetic and environmental factors are likely to act synergistically to increase a woman's risk for having a child with a neural tube closure defect.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Neural tube defects can be divided into cranial and caudal, although occasional cases may involve both (e.g., encephalocele in conjunction with myelomeningocele). The terminology of a neural tube closure defect often provides a description of the type and location of the defect. Anencephaly in the strict sense means absence of the head, however, the term practically refers to an absence of the brain and the calvarium covering the brain. Although some cases have partial sparing of supratentorial or more commonly infratentorial structures, the vast majority of cases

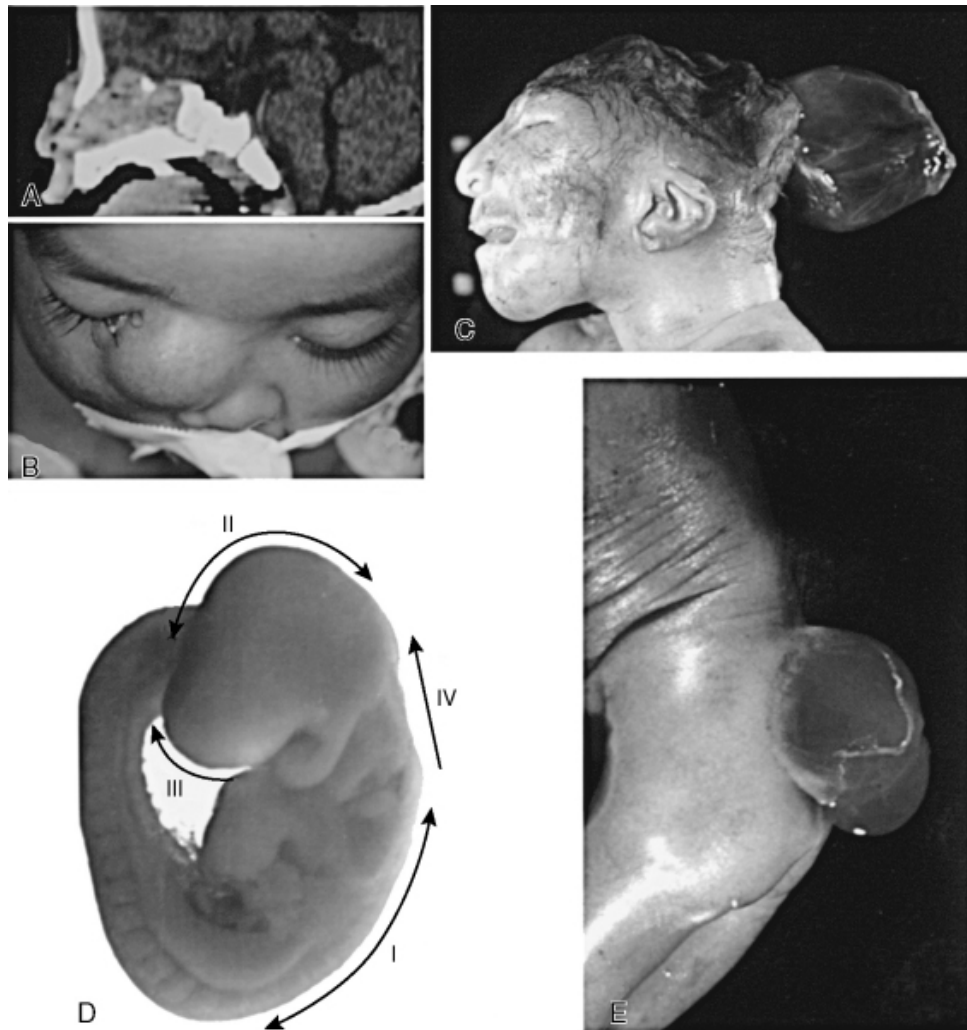

Figure 28-1. Neural tube closure defects located at multiple sites along the neuroaxis. A CT scan (A) and clinical photograph (B) of a patient with a frontal (nasal glioma) encephalocele (closure III). C, An encephalocele/anencephaly isolated to the occipital region (closure IV). D, This case showed an open defect at the top of the encephalocele with extensive loss of neural tissue, placing this case in the category of anencephaly. E, A lumbosacral myelomeningocele with an intact membrane over the defect that involved the spinal cord. A model of neural tube closure defects. Defects in closures III, IV, and I may account for the examples shown in parts A, B, C, and E, respectively. (From Golden J, Chernoff G: Intermittent pattern of neural tube closure in two strains of mice. *Teratology* 1993;47:73–80.)

show a complete absence of most of the brain. The anterior pituitary, eyes and lower brain stem are usually spared. Although the tissue fated to become the brain is present in the embryo, it is generally believed that direct contact between the neural epithelium and the amniotic fluid leads to degeneration of the former. The remaining tissue covering the basal cranium is a highly vascular and friable membrane referred to as the area cerebrovasculosa. Rachischisis refers to cases of anencephaly with a contiguous spinal defect involving at least the cervical spine region and extending for varying degrees down the spinal column. In the majority of cases there is associated polyhydramnios and a significant proportion are stillborn. Infants born alive do not survive, and their neurological function is primarily limited to brain stem and spinal reflexes. Seizures, at times resembling infantile spasms, have been observed in some infants.

Encephaloceles and cranial meningoceles are distinguished from anencephaly by the former having an epidermal

covering over the cranial neural tube closure defects. Both entities are associated with a defect in the skull with protrusion of the leptomeninges alone in the case of a meningocele, and leptomeninges and underlying brain in encephalocele. The size of an encephalocele can vary from a barely visible bulge to those larger than the infant's head. Occasionally, no clear bony defect or attachment to the underlying brain can be identified, particularly with lesions located in the inferior frontonasal region. This form of a frontal encephalocele is sometimes called a "nasal glioma," although the term is misleading because there is no neoplasm. These lesions may not be immediately obvious on external examination and may present as intranasal masses, pharyngeal obstruction, or with recurrent meningitis. Hypertelorism, median cleft lip, or hypothalamic dysfunction can also be associated. The location of an encephalocele can be helpful in the diagnosis of specific syndromes. For example, the Meckel-Gruber and Walker-Warburg syndromes are frequently associated with occipital encephaloceles;

anterior encephaloceles are found more commonly in Roberts' syndrome and as isolated malformations more commonly in Southeast Asia. Parietal encephaloceles are less common. The extent of the cortex "herniated" into the cele correlates with the neurological deficits. Malformed cortex within or adjacent to the cele, in addition, can give rise to seizures.

Neural tube closure defects involving the spinal cord can involve the meninges alone (meningocele) or the meninges and underlying spinal cord (myelomeningocele). Most caudal neural tube closure defects occur in the lumbar region, followed by the lumbosacral region, but can also be located in cervical, thoracic, or sacral regions. The terms spina bifida occulta and spina bifida cystica are also used to describe variations of these defects. These terms refer to the bony changes of the vertebral column. Spina bifida occulta is defined as a defect in the posterior bony components of the vertebral column without involvement of the cord or meninges. These defects are often found incidentally on radiographic studies or are picked up because of a subtle clinical finding such as a tuft of hair or a cutaneous angioma or lipoma in the midline of the back marking the location of the defect. On rare occasions a sinus tract may communicate from the skin to the underlying dura.

The clinical presentation is largely dependent on level and content of the defect. Pure meningoceles without involvement of the spinal cord may be largely symptomatic. Neurological disability is greatest in patients with myelomeningocele. Infants with defects at or above L2 are more likely to have skeletal deformities, including kyphosis and scoliosis, dislocated hips, and clubfeet (see later discussion). The degree of motor paresis is dependent on the level of the neural tube closure defect and is discussed in more detail under Management and Prognosis. Involvement of the kidneys, urinary tract, and bladder with various forms of incontinence and reflux is very common and similarly depends on the level of the lesion (see the following discussion).

Several disorders frequently included in the spectrum of spinal neural tube defects are tethered cords, spinal lipomas, and sacral teratomas, although these entities do not arise as a result of a failed neural tube closure. Nonetheless, spinal dysraphisms are occasionally associated with these lesions. The etiological relationship between these disorders remains unclear. Tethering of the cord can present late and insidiously with progressive gait disturbances, atrophy of various muscle groups or the entire limb, loss of reflexes, loss of sensation in particular in the sacral dermatomes, and sphincter disturbances.²⁵ The gait abnormality results from weakness and lower extremity spasticity. Pain in the gluteal, perianal, and other pelvic areas as well as the limbs associated with cramping can occur in particular with later presentation. Early and seemingly fixed deformities as well as sudden and dramatic deteriorations can also be seen. Deteriorations may occur in particular during periods of rapid growth. Partial duplication of the spinal cord, diastatomyelia, can give rise to a similar picture, although the symptoms are often more strictly unilateral.

Myelomeningocele, particularly those arising in the lumbosacral regions, are frequently associated with other defects along the neuroaxis and the surrounding mesoderm. The cranial bones may show regional thinning resulting in

radiographic and transilluminative lucencies. These defects, also known as Lückenschädel, are present in far greater than 50% of term children with myelomeningocele, but are rarely diagnosed after 2 years of age. Although these bony lucencies frequently occur in patients with myelomeningocele, especially in the additional presence of hydrocephalus, they are not specific for this disorder and may be found incidentally or in association with hydrocephalus only. The base of the skull is also abnormally flattened (platybasia) in most patients with myelomeningocele, resulting in a shallow angle between the clinoid process and the foramen magnum.

The cerebral hemispheres can show malformations that are not clearly linked to the neural tube defect. The associated anomalies range from those that are found infrequently, such as agenesis of the corpus callosum, polymicrogyria, and pachygyria, to frequent findings such as an enlarged massa intermedia. Probably the most common finding associated with myelomeningocele is the Chiari II malformation, also referred to by some authors as Arnold-Chiari malformation. This hindbrain malformation is present in greater than 95% of children with myelomeningocele. Although a broad spectrum of findings are part of the Chiari II malformation,²⁶ the change found in virtually all cases includes displacement of the cerebellar vermis (and to a lesser extent the inferior lateral cerebellar hemispheres) over the dorsal aspect of the cervical spinal cord (Fig. 28-2) within the upper vertebral column. The fourth ventricle, pons, and medulla are similarly elongated and partially located within in the spinal canal. The lower medulla may be kinked. Forking of the aqueduct, aqueductal stenosis, or aqueductal atresia may be present. Less common findings include fusion (beaking) of the inferior tectum and anomalies of cranial nerve nuclei. Hydrocephalus is a common complication of myelomeningocele, and may manifest pre- or postnatally. The etiology of the hydrocephalus is not always clear, although the aqueductal changes could account for some of the cases. Clinically, the Chiari II malformation may present with lower brain stem and cranial nerve dysfunction. Dysphagia leading to feeding difficulties, drooling, nasal regurgitation, stridor, vocal cord paralysis, and life-threatening apnea spells may all occur. Cyanotic episodes are ominous, carrying a considerable risk of death. Nystagmus, retrocollis, and opisthotonus can also be seen. Later presentation of the Chiari II malformation may include additional loss of head control, newly arising weakness in the arms, and increasing spasticity leading to quadriparesis.

In addition to dysraphism, other malformations may be concurrently found in the spinal cord.²⁶ The two most frequent abnormalities of the spinal cord are hydromyelia (dilations of the central canal) and syringomyelia (a glial lined cavity within the parenchyma of the spinal cord). They may occur in isolation or may be found together (hydrosyringomyelia). These disorders may be localized to a short segment of the spinal cord or extend along great distances. It is also important to recognize that these conditions are not specific to dysraphisms and can even occur post-traumatically. Partial (diastatomyelia) and complete (diplomomyelia) duplications of the spinal cord are occasionally present in association with myelomeningocele. These potentially associated anomalies are not

Figure 28-2. Examples of several posterior fossa anomalies. A midsagittal MRI (A) and photograph (B) of a brain with Dandy-Walker malformations. The cerebellar vermis is rotated anteriorly and there is a cystlike dilation of the fourth ventricle. C, A Chiari I malformation is characterized by a tongue of cerebellar tonsils extending over the cervical spinal cord. The cerebellar vermis is intact and shows no displacement. D, The Chiari II malformation is characterized by the cerebellar vermis extending as a tongue of tissue into the cervical spinal canal. The inferior vermis is white, corresponding to the extreme gliosis usually seen in this disorder. Note the beaking of the inferior tectum, the elongated and distorted pons and medulla, with the kinking of the lower medulla.

specific for dysraphisms of the spinal cord, and each may be found in isolation or with other CNS malformations.

DIFFERENTIAL DIAGNOSIS. The diagnosis of a neural tube defect usually is quite obvious, except in rare cases of small or hidden encephaloceles and with forme fruste lesions such as dural sinus tracts. In some cases of aplasia cutis congenita, there may be bony skull defects without cystic outpouching of components of the CNS, making the diagnosis of a neural tube defect difficult. Tumors such as caudal lipomas, teratomas, and dermoids may occasionally mimic a neural tube closure defect. The amniotic band sequence can also disrupt the neural folds and cranium, resulting in a defect resembling a neural tube closure defect.²¹ Disruptions due to the amniotic band sequence are often easily distinguished from neural tube closure defects by the asymmetry, the presence of facial clefts, and the presence of extremity amputations. The signs and symptoms of tethering of the cord and related anomalies have to be differentiated from other progressive spinal cord diseases, including tumors, multiple sclerosis, spinal cord infarction, and progressive spastic paraparesis.

EVALUATION. The diagnosis of anencephaly is readily made on examination of the affected infant. The evaluation of children with less dramatic neural tube defects is more complex. Occipital encephaloceles may be part of a syndrome with important genetic and prognostic implications. For example, the Meckel-Gruber syndrome and the Walker-

Warburg syndrome, both mentioned previously, are autosomal recessive disorders with a poor prognosis. A special case is the frontonasal encephalocele. Clear rhinorrhea from CSF leakage following the removal of a nasal “polyp” requires immediate evaluation with imaging and prophylactic antibiotic treatment instituted before surgical repair. A complete endocrine evaluation is particularly important in sphenoidal encephaloceles. In general, careful imaging, preferably using both MRI and CT scanning with bone windows, is important for the evaluation of encephaloceles to outline their content and anatomical relationships for treatment planning.

In the evaluation of the infant with spinal dysraphism, particularly the lumbosacral forms, it is important to be aware of the commonly associated Chiari II malformation as well as of the possibility of coexisting hydrocephalus. Myelomeningoceles outside the lumbosacral region have a less consistent association with hydrocephalus.

It is currently recommended that every child with myelomeningoceles be screened for the presence of hydrocephalus with at least transfontanelle ultrasound, because the development of signs and symptoms may be delayed. Careful morphological and functional urological assessment is of major importance in children with myelomeningoceles. Only in very low lesions at S3 will there be a flaccid, and therefore relatively easy to manage, bladder. Higher lesions are often associated with incoordination of the detrusor and external urethral sphincter.

MANAGEMENT AND PROGNOSIS. In anencephaly the prognosis for survival without maximal support for an affected infant is extremely poor, and a significant proportion of infants are stillborn. Because survival of live-born infants can be prolonged with the assistance of life support systems, anencephalic infants are potential organ donors, but purposeful life prolongation for this use is controversial.

The management for dysraphic disorders begins with the planning of an atraumatic delivery. The avoidance of labor by prelabor cesarean section significantly improves neurological outcome in children with myelomeningoceles.²⁷ Larger encephaloceles are also managed in this fashion. Decisions concerning the surgical management in the encephaloceles are dependent on the clinical context in which the encephalocele occurs, including the identification of syndromes and other associations important for prognosis and genetic counseling (see Van Allen and colleagues¹⁷ for a more complete list of associations and syndromes). Most encephaloceles are sporadic, however, so that prognosis and management are solely based on the extent of the individual defect. Generally, surgical excision and closure are recommended, even if there are significant associated malformations; the goal of surgery in these cases may be simply to improve caregiving for the affected infant. More urgent surgery may be indicated in the case of CSF leaks to prevent meningitis. The prognosis and neurological outcome are significantly better in anterior encephaloceles as opposed to parietal and occipital lesions, particularly those involving the posterior fossa contents (see later discussion of Chiari III). Frequently a sporadic encephalocele, frontal or occipital, can be surgically managed with fairly good outcome.

The surgical treatment of spinal dysraphism in most centers is now directed at closing all but the prognostically worst cases. Although early treatment is preferable, there are no strong data supporting improved outcome from emergency closure. Timely closure does, however, reduce the rate of infectious complications. A planned operation within the first 24 to 48 hours after delivery currently is the standard of treatment, although some delay of the closure under antibiotic coverage does not seem to adversely affect outcome. Concurrent shunting of coexisting hydrocephalus is often necessary and advisable even for what might appear to be “arrested” ventriculomegaly. Prevention of meningitis or ventriculitis is extremely important, because the outcome for cognitive development is inversely related to the occurrence of such complications. Therefore antibiotic prophylaxis is used before and around the time of surgery, in particular with open defects. A new surgical intervention that has shown significant initial promise is fetal surgery to close the defect, although further studies are required to determine which patients are the best candidates and to assess the safety and long-term outcome of this intervention.

Surgical management of the Chiari malformation itself may become necessary when prominent brain stem signs persist despite adequate treatment of the hydrocephalus.²⁸ In these selected cases decompression via suboccipital craniectomy and cervical laminectomy can be beneficial. Urological management plays a prominent role in the care of these children.²⁹ It is very important to avoid secondary

dilatation of the proximal urinary system creating the potential for chronic pyelonephritis and renal damage. Urological complications continue to be a leading cause of morbidity in children with myelomeningocele. Various conservative (intermittent catheterization, anticholinergic medication) and surgical regimens for bladder management may be appropriate.³⁰ Rectal incontinence can often be successfully managed with conservative treatment such as very regulated and scheduled emptying of the bowel. Several late complications of myelomeningoceles can arise. Scoliosis, especially with lesions at or above L2, and traction on the cord may result from the defect alone. Postsurgical complications include spinal cord infarction, compression of the cord by subarachnoid cysts, and inclusion cysts arising from trapped skin appendages.

The distribution of weakness and deficits on examination is an important predictor for later ambulation. Involvement above the L3 level in general creates motor deficits that preclude ambulation; lesions below S1 usually allow for unaided ambulation. If the deficit level falls between S1 and L3, a number of assisting devices may be useful for ambulation.³¹

Tethering of the cord may be found as a late complication after meningomyelocele repair,³² but may also occur as a “primary” abnormality (see the previous discussion). In all cases surgical untethering of the cord is recommended. The associated pain responds best to surgical treatment, and ambulation and bladder function may improve as well. However, sphincter dysfunction often remains a permanent problem even after complete release. Given the potential for rapid deterioration with incomplete neurological recovery, even prophylactic surgery in an otherwise asymptomatic child seems advisable.

Primary prevention of neural tube defects currently focuses on dietary folate replacement around the time of conception. Such a supplementation has been shown to not only reduce the risk for the birth of a second affected child, but may also be effective in reducing the primary incidence of neural tube defects. Given the early timing of the failure of neural tube closure, supplementation may be too late when an unplanned pregnancy is noted. The question of general diet fortification with folate is still being debated.³³

Prenatal detection of neural tube defects has become routine through screening programs using serum and amniotic chemistry and prenatal ultrasound. Elevated serum or amniotic fluid alpha-fetoprotein (AFP) and elevated acetylcholinesterase in the amniotic fluid are found in almost all open neural tube defects. The peak of sensitivity for maternal serum AFP levels lies somewhat later than the amniotic fluid determination and is optimal at 16 to 18 weeks' gestation. Before that time, the levels may be normal despite the presence of a neural tube closure defect. The specificity of this test is much lower, so careful follow-up testing needs to be done after the determination of an elevated value. This surveillance commonly includes a high-level fetal ultrasonography and often amniocentesis to measure AFP and acetylcholinesterase in the amniotic fluid. This determination is highly sensitive for open neural tube closure defects, but not always completely specific, since there are other causes for elevated AFP in the

amniotic fluid. AFP levels combined with acetylcholinesterase analysis in the amniotic fluid approaches a sensitivity of 100% with much improved specificity. In addition, fetal ultrasonography can provide an additional level of confidence with very high sensitivity in experienced hands at even 14 to 16 weeks' gestation. Indirect signs such as the lemon sign, referring to a symmetrical bifrontal narrowing of the skull, and cerebellar abnormalities are helpful in addition to the often-difficult direct demonstration of the defect. Fetal ultrasonography can also assist in dating of the pregnancy, an important factor in the calculation of the AFP values, as the normal and abnormal ranges are dependent on the gestational age of the fetus.

SEGMENTATION, CLEAVAGE, AND MIDLINE DEFECTS

The group of disorders discussed in this section are believed to arise from a defect in midline development. The result is a failure of midline structures, such as the corpus callosum, to form. Included are also abnormalities in the separation of the neural tube into two hemispheres. This later defect is believed to result in holoprosencephaly and the related disorders that will be discussed.

PATHOGENESIS AND PATHOPHYSIOLOGY. Completion of neural tube closure is followed by segmentation in the anterior-posterior axis. Although these segments were originally defined morphologically, recent data have demonstrated a coordinated expression of a variety of developmentally regulated genes, mostly members of transcription factor families such as the homeobox genes. In more general terms these data have suggested that the segmental organization of the nervous system is established through a combinatorial regional expression and regulation of specific developmental genes.^{34,35} These segments form the progenitors to all structures recognized in the adult nervous system. Holoprosencephaly is now believed to arise from a defect in this early dorsal-ventral patterning of the rostral neural tube midline.³⁶ In addition to the anterior-posterior organization of the nervous system, bilateral symmetry arises in the cerebral hemispheres. At approximately 5 to 6 weeks after fertilization the prosencephalon, the most rostral segment of the nervous system, shows differential growth as two distinct hemispheres. The most anterior point of the neural tube, the lamina terminalis, is the location from which the major crossing fibers between the cerebral hemisphere will arise. Both the anterior commissure and the corpus callosum have their anlagen in the lamina terminalis. From there the corpus callosum grows back over the top of the third ventricle to form its genu, body, and splenium. Failure of the prosencephalon to grow into two symmetrical hemispheres and defects in the region of the lamina terminalis are believed to give rise to the class of defects commonly referred to as cleavage defects or midline defects.

EPIDEMIOLOGY AND RISK FACTORS. Among the midline defects, holoprosencephaly is the best characterized and studied, and this section will focus primarily on this disorder as a model of a segmentation defect. Holoprosencephaly is a relatively rare malformation of the CNS, frequently associated with specific craniofacial anomalies including midline facial clefts, cyclopia, and nasal

anomalies. The incidence in live-born children with normal chromosomes has been estimated to be approximately 0.48 to 0.88 per 10,000.^{37,38} In contrast, the rate among human aborted fetuses was estimated at 40 per 10,000, indicating a high rate of fetal loss.³⁹

Several environmental/maternal factors have been associated with the holoprosencephaly sequence. In humans, the best recognized association is with maternal diabetes. Maternal ethanol consumption has also been anecdotally associated and is supported by experimental studies.³⁶ Excluding those cases of holoprosencephaly resulting from exposure to a teratogen, it is likely that the majority of remaining cases will have a recognizable genetic etiology. Furthermore, it is possible that even those cases associated with a teratogenic exposure occur against the background of a genetic predisposition, similar to the risk of a chronically alcoholic woman having a child with the fetal alcohol syndrome.

Because the holoprosencephaly sequence can occur in the setting of other well-recognized syndromes, the evaluation of a fetus, infant, or child with holoprosencephaly must include a complete investigation for other systemic anomalies. It has been estimated that up to 25% of patients with holoprosencephaly have a recognizable syndrome.^{37,38} Syndromes that may show holoprosencephaly as a feature include pseudotrisomy 13, Smith-Lemli-Opitz, Pallister-Hall, Meckel, velocardiofacial, Genoa, Lambotte, Martin, and Steinfeld syndromes.³⁶ As will be discussed in the following sections, the Smith-Lemli-Opitz syndrome, due to a defect in cholesterol biosynthesis⁴⁰ at the level of 3 β -hydroxysteroid- Δ^7 -reductase, is of particular interest because it also has a link to a specific signaling pathway involving the human sonic hedgehog homolog (SHH) molecule. Affected patients have severe hypocholesterolemia, and cholesterol is required for normal SHH signaling.

In addition to these recognized syndromes, a number of nonrandom chromosomal abnormalities have been found in patients with holoprosencephaly. Chromosomal anomalies have been reported in 24% to 45% of live-born infants,^{37,38} the most common of which is trisomy 13. This has been estimated to account for greater than 50% of the chromosomal abnormalities in patients with cytogenetic abnormalities, and up to 70% of children with trisomy 13 have holoprosencephaly. In addition to trisomy 13, several other chromosomal anomalies have been identified in patients with holoprosencephaly.³⁶

Based on nonrandom cytogenetic rearrangements, at least 12 chromosomal regions on 11 chromosomes may contain genes that may play a role in the pathogenesis of holoprosencephaly. Four of these loci have been designated HPE1 (21q22.3), HPE2 (2p21), HPE3 (7q36), and HPE4 (18p).⁴¹ Since that time, SHH was found to map within the minimal critical region for HPE3 and mutations identified. Confirmation that SHH plays a role in the pathogenesis of holoprosencephaly has come from mice that are homozygous mutant for the SHH gene and show a holoprosencephaly-like sequence.⁴² Other genes that have been identified to date while certainly not all include TGIF, ZIC2, GLI2, FAST1, SIX3, and PTCH1.⁴³ Overall, a central role for the sonic hedgehog pathway emerges,⁴⁴ but other genes are likely to also be identified.

Figure 28-3. Semilobar and alobar holoprosencephaly. **A**, In semilobar and lobar holoprosencephaly there is an apparent midline sagittal (interhemispheric) fissure (coronal section of brain). However, coronal sections reveal the cerebral cortex to be continuous across the midline. Furthermore, no corpus callosum is present. The thalamus is abnormally shaped with marked midline fusion. **B**, Alobar holoprosencephaly has no indication of a midline fissure on coronal sections or when viewing the brain dorsally. Again there is no evidence of a corpus callosum, only subcortical white matter across the midline.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Holoprosencephaly is frequently divided into subtypes according to the extent of cerebral hemisphere involvement, although these distinctions are probably artificial. The most commonly used classification scheme defines three subtypes: alobar, semilobar, and lobar holoprosencephaly.⁴⁵ Alobar holoprosencephaly is the most severe of these (Fig. 28-3A). The brain shows no evidence of a midsagittal fissure. The corpus callosum is absent and the olfactory bulbs and tracts are almost always absent as well. Varying degrees of fusion of the basal ganglia and thalamus are present. This form of holoprosencephaly is most frequently associated with severe facial malformations (see later discussion in this section). Semilobar holoprosencephaly is characterized by an incomplete fusion of the cerebral hemispheres (Fig. 28-3B). The occipital and parietal lobes tend to be more or less separated, whereas the frontal lobes show varying degrees of fusion. Again, the corpus callosum is absent in all cases and the olfactory bulbs and tracts absent in most. The basal ganglia and thalamus are variably involved but at least partially fused in all cases. In lobar holoprosencephaly a midline fissure is present over the entire dorsal aspect of the brain; however, in at least the medio-orbital region of the frontal lobe there is fusion across the midline. The olfactory bulbs and tracts are again absent in the vast majority of cases, as is the corpus callosum. The posterior fossa contents are usually unremarkable in holoprosencephaly. Only in the most severe cases of alobar holoprosencephaly can anomalous development of the cerebellum occasionally be seen. On the other hand, absence of the corticospinal tracts is a common finding and is believed to be the consequence of the severe malformation of the cerebral cortex with subsequent failure of formation of proper motor projections. A spectrum of quite distinctive facial dysmorphisms can be part of the holoprosencephalic malformation sequence. These facial abnormalities are expressions of the underlying profound disturbance of midline development, affecting prechordal mesoderm important in facial development as well. The facial phenotypes can be ranked in descending

order of their severity: (1) cyclopia (the eye and orbits are fused or in various states of incomplete separation, agnathia may also be present); (2) ethmocephaly (instead of a nose, a proboscis is present and often located above the incompletely separated, or severely hypoteloric, eyes); (3) cebocephaly (the nose is between and below the hypoteloric eyes, but there is only a single blindly ending nostril); (4) premaxillary agenesis or aplasia of the primary palate, associated with hypotelorism and often midline cleft lip and palate; (5) milder facial dysmorphism with hypotelorism, flat base of the nose, and milder midline or bilateral clefting; (6) minimal forms such as single central incisor. While it is generally true in the holoprosencephaly spectrum that the face predicts the brain,⁴⁶ exceptions do occur. In general, the severe facial dysmorphisms of cyclopia, cyclopia with agnathia, ethmocephaly, cebocephaly, and severe hypotelorism with agenesis of the primary palate and a median cleft lip and palate usually go along with the severe alobar form of holoprosencephaly. The correlation of severity of the facial appearance and brain morphology is less pronounced at the mild end of the spectrum of facial phenotypes. Although the full-fledged facial phenotypes seem to be always associated with holoprosencephaly, cases of, for example, agnathia (but without cyclopia) or central cleft lip and palate have been seen in patients with a morphologically normal-appearing brain and also with brains that have malformations distinct from the holoprosencephaly sequence. The reverse correlation, namely, that a holoprosencephalic brain necessarily goes along with an abnormal brain, is less strict, as a normal face can be seen even in severe holoprosencephaly. Distinct genetic causes for holoprosencephaly with a normal face are emerging (e.g., *ZIC2* mutations). Thus, the brain does not necessarily predict the face.

The clinical presentation of holoprosencephaly is very much dependent on the degree of CNS involvement. Infants with severe alobar forms often die shortly after birth. Survivors frequently present with severe mental retardation, seizures with infantile spasms early on, severe motor impairments, poikilothermia, and endocrine insufficiencies.

In the milder forms of holoprosencephaly, longer survival with various degrees of psychomotor retardation is possible. Endocrine dysfunction may become apparent, with diabetes insipidus and growth hormone deficiency often reported. It should be re-emphasized that only the “classical” facial phenotypes are predictive of the severe alobar holoprosencephaly with its associated very poor prognosis; a number of partial facial phenotypes, such as midline cleft lip or midface hypoplasia, are not necessarily associated with the most severe malformations in the spectrum.¹⁷

In families with autosomal dominant holoprosencephaly, carriers of the gene with minimal expression of the defect (e.g., hypotelorism or a single central incisor) can be neurologically normal. There may be considerable variability of expression within a given family, with severely involved cases occurring alongside milder ones. Autosomal recessive holoprosencephaly has been reported as well and in some families is associated with heart and limb defects.

EVALUATION. Most cases of holoprosencephaly occur sporadically, but may also be a feature of one of several malformation sequences or syndromes.¹⁷ Therefore, part of the clinical evaluation of a patient with holoprosencephaly must include a careful workup for additional malformations, since this information may provide the diagnosis of a specific syndrome with potentially far-reaching genetic implications. Because of the associations with some deletion/microdeletion syndromes, high-resolution karyotype analysis (+/–FISH analysis) (see Chapter 25) with special emphasis on chromosomes 2p21, 3p, 7q36, 13q, 18p11.3, and 21q22.3 is recommended in all cases of holoprosencephaly. Specific gene mutation analysis is also warranted for SHH, TGIF, PTC, and SIX3 in selected cases. If the affected proband is not available, chromosome analysis in the parents is important to rule out a carrier status for a balanced translocation. Possible misdiagnoses in the severe forms of alobar holoprosencephaly include hydranencephaly, hydrocephalus, and large, expanded interhemispheric cysts that sometimes are associated with agenesis of the corpus callosum. Expanded large posterior third ventricular cysts can be mistaken for semilobar holoprosencephaly. Bridging of cerebral cortex across the midline deep in the interhemispheric fissure can be missed in very mild cases of lobar holoprosencephaly and is best evaluated on coronal T₁-weighted MRI. The prenatal diagnosis of holoprosencephaly is largely based on ultrasound examination. A first trimester diagnosis is possible based on ultrasound findings of a lack of a midline echo indicative of a monoventricle, cyclopia or marked hypotelorism, a flattened profile of the nose, and microcephaly. Transvaginal ultrasound enhances the visibility of these findings, especially early in gestation. Prenatal diagnosis by ultrasound of mild forms such as lobar holoprosencephaly may be impossible.

MANAGEMENT AND PROGNOSIS. The management of a patient with holoprosencephaly depends on the extent of clinical involvement, and focuses predominately on seizure control (see Chapter 52). The prognosis for all live-born children with severe forms of holoprosencephaly is extremely poor. The rare cases associated with true hydrocephalus due to CSF flow obstruction need to be differentiated from ventriculomegaly as a feature of the malformation itself, and treated with VP shunting. Prognosis similarly

parallels the ability to control the seizures. Mental retardation may be mild in the least severely affected individuals, but is almost always profound in the more severely affected individuals. In cases of holoprosencephaly with less complete CNS involvement, surgical correction of the craniofacial malformations, such as cleft lip or palate, may be appropriate. Endocrine dysfunctions respond to hormone replacement therapy.

OTHER SEGMENTATION AND CLEAVAGE DISORDERS

Septo-optic dysplasia is pathologically defined as absence of the septum pellucidum in combination with hypoplastic optic nerves. This clinical constellation of symptoms and signs has also been referred to as De Morsier syndrome. Other abnormalities are variably reported, suggesting considerable heterogeneity underlying this phenotype. Clinically there is optic nerve hypoplasia resulting in visual impairment, endocrine abnormalities resulting from hypothalamic-pituitary insufficiency, and not infrequently seizures, especially in cases where there has been disruption of cortical development as well. The degree of visual impairment can vary from blindness leading to the development of amaurotic nystagmoid eye movements a few months after birth, to normal vision in a few cases. The endocrine insufficiencies can cause symptomatic hypoglycemia and diabetes insipidus, and later growth hormone deficiency may become apparent. These can and should be treated by standard endocrine replacement protocols. Although retardation of cognitive development occurs, especially in patients with obvious concomitant cortical anomalies, a number of cases with normal cognitive development are on record. Most cases of septo-optic dysplasia have been sporadic; however, there are two observations in siblings and in cousins suggesting the existence of a form with autosomal recessive inheritance, associated with mutations in the homeobox gene HESX1. It is an important consideration in the differential diagnosis in children presenting with optic hypoplasia.⁴⁷

Agenesis of the corpus callosum can be found as an isolated malformation or in association with other malformations and chromosomal anomalies.¹⁷ A pericallosal lipoma may be associated with the agenesis of the corpus callosum. A growing number of inborn errors of metabolism also include agenesis of the corpus callosum as part of their clinical spectrum. In complete absence of the corpus callosum the cingulate gyrus is altogether absent and sulci are found radiating down the medial aspect of the brain from the dorsal surface to the high riding roof of the third ventricle (Fig. 28-4). Coronal sections or images often reveal slightly dilated ventricles with an irregular “batwing” contour. A white matter tract, known as the bundle of Probst, can frequently be found running in the anterior-posterior direction just above the lateral ventricle where the fibers of the corpus callosum would normally collect into the commissure. Partial agenesis is recognized by the absence to variable degrees of the posterior corpus callosum with sparing of the rostrum and genu. In cases of partial agenesis of the corpus callosum the cingulate gyrus is present only to the extent that the corpus callosum exists. The anterior commissure, also derived from the

Figure 28-4. Partial and complete agenesis of the corpus callosum. **A**, Midsagittal MRI of a patient with complete agenesis of the corpus callosum. The medial gyri are seen radiating to the third ventricle. **B**, Midsagittal section of the brain from a patient with complete agenesis of the corpus callosum. A comparison of parts A and B shows remarkably similar findings. **C**, Coronal MRI of another patient with agenesis of the corpus callosum. The lateral ventricles show the classic batwing form, and dilation is seen in the temporal horns of the lateral ventricles and the third ventricle. **D**, Midsagittal section of a brain with partial agenesis of the corpus callosum. The partial corpus callosum present (arrowheads) extends from the lamina terminalis posteriorly. The cingulate (partially obscured by the arrowheads) extends the length of the corpus callosum. A sulcus (arrow) extends from the dorsal surface of the brain to the third ventricle only, posterior to the formed corpus callosum.

lamina terminalis, is absent in cases of complete agenesis of the corpus callosum, but is usually spared in cases of partial agenesis of the corpus callosum.

Isolated agenesis of the corpus callosum is sometimes discovered incidentally either on imaging studies that were obtained for other reasons or at autopsy. In isolation, the abnormality can be clinically largely silent and deficits may only be discovered on careful neuropsychological assessment. Findings resembling disconnection syndromes have been described in some patients, however, this is by no means a constant feature and in the majority of patients this cannot be demonstrated. Patients with agenesis of the corpus callosum have a higher incidence of seizures and mental retardation, partially reflecting the slightly higher incidence of telencephalic migrational abnormalities also seen in these patients. It should be noted however, that patients with mental retardation or seizures are also more likely to have CNS imaging that skews the ascertainment of clinicopathological correlations in agenesis of the corpus callosum toward more affected individuals.

Because it can be assumed that the clinical manifestations of agenesis of the corpus callosum most often depend on the associated CNS anomalies rather than on the lack of the corpus callosum itself, careful assessment for such associated malformations is mandatory. Although agenesis of the corpus callosum can be diagnosed on a CT scan (high-riding third ventricle, parallel configuration of the lateral ventricles, and colpocephaly), MRI is far superior in diagnosing associated structural abnormalities such as disturbances of neuronal migration. Partial agenesis of the

corpus callosum is also seen very clearly on sagittal MRI. Midline cysts not associated with agenesis of the corpus callosum, holoprosencephaly as well as extreme hydrocephalus with thinning or disruption but without agenesis of the corpus callosum, need to be considered in the differential diagnosis. In secondary disruption of the corpus callosum, associated developmental features such as lack of the cingulate gyrus and presence of a bundle of Probst are not found. The potential diagnosis of an underlying metabolic disorder (e.g., nonketotic hyperglycinemia, infantile lactic acidosis associated with pyruvate carboxylase or PDH deficiency, Smith-Lemli-Opitz syndrome, and Zellweger syndrome) has to be considered, depending on the clinical context. In patients with additional malformations of the brain or extraneural structures, a karyotype should be performed as well. A special problem is posed by the prenatal detection of absence of the corpus callosum on ultrasound. The presence of additional abnormalities and an abnormal karyotype is a poor prognostic indicator for developmental outcome, whereas outcome can be favorable if the agenesis of the corpus callosum is a truly isolated malformation.⁴⁸ However, subtle associated brain malformations can be impossible to detect on prenatal ultrasound.

Arrhinencephaly, or absence of the olfactory bulbs and tracts, is also considered in the midline defects although the pathogenesis may be quite distinct. Arrhinencephaly can be found as an isolated malformation or in conjunction with a variety of malformation syndromes. Clinically, bilateral arrhinencephaly manifests as anosmia. Although

arrhinencephaly is frequently included in the midline dysplasias and can represent a mild manifestation within the holoprosencephaly spectrum, it would be incorrect to conclude that every isolated case of arrhinencephaly belongs with this spectrum. Quite likely, arrhinencephaly can result from a number of independent mechanisms. One example of a non-holoprosencephaly-sequence syndrome associated with arrhinencephaly is Kallmann syndrome. This syndrome is characterized by a combination of arrhinencephaly resulting in anosmia with hypogonadotropic hypogonadism, resulting from gonadotropin-releasing hormone (GnRH) deficiency.⁴⁹ Other neurological features may be associated. The syndrome can be inherited in an autosomal dominant, recessive, or X-linked recessive pattern. The gene for the X-linked form has been identified. It shares homology with neural cell adhesion molecules, and the developmental defect has been linked to the failure of GnRH producing neurons to reach the hypothalamus.⁴⁹

NEURONAL MIGRATION DEFECTS

PATHOGENESIS AND PATHOPHYSIOLOGY. Anomalous cerebral cortical development is generally characterized as a cortical migrational abnormality, although an actual defect in migration has only been conclusively demonstrated for a relatively few disorders. Recently Rorke⁵⁰ has hypothesized a variety of factors that must be considered in the pathogenesis of cortical migrational abnormalities. Among the various components of development, cellular proliferation, cell death, postmigrational intracortical growth and development, and extracellular matrix abnormalities can each be implicated as a possible pathogenetic mechanism.

The human cerebral cortical malformations classified as disorders of neuronal migration include the lissencephaly/pachygyria/subcortical band heterotopia spectrum, periventricular nodular heterotopia, and polymicrogyria. The lissencephalies and periventricular nodular heterotopia clearly represent cell migration defects. However, other malformations, such as polymicrogyria, have pathogeneses yet to be elucidated. Because the classification relies more on pathogenic mechanisms than on clinical grounds, these divisions are presented in this section.

Lissencephaly

Lissencephaly was derived from the Greek words “lissos” (smooth) and “encephalos” (brain), and describes the smooth appearance of an agyric brain. Microscopic examination of the cerebral cortex is variable, but the normal six-layer cytoarchitecture is absent in all cases. Lissencephaly has become the paradigm of a neuronal migration disorder.

Classical Lissencephaly (Type I)

Classical lissencephaly, also known as type I lissencephaly in the pathology literature, is a malformation in which the surface of the brain is completely, or nearly completely, devoid of gyri and sulci (Fig. 28-5). Macroscopically the malformation spectrum ranges from agyria and pachygyria

to subcortical band heterotopia with a relatively normal gyral pattern.⁵¹ Histologically classical lissencephaly reveals a four-layered cortex replacing the normal six-layered ribbon.⁴⁹ The outermost layer is the molecular layer (layer 1), layer 2 is a band of pyramidal neurons, layer 3 is composed of myelinated fibers and fewer neurons. This layer can be seen by neuroimaging. Finally, layer 4 is composed of a broad band of disorganized neurons. More recently additional patterns other than these four layers have been identified and correlated with specific mutations.⁵² The white matter occasionally contains gray matter heterotopia. Anomalies of the inferior olivary nucleus, cerebellum, and the corticospinal tracts may also be present.

Classical lissencephaly due to deletions or mutations of the LIS1 gene on chromosome 17p13.3 is found in the Miller-Dieker syndrome (MDS) and isolated lissencephaly sequence (ILS). MDS is a contiguous gene syndrome and is due to deletions of chromosome 17p13.3 involving the LIS1 gene and presumably other specific genes at this chromosomal locus including 14–3-3c.⁵³ Patients have distinct facial features and may have other associated congenital anomalies, such as omphaloceles or cardiac anomalies. In contrast, ILS is associated with small deletions or intragenic mutations of LIS1.

Patients with MDS usually have lissencephaly at the severe end of the spectrum with complete agyria. In ILS the cortical malformation ranges between agyria and pachygyria. The cortical malformation with a LIS1 abnormality is more severe posteriorly,⁵⁴ whereas patients with lissencephaly and DCX mutations show a more severe involvement of the frontal lobes (see discussion in the next paragraph). The overall severity of the lissencephaly in ILS appears to be related to the type and location of the mutation.

Mutations in the DCX gene located on the X chromosome are associated with subcortical laminar heterotopia, also known as “double cortex,” in females.^{55,56} The assumed mechanism for this anomaly is explained by the normal and random X-inactivation that occurs in females. When the chromosome carrying the mutated copy of DCX is inactivated, that cell will presumably behave like a normal cell and migrate to the cortical plate. In contrast, if the chromosome with the normal copy of DCX is inactivated, only the mutant allele will be expressed. Thus, two populations of cells exist in the ventricular zone. Those cells expressing the mutant allele become localized in the white matter forming a band of heterotopic neurons, whereas the cells expressing the normal copy migrate to form the cortical plate in the normal location. Males with DCX usually have classical lissencephaly, but have also presented with subcortical laminar heterotopia. Both the type of mutation and somatic mosaicism have been associated with this milder phenotype in males. In pedigrees in which females have subcortical laminar heterotopia and males lissencephaly, a DCX mutation has so far always been identified. In females with sporadic subcortical laminar heterotopia the figures vary, but in those with bilateral diffuse bands, or thin frontal bands only, the mutation rate appears to be high.

Other Lissencephaly Syndromes

Several other syndromes with lissencephaly as a component have been identified (see www.geneclinics.org).

Figure 28-5. Lissencephaly type I and type II. **A**, A brain from an 8-month-old infant with Walker-Warburg syndrome demonstrating type II lissencephaly. Note the smooth surface of the brain; slight irregularities of the cortical surface can best be appreciated in areas of light reflection on the specimen. **B**, A coronal section stained for myelin that demonstrates the four layers of type I lissencephaly (e.g., the Miller-Dieker syndrome): 1 corresponds to the molecular layer, 2 is a cellular layer with mostly large neurons, 3 is a layer containing myelinated fibers, and 4 is a broad heterogeneous cell-rich layer. Note that the cortical plate takes up more than half of the total thickness of the cerebral mantle. **C**, A histological section through the cerebral mantle of a 20-week gestational age fetus with Walker-Warburg syndrome. One half of the thickness of this section is taken up by the totally disorganized cortical plates (*white bar*). In addition there are subcortical heterotopias pointed out by the arrows. **D**, Age-matched control. Here the cortical plate (*white bar*) takes up only a fraction of the whole thickness of the mantle. **E**, A T₂-weighted coronal MR image of type I lissencephaly.

The best characterized of these is lissencephaly with cerebellar hypoplasia. Recently linkage to RELN was found in two consanguineous pedigrees. The similarity of the brain defects to those seen in the Reeler mouse made this a suitable candidate gene. Further studies identified distinct RELN splicing mutations in each family.⁵⁷ To date the pathology of the lissencephaly and cerebellar hypoplasia has not been reported in a patient with a known RELN mutation. However, this does suggest that other genes in the RELN pathway are good candidates for lissencephaly with cerebellar hypoplasia and related disorders. Additional variants of lissencephaly have been identified radiographically and pathologically; the genetic bases for these have not yet been delineated.

X-linked lissencephaly with ambiguous genitalia (XLAG) has also been genetically characterized as mutation in ARX.⁵⁸ These males have the most severe phenotype and often exhibit severe epilepsy and do not live past the neonatal period. Heterozygous females may have agenesis

of the corpus callosum. Interestingly, other mutations in ARX result in various neurological defects including infantile spasms, mental retardation, and autism.⁵⁹

Cobblestone Lissencephaly (Type II)

Cobblestone lissencephaly, also known as type II lissencephaly in the pathology literature, is also referred to as “cobblestone cortex.” It occurs in a group of disorders associated with congenital muscular dystrophy and eye abnormalities. The Walker-Warburg syndrome, muscle-eye-brain disease, and Fukuyama congenital muscular dystrophy are entities within this group and appear to be autosomal recessive. In contrast to classical lissencephaly in which there is a slowing or delay in cell migration, the pathogenesis of cobblestone lissencephaly is believed to be an overmigration. Disruption of the pial-glial limitans results in cells migrating past the cortical plate proper and into the leptomeninges, forming a rind of neurons

admixed with the leptomeninges over the surface of the brain (see Fig. 28-5). All the cobblestone lissencephalies appear to be related to *O*-mannosyl glycosylation defects specifically of α -dystroglycan, an extracellular matrix receptor expressed both in skeletal muscle and in the CNS.^{60,61} Agenesis of the corpus colosum, hindbrain deformities including a small pons, cerebellar hypodysplasia, and Dandy-Walker malformation are also frequently associated with this spectrum of disorders. Neuroimaging can identify these cerebral malformations, as well as pachygyria and polymicrogyria, white matter abnormalities, hydrocephalus, and posterior cephaloceles.⁶² It has now become apparent that the following condition forms a continuous spectrum of disorders involving the brain, skeletal muscle and less consistently the eyes. Mutations in fukutin related protein (FKRP) are capable of underlying the entire spectrum of phenotypes.⁶³

Walker-Warburg syndrome is the most severe of these disorders. The eye abnormalities include microphthalmia, cataracts, glaucoma, and retinal dysplasia. A congenital muscular dystrophy is also a constant finding. Prognosis is usually poor with death within the first few years of life. The surface of the brain shows smooth and nodular areas, appearing like a cobblestone street. In cross section, the cortical band is thickened but not to the same extent as in classical lissencephaly. The six-layer cerebral cortex is replaced with two broad bands of neurons. The outer band is a disorganized collection of neurons, glia, collagen bundles, and blood vessels. The inner layer is a disorganized collection of neurons thought to be the remnant of the true cortical plate. The pial-gliar limitans appears disrupted at multiple points and can usually be found between these two disorganized layers of gray matter. The original genes identified in this condition are the *O*-mannosyltransferases POMT1 and POMT2.

Muscle-eye-brain disease of Santavouri, most commonly reported in the Finnish population, is generally milder than Walker-Warburg syndrome, with a longer survival time. Eye abnormalities can be similar to Walker-Warburg syndrome, with myopia being the most consistent feature. It is also associated with a muscular dystrophy (Video 99, Gower's Sign). Muscle-eye-brain disease has been linked to 1p32-34 in Finnish patients and the original gene identified as an enzyme involved in Golgi-based *O*-linked glycosylation (protein *O*-mannose beta-1,2-*N*-acetylglucosaminyltransferase POMTn1).⁶⁴

Fukuyama congenital muscular dystrophy is another disorder with some features that resemble Walker-Warburg syndrome and muscle-eye-brain disease; however, the involvement of the eye and brain is less severe, compared to Walker-Warburg syndrome in particular. Patients show psychomotor deficits and progressive loss of muscle function. Linkage to chromosome 9q31 was established in Japan, where it is common; subsequently a novel gene was identified encoding the protein now named fukutin.⁶⁵ Fukutin also appears to have a role in *O*-mannosyl glycosylation, so that the defects in CNS development and in muscle must be related to faulty glycosylation of specific muscle and brain proteins such as α -dystroglycan in particular. Fukuyama congenital muscular dystrophy is extremely rare outside Japan. Interestingly, an ancient 3'UTR retrotransposon insertion, yielding reduced but intact

mRNA expression, has been identified as the molecular basis for many of the Japanese cases.⁶⁵ Others within Japan and elsewhere may have mutations affecting the coding region, then presenting as Walker-Warburg syndrome.

Periventricular Nodular Heterotopia

Heterotopia are ectopic collections of neurons. The pathogenesis of heterotopia located in the cerebral white matter is believed to be a failure of neurons to migrate to the cortical plate. They may occur as single lesions adjacent to the ventricle or in the more superficial white matter. In some cases, there are multiple nodules lining the ventricles. This latter entity is known as periventricular nodular heterotopia (PVNH). Microscopic examination shows that many neurons remain in the ventricular zone and accumulate as nodules lining the ventricular surface.

Studies of families with women who have PVNH associated with epilepsy and pregnancy loss consistent with lethality in males pointed toward a PVNH locus on the X chromosome. Linkage was found to Xq28 in a number of families, and subsequently mutations in the gene coding for the actin crosslinking protein filamin 1 or filamin A (FLN1), were identified in patients with PVNH.⁶⁶ The majority of patients with FLN1 mutations have diffuse continuous heterotopia around the lateral ventricles, but the cortex appears relatively normal. One of the mechanisms explaining the phenotype of PVNH in females is random X-inactivation resulting in two populations of neurons, those expressing the mutant allele, which presumably reside in the periventricular region as heterotopia and those that express the normal allele and migrate out to the cortical plate. A recessive PVNH locus has been identified more recently, caused by mutations in the gene ARFGEF2 on chromosome 20, in this case often associated with microcephaly.⁶⁷

Single or multiple heterotopia are collections of disorganized gray matter in inappropriate locations (Fig. 28-6). Heterotopia in the cerebral hemispheres, other than the subcortical band heterotopia and bilateral periventricular heterotopia described previously, can take on one of many patterns. They may occur as focal, isolated anomalies found incidentally upon imaging or at autopsy, or they may have clinical manifestations as described following. Occasionally an isolated heterotopian or multifocal cerebral heterotopia is associated with an overlying cortical malformation such as polymicrogyria.⁶⁸ In addition to white matter heterotopia, glial and neuroglial heterotopia are often found in the leptomeninges overlying a cortical anomaly or around the base of the brain. The displaced tissue can form a radiographically and grossly identifiable plaque over the surface of the brain.

Polymicrogyria and Other Disorders of Cortical Development

Polymicrogyria is frequently recognized as a fine stubbling on the surface of the brain (described as "Moroccan leather" in appearance). By MRI and gross examination of brain sections, the cerebral cortex shows a complex set of small gyri that appear fused to each other. Microscopic

Figure 28-6. Periventricular nodular heterotopia. A, MRI from a patient with extensive periventricular heterotopia. The heterotopia are the same signal intensity as the cerebral cortex and scallop the margin of the ventricular surface. (Courtesy of Dr. C. Walsh.) Histological sections from a normal fetus at 20 weeks' gestation (B) and from a similar age fetus with periventricular heterotopia (C). The germinal tissue normal present around the angle of the lateral ventricle is replaced by several nodules of maturing gray matter (heterotopia).

examination confirms the gross impression, highlighting the small complex gyri and fusion of layer 1. Controversy exists as to whether polymicrogyria is a malformation or a disruption of development. The answer is likely that both mechanisms are involved in different forms of polymicrogyria. Given that polymicrogyria is almost always present at the margins of disruptions such as porencephaly and in the setting of malformation such as Zellweger's syndrome and triploidy, the conclusion often drawn is that polymicrogyria has multiple pathogeneses. The identification of mutations in GPR56, a G-coupled receptor, in bilateral frontoparietal polymicrogyria lends further support to the genetic basis in some cases.⁶⁹ Additional genetic loci almost certainly exist, in particular for the more common perisylvian form, for which X-linked inheritance has been described.⁷⁰ Although there are certain microscopic differences depending on whether the polymicrogyria is caused by disruption or malformation, there still exists some overlap in the microscopic features of polymicrogyria regardless of the presumed pathogenesis. Unlike lissencephaly/pachygyria, the border between polymicrogyria and normal cortex is quite distinct and layer 6 in adjacent normal cortex and the deepest layers of the malformed polymicrogyric cortex are contiguous (Fig. 28-7). Based on the pathological features of polymicrogyria, the timing is later in neocortical development, generally believed to arise from defects occurring between 17 to 18 weeks' and 24 to 26 weeks' gestation.

Focal cortical dysplasias or cortical migrational anomalies are another group of anomalies of cerebral cortical development that are being recognized with increasing frequency (Fig. 28-8). The increasing practice of surgery in the management of intractable seizures has resulted in the recognition of a variety of cortical malformations in a significant number of cases. Although polymicrogyria and pachygyria have been seen in many cases, the most frequent anomaly has been labeled focal cortical dysplasia. This disorder is characterized by a disruption in the lamination

pattern and maloriented neurons in inappropriate layers including layer 1 and in the cerebral white matter.⁷¹ The pathogenesis remains unknown.

EPIDEMIOLOGY AND RISK FACTORS. The incidence of neuronal migrational abnormalities disorders is unknown. Most of the cortical migrational disorders, particularly the diffuse ones, show a variety of inheritance patterns.⁶² Other cases show no clear inheritance and appear to be sporadic. A variety of environmental risk factors have been associated with the development of neuronal migrational disorders, including retinoic acids, methylmercury, and radiation. In utero infections, particularly viral, are also known to result in cortical migrational abnormalities. The pathogenesis for viral-induced migrational disorders remains unknown, although a destructive process is speculated to underlie the defect.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. The most striking clinical context in which type I lissencephaly is seen is the Miller-Dieker syndrome. Classical facial features include bitemporal hollowing, a rather short nose with a broad bridge and upturned nares, long and thin upper lip, small chin, and mildly low-set and posteriorly rotated ears. Although this constellation is referred to as the Miller-Dieker facial dysmorphism, the findings can be rather subtle. Most individuals with type I lissencephaly present in the neonatal period with marked hypotonia. Later, a spastic quadriplegia will dominate the picture. Seizures are a constant part of the clinical picture; they can start as neonatal seizures, but more commonly present as infantile spasms with myoclonic and tonic seizures, that later lead into a Lennox-Gastaut syndrome with the additional occurrence of atonic seizures. The electroencephalogram (EEG) typically shows fast α - and β -activity admixed with high-amplitude slow activity. Mental and psychomotor retardation are usually profound. Cardiac anomalies occur in 20% to 25%, and there can be genital anomalies in about 70% of males.

Figure 28-7. Polymicrogyria. The border of polymicrogyria and normal cortex. The border is extremely well delineated. The polymicrogyria is characterized by fusion of layer 1, continuity of layer 4, and extensive undulating folds of cerebral cortex.

Type II lissencephaly occurs in a group of disorders associated with congenital muscular dystrophy, often involving the eyes as well. The Walker-Warburg syndrome, muscle-eye-brain disease, and Fukuyama muscular dystrophy are entities within this group, but they are best viewed as a continuous spectrum of severities.⁶¹

Walker-Warburg syndrome represents the most severe form of these disorders with a high proportion of neonatal fatality. The brain malformation often is complex with associated hydrocephalus, cerebellar hypoplasia (and occasionally Dandy-Walker malformation), and sometimes an occipital encephalocele. Clinically Walker-Warburg syndrome is characterized by profound hypotonia in the neonatal period due to the combined muscle and CNS involvement. The eyes can be affected in a number of ways, most frequently by retinal dysplasia, although anterior chamber malformations, cataracts, choroidal colobomata, optic nerve hypoplasia, and microphthalmia can all occur. Serum creatine kinase (CK) levels are elevated. Arthrogryposis may be present, and additional contractures may develop later.

Muscle-eye-brain disease of Santavouri has many features that resemble Walker-Warburg syndrome but is milder. The disorder is most prevalent in Finland⁷² but clearly occurs worldwide. This condition also presents at birth or during the first few months of life with hypotonia and weakness. Serum CK levels are consistently elevated after 1 year of age and often earlier. Subsequent psychomotor development is markedly delayed; however, many patients will acquire the ability to stand and walk. Mental retardation and seizures are common. The EEG is usually abnormal and progressively so after about 6 to 7 years of age. Most patients show a progressive motor deterioration, confounded by increasing spasticity and contractures by 5 years of age. The eye abnormalities consist of high myopia, retinal degeneration, and optic atrophy. Congenital glaucoma and juvenile cataracts may also be present. The visual evoked potentials tend to be progressively delayed and of abnormally high amplitude with an abolished ERG

Figure 28-8. Focal cortical dysplasia. A horizontal MRI from a patient with focal cortical dysplasia. The left hemisphere shows a normal cortical ribbon; however, in the left hemisphere posterior frontal lobe, the cortical ribbon is abnormally thickened and the sulcal pattern is lost. The underlying white matter may be slightly thin.

at the same time. Neuroimaging often reveals less severe, but comparable findings of muscle-eye-brain disease to Walker-Warburg syndrome. A small pons and cerebellar malformation are a fairly consistent finding. Hydrocephalus is relatively frequent, and patchy white matter involvement may be detected on T₂-weighted MRI especially early on.

Fukuyama congenital muscular dystrophy is the second most common muscular dystrophy in Japan⁷³; only Duchenne muscular dystrophy is identified more frequently. It appears to be extremely rare outside Japan, although similarities to the other conditions are obvious. In contrast to muscle-eye-brain disease and Walker-Warburg syndrome, eye involvement is generally less frequent and less severe. When present, ocular findings include myopia and optic atrophy. Patients show considerable psychomotor retardation and progressive muscular weakness and contractures. Seizures occur in about 50% of cases. MRI of the brain demonstrates the areas of pachygyria as well as polymicrogyria. Areas of abnormal T₂ signal on MRI can be seen in the white matter. The cerebellum is only mildly affected and hydrocephalus is rare.

Polymicrogyria has a less heterogeneous clinical presentation than lissencephaly. For all practical purposes, the different forms of polymicrogyria, independent of their syndromic or etiological context, present with seizures and potentially also mental retardation, depending on the extent of the abnormality. Perisylvian polymicrogyria may present with pronounced oromotor discoordination (developmental Foix-Chavany-Marie syndrome). The various syndromic associations of polymicrogyria are discussed later under Differential Diagnosis.

Heterotopia can be sporadic, inherited as a simple mendelian trait, or may be part of a more complex syndrome. When in isolation, the main presenting feature is seizures of various kinds, but they are by no means obligatory. Onset of the seizures can be from childhood (most commonly) to adulthood. Focal, multifocal, and generalized seizures can occur, with infantile spasms and the Lennox-Gastaut syndrome seen at the severe end of that spectrum. Other neurological problems such as motor impairments and mental retardation may coexist, especially if microcephaly is present as well. The risk for these additional manifestations is lowest when the abnormality is localized to the periventricular region, higher in the white matter heterotopia, and highest in the diffuse subcortical band heterotopia. However, even in the latter condition quite normal psychomotor development can be seen, although infrequently.

The initial presentation of cortical dysplasia is most commonly the onset of various types of seizures. With this presentation there are no clear signs or symptoms that would predict a cortical dysplasia versus another cortical lesion. The age of seizure onset tends to be in childhood, but can be delayed into adulthood or can be as early as infancy.⁷⁴ When presenting in infancy, the clinical picture can vary from clearly focal appearing seizures to infantile spasm with relatively minimal or no focal clinical or EEG features. Later, the seizures may also include tonic seizures as well as drop attacks. Onset during the first few days of life as an early infantile epileptic encephalopathy has also been described.⁷⁵ EEG findings can be quite variable.^{74,76}

DIFFERENTIAL DIAGNOSIS. Among the conditions with lissencephaly type I, the Miller-Dieker phenotype is distinguished from ILS by the lack of distinctive facial features in the latter. However, some degree of bitemporal hollowing and a small chin may be seen in ILS as well. Furthermore, FISH analysis has demonstrated microdeletions in a significant number of ILS cases.⁷⁷ However, other probes appear to distinguish the two entities, suggesting a difference in the physical extent of the deletions. Whether the obvious contiguous gene hypothesis, involving the loss of multiple adjacent genes, accounts for the additional anomalies in the Miller-Dieker syndrome awaits more detailed analysis of such genes (as shown for 14-3-3ε). Other cases of ILS could possibly result from mutations in other genes.

The differential diagnosis of the lissencephaly II syndromes can be quite difficult at times. These difficulties are reflected in the many essentially synonymous designations of these syndromes, including the muscle-eye-brain syndrome, HARD +/- E (hydrocephalus, agyria, retinal dysplasia, +/- encephalocele) and CODM (congenital ocular dysplasia/muscular dystrophy) syndromes, Walker-Warburg syndrome, and Fukuyama congenital muscular dystrophy, which vary in their degree of severity and involvement. However, they can now all be included in the genetically heterogeneous group of disorders of *O*-mannosyl glycosylation of mainly α -dystroglycan.⁶¹

Many other syndromes and associations may show variable forms of lissencephaly, pachygyria, and polymicrogyria as features, and many cases are not easily classified into any particular syndrome (Table 28-2).⁷⁸ Discussions of these rare disorders has recently been reviewed.⁶² A number of metabolic conditions can also be associated with pachygyria/lissencephaly. The most frequent syndrome to show such an association (along with polymicrogyria) is the Zellweger syndrome.⁷⁹ This is a disorder of peroxisomal biogenesis that is characterized by marked neonatal hypotonia, facial dysmorphism, wide-open fontanelles, and renal and hepatic abnormalities. Neonatal adrenoleukodystrophy and bifunctional enzyme deficiency are also peroxisomal disorders that may show migrational abnormalities. Glutariaciduria type II, pyruvate dehydrogenase deficiency, non-ketotic hyperglycemia, and sulfite oxidase deficiency/molybdenum cofactor deficiency are examples of other metabolic disorders that occasionally include cortical dysplasia as one of the manifesting features.

The differential diagnosis of conditions with polymicrogyria is extensive,^{61,62} reflecting the nonspecific nature of the malformation. In addition to the lissencephaly II conditions discussed already, Aicardi, Neu Laxova, Zellweger, and Smith-Lemli-Opitz syndromes could be mentioned as monogenic conditions. Polymicrogyria can also occur with a variety of chromosomal abnormalities. As outlined previously, disruptive and destructive disorders can have polymicrogyria associated with them. The most common association is with congenital cytomegalovirus (CMV), and the timing of this is probably similar to the disruptions of pencephaly and hydranencephaly. In fact, both of these disorders have been reported with congenital CMV infection as well as other congenital infections. Extensively fused

TABLE 28-2

Summary of Syndromes with Cortical Malformations*

| DISORDER | CEREBRUM | CEREBELLUM | HYDROCEPHALUS | EYE | MUSCLE | OTHER |
|-------------|----------|------------|---------------|-----|--------|-------|
| MDS | A | - | - | - | - | - |
| ILS | A | - | - | - | - | - |
| WWS | A,P,E | + DWS | + | + | + | + |
| MEB | A,P,E | + DWS | + | + | + | - |
| Fukuyama | A,P | + | +/- | +/- | + | - |
| NL | A,P | + | - | + | - | + |
| Zellweger's | A,P | + | - | - | - | + |
| NRS | A | + | - | - | - | - |

*Not a complete list.

A, agyria; DWS, Dandy-Walker malformation; E, encephalocele; ILS, isolated lissencephaly sequence; MDS, Miller-Dieker syndrome; MEB, muscle-eye-brain disease; NL, Neu-Laxova syndrome; NRS, Norman Roberts syndrome; P, pachygyria; WWS, Walker-Warburg syndrome.

polymicrogyria can be difficult to differentiate from pachygyria on imaging.

Periventricular as well as subcortical band heterotopia can occur as X-linked inherited conditions, mapping to different regions on the X chromosome.⁸⁰ In familial band heterotopia, affected females present with the heterotopia and often seizures, whereas affected males show a more severe brain malformation, including lissencephaly. This may be due to random X-inactivation in females preventing full expression of the defect, and also raises the possibility that a spectrum of developmental disturbances, from focal heterotopia to lissencephaly, exists with a common pathogenesis.^{77,81,82} In familial periventricular heterotopia affected male family members also have a more severe malformation and clinical phenotype than affected female siblings.⁸² Recessive periventricular heterotopia may be associated with microcephaly.⁶⁷ Again, a number of syndromes include neuronal heterotopia with some regularity. For example, in Aicardi syndrome heterotopia are as constant a feature as agenesis or hypoplasia of the corpus callosum. Retinal lacunae, cerebellar abnormalities, and hemivertebrae may also be found in this syndrome. Aicardi syndrome is probably an X-linked dominant male lethal condition, so that only girls are affected clinically. The presentation includes severe early seizures (infantile spasms) and profound psychomotor retardation. The list of metabolic conditions associated with polymicrogyria includes the peroxisomal disorders as well as Smith-Lemli-Opitz syndrome, an inborn error of cholesterol metabolism diagnosed by demonstrating an elevated level of plasma 7-dehydrocholesterol.

Polymicrogyria and focal cortical dysplasia can be difficult to differentiate because of the similar clinical presentation with seizures. Imaging is the mainstay of diagnosis (see discussion in the Evaluation section). The so-called “benign focal epilepsies of childhood” are important to differentiate from “fixed” cortical malformations, because the prognosis and management are different.

EVALUATION. The diagnosis of the Miller-Dieker syndrome and also the isolated lissencephaly sequence is based on the finding of a smooth brain surface with widely open sylvian fissures on neuroimaging studies, an appearance that has been referred to as the figure 8 sign. The broad cortex in relation to the extremely narrow white matter can be seen on MRI. Cytogenetically visible deletions of the critical chromosomal region 17p13.3 are seen in about two thirds of clinically convincing cases.⁷⁷ More than 90% of cases show loss of this critical region when FISH analysis is employed.

Cobblestone (type II) lissencephaly has an appreciably different MRI appearance, with a gray-to-white matter ratio of 1:1. As for all of the other disorders of neuronal migration, careful evaluation of the morphology of the cortex by MRI is essential. In cases of cobblestone lissencephaly/pachygyria, especially in the presence of associated CNS malformations or abnormalities of the eyes, the group of congenital muscular dystrophies with eye and brain involvement has to be considered. Determination of serum CK levels and muscle biopsy may become necessary. Once the diagnosis of a congenital muscular dystrophy with structural brain abnormalities has been made, the differential diagnosis between the individual conditions should

follow the preceding considerations. Prenatal diagnosis of the Walker-Warburg syndrome by ultrasound is possible, though not always easy. The posterior fossa anomalies and demonstration of retinal detachment are helpful.

The workup for focal cortical abnormalities of migration also relies heavily on extremely high-quality MRI, as some of these lesions can be very hard to detect. Clinical suspicion must remain high and hints, such as delayed myelination in a cortical region, may be valuable in defining the location of the abnormality. The value of functional imaging techniques such as positron-emission tomography, single-photon emission computed tomography, and perfusion-diffusion MRI at this point cannot be generalized. These techniques are under active development. Several special MRI techniques, such as three-dimensional (3D) surface rendering, are being evaluated for this purpose and also appear quite promising. At a minimum, high-resolution imaging with thin cuts and optimal gray to white matter resolution for the age of the patient is essential. On EEG, focal very high amplitude rhythmic activity is quite characteristic of cortical dysplasias; however, it is recorded in less than half of the cases. Other EEG patterns, such as focal abnormal fast activity, have no particularly predictive value for a focal dysplasia. At times the surface EEG can be quite normal or appear to show primary generalized spike and wave discharges. An additional important diagnostic problem is the question whether the underlying lesion is unifocal or multifocal. Multifocal discharges on the EEG do not necessarily mean multifocality of the dysplasias, though they certainly can. Conversely, electrographic evidence for only one focus does not exclude the existence of additional foci. Long-term videotelemetry monitoring may be helpful in evaluating these questions. In cases in which seizures are resistant to medical management and there is a high degree of suspicion for a focal cortical abnormality but lack of noninvasive evidence, intraoperative electrophysiology may prove useful. Guided by this approach, resected pathological material will often show features of cortical dysplasia.

MANAGEMENT AND PROGNOSIS. In general, the prognosis for patients with Miller-Dieker syndrome and the Walker-Warburg syndrome is very poor and many patients do not survive infancy. Very little psychomotor development, if any, takes place. Insertion of a gastric tube may be necessary to provide adequate nutrition, prevent aspiration, and facilitate care. Treatment of the frequently prominent seizures follows general guidelines. Whereas most cases have poor outcome, milder cases are on record for both syndromes.

In the congenital muscular dystrophies with structural brain abnormalities the brain malformation may require surgical intervention for the hydrocephalus or sometimes for the encephalocele in the Walker-Warburg syndrome. If the hydrocephalus is due to aqueductal stenosis and a Dandy-Walker anomaly is present, shunting of both the lateral ventricles and the posterior fossa cyst may become necessary. The prognosis is better in muscle-eye-brain disease, and although patients often acquire the ability to walk, there may be secondary deterioration because of increasing spasticity. In this condition, the ophthalmological management becomes very important: high myopia, cataracts, glaucoma, and retinal detachment may all require intervention.

Because the resulting epileptic syndrome in disorders of neuronal migration is frequently medically intractable, surgical extirpation of the lesion is often desirable, and earlier surgical intervention may improve the overall developmental prognosis by preventing the development of an epileptic encephalopathy. For an isolated focus of polymicrogyria or cortical dysplasia presenting with intractable seizures, extirpation can be a curative option; however, multifocality is not an automatic contraindication against the surgery, because extirpation of a major focus may result in overall improvement of seizure control. The pre-surgical and intraoperative evaluation is essential for success of the surgery and is dealt with in detail by Wyllie.⁸³ For isolated epileptogenic heterotopias, surgical excision also is an option, whereas the drop attacks that can be seen in the diffuse bilateral band heterotopias may respond to callosotomy.⁸⁴

Other Disorders of Neuronal Migration and Cortical Formation

Ulegyria is another distinct cortical anomaly. It is best characterized as a fusion of layer 1 at the depths of sulci with relative sparing of the crests of the gyri. The fusion is frequently associated with gliosis in the cortex, neuronal loss, and obliteration of the cortical lamination. The scarring at the depth of a sulcus and sparing at the surface of the brain results in a mushroom appearance when the gyrus is viewed on cross section. These lesions have very well-defined borders and discrete islands of preserved neurons within the lesion. The histology and location, frequently in an arterial zone, has led to the contention that ulegyria arises late in gestation or in early neonatal life as a vascular injury to the immature cortex, possibly related to a hypoperfusion. Ulegyria may be clinically silent or cause seizures similar to polymicrogyria discussed previously.

Megalencephaly, or an enlarged brain volume, can be sporadic, autosomal dominant, autosomal recessive, or part of a recognized syndrome or disease (Table 28-3).⁷ In generalized megalencephaly, a diffuse broadening of the cerebral gyri, an increased white matter and grey matter volume, and frequently normal sized ventricles occur. The brain is usually microscopically normal, although several reports have suggested an increased cell volume. In the familial megalencephaly with autosomal dominant inheritance, the majority of cases are neurologically normal. Hydrocephalus and extracerebral fluid collections have to be ruled out by imaging in all cases.

Hemimegalencephaly (Fig. 28-9) may occur in isolation or be associated with a specific syndrome, the most widely recognized of which are the Beckwith-Wiedemann syndrome and the linear sebaceous nevus syndrome. The abnormally large cerebral hemisphere shows regions of broad and fused gyri. Cross sections of the hemispheres reveal regions of thickened cerebral cortex and frequently heterotopia in the cerebral white matter. Microscopically the hemisphere shows marked disorganization with regions resembling pachygyria. In other regions the neurons of the malformed cortex are abnormally spaced and disorganized in orientation. The clinical presentation of hemimegalencephaly is quite variable.⁸⁵ One clue to the possible

Metabolic Disorders

Alexander disease
Canavan disease (N-acetylaspartoacylase deficiency)
GM₁ and GM₂ gangliosidosis
Glutaricaciduria type 1

Other Associations

Achondroplasia
Agenesis of the corpus callosum

existence of hemimegalencephaly is the identification of body asymmetries, especially of the skull and face, or the recognition of other features of a syndrome associated with hemihypertrophy. Most patients with hemihypertrophy present during the first year of life with frequent, focal seizures or infantile spasms. Some infants show asymmetries of motor development that can be subtle or present as frank hemiparesis. The EEG is variable, showing a fast rhythmic pattern in the alpha to beta range, burst-suppression patterns, spike-wave, or repetitive triphasic complexes. Some authors assign a poor prognosis to repetitive triphasic complexes. Mental retardation is frequently associated with hemimegalencephaly and appears to be primarily correlated with the severity of the epilepsy. Patients with normal development and intelligence and well-controlled partial seizures have been reported. The association of hemimegalencephaly with Wilms' tumor of the kidney is important to recognize. Given the difficulties of medical seizure control in the majority of cases and the adverse effects that ongoing seizures potentially have for developmental outcome, early modified hemispherectomy has been repeatedly advocated and successfully performed in these children.⁸⁶

Microcephaly is defined by the head circumference being two standard deviations (SD) below that predicted by the body size. This definition does not provide any indication of the nature of the brain abnormality. The etiology of microcephaly is complex (Table 28-4) and includes conditions that restrict brain growth (such as the craniosynostosis), destroy formed brain substance before completion of brain growth (e.g., hypoxic-ischemic insults and some infections), or intrinsically impair brain growth. The latter

Figure 28-9. Hemimegalencephaly. A horizontal T₂-weighted MRI demonstrates the moderately larger right hemisphere compared to the left. The cerebral cortex is poorly defined on the right side and the T₂ imaging highlights the abnormal signal intensity of the cerebral white matter on the same side.

can be the result of a metabolic insult (exogenous or inborn) or a defect within the developmental process of brain formation itself (as is assumed to be the case in the “primary” genetic microcephalies, the chromosome breakage syndromes, and the majority of syndromes associated with microcephaly). It should be kept in mind that a small head circumference at birth does not rule out metabolic conditions, nor does a normal head circumference at birth rule out primary genetic causes of microcephaly. Microcephaly is a manifestation of many syndromes and is very common in syndromes that have mental retardation and cortical migration abnormalities as a component. Jones²¹ compiled 39 syndromes with microcephaly as a frequent component and an additional 21 syndromes associated occasionally with microcephaly. One hundred and seventy-six syndromes have been reported with at least one case of documented microcephaly.¹⁷ Patients who appear to have a “primary” form of significant microcephaly, meaning not associated with other malformative features, are sometimes referred to as having microcephalia vera. This heterogeneous condition (autosomal recessive and X-linked forms have been identified) shows a striking reduction of head circumference of more than 3 SD below the mean. Six recessive genetic loci are known, two genes have been identified so far, including microcephalin (MCPH1) and the more common ASPM.⁸⁷ There is no facial dysmorphism associated. Other forms are classified morphologically based

TABLE 28-4

Various Conditions Associated with Microcephaly

Primary Small Brain Size

Nongenetic insults (pre-, peri-, postnatal)

- Infectious
- Vascular disruption, hypoxic-ischemic insult
- Irradiation
- Toxins and teratogens
- Malnutrition
- Metabolic
- Trauma (including shaken baby)

Genetic conditions

- Chromosomal disorders (e.g., trisomy 21, trisomy 13, 5p- [cri du chat] syndrome)
- Metabolic and degenerative conditions with onset before completion of brain growth (e.g., phenylketonuria, Smith Lemli-Opitz syndrome, infantile neuronal ceroid lipofuscinosis)
- Chromosomal instability and premature aging disorders (e.g., Bloom syndrome, Cockayne syndrome, Nijmegen breakage syndrome)
- Monogenic or sporadic “syndromic” disorders (e.g., Cornelia de Lange syndrome, Meckel syndrome, Rubinstein-Taybi syndrome; also microcephalia vera (MCPH1–6) and microcephaly “plus”)

Restriction of Brain Growth

Disorders of bone and cartilage

- Nongenetic (endocrinopathies)
- Genetic (craniosynostosis, skeletal dysplasias)

External restriction of skull growth in utero

on the degree of associated cortical (such as pachygyria) and hindbrain (such as cerebellar hypoplasia) abnormalities. Individuals with striking microcephaly may be significantly mentally retarded and have no recognizable speech, but are often described as having a relatively preserved personality. Although these patients often have a somewhat lumbering gait, there is a paucity of other neurological findings. Skull films at birth show the sutures to be present. The brains are usually quite small, less than 300 g (normal, 1200 to 1500 g), and show a primitive appearing gyral pattern. In some cases the cortex is thickened and disorganized without clear lamination. Isolated microcephaly can also be transmitted as an autosomal dominant trait. In this condition the degree of microcephaly usually is not as pronounced, and intelligence is relatively preserved. Given the preponderance of genetic conditions presenting with isolated microcephaly, Tolmie and colleagues⁸⁸ calculated an empirical recurrence risk of 19% after a single affected proband.

POSTERIOR FOSSA ANOMALIES

PATHOGENESIS AND PATHOPHYSIOLOGY. The development of the brain stem and cerebellum has been extensively investigated at the anatomic, cellular, and molecular levels.⁴³ The cerebellum is entirely derived from the rhombic lip, a dorsal ridge of the developing neural tube located at the junction between the midbrain and hindbrain (rhombencephalon). Proliferation and migration at the rhombic lip results in caudal growth of the cerebellar anlagen, resulting in the cerebellum forming the roof of the fourth ventricle. Complete aplasia of the cerebellum is an extremely rare condition and most cases are believed to represent secondary disruptions of normal development, primarily on a vascular basis. Cerebellar hypoplasia on the

other hand is more common and diverse in its etiology. Single gene disorders are emerging for cerebellar hypoplasia, such as an X-linked form with mental retardation caused by mutations in the gene *oligophrenin*.⁸⁹

In the 1890s Chiari described a group of malformations of the posterior fossa, each characterized by a displacement of the cerebellum.⁹⁰ Chiari II malformations, also known as the Arnold-Chiari malformation, have been described previously in this chapter (see Neural Tube Defects). Chiari I malformations are distinguished from Chiari II malformations by the displacement of the cerebellar tonsils (as opposed to the vermis in cases of the Chiari II malformation) over the cervical spinal cord (see Fig. 28-2). The Chiari I malformation is occasionally equated with herniation syndromes involving pressure coning and necrosis of the cerebellar tonsils. These two entities, however, should remain distinct, the Chiari I representing a malformation with resultant cerebellar displacement and the other entity the result of increased pressure within the posterior fossa. Occasionally hydromelia or syringomyelia may be associated with the Chiari I malformation, as with the Chiari II malformation; however, myelomeningoceles are not associated with Chiari I malformations.

The rare Chiari III malformation represents a displacement of the cerebellum into an occipital encephalocele. Occipital encephaloceles can involve either the occipital lobes of the cerebral hemispheres or the posterior fossa elements. As mentioned previously, encephaloceles involving the posterior fossa elements, and the cerebellum in particular, frequently carry a poor prognosis.

The Dandy-Walker malformation, by the strictest definition, includes a cystlike dilation of the fourth ventricle, an anteriorly rotated cerebellar vermis that is partially or completely absent, and an enlarged posterior fossa with an elevated tentorial insertion.⁹¹ The Dandy-Walker malformation is not a true cyst of the fourth ventricle, but a cystlike dilation of the ventricle resulting from the abnormally anteriorly rotated vermis and an extended posterior medullary vellum. This condition is extremely heterogeneous, in a subgroup of patients deletions of the zinc-finger transcription factors *ZIC1* and *ZIC4* were detected.⁹²

Joubert's syndrome is due to absence or partial absence of the cerebellar vermis, but this syndrome can be distinguished neuropathologically from the Dandy-Walker malformation by the absence of a cystically dilated fourth ventricle. Relatively few brains clinically diagnosed as Joubert's syndrome have been pathologically studied. One problem related to understanding the pathological findings in this syndrome is the difficulty of a clearly defining a clinical syndrome, as the diagnosis relies on MRI findings. Patients described as having Joubert's syndrome have shown a wide spectrum of clinical findings (see discussion later in the chapter), including variation among different families, suggesting possibly more than one etiology and clearly demonstrating genetic heterogeneity. Mutations in two genes have been identified in patients with Joubert, *AHI1* and *NPHP1*, the latter gene being associated with nephronophthisis.⁹³ At least two additional gene loci exist on chromosomes 9 and 11.

Möbius' syndrome involves focal deficits primarily involving cranial nerves VI and VII and can be unilateral or bilateral. Although disagreements exist as to the precise

definition of this syndrome, the presence of bilateral deficits of both cranial nerves VI and VII justify the designation. Whether unilateral deficits involving one or multiple cranial nerves should be included as cases of Möbius' syndrome remains controversial. Although very few cases have been studied pathologically, most data agree that destructive lesions, frequently assumed to be vascular in origin, are the basis for most cases of Möbius' syndrome. Whether congenital absence of cranial nerve nuclei exists as a distinct entity is unknown. The latter condition has been genetically linked to chromosome 3 in some families.

Several clinical syndromes are believed to result from a "miswiring" in the nervous system that is from the establishment of aberrant neural connections resulting from failure of certain connections to form or be maintained. Duane's syndrome is discussed later. Another example of this phenomenon is the Marcus Gunn phenomenon, in which patients present with a jaw-winking and elevation or drooping eyelids provoked by sucking in the infant, smiling, swallowing, or speaking. Usually this phenomenon becomes less pronounced with age. This syndrome is believed to result from misdirected neuronal connections between cranial nerves III and V and other cranial nerves.

EPIDEMIOLOGY AND RISK FACTORS. Given the diverse group of anomalies that afflict the posterior fossa, it is impossible to give a concise estimate for the incidence or prevalence of this group of disorders. Some of the anomalies are found in almost constant association with other malformations. For example, the Chiari II malformation (discussed with myelomeningoceles) is almost uniformly associated with lumbosacral neural tube closure defects and thus the incidence parallels the incidence of myelomeningoceles. Other anomalies, like the Dandy-Walker malformation, may be found either as an isolated malformation, in conjunction with other malformations (e.g., cardiovascular), or as part of a syndrome (e.g., Meckel-Gruber syndrome, Walker-Warburg syndrome). Risk factors also vary depending on the malformation in question. Möbius' syndrome, for example, is found more frequently among children born with congenital heart malformations than in isolation. Dandy-Walker malformations have been associated with maternal retinoic acid exposure and warfarin exposure. A complete discussion of the risk factors and associated syndromes involving the posterior fossa has recently been compiled.¹⁷

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Cerebellar hypoplasia and aplasia may present with any combination of hypotonia, motor delays, cognitive delays, ataxia and head/truncal titubations, irregularities of speech rhythm, and nystagmus. However, clinically asymptomatic cases of cerebellar hypoplasia or even aplasia are well documented in the older literature.

The Dandy-Walker malformation is clinically quite heterogeneous. In addition to cerebellar features, some cases exhibit other CNS abnormalities such as agenesis of the corpus callosum, brain stem anomalies, and migrational abnormalities that will have bearing on the clinical picture. Mental retardation is also variable and frequently correlates with the presence of associated anomalies. Patients without associated anomalies may have relatively normal intelligence and development.⁹⁴ The evaluation of an individual with the Dandy-Walker malformation therefore requires a

careful search for such associated abnormalities. Ataxia and brain stem dysfunction are often the presenting features and are believed to result from local pressure effects on the brain stem and cerebellum. Due to pressure fluctuations in the posterior fossa, these symptoms can occur intermittently. Presentation can be as late as in adulthood with headache and progressive neurological deterioration. Although hydrocephalus is often included in the definition of the Dandy-Walker malformation, it is often not present at birth, and may develop and present in the first year of life or later. Although occasionally a clear etiology for the hydrocephalus, such as aqueductal stenosis, is identified, in most cases there is no clear obstruction of CSF flow. Lack of patency of the foramen of Magendie and the foramina of Lushka, once considered the pathogenesis of the malformation, is rare and unlikely to be the etiology of the hydrocephalus in most cases.

Joubert's syndrome classically presents with abnormalities of respiratory rate control in infancy (in particular episodic tachypnea, but also respiratory pauses), rhythmic tongue protrusion, abnormal eye movements, ataxia, and mental retardation.^{95,96} Structural eye abnormalities such as chorioretinal colobomata have been described. The degree of developmental delay can be quite variable and is not uniformly as severe as initially thought. In variants of Joubert's syndrome there may be significant kidney involvement (nephronophthisis in NPHP1)

Chiari I malformation has a clinical spectrum that has broadened in recent years with the increasing use of MRI, the imaging modality of choice for the diagnosis of this condition. As opposed to the Chiari II malformation (see previous discussion of neural tube closure defects), the Chiari I malformation usually becomes symptomatic in teenage to early adult years, although the initial presentation can also be in an infant or older adult. The initial complaint is often neck pain, at times presenting with torticollis or retrocollis. If cervical spinal cord syringomyelia coexists, symmetrical, asymmetrical, or even totally unilateral arm pain can be the initial complaint. Neurological symptoms and signs also are dependent on the neural structures involved. Predominant impairment of the brain stem and cerebellar tonsils by either compression at the level of the foramen magnum or by extension of the syrinx into the brain stem (syringobulbia) can lead to a variety of brain stem and cerebellar signs. In the very young age group, sleep apnea, stridor, and feeding difficulties may be the presenting symptoms. Eye movement abnormalities are relatively common. Oscillopsia is reported by the patient, and a variety of forms of nystagmus can be seen on examination. Downbeating nystagmus (Video 31, Downbeat Nystagmus), especially when accentuated by lateral downgaze, should alert the examiner to a potential problem at the craniocervical/pontomedullary junction. Torsional nystagmus may also be present, especially in the presence of syringomyelia/syringobulbia. Lower cranial nerve impairment can lead to dysphagia and aspiration, which may first present as late as the eighth decade. When complicated by syringobulbia, asymmetrical cranial nerve involvement up to cranial nerve V may be present. Imbalance and vertigo with truncal ataxia may indicate impairment of the vestibulo- and spinocerebellar systems. With the coexistence of syringohydromyelia this clinical picture becomes even

more complicated. Forty percent to 75% of cases of Chiari I have an associated syringomyelia, depending on the series and method of ascertainment.⁹⁷ When the patient is presenting with symptoms referable to the spinal cord, syringomyelia can be demonstrated in over 90% of cases. The most common location of maximal expansion is C4 to C6, though the cavity can expand up and down the entire cord. The cavity often is centrally or slightly asymmetrical located, thus first impairing crossing fibers in the anterior spinal commissure. Since these fibers carry sensory information for predominantly pain and temperature, and the posterior columns can be relatively spared, a dissociated sensory loss may result; thus, pain and temperature sensation may be disturbed in a capelike distribution over the shoulders and down the arms, while light touch and joint position remain relatively unaffected. Compromise of the anterior horn cells may result in patchy weakness, amyotrophy, and loss of reflexes in the arms. These findings are often asymmetrical or even unilateral. With expansion of the cavity additional symptoms, including long tract signs and symptoms, can become apparent. Another important manifestation of syringomyelia, especially in childhood, is progressive scoliosis, sometimes the earliest sign of a syringomyelia. Skeletal anomalies of the skull base can be associated with the Chiari I malformation as well, most frequently basilar impression (see discussion in Skull Base and Neck Deformities section). Other skeletal anomalies of the craniocervical junction associated with the Chiari I malformation include the Klippel-Feil anomaly and atlanto-occipital assimilation.

In contrast to these predominantly cerebellar syndromes, other conditions have more clinical signs of brain stem dysfunction. In the broadest clinical definition Möbius' syndrome refers to a combination of bilateral symmetrical and asymmetrical facial weakness associated with abnormalities of horizontal gaze, most often deficiencies of abduction. Other cranial nerve functions can be impaired as well, especially IX, XII, V, and occasionally III. The impairment of lower cranial nerves can lead to early feeding difficulties, problems with swallowing, and atrophy of the tongue that is frequently unilateral. Neurosensory deafness may also be associated. A variety of somatic anomalies may be present in patients with Möbius' syndrome.⁹⁸ At least 50% of cases have limb anomalies. Thirty percent have talipes deficiencies, and 20% exhibit hypoplasia of digits, transverse terminal defects, or syndactyly. The Poland anomaly (absence of the pectoral muscle with or without radial ray abnormality of the upper extremities) and the Klippel-Feil anomaly can also be associated. Concurrent congenital heart disease, urinary tract anomalies, and hypogonadism/hypogonitalism are less frequent. Mild mental retardation is reported in 10% to 15% of patients with Möbius' syndrome; however, psychomotor development can also be slowed because of communication and social interaction problems that may result from the cranial nerve palsies. Most cases of Möbius' syndrome appear to occur sporadically, and may in some cases indicate a disruptive sequence. The association with Poland anomaly is sometimes referred to as Poland-Möbius' syndrome and may be familial.

Another syndrome involving cranial nerve nuclei is Duane's syndrome. This syndrome consists primarily of limited abduction with widening of the palpebral fissure

on attempted abduction and globe retraction on the affected side on attempted adduction. It is due to deficient abducens innervation to the lateral rectus with compensatory innervation by cranial nerve III. Again, most of the described cases have been sporadic; however, familial occurrences have been seen in the context of a number of anomalies such as limb anomalies, eye anomalies, and deafness.⁹⁸ The combination of Duane anomaly, Klippel-Feil anomaly, and perceptive deafness has been referred to as Wildervanck (cervico-oculo-acoustic) syndrome. It is of uncertain inheritance. Marcus-Gunn (jaw-winking) syndrome consists of unilateral ptosis, with elevation of the ptotic lid to a position higher than the opposite side upon opening of the mouth, especially with deviation of the mouth to the opposite side. This is often first noted in the infant while sucking. There are a few families with a suggestion of a dominant mode of inheritance with incomplete penetrance.

DIFFERENTIAL DIAGNOSIS. Cases of congenital cerebellar hypoplasia have been reported as autosomal recessive and probably also with X-linked inheritance.⁹⁹ Cerebellar hypoplasia and pontocerebellar hypoplasia have been associated with a number of other syndromes.⁹⁹ Together these findings indicate that cerebellar hypoplasia is genetically heterogeneous. A member of a recently recognized group of metabolic disorders of protein glycosylation (CDG syndrome type Ia) can also present with a picture of neonatal olivopontocerebellar atrophy.¹⁰⁰ Prenatal cytomegalovirus infection also needs to be investigated in infants with congenital cerebellar hypoplasia or aplasia, especially in cases with coexisting deafness and retinopathy.

Because the Dandy-Walker malformation may be part of a considerable number of syndromes,¹⁷ evaluation of the internal organs, particularly the heart and kidneys, as well as a skeletal and muscular assessment¹⁰¹ is essential once a Dandy-Walker malformation is recognized. Differential diagnostic considerations have to include conditions that can cause cystlike expansions in the posterior fossa. These include arachnoid cysts, mega cisterna magna, and cystic tumors. MRI is the imaging modality of choice given the problems of visualizing the posterior fossa by CT scanning. True cysts, such as arachnoid or ependymal cysts, in the posterior fossa may mimic a Dandy-Walker malformation; however, in contrast with the enlarged fourth ventricle associated with Dandy-Walker malformations, the fourth ventricle is compressed in the presence of a true cyst.

In Joubert's syndrome there is no cystic dilatation in the posterior fossa, so that the cerebellar hemispheres are seen to lie closely opposed without an intervening vermis. The characteristic MRI finding is the "molar tooth" sign, generated by the abnormally thick and straight superior cerebellar peduncle. This sign is seen in a number of Joubert-related conditions,¹⁰² including the oro-facio-digital syndrome type VI of Papp-Varadi, as well as other syndromes with vermal hypoplasia/agenesis.¹⁰¹ Patients with oro-facio-digital syndrome type VI of Papp-Varadi often have an unusual Y-shaped partially duplicated metacarpal on hand x-rays, and sometimes hamartomatous nodules under the tongue can be found. An unequivocal distinction between these syndromes is not always possible.

The differential diagnosis in the Chiari I malformation with syringomyelia is broad given the protean range of the possible clinical symptoms. Multiple sclerosis, spinal

muscular atrophy (Video 33, Spinal Muscular Atrophy), amyotrophic lateral sclerosis (Video 236, ALS-Parkinsonism Dementia), spinocerebellar ataxias (Video 207, Spinal Cerebellar Atrophy III), mononeuropathy multiplex, cervical disc and degenerative disease, and a variety of other disorders of the spinal cord and cerebellum can all be confused with the condition on clinical grounds. Imaging will resolve the majority of these differential diagnostic points. The situation can be more difficult in patients with prominent neurological symptoms but only borderline abnormal findings on imaging. Alternative diagnoses have to be considered seriously in that scenario. A cavity in the spinal cord can also have a traumatic (hematomyelia), inflammatory (necrotizing myelopathy), metabolic (Leigh disease), or neoplastic (astrocytoma and ependymoma) basis. Of the neurocutaneous disorders neurofibromatosis I and von Hippel-Lindau disease can be associated with a syrinx. Demonstration of a flow void within the cavity by MRI can be helpful to demonstrate continuity with the CSF spaces.

Möbius' syndrome must be differentiated from neuromuscular diseases with a prominent component of facial weakness, especially those with involvement of the extraocular muscles. In boys, centronuclear myopathy in particular should be considered because of the congenital presentation in the X-linked form. Mitochondrial myopathies (Video 38, Facial Myopathy and Ophthalmoplegia), myasthenic syndromes (Video 225, Myasthenia Gravis), and in cases with only facial involvement, myotonic dystrophy and facioscapulohumeral dystrophy as well as some of the structural congenital myopathies (Video 13, Myopathic Gait) need to be considered. In cases with an unclear history of symptom onset, a multitude of acquired causes for multiple cranial nerve palsies has to be considered. These causes include trauma to the skull base and cranial nerves; infection of the meninges, skull base, and cavernous sinus; inflammation of the nerves, brain stem, or cavernous sinus; tumors of the skull base; and meningeal neoplastic spread.

Differentiation between Möbius' and Duane's syndromes should be possible in most cases given the sparing of the face and lower cranial nerve nuclei in the latter. Duane's syndrome itself needs to be differentiated from other causes of abducens palsy in childhood, when the elaborate co-innervation phenomena of Duane's syndrome are usually not seen. More bizarre associated eye movement abnormalities can be seen in Duane's syndrome and may confuse the picture. The globe retraction can sometimes be difficult to appreciate, especially in infants.

EVALUATION. Imaging for posterior fossa malformations is best done with MRI. The relationship between the cerebellar vermis and fourth ventricle and cisterna magna needs particular attention. Diagnosis of cerebellar and pontine hypoplasias can be difficult in mild cases and strictly speaking requires age-matched control subjects for comparison. As mentioned before, for any unusual posterior fossa anomaly, screening for additional malformations may lead to a syndrome diagnosis. Ultrasound of the heart and internal organs, a skeletal x-ray survey, and an ophthalmological evaluation are recommended. In cases of young patients with Joubert's syndrome an overnight sleep study may alert to respiratory irregularities and apnea spells. In cases of hydrocephalus associated with the Dandy-Walker

malformation, evaluation should follow the guidelines outlined in the section on hydrocephalus.

Diagnosis of the Chiari I malformation as well as of syringomyelia relies on clinical suspicion as well as on adequate imaging. The imaging modality of choice is (as previously mentioned) MRI, especially sagittal images. The now routine inclusion of these images in any MRI study of the head has led to the discovery of a number of asymptomatic Chiari I malformations and asymptomatic cases of syringomyelia. It has also become apparent that the clinical picture is broader and more varied than the classical clinical syndromes described. The question frequently arises about the significance of low-lying tonsils that are discovered incidentally on a cranial MRI examination. The tonsils normally retract upward with age so their location must be interpreted in an age-dependent context. The cut-off in the first 10 years of life appears to be 6 mm below the level of the foramen magnum, from 10 to 30 years it would be 5 mm, and after that 4 mm. Herniations greater than 12 mm are almost invariably symptomatic; on the other hand, about 30% of individuals with significant displacements of 5 to 10 mm are asymptomatic.¹⁰³ Similarly, syrinx cavities can be quite large with minimal clinical symptoms.

Patients with the different brain stem syndromes need to be evaluated in an effort to rule out disorders that may mimic these syndromes (see Differential Diagnosis) and also to define the extent of the abnormalities and establish the presence of any associated malformations. In Möbius' syndrome this may require (in addition to a careful neurological and ophthalmological examination) brain stem auditory evoked responses; CK determination; imaging of the brain, posterior fossa, and skull base by MRI; a skeletal radiographic survey; and echocardiography.

MANAGEMENT AND PROGNOSIS. Treatment of the Chiari I complex consists mainly of decompressing the structures trapped in the foramen magnum. Surgical approaches for pediatric¹⁰⁴ and adult¹⁰⁵ patients are comparable. Most often a suboccipital craniectomy, with or without dural patch grafting, and cervical laminectomies are performed, but anterior approaches may become necessary in selected cases to achieve satisfactory decompression. Occasionally, very large syrinx cavities require drainage by fenestration or shunting into the subarachnoid space. In general, the decompressive surgery at the foramen magnum is the more successful of the two,¹⁰⁵ and coexisting syrinx cavities may even shrink or resolve postoperatively without further intervention. Signs and symptoms referable to brain stem compression respond better to surgery than symptoms related to the spinal cord, even when syrinx decompression is included in the operation. Major preexisting sensory or motor deficits are poor prognosticators for functional recovery.¹⁰⁴

Treatment of the Dandy-Walker malformation is also surgical by shunting of the hydrocephalus and the dilated fourth ventricle via a double ventriculo- and cystoperitoneal shunt.¹⁰⁶ This intervention may allow for normal mental development in the absence of additional CNS malformations.

The respiratory abnormalities associated with Joubert's syndrome usually improve after infancy. If significant and life-threatening apnea periods occur, home ventilation may be utilized successfully during the initial high-risk period.

In case of severe feeding difficulties the placement of a gastric tube may be appropriate. Psychomotor retardation is not as uniformly severe as initially thought, and efforts to ensure best possible cognitive development should be undertaken.

Although disabilities resulting from the Möbius' syndrome can initially be very significant, including feeding difficulties and language problems, these tend to improve with time. Therefore, temporary placement of a feeding tube may be indicated in severe cases. The facial immobility can cause a significant social handicap and needs to be addressed in the management plan for such patients.

ABNORMALITIES OF THE SKULL AND SPINE

Craniosynostosis

PATHOGENESIS AND PATHOPHYSIOLOGY. Craniosynostosis refers to the premature fusion of one or more of the cranial sutures.¹⁰⁷ The premature fusion of cranial sutures results in abnormal and often asymmetrical growth of the cranium with resulting effects on both the underlying brain and the outward appearance of the head. There may be nonprogressive hydrocephalus in patients with craniosynostosis. Intracranial pressure may be elevated with or without hydrocephalus, especially when the absolute intracranial volume is increased (as can be the case in sagittal synostosis). Significant advances in understanding the pathogenesis of craniosynostosis are based on the recognition that mutations in members of a family of genes segregate with craniosynostosis and syndromes with craniosynostosis as one of the features. Point mutations in the fibroblast growth factor receptors (FGFRs) were first recognized in the FGFR2 gene in Crouzon's syndrome and subsequently also in Apert's, Jackson-Weiss, and Pfeiffer's syndromes. Mutations in FGFR1 are found in Pfeiffer's syndrome. These findings have clearly linked these genes to the development of craniosynostosis.¹⁰⁸ Many of these syndromes have overlapping defects in other parts of the musculoskeletal system and other organ systems that are likely to result from the pleiotropic expression of the FGFRs. Mapping of the mutations in the FGFRs has shown that mutations in different parts of these receptors, including the intracellular, the extracellular, and the transmembrane domains, account for some of the variation in clinical expression. FGFR2 mutations are the most common.¹⁰⁷ Why mutations in different regions of these genes have such unique phenotypes is currently speculative. Some of the mutations render the receptor constitutively active, explaining the dominant inheritance. Several syndromes associated with a dwarfed stature can also result from mutations in an FGFR. Specifically thanatophoric dysplasia and achondroplasia/hypochondroplasia result from mutations in FGFR3.¹⁰⁸ Some cases of thanatophoric dysplasia include a cloverleaf skull, a severe form of craniosynostosis (see Clinical Features and Associated Disorders section). It is already clear that other genes are also involved in the development of craniosynostosis.¹⁰⁹ For example, mutations in the homeobox gene MSX2 have been linked to the Boston type of craniosynostosis¹¹⁰ but appear to be rare. Mutations in TWIST underly Saetre-Chatzen syndrome. In addition to these

now molecularly characterized syndromes, there are many cases of craniosynostosis that are of unknown etiology and others arise from apparently nongenetic causes, such as the amniotic rupture sequence.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. In 1988, Cohen¹¹¹ reviewed all the syndromes with craniosynostosis as one of the features recognized up to that date. He found 64 described syndromes; over the subsequent years many more have been added. About 80% to 90% of all cases of craniosynostosis are sporadic and not part of a recognized syndrome. The sagittal suture is most often affected, leading to an elongated appearance of the skull with a normal face. This skull shape is referred to as scaphocephaly or dolichocephaly. Girls are affected slightly more often than boys and there are usually no neurological deficits associated with this craniosynostosis. Although the biparietal diameter is low, the actual head circumference is usually above the 95th percentile, so that the actual intracranial volume is normal or even increased. Impairment of brain growth usually does not occur, although the intracranial pressure may be elevated in some cases. Premature closure of the lambdoid sutures can occur in an asymmetrical fashion (plagiocephaly) or symmetrically (brachycephaly) (Fig. 28-10). Both conditions occur more commonly in boys. Brachycephaly, in particular, has a higher incidence of neurological complications and mental retardation. Optic atrophy with resulting visual impairment can be caused by traction of the chiasm and optic nerves due to upward displacement of the chiasm in the foreshortened skull. Increased intracranial pressure may also develop in premature synostosis of the coronal sutures and lead to optic atrophy as well as to more diffuse neurological damage. The incidence of mental retardation in brachycephaly remains high even in cases after surgical correction of increased intracranial pressure. Metopic craniosynostosis is rather rare and often occurs in a syndromic context such as the Opitz trigonocephaly syndrome (C syndrome) or in conjunction with holoprosencephaly. Asymmetrical closure of the lambdoid suture leads to another form of plagiocephaly. These single suture synostoses can be very mild phenotypically. A particularly severe situation can result from the combined closure of the coronal and sagittal sutures (oxycephaly). Here microcephaly and crowding of the intracranial content may result. In the most severe form, the sagittal, coronal, and lambdoid sutures are affected, resulting in the cloverleaf, or trilobed, skull (Kleeblattschädel). Patients with the cloverleaf skull anomaly show a bulging forehead, proptotic eyes, and severe neurological impairment.

Syndromic craniosynostosis accounts for only about 15% of cases of craniosynostosis. The two most common conditions are Crouzon's and Apert's syndrome, which account for about two thirds of syndromic craniosynostosis cases. In Crouzon's syndrome synostosis of the coronal, sagittal, and lambdoid sutures are the most common. Ocular proptosis resulting from shallow orbits is a constant feature. Visual impairment occurs in about half of the patients.¹¹² Traction and compression in the optic canals leads to optic atrophy in 22% of cases and legal blindness in 7%.¹¹³ Conductive hearing loss is quite common and occurs in about 55% of patients.¹¹³ Headaches are a concern in about one third of the patients, and seizures have

Figure 28-10. Craniosynostosis. A three-dimensional reconstruction of MRI from a patient with Apert's syndrome. The coronal sutures are prematurely closed and the sagittal suture is abnormally wide.

been reported in up to 12% of patients.¹¹³ Mental deficiency is rare. This disorder follows autosomal dominant transmission. Apert syndrome (acrocephalosyndactyly) is an autosomal dominant disorder characterized by coronal synostosis in conjunction with a malformed and short cranial base resulting in a short and high skull (brachytrurricephaly) and hand anomalies. Platybasia is often associated. In infancy there is a wide and gaping defect in the region of the sagittal and metopic sutures. Again visual impairment is common.¹¹² Optic atrophy and conductive hearing loss can also occur in Apert syndrome. As opposed to Crouzon's syndrome, mental deficiency is common in this condition; in one series half of the patients had an IQ below 70.¹¹⁴ However, normal or above average intelligence can certainly be seen. The structure of the CNS can be affected in a number of ways; the most frequent includes agenesis or hypoplasia of the corpus callosum, migrational anomalies, and gyral abnormalities. Ventriculomegaly does not necessarily mean hydrocephalus, which is rather uncommon in Apert's syndrome. Hand anomalies in Apert's syndrome consist of fused middle fingers involving at least digits 2, 3, and 4. For most of the more severe craniofacial syndromes with craniosynostosis upper airway obstruction can become a problem relevant for management.¹¹⁵

DIFFERENTIAL DIAGNOSIS. Craniosynostosis is a defining feature of many syndromes.¹⁷ Metabolic conditions that can lead to a premature fusion of cranial sutures include hyperthyroidism, hypercalcemia, and hypophosphatasia. Asymmetries of the skull are also seen in other conditions without craniosynostosis such as hemimegalencephaly, hemiatrophy, and unilateral destructive lesions of the brain that result in a marked size difference between

the two cerebral hemispheres. The amniotic band rupture sequence can also give dramatic alterations in skull shape. A small head per se does not mean premature closure of the sutures, but retarded brain growth as a primary abnormality has to be considered. Earlier closure of the sutures can be seen under these circumstances and this constellation would not be considered a craniosynostosis. Severe constraint in utero can have the same effect. A number of other position-dependent asymmetries of skull shape can be seen, especially in hypotonic infants or infants with other external restrictions of skull growth. Finally, there exists a long list of syndromes that include unusual skull configurations not based on premature fusion of cranial sutures.

EVALUATION AND MANAGEMENT. Although skull films were traditionally the modality of choice for the evaluation of craniosynostosis, CT with 3D reconstructions are now the method of choice for the evaluation of the cranial skeleton and planning of management. The goal of evaluation should not only be the delineation of the various anatomical abnormalities, but also an attempt at a specific diagnosis in a given case of craniosynostosis. This may include the clinical recognition of a syndrome; direct mutation analysis of selected FGFR genes may be appropriate in selected cases.

Treatment for the craniosynostosis is surgical and involves excision of the fused suture and separation of the bony margins by an implanted matrix. Good results can usually be obtained,¹¹⁶ especially when surgery is performed before 6 months of age. Given that the intracranial pressure can be elevated with single suture synostosis, the indication for repair has moved away from purely cosmetic indications. For the Kleeblattschädel deformity, early subtotal craniectomy is the only reasonable attempt at correction, although the severity of the overall condition may prohibit invasive treatment. The acrocephalosyndactyly syndromes may require surgical approaches to the associated hand malformations, in particular polydactyly and syndactyly. Careful attention needs to be paid to vision and hearing in craniosynostosis patients. Hearing aids may be necessary for adequate communication and language development. Shunting for hydrocephalus is rarely necessary.

Other Disorders of the Skull and Spine

Dwarfism

Although dwarfism is primarily a defect of the musculoskeletal system, central and peripheral nervous system manifestations are encountered in a variety of these disorders associated with short stature, most of which are beyond the scope of this chapter. The most frequent neurological manifestations are a result of impingement of the nervous system as a result of narrowing of bony foramina. For example, in some dwarfism syndromes, such as achondroplasia, narrowing of the foramen magnum can obstruct CSF flow and result in hydrocephalus. In achondroplasia the development of clinical symptoms usually requires a narrowing of the foramen magnum to under -3 to 4 SD (standard deviations are available in radiology texts). Thanatophoric dysplasia, due to mutations in the same genes as achondroplasia (see preceding discussion), has a

Figure 28-11. Thanatophoric dysplasia. A ventral view of the brain from a 20-week fetus with thanatophoric dysplasia. Radially oriented, deep fissures in the medial temporal lobe replace the normal smooth surface at this age and are pathognomonic for this disorder.

unique neuropathology of the brain¹¹⁷ with deep radial fissures arranged as spokes on a wheel distorting the temporal lobes (Fig. 28-11). Microscopically the temporal lobes, particularly medially, are disorganized, often showing polymicrogyria. Polymicrogyria may also occur outside the temporal lobes.

The diagnosis of thanatophoric dysplasia is important for management decisions and for the purpose of genetic counseling. Clinically there are short limbs, a narrow thorax with short ribs, a short spine with flat vertebral bodies, and large-appearing cranium with flat nasal bridge. There are two subtypes: the more common type I with bowed bones but no cloverleaf skull, and a second form (type 2) with straight bones but with a complex craniosynostosis giving rise to the cloverleaf skull. Hydrocephalus is common with the type II form. Both forms are associated with mutations in FGFR3.

Achondroplasia can be associated with a number of neurological complications.¹¹⁸ Stenosis at the level of the foramen magnum can cause a high cervical or lower medullary myelopathy. In case of the latter apneic spells or respiratory insufficiency can result; the former can give rise to long tract symptomatology including frank quadriplegia. Stenosis of the spinal canal with myelopathy or radiculopathy can occur at any level. Careful assessment for lower extremity hyper-reflexia, clonus, and Babinski's sign is important for the early recognition of a myelopathy. Surgical decompression may become necessary in these cases. The development of hydrocephalus in achondroplasia may be due to stenosis at the level of the foramen magnum, though this is not very common. A milder degree of hydrocephalus has been postulated to be due to impaired CSF resorption because of diminished venous return from the cranial compartment. A degree of macrocephaly, however, is part of the "normal" clinical manifestations of achondroplasia and does not automatically imply hydrocephalus. Thus, head circumference measurements should be compared with head circumference charts specifically corrected for achondroplasia. The numerous skeletal dysplasias,

many of which have secondary neurological complications, are beyond the scope of this chapter (see McKusick¹¹⁹ for complete discussions).

Skull Base and Neck Deformities

Malformations and deformities of the skull base can be part of a number of conditions. Included among these are craniosynostosis syndromes (short and steep cranial base), neurofibromatosis 1 (aplasia of the sphenoid wing), Chiari type I and II (platybasia, flat cranial base), osteogenesis imperfecta (basilar impression, invaginated cranial base), and Hajdu-Cheney syndrome (basilar impression), as well as others. They can also occur in isolation or in a familial context. Other conditions such as Paget's disease, rickets, rheumatoid arthritis, and hypoparathyroidism have to be considered in the differential diagnosis. Nuchal pain and vertigo may be early and nonspecific complaints. If present, downbeating nystagmus in primary position accentuated by gaze position down and out may provide a diagnostic clue for pathology at the craniocervical junction. The neurological syndrome of basilar impression, including platybasia and the more extreme convexobasias, can begin insidiously with increasing spasticity in the lower extremities, ataxic gait, and loss of proprioception also in the upper extremities. In addition, lower cranial nerve function, including dysphagia, may become impaired late in the course.¹²⁰ The neck may be short and cervical motility impaired, and there may be nuchal pain in addition causing neck stiffness and torticollis at presentation. Symptoms and signs of associated conditions such as the Chiari malformations and syringomyelia can complicate the picture. Sagittal CT reconstruction plus sagittal MRI is the optimal imaging modality combination to confirm the diagnosis and delineate the bony abnormalities. Surgical decompression at the foramen magnum is the treatment of choice, occasionally requiring additional laminectomies of C2 and C3 with cervico-occipital fusion. Platybasia (defined as the angle between planes of the anterior cranial fossa and the clivus being greater than 140 degrees) in isolation is generally asymptomatic.

Congenital fusion of the cervical vertebrae is known as the Klippel-Feil anomaly. Presumably this reflects a failure of segmentation rather than a secondary fusion. This anomaly can be part of a number of syndromes (such as Turner's, Noonan's, and Wildervanck's syndromes), but can also occur sporadically or be inherited in isolation as an autosomal dominant or autosomal recessive trait. The fusion of vertebrae can extend beyond the cervical spine, but most commonly is restricted to levels C2 and C3 or C5 and C6. Clinically there is a short neck, low posterior hairline, and limitation of neck movements, in particular rotation and bending to the sides. Atlanto-occipital anomalies are frequently associated with the Klippel-Feil anomaly and one of the major reasons for associated morbidity. Kyphosis and scoliosis are often associated, as is spina bifida occulta in some cases.¹²¹ Many patients also have a variety of genitourinary anomalies, including unilateral renal agenesis.¹²¹ Hearing impairment can be seen in about 20%. Other skeletal malformations such as the Sprengel deformity can be associated. The main neurological complications result from craniocervical instability with the possibility of spinal cord

compromise. It has also been noted that patients with the Klippel-Feil anomaly may have mirror movements on neurological examination,¹²² but the reason for this observation is not clear.

Occipitalization of the atlas, or assimilation of the atlas, refers to the fusion of the anterior arch and ring of C1 with the foramen magnum. A Chiari type 1 malformation, Klippel-Feil anomaly, achondroplasia, and syringomyelia may be associated. Atlantoaxial instability (atlas-dens interval greater than 3 mm) can occur in rheumatoid arthritis but also in a number of genetic conditions and syndromes, most notably Down's syndrome. It is recommended to screen trisomy 21 patients at 5 and 10 years for atlantoaxial instability and if present restrict potentially harmful physical activities.

Compressive Neuropathies

HISTORY AND DEFINITIONS

A variety of neurological disorders result from abnormalities of bones, ligaments, muscles, and other mesenchymal tissue that compress the nervous system. In many instances the result is a focal disorder of nervous system function such as a mononeuropathy, a root syndrome, or the compression of intracranial contents by abnormalities of the skull. Much of our clinical knowledge of the peripheral system is derived from these kinds of lesions—for instance, the dermatomal map, which every student of the nervous system carries in his or her black bag, is in part derived from the study of patients with a herniated disc and root compression. Much of the standard neurological examination of the sensory system is derived from studies carried out by Henry Head 80 years ago in patients (including himself) who had lesions of individual peripheral nerves.

DEGENERATIVE STRUCTURAL DISORDERS

Degenerative Disc Disease

PATHOGENESIS AND PATHOPHYSIOLOGY. The vertebral disc is composed of the inner gelatinous nucleus pulposus and the surrounding annulus fibrosus. Vertebral disc herniation refers to rupture of the annulus with displacement of the central nucleus. In youth, the disc is highly elastic. With age, the direct vascular supply to the vertebrae and discs decreases, and they suffer the accumulated effects of axial loading. The resulting decreases in water content, oxygen content, and metabolic efficiency lead to a disc that is more compressible, less elastic, and more prone to rupture. Disc rupture and herniation can cause pain by several mechanisms. The periosteum of the bony spine, the ligaments, the outer fibrous annulus of the vertebral discs, and the dura are all innervated by nociceptive afferents from the spinal nerves. A ruptured fibrous disc may generate local pain due to mechanical stress on these pain-sensitive structures. Also, the exposed disc material has a direct toxic effect and elicits a local inflammatory response, which may promote increased pain sensitivity.

In addition to these local effects, the herniated disc material may compress the spinal roots by protruding into the lateral recess or the neural foramen. It may also protrude into the spinal canal, compressing the spinal cord in the cervical, thoracic, or upper lumbar region, or the cauda equina in the lumbosacral region. Details of the mechanisms by which compression causes neurological dysfunction are complex and probably include mechanical alteration of axonal membranes, impaired axonal flow, and ischemia due to compromise of the microcirculation with resultant edema and eventual demyelination. Finally, regional muscle spasm may accompany other effects, adding to the pain and disability.

The accumulation of degenerative lesions in the spine may compromise the area of the central canal available to the spinal cord in the cervical region or to the cauda equina in the lumbosacral region enough to cause symptomatic spinal stenosis with or without discrete disc herniation. These lesions include degenerative discs that bulge posteriorly, a hypertrophied ligamentum flavum that bulges anteriorly, and hypertrophied facet joints that crowd into the bony canal posterolaterally (Fig. 29-1). Less common lesions may contribute to the problem, hastening significant stenosis: congenitally short pedicles, spondylolisthesis without spondylolysis, or abnormal angulation of the bony spine.

EPIDEMIOLOGY AND RISK FACTORS. Vertebral disc degenerative changes are a universal accompaniment of aging. Teenagers rarely develop symptomatic disc herniation. The peak incidence of symptoms occurs between the ages of 30 and 50. Patients often describe the onset of low back pain, usually remittent and without specific features in their 20s, perhaps after identifiable trauma, and the specific symptoms that lead to the diagnosis of disc herniation are often not preceded by further trauma. The accumulation of degenerative changes to the annulus and the preservation of the expansile gelatinous nucleus, overlapping with a period of life when job and sports-related activities increase the amount of mechanical stress on the body, probably account for this peak in the incidence of disease. The incidence then falls off in the older population, probably due to lack of mobility of the desiccated disc

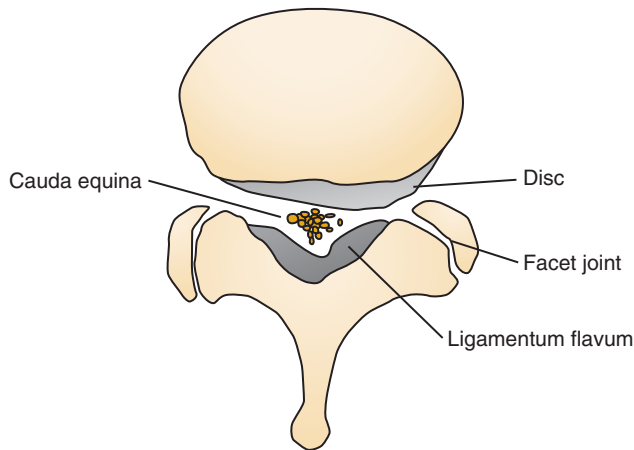

Figure 29-1. Lumbar spinal stenosis. L4 vertebra in cross section. Posterior bulging of the intervertebral disc, hypertrophy of degenerated facet joints, and hypertrophy of the ligamentum flavum crowd into the central canal to cause lumbar spinal stenosis.

and the relative lack of physical activity. Women and men are affected approximately equally.

There is a tendency toward disc herniation in some families, such as those with congenital spinal anomalies, including fused and malformed vertebrae and lumbar spinal stenosis due to short pedicles. Patients with increased weight and tall stature are at increased risk for this condition. Acquired spinal disorders, such as common degenerative arthritis and ankylosing spondylitis, also predispose to disc degeneration. Various behaviors that increase risk include sedentary occupations, physical inactivity, motor vehicle use, vibration, and smoking. In younger women, pregnancy and delivery are associated with lumbosacral herniation, and new symptoms of cervical disc herniation may occur in part because of the bending and lifting involved in child rearing.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. The most common site of disc herniation in the cervical region is the C6–C7 level, followed by C5–C6, C7–T1, and C4–C5. Patients typically develop local pain in the neck that radiates to the shoulders or the interscapular region. In the most common lateral herniations, radicular symptoms ensue. These symptoms include pain in the shoulder and arm, which may follow a dermatomal pattern but more typically is deep and aching and only roughly corresponds to the involved dermatome. At the cervical levels, the roots emerge laterally to exit through the neural foramina *above* the correspondingly numbered vertebral bodies. Because the spinal cord and bony vertebral levels are roughly aligned in the neck, the level of herniation corresponds to the level of root irritation. Hence, C6–C7 herniation affects the C7 root (Fig. 29-2). Pain may be exacerbated by coughing or straining. Numbness is more likely to supply reliable localizing information than pain. Compression of the C6 root typically causes numbness in the thumb and index finger, and compression of the C7 root typically involves the index and middle fingers. When compression is severe, myotomal weakness, reflex loss, and with time, fasciculations and atrophy may ensue. With C6 compression, the biceps, brachioradialis, pronator teres, and radial wrist extensors may be weak, and the

Figure 29-2. Cervical disc herniation. At the cervical levels, roots emerge from the spinal cord near their level of exit. Each root emerges above its corresponding vertebra, with C8 emerging between C7 and T1. Posterolateral herniation at this level causes compression of the exiting root (*horizontal hatching*). Hence, C6–C7 herniation causes C7 compression, and so on. A large central herniation in this region can compress the spinal cord and cause a cervical myelopathy (*vertical hatching*).

brachioradialis and biceps reflexes may be diminished or lost. With C7 compression, the wrist and finger extensors and the triceps are typically weak. The triceps reflex may also be diminished or absent. With C8 compression, there is often interscapular pain and pain in the medial aspect of the arm and hand with weakness of the intrinsic hand muscles. The finger flexor reflex may be lost. Lesions above C6 are less common and are associated with correspondingly more proximal sensory symptoms and weakness. Lesions of the C5 root may cause shoulder pain and pain and numbness in the lateral aspect of the upper arm. Muscles innervated by the C5 root include infraspinatus, supraspinatus, deltoid, and biceps. Lesions above this level may cause neck pain and sensory loss in the neck, supraclavicular area (C3), and acromioclavicular area (C4) of the shoulder. Lesions involving the spinal cord or roots above C4 may paralyze the diaphragm and cause respiratory compromise (Table 29-1).

In the lumbosacral region, the most common site of herniation is the L5–S1 level, followed by the L4–L5 level and then higher levels. Symptoms of lumbosacral herniation often follow lifting or twisting injuries, or they may result from accumulated low-level trauma. Pain typically occurs in the parasacral area and radiates to the buttocks. Below C8, the roots exit through the neural foramina *below* the correspondingly numbered vertebrae. With posterolateral lumbosacral disc herniation—the most common type—the emerging root usually escapes entrapment above the protruding disc, and the affected root is one nervous segment lower. Hence, L5–S1 herniation affects the S1 root (Fig. 29-3). With S1 root entrapment, pain and numbness radiate to the posterior aspect of the thigh and, especially when the root is stretched, into the posterolateral lower leg, lateral heel, and sole. This pattern can sometimes be demonstrated by straight-leg raising—the smaller the angle of elevation required to elicit radicular pain, the greater the suggestion that root compression is responsible.¹ Reproduction of pain with elevation of the opposite leg (a so-called

TABLE 29-1

Cervical Radiculopathies

| ROOT | MUSCLE WEAKNESS | ACTION | LOCATION OF PAIN | REFLEX CHANGE |
|------|--------------------------------|---|---|-----------------|
| C5 | Deltoid | Shoulder abduction (15–90°) | Lateral shoulder | Biceps |
| | Biceps | Elbow flexion | Lateral upper arm | |
| | Supraspinatus Infraspinatus | Shoulder abduction (0–15°) Humerus external rotation | Lateral epicondyle | |
| C6 | Brachioradialis (5,6) | Elbow flexion in semipronation | Posterior shoulder, lateral forearm Thumb and index finger | Brachioradialis |
| | Pronator teres (6,7) | Pronation | | |
| | ECR (6,7) | Radial wrist extension | | |
| C7 | Triceps (6,7,8) | Elbow extension | Posterior shoulder Medial forearm | Triceps |
| | ECR (6,7) | Radial wrist extension | | |
| | ED (7,8) | Finger extension | | |
| C8 | Flexor pollicis longus | Thumb flexion | Interscapular medial forearm | Finger flexors |
| | FDS, FDP | Finger flexion | | |
| T1 | Interossei | Finger abduction | Medial forearm | None |
| | Abductor digiti minimi | Little finger abduction | | |

Actual motor innervation is multisegmental. Most of the myotomal overlap is disregarded here to emphasize clinically useful localization. ECR, extensor carpi radialis; ED, extensor digitorum; FDP, flexor digitorum profundus; FDS, flexor digitorum superficialis.

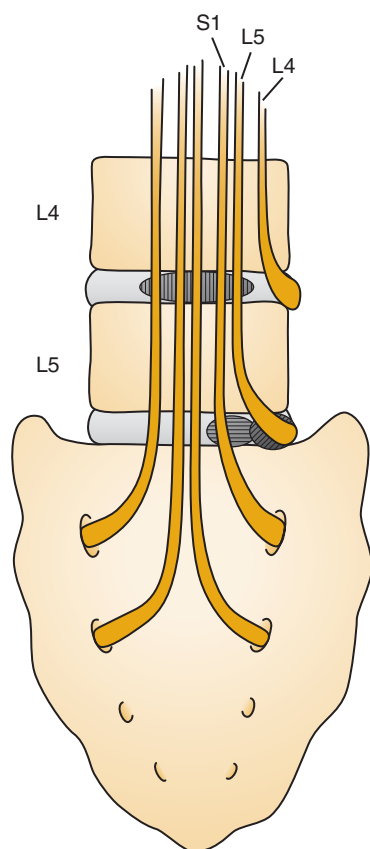

Figure 29-3. Lumbar disc herniation. The most common posterolateral herniation compresses the nerve root traveling downward to emerge one level below the level of the exiting root. Hence, L5–S1 herniation most commonly compresses the descending S1 root (*horizontal hatching*). More lateral herniation may compress the root exiting at the level of herniation (*diagonal hatching*). A large central herniation may compress multiple bilateral descending roots of the cauda equina (*vertical hatching*).

“crossed straight leg raise sign”) may be even stronger evidence of root compression.² Some patients with symptoms that are exacerbated by root traction avoid full weight

bearing on the heel of the involved side, standing with the knee flexed and the heel off the floor. When pain is less severe, symptoms may be elicited by having the patient walk on the heels. The gastrocnemius and hamstrings may be weak, and the ankle jerk may be diminished or lost. More lateral herniation of the L5–S1 disc or herniation of the L4–L5 disc may entrap the L5 root. Here the pain may be similar, but with symptoms and findings corresponding to the L5 dermatome and myotome. Numbness is most marked on the dorsum of the foot. Weak muscles include the foot elevators (tibialis anterior group), evertors (peronei), and invertors (tibialis posterior), and the toe extensors (extensor hallucis longus). Herniation at higher levels in the lumbosacral region causes pain, numbness, and weakness corresponding to the roots involved (Table 29-2).

In addition to these radicular syndromes, patients with central herniation in the cervical or thoracic region may develop pain and acute myelopathy, with spasticity and quadriparesis or paraparesis, sensory loss at or below the segmental dermatome of the lesion, hyperactive reflexes, and Babinski’s signs. Reflexes are sometimes decreased in the hours or days after an acute lesion, later becoming increased as expected. Patients with central lumbosacral herniation may develop acute compression of the cauda equina. This causes radicular pain, paresthesias, and sensory loss referable to multiple bilateral roots, bilateral leg weakness, and loss of lower extremity reflexes. Bowel and bladder dysfunction may occur early. When subtle, this dysfunction may be limited to asymptomatic bladder retention noted only on postvoid catheterization. When compression is more severe, there may be perianal and perineal sensory loss, loss of anal tone and reflexes (reflex anal sphincter constriction due to perianal skin stimulation or “anal wink” and the bulbocavernosus reflex), and fecal and urinary retention and incontinence.

Degenerative herniation in the thoracic region is uncommon, and symptoms and findings at these levels should raise a suspicion of other underlying lesions, such as tumor or abscess. Disc herniation at this level may cause radiating dermatomal pain due to root compression, but spinal cord compression and resultant myelopathy is more common.

TABLE 29-2

Lumbosacral Radiculopathies

| ROOT | MUSCLE WEAKNESS | ACTION | LOCATION OF PAIN | REFLEX CHANGE | |
|-----------------|---------------------------------------|--------------------------|----------------------------|---------------------|-------|
| L1 | Iliopsoas (sometimes but mainly L2,3) | Hip flexion (mainly 2,3) | Inguinal crease | None | |
| L2 | Iliopsoas (2,3) | Hip flexion | Anterior and lateral thigh | Cremasteric | |
| L3 | Adductor group | Hip adduction | Medial thigh and knee | Knee | |
| L4 | Quadriceps | Knee extension | Medial lower leg | Knee | |
| | Tibialis anterior | Foot dorsiflexion | | | |
| L5 | EHL, EHB | Great toe extension | Anterolateral lower leg | Tibialis posterior | |
| | EDL, EDB | Toe extension | Dorsum of foot | Internal hamstrings | |
| | Tibialis anterior | Foot dorsiflexion | | | |
| | Peroneii | Foot eversion | | | |
| | Tibialis posterior | Foot inversion | | | |
| | Gluteus medius | Hip abduction | | | |
| | Internal hamstrings | Knee flexion | | | |
| | S1 | Biceps femoris | Knee flexion | Lateral heel | Ankle |
| | | Gastrocnemius soleus | Foot plantar flexion | Sole of foot | |
| | | FDB | Toe flexion | | |
| Gluteus maximus | | Hip extension | | | |

Actual motor innervation is multisegmental. Most of the myotomal overlap is disregarded here to emphasize clinically useful localization. EDB, extensor digitorum brevis; EDL, extensor digitorum longus; EHB, extensor hallucis brevis; EHL, extensor hallucis longus; FDB, flexor digitorum brevis.

The symptom most suggestive of lumbar spinal stenosis is neurogenic claudication. Low back pain radiates to the buttocks and thighs and may extend more distally along the lumbosacral dermatomes. This pain is brought on by walking. Unlike vascular claudication, rest in the upright position does not relieve the pain, but rest while seated or bending forward, such as leaning on a shopping cart, may provide relief. Pain is exacerbated by spinal extension, for example with downhill walking. When spinal stenosis is severe, patients bend forward while walking. Pain may be mechanical, due to bone, ligament, and joint involvement, or radicular, due to compromise of nerve roots in the lateral recesses or neural foramina.

Proximal root entrapment may increase the vulnerability of peripheral nerves to dysfunction due to distal entrapment. This “double crush” phenomenon is presumed to be a result of disturbed axoplasmic flow and disrupted architecture of the neurofilaments. Therefore, when surgical correction of a distal entrapment fails to provide the expected relief, a superimposed compressive radiculopathy should be considered.

DIFFERENTIAL DIAGNOSIS. Disc herniation must be differentiated from other causes of neck, back, and extremity pain; radiculopathy; and myelopathy. Malignant and benign tumors affecting the spine; infection; epidural hematoma; various arthritides, including rheumatoid arthritis, ankylosing spondylitis, and Reiter’s syndrome; and other spondyloarthropathies may present with similar early symptoms and signs. Various anomalies, such as conjoined spinal roots and multiple roots emerging through a single foramen, may also be confused with disc disease. Degenerative arthritis of the spine can cause symptoms by many mechanisms, including disc herniation, and the particular sources of symptoms in a given patient should be differentiated as clearly as possible to allow directed therapy.

EVALUATION. A careful history and physical examination are critical in the evaluation of disc herniation. Even asymptomatic patients have a high incidence of anatomical lesions detectable with imaging of the spine. To detect

clinically relevant illness properly, it is therefore essential to correlate symptoms and signs as closely as possible with anatomical findings on imaging studies. The initial history should screen for problems that raise a suspicion of severe underlying disease. All patients should be questioned about trauma, cancer, infections, recent fever, and the use of anticoagulant medications. Family history and risk factors for tumor, infection, hematoma, and various disorders that predispose to disc disease should be elicited. The physical examination, likewise, is done to seek evidence of other severe underlying disease and to localize and classify pain or deficits as myelopathic, radicular, neuropathic, or musculoskeletal. It is most important to immediately establish the presence of major deficits that demand rapid diagnosis and treatment. These include the cauda equina/conus medullaris syndromes, acute or progressive myelopathy, and severe radicular motor deficits. If, on the other hand, history and findings are consistent with a ruptured disc with either no deficit or a mild to moderate one, it is reasonable to temporize before pursuing invasive or expensive evaluations. If plain radiographs of the affected area reveal no evidence of unexpected lesions, conservative therapy for disc herniation may be tried before further imaging is performed. This approach is justified by the good prognosis for spontaneous recovery of patients with acute radiculopathy and mild to moderate deficits. When history and clinical examination leave doubt about lesion localization, electromyography (EMG) can confirm the diagnosis of radiculopathy or suggest other localizations, such as plexopathy or neuropathy. EMG is more sensitive if it is delayed until at least 10 to 14 days after the onset of a new deficit.

The tests available for imaging include plain radiographs, computed tomography (CT), myelography with or without CT, and magnetic resonance imaging (MRI). X-ray studies can be used to screen for unexpected infection, tumor, or deformity of the bony spine. Radiographs cannot show the neural tissues or the disc itself, but loss of disc space height and other degenerative changes may provide indirect diagnostic information. Interpretation of

plain radiographs must be tempered by an awareness of the high frequency of degenerative findings in asymptomatic populations. Plain radiographs taken under conditions of flexion and extension can also be used to assess spinal stability. Myelography is invasive, indirect, and nonspecific; however, it retains certain advantages even in the era of MRI, since it best defines the root sleeves. Although myelography alone cannot distinguish between osteophytes and a herniated disc compromising a foramen, when combined with CT, it provides the best visualization of lateral pathology and small osteophytes. It is now most commonly used to answer specific questions that remain after the MRI examination. CT is superior to MRI in distinguishing soft tissue from bone. When imaging is required, however, MRI is preferred in most cases. It demonstrates bone and soft tissues directly, easily allows multiplanar visualization, and is suited to the simultaneous visualization of multiple levels. The visual contrast between epidural fat and the cerebrospinal fluid-filled thecal sac allows accurate assessment of subtle compression in most cases.

Lumbar spinal stenosis is best evaluated by CT or MRI. MRI best demonstrates the relationship of the bony and neural structures. CT is more sensitive for compromise of the lateral recess. Although the dimensions of the bony canal can be used as guidelines, diagnosis of spinal stenosis must ultimately be based on the correlation of stenosis with the clinical findings. The transverse interfacet dimension should be greater than 16 mm, with a dimension of less than 10 mm indicating severe stenosis. An anteroposterior dimension of less than 12 mm suggests stenosis; however, this finding is less sensitive in patients with symptomatic disease. A lateral recess of 3 mm or less suggests stenosis.

MANAGEMENT. The crucial initial step in management of patients with disc herniation syndrome is to identify those lesions that merit further evaluation and immediate therapy. In the remaining cases, the good prognosis for early recovery justifies a trial of conservative therapy before definitive imaging is done. Conservative therapy includes rest in a position of comfort followed by early remobilization, gentle exercises, and analgesics for pain as needed. Nonsteroidal anti-inflammatory agents probably provide little relief in most cases. For severe pain, judicious time-limited use of narcotics should be considered. Oral and epidural corticosteroids can be helpful. Many other modalities are available, but there are few reliable data about their effectiveness in populations: medical and physical measures (e.g., ice, heat, massage, ultrasound, transcutaneous electrical nerve stimulation, acupuncture, exercise, and traction), or medications intended for secondary muscle spasm.³ If improvement within the initial 4 to 6 weeks is not satisfactory, it is helpful to confirm the diagnosis by imaging. This may provide a diagnosis of an unsuspected condition, localization for epidural steroid injection, or information about suitability for eventual surgery. Surgery for persistent low back pain without radiculopathy is controversial at best; spinal fusion may offer some benefit in carefully selected patients.⁴

Clear indications for surgery include acute myelopathy, cauda equina syndrome, severe or progressive motor deficits, and intractable pain. When conservative measures fail to provide a satisfactory response within 6 to 12 weeks, surgery can also be considered. Studies comparing the

outcome of surgical therapy with conservative care for disc herniation suggest that early recovery occurs more often with surgery. Although the benefits of surgery are lost with prolonged follow-up periods, it is important to point out that in an often-cited study of lumbar disc herniation, subjects receiving conservative therapy who did not respond eventually underwent surgery.⁵ Newer microsurgical techniques allow shorter hospitalization and rehabilitation periods but have not been shown to improve long-term outcome. The success rate of chymopapain chemonucleolysis has not reached that of surgery in most hands; this treatment carries significant risks and its use remains controversial. Although techniques continue to evolve, percutaneous nucleotomy has also been disappointing and should not be pursued given the current level of experience.

For patients with lumbar spinal stenosis, initial therapy is symptomatic, with analgesics, pain-modulating medications, and physical and occupational therapy. When significant disability and pain remain despite conservative measures, referral for surgical decompression should be considered.

PROGNOSIS AND FUTURE PERSPECTIVES. The prognosis for the relief of pain and a full functional recovery is good. With bed rest alone, Weber found that 70% of patients experienced decreased pain and improved function within 4 weeks, and 60% had returned to work.⁶ Seventy percent were functionally unrestricted at 1 year. With selective surgery, 90% of patients should have a good functional recovery within a year. Patients with psychosocial problems tend to do worse with either therapy, but those with appropriate indications respond better to surgery. Sensory dysfunction does not recover as fully as motor function, and a large proportion of patients retain some sensory deficits. Patients in whom relapse occurs should be re-evaluated for new lesions that are potentially amenable to surgery; however, the success rate of surgery declines with repeated procedures, and a significant proportion of patients with disc herniation experience relapse and chronic low back pain.

Research into the mediators and biomechanics of pain may further elucidate the mechanisms of pain in disc disease and lead to new conservative therapies. Improved imaging techniques may further refine the selection of patients for surgery. Improved surgical selection and further refinements in surgical technique may continue to improve outcome and shorten the period of disability.

Cervical Spondylosis

PATHOGENESIS AND PATHOPHYSIOLOGY. Degenerative changes of the spine universally accompany aging, and the accumulation of these changes in the cervical spine constitutes cervical spondylosis. These spondylosis changes become clinically important when they cause pain or neurological dysfunction. Aging leads to desiccation and shrinkage of the intervertebral discs. The resultant loss of vertebral height narrows the intervertebral foramina. The weakening of the containing fibrous annulus allows bulging of the desiccated discs, which may then form transverse bars that protrude posteriorly, compromising the spinal canal. Their protrusion more laterally into the foramina may further compromise this space. Osteophytes

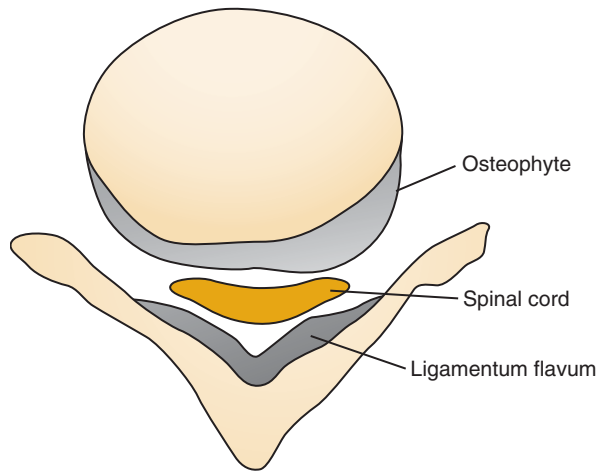

Figure 29-4. Cervical spondylosis. C5 vertebra in cross section. Posterior osteophytes of the vertebral endplate and hypertrophy of the ligamentum flavum compromise the cervical spinal canal and cause flattening of the spinal cord.

and hypertrophic osteoarthritic changes of the facet and uncovertebral joints may further impinge on the spinal canal and foramina. Hypertrophy of the ligamentum flavum, interposed between the vertebral laminae at each level, and hypertrophy or ossification of the posterior longitudinal ligament, which runs along the anterior wall of the spinal canal, may compromise this space even more (Fig. 29-4).⁷ Intuition suggests that compression of the cervical spinal cord and nerve roots by the stenosis of the spinal canal and foramina is responsible for the myelopathy and radiculopathies characteristic of cervical spondylosis. However, a finer understanding of the pathogenesis of this disorder has been elusive. Proposed explanations of the neurological deficit include (1) direct compression by stenosis adequate to compromise the cord and roots and to cause disturbance of functions such as membrane ion channel conductance and axonal transport, (2) rubbing of the spinal cord and roots on protruding skeletal structures that may not themselves be severely compressive but adequate to cause similar functional disturbances, and (3) arterial or venous compromise.⁸ All of these factors may play a role. Pathological study shows the presence of distorted and flattened spinal cords that correspond to spondylotic bars. Demyelination of the lateral columns occurs at the stenotic site and caudally and of the posterior columns rostrally. This demyelination corresponds to the sites of rubbing: anteriorly and inferiorly with neck flexion and posteriorly and superiorly with extension. In the central gray matter ischemic changes with neuronal loss are seen. Sometimes syringomyelia can be found. Root sleeves may be thickened and rootlets adherent.

EPIDEMIOLOGY AND RISK FACTORS. The major risk factor for cervical spondylosis is aging. Although trauma may contribute, there is usually no history of significant trauma. Screening of asymptomatic patients shows a high frequency of spondylotic changes that increases with advancing age. By age 59, 70% of women and 85% of men have changes on radiographs, and by age 70, the number increases to 93% of women and 97% of men.⁹ Up to 75% of these patients have abnormal neurological findings

by age 65, but fewer have related symptoms.¹⁰ Heavy labor and especially occupations that expose the patient to vibration probably increase the risk of spondylosis.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. The major clinical features are the symptoms and signs referable to cervical myelopathy and radiculopathy. Patients may complain of neck pain and pain radiating into the arms. There may be weakness of the legs and sensory loss, especially of position sense. The weakness or sensory loss may be discovered when an elderly patient presents for gait problems or falls rather than after a direct complaint. Bowel and bladder dysfunction are uncommon complaints accompanying advanced cervical myelopathy. Most commonly, the onset of symptoms is insidious; however, occasionally an elderly patient with spondylosis presents with catastrophic onset of quadriplegia or paraparesis after a fall.

Typically, there is some limitation of neck mobility. Examination of the cranial nerves should be normal, although the jaw jerk may be increased in some cases. Weakness is common in the lower extremities, especially in the hip flexors, knee flexors, and extensors of the feet and toes. Tone in the lower extremities is increased, and Babinski's sign may be present. Sensory loss to light touch, vibration, and joint position is sometimes found. Deficits in lower extremity motor function are determined by the degree of myelopathy. Findings in the upper extremities depend on the spinal level involved and the degree of cord or root compression. Compression of nerve roots, and possibly anterior horn cell dysfunction from cord compression, especially in the lower cervical region, can manifest as atrophy, weakness, and fasciculations in the affected myotomes—leading to a combination of lower and upper motor neuron signs that can mimic amyotrophic lateral sclerosis. Sensory loss in the upper extremities may also be seen, following a simple radicular pattern or, more commonly, a patchy distribution, presumably due to multiple root and cord involvement.

The main associated features are those of disorders that compromise the cervical spine and predispose to osteoarthritis. These include prior trauma, prior disc herniation, various congenital anomalies of the cervical spine, and underlying systemic arthritic disorders.

DIFFERENTIAL DIAGNOSIS. Because cervical spondylosis is a common radiological finding in asymptomatic patients, radiological tests can be misleading, and a proper differential diagnosis is particularly important. When a patient presents with a combination of radicular and myelopathic sensorimotor signs and symptoms, the diagnosis of spondylotic disease is not difficult. However, this clinical presentation is not common, and in most patients either myelopathy resulting from central protrusions or radiculopathy resulting from lateral protrusions predominate. The differential diagnosis must therefore include conditions that cause pure myelopathy, pure radiculopathy, and combined myelopathy and radiculopathy. Because compressive myelopathy frequently causes patchy dysfunction at the affected spinal level, the differential must also include diseases that affect specific spinal cord subsystems (e.g. motor neuron disease or combined systems degeneration).

The syndrome of slowly progressive spastic weakness of the extremities, worse in the lower than in the upper

extremities, may be produced by a variety of pathological causes. Some of these are listed here along with clues that may help to distinguish them from spondylotic myelopathy.

Multiple Sclerosis. Age of onset, gender, and types of neurological findings do not reliably distinguish chronic spinal multiple sclerosis. Visual complaints, mental status changes, and early bowel or bladder dysfunction are helpful clues. Cranial MRI may demonstrate subcortical and periventricular hyperintensities on T₂-weighted images in the majority of patients with multiple sclerosis. Visual evoked responses and oligoclonal bands in the CSF, if abnormal, are helpful (see Chapter 48).

Amyotrophic Lateral Sclerosis. In most patients with amyotrophic lateral sclerosis, lower motor neuron signs are evident from the beginning, but spasticity predominates in a few. The finding of muscle atrophy and relatively increased reflexes in the same myotome strongly suggests amyotrophic lateral sclerosis. Bulbar symptoms or signs should be carefully sought on examination and should be evaluated with EMG. The sensory loss from radicular or long tract involvement, common in cervical spondylosis, should be absent in all forms of motor neuron disease. In one recent series, 5% of patients with amyotrophic lateral sclerosis underwent a cervical laminectomy in the hope of arresting progressive spasticity, emphasizing how commonly the two conditions coexist (see Chapter 36).

Primary Lateral Sclerosis. A few patients with a slowly progressive, purely spastic condition are found to have a degenerative disease allied to amyotrophic lateral sclerosis, but without lower motor neuron features.

Subacute Combined Degeneration of the Spinal Cord. Vitamin B₁₂ deficiency, common, sometimes disabling, and easily treatable, should never be overlooked. Low serum vitamin B₁₂ level, hypersegmented polymorphonuclear leukocytes, and macrocytic anemia are often found in early cases. The lesions of vitamin B₁₂ deficiency begin in the cervical or thoracic cord, and deficits are often primarily sensory, which is uncommon in patients with cervical spondylosis (see Chapter 40).

Dural Arteriovenous Fistula. Several decades ago it was believed that spinal arteriovenous malformations presented either as subarachnoid hemorrhage or as the lumbar syndrome of painful cauda equina deficits. It is now known that small arteriovenous fistulas in the spinal dura can cause myelopathy with either a stepwise progression or abrupt onset. Most malformations are seen on MRI or myelography; however, some require selective angiography of the segmental arteries that supply the cord for definitive diagnosis.

Lyme Radiculomyelitis. Neuroborreliosis can cause a combined polyradiculopathy and myelopathy. Cranial neuropathies, mononeuropathies, and radicular symptoms at more than one spinal level commonly accompany the findings attributable to the cervical spine and strongly discourage a diagnosis of compressive myelopathy. Serum and CSF antibodies to the causative spirochete and CSF lymphocytic pleocytosis are typically present.

Myelopathy Associated with HIV/AIDS. Subacute vacuolar change in the spinal cord may develop in patients with human immunodeficiency virus infection, usually in those with frank acquired immunodeficiency syndrome (AIDS) and a history of multiple opportunistic infections. Most patients are younger than the average patient with

spondylosis. This entity often manifests as an ascending sensory disorder (see Chapter 44).

HTLV-I Myelopathy. Slowly progressive spastic paraparesis with early bladder involvement in a patient from a region endemic for human T-cell leukemia-lymphoma virus (HTLV)-I infection should prompt suspicion of this infectious cause. Patients typically have milder spasticity of the upper extremities. Diagnosis can be made by identifying the presence of antibodies to HTLV-I in serum (see Chapter 41).

Familial Spastic Paraplegia. These patients can be recognized by their family history of progressive leg weakness and gait difficulty in several relatives. The most common inheritance pattern is autosomal dominant linked to mutations in the spastin gene on chromosome 2p (SPG4). However, other autosomal dominant (atlastin, SPG3, SPG6), autosomal recessive (paraplegin, spartin), and X-linked (SPG1, SPG2) types also occur. Commercial testing for mutations in the spastin, atlastin, and NIPA1 (SPG6) genes are now available.¹¹

Syringomyelia. Cervical syringomyelia may occur in isolation or in association with the Chiari malformation, trauma, or tumor. Patients typically have lower motor neuron signs in the upper extremities due to involvement of the central gray matter and upper motor neuron signs in the upper and lower extremities due to involvement of the descending corticospinal tracts. Segmental ("suspended") loss of spinothalamic sensation, neck, back, and extremity pain with a "neuropathic" quality, and the context of an associated underlying problem suggest the diagnosis. MRI demonstrates the syrinx.

Compressive Lesions at the Craniocervical Junction. The Chiari malformation can cause myelopathy, vertigo, and ataxia. There may be an associated syringomyelia. Basilar impression due to instability of the atlanto-occipital joint or atlantoaxial instability, as in rheumatoid arthritis, may cause slowly progressive myelopathy. In achondroplasia, craniocervical myelopathy and spinal stenosis at other levels are very common.^{12,13} These lesions often occur in the context of spondylotic lesions, and it is very important to clarify the source of progressive findings. Certain tumors, such as meningiomas, schwannomas, or neurofibromas at the craniocervical junction may also mimic the signs of cervical spondylosis (Fig. 29-5). Often the history suggests a loss of function on one side followed by progression of signs to all four extremities. Downbeating nystagmus suggests the localization. Imaging high enough to demonstrate the craniocervical junction is crucial before cervical myelopathy is attributed to spondylotic lesions.

EVALUATION. Evaluation begins with a careful history and examination. This is especially important because of the known high rate of radiological spondylotic abnormalities in asymptomatic populations. It is very important to establish the best possible correlations between the clinical findings and the imaging abnormalities. Available imaging modalities include plain radiographs, CT myelography, and MRI. Plain films can show many of the degenerative changes of bony elements, however, they do not reveal the relationship of these to the neural structures. Simple flexion and extension films performed with care can also demonstrate spinal instability that is not apparent on MRI or CT myelography. MRI can demonstrate the dimensions

Figure 29-5. Neurofibromatosis. Sagittal (A) and axial (B) T₂-weighted MRI scan of the cervical spine. Intradural nodular neurofibromas are seen compressing the spinal cord anteriorly at the C3–C4 and C6–C7 levels. This 27-year-old woman with neurofibromatosis had no symptoms but mild myelopathic features on examination.

of the spinal canal and foramina and distortion of the spinal cord or roots caused by the impingement of bony structures. Gadolinium enhancement can demonstrate the presence of alternative lesions that may be under consideration. CT myelography can be used to answer any questions that remain after MRI. The myelogram may fail to show complete block even when significant spondylotic myelopathy is present.

MANAGEMENT. Conservative management of cervical spondylosis includes immobilization with a cervical collar and the use of non-narcotic, nonsteroidal medications for pain. The symptoms and signs in most patients stop progressing with this therapy, and in some patients they improve. However, controlled studies evaluating the benefit of immobilization are limited.¹⁴ When radicular pain is the major problem demanding further intervention, epidural steroid injections can be effective. We refer patients for neurosurgical evaluation and surgical therapy when their myelopathy is severe or if it progresses despite these conservative measures, after careful consideration of other diagnostic possibilities as listed earlier. There has been no documentation of long-term benefit from surgery, although many series have shown evidence of benefit in the short term.¹⁴ Posterior decompressive laminectomy is the procedure that has the longest history. However, unless it is performed over many levels, it will not relieve multilevel compression. Wide decompression performed over a number of segments may be complicated in later years by a swan neck deformity owing to the loss of posterior supporting elements. The anterior approach with interbody fusion is especially suitable for patients with single level nerve root compression. Its benefits for cord compression are less well defined. When radicular symptoms are due to bony osteophytes, foraminotomy may relieve the symptoms and signs of root compression. Although the benefit of surgery has not been systematically validated, and many patients improve spontaneously or with immobilization by a collar, clinical experience with individual cases suggests that selected patients do benefit and show marked improvement shortly after decompressive surgery.

PROGNOSIS AND FUTURE PERSPECTIVES. The natural history of cervical spondylosis is not known. Although the course of the disease is progressive and most patients have chronic symptoms, a large majority of patients remain stable for many years and do not require surgical intervention.

MRI has greatly advanced the precision of diagnosis while sparing patients the discomfort and risk of myelography. Future advances in imaging may further facilitate diagnosis. Rowland has pointed out our lack of knowledge of the natural history of cervical spondylosis as well as the need for controlled trials that demonstrate the effects of surgery and clarify surgical indications.¹⁵ Such studies, if they are done, will require a cooperative effort and careful definition of clinically relevant questions.

Ankylosing Spondylitis

Ankylosing spondylitis (AS) is one of the seronegative arthritides. This group includes Reiter's syndrome and psoriatic arthritis. There is a close association with the HLA-B27 haplotype, and the disease is more than three times more common in men than in women. In many patients, the disease seems to progress slowly for years, primarily with back pain, and then stabilizes without much disability. In some cases the disease progresses to total spinal fusion, producing a typical "bamboo spine" on x-ray. In all patients, the presence of sacroiliac joint disease on radiographs is required to make the diagnosis. There are two major neurological complications of AS, cauda equina syndrome of unclear etiology and several types of cervical spinal cord compression due to dislocation or deformity (Video 247, Ankylosing Spondylitis).

Ankylosing spondylitis is less common in black populations and in people of Japanese ancestry, in parallel with the lower expression of HLA-B27 in these groups. There is a considerable familial incidence of AS. Approximately 20% of patients with AS have disease in peripheral joints, not in the vertebral column or pelvis, and it is in this group that the neurological complications seem to be most frequent.

AS patients with cauda equina syndrome have gradual and relatively symmetrical loss of function in the L5, S1, and S2 roots.¹⁶ Both motor and sensory fibers are affected. Foot drop, weakness of plantar flexion, and perianal sensory loss are typical. Nearly all patients develop bladder and bowel incontinence. The cervical spine disorder most often associated with AS is instability at the craniocervical junction because of ligamentous laxity at the level of the odontoid process.¹⁷ Some patients have stepwise subluxation of the cervical spine, resembling that seen in seropositive rheumatoid arthritis. In either case, myelopathy may develop, often with sensory loss in the hands as well as quadriparesis. As in rheumatoid arthritis, there may be marked instability of the cervical spine or craniocervical junction with much local pain, sudden changes in neurological symptoms with postural change, and eventual need for surgical fusion. Patients with AS may have uveitis or cardiac disease. Fractures of the fully or partially fused spine are common, especially if osteopenia exists.

The cauda equina syndrome can be confused with lumbar disc disease, but the distinguishing features of the former are symmetry and early loss of bladder function. The craniocervical instability of AS produces a myelopathy that may be insidious and difficult to distinguish from diffuse non-neurological weakness, myopathy, or generalized neuropathy.

The diagnosis should be confirmed radiologically. There are specific radiographic criteria for the diagnosis of AS.¹⁸ Cauda equina syndrome is accompanied by a distinctive radiological change, consisting of a wide patulous distention of the subarachnoid space in the sacral region, often with erosion of the overlying sacral bone. The cause of this distended space is unknown, nor is it clear how this distention contributes to nerve root dysfunction.¹⁹ CSF examination does not suggest arachnoiditis. The cervical spine should be fully visualized by MRI, and the position of the odontoid should be carefully noted. In rheumatoid arthritis patients, widening of the space between the odontoid and the arch of C1 (normally 3 mm or less) is observed. In AS, unrecognized fracture, odontoid dislocation, or atlantoaxial dislocation can occur.

Unfortunately, no specific therapy is available for patients with the cauda equina syndrome. A scattering of case reports indicate that some authors have attempted decompression of the thecal sac. Decompressive laminectomy is of no value. Fractures or cervical dislocations may require fusion.

COMPRESSIVE STRUCTURAL DISORDERS

Fibrous Dysplasia

PATHOGENESIS AND PATHOPHYSIOLOGY. Our understanding of the pathogenesis of fibrous dysplasia has advanced greatly in recent years. Investigators have identified a missense point mutation of the gene that codes for the alpha subunit of the G-protein, $Gs\alpha$, in affected bone and other tissues in patients with fibrous dysplasia and the McCune-Albright syndrome (polyostotic fibrous dysplasia, café au lait spots, and precocious puberty in females).²⁰ The absence of this mutation in unaffected tissues in patients with the disease suggests that a somatic

mutation occurs early in embryogenesis to create a genetic mosaic. The mutated $Gs\alpha$ proteins activate adenylate cyclase and increase signaling through the cyclic adenosine monophosphate (cAMP)–protein kinase A pathway.²¹ Recent work suggests that the resultant phosphorylation of transcription factors enhances transcription of the proto-oncogenes *c-fos* and *c-jun* and translation of their proteins in affected tissues.^{22,23} These findings surely represent only part of the molecular story, and it is likely that enhanced production of other oncoproteins will be discovered.²⁴

These molecular changes result in a gain of function that probably underlies the bony and endocrine pathophysiology of fibrous dysplasia. The functional result is a disorder of lamellar bone remodeling and repair. The pathological result is replacement of normal bone and marrow elements by vascular fibrous tissue. This tissue is composed of whorls of proliferating fibroblasts with haphazardly arranged trabeculae of metaplastic bone and fluid-filled cystic areas lined by multinucleated giant cells. The appearance is similar to that of osteitis fibrosa cystica due to hyperparathyroidism but is distinguished by the absence of osteoblasts. The abnormal bone originates from the medullary cavity and grows outward, thinning the bony cortex.²⁵ The high prevalence in puberty, the accelerated expansion of lesions during pregnancy, and the association with precocious puberty in females in the McCune-Albright syndrome^{26,27} suggest a hormonal influence that is, so far, poorly understood. Estrogen and progesterone receptors have been identified in affected bone.²⁸ Patients with fibrous dysplasia have accelerated turnover of bone, and many have elevated serum alkaline phosphatase levels, reflecting increased osteoblastic activity. Those with extensive disease also have elevated urinary hydroxyproline, reflecting increased turnover of collagen, a measure of the activity of osteoclasts. Serum calcium and inorganic phosphorus remain normal, reflecting compensatory increases in bone formation and resorption. Fibrous dysplasia is generally considered to occur sporadically. Sassin and Rosenberg found no positive family histories among 50 cases with cranial fibrous dysplasia.²⁵ This result is consistent with the current hypothesis that the disorder results from a somatic mutation early in embryological development.

EPIDEMIOLOGY AND RISK FACTORS. The age of onset is variable, but the disorder most commonly presents in childhood, especially during the period of most rapid bone growth. However, in one series of 50 patients with fibrous dysplasia of the skull, over half came to medical attention after age 18. There is no difference in incidence based on race or sex for the most typical forms.²⁵ However, the McCune-Albright syndrome occurs more frequently in females. As noted earlier, the bony lesions may expand at an accelerated rate during pregnancy.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. About 70% of patients have the monostotic form involving a single bone. The remainder have the disseminated polyostotic form, which is often predominantly unilateral. Sites of involvement vary, the ribs and long bones being the most common sites. The skull is involved in about 50% of polyostotic cases and in 10% to 27% of monostotic cases.²⁵ Most of the clinical manifestations that prompt neurological evaluation are due to skull involvement. Table 29-3 shows the frequency of skull bone involvement found in a series of 50 patients.²⁵ A more

TABLE 29-3

Frequency of Skull Bone Involvement by Fibrous Dysplasia

| BONE | NUMBER OF CASES (N = 50) |
|----------------------|--------------------------|
| Frontal | 28 |
| Sphenoid | 24 |
| Frontal + sphenoid | 18 |
| Optic canal involved | 10 (3 bilateral) |

recent series found the ethmoids to be most commonly involved.²⁹ Lesions causing complications may be overrepresented in these series, since they are more likely to be referred for specialty care. Patients may present with a variety of focal neurological findings secondary to the compressive effects of the involved bone (Fig. 29-6). Visual impairment followed by hearing loss and tinnitus are the most common presenting neurological complaints. Although various other cranial neuropathies may occur as a result of the compressive effects of involved bone, these are rare enough that none were seen in two large studies of cases involving the skull.^{25,30} Optic nerve compression with visual symptoms is common when the frontal and sphenoid bones are involved. A proptotic and downward displaced eye is often seen when these bones are involved and should prompt questions about visual symptoms and a radiological evaluation of the optic canal. Patients with stenosis of the optic canal may complain of decreased acuity or blurring of vision, scintillating scotoma, flashing light, or graying of vision when pressure is applied to the globe. Optic atrophy may be seen on funduscopic examination. Visual symptoms may be slowly progressive, and they have often been present for some time when the patient presents. Patients may also have progressive facial asymmetry and deformity resulting from facial nerve involvement. Patients with hearing deficits typically have conductive loss due to stenosis of the external canal and middle ear by the involved temporal bone. A nonthrobbing headache may be a common complaint as well. Sassin and Rosenberg's patients also had an increased incidence of seizures (6 of 50), confirming the findings of prior reports.²⁵ The reason for this association is not known.

Fibrous dysplasia has been associated with various other disorders. Cutaneous hyperpigmentation occur in over 50% of those with the polyostotic form. The McCune-Albright syndrome consists of polyostotic fibrous dysplasia, usually largely unilateral, with café au lait spots and various forms of endocrine hyperfunction, especially precocious puberty in females.^{26,27} Rarely, other endocrine abnormalities, including hyperthyroidism, acromegaly, Cushing's syndrome, hyperparathyroidism, and diabetes mellitus may occur. Some patients may have a progressive diffuse facial deformity called leontiasis ossea; however, this deformity may be caused by other disorders as well, including Paget's disease and craniometaphyseal dysplasia.³⁰ Malignant transformation to sarcoma occurs in about

Figure 29-6. Fibrous dysplasia. Sagittal T₁-weighted MRI scan of the head. Fibrous tissue is seen replacing bone of the occiput and skull base. This patient presented with acute hoarseness that was presumed to be due to compression of the accessory nerve in the skull base.

0.5% of patients with fibrous dysplasia and 4% of those with the McCune-Albright syndrome.³¹ This tumor is rare in the skull.³⁰

DIFFERENTIAL DIAGNOSIS. Fibrous dysplasia must be differentiated from benign and malignant neoplasms, including meningioma with adjacent hyperostosis, sarcoma or fibroma replacing bone, bone cysts, and various orbital masses, including eosinophilic granuloma, Hand-Schüller-Christian disease, and orbital pseudotumor.^{30,32} In addition, other metabolic diseases of bone must be considered, including Paget's disease, hyperparathyroidism, hyperostosis frontalis interna, osteopetrosis, and craniometaphyseal dysplasia (Pyle's disease). In general, age of onset, other clinical features, and radiological features easily distinguish these disorders. Rarely, the cranial hyperostosis found in hematological disorders or cyanotic heart disease causing bone marrow hyperplasia may cause confusion.

EVALUATION. Evaluation should seek to distinguish fibrous dysplasia from other tumors or metabolic diseases and to assess the presence of deficits that require follow-up or surgical intervention. Plain x-ray, CT, and MRI can distinguish fibrous dysplasia from tumors and characterize other metabolic disorders. Meningioma with adjacent hyperostosis is distinguishable on CT and MRI by its typical enhancement and its extension into the cranial cavity. Fibrous dysplasia expands into the outer table, leaving the inner table and cranial contents undisturbed.³⁰ Imaging dedicated to the optic foramina should be done when the frontal and sphenoid bones are involved. Skeletal survey and increased uptake on bone scintiscanning can identify asymptomatic areas of involvement. Serum alkaline phosphatase levels are often elevated, but serum calcium and inorganic phosphorus are normal, helping to differentiate hyperparathyroidism. When following patients with frontal and sphenoid involvement who have not had surgery,

photographs of the head, quantitation of proptosis, documentation of acuity and visual fields, and funduscopic examinations for optic atrophy should be performed along with radiological views of the optic canal. These parameters may then be followed every 3 to 6 months until it is clearly established that no progressive visual loss has occurred. The onset of pain, increasing alkaline phosphatase levels, rapid growth, or invasion into cortical bone should raise a suspicion of possible malignant transformation. Biopsy may be needed to distinguish progression of fibrous dysplasia from malignant transformation.

MANAGEMENT. Because of a lack of medical therapies, treatment has been primarily surgical. Recently bisphosphonates alone and in combination with surgery have been shown to relieve bone pain, to prevent fractures, to lower the levels of markers of disease activity, and to decrease disability.^{33–35} When visual symptoms are present in patients with a small or diminishing optic canal, surgical decompression by unroofing of the optic canal can in most cases arrest progression. Such treatment rarely leads to significant return of function, therefore, patients at risk for visual loss must be closely followed. The lesions are highly vascular, and intraoperative bleeding and intrabony hematomas may complicate surgery. Radiotherapy is contraindicated because it greatly increases the risk of malignant transformation. Because lesions may progress more rapidly during pregnancy, careful follow-up, especially for visual symptoms, must be maintained. Decisions about surgery during pregnancy should be based on the neurological status of the patient.

PROGNOSIS AND FUTURE PERSPECTIVES. The course in most cases is benign. Leeds and colleagues followed 15 patients for 6 to 39 years and found that radiological progression was slight or equivocal in all but two patients.³⁰ Although the lesions become less active after skeletal maturation, progression does not necessarily stop with bone growth, and the lesions may reactivate during maturity. The increased understanding of this disease and the development of bisphosphonates have now provided a promising new medical therapy for patients with significant symptoms. Recent success in elaborating the molecular mechanisms of intracellular signaling and their alterations in fibrous dysplasia and other diseases has made it possible to deepen our understanding of the pathogenesis of fibrous dysplasia. The elaboration of this work is likely to clarify the endocrinological manifestations of fibrous dysplasia and to lead to further refinements in therapy.

Paget's Disease

PATHOGENESIS AND PATHOPHYSIOLOGY. Paget's disease (osteitis deformans) is a metabolic bone disease of unknown etiology characterized by increased osteoclast size and activity, resulting in resorption of bone followed by reactive new bone formation. This process produces areas of bone resorption with new bone laid down in an abnormally dense mosaic pattern. The osteoclasts in affected bone contain nuclear and cytoplasmic virus-like inclusions and paramyxoviral transcripts, and evidence has been presented of an association with various paramyxoviruses, including measles virus, respiratory syncytial virus, and canine distemper virus. However, the role that

viral infection may play in the pathogenesis remains unclear. It has been speculated that the disorder represents the late effect of viral infection on osteoclasts or their precursors and that affected osteoclasts tend to form multinucleated syncytia, which have increased resorptive activity. Normal osteoblasts may then be stimulated by the primary pathological osteolytic disorder. Some familial and nonfamilial cases of Paget's disease have been linked to mutations in the SQSTM1 gene on chromosome 5q, which encodes p62 protein, a ubiquitin-binding protein implicated in some of the proposed mechanisms leading to Paget's disease.³⁶ Although studies have suggested susceptibility loci on chromosomes 6p and 18q in some families, subsequent studies have confirmed the genetic heterogeneity of Paget's disease and the infrequency of linkage to these loci.^{37–39}

EPIDEMIOLOGY AND RISK FACTORS. Paget's disease is the second most common metabolic bone disease in the elderly population, after osteoporosis. It is most common in patients of northern European ancestry and is uncommon among Asians and Africans. Males predominate slightly. The prevalence in the elderly population of the United States is 1% to 3%, with 0.1% to 0.2% of patients having significant symptoms.⁴⁰ The risk is increased in relatives of those affected, but pedigrees do not support direct inheritance.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. The disease typically begins in middle age or later and varies from limited asymptomatic involvement of a single or few sites to widespread symptomatic disease. The femur, pelvis, and spine are most commonly affected, although any bone may be involved. Skull involvement is also common. The most typical presenting symptoms are focal progressive bone pain, deformity due to expansion of bone, and structural failure such as vertebral compression fracture or bowing of weight-bearing long bones. Enlarging hat size due to progressive skull expansion is a classic symptom. Other typical facial changes include enlarged coarsened orbits and prognathism. Patients may also notice focal increases in skin temperature due to increased blood flow at affected sites. The most common neurological symptoms are headache, deafness, and problems resulting from spinal disease. The cause of the deafness is unclear. Both auditory nerve compression and involvement of the middle ear ossicles have been suggested as mechanisms; however, autopsy studies have not borne out either hypothesis.^{40,41} The main mechanisms presumed to cause neurological symptoms are compression of neural and vascular structures by overgrowth of bone into limited spaces, traction on neural structures displaced by bony deformity, and possibly a vascular steal phenomenon resulting from the local high blood flow demand of pagetic bone (Table 29-4). Involvement of the skull may cause basilar impression with consequent problems, including headache, ataxia, hydrocephalus, myelopathy, or cranial neuropathies. Patients may develop intervertebral disc lesions and spinal stenosis and, rarely, extramedullary hematopoiesis. These lesions may cause back pain or may progress to cause spinal cord and nerve root compression. Yet compressive symptoms due to spinal disease are uncommon, and when they occur in patients with Paget's disease, the possibility of sarcomatous degeneration should

TABLE 29-4

Neurological Complications of Paget's Disease of Bone

| DEFICIT/LOCALIZATION | PROPOSED MECHANISMS OF INJURY |
|--|---|

Major categories are listed in order of decreasing relative frequency. Among cranial nerve deficits, those of the lower cranial nerves are most common.

Figure 29-7. Paget's disease of bone. Head CT bone windows show thickening of the bony calvarium with osteosclerotic and lytic lesions.

be considered. High-output heart failure due to shunting within highly vascular bone is possible but rare.

From 1% to 5.5% of patients with Paget's disease develop osteogenic sarcoma.⁴² Other tumors, such as giant cell tumor of bone, are less common. The pagetic osteogenic sarcoma is osteolytic, and pathological fracture is the most common presentation. Malignant degeneration should also be suspected when pain or a rapid increase in growth is noted or when compressive spinal findings emerge. About 5% of patients have hyperparathyroidism, but the mechanism of this association is not known. A complex array of vitamin D-related disorders may also accompany Paget's disease.

DIFFERENTIAL DIAGNOSIS AND EVALUATION. The differential diagnosis includes primary and metastatic bony tumors, especially prostate cancer, and other metabolic

bone disorders that produce lytic lesions and hyperostosis. Degenerative arthritis may cause diagnostic confusion as to the source of symptoms, especially when the two diseases coexist.

Plain radiographs are still the primary means of diagnosis. Affected bones are expanded, often with thickening of the cortex. There may be a peripheral edge of lytic fronts and a small intracortical lytic area. It is common to find lytic lesions predominating in the skull. The most striking feature is typically osteosclerosis, which may have a fluffy appearance. The sclerosis is often intermixed with lytic disease. Uniformly sclerotic "ivory" vertebrae may be seen. Radionuclide scanning demonstrates greatly increased uptake and is the most sensitive test to establish the extent of involvement. CT can be used to distinguish osteolytic lesions missed on plain radiographs and can identify soft tissue masses (Fig. 29-7). In this regard, it may be an important adjunct in the differentiation of benign lesions from tumor. The urinary hydroxyproline-creatinine ratio is elevated, reflecting increased bone resorption. Greatly elevated bone alkaline phosphatase levels reflect increased osteoblastic activity and are characteristic. The relative elevations of these values reflect the predominance of either lytic (early) or blastic (late) disease. Serum calcium is usually normal unless some other factor, such as immobilization, tips the balance in favor of resorption and hypercalcemia. Inorganic phosphorus is normal or slightly elevated. When malignant degeneration is suspected, as in a patient with a pathological fracture, early biopsy should be pursued.

MANAGEMENT. The management of Paget's disease has changed in recent years. Both bisphosphonate and calcitonin attack the underlying metabolic disorder by inhibiting bone resorption. Newer bisphosphonate derivatives offer advantages that have made them emerge as the favored therapy, yet both bisphosphonate and calcitonin are still used to prevent the development of long-term complications. Etidronate, the first bisphosphonate available, provides definite benefit by inhibiting osteoclast activity. However, it interferes with the normal mineralization of new bone. The third-generation bisphosphonates, such as

pamidronate, alendronate, and risedronate, are similarly effective without impairing mineralization at effective doses.⁴³ These agents have longer half-lives than etidronate, may be given in short courses intravenously, and alendronate can be given chronically by mouth.⁴⁴ The urinary hydroxyproline level begins to fall within days of an intravenous dose; serum alkaline phosphatase levels decline later and more gradually. Bisphosphonates remain in bone for a long time and may promote prolonged remissions. Subcutaneous or nasally administered calcitonins also inhibit osteoclasts, resulting in symptomatic relief. However, the effect is short-lived, and the agents must be continued to maintain this effect. A loss of effect during therapy may be due to the formation of neutralizing antibodies, which occurs in about one fourth of those treated, or to the downregulation of calcitonin receptors.⁴⁵ The cytotoxic agent plicamycin, used for hypercalcemia of malignancy, causes a rapid improvement but is more toxic than the bisphosphonates or calcitonins. Gallium nitrate has anti-osteoclastic activity, but data on its clinical use do not support its use outside controlled trials. The goals of treatment are to normalize metabolism as evidenced by biochemical markers and to relieve symptoms. Most patients obtain relief from bone pain. Stabilization of neurological deficits often follows therapy and occasionally includes improvement of hearing. There has been radiological evidence of healing of osteolytic lesions. Patients who develop compressive spinal cord syndromes unresponsive to medical therapy require surgical intervention. Malignant lesions should be treated aggressively with radical resection for best results. Chemotherapy has not yet been shown to be effective. Early detection of malignancy is currently the only available way to improve survival. Patients require life-long surveillance for tumor recurrence. With the currently available array of effective therapies for Paget's

disease, it is most important that patients be properly referred for expert care.

PROGNOSIS AND FUTURE PERSPECTIVES. Many patients remain asymptomatic. Newer drug therapies can now address bone pain and other rarer symptoms and may offer long-term remission. However, as noted previously, prevention or early detection of neurological deficits is essential to avoid loss of function, since therapy is more likely to arrest than to reverse deficits. The prognosis after malignant degeneration, however, remains poor, with approximately 10% survival at 5 years.⁴⁶ Research in Paget's disease has produced advances in the understanding of the possible underlying etiology, genetic associations, the metabolic processes that promote the disorder, and the application of new therapies. Further clarification of the viral hypothesis, elaboration of genetic associations, development of improved diagnostic metabolic markers, and refinement of management with antiosteoclastic agents are expected in the future.

Other Compressive Disorders

Numerous less common structural disorders are sometimes associated with compressive neurological signs and symptoms, including hyperostosis frontalis interna, anomalies of the craniocervical junction, congenital and acquired abnormalities of the spinal cord, generalized skeletal abnormalities, and miscellaneous disorders such as arachnoid diverticula. The clinical signs and symptoms of these disorders are summarized in [Table 29-5](#).

Compressive Neuropathies

Compressive neuropathies should be distinguished from focal neuropathies. Although all compressive neuropathies

TABLE 29-5

Other Structural Disorders and Associated Neurological Syndromes

| DISORDER | NEUROLOGICAL SYNDROME |
|--|---|
| Hyperostosis frontalis interna | Headache |
| Anomalies of the craniocervical junction region | |
| Basilar impression | Brain stem, cerebellar, and cranial nerve compression |
| Chiari malformation | Brain stem, cerebellar, and cranial nerve compression |
| Atlantoaxial subluxation (e.g., congenital, rheumatoid arthritis, Down's syndrome) | Cord/lower brain stem compression |
| Congenital and acquired abnormalities of the spinal cord | |
| Klippel-Feil syndrome | Cord and root compression |
| Scoliosis | Cord and root compression |
| Kyphosis | Cord and root compression |
| Generalized skeletal abnormalities | |
| Achondroplasia | Spinal stenosis, disc disease, basilar impression |
| Mucopolysaccharidoses | Cord and root compression, basilar impression |
| Down's syndrome | Atlantoaxial subluxation, basilar impression |
| Osteoporosis | Cord and root compression |
| Osteopetrosis | Brain stem and cord compression |
| Osteomalacia | Cord and root compression, basilar impression |
| Osteitis fibrosa cystica (hyperparathyroidism) | Basilar impression |
| Osteogenesis imperfecta | Basilar impression |
| Miscellaneous disorders | |

| Peroneal | Fibular head | Lateral calf from knee to ankle; dorsum of foot to web space D1–D2 | Foot dorsiflexion (TA) and eversion (PL) | Reduced amplitude superficial peroneal SNAP Slowing of across-fibular head motor segment EMG abnormalities in TA, PL, but not TP, GM |
| Lateral cutaneous nerve of thigh | Inguinal ligament | Lateral thigh | None | Normal |

DUC, dorsal ulnar cutaneous nerve; FCU, flexor carpi ulnaris; FDI, first dorsal interosseous; GM, gluteus medius; IO, interossei muscles; PL, peroneus longus; SNAP, sensory nerve action potential; TA, tibialis anterior; TP, tibialis posterior.

are focal, not all focal neuropathies are due to compression. Other focal neuropathies may be ischemic, inflammatory, neoplastic, due to stretch, or idiopathic. Furthermore, compressive neuropathies are not synonymous with entrapment neuropathies. Prolonged but self-limited compression, such as may occur during anesthesia or other periods of unconsciousness, may result in a focal compressive neuropathy without entrapment. The common sites of nerve entrapment are listed in Table 29-6.

Compressive Disorders of the Median Nerve

CARPAL TUNNEL SYNDROME

PATHOGENESIS AND PATHOPHYSIOLOGY. The carpal tunnel is formed by the transverse carpal ligament anteriorly and the bones of the wrist posteriorly, laterally, and medially. The median nerve and finger flexor tendons pass through the tunnel so that narrowing of the space or inflammation of the tendon synovial sheaths (tenosynovitis) may result in compression of the median nerve. Studies with recording wicks placed in the canal show that flexion or extension elevates the canal pressure, and it is clear clinically that such wrist deviation typically worsens symptoms.⁴⁷ Although nonspecific tenosynovitis is the most common cause of rising canal pressure, other causes may be relevant: amyloidosis may infiltrate the tendon sheaths, rheumatoid arthritis may cause synovial tissue to invade the canal, or hypothyroidism may cause tissue edema.

CLINICAL FEATURES. The median nerve may be compressed at the wrist within the carpal tunnel, resulting in the carpal tunnel syndrome (CTS). The principal symptom of CTS is a sensation of nocturnal paresthesias in the hand. The patient often awakens and feels the need to shake out the hand. When unilateral, symptoms are typically in the dominant hand, unless there is a history of a predisposing factor such as a fracture or rheumatoid arthritis affecting the nondominant wrist. With increased severity, there

may be intermittent pins and needles paresthesias in the hands during activities such as driving a car or even continuous numbness in several fingertips. When continuous sensory symptoms are present, the clinical finding of a sensory disturbance “splitting” the fourth digit is helpful in defining a median nerve lesion. Weakness of thumb abduction (thumb movement perpendicularly away from the palm), through action of abductor pollicis brevis (APB) or atrophy of the thenar eminence is occasionally present, but in most patients, the physical examination is normal. Signs of mechanical irritability of a nerve, when elicited properly, are helpful. In particular, induction of tingling or brief electrical sensations in the tips of any of the second through fourth digits with tapping of the wrist over the median nerve (Tinel’s sign) is highly suggestive of CTS. Phalen’s sign (sensory symptoms within 1 minute of sustained wrist flexion) is most helpful when the symptoms include paresthesias in the sensory distribution of the median nerve. When these maneuvers produce wrist pain alone, or vague sensory symptoms, they should not be interpreted as independent evidence of median nerve compression (Video 217, Anterior Interosseous Neuropathy, Pinch Sign).

ELECTROPHYSIOLOGICAL ASPECTS. Electrophysiological studies (EMG and nerve conduction studies) can be extremely helpful in establishing the diagnosis. Considerable uncertainty remains, however, about appropriate cut-off points of “normal” values because differing definitions of the gold standard for normal function have been applied in numerous studies.

Nonetheless, consensus does exist that sensory studies are more sensitive than motor studies for detection of CTS and that performance of any of three sensory comparison studies is more sensitive than more routine sensory tests.⁴⁸ A reasonable approach to electrophysiological diagnosis is to start with performance of median-second digit and ulnar-fifth digit antidromic sensory studies. If these studies are normal, a more sensitive comparison study such as the median-ulnar mixed palmar interlatency

difference can be performed.⁴⁹ Median-APB motor studies are also typically performed. The wide range of normal values for all of these studies creates problems of interpretation in some cases.^{50–53} The value of needle EMG studies when nerve conduction studies are diagnostic for CTS has been debated.^{54,55} There are electrophysiological severity grading scales that depend on needle EMG results, but because these scales are not clearly of value in determining management, the additional discomfort to the patient is usually a significant deterrent.⁵⁶

TREATMENT. Many patients with CTS are managed successfully by conservative means. Use of a wrist splint at night and for particular activities, such as long periods of driving, during the day, should be advocated. The splint should hold the wrist in a relatively neutral position. Prolonged or continuous wrist splinting may lead to reduced range of motion and should be discouraged.

The role of steroid injections for treatment is controversial.^{57–59} It is clear that injections into the carpal tunnel may damage the median nerve; short- or long-term benefit superior to sham treatment or the use of wrist splints has not been established. Some authors have advocated injections proximal to the carpal tunnel as an effective treatment, yet this approach has not been compared to conservative therapy with wrist splints or no intervention.⁶⁰

Patients who have persistent symptoms following conservative management should be considered for surgical treatment. The results of surgical release are generally excellent. Forty percent of patients are asymptomatic following surgery, and another 40% have only trivial residual symptoms. Postoperative long-lasting incisional pain, slight weakness of the wrist, and neurological worsening have been found in 10% of patients in surgical outcome studies.⁶¹ Several procedures for endoscopic carpal tunnel release have been introduced. Overall, these seem to have efficacy that is about equal to that achieved with standard release procedures.⁶² A recent comparison of steroid injection with open surgery demonstrated improved symptomatic and electrophysiological outcomes in patients who underwent surgery.⁶³

COMPRESSION OF THE MEDIAN NERVE AT SITES OTHER THAN THE WRIST

Median neuropathies may occur in the axilla from crutches, subclavian or axillary artery aneurysms, or hematomas. In the upper arm, compression during deep sleep or unconsciousness may occur. At the elbow, supracondylar spurs and ligaments are rare causes of compression.

Many patients with forearm pain receive a diagnosis of pronator teres syndrome. This syndrome has been variously defined. A “true” pronator teres syndrome resulting in compression of the median nerve by the pronator teres muscle is extremely rare, with very few well-documented cases published in the literature.⁶⁴

Compressive Disorders of the Ulnar Nerve

ULNAR NEUROPATHIES AT THE ELBOW

PATHOGENESIS AND PATHOPHYSIOLOGY. The ulnar nerve may be compressed at the region of the elbow,

either at the condylar groove or the cubital tunnel. Though the terms “tardy ulnar neuropathy” and “cubital tunnel syndrome”⁶⁵ have been used to refer to all ulnar neuropathies at the elbow, they should be reserved for much more specific syndromes. Habitual elbow leaning and prolonged elbow flexion, particularly during sleep, are the most likely causes of ulnar compressive neuropathy. Alterations in elbow anatomy, such as old fractures or the deformities of rheumatoid arthritis, may predispose to the development of ulnar neuropathy. Diabetes mellitus is a predisposing factor.

CLINICAL FEATURES. The most common symptoms are numbness and paresthesias in the medial hand, fifth digit, and medial fourth digit. When there is significant motor involvement (typically developing much later than sensory symptoms) difficulty with fine movements such as turning a key or buttoning may occur. Pain is of little localizing value when present, though symptoms of focal mechanical irritability, as with all compression neuropathies, are much more specific (Video 218, Ulnar Neuropathy, Wartenberg Sign).

The sensory examination is important, particularly in early disease, where sensory abnormalities may be the only findings. Involvement of the dorsal ulnar cutaneous and ulnar sensory territories results in a sensory disturbance that includes the dorsal and ventral medial hand up to the level of the wrist, the medial aspect of the fourth digit, and all of the fifth digit. Sparing of the dorsum of the hand may suggest an ulnar neuropathy at the wrist, though the selective fascicular involvement of the nerve when compressed at the elbow makes this sign unreliable. Clinical evaluation should include a careful study of the pattern of weakness. Ulnar neuropathy causes weakness of adduction of all fingers and abduction of the second through fourth digits. Involvement of flexor digitorum profundus (FDP) may result in weakness of flexion of the terminal phalanx of the fourth and fifth digits, and wrist flexion, particularly medially, may be weak from involvement of the flexor carpi ulnaris (FCU). Weakness of ulnar-innervated forearm muscles (FDP and FCU) is typically a very late sign, because the fibers serving these muscles are centrally located within the ulnar nerve as it passes through the elbow.

With lesions of the ulnar nerve above and at the elbow, there can be atrophy and flattening of the hypothenar eminence and interossei. When attempting finger extension, the hand may demonstrate a “claw-hand” deformity (*main en griffe*), with the fifth, the fourth, and, to a lesser degree, the third fingers hyperextended at the metacarpophalangeal joints (MCP) and flexed at the interphalangeal joints (Video 220, Ulnar Neuropathy, Main En Griffe). Hyperextension across the MCP results from weakness of the interossei and ulnar lumbricals leaving the action of the long finger extensors unopposed. This hyperextension results in flexion at the interphalangeal joints due to tension from the long finger flexors. Ulnar paresis or paralysis also affects flexion at the distal interphalangeal joints of the fourth and fifth fingers, adduction and abduction of the second to fifth fingers, and abduction and opposition of the fifth finger. Froment’s prehensile thumb sign (*signe du journal*) may be present as a result of adductor pollicis weakness (Video 219, Ulnar Neuropathy, Froment Sign).

When grasping and pulling a piece of paper with the thumb and index finger, the patient with ulnar neuropathy extends the proximal phalanx of the thumb and flexes the distal phalanx, rather than adducting the fully extended thumb against the curled index finger.

ELECTROPHYSIOLOGICAL ASPECTS. The electrophysiological evaluation should focus on the amplitudes of the ulnar-fifth digit and dorsal ulnar cutaneous sensory nerve action potentials (SNAPs), including comparison to the contralateral side, and the ulnar-ADM (abductor digiti minimi) and ulnar-FDI (first dorsal interosseus) across elbow motor conduction velocities, including short-segment incremental (“inching”) studies. Needle EMG studies of ADM, FDI, and flexor carpi ulnaris are also helpful. A common finding is reduction in the amplitudes of the SNAPs without localizing across elbow slowing, resulting in a nonlocalizing ulnar neuropathy by electrophysiological criteria.

TREATMENT. Conservative management, consisting of avoiding elbow pressure and prolonged flexion, is effective in most patients.⁶⁵ The decision to recommend surgical treatment is almost always made with great reluctance, as clinical experience with the benefits of surgical approaches is often discouraging. Three surgical procedures are performed. *Cubital tunnel decompression* is limited to sectioning of the flexor carpi ulnaris aponeurosis. *Anterior transposition* of the nerve involves sectioning of the aponeurosis followed by mobilization of the nerve out of the condylar groove with placement either subcutaneously or submuscularly. *Medial epicondylectomy* removes the bony prominence against which the ulnar nerve abuts and variously “stretches” the aponeurosis.

COMPRESSION OF THE ULNAR NERVE AT SITES OTHER THAN THE ELBOW

The ulnar nerve is occasionally compressed at the wrist or in the palm and rarely in the upper arm or axilla. In the palm, repeated external pressure rather than ongoing structural compression is usually the cause, though ganglionic cysts in the hand and at the wrist are an important cause to recognize. Because of the detailed pattern of branching of the distal ulnar nerve, several distinct clinical syndromes may occur, including palmar ulnar sensory loss (without dorsal ulnar cutaneous involvement) and weakness of hypothenar, other nonhypothenar ulnar innervated hand muscles, or both. Electrophysiological studies may be of significant value in distinguishing these cases from ulnar neuropathy at the elbow.

Compressive Disorders of the Radial Nerve

In distinct contrast to the well-defined chronic structural or compressive causes of median and ulnar neuropathies, chronic compressive neuropathies of the radial nerve are rare. Subacute or acute compression is much more common. This may be caused by crutches in the axilla, by compression against the shaft of the humerus during deep sleep or unconsciousness (“Saturday night palsy”), or by fractures of the humerus. One chronic syndrome may occur, affecting the superficial radial nerve, a purely sensory

branch that is vulnerable to compression near the wrist from a bracelet or wrist watch. The clinical features of the largely acute syndromes are straightforward and are understood from the anatomy of the radial nerve. Weakness of wrist and finger extension is the most obvious clinical feature. Involvement of the brachioradialis, as determined by its bulk when contracted, is important in localization to the upper arm when the triceps is spared. Apparent weakness of finger abduction with severe finger extensor weakness should not be interpreted as ulnar nerve involvement; the inability to extend the fingers results in considerable loss of mechanical advantage for abduction. Sensory loss is typically in the territory of the superficial radial nerve in the dorsal web space.

There is a radial tunnel located beneath the extensor carpi radialis, 3 to 4 cm distal to the lateral epicondyle, and the “radial tunnel syndrome” has been variously used to refer to a syndrome of compression of the posterior interosseous nerve (PIN), the distal pure motor branch of the radial nerve, in its course through the supinator muscle. The existence of a compressive syndrome of the PIN is uncertain. At best, it is extremely rare. When the “radial tunnel syndrome” is limited to refractory forearm pain and tenderness, terms such as “resistant tennis elbow” seem more applicable. Attributing pain to compression of the PIN without demonstrable weakness or electrophysiological findings is usually a mistake and should be avoided.

Compression of the Medial Cord or Lower Trunk of the Brachial Plexus: Thoracic Outlet Syndrome

CLINICAL FEATURES. It is important to distinguish true neurogenic thoracic outlet syndrome (TOS) from other syndromes labeled thoracic outlet syndrome, often as an explanation for chronic pain.⁶⁶ True neurogenic TOS is rare and has a highly characteristic presentation. It results from compression of the medial cord or lower trunk of the brachial plexus due to a rudimentary cervical rib or aberrant band between the transverse process of the C7 vertebra and the sternum or first or second rib.

Gradually progressive weakness and wasting of median and, to a lesser extent, ulnar innervated hand muscles with medial forearm and ulnar hand sensory disturbance is the hallmark presentation of this disorder. This pattern of involvement is so distinctive that little else besides a medial cord or lower trunk plexus lesion can cause it—neurogenic TOS should be considered whenever one encounters a pattern of median weakness with ulnar sensory disturbance. A T1 root lesion or intramedullary cord lesion, such as a syrinx, might produce a similar picture; the presence of Horner’s syndrome should alert one to these localizations (Video 17, Horner’s Syndrome).

EVALUATION. Nerve conduction studies and EMG are valuable in the evaluation of this disorder. The electrodiagnostic findings are distinctive. Reduction in amplitudes of the ulnar, dorsal ulnar cutaneous, and medial antebrachial cutaneous sensory nerve action potentials distinguish this disorder from intraspinal (T1 root or cord) causes. Reduction in amplitudes of median-APB and, to a lesser extent, ulnar-ADM compound muscle action potentials and needle EMG abnormalities in these muscles but not median-innervated

Figure 29-8. A 23-year-old woman with true neurogenic thoracic outlet syndrome secondary to cervical ribs. She complained of 10 years of right hand, forearm, and finger flexor cramps and 3 years of progressive right hand weakness and numbness of medial hand and forearm. Examination showed thenar greater than hypothenar weakness and wasting. Electrodiagnostic studies demonstrated absent ulnar and medial antebrachial cutaneous sensory nerve action potentials and absent median to abductor pollicis brevis compound motor action potential (CMAP), with normal amplitude for ulnar to abductor digiti minimi CMAP. **A**, AP cervical spine view demonstrating bilateral cervical ribs. **B** and **C**, Oblique views demonstrating articulating ribs (arrows).

middle trunk and lateral cord muscles (pronator teres and flexor carpi radialis) are characteristic.

Radiological studies are also crucial in the evaluation of this disorder. Plain cervical spine films may demonstrate a rudimentary cervical rib (Fig. 29-8). These ribs may also be seen on chest anteroposterior (AP) lordotic views, though less well. MRI of the neck and plexus characteristically does not show the ribs and may be falsely reassuring. However, MRI may be of value in excluding other causes, such as neoplastic invasion of the medial cord of the plexus.

TREATMENT. The treatment of true neurogenic TOS requires surgical removal of the rib or aberrant band. Surgical exploration may be indicated in a typical case without a radiologically verified rib or ligamentous band.

Compressive Disorders of the Lower Extremities

With the exception of the common peroneal nerve at the fibular head and the lateral femoral cutaneous nerve of the thigh at the inguinal ligament, chronic compressive neuropathies of the lower extremities are rare. Acute compressive syndromes as with the upper extremity, however, may occur. Acute major trauma, deep hemorrhage, tumor, surgical complications, and ganglionic cysts account for most of these. Some postoperative focal neuropathies are caused by stretch injuries to nerves.

COMMON PERONEAL NEUROPATHY AT THE FIBULAR HEAD

CLINICAL FEATURES. Acute compression of the common peroneal nerve at the fibular head results from its vulnerable fixed position against the fibula. Similar to many acute compressive syndromes, vulnerable positioning

during deep sleep or prolonged unconsciousness with the legs crossed or flexed at the knees is the most common cause. Chronic compression from habitual or occupational leg crossing or deep knee flexion is also common. Loss of eversion of the foot, if the superficial division is involved, or of dorsiflexion of the toes and ankle, if the deep division is involved, or of both, may occur. Sensory loss is much more apparent with lesions of the superficial division. The sensory loss involves the distal two thirds of the lateral calf, the lateral malleolus, the dorsum of the foot, and the medial three or four toes up to the interphalangeal joint. With lesions of the deep division, the sensory loss is smaller and involves the small web space area between the first and second toes and the adjacent portion of the dorsum of the foot. In common acute compressive peroneal lesions, pain is not a typical complaint, and there are few or no sensory symptoms. With compression from ganglionic cysts or other masses, patients may experience radiating pain and slowly progressive motor and sensory disturbances.

ELECTROPHYSIOLOGICAL ASPECTS. Electrophysiological evaluation of the peroneal nerve can be extremely helpful in establishing a diagnosis of peroneal neuropathy at the fibular head. The superficial peroneal sensory nerve action potential may or may not be reduced, depending on whether there is axonal degeneration or just focal demyelination at the fibular head. The peroneal-EDB (extensor digitorum brevis) and peroneal-TA (tibialis anterior) motor studies may demonstrate a focal segment across the fibular head with conduction block or slowing. Needle EMG studies may show abnormalities in tibialis anterior and peroneus longus, but not other L5 muscles such as tibialis posterior, hamstrings, or gluteus medius.

COMPRESSION OF THE LATERAL CUTANEOUS NERVE OF THE THIGH

Lateral cutaneous neuropathy of the thigh, also referred to as meralgia paresthetica, is also a common focal neuropathy in the legs. This purely sensory nerve arises directly from the lumbar plexus at the fusion of the dorsal divisions of the ventral primary rami of L2 and L3. The nerve has a variable course at the inguinal ligament, where it may pierce the ligament or pass above or below it. Although compression by the inguinal ligament is rarely documented, it is widely believed that entrapment or angulation at the inguinal ligament is the cause of neuropathy in most patients with this syndrome.

Pain and paresthesias, often burning or stinging in the lateral thigh, are the typical symptoms. There is no weakness or alteration in the knee reflex. Electrodiagnostic studies are helpful only if a femoral neuropathy is suspected, because they are typically normal in meralgia paresthetica. The natural history is often of spontaneous improvement, though some patients do have long-lasting symptoms, and surgical procedures are quite effective.⁶⁷

OTHER COMPRESSIVE DISORDERS OF THE LOWER EXTREMITIES

There are other uncommon compressive neuropathies of the lower extremities. The distal portions of the tibial and peroneal nerves in particular may be affected by chronic external trauma. Two syndromes that are rare at best deserve discussion: the piriformis syndrome and the tarsal tunnel syndrome.

The piriformis syndrome is often invoked to explain buttock pain of unknown cause; the implication is that compression of the proximal sciatic nerve as it passes under or through the piriformis muscle is the cause. Documentation in the literature of cases with clinical and electrodiagnostic findings of a sciatic neuropathy is extremely rare, and in an extensive survey, only two cases came close to meeting rigid criteria.⁶⁸ It has been suggested that, as with neurogenic thoracic outlet syndrome, the diagnosis of true neurogenic piriformis syndrome be reserved for such extremely rare cases.

Similarly, the tarsal tunnel syndrome, consisting of pain in the ankle with or without paresthesias in the sole of the foot, has been attributed to compression of the distal tibial nerve as it passes through the tarsal tunnel at the ankle. Although referrals for tarsal tunnel syndrome are common in electrodiagnostic laboratories, convincing cases clinically or electrophysiologically are extremely rare.

Noninfantile Refsum's Disease
Abetalipoproteinemia (Bassen-Kornzweig Syndrome)
An α lipoproteinemia (Tangier's Disease)

The storage diseases are characterized by pathological reactions that lead to the intracellular accumulation of abnormal material in the nervous system. They include disorders that may affect the entire nervous system, primarily the gray or white matter. Most, but not all, are pediatric conditions, but adult variants are being recognized more often. This discussion deals primarily with the neurological aspects of these diseases.

NEURONAL CEROID-LIPOFUSCINOSES

Neuronal ceroid-lipofuscinoses (NCLs) are a group of lysosomal storage diseases characterized by neurological symptoms and the accumulation of autofluorescent waxy lipopigments within the lysosomes of neurons and other cells. The conglomerate term neuronal ceroid-lipofuscinoses was coined by Zeman and Dyken in 1969 to emphasize the neurological involvement, clinically and pathologically.¹ The disorders are linked to a number of celebrated names in neurological history, including Batten, Jansky, Bielschowsky, Santavuori, and Kufs, each of whom described clinical variants of these multidimensional disorders. In 1998, a classification of eight forms of NCLs was developed to consolidate earlier clinical and genetic descriptions (Table 30-1).²

PATHOGENESIS AND PATHOPHYSIOLOGY. In the NCLs, waxy lipopigments, composed of ceroid and lipofuscin, accumulate in neurons and non-neuronal tissue. The ceroid composition of inclusion bodies varies in different forms of NCL. "Subunit c" of mitochondrial ATP (adenosine triphosphate) synthase accumulates in all forms of NCL, except for the infantile form or Santavuori disease (NCL 1) in which sphingolipid activator proteins, saposines A and D, accumulate.³ In addition to proteins, storage material

includes lipids, metals, and dolichyl pyrophosphoryl oligosaccharides. All subsequent symptoms are based on this accumulation, which activates cellular dysfunction and death in differently maturing groups of neurons of the cerebral cortex and retina. It has been speculated that cellular death is apoptotic.⁴ A combination of metabolic and mechanical factors also lead to the dysfunctional state. The lipopigments accumulate first in the larger neurons and tend to cluster around the axonal hillock. Inert lipopigments and debris progressively accumulate in an area rich in inhibitory synapses. Thereafter, the waxy pigments gradually spread to other parts of the neuron, ultimately involving the rest of the cell body while sparing the dendritic tree. Progressive swelling of the neuron occurs, followed by cellular death, subsequent disruption of the cell membranes, extracellular extrusion of debris, and its accumulation within scavenger cells. By this time, smaller neurons are involved as well as glia, endothelium, and fibrocytes. Lipopigments accumulate to a mild extent in almost all cells of the body, including lymphocytes, eccrine cells, fibroblasts, endothelial cells, ganglion cells of the rectum, and conjunctival cells. This observation permits detection of the "diagnostic" cytosomes without the need for brain biopsy. It must be emphasized, however, that the absence of such material in non-neuronal sites does not exclude the diagnosis, and the presence of similar osmophilic bodies does not establish it.

The slow process of waxy pigment accumulation first in the axonal hillock may account for the epileptogenesis that is often present, particularly in the late infantile (NCL 2), the classic juvenile (NCL 3), and the juvenile Northern epilepsy (NCL 8) forms. It is speculated that classic seizures are precipitated by an overriding glutaminergic state caused by cancellation of the inhibitory influences at the axonal hillock. Hyperglutaminergic states may also lead to more rapid loss of other neurological functions.

TABLE 30-1**Neuronal Ceroid-Lipofuscinoses**

| TYPE | NAME | ENZYME DEFICIENCY | PROMINENT CYTOSOME | STORAGE | GENETICS | AGE OF ONSET | MAJOR SIGNS |
|-------|---------------------------------------|----------------------------|--------------------|-----------|--------------|--------------|---|
| NCL 1 | Santavuori's (acute infantile) | PPT1 | GROD | SAP | 1p32(AR) | 3–18 months | Fulminating psychomotor deterioration, seizures |
| NCL 2 | Bielschowsky's (acute late infantile) | TPP1 | CV | Subunit c | 11p15(AR) | 2–4 years | Seizures followed by acute decline in motor and mental functions with vegetative state in 2 years |
| NCL 3 | Batten's (juvenile chronic form) | Battenin | FP | Subunit c | 16p12(AR) | 4–12 years | Blindness, seizures, dementia; mixed pyramidal and extrapyramidal signs |
| NCL 4 | Kufs' (adult) | Not known | GROD, FP, RL | Subunit c | AR or AD | Adult | Chronic motor, cerebellar, or extrapyramidal signs and mental deterioration, seizures |
| NCL 5 | Finnish variant (childhood) | 407 amino acids protein | CV, RL, FP | Subunit c | 13q22(AR) | 4–7 years | Blindness, dementia, seizures |
| NCL 6 | Lake's (late infantile) | Linclin | CV, RL, FP | Subunit c | 15q21–23(AR) | 2–8 years | Blindness, seizures, chronic myoclonus |
| NCL 7 | Turkish variant (late infantile) | Not known | FP, CV, RL | Subunit c | AR | 1–6 years | Seizures, followed by psychomotor decline |
| NCL 8 | Northern epilepsy (juvenile) | Lysosomal membrane protein | RL, CV | Subunit c | 8p23(AR) | 5–10 years | Seizures, mental deterioration, motor impairment |

AD, autosomal dominant; AR, autosomal recessive; CL, curvilinear profile; FP, fingerprint profile; GROD, granular osmiophilic deposits; PPT1, palmitoyl protein thioesterase 1; RL, rectilinear profile; SAP, saposins A and D; Subunit c, subunit c of ATP synthase; TPP1, tripeptidyl peptidase 1.

All NCLs are autosomal recessive except for the rare families with the adult autosomal dominant form of Kufs' disease as first described by Boehme in 1971. Six of the eight genes underlying NCL have been identified. It is notable that the proposed gene defects are different for the different forms of the disorder (see [Table 30-1](#)). The infantile form (NCL 1) results from a lysosomal palmitoyl-protein thioesterase 1 (PPT1) deficiency due to mutations of the PPT1 gene on chromosome 1q32. Bielschowsky's disease (NCL 2) results from a lysosomal tripeptidyl peptidase 1 (TPP1) deficiency due to mutations in the TPP1 gene on chromosome 11p15. In the classic juvenile form (NCL 3) a genetic defect exists in chromosome 16p12. The genes of the childhood Finnish (NCL 5), early juvenile (NCL 6) and juvenile Northern epilepsy (NCL8) forms are carried on chromosomes 13p31–32, 15q21–23 and 8p23,⁵ respectively. In some families, NCL 7 is allelic to NCL8.⁶ The proteins encoded by these last four genes are proteins of predicted transmembrane topology (for NCL 3 the protein is called Battenin and for NCL 6 the protein is called linclin). The function of these proteins remains elusive. The loci for the adult form (NCL 4) and the Turkish variant (NCL 7) are not known.

EPIDEMIOLOGY AND RISK FACTORS. These genetic diseases are probably present in all ethnic and racial groups around the world. One series in the United States found that NCL 3 was the most common form, followed by NCLs 2, 1, 7, 4, and 6 (see [Table 30-1](#)), in that order. These data agree with experiences in Germany, Britain, the Netherlands, and Sweden. In Poland, on the other hand, the late infantile (NCL 2) form is encountered more frequently. This may possibly hold true for the other Eastern European countries as well. In Finland, the more common type is the acute infantile Santavuori form. It is so common there and so rare elsewhere that it is often called the Finnish form. In Saudi Arabia, the vast majority of NCL patients suffer from a form that is relatively uncommon in the United States, the early juvenile NCL 6. All the families with NCL 7 are from Turkey.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. The rapidly progressive infantile form or Santavuori's disease (NCL 1) has its onset within the first year of life, after a symptom-free period between birth and 3 months of age. Then a sudden and dramatic psychomotor collapse occurs with loss of neurological (irritability, hypotonia, ataxia) and visual functions. The collapse may or may not be associated with drug-refractory seizures or severe myoclonus. After the age of 2 years, a brownish discoloration of the macula, retinal degeneration, and optical atrophy are noted. Death occurs between 8 and 13 years of age. Variants mimicking late infantile and juvenile NCL have been described.

In the acute late infantile form or Bielschowsky's disease (NCL 2), on average, the first symptom seldom appears after 4 years of age. The condition's hallmark is a seizure disorder that begins precipitously, progresses rapidly, and ultimately becomes refractive to all anticonvulsant medications. The initial seizures are usually described as drop attacks, myoclonic, partial, or generalized seizures, although nearly all types of seizure often occur within a short period of time. In this rapidly developing disorder, severe intellectual and mental deterioration is seen. The child becomes nonambulatory, usually before the age of 6 years. During this time,

vision is progressively lost, yet because of the general loss of neurological function, such an isolated sign is often not recognized. Compared to patients with the juvenile form, a characteristic retinopathy occurs with striking retinal artery attenuation, patches of retinal atrophy, and symmetrical macular granular degeneration.

In the classic juvenile chronic form (NCL 3) or Batten's disease, onset, which includes neurological dysfunction, usually occurs between the ages of 5 and 15 years.⁷ Patients may be referred initially to an ophthalmologist or psychiatrist. By age 10, the patient is most often referred to a neurologist. The obvious behavioral symptoms have progressed from a learning deficiency to frank dementia. Likewise, visual dysfunction has usually progressed to blindness. There is a slow and steady progression of neurological symptoms. Three stages of clinical deterioration occur. The first phase involves visual and behavioral disturbances, and the middle phase consists of seizures and motor dysfunction related to a mixture of pyramidal and extrapyramidal symptoms (Video 114, Ceroid Lipofuscinosis). In the terminal phase the preceding symptoms may become much worse, and there may be changes in affect and motor signs including myoclonus. The three phases are steadily progressive and form an overall monophasic illness that distinguishes NCL 3 from the other disorders described in this chapter (Video 253, Batten's Disease).

As a general rule, phase one lasts from 6 months to 5 years, phase two from 2 to 10 years, and phase three from 1 to 10 years. This pattern results in a life expectancy that ranges from 3 to 25 years after the initial visual-neurological symptoms are noted. The course of the disease is generally directly proportional to control of the seizures. Once seizures become refractory and frequent, the course proceeds rapidly downhill to a vegetative state.

In Kufs' adult form of NCL (NCL 4), the onset is usually before age 40 years. Progressive dementia is preceded by two major clinical presentations.⁸ Type A begins with late-onset progressive myoclonic epilepsy (Video 46, Myoclonic Epilepsy) and subsequent subacute loss of mental functions but relative preservation of motor functions. Type B is marked by predominant motor dysfunction. This dysfunction may become manifest as pure cerebellar ataxia or progressive rigidity or parkinsonism.⁹ NCL 4 is not associated with retinal changes. Life expectancy is shortened.

The childhood form or Finnish variant (NCL 5) presents with visuomotor problems or behavior problems between 4 and 7 years of age. Mental deterioration often precedes the onset of retinal degeneration, seizures, and myoclonus.

The late infantile "gypsy" variant form or Lake's disease (NCL 6) has clinical features that overlap those of the late infantile and juvenile forms. There may be fewer retinal abnormalities than in NCL 2 or NCL 3, but other features characteristic of both the juvenile and late infantile forms are seen. Onset occurs between 18 months and 8 years of age, and the course is subacute compared to the chronic juvenile and acute late infantile forms of the disease.

The Turkish late infantile variant (NCL 7) has a phenotype similar to Bielschowski's disease. The juvenile Northern epilepsy form of NCL is characterized by onset of epilepsy (generalized tonic-clonic, complex partial seizures) between 5 and 10 years of age. Mental regression is slow. Retinal degeneration is never observed. Dysarthria and

incoordination become severe in adulthood. Life expectancy is normal.

DIFFERENTIAL DIAGNOSIS. The most important step in the differential diagnosis is to identify the order of the characteristic symptoms, taking into account the fact that the retinal picture may be of greatest importance. This evaluation separates the retinal NCLs (NCL 1, 2, 3, 5, 6, and 8) from the nonretinal NCLs (NCL 4 and 7). The differential diagnosis for the group includes all neurodegenerative diseases characterized by epilepsy, blindness, motor failure, and dementia, including the gangliosidoses and sphingomyelinoses.

EVALUATION. A battery of laboratory tests is important in the workup of NCL patients. Neuroimaging studies show abnormalities characteristic of the type and stage of disease and demonstrate that most NCLs are ultimately atrophic poliodystrophies involving the cerebral cortex. Certain unique types such as the spinocerebellar form show selective involvement of the cerebellum in which autofluorescent storage material accumulates in Purkinje cells.¹⁰ In NCL patients with epilepsy, electroencephalography (EEG) shows epileptogenic patterns. Electroretinograms are decreased or absent in patients with the retinal NCL types. Particularly in NCL 2, exaggerated evoked potential responses are seen, especially following tactile or somatosensory stimulation. Evoked potential exaggeration also occurs in some other NCLs.

Clinical and histopathological evaluations are essential to make the specific diagnoses. Ultrastructural cellular cytosome alterations are seen on electron microscopy in extracerebral tissue such as ganglion cells in the rectal submucosa, in eccrine cells and fibrocytes of the skin, in endothelial cells in vessels, in lymphocytes in the peripheral blood (NCL 3), and in conjunctival cells. Extracerebral evaluation may not be entirely infallible. Many current diagnostic problems stem from confusion about the cytosomes themselves. Osmophilic inclusions occur frequently as an artifact of tissue preparation for electron microscopy and do not always represent the diagnostic inclusion of the NCL. Four suggestive cytosomes are important, and two of these are diagnostic (see Table 30-1). The osmophilic fingerprint cytosomes (FPs) are highly characteristic as lymphocytic inclusions in NCL 3. FPs without membrane-bound vacuoles are seen in biopsy samples of NCL 4, 5, 6, and 7. The second diagnostic osmophilic cytosome is the curvilinear body (CL), which characterizes NCL 2. Some atypical curvilinear profiles (CV) are seen in NCL 5, 6, 7, and 8. The third important ultrastructural cytosome are the “granular osmophilic deposits” (GROD), which are dominant cytosome in NCL 1, but can be seen in association with other inclusions in NCL 4 and 8. The fourth inclusion is the rectilinear body (RL). RL is seen in association with other inclusions in NCL 4, 5, 6, 7, and 8. The least diagnostic cytosome is the classic lipofuscin body.

A large proportion of the storage material involved in NCL consists of the mitochondrial protein called subunit c. This material is found in very high quantities in NCL 2 but is also seen in increased amounts in other NCLs except NCL1. The most direct and precise means of confirming the diagnosis of NCL 2 is based on the enzyme assay of TPP1 in fibroblasts.¹¹ Lymphoblast palmitoyl protein thioesterase (PPT) levels are less than 0.2 pmole/minute/mg in NCL1 (normal levels 1–3).

MANAGEMENT. Bone marrow transplant and embryonic stem cell transplant may be shown to be beneficial in selective patients. Symptomatic treatment, particularly proper anticonvulsant therapy, is important in all NCL disorders. Sodium valproate has been used with success. Antioxidants may improve the symptoms in some cases, and trials of these medications have been undertaken in patients with NCLs 1, 2, 3, and 6. It has been suggested that long-term antioxidant treatment and vitamin E may delay loss of intellectual and motor function and may be helpful in seizure control as well. Extrapyraxidal symptoms such as dystonia and myoclonus are treated symptomatically, and behavioral modification techniques may be useful, particularly in the chronic forms. If the symptomatology is of long standing, palliation of the symptoms may be extremely useful in supporting a long and often useful life for the patient. School placement and modified educational programs are important in patients with the chronic forms of disease.

LIPIDOSES

Gangliosidoses

As a group, the gangliosidoses (Table 30-2) are autosomal recessive lysosomal storage disorders characterized biochemically by accumulation of gangliosides, a molecule composed of ceramide and a sialic acid (an oligosaccharide containing *N*-acetylneuraminic acid). Blocks at various intermediate steps of ganglioside catabolism cause accumulation of specific gangliosides GM₁, GM₂, and GM₃ in nervous system and other tissues. GM₁ gangliosides accumulate when β -galactosidase, a component of the lysosomal multienzyme complex (LMC), is deficient. This LMC contains β -galactosidase, sialidase, *N*-acetylgalactosamine-6-sulfate sulfatase, and the lysosomal carboxypeptidase (cathepsin A). LMC is involved in catabolism of glycolipids, glycoproteins, and mucopolysaccharides. GM₁ gangliosidosis and Morquio type B disease are caused by mutations in the β -galactosidase gene on chromosome 3p21.¹² Galactosialidosis is caused by mutations in the cathepsin A gene on chromosome 20q13 and results in a β -galactosidase and sialidase deficiency.¹³ *N*-acetylgalactosamine-6-sulfate sulfatase deficiency causes Morquio type A disease (see mucopolysaccharidoses). Sialidase deficiency leads to sialidosis (see mucolipidoses). GM₂ gangliosides accumulate when the activity of hexosaminidase A, a heteropolymer of α and β polypeptides, is deficient or when the GM₂ glycoprotein activator is deficient. GM₂ gangliosidoses with hexosaminidase A deficiency can result from mutations in either the α subunit on chromosome 15q23 (type I GM₂ gangliosidosis) or the β subunit on chromosome 5 (type II GM₂ gangliosidosis or Sandhoff's disease).¹⁴ GM₂ gangliosidosis with partial or no hexosaminidase A deficiency results from mutations in the GM₂ glycoprotein activator gene on chromosome 5q32–33 (type III GM₂ gangliosidosis).¹⁵ GM₃ gangliosides accumulation results from *N*-acetylgalactosaminyl transferase deficiency, an enzyme important in the synthesis of GM₁ and GM₂ from GM₃. In all forms, the ganglion cells in the submucosal enteric plexus contain characteristic lysosomal inclusions with various membranous and vesicular profiles.

TABLE 30-2

Gangliosidoses

| TYPE | NAME | ENZYME DEFECT | STORAGE PRODUCT | GENETICS | AGE OF ONSET | PRIMARY CLINICAL FEATURES |
|--|---------------------------------|---|---|---------------------|----------------------|--|
| GM ₁ gangliosidosis type I | Infantile form | β-Galactosidase | GM ₁ | Autosomal recessive | Birth | Cherry-red spot in 50%, edematous face, hepatosplenomegaly, seizures, mental and motor retardation |
| GM ₁ gangliosidosis type II | Late infantile form | β-Galactosidase | GM ₁ | Autosomal recessive | 6–18 months | As above, but slower in evolution |
| GM ₁ gangliosidosis type III | Adult form | β-Galactosidase | GM ₁ | Autosomal recessive | Adult | Prominent extrapyramidal signs without hepatosplenomegaly |
| β Galactosidosis | | β-Galactosidase and sialidase | GM ₁ | Autosomal | Variable | Same as GM ₁ gangliosidosis |
| GM ₂ gangliosidosis type I | Tay-Sachs: infantile form | Hexosaminidase A | GM ₂ | Autosomal recessive | Infants | Hyperexcitability, blindness, cherry-red spot |
| GM ₂ gangliosidosis type II | Juvenile form | Hexosaminidase A | GM ₂ | Autosomal recessive | 5 years | Seizures, dementia, pyramidal and extrapyramidal motor signs |
| GM ₂ gangliosidosis type III | Adult form | Hexosaminidase A | GM ₂ | Autosomal recessive | Adult or adolescence | Variable pictures, including myelopathic, motor neuron, or extrapyramidal signs |
| GM ₂ gangliosidosis: Activator factor abnormality | | Partial hexosaminidase A deficiency due to activator factor dysfunction | GM ₂ | Autosomal recessive | Childhood | Similar presentation to Tay-Sachs disease |
| GM ₂ gangliosidosis | Sandhoff's disease | Hexosaminidase A and B | Globoside and GM ₂ ganglioside | Autosomal recessive | Infants | Clinically similar to Tay-Sachs but with hepatosplenomegaly |
| GM ₃ gangliosidosis | Hematoside sphingolipodystrophy | N-acetylgalactosaminyl transferase | GM ₃ (hematoside) | Autosomal recessive | Infants | Respiratory difficulties, seizures, with delayed motor and mental retardation |

PATHOGENESIS AND PATHOPHYSIOLOGY. All the gangliosidoses are characterized by storage of abnormal gangliosides in neurons and other parts of the nervous system (see Table 30-2). In all of the gangliosidoses, there is a dramatic accumulation of lipid that distends the neuronal cell body; the resulting mechanical factors interfere with metabolic function and ultimately destroy the cell. Different neuronal populations are involved and produce different symptoms. The storage is primarily neuronal and tends to occur mainly in the polioencephalon in large neurons. The weight and volume of the affected brain increase markedly during the second year of life; it can often weigh well over twice the normal amount for age and sex. Thereafter, cystic degeneration of the remaining cortex and subcortex occurs. The neuropathological process is not limited to the brain, and motor neurons of the anterior horn cells of the spinal cord are also affected. Pathological examination of these disorders reveals distorted and ballooned neurons. Fusiform swelling of the axons, termed torpedoes, occurs, and astrocytic proliferation is seen. White matter degeneration occurs secondary to the neuronal dysfunction and cell death. Electron microscopic studies show the gangliosides usually tightly packed within the individual cells. In most gangliosidoses, these cytosomes, or membranous cytoplasmic bodies, are osmophilic and often take on a loosely "whorled" form.

EPIDEMIOLOGY AND RISK FACTORS. These exclusively autosomal recessive genetic disorders are globally distributed. Because intermarriage among relatives increases gene frequency, there are often pockets of these diseases in certain sequestered populations. Thus, type I GM₂ gangliosidosis, or Tay-Sachs disease, has a high frequency among Ashkenazi Jews. Although this disease was once considered rare in black populations, it has been recently noted to occur in the southern United States in areas with a history of consanguinity.¹⁶ In Saudi Arabia, which has high consanguinity and reproduction rates, there is also a high gene frequency of the GM₂ gangliosidosis known as Sandhoff's disease.¹⁷

CLINICAL FEATURES AND ASSOCIATED DISORDERS. GM₁ gangliosidoses, also known as generalized gangliosidosis,¹⁸ affect the brain and organs outside the central nervous system.¹⁹ Keratan sulfate, a mucopolysaccharide, is the major storage material in the liver; GM₁ ganglioside accumulates in nerve cells. Urine mucopolysaccharides are usually normal. Galactose-containing oligosaccharides are excreted in urine²⁰ and bone marrow biopsy may show foamy histiocytes. There are clinical similarities between children with these diseases and those with mucopolisidoses. In *type I GM₁ gangliosidosis (infantile form)*, the onset of symptoms is at birth or shortly after. Non-pitting edema of the face and extremities produces a dull, heavy-appearing facies with frontal bossing, depressed nasal ridge, low-set ears, and large maxilla. The gums and tongue may be large. Ocular signs include a cherry-red spot in about 50% of such patients, but corneal clouding is unusual. Macrocephaly may be noted. Hepatosplenomegaly is frequently prominent. Intellectual and motor developments are retarded from birth, and children eat poorly, gain weight slowly, and are generally weak and uncoordinated. Joints tend to be enlarged, and the long bones are wide in the center and tapered at the ends; kyphoscoliosis and breaking of vertebrae are usual. Myotactic hyperreflexia, hypertonus,

and flexion contractures occur. Seizures usually occur late in the disease, and affected children, blind, deaf, and in respiratory failure associated with infection, die by the age of 2 years. A subgroup of patients with infantile GM₁ gangliosidosis present with a cardiomyopathy resembling Pompe's disease.

Type II GM₁ gangliosidosis (late infantile form) follows a more prolonged course and shows a less precipitous decline in activity. There is no visceral storage or bone involvement. Vision is preserved. Onset of symptoms occurs between 6 and 18 months. Incoordination, spasticity, mental impairment, and seizures are progressive. The affected patients may appear normal through the first years of life. Death occurs before 10 years of age.

Type III GM₁ gangliosidosis (adult type) is characterized by a slowly progressive course with predominant extrapyramidal signs of dystonia and postural reflex impairment. Rigidity is common, and speech disturbances and increased muscle tone are frequent additional features. Neuronal ganglioside storage occurs in the basal ganglion,²¹ and in contrast to the infantile form, no visceral or skeletal changes occur. Magnetic resonance imaging (MRI) demonstrates symmetrical high-intensity lesions in the putamen on T₂-weighted images. It has been suggested that the putaminal lesions may be primarily responsible for the dystonia.²² Intellectual deterioration is always present, usually in association with incoordination, spasticity, myoclonus and seizures. Survival is prolonged.

Galactosialidosis affects the neurons and organs outside the nervous system. Gangliosides are stored in the nervous system while sialyloligosaccharides and sialoglycoproteins are stored in other tissues. Urine mucopolysaccharides are normal. Sialyloligosaccharides are found in the urine²⁰ and bone marrow biopsy may show foamy histiocytes. Vacuolated lymphocytes are frequently found in the blood smear. Three clinical phenotypes are recognized. *Type I (infantile)* resembles GM₁ gangliosidosis, except for milder seizures and corneal clouding as additional findings in 50% of patients. Cherry-red spots are noted in half of the patients. *Type 2 (juvenile)* is characterized by the triad: myoclonus, ataxia, and angiokeratoma. Mental deterioration and visceromegaly are not features of this disorder. Visual impairment results from corneal clouding and cherry-red spots.¹⁴

GM₂ gangliosidoses affects primarily the nervous system where GM₂ gangliosides are stored. Visceromegaly and bone dysplasia are not a feature, except for Sandhoff's disease. Urine mucopolysaccharides are normal, except in Sandhoff's disease. Oligosaccharides are not found in the urine, and bone marrow contains no storage cells. Vacuolated lymphocytes are not in the blood smear. The clinical features of all three types of GM₂ gangliosidoses are essentially identical with progressive dementia and cherry-red spots as cardinal features. The symptoms in Tay-Sachs disease (infantile form) are uniform in type and timing of development. The first clinical manifestations occur within 6 months of birth, yet the infant appears normal for the first 3 months. Initially, excessive hyperexcitability and irritability develop, and infants have a heightened startle reflex to noises and tactile stimuli. Hypotonia and a delay in motor and mental development are characteristic. During the first 6 months of life the child's visual acuity is usually deficient and continues to deteriorate to the point of

blindness by 1 year of age. The early blindness is thought to be retinal in origin, since the GM₂ ganglioside storage lesion is within the ganglion cells of the macula, and normal pupillary responses persist. The macular cherry-red spot, appearing in all cases within the first 3 months of life, is highly characteristic, although it tends to disappear late in the disease owing to total retinal atrophy. The color of the macula has little pathophysiological significance compared to the milky, whitish halo found around the macular region.¹² This finding is a result of the buildup of opaque gangliosides. Because of this macular lesion, the baby has fixation defects and searching conjugate eye movements. At times, the extreme hyperexcitability and reactivity suggest frank seizure activity. If seizures occur, they are of a myoclonic character that closely resembles infantile spasms (see Chapter 52). The progression of symptoms continues through the second and sometimes third year of life, and most children die before the age of 4. Megalencephaly is predominant even in the terminal stages.

A juvenile variant of type II GM₂ gangliosidosis follows a much different course. These children first become ill after 5 years of age, and death occurs within 10 years following a course of seizures, progressive dementia, and cerebellar, pyramidal, extrapyramidal, and spinal dysfunction as well as optic atrophy.²³ This form of the disease may present as a progressive pure form of dystonia and dementia that begins before 5 years of age. Later in life these patients have a hypokinetic-rigid syndrome. These cases differ from the classic form of GM₂ gangliosidosis in the regional preferences of the storage process.²⁴ MRI shows mild to moderate brain atrophy.

Adult-onset type III GM₂ gangliosidosis has been reported with a number of phenotypic patterns, and the clinical picture may vary within families. Adults between 16 and 28 years of age, who have had very mild symptoms in childhood, develop pronounced motor symptomatology. In some patients, spinocerebellar degeneration is predominant.²⁵ These individuals do not have seizures, fundoscopic abnormalities, or dementia. Other adult patients may show predominant extrapyramidal abnormalities with dystonia and choreoathetosis (Video 64, Generalized Dystonia; Video 257, Post-Hemiplegic Athetosis).²⁶ Some cases resemble juvenile spinal atrophy,²⁷ and others have a pure psychosis without cognitive decline.²⁸ A burning dysesthesia may be the presenting complaint.²⁹

Patients with Sandhoff's disease have clinical symptoms that are similar to those characteristics of Tay-Sachs disease, with hyperacusis, decreased vision, a cherry-red macular spot, decerebrate rigidity, and megalencephaly. In addition, hepatosplenomegaly is seen, and the tubular epithelial cells of the kidneys are filled with sphingolipids. Cardiomyopathy and mitral insufficiency may be present, and death usually occurs between 2 and 4 years of age.³⁰ There are some variants of Sandhoff's disease, including a juvenile form in which patients are normal until 5 years of age, when they develop a progressive cerebellar ataxia, slurred speech, intellectual deterioration, and progressive hyperreflexia and hypertonia. Fundoscopic examination may be normal (Video 80, Hyper-reflexia; Video 91, Cerebellar Ataxia).

A few cases have been reported of infants with severe neurological and systemic problems that have been traced

to excessive accumulation of GM₃ ganglioside (*hematoside*) in tissues²³ without GM₁ or GM₂. In these cases, there is a decrease in the enzyme *N*-acetylgalactosaminyl transferase, which is important in the synthesis of GM₁ and GM₂ from GM₃. These infants have pronounced respiratory difficulties in the first weeks of life, when generalized seizures become prominent. Poor motor and mental development is typical, and dysplastic features such as an enlarged tongue, high-arched palate, inguinal hernia, and loose skin are found. The hands and feet are broad, and there is marked hirsutism. Generalized muscle hypotonia, poor responses, and diminished reflexes develop, but the optic fundi are normal, and the liver and spleen are minimally enlarged. Because of dysphagia and difficulty in feeding, death usually occurs within the first few months of life. On autopsy, spongy degeneration in the brain stem and diencephalon is evident, and intracytoplasmic bodies are seen in astrocytes.

DIFFERENTIAL DIAGNOSIS. The other group of degenerative disorders that should be considered in the differential diagnosis is the cerebrotretinal syndromes. In patients with some variant forms, such as the neuronal ceroid-lipofuscinoses, primary movement disorders and spinocerebellar degeneration must be considered.

EVALUATION. The electroretinographical abnormalities and delayed or absent visual evoked responses suggest a retinal involvement. Urine oligosaccharides are abnormal in GM₁ gangliosidosis and galactosialidosis. Urine mucopolysaccharides are abnormal in Sandhoff's disease. Elevated GM₁ ganglioside levels in the cerebrospinal fluid (CSF) are not specific of GM₁ gangliosidosis. No biochemical marker is found in other GM₂ gangliosidoses. Definite diagnosis requires testing of specific enzymes. In GM₂ gangliosidosis, false-positive results are seen in patients treated with oral steroids or pregnant. Pseudodeficiency has also been reported in a non-Jewish patient; the diagnosis can be confirmed by DNA testing.³¹ False-negative results are due to specific mutations in the hexosaminidase gene³² or to GM₂ glycoprotein activator gene deficiencies. Identification of storage material in rectal biopsy may be in helpful in such cases

Special testing is warranted for populations at particular risk. Since approximately 80% of patients with Tay-Sachs disease are of Jewish ancestry, massive population screening studies of white blood cell enzymes to detect the carrier state have been successful. Amniotic fluid removed early in pregnancy and chorionic villi may also be studied to determine whether the Tay-Sachs disorder is present. Several pitfalls should be avoided in diagnosing patients with gangliosidosis. For example, there is often confusion between Sandhoff's disease and Tay-Sachs disease because of similar clinical and biochemical results. DNA testing, coupled with enzyme analysis, provides a good level of sensitivity and specificity.

MANAGEMENT, PROGNOSIS, AND FUTURE PERSPECTIVES. Definitive treatment is not available for patients with most of the gangliosidoses, but some experimental approaches may be effective. Enzyme replacement therapy with multiple laminar liposomes coated with human IgG has not been effective.²³ Bone marrow transplantation is being used, but the attendant risks of radiation to the brain and chronic immunosuppressive therapy are worrisome.

Palliative therapies are helpful. The prognosis remains dismal. Future research with enzyme replacement, inhibitors, and activators; identification of new enzyme activators; and genetic counseling are all indicated.

Sphingomyelinoses

As a group, the sphingomyelinoses are lysosomal storage disorders of autosomal recessive inheritance characterized biochemically by the accumulation of sphingomyelin, a molecule containing a ceramide, a phosphoric acid ester, and choline.

There are at least four types of sphingomyelinoses or Niemann-Pick disease (types A, B, C, and D), all of which are neurodegenerative disorders except type B (Table 30-3). A prominent visceromegaly is the rule, except for some patients with late onset type C and D diseases. A rapid deterioration is more frequent in patients with early onset. In contrast, late onset cases are characterized by a slow progression. Approximately 50% of affected patients belong in the type A group, characterized by severe neurological symptoms. Type A and B diseases result from molecular defects in the acid sphingomyelinase (ASM). The ASM gene is mapped to chromosome 11p. Type A and type B diseases are caused by allelic point mutations and deletions within the ASM gene. Type C disease results from molecular defects in either NPC1 protein, a lysosomal permease belonging to one of the superfamilies of efflux pumps, or in the HE1 protein, a protein that interacts with NPC1.^{33,34} The NPC1 gene has been identified and maps to chromosome 18q11. The HE1 gene maps to chromosome 14q24. Niemann-Pick disease type C results from mutations in the NPC1 gene (NPC1) or in the HE1 gene (NPC2). Niemann-Pick disease type D is an allelic variant of NPC1.³⁵

Type A disease, or infantile form, is marked by failure to thrive, hypotonia, and hepatosplenomegaly. A macular cherry-red spot is noted in 50% of patients. Eye movements are normal. Seizures are common. Developmental regression with loss of reactivity to the environment is relentless. Recurrent infection is often a major problem, and death occurs before 5 years of age. In some cases, peripheral nervous system involvement is detected with slow nerve conduction velocities. In such patients type C disease can be classified into four major groups according to the onset of neurologic symptoms, that is, early infantile, late infantile, juvenile, and adult forms. In the early infantile form, cholestasis and biliary atresia are associated with a rapid neurologic deterioration. In the late infantile form, the patients usually seem normal until 2 years of age; psychomotor deterioration with ataxia, dysarthria, and drooling is slow. Most patients belong to the juvenile form, also known as dystonic juvenile lipidosis. These patients may present with behavior and motor difficulties. They often develop dystonia with selectively swollen cells in the basal ganglia. Dystonia starts distally and gradually becomes generalized. Features of supranuclear vertical gaze palsy are noted when the patient is asked to look down. Patients may never develop visceromegaly. Degeneration of the macula may be associated with a cherry-red spot. In the adult form, cognitive and psychiatric disturbances (psychosis, catatonia) may be prominent. Vertical

supranuclear palsy leads to difficulties negotiating stairs. Visceromegaly is mild when present. Type D or Nova Scotia variant, is characterized by early onset of hepatosplenomegaly and neurologic difficulties similar to those seen in type C beginning between the second and the fourth years of life. The clinical course is protracted with survival in adulthood.³⁶ In patients with Niemann-Pick disease, foamy histiocytes can be found in bone marrow and spleen, and hepatic cells show small clusters of histiocytes that resemble sea-blue histiocytes.³⁷ No unusual characteristics mark the plasma lipoprotein profile.

Most histological information has been obtained from studies of the infantile or type A form. Very often the central nervous system of these patients is gliotic, small, and atrophic. The gray matter shows necrotic changes with large neurons that are distended and ballooned with apparent storage of sphingomyelin. In some patients, there are extensive abnormalities in the spinal cord, midbrain, and cerebellum. The white matter is rarely affected. Changes in retinal cells similar to those in the brain are seen. Biochemical assay of membranous cytoplasmic bodies reveals large amounts of sphingomyelin and cholesterol.

The differential diagnosis rests with the other storage diseases. In patients with type A (with hepatosplenomegaly) and type C (with vertical supranuclear palsy) separation from the cerebrosidoses can be difficult. Dystonia with intellectual deterioration has been reported in NPC1, juvenile onset metachromatic leukodystrophy and the late onset gangliosidoses. Diagnosis is suspected on identifying excessive amounts of sphingomyelin and the foamy cells. The definite diagnosis is made by measuring sphingomyelinase activity or by linkage analysis and sequence analysis of the mutated genes. Antenatal diagnosis of types A and B disease can be made. Of the various therapy approaches, hematopoietic stem cell-mediated gene therapy and exogenous recombinant protein replacement have attracted the most interest.

Cerebrosidoses

Cerebrosidoses are autosomal recessive diseases characterized by lysosomal storage of cerebroside, a molecule composed of ceramide and hexose. Lipid-laden macrophages, Gaucher's cells, are found in most tissues. Gaucher's cells have an eccentric nucleus and a wrinkled tissue paper cytoplasm. In the vast majority, the enzyme glucocerebrosidase (glucosylceramide β -glucosidase) is deficient. The abnormal gene is located on chromosome 1q21. Rare cases are caused by a deficiency of Saponin C, a heat-stable cofactor required for normal catalytic function of glucocerebrosidase (see [metachromatic leukodystrophy](#)). There are three forms of cerebrosidosis or Gaucher's disease: type I (adult), type II (infantile), and type III (juvenile) (see Table 30-3). Gaucher's disease is the most frequently reported of the lysosomal storage disease, and particularly frequent among Ashkenazi Jews.²³ Type I disease, so-named because it was first described by Gaucher, is the chronic, non-neuropathic form.³⁸ This form is usually found in adults and is a predominantly chronic disease involving the viscera (splenomegaly hypersplenism) and blood-forming tissues (bone crisis). Type II, on the other hand, is an acute neuropathic disease found in infants.

TABLE 30-3

Sphingomyelinoses (Niemann-Pick Disease) and Cerebrosidoses (Gaucher's Disease)

| TYPE | NAME | ENZYME DEFECT | STORAGE PRODUCT | GENETICS | AGE OF ONSET | PRIMARY CLINICAL FEATURES |
|--------------------------|--|-----------------------------|-------------------------------|---|--|--|
| Sphingomyelinoses | | | | | | |
| Type A | Classic Niemann-Pick disease | Sphingomyelinase | Sphingomyelin | Autosomal recessive: prenatal detection available | Infants | Hepatosplenomegaly, Niemann-Pick cells in bone marrow Prominent neurological findings, motor and mental retardation, cherry-red spot in 50% |
| Type B | Non-neurological variant | Sphingomyelinase | Sphingomyelin | Autosomal recessive: prenatal detection available | Chronic progressive | No neurological signs and massive hepatosplenomegaly |
| Type C | Childhood or adult | NPC1 protein or HE1 protein | Sphingomyelin and cholesterol | Autosomal recessive | 2-4 years chronic and progressive or adult onset | Hepatosplenomegaly variably present; Niemann-Pick cells in bone marrow Prominent neurological findings, especially dystonia |
| Type D | Nova Scotian variant | NPC1 protein | Sphingomyelin and cholesterol | Autosomal recessive | 2-4 years chronic and progressive | Clinically similar to type C. Most neurological signs may be secondary to hepatosplenopathy |
| Cerebrosidoses | | | | | | |
| Type I | Classic Gaucher's disease, chronic, non-neuropathic form | Glucose cerebrosidase | Glucose cerebroside | Autosomal recessive | Adults | Chronic disease involving viscera and blood-forming tissues, non-neurological |
| Type II | Infantile or neurological Gaucher's disease | Glucose cerebrosidase | Glucose cerebroside | Autosomal recessive | Infants | Prominent neurological signs with early opisthotonos, severe mental and motor retardation and death by age 2 years |
| Type III | Juvenile | Glucose cerebrosidase | Glucose cerebroside | Autosomal recessive | Juveniles | Variable hepatosplenomegaly and moderate neurological signs of motor and mental retardation |

It is almost always apparent by 6 months of age but may present as early as the newborn period, frequently with hyperextension or opisthotonic posturing of the head. The posturing is believed to be due to Gaucher's cells in the meninges at the base of the brain. Affected babies have early strabismus or heterotropia, generalized hypertonia, and difficulty in swallowing, a fairly consistent neurological clinical triad. Ichthyosis is the presenting symptom in some patients. Profound psychomotor retardation develops, and laryngospasm, myoclonus, bulbar impairment, supranuclear vertical and horizontal gaze palsy, and seizures may be evident. Brain MRI may be normal or show hydrocephalus. Rapidly progressive central nervous system (CNS) deterioration occurs combined with splenomegaly. Some children have relatively mild systemic symptoms. Most patients with this form of cerebrosideosis die by the age of 2 years. The course of disease is similar in many respects to the fulminating course of type A sphingomyelinosis. The infantile neuronal form of Gaucher's disease does not have a proclivity toward Jewish ancestry. Type III cerebrosideosis is a subacute neuronopathic disease, most often found in juvenile, associated with variable neurologic and systemic features. Most patients present in childhood with refractory seizures and mental decline. These patients may also have myoclonus, and the diagnosis should be considered in children with the progressive myoclonic epilepsies (see Chapter 52). In other children, ataxia and dystonia are the presenting symptoms. Horizontal supranuclear gaze palsy is a predominant sign. Death may occur between the second and fourth decades. Although this classification of Gaucher's disease into three entities is accepted, exceptions to it do occur,³⁹ such as a rare non-neuronopathic form occurring in early infancy and a neuronopathic form with supranuclear gaze palsy and parkinsonism seen in adults.⁴⁰

Full clinical assessment of neuropathic cases includes a careful neurological examination, eye movement examination, a detailed fundoscopic examination, a family history, neuropsychometric and neurophysiologic evaluations, and brain imaging. Bone marrow aspirate can be used to identify Gaucher's cells. Definite diagnosis is made by enzyme analysis. The finding of sulfatides in the urine of a patient with type II disease should suggest a prosaposin deficiency.

Intravenous enzyme replacement therapy is available using recombinantly produced glucocerebrosidase. This therapy improves the neurologic outcome in neuronopathic cases.⁴¹

Mucopolysaccharidoses

Mucopolysaccharides (Table 30-4) are constituents of connective tissue composed of alternating units of polymerized hexuronic acids and hexose amines. As a group, mucopolysaccharidoses are characterized by somatic dysplasia, slowly deteriorating mentation and motor control, storage of mucopolysaccharide within cellular lysosomes, and urinary excretion of glycosaminoglycans (heparin sulfate, dermatan sulfate, or related compounds). It is generally agreed that the causative defect in the mucopolysaccharidoses (MPS) involves lysosomal hydrolysis. Because of faulty breakdown of glycosaminoglycans, these products are stored within the lysosomes, distending the lysosome and

the cell body. Mucopolysaccharides represent the major component of the lysosomal storage material, particularly in fibroblasts. In lymphocytes, storage vacuoles have been called Reilly bodies. Because the brain is also a prime storage site, mental retardation is a prominent feature of all MPS. There are 13 subclasses of MPS (see Table 30-4).⁴²

The mucopolysaccharidoses are inherited as autosomal recessive diseases, with the exception of Hunter's syndrome, which is sex-linked. The global frequency of the varieties of MPS has not been clearly established. Population studies in the Netherlands indicated that Sanfilippo's syndrome type A is the most common form, with an estimated frequency of 1:24,000 in that population.⁴³ In British Columbia, the incidence of Hunter's syndrome was estimated at 1:78,000,⁴⁴ but in Israel its frequency may be higher. Sanfilippo's syndrome type B is seen particularly often in Greece,⁴⁴ and in the Cayman Islands a high frequency of Sanfilippo's syndrome type A has been found, with an estimated carrier frequency of 1:10.

As a group, these diseases are marked by striking somatic dysplasia, slowly deteriorating neurological and systemic symptoms, storage of mucopolysaccharides in the lysosomes, and excretion of mucopolysaccharides in the urine (see Table 30-4). Although each type has a specific enzyme deficit, the similar spectrum of clinical manifestations in all MPS disorders makes biochemical differentiation essential.

Mucopolysaccharidoses I are caused by an α -iduronidase deficiency. This enzyme is required for the hydrolysis of α -iduronic acid from the terminal end of dermatan and heparan sulfate. The gene has been assigned to 4p16.3. Three clinical syndromes result from this defect. For many reasons, Hurler's disease (type 1) has become the prototypical MPS. Patients who have this syndrome in early infancy may appear reasonably normal, but by 6 months of age it is obvious that a severe disorder is present. The abnormal facial appearance is one of the first signs noted, and hepatosplenomegaly and umbilical and inguinal hernias are soon detected. Affected infants may have chronic rhinorrhea associated with frequent colds, recurrent airway infections, and otitis media. When children with Hurler's disease attempt to sit, a characteristic kyphoscoliosis is often observed, which progresses with time. Ultimately, a frank gibbus deformity, one of the earliest described clinical features of the disease, develops. Vision is often impaired in Hurler's disease because of corneal clouding. Although the infant with Hurler's disease may develop some sitting and walking skills as well as early language skills, these are soon lost. Severe mental retardation becomes apparent, and patients are usually bedridden before the end of the juvenile period. Patients with Hurler-Scheie disease (type 2) have severe joint involvement, short stature, small thoraces, hepatosplenomegaly, coarse facial features, and corneal clouding. They may have near-normal mental abilities. The small thorax and cardiac involvement in this disease often reflect mitral valve insufficiency. Scheie's syndrome (type 3) usually occurs in individuals of normal size, and their neurological deficits are less severe than those seen in patients with types 1 and 2 disease. These patients have only mild hepatosplenomegaly with marked coarseness of the facial features or severe mental retardation. Dysostosis multiplex or bony involvement is also mild, although a common feature is carpal

TABLE 30-4

Mucopolysaccharidoses and Mucopolipidoses

| TYPE | NAME | ENZYME DEFECT | STORAGE PRODUCT | GENETICS | AGE OF ONSET | PRIMARY CLINICAL FEATURES |
|------------------------------------|-----------------------------------|---|--|---------------------|------------------------------|---|
| Mucopolysaccharidoses (MPS) | | | | | | |
| 1 | Hurler's (MPS I) | α -L-Iduronidase | Heparan sulfate (HS) and dermatan sulfate (DS) | Autosomal recessive | Birth or by 6 months | Abnormal facial appearance, hepatosplenomegaly, kyphoscoliosis, corneal clouding, mental retardation |
| 2 | Hurler-Scheie's MPS V/I | α -L-Iduronidase | Heparan sulfate (HS) and dermatan sulfate (DS) | Autosomal recessive | First year | Severe joint involvement, coarse facial features, hepatosplenomegaly, corneal clouding, but near-normal mentation |
| 3 | Scheie's (MPS V) | α -L-iduronidase | Heparan sulfate (HS) and dermatan sulfate (DS) | Autosomal recessive | First year | Normal stature and less severe neurological deficits than in types 1 and 2 |
| 4 | Hunter's (MPS II) | Iduronate 2-sulfatase | Heparan sulfate (HS) and dermatan sulfate (DS) | X-linked | First year | Similar to Hurler, but without corneal clouding |
| 5, 6, 7, 8 | Sanfilippo's A, B, C, D (MPS III) | A: Heparan sulfatase B: <i>N</i> -acetylglucosaminidase C: <i>N</i> -acetyl-CoA-acetyltransferase D: <i>N</i> -acetyl- α , D-glucosamine-6-sulfatase | A: Heparan sulfate B: Heparan sulfate C: Heparan sulfate D: Heparan sulfate | Autosomal recessive | First year | Hepatosplenomegaly and facial coarseness less than in Hunter and Hurler. Mental and motor retardation, death by age 10. |
| 9, 10 | Morquio's A, B (MPS IV) | A: Acetylgalactosamine-6-sulfatase B: β -Galactosidase | Keratan sulfate and chondroitin sulfate Keratan sulfate | Autosomal recessive | First year | Among the subgroups, C is the mildest. In all subgroups, patients excrete heparan sulfate Skeletal dysplasia with compressive neurological signs (severe in A, mild in B). No or little mental retardation. Corneal clouding 50% and organomegaly less prominent compared to other MPS. Survival to middle age |
| 11 | Maroteaux-Lamy (MPS VI) | Arylsulfatase B | Dermatan sulfate | Autosomal recessive | First year | Growth retardation, coarse features, myelopathy |
| 12 | Sly's (MPS VII) | β -Glucuronidase | Dermatan sulfate and heparan sulfate | Autosomal recessive | First year through childhood | Hepatosplenomegaly, psychomotor retardation, coarse features |
| 13 | Multiple sulfatase deficiency | Arylsulfatase A, B, and C | Dermatan sulfate and heparan sulfate | Autosomal recessive | First year | Variable signs, including mental retardation and coarse facial features |
| Mucopolipidoses (ML) | | | | | | |
| 1 | Sialidosis type 1 (ML I) | Neuraminidase (sialidase) | Oligosaccharide, glycolipids | Autosomal recessive | Adolescence | Cherry-red spot, myoclonic seizures, painful neuropathy, mildly coarse facial features |
| 2 | Sialidosis type 2 (ML I) | Neuraminidase (sialidase) | Oligosaccharide, glycolipids | Autosomal recessive | Infants | More severe than sialidosis. Facial and somatic dysmorphism, progressive mental retardation |
| 3 | I-cell disease (ML II) | <i>N</i> -acetylglucosaminylphosphotransferase | Oligosaccharide, glycolipids | Autosomal recessive | Infants | Severe disease. Facial and somatic dysmorphism, progressive severe mental retardation, hepatosplenomegaly. Death often by age 10 |
| 4 | Pseudo-Hurler's (ML III) | <i>N</i> -acetylglucosamine-1-phosphotransferase | Oligosaccharide, glycolipids | Autosomal recessive | Childhood | Mild in comparison to I-cell. Corneal clouding. Survival to adulthood |
| 5 | Berman's mucopolipidosis (ML IV) | Mucolipin I | Oligosaccharide, glycolipids | Autosomal recessive | Childhood | Most patients of Ashkenazi Jewish extraction |

tunnel symptomatology. It is rare for neurological problems to be severe enough to cause early complaints. Generally, ocular involvement, specifically corneal clouding or retinal abnormalities suggesting degeneration, lead to suspicions of an MPS disorder. In most instances, the diagnosis is not made before the age of 10 years, and frequently it is not recognized until age 20 or later.

Mucopolysaccharidosis II are caused by iduronosulfatase deficiency. The gene maps on Xq28. Two types of Hunter's syndrome have been suggested, one with predominant mental retardation and one not associated with retardation. Children with Hunter's syndrome may have a facial appearance similar to that characteristic of Hurler's syndrome, but the cornea is not clouded in Hunter's disease. In fact, corneal findings are the most important features distinguishing Hunter's from Hurler's disease. Patients with Hunter's syndrome often have a macular skin rash over the arms, shoulders, and thighs that may change in character. Urinary excretion of heparan and dermatan sulfate is similar in Hunter's and Hurler's diseases.

Mucopolysaccharidosis III or Sanfilippo's syndrome (MPS III, types 5–8) are caused by four enzyme defects: heparan sulfatase (or sulfamidase) (type A), *N*-acetylglucosaminidase (type B), acetyl-CoA *N*-acetyltransferase (type C), *N*-acetylglucosamine-6-sulfatase (type D). Type A is caused by sulfamidase gene mutations on chromosome 17q25.3.⁴⁵ Type B is caused by *N*-acetyl-CoA *N*-acetyltransferase gene mutations on chromosome 17q21.1.⁴⁶ Type D is caused by *N*-acetylglucosamine-6-sulfatase mutations on 12q14.⁴⁷ Clinical symptoms usually start after 2 years of apparently normal development and include hyperactivity, aggressive behavior, delayed speech, sleep disturbances, coarse hair, hirsutism, and diarrhea. There are only mild somatic manifestations such as short stature, slight coarsening of facial features, and mild contractures. Hepatomegaly, when present, only appears late in the course of the illness. Mental deterioration is progressive and motor impairment soon leads to loss of ambulation. Myoclonus appears late in the course of the illness. These children are bedridden in the second decade, and death usually occurs by the mid-teens. Patients with type D disease have a later onset, an attenuated phenotype with normal stature, hyperactivity, mental retardation, a slower progression and prolonged survival. Sanfilippo's syndrome is a classic example of a neurodegenerative disease with a monophasic downhill course.

Mucopolysaccharidosis IV is caused by the deficiency of two enzymes, components of the lysosomal multienzyme complex (LMC): type A is caused by *N*-acetylgalactosamine-6-sulfate sulfatase deficiency and type B is caused by β -galactosidase deficiency. Mutations in the *N*-acetylgalactosamine-6-sulfate sulfatase gene on chromosome 16q24.3 cause type A disease and mutations in the β -galactosidase gene on chromosome 3p21¹² cause type B disease. In 1929 Morquio⁴⁸ described a syndrome characterized by severe skeletal dysplasia. Clinically, the severe classic syndrome (type A) can be differentiated from mild variant (type B). In both forms, mental symptomatology is absent or only mildly present. Neurological symptoms may result from compression of the spinal cord or medulla. The skeletal changes include joint laxity, shortness of stature, pectus carinatum, shortened vertebrae, genu valgum, pes planus,

and enlarged joints. The neck is short, and the odontoid process in the cervical region is often underdeveloped, accounting for the atlantoaxial subluxation seen.⁴⁹ There are no cherry-red spots. Corneal clouding is present in 50% of cases, and hepatomegaly is less prominent than in other forms of mucopolysaccharidosis. Cardiac involvement may include aortic regurgitation. Patients usually survive until middle age.

These disorders are most easily confused with the mucopolipidoses and the GM₁ gangliosidoses because of the associated facial and somatic progressive dysmorphisms. Full general and neurological assessments are necessary, and even with a full family history, these recessive diseases may not be fully expressed in an immediate family constellation. Important laboratory evaluations include identification of mucopolysaccharides in the urine and assays for enzyme defects in leukocytes and cultured fibroblasts (see Table 30-4).

Bone marrow transplant appears to slow down neurologic deterioration. Symptomatic palliative therapies are available, but these are slowly progressive diseases, and life expectancy is limited.

Mucopolipidoses

The mucopolipidoses (MLs) are a group of autosomal recessive lysosomal storage diseases characterized biochemically by accumulation in tissues and brain of glycolipids and glycoproteins. Each of the five types of mucopolipidoses may be confused phenotypically with the mucopolysaccharidoses (see Table 30-4). However, urine mucopolysaccharides are normal, differentiating them readily from mucopolysaccharidoses. There is no specific race or ethnic predilection except for the ML type 4.

Mucopolipidosis type 1 (or sialidosis) is caused by a sialidase (neuraminidase) deficiency. Sialidase is a component of the lysosomal multienzyme complex (LMC) (see GM₁ gangliosidosis). Sialidosis is caused by several mutations in the sialidase gene on chromosome 6p.¹² Bone marrow aspirate shows foamy histiocytes and vacuolated lymphocytes. Urine mucopolysaccharides are normal. Oligosaccharides and glycoproteins are found in the urine. Sialidosis may have two phenotypes. *Sialidosis type 1 or nondysmorphic type* is also known as the *cherry-red spot–myoclonus syndrome*.⁵⁰ Patients present in the second decade with a progressive visual impairment, myoclonus, and gait abnormalities. Once visual pathology is evident, including night blindness or loss of color vision, the disease becomes progressive.⁵⁰ A cherry-red spot is uniformly present. Lens opacities may occur. Myoclonus is typically generalized. Exacerbation of the myoclonus is triggered by stimuli, smoking, and menstruation. Intellectual deterioration may be a late occurrence. Painful neuropathy, delayed nerve conduction velocity, generalized convulsive seizures, ataxia, and dysostosis multiplex ensue. Facies may be coarse but to a lesser extent than in the mucopolysaccharidoses.

In *sialidosis type 2 or dysmorphic type* the onset of symptoms always occurs early in life. Babies may be born with hydrops fetalis. The somatic and facial features are invariably coarse. Dysostosis multiplex, periosteal cloaking, and hepatosplenomegaly dominate, and contractures of major bony articulations, inguinal hernias, and mild

hepatosplenomegaly are common findings. Angiokeratoma corporis diffusum may be prominent. Neurological impairment is slowly progressive and is marked by dementia and other signs such as ataxia, hypotonia, reduced muscle mass, and cherry-red spots.

Mucopolipidosis type 2 and 3 are caused by a *N*-acetylglucosaminyl phosphotransferase, resulting in a deficient targeting and phosphorylation of the mannose in newly synthesized glycoprotein acid hydrolases. The gene for this enzyme has been designated GNPTA and maps to 4q21-q23.⁵¹ Assaying lysosomal enzymes in plasma shows increased activity of lysosomal enzymes. Bone marrow aspirates shows vacuolated plasma cells and lymphocytes. Vacuoles are also seen in fibroblasts. *Mucopolipidosis type 2* or I-cell disease presents in the neonatal area with coarse facial reminiscent of Hurler's disease, hepatosplenomegaly, umbilical hernias, kyphoscoliosis, and lumbar gibbus. Mild forms of dysostosis multiplex are seen, but these are much less severe than those seen in patients with Hurler's disease. The thorax is usually small, joint movement is restricted, and the tongue is large, often with gingival hyperplasia. Corneal haziness is common, and cardiac involvement includes cardiomegaly and aortic insufficiency. Both intellectual and motor retardation become obvious in the first months of life. These children are severely ill and frequently die in the first decade of life from cardiopulmonary failure.

Mucopolipidosis type 3 or pseudo-Hurler's disease is a milder form characterized by a later clinical onset, usually in childhood, and some may live into adulthood but are mentally retarded. Linear growth is severely affected, corneal clouding and aortic regurgitation are common, and older patients show joint stiffness. Facial coarseness is minimal.

Mucopolipidosis type 4 is caused by defect in mucolinin 1, a membrane protein involved in endocytosis and showing homology to a group of calcium channels of the TRP/TRPL family. Mucolinin 1 deficiency is caused by mutations in the MCOLN1 gene on chromosome 19p13.3-p13.2.⁵² Fibroblasts are similar to those seen in I-cell disease. Patients with mucopolipidosis type 4 lack dysmorphic features, hepatosplenomegaly, and bony changes. Visual impairment and severe corneal clouding appear in the first year of life. Myopathy and psychomotor retardation are profound.

The mucopolipidoses are most easily confused with the mucopolysaccharidoses. They are biochemically distinguishable by the lack of the mucopolysacchariduria characteristic of the MPS. There are some clinical and biochemical similarities with the GM₁ gangliosidoses. Detailed and skilled clinical evaluation of systemic as well as neurological factors is essential in addition to assays for lysosomal enzymes and mucopolysaccharides in the urine. No specific therapy is available.

GLYCOGENOSES

PATHOGENESIS AND PATHOPHYSIOLOGY. The glycogenoses or glycogen storage diseases are disorders in which glycogen accumulates within a number of tissues; These diseases are named for the specific enzyme deficiency

that occurs in the glycogen metabolic pathway (Table 30-5), and their ordering follows the enzymatic steps involved in glycogen synthesis and catabolism.^{53,54} Most enzymes are cytosolic except for the lysosomal acid α -glucosidase. If the deficient enzyme is expressed predominantly in the liver, hypoglycemia usually accompanies the clinical signs. If the deficient enzyme is expressed predominantly in muscles, the disease presents either as a pure myopathy or as a cardiomyopathy. Most glycogenoses are inherited as autosomal recessive traits, although an autosomal dominant inheritance has been documented in few families with McArdle disease, and a X-linked inheritance is seen in type VIII and IX.

EPIDEMIOLOGY AND RISK FACTORS. Most of the glycogenoses are inherited as autosomal recessive diseases. However, an X-linked inheritance has been demonstrated in the most frequent form of liver phosphorylase kinase deficiency (Hug's disease), in some patients with muscle phosphorylase kinase deficiency (Ohtani's disease), and in phosphoglycerate kinase deficiency (Bresolin's disease). An autosomal dominant transmission has been suggested in a few families with myophosphorylase deficiency (McArdle's disease). The gene responsible for most glycogenoses has been mapped (Table 30-5). Several mutations have been identified for each disorder. The molecular heterogeneity of the glycogenoses frequently results in a clinical heterogeneity. For instance, although in most patients with debranching enzyme deficiency (Cori-Forbes' disease) the disease involves the liver and the muscle, some patients (about 15%) have only liver involvement without muscle disease. This rare clinical phenotype is associated specifically with exon 3 mutations. There are pockets of these diseases in certain population. For instance, most patients with muscle phosphofructokinase deficiency (Tarui's disease) in the United States are related to the Ashkenazi Jews. The most common mutations responsible for each disorder differ in various ethnic groups. For instance, the most common mutation in North American patients with myophosphorylase deficiency (McArdle's disease) seems to be R49X. This mutation is only seen in a minority of Mediterranean patients and it has never been observed in Japan. Knowledge of the most common mutation in a specific ethnic group allows the use of molecular genetics analysis in the blood for diagnostic purposes, thus avoiding the need for a muscle biopsy.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. In Von Gierke's disease (glycogenosis type I), hypoglycemia causes many of the clinical difficulties seen in patients during the first year of life. In this period seizures are frequent, and long-standing hemiplegia and mental retardation occur. Failure to thrive, xanthomas, and isolated hepatomegaly are common, and excessive subcutaneous fat over the buttocks, breasts, and cheeks develops. Affected children usually have a protruding abdomen due to enlargement of the liver. Patients often have recurrent stomatitis frequent infections and may have isolated chronic inflammatory bowel disease.

There are three phenotypes of acid maltase deficiency (glycogenosis type II). The infantile form or Pompe's disease⁵⁴ usually presents, after normal development during the first weeks or several months of life, with hypotonia and associated weakness. A pseudohypertrophy of calf muscles is seen. Spontaneous movement declines, the cry

TABLE 30-5

Glycogenoses

| TYPE | DISEASE NAME | ENZYME DEFICIENCY | LOCATION | GENE AND CHROMOSOME | INHERITANCE |
|------|--------------|-----------------------------|-----------------------------|---------------------|-------------|
| Ia | Von Gierke | Glucose-6-phosphatase (G6P) | Liver | 1p21 | AR |
| Ib | Von Gierke | G6P transporter1 | Liver | 11 | AR |
| II | Pompe | Acid maltase | Liver, heart, muscle, brain | | |
| III | Cori-Forbes | Debranching enzyme | Muscle | 1p21 | AR |
| IV | Andersen | Branching enzyme | Muscle, heart, liver, brain | 3 | AR |
| V | McArdle | Myophosphorylase | Muscle | 11 | AR or AD |
| VI | Hers | Phosphorylase | Liver | 14 | AR |
| VII | Tarui | Phosphofruktokinase | Muscle | 1 | AR |
| VIII | Hug | Phosphorylase B kinase | Muscle | PHKA1: Xq12-q13 | XR |
| | | | Liver | PHKA2: Xp22 | XR |
| | | | Muscle, liver | PHKB: 16q12-q13 | AR |
| | | | Muscle | PHKG1: 7p12-q12 | AR |
| | | | Liver | PHKG2: 16p11-p12 | AR |
| IX | Bresolin | Phosphoglycerate kinase | Muscle | Xq13 | XR |
| X | Tonin | Phosphoglycerate mutase | Muscle | 7p12-7p13 | AR |
| XI | Tsujino | Lactate dehydrogenase | Muscle | 11 | AR |
| XII | Kreuder | Aldolase | Muscle | 16q22-q24 | AR |

AD, autosomal dominant; AR, autosomal recessive; XR, X-linked recessive.

becomes weak and struggling, and swallowing is dysfunctional. Respiratory difficulty results from the skeletal muscular weakness and inability to handle pooled nasopharyngeal secretions. Massive cardiomegaly develops, and a soft, systemic murmur is often heard at the left sternal border. Ultimately, hepatomegaly appears, and the tongue may be enlarged and protrude awkwardly. Palpation of the muscles reveals them to be firm, and muscle stretch reflexes are suppressed. Progressive debilitation occurs, and patients usually die by 1 to 2 years of age.

In the late infantile form of acid maltase deficiency or Smith's disease,⁵⁵ symptoms and signs may simulate those of Duchenne muscular dystrophy. In such patients, the gastrocnemius and deltoid muscles are firm and rubbery on palpation. There is accompanying hypertrophy of the gastrocnemius muscles, and Gowers' sign is often present. Toe walking develops with ankle contractures, and the gait is unsteady and wobbling owing to lumbar lordosis. Cardiomegaly is absent. In the adult form with acid maltase deficiency or Engel's disease,⁵⁶ weakness of the muscles develops during the third through sixth decades of life. Weakness is more prominent proximally than distally, and the pelvic girdle is involved more than the shoulders. Intercostal and diaphragmatic muscles are involved in many patients. Adults do not show enlargement of the liver, heart, or tongue. Frequently, symptoms suggesting polymyositis or late-onset muscular dystrophy cause confusion in the initial clinical diagnosis.

Three types of debranching enzyme deficiency syndrome (glycogenosis type III) have been identified: infantile, childhood, and adult. In the infantile type, early symptoms are similar to, but less marked than, those typical of Von Gierke's disease, which is associated with hypoglycemia, failure to thrive, and hepatomegaly. Patients with the infantile type are hypotonic and weak and have poor head control.

Juvenile-onset debrancher enzyme deficiency begins between the ages of 2 and 15 with exercise intolerance and associated heart failure. These patients are hypotonic and have a protuberant abdomen. Adult patients develop progressive chronic distal myopathy and neuropathy in middle age.

Clinical manifestations of the infantile branching enzyme deficiency (glycogenosis type IV) or Andersen's disease are generally seen in the first 6 months of life and are related to weakness, feeding difficulties, muscle wasting, tachypnea, failure to thrive, and hepatosplenomegaly. Such patients have poor motor and mental development, muscular hypotonia, and hyporeflexia. More benign forms of this variant present later in life with only mild hepatomegaly and elevated liver enzymes. The adult "polyglucosan body disease," characterized by diffuse peripheral and central involvement is allelic to this disorder.⁵⁷

Children affected with classic McArdle's disease (myophosphorylase deficiency) initially show decreased stamina and easy fatigability. Although onset usually occurs in childhood, neonatal presentations have been reported. Severe cramping pain, usually in the distal skeletal muscles, develops after exercise and is often associated with renal impairment. In adolescence and adulthood, patients may develop persistent weakness and moderate loss of muscle bulk. Patients with Hers' disease have no specific neurological or muscle findings but display varying degrees of growth retardation, hypoglycemia, ketosis, and hepatomegaly. In Tarui's disease,⁵⁸ motor development is normal during the first decade, but decreased muscle exercise tolerance, myoglobulinuria, and easy fatigability develop in childhood. An unusual infantile syndrome characterized by limb weakness, seizures, cortical blindness, and corneal opacifications occurs; microscopic studies reveal typical findings of neuron axonal dystrophy.⁵⁹

Mild cases of hepatophosphokinase deficiency (Hug's disease)⁶⁰ have been associated with hepatomegaly, attacks of ketonuria with fasting, and intermittent diarrhea. Hypotonia in infancy can occur. Pure muscle disease with exercise intolerance, myalgia, cramps, and weakness is reported in some other patients.

In patients with some other glycogenosis defects, such as phosphoglycerate mutase, phosphoglycerate kinase, and lactate dehydrogenase deficiencies, a link between exercise intolerance and myoglobinuria has been found. In patients with the phosphoglycerate kinase or Bresolin's disease⁶¹ deficiency, the defect is sex-linked, and hemolytic anemia, seizures, mental retardation, and exercise intolerance with myoglobinuria have been prominent features. In adults, phosphoglycerate mutase deficiency or Tonin's disease⁶² has been associated with myalgia, cramps, and myoglobinuria following exercise. Lactate dehydrogenase deficiency or Tsujino's disease⁶³ has been reported in one patient who suffered from severe myoglobinuria with exercise.

DIFFERENTIAL DIAGNOSIS. Most of the glycogen storage disorders must be differentiated from various neuropathies and muscular dystrophies. In the former, abnormalities are seldom limited to the muscle. Liver failure problems and other systemic symptoms are often obvious. Because of the liver problems present in most of these diseases, one must always consider other storage diseases such as the mucopolysaccharidoses, mucopolipidoses, sphingomyelinoses, cerebrosidoses, and gangliosidoses in the differential diagnosis.

EVALUATION. These diagnoses can usually be made by performing assays of enzymatic activity in the particular tissue most affected, such as the liver, peripheral white blood cells, muscle, and even brain. Since severe hypoglycemia is the best screening indicator of this class of disease, postprandial and glucose tolerance tests are particularly useful. A variety of other biochemical tests, such as uric acid, cholesterol, fatty acids, triglycerides, lipid profiles, and liver function tests, should be performed, as well as bone studies in specific instances. Oligosaccharides are identified in urine of patients with Pompe disease.²⁰

MANAGEMENT, PROGNOSIS, AND FUTURE PERSPECTIVES. Correction of Pompe disease by enzyme replacement with a recombinant human acid maltase is presently under clinical trial and initial results have been promising.⁶⁴ Liver transplantation has been performed with apparent beneficial results in Von Gierke's disease, Forbes's disease, Andersen's disease. Most therapies have been supportive depending on the particular syndrome involved. In Von Gierke's disease, small amounts of free glucose can be given to maintain normal glucose concentrations; dietary carbohydrates are also given, but because excessive glucose leads to glycogen storage in the liver and kidneys, small feedings of carbohydrates is the preferred method of treatment. Dietary substitution of medium-chain for long-chain triglycerides has been used, and diazoxide has been beneficial in some cases. Portal caval shunts have been used to bypass the liver. Preoperative intravenous hyperalimentation appears to eliminate some of the metabolic problems that occur following surgery.

In the debrancher syndromes, growth failure and hepatic dysfunction, including hypoglycemia, appear to improve

with the administration of oral cornstarch. Similarly, symptoms can be controlled with frequent small carbohydrate meals in Hers' disease.

In patients with McArdle's disease and Tarui's disease, a ketogenic diet has shortened the muscle recovery period from an acute physical load. High protein diet and aerobic exercise are also somewhat beneficial. Vitamin B₆ supplementation may be effective in McArdle's disease. Despite any of these interventions, the prognosis is guarded for patients with all of the glycogenoses.

LEUKODYSTROPHIES

The leukodystrophies (Table 30-6) are genetic diseases that show morphological changes in the white matter of the central nervous system. Each of the leukodystrophies most likely represents an inborn error of metabolism due to a defective gene that produces an enzymatic abnormality and metabolic derangement that affects myelin. Myelin dysfunction is the basic feature of all these disorders, and demyelination or destruction of normally formed myelin can occur as well as loss of defective myelin, called dysmyelination. Simple demyelination is typical of many sudanophilic leukodystrophies. Dysmyelination is related to an underlying genetic or metabolic disturbance, and in this type of leukodystrophy, abnormal lipids incorporated into the defective myelin sheath tend to be metachromatic when stained. Leukodystrophies may be caused by enzymatic defects that produce aberrations in peroxisome or mitochondrial function, which induces demyelination, or to enzymatic defects at specific points in the metabolic pathways of the sphingolipids.

Pelizaeus-Merzbacher Syndrome

Pelizaeus-Merzbacher syndrome is a particular type of demyelinating sudanophilic leukodystrophy and has many subtypes.⁶⁴ In all, sudanophilia is produced when neutral fat stains such as Sudan black react with the neutral fat breakdown products of myelin. Since this breakdown of myelin is the result of a variety of metabolic or acquired insults, sudanophilia provides no useful information about the pathogenic origin of the insult. Most of the early reports were based on the pathological process rather than on the clinical picture, and the common denominator histologically is the presence in the CNS of patches of dysmyelination interspaced with perivascular islands of relatively intact myelin. This pattern produces a striped or tigroid appearance and is the origin of the term tigroid leukoencephalopathy, the pathologic hallmark of all forms of Pelizaeus-Merzbacher syndrome.

Classic Pelizaeus-Merzbacher disease has a strong tendency to be more prominent in males, suggesting but not proving a sex-linked inheritance. This degenerative disorder is a primary genetic disorder of the oligodendrocytes. Oligodendrocytes are one of the major cell types in the CNS white matter. Each oligodendrocyte myelinates up to 50 axonal segments. The hallmark of the syndrome is the pathological finding of patchy losses of groups of oligodendrocytes with little sudanophilic dysmyelination.

TABLE 30-6

Leukodystrophies

| TYPE | NAME | ENZYME DEFECT | STORAGE MATERIAL | GENETICS | AGE OF ONSET | SPECIAL COMMENTS |
|--------------------------------------|--|---------------------|-------------------------------------|--------------------------------|-----------------------------|---|
| Pelizaeus-Merzbacher Syndrome | | | | | | |
| 1 | Classical | Proteolipid protein | Sudanophilic material | X-linked | Infantile | Frequently confused with cerebral palsy (slow progression) |
| 2 | Connatal | Not known | Sudanophilic material | Not known | Birth | More severe than type 1 |
| 3 | Seitelberger's disease Transitional Lowenberg-Hull disease | Not known | Sudanophilic material | Sporadic | Infantile | Death by age 5–10 years |
| 4 | Adult | Not known | Sudanophilic material | Autosomal dominant | Adult | No ocular abnormalities |
| 5 | Variant | Not known | Sudanophilic material | Not known | Variable | |
| Cockayne's Syndrome | | | | | | |
| 6 | Classic | DNA repair | Sudanophilic material | Autosomal recessive | 6–12 months | Dwarfism with CNS and PNS signs |
| Alexander's Disease | | | | | | |
| 7 | Classic infantile | GFAP | GFAP | Sporadic | Infants | Psychomotor retardation, megaloccephaly |
| 8 | Juvenile | GFAP | GFAP | Autosomal dominant or sporadic | Children 7–14 years | Prominent bulbar dysfunction with normal mentation |
| 9 | Adult | GFAP | GFAP | Autosomal dominant | Young adults | Presentation of multiple sclerosis |
| Canavan's Syndrome | | | | | | |
| 10 | Classic infantile | Aspartoacylase | <i>N</i> -acetylaspartate in plasma | Autosomal recessive | Infants | Hypotonia, megaloccephaly, blindness |
| 11 | Neonatal | Aspartoacylase | <i>N</i> -acetylaspartate in plasma | Sporadic | Newborns | Hypotonia, poor swallowing, death within first weeks of life |
| 12 | Juvenile | Aspartoacylase | <i>N</i> -acetylaspartate in plasma | Sporadic | Children 5 to teenage years | Ataxia, tremor, mental retardation with loss of vision, endocrine and cardiac disorders |

| Krabbe's Syndrome | | | | | | |
|-------------------------------------|--|---------------------------------------|---------------------------------------|---------------------|--------------------------------------|---|
| 13 | Classic, infantile | Galactocerebroside β-galactosidase | Galactocerebroside | Autosomal recessive | Infants | Irritability followed by hypertonicity, optic atrophy, and signs of neuropathy |
| 14 | Late onset | Galactocerebroside β-galactosidase | Galactocerebroside | Autosomal recessive | Usually childhood, but may be adults | Cortical blindness, optic atrophy, spasticity |
| Metachromatic Leukodystrophy | | | | | | |
| 15 | Greenfield's, classical, or late infantile | Arylsulfatase or SAP-B | Sulfatide | Autosomal recessive | Late infantile 1–24 months | Ataxia, hypotonia, bulbar signs, intellectual decline, and peripheral neuropathy |
| 16 | Scholz's | Arylsulfatase A | Sulfatide | Autosomal recessive | Juvenile 4–10 years | Gait instability, tremor, ataxia, spasticity |
| 17 | Austin's | Arylsulfatase A | Sulfatide | Autosomal recessive | Adult | Mental instability, progressive dementia |
| Adrenoleukodystrophy | | | | | | |
| 18 | Multiple peroxisomal enzyme deficiency, Zellweger's syndrome | Peroxis (1, 2, 5, 6, 12) | Excessive very long-chain fatty acids | Autosomal recessive | Neonatal | Dysmorphic features, hypotonia, seizures and feeding difficulties, with hepatosplenomegaly |
| 19 | Ulrich's disease Pseudoneonatal adrenoleukodystrophy (NALD) | Acyl-CoA oxidase | Excessive very long-chain fatty acids | Autosomal recessive | Neonatal | Coarse features, seizures, poor mental development, visual impairment |
| 20 | X-linked Siemerling-Creutzfeldt's | ABC protein | Excessive very long-chain fatty acids | X-linked recessive | Childhood onset is classic | Classic form: progressive psychomotor decline; variant can be adrenomyeloneuropathy with slowly developing spastic paraparesis of adulthood |

CNS, central nervous system; PNS, peripheral nervous system; GFAP, glial fibrillary acid protein; SAP-B, sapanin B.

Axonal degeneration accompanies dysmyelination and no axons are demonstrated where myelin sheaths are absent. Neurons are usually well preserved.⁶⁵ The X-linked Pelizaeus-Merzbacher disease (PMD) results from a defect in the oligodendrocytic synthesis of the proteolipid protein (PLP). PLP is the major CNS myelin protein, and makes up about 50% of the protein mass in the myelin. In the peripheral nervous system, the PLP is synthesized by Schwann cells and constitutes less than 1% myelin protein. PLP gene mutations on Xq22 cause PMD.⁶⁶ A prenatal diagnosis of the X-linked PMD has been made by DNA testing.⁶⁷ Contrary to the classic X-linked PMD, the transitional type of disorder (type 3) occurs sporadically. Lowenberg-Hill disease (type 4) shows autosomal dominant transmission.

Classic Pelizaeus-Merzbacher disease usually begins in the first few months of life, heralded by nystagmus and head tremor. Motor development delay occurs, and eventually ataxia, attention tremor, and choreoathetosis develop. Other signs include lower extremity spasticity, dysarthria, and optic atrophy. Motor and ocular impairments are severe compared with the mild degree of dementia. Deterioration assumes an even slower pace after 5 to 6 years of age. Clinical seizures (generalized or focal) usually appear during the later stages of the disease. Death is usually delayed until the second decade of life or early adulthood. Although not always present, a very characteristic early clinical finding may be a slow, rotary “cogwheel” nystagmus. As the patient becomes older, the nearly diagnostic ocular motility sign changes to a nonspecific movement disorder of the eyes. Jerk nystagmus is invariable.

Among the variants, in the connatal form hypotonia is severe and accompanied by feeding difficulties. Laryngeal stridor is frequently noted. Optic atrophy can be identified early. The clinical deterioration is rapid leading to death within months to a few years of life. In transitional or type III disease (Seitelberger’s disease), the clinical severity falls somewhere between that of the connatal and classic infantile forms. Invariably there is moderately severe mental retardation, and the average age of death is between 5 and 10 years. Lowenberg-Hill disease, the adult form, has a very slow course. In contrast to all other forms, no ocular features are seen, and episodic psychotic events are characteristic. It is now well accepted that one of the X-linked forms of hereditary spastic paraplegia (SPG2) is allelic to PMD. Some patients present a pure form involving only the lower extremities while others have in addition nystagmus, dysarthria, and ataxia.⁶⁸

Abnormalities of the brain stem auditory-evoked responses and sleep EEG are seen in some patients.⁶⁸ Cranial computed tomographic (CT) scans in long-standing cases have demonstrated cerebellar atrophy and focal areas of demyelination. MRI demonstrates a decreased thickness of the corpus callosum and persistent myelin islands and a reversal of the normal gray-white matter signal relationships consistent with dysmyelination.

All the leukoencephalopathies, genetic and nongenetic, should be included in the differential diagnosis. There is no specific curative therapy for Pelizaeus-Merzbacher disease, and diligent supportive care is essential for both patients and families. While the search for treatment continues, specific clinical genetic characterization and research into the biochemical basis for the diseases continue.

Cockayne’s Syndrome

Cockayne’s syndrome (see Table 30-6) is sometimes classified as a variant of Pelizaeus-Merzbacher disease because of the similar pattern of patchy demyelination among preserved islands of myelin.⁶⁹ However, in this disease there is pronounced involvement of multiple systems, suggesting a different pathogenic mechanism. The brain is small, and the white matter is atrophic. Calcifications are frequently present in the globus pallidus and cerebellum, along with mineralization of small arteries. The brain may contain a diffuse proliferation of astrocytes of bizarre appearance, predominantly in the cerebral cortex. Occasionally, Alzheimer-type neural fibrillary tangles are seen. The peripheral nervous system is also involved, with segmental demyelination with preservation of the axon cylinders. Patients with Cockayne syndrome are hypersensitive to sunlight. Cultured cells are hypersensitive to ultraviolet (UV) radiation. The protein products deficient in the various forms of Cockayne’s syndrome are involved in different aspects of the repair of damaged DNA. The common problem in patients with Cockayne’s syndrome is a failure to repair oxidation-induced damage to DNA bases. Patients with Cockayne’s syndrome suffer from defects in the “transcription-coupled repair” (TRP). Cockayne’s syndrome can arise from mutations in one of five genes. Two genetic complementary groups have been isolated in classic Cockayne syndrome. Cockayne’s syndrome type A (CSA) is characterized by deficiencies in the WD repeat protein, a subunit of RNA polymerase II TFIIF. The CSA gene is encoded on chromosome 5. Cockayne’s syndrome type B (CSB) is caused by deficiency in a helicase member of the SW12/SNF2 family of ATPases. Several mutations in the CSB gene have been described on chromosome 10q11. Another class of patients with Cockayne’s syndrome shows concurrently clinical features of xeroderma pigmentosum (XP). Three mutated genes have been identified in this group of patients: XPB, XPD, and XPG.^{69,70} All forms of Cockayne’s syndrome are inherited as an autosomal recessive traits. Both the central and the peripheral nervous system are involved.

Patients with this syndrome are often normal at birth, but in the first 6 months of life they develop a photosensitive dermatitis. In the second year, growth retardation, dwarfism, and kyphosis become apparent.⁷¹ A facial rash and a facial-somatic dysplasia with a beaklike nose are part of the early picture. Microcephaly, mental retardation, retinitis pigmentosa, and optic atrophy soon develop. Following infancy, cerebellar dysfunction, sensorineural hearing loss, and upper motor neuron signs characterize the progressive neurological syndrome. Reflexes may be difficult to elicit. Other typical features are joint deformities, abnormally advanced bone age, dental caries, and renal disease. Ophthalmic findings include retinal involvement, poor pupillary response, lenticular cataracts, corneal opacities, and impaired lacrimation. Normal pressure hydrocephalus has been implicated as a possible mechanism for some of the neurological deterioration seen in these patients, although this has not been a consistent finding.⁷²

Neuroimaging procedures reveal calcification of the basal ganglia and cerebellum, and neurophysiological testing shows nerve conduction velocity. It is probably easier to confuse this syndrome with a dysplastic cytogenetic

disturbance than with the pediatric neurodegenerative disorders or other leukodystrophies because central demyelination is one of the least striking clinical manifestations. Case reports indicate that treatment of the normal pressure hydrocephalus, when it occurs, may be beneficial (see Chapter 25). No specific curative therapy is available, and only supportive treatment may be offered.

Alexander's Disease

This degenerative disorder is a primary genetic disorder of astrocytes, one of the major cell types in the CNS white matter (see Table 30-6). As a result, there is a global dysmyelination or demyelination of the CNS. The pathologic hallmark of all forms of Alexander's disease is the presence in astrocytes of cytoplasmic eosinophilic hyaline bodies, called Rosenthal fibers. These inclusions are particularly numerous beneath the pial arachnoid membranes, beneath the ependyma and around the cerebral blood vessels, and are found throughout most of the brain. Rosenthal fibers contain the glial fibrillary acid protein (GFAP), an intermediate filament protein. Rosenthal fibers occur especially in the optic nerves, optic tracts, optic chiasm, cerebral peduncles, and spinal cord. Abnormal astrocytes are also observed in the basal ganglion, thalamus, and hypothalamus. Although the astrocytes become distended, there is no evidence of abnormal storage material within neurons. The white matter is soft and retracted and shows a variable loss of myelin, which appears more marked and diffuse in infantile cases. Axon cylinders are preserved. Rosenthal fibers in Alexander's disease result from overproduction of GFAP due to molecular alterations in the GFAP. Alexander's disease has been shown to result from multiple mutations in the GFAP gene on chromosome 17.⁷³ In all patients, the *GFAP* mutations are dominant. The mutations usually arise *de novo* or from germinal mosaicism in cases with early onset. In adult, milder mutations are autosomal dominant.⁷⁴

The rare neonatal form is characterized by early, often intractable, multifocal seizures, hydrocephalus due to aqueductal stenosis by the propagation of astrocytes containing excessive amounts of eosinophilic cytoplasmic material, lack of developmental maturation, and elevated CSF protein content.⁷⁵

The most frequent form of Alexander's syndrome is the infantile form, which has an average onset at 6 months of age. However, onset may occur at any time from shortly before birth to as late as 2 years of age. The average duration of disease is 2 to 3 years, but it can vary from a few months to several years. Predominant psychomotor retardation exists initially, and progressive spasticity and seizures in the context of megalencephaly, with or without frank hydrocephalus, develop.

In the juvenile form, which is much less common than the infantile form, onset usually occurs between 7 and 14 years of age, and the duration is approximately 8 years. Bulbar and pseudobulbar dysfunction predominates, with dysphagia, dysarthria, nystagmus, ptosis, full facial palsy, and tongue atrophy.⁷⁶ Generalized spasticity and weakness may also occur, but unlike the severe mental retardation characteristic of the infantile form, mentation tends to remain intact. The adult form of Alexander's syndrome has an early stuttering course mimicking multiple

sclerosis and characterized clinically by blurred vision, spasticity, nystagmus, dysarthria, and dysphagia. Other reported neurologic manifestations include palatal and ocular myoclonus.⁷⁷

CT changes include low attenuation in the deep cerebral white matter, most extensively in the frontal lobes and subependymal regions. The ventricles are variably enlarged. There is inconsistent abnormal enhancement of the caudate nuclei, anterior columns of the fornix, optic radiations, and periventricular areas.

Since the types of Alexander's disease are phenotypically distinct, the differential diagnosis varies by age. If one encounters an infant with chronically developing megalencephaly or macrocephaly with mild regression in psychomotor milestones in the absence of any other obvious cause, Alexander's syndrome is a highly probable diagnosis. Juvenile leukoencephalopathy must be considered in children and multiple sclerosis in adults.

No specific therapy is available for Alexander's syndrome. Much supportive care, however, is necessary, including good nutrition and generous use of antibiotics and antiepileptics. Despite these measures, the prognosis for infants and children with this disease at present is poor. Recent advances in positron emission tomography (PET) scanning and single-photon emission computed tomography (SPECT) indicate that there is an abnormal flow of spinal fluid through the blood-brain barrier. Our better understanding of this disorder may aid in developing interventions.

Canavan's Syndrome

Canavan's syndrome (see Table 30-6) is a spongy degeneration of the CNS with abnormalities found particularly in the white matter. Vacuoles accumulate in a variety of brain cells, particularly astrocytes, and produce the spongy appearance. The vacuoles result from excessive fluid accumulation in astrocytes, apparently from metabolic disturbances that produce dysmyelination.⁷⁸ Chemical changes are limited to the white matter, notably myelin, and are non-specific. There are increased water content and decreased total lipids in the white matter. Myelin breakdown products are not found. Dysmyelination is extensive, but axonal fibers and the oligodendroglia are not extensively affected. The precise cause of these abnormalities frequently remains uncertain.

The term Canavan's disease is used to describe an autosomal recessive spongy degeneration of the brain, occurring mainly among Ashkenazi Jewish individuals, and characterized by increased levels of *N*-acetylaspartic acid in the urine and plasma and aspartoacylase deficiencies in cultured skin fibroblasts.⁷⁹ It is caused by a deficiency of aspartoacylase (ASPA), an enzyme playing a role in myelin synthesis. Elevated levels of *N*-acetylaspartic acid (NAA) are found in urine, serum, and CSF. Canavan's disease results from mutations in the ASPA gene on chromosome 17p13.⁸⁰ DNA analysis is the method of choice for prenatal diagnosis.⁸¹

The three types of Canavan's disease are characterized by abnormal white matter signal on MRI and lack of involvement of peripheral nerves. Large amounts of NAA are found in urine (see Table 30-6). The infantile form, or classic Canavan's disease, begins within a few months of

birth, and death generally occurs by 3 to 4 years of age. The infant initially is hypotonic and has poor head and neck control. Megalencephaly is common by 6 months of age, and arrested development is consistent. In the second 6 months, hypotonia is replaced by spasticity and often by decorticate and decerebrate posturing. Some hyperreactivity is precipitated by auditory, visual, and tactile stimuli. Vision deteriorates as optic atrophy and nystagmus develop. Seizures of various types, including focal and myoclonic seizures, are usual, and choreoathetotic or dystonic movements can occur. Dysautonomia in the form of paroxysmal episodes of sweating, hyperthermia, vomiting, and hypotension are terminal manifestations.

The neonatal form of Canavan's disease is deadly within a few weeks and is characterized by lethargy, hypotonia, diminished spontaneous movement, and difficulty in swallowing. The rare juvenile form develops after 5 years of age and extends into adolescence. Ataxia, tremor, ptosis, and mental deterioration are characteristic. The course is characterized by progressive cerebellar symptoms, dysarthria, dementia, seizures, spasticity, and loss of vision. There is no correlation between the severity of the morphological white matter changes and the clinical presentation.⁸² Gene therapy is under investigation. Symptomatic support includes nutritional therapy and generous use of antiepileptic drugs and antibiotics. Whereas currently the prognosis is poor, future research efforts utilizing cloistered populations with the disease, such as those found in Saudi Arabia, may lead to new discoveries.

Krabbe's Syndrome

In contrast to other leukodystrophies, Krabbe's syndrome appears to be purely neurological. In these patients, there is a deficiency of the lysosomal enzyme galactocerebroside β -galactosidase (GALC). The disease is inherited as an autosomal-recessive trait. The various forms of the disease result from multiple mutations in the GALC gene on chromosome 14q24.3-q32.1.⁸³ Assays of amniotic fluid allows prenatal diagnosis, and enzymatic assays on white blood cells or serum may detect the carrier state. A saposin A deficiency is expected to be responsible for some cases of Krabbe's syndrome with near normal GALC activity.

In the CNS, the white matter is decreased in mass and is gliotic, firm, and rubbery to palpation. In the areas of demyelination, oligodendroglial cells are severely reduced in number. Globoid cells, found deep in the white matter around and within vessels, are distinctive. Their abundant cytoplasm stains positively with periodic acid-Schiff (PAS) and only faintly with Sudan black. No metachromasia is present. The small globoid cells are round and mononuclear, while the large one (varying from 20 to 50 μ m) become irregular and multinucleated. Electron microscopy reveals within the cytoplasm of the cells cytoplasmic inclusions containing both electron-dense linear or curved tubular profiles, a distinctive sign in Krabbe's disease.⁸⁴ Neurons in the pons, thalamus, and dentate nuclei show varying degrees of degeneration, but the neuronal processes of the cerebral cortex are reasonably well preserved. Involvement of the peripheral nervous system varies, and segmental demyelination has been reported.⁸⁵ Globoid cells are not seen in peripheral nerves, but histiocytes with

foamy cytoplasm and tubular inclusions have been demonstrated. Krabbe's disease is distributed worldwide and has no gender, racial, or ethnic proclivities.

There are two primary forms of Krabbe's disease, the early-onset or classic form, and the late-onset form. The early-onset type usually appears clinically between the third and eighth months of life, although biochemical and pathological changes are present in the early gestational period. Initially, the patient is irritable and has intermittent fever for no discernible reason. Episodic limb or trunk rigidity may occur, and a heightened startle response to noise, light, or touch may be apparent. Feeding problems and seizures occur frequently. Myoclonic seizures may suggest infantile spasms. Macrocephaly is uncommon, and hepatosplenomegaly is absent. There are usually no cherry-red spots. Early in the course, EEG shows a severe slowing of the background activity and abundant paroxysmal discharges. By 6 months of age, the infant develops severe hypertonus with obvious opisthotonos and decorticate-decerebrate rigidity. Reflexes may be hyperactive or hypoactive if advanced peripheral neuropathy is present. Babinski's signs are usually present along with optic atrophy. By 9 months of age, the baby is usually blind and deaf. In light of these characteristic clinical features, there is very little confusion between the diagnosis of classic Krabbe's disease and other infantile-onset degenerative conditions (Video 105, Myoclonic Seizure).

The late-onset type of Krabbe's disease is extremely uncommon. These patients first develop difficulties later in infancy, in childhood, or even in adult life.⁸⁶ The late infantile form is characterized by the onset between 6 months and 3 years of developmental regression with ataxia and stiffness, feeding difficulties, irritability, and loss of vision. The juvenile or adult form is usually characterized by a progressive amaurosis starting in late childhood, followed years later by a progressive gait impairment with spasticity or dystonia, and finally dementia. Optic atrophy and peripheral neuropathy are consistent findings late in the course of the illness.

Periventricular hyperdensities demonstrated on CT scans have been reported, particularly in the terminal phases of the classic form. MRI scans demonstrate white matter involvement of the cerebrum and cerebellum,⁸⁷ and electrophysiological evidence of peripheral nerve demyelination is prominent. Treatment at this time is limited to allogenic hematopoietic stem cell transplantation that appears to slow the progression of the disease and improve magnetic resonance images. Studies using stem cells and viral vectors to transduce transplantable cells are under way.⁸⁸

Metachromatic Leukodystrophies

The metachromatic leukodystrophies (see Table 30-6), also known as sulfatide lipidoses, are a group of lysosomal storage disorders recognized by the accumulation of excessive amounts of lipid sulfatides. The term metachromatic, as a description of the diseases, derives from the staining properties of the stored lipid sulfatides, which develop a brown or gold hue with toluidine blue rather than the usual blue of myelin. In the central nervous system, the sulfatides are stored in lysosomes of microglia and neuronal cells. In

the peripheral nervous system, the lysosomal storage of sulfatide within Schwann cells leads to a segmental demyelinating neuropathy. Outside the nervous system, the sulfatide is stored in other organs and tissues such as the kidneys, pancreas, adrenal glands, liver, and gallbladder.⁸⁹

In the classic form of metachromatic leukodystrophy, sulfatide content in the white matter is four to eight times that found in normal control subjects. Large amounts of sulfatides are found in the urine. The deficient enzyme in the classic metachromatic leukodystrophy is arylsulfatase A (ASA). A "sphingolipid activator protein" (SAP), saposin B, is a heat-stable nonenzymatic protein necessary for the normal catalytic function of ASA. The late infantile, juvenile, and adult forms of the syndrome are caused by mutations in the ASA gene located on chromosome 22q13.31.⁹⁰ Patients with metachromatic leukodystrophy due to saposin B deficiency (SAP-1 deficiency) have a near normal ASA activity and excrete in addition to sulfatides, globotriosylceramide and digalactosylceramide.⁹¹ SAP B deficiency is caused by specific mutations in the prosaposin gene on chromosome 10q21.⁹² This condition is allelic to SAP C deficiency causing Gaucher's syndrome. All forms of metachromatic leukodystrophy are inherited as an autosomal recessive trait. Aryl sulfatase A deficiency is not unique to metachromatic leukodystrophy. Aryl sulfatase A is also deficient in a mucopolysaccharidosis: multiple sulfatase deficiency, in which activity of the three isoenzymes of arylsulfatase (A, B, and C) is markedly reduced.

EPIDEMIOLOGY AND RISK FACTORS. All forms of metachromatic leukodystrophy are inherited as autosomal recessive traits. This condition is globally distributed. The prevalence of all forms of metachromatic leukodystrophy is approximately 1 in 100,000 live births. The genes responsible for the various forms of metachromatic leukodystrophy have been mapped. Several mutations have been identified for each disorder. The molecular heterogeneity of the metachromatic leukodystrophies frequently results in a clinical heterogeneity. For instances, two distinct types of arylsulfatase A mutations can be distinguished. Type O mutations tend to eliminate completely any functional gene product. Patients homozygous or heterozygous for type O mutations have invariably the infantile form of metachromatic leukodystrophy. Type R mutations tend to be associated with a small amount of residual enzyme activity. Most patients homozygous for type R mutations present an adult form of metachromatic leukodystrophy. Mixed heterozygosity between type O and type R mutations most often results in a juvenile form. Only a single phenotype generally occurs in families with more than one affected member: the age of onset, clinical presentation, and progression of the illness are similar among members of a single family. Several ethnic groups have a higher frequency of this disease. The Habbanite Jewish community in Israel has a particularly high frequency of late infantile metachromatic leukodystrophy (1.3%).

CLINICAL FEATURES AND ASSOCIATED FINDINGS. Clinically, according to the age of onset, three forms of metachromatic leukodystrophies have been recognized. The late infantile form of metachromatic leukodystrophy usually begins between the ages of 18 and 24 months, although onset may occasionally be delayed until as late

as age 4 years.^{93,94} These children develop a gait disturbance that may appear as ataxia or weakness.⁹⁵ Hypotonia is very prominent during this time. A lazy eye may be the presenting complaint. Thereafter, a rather rapid decline continues over a period of 6 months or more until steady regression persists and bulbar signs become apparent. The hypotonia becomes much worse as the disease continues, and weakness dominates during these phases. Intellectual deterioration occurs reasonably rapidly over a 6- to 12-month period. By the terminal stage, hypotonia has reverted to hypertonia and frank spasticity. Involuntary movements are obvious. Another characteristic of the classic form that distinguishes it from other forms of metachromatic leukodystrophy is the presence of megalencephaly, although this finding is not as striking as it is in the gangliosidoses or in Alexander's and Canavan's syndromes.

A peripheral neuropathy may exist even in the early stages of this disease when absence of reflexes or hyporeflexia is evident. This is a result of peripheral segmental demyelination and the deposition of sulfatide within the nerve fibers. As the CNS sulfatide deposits increase with disease progression, one can account for the turnaround in muscle tone. The hypotonia is first accentuated because of suprasegmental shock influences. These in turn are altered when suprasegmental release occurs. This is the switching point of the change from clinical hypotonia to clinical hypertonia and its associated phenomena. Seizures are a late manifestation. Patients with the classic form often die by 8 to 10 years of age. Yet other patients reach a vegetative trough and live well into their teens. By this time, such patients are indistinguishable from those with the later-onset forms of the disease.

Onset in the juvenile form occurs between 4 and 10 years of age. The majority of patients show the first symptoms during their early years at school. The first observed symptoms are usually bradykinesia and poor school performance. In the very early periods, daydreaming, confusion, and emotional lability are frequently reported. Unsteadiness of gait, usually because of pyramidal tract involvement, may be noted. Extrapyramidal dysfunction such as postural abnormalities and tremor may develop. Myotactic reflexes are usually increased even in the early stages. The rate of deterioration is usually slow and is much more variable than that of the late infantile form of the syndrome. Patients often are not bedridden even 5 to 10 years after the initial symptoms appear.

In this form usually early motor findings such as spastic gait and ataxia may be the most prominent symptoms; they are secondary to intellectual impairment. There is little tendency for hypotonia to appear. When it is manifest, a greater degree of peripheral neuropathy is evident, although even then brisk reflexes and extensor toe signs are frequently present. In spite of this, nerve conduction times are decreased. Dementia occurs but is slower to develop than in the late infantile form. Decerebrate posturing and generalized convulsions occur as a late manifestation. When the late infantile form is subacute, the juvenile form is chronic, and patients usually live for 20 years or longer.

Onset of the adult form occurs at any time after puberty. Initial symptoms frequently consist of personality and mental changes that signal the impending dementia. Other presenting symptoms include seizures and behavior changes.

Patients may show a hypospontaneity and a blunted affect or inattention and hyperactivity. Such symptoms are often misdiagnosed as schizophrenia or manic depressive illness. There are usually no clinical signs of peripheral neuropathy. Disorders of movement and posture appear later. Frank dementia becomes the central feature, occurring most frequently by the third or fourth decade of life. Often these mental symptoms in the adult are accompanied by progressive corticobulbar, corticospinal, and cerebellar changes. Visual and somatosensory evoked potentials are delayed. Even in this form, nerve conduction velocities are markedly lowered.

DIFFERENTIAL DIAGNOSIS. In any disorder showing progressive manifestations such as seizures, dementia, and motor failure, the diagnosis must be considered when signs of peripheral neuropathy are found. Consideration of other leukodystrophies depends on their phenotypic expression, as well as a variety of peripheral neuropathies without prominent central nervous system. Many variants of metachromatic leukodystrophy as well as other conditions should be considered in the differential diagnosis. Among these are multiple sulfatase deficiency that is not associated with striking leukodystrophy, should not be confused with metachromatic leukodystrophy. Also, metachromatic leukodystrophy, in which there is no clear demonstration of a deficiency in arylsulfatase A, is due in some families to deficiency of cerebroside sulfatase activator. Additionally, all leukodystrophies should be entered in the differential diagnosis. Consideration of other leukodystrophies depends on their phenotypic expression as well as a variety of peripheral neuropathies without prominent central nervous system symptoms.

EVALUATION. Spinal fluid protein concentration is usually moderately elevated, with concentrations in the 150 to 300 mg/100 mL range. There are no qualitative abnormalities in the protein profile. Demonstration of a deficiency of arylsulfatase A activity either in urine or in leukocytes confirms the diagnosis in the majority of cases. Decreased gallbladder function may be detected by a simple cholecystogram or ultrasonography examination and may be a useful adjunct in the workup. The presence of metachromatic granules in the urine is of some help and gross inspection of an office urine sample can be suggestive of the diagnosis. Brain stem, auditory, visual, and somatosensory evoked responses show some abnormalities, but the results are variable. The most consistent finding is the characteristic decreased nerve conduction velocities found in almost all forms of metachromatic leukodystrophy.

MANAGEMENT. Bone marrow transplantation in patients with late infantile metachromatic leukodystrophy due to arylsulfatase A deficiency or saposin B deficiency has reported to have little impact on long-term outcome except perhaps in patients with juvenile or adult onset. The effectiveness and safety of this therapy need further evaluation.

Peroxisomal Leukodystrophies: Adrenoleukodystrophy

The peroxisomal leukodystrophies (see Table 30-6) represent a relatively new concept for neurologists. Peroxisome

refers to the subcellular organelles in the cell body that are deranged by being absent, malformed, or dysfunctional. These conditions include neonatal disorders such as Zellweger's disease and adrenoleukodystrophy as well as later-onset adult conditions such as Refsum's disease. The pioneering work of Moser, Schutgens, and associates on the peroxisomal entities has established the fact that peroxisomal dysfunction does not invariably produce the clinical or pathological features of leukodystrophy. The peroxisome is ubiquitous in its clinical and pathological expression. In an excellent short review of these disorders, Moser⁹⁶ gives a list of 14 major peroxisomal diseases to illustrate the two categories of peroxisomal defects. One of these categories is identified as a disorder of peroxisome assembly or biogenesis (PBG). Another category encompasses disorders with a single peroxisomal enzyme defect, the prototypes being noninfantile Refsum's disease (see infra) and sex-linked adrenoleukodystrophy (XALD).⁹⁷

The pathologic hallmark of the disorders of peroxisomal biogenesis (PBG) is the finding of ghost peroxisomes. As a result, there is a concomitant loss of activity in multiple peroxisomal enzymes. Multiple biochemical abnormalities are observed: plasma very long chain fatty acids (VLCFA), phytanic acid, and trihydroxy-cholestanoic acid (THCA) are increased; the plasmalogen synthesis is decreased. The overlapping phenotypes representative of this category are Zellweger's syndrome and Ulrich's disease or neonatal adrenoleukodystrophy, and infantile Refsum's disease. These autosomal recessive conditions have their onset early in life. Patients have severe neurologic and hepatic dysfunction, craniofacial abnormalities, and hypotonia (Video 252, Neonatal Adrenoleukodystrophy). Dysmorphic features are always present. Adrenal insufficiency is subclinical. Neuropathology shows a sudanophilic leukodystrophy with signs of brain (cerebral and/or cerebellar) dysgenesis. Mutations of either of five genes encoding peroxins (PEX1, PEX2, PEX5, PEX6 and PEX12) are responsible most of these phenotypes.^{98,99}

Zellweger's disease is a severe, rapidly fatal disorder characterized by cerebrohepato-renal syndrome. Hepatomegaly, renal cysts, hypotonia, and seizures are accompanied by prominent dysmorphic features (giving these infants the premature appearance), eye findings (retinitis pigmentosa, glaucoma, cataract, and sometimes Brushfield's spots), deafness, aberrant calcific stippling of the patellae, and abnormal genitalia (hypoplasia of labia major or hypospadias). Neonatal adrenoleukodystrophy and infantile Refsum's disease differ from Zellweger's disease by their milder dysmorphic features and a very protracted course with failure to thrive and minimal psychomotor gains. Sensory hearing loss, retinal degeneration and hepatomegaly may be present. Occasionally, the symptoms occur at a somewhat later period than expected.⁹⁷ Subdural hematoma may be the presenting symptom.¹⁰⁰ One patient presented at 23 months with frequent emesis and acute mental deterioration, followed very quickly by refractive seizures. A long history of developmental, mental, and motor delay had previously been observed in this child. There tends to be a staggering course, sometimes with developmental stagnation or regression preceded or followed by improvement in stasis, visual impairment, truncal hypotonia, and limb spasticity.

The pathologic hallmark of all the peroxisomal disorders with single enzyme deficiency is the presence of peroxisomes and, in most cases, a normal plasmalogen synthesis. Only one peroxisomal enzyme is deficient and therefore metabolic abnormalities are selective, involving in general only one metabolic pathway. However when the deficient enzyme is necessary for the normal function of multiple metabolic pathways, the finding of multiple metabolic derangements may suggest a PBG disorder. Both bifunctional enzyme deficiency and oxoacyl CoA thiolase deficiency are associated with VLCFA and THCA and present with the clinical phenotype of “pseudo-Zellweger’s disease.”

The acyl-CoA oxidase deficiency is responsible for a selective elevation of VLCFA and a phenotype called “pseudo-neonatal adrenoleukodystrophy” due to dysmorphic features, hypotonia, feeding difficulties, intractable neonatal seizures, and the minimal psychomotor development observed during the first 2 years of life. Adrenal insufficiency is subclinical. Brain imaging may show contrast enhancement surrounding the demyelinated areas.¹⁰¹

In the X-linked adrenoleukodystrophy (X-ALD), the genetic abnormality has been mapped to the Xq28 region. The disease results from mutations in the ALDP gene, which encodes a peroxisomal membrane protein member of the ATP-binding cassette (ABC) family. It has been postulated that this protein transports acyl-CoA synthase to its site of action.¹⁰² The saturated VLCFA (C:25 and C:24) are increased. Adrenal insufficiency frequently leads to skin hyperpigmentation or Addisonian crisis.

Among the variants of X-linked adrenoleukodystrophy, the childhood form is usually the more fulminating disorder. Patients are completely normal until 4 to 10 years of age, when behavioral problems such as failure in school become manifest. This first sign is the result of rapid regression of auditory discrimination, spatial orientation, speech, and fine motor skills. Seizures occur in less than a third of the patients reported by Naidu and Moser.¹⁰⁰ Typically, there is a rapid clinical deterioration to spastic paraparesis, swallowing difficulties, and visual loss, culminating in a vegetative state within 2 years of the appearance of symptoms. Neuroimaging typically demonstrates a symmetrical periventricular demyelination, more prominent initially over the occipital regions, with characteristic contrast enhancement at the rim of the lesion.

In the adolescent cerebral X-ALD syndrome, signs and symptoms of cerebral involvement are manifest, yet the onset of disease usually occurs between the ages of 10 and 21. The adult form usually presents with dementia, psychiatric disturbances, seizures, spinocerebellar degeneration or spastic paraparesis with onset at some time after the age of 21. Such patients have presentations similar to those of other problems such as multiple sclerosis, schizophrenia, and brain tumor. They show a reasonably rapid regression. After many years, a demyelinating peripheral neuropathy may present the features of a hypertrophy neuropathy with onion bulb formation.

Included in the differential diagnoses are most of the leukoencephalopathies and dystrophies as well as other processes, depending on the phenotypic expression of the disorder. All early-onset disorders in which there is degeneration and dysplastic status should be considered.

Very long chain fatty acids in plasma and cultured fibroblasts are elevated in all forms of ALD and in Zellweger’s syndrome. Probably the presence of very long chain fatty acids and the other biochemical abnormalities noted previously are the major methods of making the diagnosis. However, all evaluations consistent with the severe dysmorphic and degenerative states of such patients are probably indicated.

The potential for therapy is, of course, limited for this group of diseases. In most cases, therapy is primarily directed toward supportive care. Treatment for liver dysfunction or the prothrombin deficiency with vitamin K is indicated in PBG disorders. Rehabilitative approaches are sometimes helpful. One should consider the probability of complications such as subdural hematoma and its treatment. Attempts to mediate some of the biochemical abnormalities with lipid therapy or dietary restriction of very long chain fatty acids have been tried, but they do not normalize plasma levels of the fatty acids, or red blood cell plasmalogen synthesis. Peroxisomal proliferators such as clofibrate do not induce formation of catalase-containing peroxisomes nor improve clinical status of PBG disorders.

Therapy for X-linked adrenoleukodystrophy is under active investigation at this time. Steroid replacement therapy is effective for adrenal insufficiency but does not alter the rate of progression of neurological disability. Dietary therapy with a 4:1 mixture of glycerol triolate and glycerol trierigate (Lorenzo’s oil) has normalized levels of very long chain fatty acids and plasma within 4 weeks. The results in symptomatic patients have been disappointing.¹⁰³ Therapeutic plasma exchanges are successful in reducing VLCFA, but without altering the clinical course. Various immunosuppressive therapies have been unsuccessful. Bone marrow transplantation is of benefit to patients with early neurological involvement.¹⁰⁴

OTHER LIPIDOSES

Fabry’s Disease

This X-linked lipidosis is characterized biochemically by the intralysosomal accumulation of globotriaosylceramide, galabiosylceramide, and other glycosphingolipids. The enzymatic deficiency is α -galactosidase A. The molecular structure of the gene encoding the enzyme was first identified as the full-length cDNA clone and is localized to Xq21.33-q22.¹⁰⁵ Both point mutations and deletions have been described for this gene. The majority of the glycosphingolipids is synthesized in the liver or bone marrow and thereafter is transported to cells by lipoproteins. The major substrate burden in Fabry’s disease appears to be on cellular membranes that depend on glycosphingolipids for their integrity and function. Organ storage occurs presumably because of permeable membranes that permit accumulation of high levels of circulating lipids.

In the majority of affected males, the clinical symptoms begin in late childhood or adolescence with the development of painful neuropathy, which is most pronounced in the extremities, syncopal episodes and hypohydrosis associated with heat intolerance and low-grade fever, corneal

and lenticular opacities and characteristic skin lesions, known as angiokeratoma. These dermatological features consist of ectatic blood vessels covered by thin skin and appear as discrete, slightly raised, blue or dark red spots that cluster in the groin, umbilical area, and thighs. The neurological signs are usually vascular in origin and include transient ischemic attacks, ischemic strokes, and cerebral hematomas. Renal failure and vasculopathy of the heart and brain lead to early death in adulthood. In the minority of affected males, the main manifestation is a hypertrophic cardiomyopathy. Most female carriers are asymptomatic. A minority presents with isolated acroparesthesia, cardiac symptoms or corneal dystrophy. Pathologically, storage of glycolipids in the systemic vascular system leads to progressive cardiac, CNS, and renal involvements. The CNS shows lipid accumulation in the autonomic nervous system neurons and several other regions including supraoptic, preoptic, and paraventricular nuclei. The nucleus basalis, anterior thalamus, and the hippocampus are also characteristically loaded with glycolipid, and when the cerebral cortex is involved, layers 5 and 6 demonstrate the neuronal lipid storage. In the peripheral nervous system, lipid accumulation can be observed in neurons of sensory and autonomic ganglia, in Schwann cells, and in endothelial cells and pericytes of endoneurial capillaries. Loss of small caliber myelinated and unmyelinated fibers occurs.¹⁰⁶

Because the disease is rare, carrier testing is not routinely performed. In affected pedigrees, however, α -galactosidase A analysis identifies affected males and often heterozygous females. Affected males cannot pass the disease to their sons, but all daughters are carriers.

The differential diagnosis includes conditions associated with angiokeratoma, including metabolic disorders such as neuraminidase deficiency, galactosialidosis, fucosidosis, and GM₁ gangliosidosis. Drugs that can cause corneal opacification include chloroquine and amiodarone. The treatment of Fabry's disease focuses primarily on abatement of the painful neuropathy, and carbamazepine and diphenylhydantoin, as well as neurotrophin have been used with success.¹⁰⁷ Renal transplantation has also been used in patients with severe renal failure. Recombinant α -galactosidase A replacement therapy clears microvascular endothelial deposits of globotriaosylceramide in affected tissues, reversing the chief clinical manifestations of the disease.¹⁰⁸

Noninfantile Refsum's Disease

This autosomal recessive nonlysosomal lipidosis is characterized biochemically by an isolated peroxisomal phytanoyl-CoA α -hydroxylase (PAHX) deficiency resulting in a cytoplasmic accumulation of phytanic acid. The sequence of PAHX gene is known and localized on chromosome 10p. Both point mutations and deletions have been described in the PAHX associated with Refsum disease.¹⁰⁹ Phytanic acid is a branched-chain fatty acid that is primarily derived from a diet rich in dairy products, some meat and fish. The mechanism of phytanic acid toxicity is unclear.

Clinically, Refsum's disease is known as hereditary atactica polyneuritiformis and is characterized by retinitis pigmentosa, peripheral neuropathy, cerebellar ataxia, and high protein levels in the cerebrospinal fluid without

pleocytosis. Cardiac involvement, anosmia, nystagmus and nerve deafness occur in almost all patients as well. Ichthyosis and skeletal abnormalities, particularly pes cavus and the bilateral shortening or elongation of metatarsals and metacarpals, are inconsistent systemic features. The first clinical symptoms are usually night blindness and clumsiness. Most patients have a bilateral constriction of the visual fields by the time they present. Rapid weight loss, fever, and pregnancy have been associated with acute or subacute presentations mimicking Guillain-Barré syndrome and chronic inflammatory demyelinating neuropathy. Pupillary miosis makes the fundoscopic examination difficult. Neuropathy develops slowly and is associated with proprioceptive sensory loss, absent myotactic reflexes, distal muscle wasting, and foot drop. Nerve conduction findings include slowed conduction velocities. Although neuropathy may contribute to some of the cerebellar findings, there appears to be true cerebellar ataxia in this condition. The age of neurological disability onset is highly variable from childhood to the sixth decade but usually occurs in adolescence and young adulthood. In association, cardiac involvement is of clinical significance, and tachycardia, systolic murmurs, and conduction disturbances occur. Fatal cardiac arrhythmias may be responsible for several cases of documented sudden deaths in untreated patients with Refsum's disease.

Markedly raised plasma levels of phytanic acid and occurrence of plasma phytanyl triglycerides are consistent in noninfantile Refsum's disease. Phytanic acid accumulation is not unique to Refsum's disease and is also seen in peroxisomal biogenesis defects (infantile Refsum's disease, neonatal adrenoleukodystrophy, Zellweger's syndrome and rhizomelic chondrodysplasia punctata) and isolated peroxisomal branched chain oxidation defects. In Noninfantile Refsum's disease, pristanic acid is low/normal due to lack of production from phytanic acid, distinguishing this condition from peroxisomal biogenesis defects and from isolated peroxisomal branched chain oxidation defects. Some patients with non infantile Refsum's disease may have elevated pipercolic acid levels.¹¹⁰ Pathologically, in noninfantile Refsum's disease, the peroxisomal structure is normal, distinguishing this condition from peroxisomal biogenesis defects characterized by an abnormal peroxisomes. Nerve biopsy shows "onion bulb" formation and targetoid cytoplasmic inclusion in the Schwann cell. In the central nervous system phytanic acid accumulates in neurons, glial cell of the globus pallidus and substantia nigra, ependymal cell, choroid plexus, and leptomeninges.

The differential diagnosis of Refsum's disease includes other neurological syndromes with neuropathy and ataxia, such as some mitochondrial diseases (Friedreich ataxia and neuropathy, ataxia, retinitis pigmentosa), abetalipoproteinemia, vitamin E deficiency, and Charcot-Marie-Tooth disease and their variants. Elevated plasma phytanic acid levels eliminates these diagnoses.

The diet should contain enough calories to prevent weight loss and fish, beef, lamb, and dairy products should be avoided.¹¹¹ Improvement is slow, and plasmapheresis is used as an adjunct to hasten clinical recovery. Retinal damage and nerve deafness do not improve, but the other signs may substantially abate over a very prolonged period.

Abetalipoproteinemia (Bassen-Kornzweig Syndrome)

This autosomal recessive lipid disorder is characterized biochemically by extremely low levels of serum cholesterol and triglycerides due to a defect in the intestinal microsomal triglyceride transfer protein (MTP), a protein necessary for the assembly of apolipoprotein B—containing lipoproteins (low density lipoproteins and chylomicrons). Without MTP, the apolipoprotein B is not properly lipidated and undergoes presecretory degradation. The result is absence of plasma chylomicrons and very low density lipoproteins. Intestinal fat absorption is deficient. The MTP gene is sequenced and localized on chromosome 4q. Both point mutations and deletions in the MTP gene are responsible for abetalipoproteinemia.^{112,113}

Clinical manifestations develop in the first decade of life with steatorrhea, distal sensorimotor neuropathy, and retinitis pigmentosa. Ataxia is accompanied by dysarthria, areflexia, and proprioceptive sensory loss. The presence of extensor Babinski's responses may suggest the diagnosis of Friedreich ataxia. A generalized muscle weakness and wasting accompanied by ptosis and ophthalmoparesis may also develop.¹¹⁴ Serum cholesterol and triglyceride levels are low, low density lipoproteins (LDL) are completely absent, and erythrocytes take on the appearance of acanthocytes. Because of the reduced chylomicrons, severe deficiencies of fat-soluble vitamins, namely A, K, and E, occur. Systemic signs can include cardiomyopathy and failure to thrive. Normal villi are seen in small bowel biopsies but the mucosal cells are filled with lipid droplets.

The differential diagnosis includes disorders that have combined neuropathy and ataxia, and include Friedreich disease and the hereditary sensorimotor neuropathies. Laboratory analysis and electromyographic (EMG) studies suggesting axonal neuropathy are helpful in directing the clinician.¹¹⁵ The differential diagnosis also includes those disorders with acanthocytes, namely neuroacanthocytosis, although typically the latter disorder has tics and dystonia rather than profound neuropathy and ataxia. Finally, the differential diagnosis includes all conditions associated with vitamin E deficiency because neurological abnormalities in Bassen-Kornzweig disease resemble vitamin E deficiency in other situations.

There is strong evidence, both clinically and in the laboratory, that the neurological findings relate directly to vitamin E deficiency. Vitamin E supplementation can arrest the progression of both retinal and neurological deficits.¹¹⁶ Other dietary treatments are important to overall rehabilitation status and include restricted intake of long-chain fatty acids and supplementation of other fat-soluble vitamins.

An α lipoproteinemia (Tangier's Disease)

This autosomal recessive nonlysosomal lipid storage disorder characterized biochemically by near or complete absence of circulating high density lipoproteins (HDLs) and by the cytoplasmic accumulation of cholesteryl esters and phospholipids in histiocytes, Schwann cells, neurons (spinal ganglion and spinal cord), nevus cells, smooth muscle cells, and fibroblasts. The virtual absence of circulating plasma high density lipoprotein is caused by molecular

defects in the ATP-binding cassette (ABC) transporter 1 (ABCA1), a permease belonging to one of the superfamilies of efflux pumps. The human ABCA1 gene maps on chromosome 9q31. Point mutations, insertions and deletion in the ABCA1 gene cause Tangier's disease.¹¹⁷

Tangier's disease is associated with a nonspecific peripheral neuropathy that may be motor, sensory, or mixed in type. The neuropathy presents in childhood or adulthood, but the distinctive clinical feature about affected persons is their dramatically enlarged and orange-tinged tonsils. Atherosclerosis resulting in cardiovascular disease is a common systemic complication. Plasma HDL cholesterol is extremely low or absent.

Various Transporter Defects

Lesch-Nyhan Disease (Hypoxanthine-Guanine Phosphoribosyltransferase Deficiency)

Congenital Disorders of Glycosylation (CDG) (Carbohydrate-deficient Glycoprotein Syndrome)

Porphyrias

Neurotransmitter-related Disorders

A large number of diseases, at least 70, involve the metabolism of organic and amino acids. Some diseases present as repeated episodes of acute metabolic decompensation, and the central nervous system (CNS) involvement is usually secondary to the accompanying acidosis, hypoglycemia, or hyperammonemia or to the elevated concentration of amino acids. Nevertheless, it is the secondary involvement of the CNS that is important and is the main problem requiring management. Another group of these disorders involves the CNS primarily, with the systemic disease being negligible. Such disorders are difficult to label at the time of initial encounter as either an organic or amino acid disorder because there are no episodes of acid-base disturbance or disturbance of glucose or ammonia metabolism. They can only be diagnosed by specialized biochemical tests. The recent advent of tandem mass spectrometry is changing the practice of neurometabolic diseases since it provides a rapid diagnosis.^{1,2} In many instances the child will become neurologically crippled before the diagnosis is suspected and ascertained. A third group of disorders have an impact on both the CNS and peripheral tissues. Likewise, mitochondrial enzyme defects treated later in the chapter can be classified by age of presentation. Childhood disorders are classified in [Table 31-1](#) according to their main presenting features and age.^{1,2} The porphyrias are primarily adult-onset disorders.

AMINOACIDOPATHIES AND ORGANIC ACIDOPATHIES

Neonatal Disorders

The Advent of Neonatal Screening Programs

It has been more than 35 years since a neonatal screening test program was established for phenylketonuria (PKU). These initial efforts were based on an inhibition assay developed by Dr. Robert Guthrie.³ In the 1980s, several other diseases were added to such screening programs.⁴ The major breakthrough came from the adoption and modification of a tandem mass spectroscopy system (MS/MS)⁵⁻⁷ that now can fit the needs of mass screening programs.⁸⁻¹⁰ The method is easy to use and yields rapid results. The analytic time is approximately 90 seconds and preparation time for a batch of 96 samples is approximately 2 hours. In one analytic panel, 30 or more organic and aminoacidemias can be screened ([Table 31-2](#)). The method is nearly always free of false-negative and false-positive results. Some abnormal values, either elevations or depressions, are very specific and pathognomic of inborn errors if other causes are excluded. For example, high octanoyl carnitine levels occur in medium-chain acyl-CoA dehydrogenase (MCAD) deficiency. Depressed methionine levels occur in methylenetetrahydrofolate reductase deficiency. Clinical

TABLE 31-1

Different Clinical Presentations of Amino Acid and Organic Acid Disorders According to Age and Symptoms

| Neonatal Disorders with Devastating Metabolic Disease |
|---|
| Maple syrup urine disease (MSUD) (branched-chain aminoacidemia) |
| Urea cycle disorders |
| Nonketotic hyperglycinemia |
| Propionicacidemia, methylmalonicacidemia, and isovalericacidemia |
| Certain phenotypes of 3-hydroxy-3-methylglutaryl-CoA lyase deficiency |
| Holocarboxylase synthetase deficiency |
| Pyruvate dehydrogenase and pyruvate carboxylase deficiencies |
| Cytochrome-c oxidase deficiency |
| Carnitine/carnitine-acyl translocase deficiency |
| Long-chain acyl-CoA dehydrogenase (LCAD) deficiency |
| Medium-chain acyl-CoA dehydrogenase deficiency (MCAD) with early neonatal death |
| Multiple acyl-CoA dehydrogenase deficiency |
| Certain phenotypes of 3-methylglutaconicacidurias |
| Later Infancy Disorders with Recurrent Metabolic Decompensation |
| Intermittent, or intermediate MSUD |
| Late-onset urea cycle disorders |
| Arginase deficiency |
| Certain phenotypes of 3-hydroxy-3-methylglutaryl-CoA lyase deficiency |
| Certain phenotypes of propionicacidemia and methylmalonicacidemia |
| Ethylmalonicaciduria and malonicaciduria |
| Certain phenotypes of 3-methylglutaconicacidurias |
| β -Ketothiolase deficiency |
| Later Infancy and Childhood Disorders with Prominent Neurological Manifestations |
| Classic and bipterin-dependent hyperphenylalaninemia |
| Homocystinuria due to cystathionine β -synthase deficiency |
| Disorders of folate and vitamin B ₁₂ metabolism with homocystinuria |
| 4-Hydroxybutyricaciduria |
| Glutaricaciduria type 1 |
| Certain phenotypes of 3-methylglutaconicacidurias |
| Carnitine palmitoyl transferase (CPT) I and II deficiencies |
| Adenosine triphosphate synthetase deficiency |
| Certain phenotypes of MCAD and LCAD deficiencies |
| Biotinidase deficiency |

interpretation is essential, however, because the biochemical results are extremely accurate but still do not always indicate a primary inborn error of metabolism. For example, elevation of octanoyl carnitine might also be observed under valproate treatment, and hypomethioninemia might also reflect general protein malnutrition. Therefore, these screening tests require clinical interpretation.

The impact of screening programs and early intervention is increasingly clear worldwide. Patients with glutaricaciduria identified in the early neonatal period are growing as normal children under treatment. A large number of children with organic and aminoacidemias detected by neonatal screening are today developing clinically as healthy children. Certain other disorders such as 3-hydroxy-3-methylglutaryl-CoA lyase deficiency, β -ketothiolase deficiency, methylenetetrahydrofolate reductase deficiency, isovalericacidemia, PKU of both types, methylmalonicacidemia, MCAD, citrullinemia, and argininosuccinicaciduria, when identified in the neonate, almost always can be treated with rewarding results. In spite of this progress, some identified disorders remain untreatable. Severe phenotypes of propionicacidemia and methylmalonicacidemia, severe phenotypes of other fatty acid oxidation disorders, and glutaricaciduria type 2 cases still experience severe morbidity or an early death despite management.

Maple Syrup Urine Disease

PATHOGENESIS AND PATHOPHYSIOLOGY. In 1962, Menkes and colleagues observed an unusual odor, like that of maple syrup, in the urine of four infants who died of progressive encephalopathy in the first few weeks of life (Fig. 31-1).¹¹ Maple syrup urine disease (MSUD) is a disorder of branched-chain amino acid (BCAA) metabolism, in which the concentrations of L-leucine, L-isoleucine, and L-valine, as well as their corresponding α -ketoacids, are elevated in body fluids. The branched-chain α -ketoacid dehydrogenase (BCKAD) is deficient, and the disorder is inherited as an autosomal recessive trait. It is a multienzyme complex that contains three major subunits: E1,

TABLE 31-2

Disorders That Can Be Screened by Tandem Mass Spectroscopy (MS/MS)*

| ORGANIC ACIDEMIAS | AMINO ACID AND OTHER DISORDERS |
|--|---|
| Propionicacidemia | Hyperphenylalaninemia, classic |
| Methylmalonicacidemia | Hyperphenylalaninemia, bipterin dependent |
| Isovalericacidemia | Branched-chain amino acidemia (maple syrup urine disease); classic, intermittent, and intermediate variants |
| 3-Hydroxy-3-methylglutaryl-CoA lyase deficiency | Citrullinemia |
| β -Ketothiolase deficiency | Argininemia |
| Multiple carboxylase deficiency | Argininosuccinicacidemia |
| Short-, medium-, and very long-chain acyl-CoA dehydrogenase deficiencies | Lysinuric protein intolerance |
| Carnitine/acylcarnitine translocase deficiency | Hyperlysinemia |
| Carnitine palmitoyl-CoA transferase deficiency types 1 and 2 | Hyperprolinemia |
| Multiple acyl-CoA dehydrogenase deficiency | Nonketotic hyperglycinemia |
| Pyroglutamicaciduria | Homocystinuria |
| Pipecolicaciduria | Disorders due to cobalamin mutations |
| | Methylenetetrahydrofolate reductase deficiency |

*Several of these disorders have been identified in the metabolic service of King Faisal Specialist Hospital and Research Center, Saudi Arabia, during the past 8 years through MS/MS.

Figure 31-1. Maple syrup urine disease and homocystinuria. Clockwise, from left upper corner. The facial and generalized erythematous, scaly, weeping rash in acute, untreated maple syrup urine disease (MSUD). Spastic quadriparetic posture and increased fat pads in cheeks of an infant with poorly managed MSUD. CT of the brain showing left occipital infarct in patient with homocystinuria. Gangrenous fingertips in homocystinuria.

a decarboxylase; E2, an acyltransferase; and E3, a lipoamide dehydrogenase (dihydrolipoic dehydrogenase). The activity of BCKAD is regulated either by inhibition of reaction products or substrate analogues by reversible phosphorylation/dephosphorylation of the E1 subunit or by the regulation of gene expression through such hormones as insulin and corticosteroids, or l-carnitine, or by glucose. The chromosome location of the genes of the subunits and of complementary DNAs is established (Table 31-3). Mutations of the subunits from different ethnic groups have been identified.

The severe CNS symptoms of the disease have been attributed to brain edema, caused by elevated BCAAs, particularly L-leucine. The neuropathological finding in patients who die is generalized spongy CNS degeneration, similar to other disorders such as nonketotic hyperglycinemia.

EPIDEMIOLOGY AND RISK FACTORS. The worldwide frequency based on routine screening data from 26.8 million newborns is about 1 in 185,000.¹² The disease is common in consanguineous communities; for example, among the Mennonites of Pennsylvania, the incidence is 1 in 176. It is encountered frequently in the Middle East, particularly in the Arabian peninsula, where its frequency may be as high as 1 in 2000.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. The classical form of MSUD usually presents within the first 2 weeks of life and rarely beyond 1 month of age. The prodromal symptoms include refusal to feed, vomiting, increasing lethargy, and seizures, with eventual coma. Because the cerebral peduncles and the dorsal part of the brain stem are the earliest parts of the CNS involved, the

patient develops opisthotonus and primitive reflexes are usually absent. The initial clinical diagnosis is commonly meningitis or sepsis; because such patients frequently have associated sepsis, the primary diagnosis may be missed for many days. Cerebral edema leads to tone disturbances, alternating between increased tone and hypotonia. Seizure activity is usually clonic or myoclonic with eyes rolling upward. Early optic atrophy is usual and recedes only if the therapeutic intervention is prompt. When the presence of disease is not recognized at this stage, or the neonate is not managed appropriately, the infant becomes blind and has severe spastic quadriplegia (see Fig. 31-1). Undiagnosed patients usually develop apnea and die. When treated appropriately, the symptoms will gradually disappear. In well-managed patients, mild to moderate hypotonia (particularly axial hypotonia) persists during the first year of life; eventually, mild to moderate cerebellar ataxia will remain as the only neurological sequela.

The symptoms of MSUD reappear as overwhelming illness and coma in patients with disorders that lead to protein catabolism, especially infections and diarrhea. When these conditions are not managed appropriately, they lead to further neurological deterioration or death. Clinical symptoms and the course of the disease are milder in infants who are diagnosed through neonatal screening and treated before the initial metabolic crisis. In contrast, a patient with late-diagnosed MSUD experiences frequent recurrent episodes, requires prolonged hospital care, and poses significant management problems without ever improving.

TABLE 31-3

Chromosomal Locations of Diseases

| DISEASE AND ENZYME(S) | CHROMOSOME LOCATION |
|---|--|
| Maple syrup urine disease: branched-chain alpha-ketoacid dehydrogenase (E1, E2, and E3 subunits) | E1 α : 19q13/1–q13/2; E1 β : 6p21–p22; E2: 1p31; and E3: 7q31–q32 |
| Propionicacidemia: propionyl-CoA carboxylase | α Subunit: 13q32; β subunit 3q13–3q22 |
| Methylmalonicacidemia: methylmalonyl-CoA mutase, hydroxycobalamin reductases, adenosyl transferase and cobalamin A–F groups | Mutase: 6p12–p21.2; others are unknown |
| Urea cycle disorders: carbamoylphosphate synthetase (CPS), ornithine transcarbamylase (OTC), argininosuccinicacid (ASA) synthetase, ASA lyase | CPS: 2p OTC: Xp21.1 ASA synthetase: 9q34 ASA lyase: 7cen–p21 12q22–224.1 |
| Classic PKU: phenylalanine hydroxylase | GTP cyclohydrolase: 14q22.1–q22.2 |
| Biopterin-dependent PKU: GTP cyclohydrolase, 6-pyruvoyl-tetra-hydropterin synthase (6PTS), dihydropterin reductase (DHPR), and 4 α -carbinolamine dehydratase (PCD) deficiencies | 6PTS: cDNA available DHPR: 4p15.3 PCD: 10q22 |
| Homocystinuria: cystathionine β -synthase | 21q21–q22.1 |
| Glutaricaciduria type 1: glutaryl-CoA dehydrogenase | 19p13.2 |
| Biotinidase deficiency: biotinidase | 3p25 |

TABLE 31-4

Differential Diagnoses of Coma in Neonate: Clinical Findings

| DISEASE | TONE | SEIZURES | DYSMORPHIA | LIVER DISEASE | INFECTIOUS COMPLICATIONS |
|----------------------------------|---|---------------------------|---|---|--------------------------|
| Maple syrup urine disease (MSUD) | Alternating tone | Myoclonic or clonic | Absent | Absent | Almost always present |
| MSUD (recurrent crisis) | Not specific | May be present | Absent | Absent | May be present |
| Urea cycle disorders | Severe hypertonia | Usually myoclonic | Absent | Absent | May be present |
| Various organic acidemias | Hypotonia (propionic-acidemia), hypertonia (methylmalonicacidemia and isovalericacidemia) | Myoclonic or clonic | Facial and CNS dysmorphism present in propionicacidemia and pyruvate dehydrogenase deficiency | Present in cytochrome-c oxidase deficiency or oxidative phospho-rylation diseases | Almost always present |
| Fatty acid oxidation disorders | Myopathy or cardiomyopathy | As caused by hypoglycemia | Only type 2 glutaric aciduria | Only type 2 glutaric-aciduria | Usually absent |
| Nonketotic hyperglycinemia | Severe hypotonia, stridor, hiccups | Severe, usually myoclonic | CNS dysgenesis such as absent corpus callosum | Absent | Usually absent |
| Zellweger's syndrome | Severe hypotonia | Severe, usually myoclonic | Facial, CNS dysgenesis, cysts in organs | Severe liver involvement | Usually absent |
| Nesidioblastosis | None | As caused by hypoglycemia | None | None | None |

The odor of infants is that of burnt sugar, or maple syrup. It is easily recognized in the urine, hair, axillae, and perineum or in cerumen; it is best appreciated on frozen urine, because the smell is caused by compounds with oily characteristics accumulating on the frozen surface.

When the levels of BCAA are not monitored frequently during dietary management, abnormal ratios of leucine/isoleucine or of valine ensue. This situation manifests as severe dermatitis, described as scalded skin syndrome (see Fig. 31-1). The dermatitis will resolve when the ratios of amino acids are normalized. A number of MSUD variants have been described.¹³

DIFFERENTIAL DIAGNOSIS. Clinically, the most important differential diagnoses are other causes of neonatal coma, and many can be differentiated by clinical (Table 31-4) or by simple laboratory observations (Table 31-5). In the neonate, MSUD is almost always confused with sepsis or meningitis, and the disease is usually associated with either one. The diagnosis of MSUD is suspected only after the sepsis or meningitis workup reveals normal results. Precious therapeutic time will be lost, causing severe neurological crippling or death. MSUD must always be ruled out in any neonate with lethargy progressing to coma; with alternating tone changes; in the absence

TABLE 31-5

Differential Diagnoses of Coma in Neonate: Laboratory Findings

| DISEASE | BLOOD pH | BLOOD GLUCOSE | BLOOD AMMONIA | BLOOD LACTIC ACID | URINE KETONES | SPECIAL FINDINGS |
|----------------------------------|--|--|------------------------------|---|---------------------------------------|--|
| Maple syrup urine disease (MSUD) | Normal | Normal | Normal | Normal | Trace or absent | Elevated branched-chain amino acids and branched-chain ketoacids in urine |
| MSUD (recurrent crisis) | Acidosis | Moderate/severe hypoglycemia | Normal | Normal | Moderate/severe ketonuria | As in neonatal period |
| Urea cycle disorders | Alkalotic or normal | Normal | Rapid elevation | High in argininosuccinic-aciduria and citrullinemia | Absent | Citrulline values differentiate various types; high oroticaciduria in certain types |
| Various organic acidemias | Overt/compensated acidosis w/large-base excess | May be mild/moderately low | Usually elevated | Usually elevated | Trace/strong (+) in various disorders | Urine organic acids, blood acylcarnitines |
| Fatty acid oxidation disorders | Usually normal | Usually moderately/severely low | Variable, but usually normal | May be elevated | Absent | Urine organic acids, blood and urine acylcarnitines |
| Nonketotic hyperglycinemia | Normal | Normal | Normal | Normal | Normal | Elevated glycerine in blood and cerebrospinal fluid |
| Zellweger's syndrome | Normal | Normal | Normal | Normal | Normal | Elevated liver enzymes and very long-chain fatty acids in blood; pipecolic acid in urine |
| Nesidioblastosis | Normal | Low with inappropriately elevated insulin levels | Normal | Normal | Normal | Blood glucose and insulin determined at the same time |

of changes in blood pH, glucose, and ammonia; and regardless of the presence of an infection. In variant forms of the disease, the diagnosis is usually reached when either blood amino acids or urine organic acids are studied in a child with periodic coma or in a child with pyramidal or cerebellar signs.

EVALUATION. Test findings should be grouped into two age categories: one for neonatal and one for episodes after 6 months of age. In the neonatal period, the disease almost never causes significant hypoglycemia, nor acidosis, ketonuria, or hyperammonemia. Therefore, the presence of coma in a neonate who has nearly normal clinical biochemical findings should immediately suggest MSUD. Definite diagnosis is through determination of amino acids in plasma or in urine, which shows significant elevations of L-leucine, isoleucine, and valine. Leucine concentration in blood is always higher than that of the other BCAAs. BCAAs or BCKAD can be measured either by chromatographic techniques or more rapidly by MS/MS determinations. A quick spot test of the ketoacids in the urine is a strongly positive yellow flocculation when 2,3-dinitrophenylhydrazine is added. After 6 months of life, when recurrent acute metabolic decompensation occurs, it is accompanied by mild to moderate hypoglycemia, severe acidosis, and ketonuria.

The electroencephalogram (EEG) of the newborn with MSUD has a characteristic sharp wave pattern described as comblike rhythm.¹⁴ After proper management, the EEG may be normal between attacks or there may be a generalized slowing of the background and paroxysmal discharges, indicative of the ongoing metabolic disease. In older patients, leucine loading may lead to EEG abnormalities. Even in well-controlled patients, seizure disorder may appear later during childhood, requiring anticonvulsive treatment.

Neuroimaging is a valuable tool, particularly when amino acid determination is not immediately available. In the neonate, it causes a characteristic appearance of white matter attenuation suggestive of brain edema that appears as early as 9 days of life despite dietary treatment. The MSUD edema initially involves the deep cerebellar matter, the dorsal part of the brain stem, the cerebral peduncles, and the dorsal limb of the internal capsule. Eventually, marked generalized diffuse edema appears in the central white matter and is particularly prominent in the frontal areas. The edema subsides after several months of treatment, with mild to severe atrophy of the brain remaining, as evidenced by enlarged ventricles and prominent sulci. The severity of these findings depends on the stage of the disease at which the treatment is initiated. In well-managed patients, the neuroradiological sequelae may be increased cerebellar foliation, cerebellar white matter disease, or cerebellar atrophy supporting the clinical presence of ataxia; this last finding may be the only neurological sequela in such children.

MANAGEMENT. Treatment consists of emergency reduction of increased BCAAs in blood. In patients diagnosed early, peritoneal dialysis or hemodialysis should be attempted. A secure central line must be placed, because intensive parenteral nutrition and antibiotics are used for several weeks to prevent catabolism and prompt anabolism. Specific amino acid solutions without BCAA for par-

enteral nutrition, in MSUD and other disorders of BCAAs, are available from PharmThera (Memphis, TN).¹⁵ Insulin drip, using diluted insulin solutions, must be initiated to ensure anabolism. Blood levels of BCAAs must be measured initially once or twice daily to monitor the reduction of the level of BCAAs; this is best done by MS/MS. A simple clinical guideline to therapy is to follow weight gain in a nonedematous neonate. The treatment usually leads to daily weight increments for about 10 days, at which time the blood leucine level is reduced below 1000 μM . Oral intake of special mild formulas with restricted BCAAs must then be resumed, and parenteral nutrition must be discontinued gradually. A neonate with MSUD is usually difficult to feed, and either a nasogastric tube or temporary button gastrostomy may be used for this purpose.

Once the acute metabolic decompensation is controlled, the patient is placed on BCAA-restricted formulas such as Ketonex or other MSUD formulas. Chronic management is difficult because it requires provision of BCAAs in amounts that permit growth but that do not cause significant BCAA elevations. This requires frequent amino acid analysis and can be achieved only in tertiary care centers where easy access to high-performance liquid chromatography or MS/MS is available. Patients should receive thiamine supplementation and L-carnitine; when metabolic decompensation occurs, leucine should be restricted.

PROGNOSIS, PREVENTION, AND PRENATAL DIAGNOSIS. Prognosis depends on early detection and treatment. Patients whose disease is diagnosed before the initial metabolic attack will grow as nearly normal children, despite recurrent attacks in later infancy. Successfully managed patients will have a near-normal IQ and normal school performance.^{16,17} A neonatal screening should be mandatory in countries where the disease is prevalent. The safety window of classic MSUD is only a few days; therefore, newborns should be screened for this disease at 24 to 48 hours of life. This can be achieved either by a Guthrie test or, more easily, by MS/MS. The BCKAD activity can be measured in cultured amniotic cells.¹⁸ If the mutation is known, this can be achieved by molecular genetic studies.

Urea Cycle Disorders

PATHOGENESIS AND PATHOPHYSIOLOGY. Recognized only during the past 40 years, the urea cycle disorders (UCDs) include argininosuccinicaciduria (ASA uria; ASA lyase deficiency),¹⁹ citrullinemia (ASA synthetase deficiency),²⁰ ornithine transcarbamoylase (OTC) deficiencies,²¹ and carbamoylphosphate synthetase (CPS) deficiency (Fig. 31-2).²² Ammonia is detoxified through five synthetic enzymes and one enzyme that synthesizes an activator for the initial step. The initial three enzymes are in the mitochondria, and the latter three are in the cytosol. This cyclic process both generates and hydrolyzes L-arginine, which is an essential amino acid in infants and important for normal development of the brain. When only one of the activities on this pathway is deficient, hyperammonemia and CNS symptomatology ensue. This usually occurs during the first few days to weeks of life and is one of the major causes of devastating metabolic disease of the newborn.

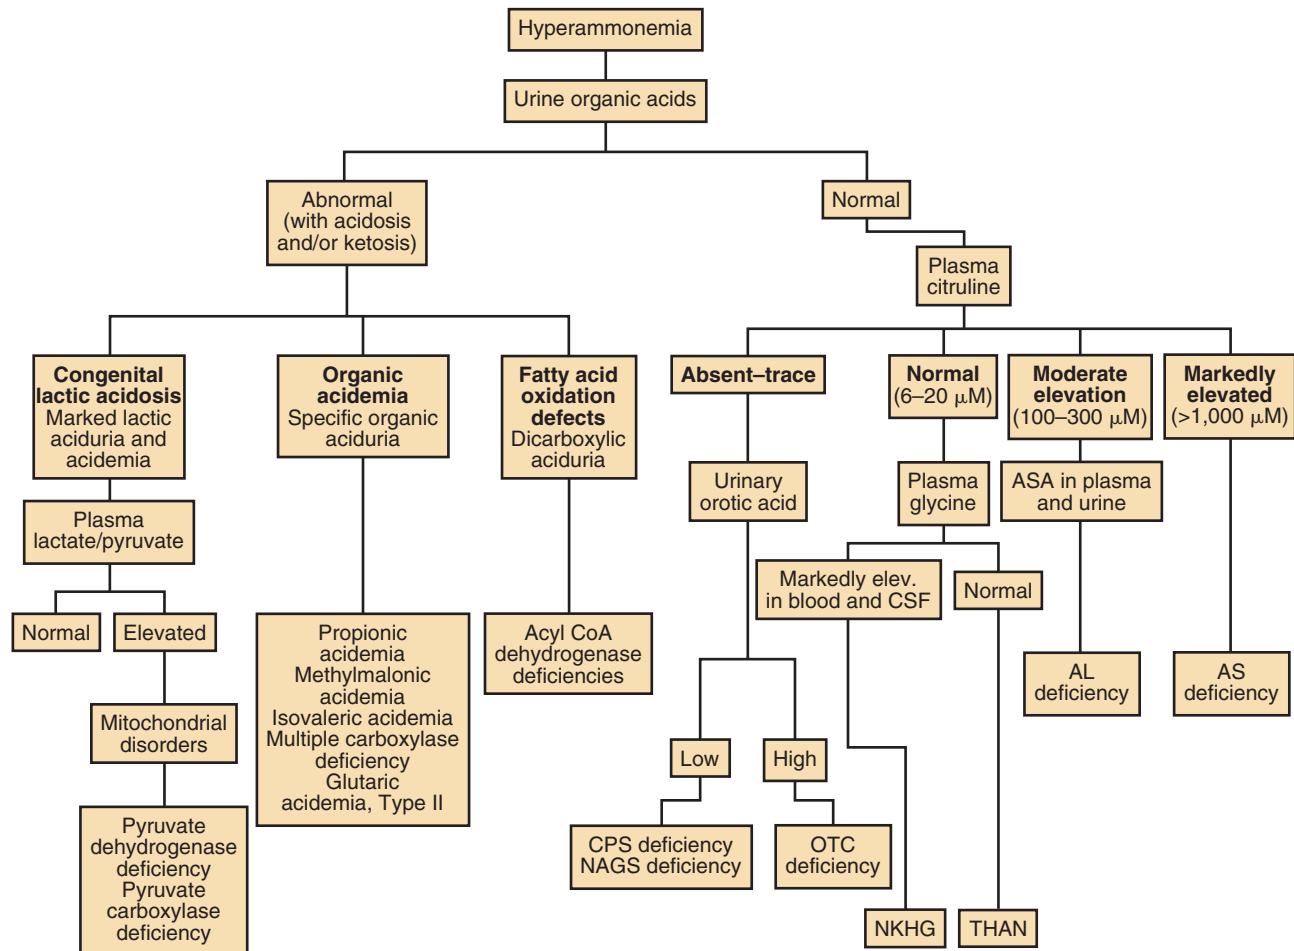

Figure 31-2. Algorithm for approach to neonatal-onset hyperammonemia. AL, argininosuccinate lyase; AS, argininosuccinate synthetase; ASA, argininosuccinic acid; CPS, carbamoylphosphate synthetase; NAGS, *N*-acetylglutamate synthetase; NKHG, nonketotic hyperglycinemia; OTC, ornithine transcarbamylase; THAN, transient hyperammonemia of the newborn. (From Batshaw ML: Errors of urea synthesis. *Ann Neurol* 1994;35:133-141. Copyright 1994 John Wiley & Sons. Reprinted by permission of John Wiley & Sons, Inc.)

The UCDs cause hyperammonemia, and the clinical picture is similar in all forms of neonatal UCD. The gene locations of urea cycle enzymes are shown in Table 31-3, and complementary DNA is available for most of them.

When any of the aforementioned enzymes is deficient, ammonia cannot be converted into urea, leading to hyperammonemia within the first week of life. Unlike hepatic coma, in which ammonia is only one of the many putative toxins, in neonatal UCD, ammonia is the only cause of encephalopathy. Blood ammonia concentrations exceeding 300 μM are highly neurotoxic, particularly when prolonged. Primate models with induced hyperammonemia closely mimic the clinical, neurophysiological, and neuropathological findings observed in human neonatal UCD. In late-onset forms of ASA synthetase and lyase deficiencies, levels of citrulline, ASA, and ASA anhydride are elevated between crises when the patient is asymptomatic. This suggests that the acute neonatal symptoms of these diseases are due to hyperammonemia and not to elevated levels of urea cycle amino acids. Support for this theory is the family reported by Issa and associates²³ in which one neonate with citrullinemia died with hyperammonemia while her twin brother remained asymptomatic with elevated levels of citrulline. This point is of

paramount importance for the management and prognosis of UCDs.

The swelling of astrocytes in UCDs is due to hyperammonemia and might be caused by the concomitant elevation of glutamine. When glutamine synthetase is inhibited, cerebral edema caused by hyperammonemia can be prevented. In OTC deficiency, the hyperammonemia encephalopathy is shown to be related to brain glutamine accumulations, as demonstrated by magnetic spectroscopic studies.

EPIDEMIOLOGY AND RISK FACTORS. Fortunately, the UCDs are rare disorders. All, except OTC deficiency, are inherited as autosomal recessive traits. The OTC gene is on chromosome X, and its severe form is encountered only in males. The heterozygote female is discussed among UCDs of late onset. The cumulative frequency of all types of neonatal UCDs in Japan is 1 in 46,000 births; and the frequency for OTC deficiency in Japan was reported to be 1 in 80,000. In the Massachusetts screening program, the incidence of ASA lyase deficiency was 1 in 70,000,²⁴ and in a Quebec screening program, it was 1 in 77,000.²⁵ Approximately 65 cases of ASA lyase deficiency have been reported. The incidence of ASA synthetase deficiency (citrullinemia) in the Quebec program was 1 in 250,000 births.²⁵ In the Middle East, the most common forms of

neonatal UCD are ASA lyase and synthetase deficiencies and they might occur in 1 in 2000 to 3000 births.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. All forms of neonatal UCDs manifest nearly identical clinical symptoms. The infant is usually the product of normal pregnancy and delivery, with normal Apgar scores, and remains normal usually for 24 to 72 hours. Shortly thereafter, however, the infant becomes lethargic and refuses to feed; this quickly progresses to coma and is associated with hypothermia, hyperventilation, and respiratory alkalosis. Because cerebral edema appears early in the acute event, the bulging fontanelle erroneously leads to a diagnosis of meningitis with sepsis or pneumonia. If a coma workup is neglected, the neonate will die within a few days with a missed diagnosis. Brittle hair showing trichorrhexis nodosa in ASA lyase deficiency is encountered later during infancy and is not a prominent feature if the infant is given adequate amounts of L-arginine. Patients with ASA lyase deficiency might also have moderate to severe hepatomegaly. Phenotypical variability is the function of different mutations. Metabolic consequences also depend on the availability of compounds that might serve as an ammonia sink; for example, OTC deficiency is less severe than CPS deficiency and ASA synthesis that proceeds normally from citrulline might serve as a store for waste nitrogen.

DIFFERENTIAL DIAGNOSIS. The diagnosis is quickly reached by the uniform clinical presentation of the neonatal UCD. Differential diagnosis for neonatally important organic acidemias is by measurement of blood pH, lactic acid, ketone bodies, and glucose (Table 31-6; see also Table 31-5). The hyperammonemia observed in organic acidemias is associated with overt or compensated metabolic acidosis, whereas in UCDs the blood pH is usually normal or alkalotic. Blood glycine and urine ketones are elevated in the major ketotic organic acidemias of the neonate, which is not the case in UCDs. It is important to differentiate various types of UCD from CPS and OTC deficiencies. This differential diagnosis is essentially reached by measurements of specific amino acids in plasma and of orotic acid in the urine. *N*-acetylglutamate (NAG) synthetase deficiency may be proven clinically by normalization of ammonia after administration of 250 to 500 mg/kg/day NAG in a suspect case. It is now possible to diagnose citrullinemia and ASA uria rapidly within a few hours in a suspected case by MS/MS. The simultaneous measurement of acylcarnitines with amino acids particularly eliminates any confusion arising from other diseases with coexistent lactic acidemia.

EVALUATION. Any neonate with coma and devastating metabolic disease should receive a battery of clinical biochemical tests, including a determination of ammonia in addition to blood gases, pH, blood glucose, urea, and lactate (see Table 31-5). These data provide a provisional diagnosis of a UCD within hours, and a definite diagnosis can be made by the measurement of specific amino acids and orotic aciduria.

MANAGEMENT. Prompt intervention before the emergence of significant hyperammonemia is beneficial. The treatment consists of two phases: (1) rescue of the neonate from hyperammonemic coma and (2) maintenance of normal physical and intellectual growth between metabolic crises with recurrent hyperammonemia. The essential medications for both phases of treatment in UCD are phenylacetate or phe-

*Diseases are listed by order of most likely age presentation. The molecular genetics class is given in parentheses.

nylbutyrate and L-arginine. These medications bind and remove ammonia through alternate pathways as hippurate (1 M ammonia per mole of benzoate) and phenylacetylglutamine (2 M of ammonia per mole of phenylacetate or phenylbutyrate). In ASA synthetase and lyase deficiencies, L-arginine is used because it is converted into citrulline and ASA, respectively, and thus provides an ammonia sink. To avoid cerebral edema, recurrent episodes of hyperammonemia should be treated vigorously at the earliest clinical sign of decline, such as lethargy, irritability, vomiting, or behavior change, or before the plasma ammonia level increases to three times its normal limit.²⁶

Treatment between episodes of metabolic decompensation provides enough protein to ensure adequate growth but avoids hyperammonemia and elevated plasma glutamine levels. In CPS and OTC deficiencies, during the first 6 months of life, a diet that contains a 0.7-g/kg/day mixture of essential amino acids (using UCD formulas available from Mead Johnson, Princeton NJ, or Milupa, Hillington, Middlesex, UK) together with normal milk protein 0.7 to 2 g/kg/day is given and the plasma amino acid levels are

monitored. More recently, orthoptic liver transplantation has been recommended for the definitive treatment of UCD; the rewarding results of this treatment in seven patients with UCD have been reviewed.²⁷

Fatality relates directly or indirectly to the consequences of acute brain edema. Even if this complication is prevented, acute hyperammonemia either initially or intermittently can lead to intracerebral and subdural hemorrhage. No infant with a UCD should be given valproate because it may cause liver failure and death.²⁸

PROGNOSIS AND PREVENTION. Neurological outcome and morbidity depend on early diagnosis and appropriate treatment. Long-term studies suggest that use of phenylbutyrate with diet therapy offers the best chance of survival. Hyperammonemia of acute decompensation in ASA lyase and synthetase deficiencies is easily controlled by intravenous or oral administration of L-arginine; with subsequent use of diet and phenylbutyrate, the survival rate is 90%.

The neurological outcome in CPS and OTC deficiencies, even when treated appropriately, is only fair, with an average IQ score of 53 ± 6 .²⁹ Spastic gait is the eventual neurological sequela. The relatively poor prognosis in these two diseases is due to the unusual severity of hyperammonemia, its early onset, and its difficult management with frequent recurrent hyperammonemic episodes. On the other hand, both argininosuccinicaciduria and citrullinemia have a better neurological prognosis if they are identified before the initial acute metabolic decompensation and treated appropriately.

No large-scale study for the neonatal screening of UCD has been reported. The short safety window requires screening procedures that provide rapid results. The method should also have low false-negative results and be able to identify the milder forms of the disease. The newly described MS/MS procedure using dried blood spots has been able to identify both citrullinemia and argininosuccinicaciduria before the emergence of hyperammonemia and thus is useful for such mass screening of these two disorders. When the MS/MS-based orotic acid screen becomes possible, OTC deficiency should also be screenable. At present, there is no possibility of screening for the CPS deficiency. All subsequent newborns in a family with a previous newborn with UCD should be treated as such, until proved otherwise.

Propionicacidemia

Of the disorders that present as devastating neonatal metabolic disease listed in Table 31-1, propionicacidemia and methylmalonicacidemia are encountered more frequently than the others.

PATHOGENESIS AND PATHOPHYSIOLOGY. Propionicacidemia was first described by Nyhan and associates in an infant with episodic ketoacidosis, elevated plasma glycine (ketotic hyperglycinemia), and protein intolerance.³⁰ The disease is caused by the deficiency of propionyl-CoA carboxylase (PCC) and the inheritance is autosomal recessive. Propionyl-CoA is generated through the breakdown of L-isoleucine, valine, threonine, methionine, cholesterol, and odd-numbered, short-chain fatty acids. The enzyme is a polymer composed of nonidentical subunits (α and β), with the native enzyme being a hexamer. Its cofactor is biotin, which is bound to an epsilon-amino group

of lysine in the α subunit. The chromosomal locations of subunits are known, and complementary DNA is available (see Table 31-3). The deficiency of either subunit causes propionicacidemia.

Deficiency of PCC results in the accumulation of propionyl-CoA, which passes into circulation as propionylcarnitine or propionylglycine. Alternate pathways generate methylcitric acid, 3-hydroxypropionic acid, and tiglic acid. The toxic effects in CNS, bone marrow, and other tissues may be due to the accumulation of excess propionyl-CoA, depletion of the intramitochondrial free CoA pool, or toxic effects of compounds formed secondarily. Hyperglycinemia may be nonspecific and be due to inhibition of glycine cleaving enzyme. Hyperammonemia might be due to the inhibition of CPS I by the accumulating propionyl-CoA. Hypoglycemia might be due to the inhibition of pyruvate carboxylase or malate shuttle by elevated intramitochondrial propionyl-CoA. Despite the association of severe ketoacidosis during metabolic crisis, the mechanism of excess ketone body generation is not clear.

EPIDEMIOLOGY AND RISK FACTORS. The disease may be rare in the United States and Canada, affecting 1 in 250,000 to 500,000 births. However, in the Middle East, particularly in Saudi Arabia, it may be as high as 1 in 1000 births.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. The disease manifests from newborn to late infancy with acute decompensation as seen in other organic acidurias. A prodrome of vomiting and refusal to feed progresses to lethargy and coma within days. The infant becomes quickly dehydrated and may experience clonic, myoclonic, or grand mal seizures. Physical examination reveals severe central hypotonia, both during and in between crises. The oral mucosa, angles of the mouth, and perineal area usually show evidence of candidiasis. Facial appearance is usually typical, with depressed nasal bridge and long philtrum; there may be associated abnormalities of the nipple.³¹ Vomiting may be so severe that the infant might be operated on for pyloric stenosis or intestinal obstruction. Approximately 30% of the infants might present with immune deficiency, seizure disorder, or acute extrapyramidal signs such as choreoathetosis and dystonia.³¹

DIFFERENTIAL DIAGNOSIS. Two organic acidemias, methylmalonicacidemia and isovalericacidemia, in the neonate cause severe ketoacidosis, but both show increased muscle tone, whereas the tone in propionicacidemia is severely decreased. Patients with isovalericacidemia in crisis usually have a "sweaty feet" smell known to be associated with the disease. Propionicacidemia associated with immune deficiency might be confused with other disorders with immune deficiency.³¹ The urine and blood in infants with multiple carboxylase deficiency will show other intermediates, such as methylcrotonylglycine or isovalerylcarnitine.

All neonates with organic acidemia, all infants with symptoms suggestive of immune deficiency in association with thrombocytopenia or ketosis, and all infants with idiopathic seizure disorder or acute extrapyramidal tract signs should be tested for propionicacidemia, particularly where its prevalence is high.

EVALUATION. In early neonatal form, hyperammonemia is severe, usually exceeding 1 mM; in repeated episodes, it is usually moderate, rarely exceeding 300 μ M;

there is severe acidosis with accumulation of massive amounts of ketone bodies. Lactic acidosis is mild, rarely exceeding 6 mM. Hypoglycemia is usually moderate, rarely decreasing below 2 mM. Propionicacidemia has serious deleterious effects on bone marrow cells; neutropenia and thrombocytopenia are common. The platelet count usually drops several days after the onset of coma, while ketonuria is waning.³¹ If it is not appreciated, the patient will have bleeding, particularly intracranially. Propionicacidemia causes severe depletion of T lymphocytes, and the patient will experience frequent infections and sepsis due to unusual gram-negative organisms or *Candida*.

The diagnosis is made by detecting 3-hydroxypropionic acid, propionylglycine, and methylcitrate in the urine by gas chromatography/mass spectrometry or by estimating elevated glycine and propionylcarnitine and decreased free carnitine levels in blood through MS/MS. Propionylcarnitine will be elevated both in propionicacidemia and methylmalonicacidemia; if desired, PCC activity can be measured in leukocytes and cultured fibroblasts. Biochemical findings of propionicacidemia are also seen in multiple carboxylase deficiency owing to holocarboxylase synthetase or biotinidase deficiencies.

MANAGEMENT. Treatment of initial or acute crisis is by administration of high amounts of glucose and bicarbonate, together with insulin drip, intravenous L-carnitine (50 to 75/mg/kg every 6 hours), and optimum antibiotic coverage to treat sepsis, if present. When amino acid mixtures with restricted BCAAs are available, they can be added to the total parenteral nutrition. Vomiting during or between crises is controlled by intravenous or oral administration of ondansetron. Platelet count should be monitored daily during acute episodes; when it decreases below 50,000/ μ L, platelet transfusions should be given. It is advisable to place a gastrostomy with fundoplication during the first few years to manage chronic anorexia and vomiting. Once the patient's condition has stabilized, oral feeding with special propionicacidemia formula restricted in isoleucine and valine should be resumed, together with oral carnitine, 100 to 200 mg/kg/day, and Polycitra solution, 2 to 4 mL/kg/day. The patient should never be permitted to fast because excessive odd-numbered, short-chain fatty acids stored in the adipose tissue of propionicacidemia patients will mobilize and prompt a crisis. Metronidazole at a dose of 7.5 mg/kg/day should be used to decrease intestinal sources of propionate. Human growth hormone has been used as an adjunctive treatment. Sepsis, intracranial bleeding, and pancreatitis are dreaded complications.

PROGNOSIS AND PREVENTION. The prognosis in propionicacidemia is usually poor, with 50% of the patients dying and at least 25% showing mental retardation. Chronic hypotonia causes delayed acquisition of motor milestones. A routine neonatal screening test is not uniformly available. Preliminary results of a tandem mass spectrometry-based procedure indicated its value in detecting the disease within 24 to 48 hours, before the initial crisis.

Methylmalonicacidemia

PATHOGENESIS AND PATHOPHYSIOLOGY. Methylmalonicacidemia was first described by Oberholzer and

co-workers in 1967 in infants critically sick with profound ketoacidosis and accumulation of methylmalonic acid in blood and urine.³² The disease is a family of disorders caused by defective activity of methylmalonyl-CoA mutase (mutase [0] or mutase [-] complementation groups) or by defective intramitochondrial processing of vitamin B₁₂ (cblA and cblB complementation groups). Other disorders of vitamin B₁₂ will cause methylmalonicaciduria but are not associated with the periodic acidotic crisis of methylmalonicacidemia. They are associated with homocystinuria and are presented in the section on neurological diseases associated with homocystinuria.³³

Genetic heterogeneity of the disease is evidenced by some phenotypes being responsive to large doses of vitamin B₁₂ whereas no response is observed in others. The defects in the mutase are either (0) with no, or (-) with little, residual activity. The cofactor of the enzyme is 5'-deoxyadenosylcobalamin, and complementation groups cblA and cblB represent its defective synthesis. The toxic effects of intracellular accumulating methylmalonyl-CoA are similar to those of propionyl-CoA. All variants of methylmalonicacidemia are determined by autosomal recessive genes. The chromosome location of the mutase is known, and its complementary DNA is available (see Table 31-3).

EPIDEMIOLOGY AND RISK FACTORS. The incidence of methylmalonicacidemia in the Massachusetts screening program was 1 in 48,000.²⁴ The disorder is more common in the Middle East, probably occurring in 1 in 1000 or 2000 births.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. The usual presentation in the neonate is as a typical organic acidemia with overwhelming illness, similar to the presentation of propionicacidemia or isovalericacidemia. These episodes recur either as a consequence of excessive protein intake or from increased protein catabolism through vomiting or infections. The acidosis is usually so severe that the patient will be admitted in shock and might die. Mucocutaneous candidiasis is common, disappearing with appropriate management. The patient usually has increased muscle tone. Seizures, when present, are clonic or myoclonic. As in propionicacidemia, patients with methylmalonicacidemia are prone to a variety of infections and sepsis by unusual organisms. Facial dysmorphism includes high forehead, epicanthal folds, and a triangular mouth. Between episodes, the patient will appear normal, with only mild or no developmental delay.

Patients who are poorly managed, particularly those with vitamin B₁₂-unresponsive variants, might suffer infarcts (metabolic stroke) in the globus pallidus or internal capsule and may develop hemiplegia and acute dystonia. Failure to thrive and failure of linear growth are common. As in propionicacidemia, anorexia and chronic vomiting are usual. The patient may develop acute pancreatitis.³⁴ Poorly managed children with methylmalonicacidemia will develop nephropathy due to tubulointerstitial nephritis or less often to urate nephropathy.

DIFFERENTIAL DIAGNOSIS. Most considerations listed for propionicacidemia are also true for methylmalonicacidemia; both propionicacidemia and isovalericacidemia present with massive ketonuria during crisis, the differential diagnosis of which is given in the previous section on propionicacidemia. The same criteria that are listed

under propionicacidemia should be used to evaluate any child for possible methylmalonicacidemia.

EVALUATION. The acute episode is characterized by severe acidosis with massive ketone body accumulation. Initial episode in a newborn is always accompanied by significant hyperammonemia, whereas blood ammonia values are only mildly elevated in repeated episodes. Hypoglycemia is usually moderate and rarely below 3 mM. There may be mild elevation of plasma glycine levels. During acute episodes, neutropenia and thrombocytopenia are common. Poorly controlled patients show hyperuricemia. A definite diagnosis of the disease is made by detecting massive methylmalonicaciduria; a neonate may excrete up to 1 g/day (normal adult, <5 mg/day). Plasma concentrations of methylmalonic acid in crisis may be as high as 0.2 to 2.5 mM (normally not detectable). Levels of propionylcarnitine in blood are elevated both during and between crises. Other organic acids in urine are those seen in propionicacidemia. Mutase activity may be measured in a variety of ways in specialized laboratories. The cblA and cblB mutants are identified by complementation studies. Clinical follow-up is by determination of blood levels of methylmalonic acid.

MANAGEMENT. The treatment of acute metabolic crisis is similar to those measures described for propionicacidemia. Exceptions for methylmalonicacidemia are the use of overhydration with adequate calories and no requirement for insulin drips. A patient with methylmalonicacidemia in crisis should be given excessive amounts of intravenous fluids, to clear the circulation from methylmalonic acid. Acidosis in methylmalonicacidemia is usually more severe than in propionicacidemia, requiring very large amounts of bicarbonate, which might quickly lead to hypernatremia. In such instances, tromethamine (Tham) 40 mL/kg/day in six divided doses may be used for 2 to 3 days. The intravenous use of carnitine shortens the crisis significantly.

All patients with methylmalonicacidemia are restricted in their intake of isoleucine, valine, threonine, and methionine, using the same diet for patients with propionicacidemia. Every patient with methylmalonicacidemia should be tested for response to vitamin B₁₂ by administering daily 1 mg hydroxycobalamin intramuscularly. Patients with cblA, methylmalonicacidemia with mutase (–), and half of the patients with cblB or mutase (0) will respond to vitamin B₁₂. The outcome in the responsive patient is favorable, requiring less stringent control of protein intake. Protein requirement of vitamin B₁₂–unresponsive patients must be individualized, providing a minimal amount of the restricted amino acids that will permit growth but that will not lead to frequent decompensation. Generous amounts of calories are supplied through lipids and carbohydrates. Management of unresponsive methylmalonicacidemia is not easy, requiring enormous effort from physician, dietitian, and parents. Other therapeutic measures include metronidazole, 7.5 mg/kg/day; oral carnitine, 100 to 200 mg/kg/day; Shohl's solution, 2 to 4 mL/kg/day; and intramuscular hydroxycobalamin, 1 mg every other day. Patients with methylmalonicacidemia tend to be short and obese; human growth hormone has been used to increase growth and lean body mass and to decrease adipose tissue.

There is no treatment for renal disease due to interstitial nephritis. Allopurinol may be used in patients with high uricacidemia. Patients with methylmalonicacidemia who have basal ganglia infarcts might have cblC or cblD mutations, and homocystinuria should always be investigated in any patient with methylmalonicacidemia. No therapeutic measures, other than standard supportive therapy, are available for pancreatitis.

PROGNOSIS. The addition of L-carnitine and metronidazole to the management of this disorder has changed the prognosis. Van der Meer and colleagues³⁵ have pointed out that although most patients before 1985 died, those after 1985, when these drugs were introduced, survived with improved general health. The lifestyle of a well-managed patient with methylmalonicacidemia will be normal, without mental retardation, or developmental or motor delay.

Disorders of Later Infancy with Recurrent Metabolic Crises

Late-Onset Urea Cycle Disorders

PATHOGENESIS AND PATHOPHYSIOLOGY. Late-onset disease has been described in patients with CPS, OTC, ASA synthetase, ASA lyase, and arginase deficiencies. They will appear from the first year of life to adulthood with abrupt episodes of acute hyperammonemia. Initial crisis will occur usually when the infant is weaned from breast milk or from low-protein formulas to cow's milk formulas. Decompensation can also occur when the patient ingests a high protein load or experiences increased catabolism (e.g., infection). These episodes readily abate with cessation of protein intake.

EPIDEMIOLOGY AND RISK FACTORS. Patients with a late-onset UCD are rare. The heterozygote female for OTC deficiency is at risk of developing symptoms; when a male infant with OTC deficiency is born, the mother has to be instructed for possible late-onset disease. Terheggen and associates, in 1969,³⁶ described argininemia in two sisters with spastic paraplegia (arginase deficiency). Arginase deficiency is rare. The mechanism for the toxicity of excess arginine is not known. Whether this is due to impaired neurotransmitter metabolism or to excess nitric oxide production from elevated arginine is not clear. Two forms of arginase are known: A-I and A-II. The A-I isozyme contributes 98% of the liver activity and is deficient in patients with argininemia. It is inherited as autosomal recessive.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. The symptoms are remarkably similar among various types of late-onset UCD. Sudden hyperammonemia leads to such neurological signs as seizures and apnea. It may be preceded by vomiting and lethargy progressing to disorientation, ataxia, amblyopia, and eventually coma. The late-onset CPS deficiency is rare. On the other hand, OTC deficiency may be mild in a male and may first manifest as early as 6 weeks or as late as 6 years. Since infections trigger hyperammonemia, late-onset OTC deficiency may be confused with Reye's syndrome. In symptomatic heterozygotes or mild OTC deficiency, growth and mental retardation are seen in half of patients. The use of valproate in OTC carriers may also cause liver toxicity. Late-onset OTC deficiency is associated with a high mortality rate.

ASA synthetase deficiency was first reported in a 9-month-old girl with mental retardation. In Japan, a variant form of this disease is found to occur as late as 48 years of age. The symptoms in such cases are nonspecific and include bizarre behavior, psychotic episodes, delusions, hallucinations, insomnia, and endocrine disturbances, such as delayed menarche. ASA lyase deficiency may also occur late in infancy or adults. These cases present as mental retardation or ataxia, or the patient might be totally asymptomatic. This heterogeneity might be explained by the studies of McInnes and colleagues, which indicated at least 12 allelic mutations leading to extensive genetic heterogeneity.³⁷ Immunoblot analysis shows a wide variation in size and amount of enzyme protein in patients. The presentation of arginase deficiency is heterogeneous. Early development is usually unremarkable, but developmental delay and psychomotor retardation will definitely appear by 3 years. Progressive spastic diplegia is by far the most common motor deficit, seen by 5 years.³⁸ Seizures are present in half of the patients and are often generalized tonic-clonic. These symptoms improve or regress on dietary restriction of arginine.

DIFFERENTIAL DIAGNOSIS. The clinical presentations of all of late-onset UCDs are alike, because only the laboratory findings will identify exact diseases. Oroticaciduria is a common feature except for partial CPS I deficiency. By definition, the mother of a patient with OTC deficiency is a carrier; the presence of the mutant gene in other females related to the mother must be ruled out by allopurinol testing, provided that other diseases that give a positive result are absent.³⁹ Although it is the most common presenting symptom of arginase deficiency, spastic diplegia has many other causes (e.g., periventricular hemorrhage in a premature infant or hypoxic brain injury). In these conditions, spasticity is either static or progresses slowly. When spastic diplegia is progressive, familial spastic paraplegia, worsening of an existing hydrocephalus, spinal cord cysts, or tumors should be ruled out.

Hyperammonemia is encountered in other disorders. Reye's syndrome can be differentiated by the elevated transaminase and high plasma lysine levels. Patients with liver failure usually have elevated plasma methionine and tyrosine levels, which are not observed in UCDs of various types. Patients with valproate toxicity have elevated valproylcarnitine levels and deficiency of free carnitine in studies with tandem mass spectrometry.

Any infant or child who develops sudden lethargy or coma after a high-protein meal, infection, and prodrome of vomiting should be immediately evaluated for changes in blood gases, ammonia, lactic acid, and ketones. Arginase deficiency should be ruled out in all children with spastic diplegia. The definite diagnosis of a UCD, or an organic acidemia, will be reached by using high-pressure liquid chromatography, gas chromatography/mass spectrometry, and MS/MS techniques in blood and urine samples. Any infant or child with psychomotor retardation or seizures with no clear cause, or with progressive encephalopathy, should be studied by measurement of plasma amino acids and in some cases by the study of urinary organic acids.

EVALUATION. The laboratory findings are the same as those described for neonatal onset UCD, except the hyperammonemia and elevation of specific amino acid and orotic acid levels are only prominent during the acute

metabolic crisis. Both ASA synthetase and ASA lyase deficiencies are readily diagnosed by the plasma amino acid profile during the acute episode. Plasma arginine is elevated 2 to 10 times normal in arginase deficiency, and arginase in red blood cells is deficient. Hyperammonemia is not a constant feature of arginase deficiency but is found during a catabolic event (e.g., an infection or consumption of high-protein diet). A urine sample may show oroticaciduria and increased excretion of arginine.

MANAGEMENT. The treatment is approximately the same as that for UCD in the neonatal period: protein restriction, sodium phenylbutyrate, and L-arginine in doses previously described. Such patients should receive low-protein diets. No specific treatment exists for arginase deficiency. Reduction of protein intake might lead to improvement of the continued disease progression and at times dramatic resolution of the symptoms. Cognitive dysfunction appears to be amenable to diet therapy, and improvement of spasticity has been observed in 30% of patients with arginase deficiency. Late-onset UCDs show the same complications as described for the acute neonatal form.

PROGNOSIS AND PREVENTION. Prognosis depends on rapid identification and adequate management. A survey of 12 patients with late-onset ASA lyase deficiency indicated no eventual impairment in intellectual and psychomotor development. Arginase deficiency may be managed with success and arrest of the disease. All subsequent newborns of a family with UCD should be investigated for the disease. The maternally related female members of the extended family with OTC deficiency must be investigated for the presence of the mutated gene either by molecular genetic studies or by allopurinol loading.

Progressive Diseases of Infancy and Childhood

A large number of amino and organic acid disorders appear primarily with neurological symptoms. Only four disorders, phenylketonuria (classic form and bipterin-dependent variant), homocystinuria, glutaricaciduria type 1, and biotinidase deficiency are presented here.

Deficiency of Phenylalanine Hydroxylase

PATHOGENESIS AND PATHOPHYSIOLOGY. Although phenylalanine hydroxylase (PAH) is a liver enzyme, the clinical manifestations of classic PKU relate to the CNS. There are no abnormal metabolites formed in classic PKU but only excessive amounts of normal compounds. Therefore, it is logical to assume that elevated levels of blood phenylalanine are responsible for the toxicity. Both animal models and magnetic spectroscopic studies in human brain indicate that phenylalanine levels exceeding 1.3 mM affect the brain metabolism adversely and account for acute phenylalanine toxicity. The threshold for chronic toxicity may be much lower. Acute and chronic adverse effects of high blood phenylalanine on brain can be prevented by high doses of BCAAs. Because both phenylalanine and BCAAs share the same transport system, it is conceivable that mutual competition of neutral amino acids at the L-transport system may account for some of these toxic effects. Some patients diagnosed to have mild hyperphenylalaninemia in the past might have had

carbinolamine dehydratase deficiency. Fair features and hypopigmentation are caused by the inhibition of tyrosinase by hyperphenylalaninemia. Location of the PAH gene is given in Table 31-3, and its complementary DNA is available.

EPIDEMIOLOGY AND RISK FACTORS. The disease occurs at varying frequency. The highest frequency is in Turkey with 1 in 2600 births; it is lower among Japanese at 1 in 140,000. Ashkenazic Jews and Finns each have an incidence of 1 in 200,000 births.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. PKU usually manifests after 1 year of age as mental retardation. The late emergence of physical findings is the rationale for screening tests in all newborns. The safety window is approximately 6 weeks; by 1 year of age, the untreated child might lose 50% on IQ measurements. The infant is usually born prematurely and has a fair complexion and eczematoid lesions. Myoclonic seizures might occur as early as 4 months of age, and developmental delay appears between 6 and 18 months of age. Some patients develop normally until 1 year but then lose the milestones. Despite severe CNS involvement, no pyramidal or extrapyramidal signs are usually detected.

Children with untreated or poorly managed PKU usually end up in institutions. A review of 51 never-treated patients followed for more than 20 years indicated 25% had seizure disorders, half were profoundly retarded, and about half were moderately impaired.⁴⁰ Approximately two thirds of untreated patients develop microcephaly. Autistic behavior may also emerge. Aggressive, hyperactive behavior is common in poorly managed patients, which becomes less noticeable on lowering the blood phenylalanine level. In well-controlled patients, ingestion of food with high phenylalanine content at any time during life will cause confusion and a clear-cut fall in school performance.

DIFFERENTIAL DIAGNOSIS. In neonates with severe liver disease, levels of most plasma amino acids, notably tyrosine and methionine, are elevated; at times, that of phenylalanine may also be moderately high. Occasionally, isolated elevation of the blood phenylalanine level (up to 250 μM) will occur transiently in a normal neonate. In such infants, a repeat study at 4 to 6 weeks usually indicates normal phenylalanine, and the infant will not develop any signs of PKU later in life. The reasons for this transient hyperphenylalaninemia remain obscure.

Other common causes of childhood mental retardation include hyperprolinemia, homocystinuria, and fragile-X syndrome. Clinically, hyperprolinemia cannot be distinguished from mild PKU except by the amino acid analysis. Patients with a missed diagnosis of homocystinuria will have its classic phenotype, which is not observed in classic PKU. Patients with fragile-X syndrome are mostly males with typical facial features of the disease, severe autism, or mental retardation; molecular genetic studies identify the disease (Video 254, Fragile X).

Many developing countries do not have a neonatal PKU screening program. Therefore, any infant with seizures, developmental delay, or fair features in a community with dark complexion, and any child with mental retardation, hyperactivity, and aggressive behavior should be evaluated for classic PKU.

EVALUATION. The blood phenylalanine level is elevated ($>120 \mu\text{M}$), usually more than 1 mM, and the blood

phenylalanine/tyrosine ratio is higher than 2, as determined by high-protein liquid chromatography or tandem mass spectrometry techniques. The green color produced by acidic ferric chloride in the urine of PKU patients is caused by the presence of phenylpyruvic acid. This compound is labile, disappearing from urine stored cold or frozen in 1 to 2 days. This test must be done on freshly collected urine. Computed tomography (CT) or magnetic resonance imaging (MRI) reveals demyelination or dysmyelination in central white matter, disappearing on treatment and reappearing if treatment is discontinued.

PROGNOSIS AND PREVENTION. Well-controlled studies indicate that prognosis is extremely rewarding if treatment is started in the first month of life. The North American Collaborative Study of patients to 12 years of age indicates that the longest treated patients who had phenylalanine values less than 900 μM had the best IQ and psychological test scores.⁴¹ Numerous studies indicated deterioration of IQ, deviant EEG findings, and emergence of demyelination on MRI if the treatment is discontinued at or about school age. It is prudent to continue the treatment as long as possible, well into adolescence. Parents should be warned that a well-treated patient will function normally in daily life but may show significant deficits in conceptual, visuospatial, and language-related tasks; in reading and arithmetic skills; in attention span; and in problem-solving abilities.

Classic PKU was one of the first inborn errors of metabolism for which neonatal screening was applied.³ Hyperphenylalaninemia and disturbed ratio of phenylalanine/tyrosine in a neonate with classic PKU may be apparent as early as 24 hours but definitely by 3 to 7 days of life. Given the 6-week safety window, neonatal screening for PKU may be done during the first month. Any positive screening result should be rechecked within 1 month. The conventional procedure for PKU screening is the Guthrie test. The problem of false-positive results and the anxiety created in the family recalled for repeat testing led to the exploration of other techniques. More recently, MS/MS-based screening procedures have been described that have less problems with false-negative and false-positive results, because, in addition to phenylalanine estimation, they provide an accurate phenylalanine/tyrosine ratio.^{1,2}

The principle of treatment is to restrict dietary intake of phenylalanine. There are numerous formulas for this purpose that have been in use since the mid-1950s. Treatment should be monitored by monthly or bimonthly measurement of plasma amino acids, to ensure that phenylalanine and other essential amino acids are not lower than normal. Given the beneficial effects of BCAAs in preventing the adverse CNS manifestations of hyperphenylalaninemia, they may be used to supplement the diet. Patients with PKU should avoid consuming food or drinks that contain aspartame, an artificial sweetener (*N*-aspartylphenylalanine), because intestinal hydrolysis liberates phenylalanine.

Successful management of many females with PKU has resulted in normal lifestyle, marriages, and child bearing. Infants born to mothers with PKU, however, have numerous congenital defects, such as microcephaly, impaired somatic growth, and heart disease.⁴² Because similar defects are not seen among offspring of fathers with PKU, it is apparent that high blood phenylalanine levels in the mother

are the cause. Although no threshold is agreed on, fetal outcome is satisfactory if the maternal blood phenylalanine levels are maintained at less than 600 μM throughout the pregnancy.

Biopterin-Dependent Hyperphenylalaninemia

PATHOGENESIS AND PATHOPHYSIOLOGY. Defective synthesis of biopterin (BH_4) causes disruption in several biochemical functions. Deficiencies of the first two steps, that is, guanosine triphosphate cyclohydrolase (GTP-CH) and 6-pyruvoyltetra-hydropterin synthase (6PTS), are known as synthetic defects. The hydroxylase reacts with BH_4 , converting it to its hydroxy form 4 α -carbinolamine, which is then dehydrated by primapterin carbinolamine dehydratase (PCD) to quinoid dihydrobiopterin, which is labile and must be reduced back to BH_4 through a reaction that uses reduced nicotinamide adenine dinucleotide and is catalyzed by dihydropteridine reductase (DHPR). The deficiencies of the latter two enzymes are known as recycling defects. Because primapterin is excreted in PCD deficiency, the disease is also called primapterinuria. BH_4 is a cofactor for enzymes of the initial step in dopamine and serotonin synthesis; when it is not available, neurotransmitter and autonomic function, both in the CNS and periphery, are disturbed. In addition, BH_4 is a cofactor for the generation of nitric oxide in the CNS, which is a neurotransmitter/modulator. Deficiency of BH_4 causes severe autonomic irregularities and mental retardation and, ultimately, is not compatible with life. Severe cardiopulmonary dysrhythmia, fluctuating blood pressure, sleep irregularities, and early unexpected death may be explained by these considerations. Because 4 α -carbinolamine can be spontaneously dehydrated, PCD deficiency does not cause severe disease. In BH_4 -dependent PKU, neurological manifestations are severe in the presence of mild hyperphenylalaninemia, suggesting that trace BH_4 levels are sufficient to promote the phenylalanine hydroxylase reaction in liver but not high enough for adequate hydroxylation of tyrosine and tryptophan in the CNS. All four diseases are inherited as autosomal recessive. The location of their genes is shown in Table 31-3.

EPIDEMIOLOGY AND RISK FACTORS. Hyperphenylalaninemia due to BH_4 deficiency is rare and accounts for 2% of all PKU cases. An international database in 1995 for abnormal BH_4 metabolism indicated the following⁴³: 12 patients with GTP-CH deficiency, 182 with 6PTS deficiency, 87 with DHPR deficiency, and 12 with PCD deficiency. The overall frequency is estimated to be 1 in 10⁶ births. In some parts of the world these defects occur more frequently (e.g., 10% in Italy, 15% in Turkey, 19% in Taiwan, and 68% in Saudi Arabia).

CLINICAL FEATURES AND ASSOCIATED DISORDERS. The signs seen in this disorder are remarkably similar except for PCD deficiency.⁴⁴ The classic presentation is an infant, usually of low birth weight, who develops normally for 2 to 3 months. Then myoclonic seizures appear approximately at 3 months, probably due to serotonin depletion. Bradykinesia is apparent particularly when the infant is naked. The infant lies expressionless. Initially, there may be hypotonia, but soon after "lead pipe" or "cog-wheel" rigidity appears (Fig. 31-3). These are parkinsonian

features caused by deficient dopamine. In fact, extensor posturing of the extremities, opisthotonic arching of the back, and pronation of hands are common. Oculogyric crisis, involuntary dystonic movements, and tremors may be observed. Feeding is difficult owing to difficulties in swallowing, and the patient drools because of inability to manage secretions. Early failure to thrive and fair features of PKU are observed. Development arrests at 2 to 3 months, unless the disorder is treated. The patient suffers from severe bronchopneumonia from respiratory irregularities and is often admitted to an intensive care unit for cardiorespiratory difficulties, usually dying before 5 years of age. Those children who survive remain profoundly retarded. Episodes of hyperthermia without infection, fluctuating high blood pressure, and reversed diurnal rhythm of sleep have been described. Deficiency of DHPR, in general, shows a more severe progression of the disease, whereas GTP-CH deficiency might be milder and missed in some instances. The clinical picture of PCD deficiency is essentially that of a mild PKU, and it is not unusual for such a patient to be classified as having transient hyperphenylalaninemia.

DIFFERENTIAL DIAGNOSIS. All infants with parkinsonian signs, myoclonic seizures, unexpected fair features, unexplained failure to thrive, unexplained severe bronchopneumonia or cardiopulmonary arrest, unexplained hyperthermia, and fluctuating blood pressure should be studied for the presence of 6PTS and DHPR deficiencies. Blood amino acids, particularly phenylalanine, should be determined in all children with mental retardation. Even when mild hyperphenylalaninemia is found, BH_4 loading, DHPR activity in red blood cells, and pterin measurement in urine should be performed.

EVALUATION. Hyperphenylalaninemia is usually not as severe as in classic PKU. The end products of catecholamine and serotonin metabolism in cerebrospinal fluid (CSF) and urine, such as 5-hydroxyindoleacetic, homovanillic, and vanillylmandelic acids, are considerably lower than normal. The characteristic findings are in the urinary pterin metabolites. In GTP-CH deficiency, both neopterin and biopterin are low in the urine. In 6PTS deficiency, the urine neopterin level is very high and that of biopterin is very low or undetectable, leading to a greatly elevated neopterin/biopterin ratio. The urinary excretion of pterins may range from normal to massively elevated in DHPR deficiency. In PCD, an unusual pterin, primapterin, is detected in the urine. The pterin assay has been adapted to be used with dried urine spots on filter paper.⁴⁵

Another option is to perform a BH_4 loading dose, given 2 mg/kg IV or 7.5 to 20 mg/kg orally in divided doses. This will lower plasma phenylalanine to within normal limits within 8 to 12 hours if a patient has BH_4 -dependent PKU. In 6PTS deficiency, the excretion of neopterin will rapidly decrease on BH_4 loading. The BH_4 loading must be done while the patient is on a normal diet. An occasional patient with 6PTS deficiency with normal CSF finding but abnormal plasma and urine phenylalanine and pterin values has been described. This milder form of the disease is called the peripheral type. It is important to measure the red blood cell DHPR activity to rule out DHPR deficiency, because a BH_4 loading test might miss an occasional patient. Levels of prolactin are elevated in various forms

Figure 31-3. Glutaricaciduria, biotinidase deficiency, and bipterin-dependent phenylketonuria. Clockwise from left upper corner: Infant with glutaricaciduria type 1 (GAT1) showing dystonic posture and rigidity in flexion. MRI of the brain showing open operculum sign and frontotemporal atrophy in infant with GAT1. Alopecia in a biotinidase-deficient 9-month-old infant with frequent myoclonic seizures from age 3 months. Infant with bipterin-dependent phenylketonuria due to 6-pyruvoyl-tetra-hydropterin synthase (6PTS) deficiency showing dystonic grimacing and fisting of hands and hypotonic pithed frog posture of legs.

of BH₄ deficiency and might provide a rapid clue to the presence of these diseases.

MANAGEMENT. The patients with BH₄ deficiency should be treated with BH₄, which is available from either Milupa, Hillington, Middlesex, UK, or Schirks Laboratories, Jona, Switzerland. The standard therapy is 20 mg/kg/day BH₄ given in three to four equal doses. All patients with proven diagnosis should be immediately placed on neurotransmitter precursors, which do not require hydroxylation. These are levodopa, 15 mg/kg/day and L5-hydroxytryptophan, 4 mg/kg/day, together with 2 to 4 mg/kg/day carbidopa. The best results are obtained when neurotransmitter therapy is combined with BH₄. Therapeutic results should be followed by plasma phenylalanine, prolactin and, when possible, urine pterins. Additional supplementation of folate is given in DHRP deficiency because it results in reduction of synthesis of tetrahydrofolate.

PROGNOSIS AND PREVENTION. Certainly the majority of the patients with 6PTS deficiency will respond well to the therapy and will grow as normal children. However, prognosis in all BH₄-dependent PKU is guarded, particularly in DHRP deficiency, because many patients have neurological impairment despite vigorous and early therapy. The hyperphenylalaninemia of various forms of BH₄ deficiency can be identified in routine screening tests; however, the diagnosis in a patient with GTP-CH deficiency was missed in the neonatal screening. Prenatal diagnosis has been achieved in DHRP and 6PTS deficiencies.

Homocystinuria: Cystathionine β -Synthase Deficiency

PATHOGENESIS AND PATHOPHYSIOLOGY. Two important groups of diseases involving methionine metabolism are (1) homocystinuria due to the deficiency of cystathionine β -synthase (CBS) and (2) homocystinuric syndromes with abnormalities of folate or vitamin B₁₂ metabolism with or without methylmalonicaciduria.⁴⁶ CBS deficiency, commonly known as homocystinuria, was reported in 1962.⁴⁷ The recognition of homocystinuric syndromes is more recent.⁴⁸

The primary metabolic consequence of CBS deficiency is intracellular homocysteine accumulation. The cells then excrete the compound to plasma where the elevated levels exist either as free or as oxidized to homocystine, to mixed disulfides with cysteine, or with other sulfhydryl groups in proteins. When homocysteine is elevated in plasma, homocystine is excreted through the urine. Homocysteine is located at the crossroads of important biochemical reactions.

Homocysteine is an end product of biochemical reactions that utilize methylation. Biological methylations are achieved by activated methionine, S-adenosylmethionine. Once the methyl group is transferred, remaining S-adenosylhomocysteine is hydrolyzed into homocysteine and adenosine. Homocysteine must then either be reconverted into methionine or condensed with serine by CBS into cystathionine and excreted. These two paths are catalyzed by several different enzymes. The cystathionine

synthesis is catalyzed by CBS, whereas the remethylation through the use of methyltetrahydrofolate is catalyzed by 5-methyltetrahydrofolate–homocysteine S-methyltransferase (methionine synthetase) or through other enzymes from betaine if the latter compound is used as a therapeutic agent. When CBS is deficient, homocysteine is elevated and thus hypermethioninemia and homocystinuria ensue; urine contains no cystathionine. Hypermethioninemia is due to increased methylation of homocysteine in liver by folate-dependent methylating enzymes. Numerous physiological disturbances account for the symptoms of CBS deficiency.

High homocysteine may cause undesirable disulfide cross-linkages, disrupting fibrillin. Among other vasoactive properties, homocysteine impairs the protein C–activating cofactor activity of thrombomodulin, and this feature may be involved in thrombotic events. In addition, both L-homocysteic acid and homocysteine-sulfinic acids derived from homocysteine are present in the urine of CBS-deficient patients. These two compounds are potent agonists for N-methyl-D-aspartate (NMDA) receptors and might cause neuronal damage as a result of excessive stimulation of NMDA receptors. Two primary groups of patients are identified, based on their response to pyridoxine. In pyridoxine-responsive patients, a small residual activity of CBS is present that is enhanced by large doses of pyridoxine. Although the control activity does not attain control levels, it becomes sufficient to maintain a low level of the homocysteine pool. The CBS gene is mapped (see Table 31-3).

In 1967, it was shown that the biochemical abnormalities in some patients with CBS deficiency could be corrected by administering large doses of pyridoxine.⁴⁹ Large international surveys indicate that approximately half of the patients are pyridoxine responsive. These patients are clinically heterogeneous, with some showing a clear-cut response and others a less dramatic response. Even the most responsive patient will have elevated plasma methionine and homocystinuria when loaded with methionine; therefore, they should be kept under continuous treatment.

Because of interactions between folate and vitamin B₁₂ with homocysteine metabolism, homocystinuria occurs in acquired or inherited disorders of folate or vitamin B₁₂.

EPIDEMIOLOGY AND RISK FACTORS. The cumulative frequency of CBS deficiency for countries with screening programs is 1 in 344,000. In parts of New South Wales in Australia this might be as high as 1 in 65,000 to 1 in 75,000. The disease is common in the Middle East, possibly occurring in 1 in 1000 to 1 in 2000 births. Approximately 75 patients with cblC and 30 with methylenetetrahydrofolate reductase deficiency are known.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. The phenotype of few diseases is as impressive as that of CBS deficiency, because numerous organs are involved. The main systems affected are the eye, the vascular system, the CNS, and the skeletal system.

Eye. Dislocation of the lens, ectopia lentis, is a constant feature but occurs usually after 2 years. The rate of lens dislocation is higher among patients who do not respond to pyridoxine. Marked myopia is associated with the loosened or subluxated lens. Cataracts, acute pupillary block glaucoma, and retinal degeneration may be additional complications.

Vascular System. Thromboembolic phenomena are dreaded complications of the disease, accounting for high morbidity and mortality rates (see Fig. 31-1). They can occur at any age and in any vessel. Thrombosis in CNS causes neurological signs, such as hemiplegia, dystonia, or seizures; in the eye, optic atrophy; and in the kidney, severe hypertension. The risk of thrombosis is less in pyridoxine-responsive patients.

Central Nervous System. Mental retardation and neurological abnormalities are the main features. The developmental delay is usually apparent by the second year of life. Patients with pyridoxine-responsive disease are less affected. The degree of mental retardation varies between severe to normal, and it is not unusual to encounter an occasional pyridoxine-unresponsive child with normal or high IQ. Besides the neurological findings related to thrombotic events in the CNS, approximately 20% of the patients will suffer from seizures, mainly generalized convulsions. It is common for these individuals later in life to suffer from episodic depression, behavior disorders, and other personality disorders.

Skeletal Findings. Osteoporosis is a common late complication, and half of the patients will show some evidence of it by 20 years of age. It is more severe and appears earlier in pyridoxine-nonresponsive patients. Biconcave vertebrae are seen. The maturation of the skeleton is abnormal and leads to lengthening of the long bones (dolichostenomelia), which accounts for the marfanoid appearance of patients.

Other Features. Females with CBS deficiency experience frequent fetal loss. The offspring of men with CBS deficiency are normal. The risk factors for early vascular disease among heterozygotes and those individuals with mild homocystinemia have been investigated in detail. Since the pioneering publication by Wilcken and Wilcken,⁵⁰ numerous reports and reviews support that preceding homocystinemia in normal subjects with mild homocystinemia may be responsible for vascular disease. However, most obligate heterozygotes do not have overt clinical atherosclerotic disease, and more studies are needed to conclude the risk factor for carriers.

DIFFERENTIAL DIAGNOSIS. Several symptoms of CBS are shared by other disorders. Lens abnormalities are encountered in a number of ophthalmological diseases. Another abnormality of sulfur metabolism, sulfite oxidase deficiency, also causes ectopia lentis. Thromboembolic phenomena and mental retardation are encountered in a large number of clinical conditions and are not detailed. The neurological symptoms of folate or vitamin B₁₂ metabolic abnormalities are not specific. Their presence is first suspected either by macrocytic anemia or by a positive urine homocystine test.

All children with lens, vascular, and CNS signs of CBS deficiency should be evaluated for homocystinuria. Any child with macrocytic anemia or neurological symptoms associated with a positive urine homocystine test should be evaluated for a possible defect in folate or vitamin B₁₂ metabolism.

EVALUATION. The most consistent laboratory feature is homocystinuria. An easy test is urinary sodium nitroprusside reaction. If positive, homocystine should be identified by other procedures because most sulfur amino acids will yield a positive test. Some patients with pyridoxine-responsive

disease will show marked responses to low doses of pyridoxine and the urine in such patients might give false-negative results. In most patients, blood methionine levels will be significantly elevated, which is a clue to CBS deficiency, unless a liver pathological process exists. Whereas in CBS deficiency homocystinuria is accompanied by elevated blood levels of methionine, other diseases associated with homocystinuria have accompanied hypomethioninemia and cystathioninuria. Some of these disorders show other laboratory findings, such as methylmalonicaciduria and megaloblastic anemia.

MANAGEMENT. The medical management of CBS deficiency requires correction of biochemical abnormalities, with the goal of preventing or halting the disease or improving the reversible clinical manifestations. This is best achieved in a newborn before any complication of the disease becomes apparent. Patients who are pyridoxine responsive require the administration of large amounts of pyridoxine. A patient should not be considered unresponsive until a dose of 500 to 1000 mg/day is given for several weeks. The dose of pyridoxine recommended varies from as little as 25 mg/day to as large as 1200 mg/day. The neuropathy and ataxia resulting from the toxic effect of pyridoxine is not encountered in doses of 500 mg/day for at least as long as 2 years. Although it is not uniformly agreed on, pyridoxine-responsive patients should be given a methionine-restricted, cystine-supplemented diet, since they have reduced tolerance for high doses of methionine. Folate repletion may be necessary for pyridoxine responsiveness, and folate, 5 to 10 mg/day, should be provided. The preventive use of anticoagulants such as aspirin is also controversial; if used they should be given in small quantities, such as 325 mg/day or less to an adolescent.

Patients who are not pyridoxine responsive and who are diagnosed later during childhood should be treated with large doses of betaine, 50 to 100 mg/kg/day. The compound increases the rate of homocysteine methylation by the action of a liver enzyme, betaine homocysteine methyltransferase. It reduces plasma homocysteine and increases methionine. In conjunction with diet therapy, it usually improves the clinical condition and retards the progression of disease. The best results are obtained in newborns detected to have the disease by providing a diet restricted in methionine and supplemented with cystine. At least four such formulas are commercially available and, when used together with betaine, ensure normal growth and psychological development. Experience is limited for the outlook of pyridoxine-responsive infants identified neonatally.

PROGNOSIS AND PREVENTION. Untreated patients with CBS deficiency die as a result of thromboembolic phenomena; death occurs much less often in pyridoxine-responsive patients. The outcome is excellent in early-diagnosed and treated pyridoxine-responsive children. The mental development is normal, and thromboembolic phenomena are minimal or absent. The best one can hope for in a pyridoxine-unresponsive patient diagnosed late is to arrest the progression of the disease by treatment. By strict adherence to the therapy outlined, it is possible to normalize mental development in neonatally diagnosed pyridoxine-unresponsive patients.

In other syndromes associated with homocystinuria, the prognosis depends on early detection, early treatment, and

the degree of the responsiveness of the disease to treatment. The neurological prognosis for the cblG and methyltetrahydrofolate reductase-deficient group is not as good as the others. Approximately 50 million newborns in the world, mainly in Japan and the United States, have been screened for CBS deficiency. The disease may be screened through blood methionine or urine homocystine tests. The drawback of methionine-based screening is that only a few patients with the pyridoxine-responsive variant have so far been identified, whereas these are the patients that will benefit most from early detection. Screening based on homocystine detection in urine has also been disappointing. The efficiency and false-positive and false-negative results of screening tests for CBS deficiency have not yet been settled.

Disorders of Lysine and Tryptophan Metabolism: Glutaricaciduria Type 1

PATHOGENESIS AND PATHOPHYSIOLOGY. Glutaric aciduria type 1 (GAT1) (see Fig. 31-3) was first described in 1975⁵¹ and is caused by deficiency of glutaryl-CoA dehydrogenase (GCDH), which is on the catabolic pathways of L-lysine and L-tryptophan. The presence of glutaric, 3-hydroxyglutaric, and glutacetic acids in urine is pathognomonic for the disease. Excess glutaryl-CoA leads to the formation of glutarylcarnitine, which can be detected both in blood and urine. The concentration of acids in the blood is not high enough to disturb the acid-base balance; because there is no inhibition of ketone body and lactate utilization, or of urea formation, the disease does not usually cause acidosis or hyperammonemia. Its significant metabolic sequel is solely in the CNS. Chromosome location of GCDH is shown in Table 31-3.

The mechanism of toxicity of glutaric acid in the CNS is beginning to be understood. Neither the degree of GCDH deficiency nor the amount of glutaric aciduria correlates with the severity of the disease. 3-Hydroxyglutaric acid induces excitotoxic cellular injury by activating *N*-methyl-D-aspartate receptors. Glutaric and 3-hydroxyglutaric acids indirectly modulate glutamergic and GABAergic neurotransmission, which results in an imbalance of excitation and inhibition. Potentiation of this neurotoxicity is probably effected by cytokine-stimulated nitric oxide production, decrease in energy metabolism, and lowering of cellular creatine phosphate levels. Maturation-dependent changes in the expression of neuronal glutamate receptors may influence vulnerability to 3-hydroxyglutaric and glutaric acids.⁵² Autopsy of brain in advanced cases shows severe neuronal loss and fibrous gliosis in basal ganglia, with some spongy degeneration of cortical white matter, indicating these as the target areas.

EPIDEMIOLOGY AND RISK FACTORS. The disease is not rare but might be underdiagnosed. Over 100 patients have been described, 20 of whom are from the Middle East. It is estimated to affect 1 in 30,000 persons in Sweden. It is especially common in consanguineous communities, such as in Saudi Arabia, among the Sauteaux/Ojibway Indians in Canada, and in the United States among the Amish community in Pennsylvania.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. The infant is normal at birth, and the only detectable

symptom might be macrocephaly (Video 92, Glutaric Aciduria Type 1). A typical history is rapid neurological deterioration and loss of developmental milestones after an infectious episode, which is usually mistaken for meningitis or encephalitis because a slight increased CSF protein level is usual. Seizures, dystonia (see Fig. 31-3), and choreoathetosis appear soon after and worsen, leading to a diagnosis of choreoathetoid cerebral palsy or postencephalitic cerebral palsy. Repeated viral infections each cause further deterioration, and the patient will eventually be severely crippled. Almost all patients show absolute or relative macrocephaly. In some patients, the clinical picture will be mild and no further deterioration will occur, particularly if no intercurrent viral infection takes place. An occasional infant identified through screening will show no or minimal neurological signs and will have macrocephaly and neuroradiological findings of GAT1, suggesting prenatal onset of the disease.

EVALUATION. All infants with acute or chronic extrapyramidal signs should be investigated for GAT1. Results of routine blood cell counts, blood chemistries, and amino acid determinations are normal even in the most advanced patient; unless the neurologist suspects and orders special tests, the disease remains undiagnosed. The characteristic biochemical findings are the presence of glutaric, 3-hydroxyglutaric, and glutaconic acids in the urine and of glutaryl-carnitine in blood and urine. Use of MS/MS to detect glutaryl-carnitine in blood and urine has proved to be an unfailingly rewarding means of diagnosis.

The neuroradiological studies reveal a widened sylvian fissure or the “open opercular” sign (see Fig. 31-3), dense basal ganglia, total atrophy of the caudate heads in advanced disease, and evidence of mild white matter disease in the centrum ovale.⁵³ These occur before the emergence of neurological deterioration. Findings on MRI or CT of the brain are characteristic of GAT1, and an experienced neuroradiologist will report the presence of the disease before the results of biochemical tests become available.

DIFFERENTIAL DIAGNOSIS. Among infants and young children with striatal necrosis, some have other definable causes, such as 3-methylglutaconicaciduria, propionicacidemia, or oxidative phosphorylation disease. Their clinical and laboratory presentations are different, and macrocephaly and the wide opercular signs are absent. Other causes of macrocephaly in infancy include Canavan’s disease, Alexander’s disease, and L-2 hydroxyglutaricaciduria. These conditions are progressive pyramidal tract diseases and should not be confused with GAT1.

MANAGEMENT. Treatment may be rewarding if initiated before the clinical manifestations of the disease. The treatment of choice is reducing lysine and tryptophan intake. Such formulas are available. The medications used are L-carnitine orally, 100 to 200 mg/kg/day; riboflavin, 50 mg/kg/day; and baclofen, 5 to 10 mg three times daily. The exact mechanism of action of baclofen is not known, but it has been effective in some instances. In one patient, vigabatrin caused significant clinical improvement. All intercurrent infections, particularly those with viral etiology, demand immediate intervention by administering L-carnitine intravenously (50 to 100 mg/kg repeated every 6 hours) and providing adequate calories through glucose

and insulin drip. These treatments will be of little value in patients who have already suffered significant damage to striatum.

PROGNOSIS AND PREVENTION. Prognosis is poor for patients who have been diagnosed late, although the treatment might slow the progression of the disease. Limited information is available for patients diagnosed early. Prenatal diagnosis of the disease is made through study of organic acids in amniotic fluid or by measuring GCDH in cultured amniotic cells. MS/MS-based neonatal screening identifies GAT1.

Succinic Semialdehyde Dehydrogenase Deficiency (4-Hydroxybutyric Aciduria)

PATHOGENESIS AND PATHOPHYSIOLOGY. Succinic semialdehyde dehydrogenase (SSADH), together with γ -aminobutyric acid (GABA) transaminase, converts GABA to succinic acid, which enters the Krebs’ cycle. In patients with SSADH deficiency, GABA is converted instead into 4-hydroxybutyrate (γ -hydroxybutyrate or GHB), the neurotoxic agent which accumulates in urine, serum, and CSF. It may act as a neurotransmitter. The SSADH gene maps to 6p22 and some mutations have been found.

EPIDEMIOLOGY AND RISK FACTORS. Age at diagnosis ranges from neonates to 21 years and the disorder is probably autosomal recessive. About 350 patients had been identified by 2002.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Typically SSADH deficiency is a static or slowly progressive encephalopathy, with onset in late infancy or early childhood somewhat nonspecifically as developmental delay, hypotonia, and mental retardation. In addition, seizures, disproportionate delay in speech and language development, and ataxia occur in about one half. There also may be inattention, hyperactivity, aggression, self-injurious behavior, hallucinations, and autistic behavior.

EVALUATION. The clue to this diagnosis is brain MRI, where there are T₂-weighted hyperintensities symmetrically in the globus pallidus, but which may also be seen in multiple areas. Magnetic resonance spectroscopy (MRS) is normal. Tandem mass spectroscopy (tandem MS or MS/MS) should pick up the 4-hydroxybutyric acid peak. Standard organic acid assays done with gas chromatography-mass spectrometry (GCMS) often miss it, because it is a volatile compound, which may be lost during extraction, and will be obscured within a large urea peak in a total ion chromatogram. Standard organic acid testing needs to be modified by adding a selective ion monitoring mass spectrometry screen which specifically searches for 4-hydroxybutyrate.

DIFFERENTIAL DIAGNOSIS. Any patient with mental retardation and ataxia of unknown etiology, particularly if absence or tonic-clonic seizures occur and particularly if T₂ hyperintensities in basal ganglia, but particularly globus pallidus, are seen in brain MRI.

MANAGEMENT. There is no standard therapy. Rational strategies include using vigabatrin, which is a GABA transaminase inhibitor, and therefore would reduce formation of succinic semialdehyde, the substrate for SSADH and precursor of 4-hydroxybutyrate. However, vigabatrin would

also increase GABA levels, whose effects may not be desirable. Limited experience has shown inconsistent results. GABA-B antagonists, taurine, GHB receptor antagonists, and naloxone are being tried in animal models.

PROGNOSIS AND PREVENTION. The disorder is underrecognized, mainly because routine organic acid screens by GCMS miss the GHB peak. The disorder is probably more common than thought, and increased diagnostic accuracy has potential for rational therapy and prenatal diagnosis. As an aside, GHB was originally developed as an anesthetic and sedative, and is used to manage cataplexy and alcohol and opiate withdrawal syndromes, as a recreational drug of abuse, and notoriously, to subdue victims for the purpose of sexual assault.⁵⁴

Biotinidase Deficiency

Biotinidase deficiency was first recognized in 1983, among patients with late-onset multiple carboxylase deficiency.⁵⁵ The worldwide frequency among 8 million newborns is 1 in 112,000 (Video 93, Biotinidase Deficiency).⁵⁶ Biotin is the cofactor for such carboxylases as propionyl-CoA, 3-methylcrotonyl-CoA, acetyl-CoA, and pyruvate carboxylase. The most important source of biotin is through biotinidase; hence, when biotinidase is absent, a state of biotin deficiency gradually emerges. Biotinidase activity in brain is very low,⁵⁷ and the brain totally depends on the transfer of biotin across the blood-brain barrier. When biotin is deficient, pyruvate carboxylase in the CNS might decrease, leading to localized lactic acidosis. Biotinidase-deficient patients suffer from central deafness before treatment, and hearing usually does not improve after treatment. The reason for selective targeting of the auditory center is unknown. Alopecia (see Fig. 31-3) and dermatitis in these patients are possible owing to depletion of fatty acids as a result of deficient acetyl-CoA carboxylase activity. Approximately 55% of patients develop clonic or myoclonic seizures, hypotonia, and developmental delay between 3 and 6 months of age. Hearing abnormality coincides with the emergence of seizures. Dermatitis, visual problems, and ataxia are the final events. The changes in acylcarnitines and organic acids appear only during acute decompensation, and the disease cannot be identified through these compounds. Individuals with partial deficiency might be at risk only for cutaneous symptoms. Immunological dysfunction manifests as candidal dermatitis as described for propionicacidemia and methylmalonicacidemia.

Colorimetric and fluorometric procedures are available for measurement in serum. Prenatal diagnosis has not yet been reported. During acute decompensation, the blood acylcarnitine and urine organic acid profiles are the same as seen in holocarboxylase synthetase (HCS) deficiency. Biotin-responsive mild forms of HCS deficiency and milder forms of propionicacidemia must be ruled out by clinical and laboratory observations. Alopecia and rash can be encountered in deficiency of zinc or essential fatty acids. Biotinidase deficiency might be confused with severe combined immune deficiency.

Deafness persists even in a well-treated patient, but alopecia and other symptoms disappear with treatment. As little as 5 to 30 mg of biotin will be curative.

INHERITED DISORDERS RELATED TO VITAMIN METABOLISM

Certain disorders result from inborn errors of metabolism involving vitamins. Some of these disorders lead to severe neurological crippling unless recognized early and treated. Three such disorders that are of neurological interest will be discussed.

Biotin-Responsive Basal Ganglia Disease

PATHOGENESIS AND PATHOPHYSIOLOGY. This is a novel disease described recently.⁵⁸ A gene locus on chromosome 2q36.3 has been shown, with mutations in SLC19A3,⁵⁹ thought to be related to the biotin transporter in brain.

EPIDEMIOLOGY AND RISK FACTORS. The disease has been described among consanguineous communities of the Arabian peninsula and Middle East⁵⁸ (Saudi Arabia, Yemen, and Syria). Initially 10 patients were reported. More recently five more Saudi children with the disease were added to this list. One or two new patients are diagnosed per year at one tertiary care center, but the disease is probably underrecognized.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. This disorder usually presents with confusion, dysarthria, and signs of a subacute encephalopathy between ages 5 and 14 years. It evolves into rapid coma with seizures, pyramidal and extrapyramidal signs, such as facial paralysis, severe cogwheel rigidity, dystonic and oculogyric posturing, and choreoathetosis. The eye-grounds remain normal. In the Arab families in which the disease was described, 80% of the parents were products of first-cousin marriages, and the remaining of second-cousin marriages. When untreated the disease was lethal. In 80% of the families, additional childhood deaths could be attributed to this disease retrospectively, although the diagnosis was not specifically established. There were no significant comorbid associations; in one family a brother had a tic disorder, in another the patient had a complex congenital heart disease, and in a third family there was a brother with mental retardation of unknown cause. This disease presents as an acute encephalopathic crisis that resolves within 1 or 2 days when the appropriate treatment is given. The acute neurological manifestations reappear within 1 month if treatment is discontinued. The longest follow-up is now 15 years. All of the patients except one remain neurologically healthy on treatment, and the older ones are either university students or are leading a successful professional life.

DIFFERENTIAL DIAGNOSIS. Several diseases of childhood should be considered, including dopa-responsive dystonia,⁶⁰ idiopathic dystonia of childhood, and childhood parkinsonism resembling dopa-responsive disease but without diurnal variation and only a mild response to dopa.⁶¹ Postinfectious benign acute basal ganglia destruction is preceded and precipitated by an infectious process. It is an extrapyramidal tract disease sharing many features of biotin-responsive encephalopathy, except chorea and seizures are absent. It usually disappears within 1 month. Finally, biotinidase deficiency⁶² usually manifests with myoclonic seizures in early infancy with hair loss, rapid hearing loss, and dermatitis. In contrast to biotin-responsive

encephalopathy, at presentation there are no extrapyramidal signs in biotinidase deficiency. The diagnosis is easily and rapidly diagnosed by the determination of biotinidase in serum.

EVALUATION. The evaluation usually starts with the clinical assessment and a consideration of the differential diagnosis for other childhood extrapyramidal diseases. In this disorder, all chemistries, lactate, pyruvate, ammonia, amino acid profile, cholesterol, uric acid, very long-chain fatty acids, phytanic acid, biotinidase, MS/MS studies for blood, urine organic acids by gas chromatography/mass spectroscopy (GC/MS), EEG, brain stem auditory evoked potentials, visual evoked potentials, nerve conduction studies, electromyogram (EMG), and in fibroblasts, pyruvate carboxylase and propionyl-CoA carboxylase activities are unremarkable. The pathognomonic finding is the MRI of the brain that shows degeneration of the centers of the caudate heads and of putamina (Fig. 31-4). During an acute crisis, central white matter disease, as well as these structures, shows edema. Upon treatment, the changes observed in the basal ganglia persist despite total resolution of the neurological manifestations. In the oldest patient, now 23 years of age, despite a normal neurological status, these changes are still present with no further deterioration.

MANAGEMENT. The treatment is oral biotin 10 to 15 mg/kg/day. If detected early, even the most severe neurological signs will disappear within 24 to 48 hours with a return to normalcy. This response is not observed in any other basal ganglia disease of childhood. The symptoms will reappear within 1 month if the patient discontinues this treatment.

PROGNOSIS AND PREVENTION. The prognosis depends on provision of biotin. A missed diagnosis for more than 7 to 10 days after the first crisis or many repeated neurological crises due to noncompliance with biotin treatment or misdiagnosis results in permanent neurological crippling. As revealed by the family histories, a prolonged course of untreated disease leads to death. The pathognomonic MRI findings may be detected in totally asymptomatic siblings as early as 24 months. Such children must be placed on preventive treatment with biotin to prevent a neurological crisis. At present there are three such cases, all siblings to an index case who have been under treatment for 2 to 8 years, without abnormal neurological signs.

Disorders of Vitamin B₁₂ Metabolism

PATHOGENESIS AND PATHOPHYSIOLOGY. Vitamin B₁₂ follows a complex metabolic route before its conversion into an active form that functions in the metabolism of methylmalonic acid and homocysteine. Intrinsic factor is necessary for gastrointestinal absorption. A specific receptor, cubilin, is required for its internalization and a specific globulin in plasma, transcobalamin II, is required for its transport to cells where it is stored in lysosomes as transcobalamin II–B₁₂ complex. Defective cytoplasmic release leads to cobalamin (Cbl) F complementation with stored lysosomal vitamin B₁₂, causing a condition reminiscent of cystinosis. Vitamin B₁₂ must be converted to a chemical form that can attach for further conversions (cobalamin C and D mutation groups) and then attach to a specific methyltransferase. Methyltransferase deficiency

Figure 31-4. The brain MRI of a patient with biotin-responsive encephalopathy showing bilateral symmetrically increased T₂ signal intensity within the central parts of the caudate nuclei and in the putamen.

leads to absent methylcobalamin. Mitochondrial vitamin B₁₂ participates in the formation of adenosylcobalamin, a cofactor for methylmalonyl-CoA mutase.

The defects in intrinsic factor, cubilin,⁶³ transcobalamin II, CblF, CblC, and CblD result in deficient methylation function as well as defective metabolism of methylmalonyl-CoA. Thus, such disorders are characterized by a combination of homocystinuria and methylmalonic aciduria. In contrast, defects in mitochondrial adenosylcobalamin formation (CblA and CblB) result only in methylmalonic acidemia.

Among these disorders, cubilin defect (Imerslund-Graesbeck syndrome),⁶³ transcobalamin II deficiency,⁶⁴ and CblC deficiency⁶⁵ cause significant neurological morbidity.

EPIDEMIOLOGY AND RISK FACTORS. The congenital deficiency of intrinsic factor has been described mainly in Mexican kindred. The prevalence of cubilin deficiency is high among Arabs¹ and Scandinavians; it is primarily a Finnish disease. The CblC deficiency accounts for most of the inborn errors of cobalamin metabolism. Because some of these disorders manifest in late childhood, a younger sibling might be asymptomatic and should be tested for the possible presence of the disorder.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Phenotypic expression may be varied. In an early infantile form, the presentation includes failure to thrive, hypotonia, and lethargy with pancytopenia and hepatic dysfunction. Renal involvement includes thrombotic microangiopathy due to hyperhomocystinemia. Diffuse hepatic steatosis, early pigmentary retinopathy, facial dysmorphism, congenital heart disease, microcephaly, hydrocephalus, and hip dislocation can be associated features.

In the late-onset phenotype of adolescence or early adulthood, the child develops normally in early life and may even start school in good health. In a typical case, school performance deteriorates and dysarthria, unsteady gait, pyramidal tract signs, and lethargy progress to dementia. Atypically, the presentation may be psychosis and progressive peripheral neuropathy severe enough to require mechanical ventilation.⁶⁶ Relapsing-remitting or subacute myelopathy develops with the pattern of subacute combined degeneration of the cord, leading to impaired vibration and position sense, and extensor Babinski responses.

DIFFERENTIAL DIAGNOSIS. The early infantile form can be confused with other infantile diseases that cause failure to thrive, especially mitochondriopathies, and peroxisomal diseases. The presence of dysmorphic features may suggest a chromosome abnormality but pancytopenia and abnormalities in urine homocystine screening tests will identify the CblC disease. Many disease features are also present in methylenetetrahydrofolate reductase deficiency (MTHFR). A GC/MS study, however, indicates methylmalonic aciduria and MS/MS indicates elevated propionylcarnitine, which will be absent in MTHFR deficiency.

The later childhood phenotype in a boy will be confused mainly with X-linked adrenoleukodystrophy (X-ALD), X-linked adrenomyeloneuropathy, L-2-hydroxyglutaric aciduria, childhood-onset metachromatic leukodystrophy, and amyotrophic lateral sclerosis. Megaloblastic anemia, thrombocytopenia, hypersegmented polymorphonuclear leukocytes, elevated lactate dehydrogenase, homocystinuria with elevated cystathioninemia and cystathioninuria, methylmalonic aciduria, elevated propionylcarnitine, and normal levels of C-26 fatty acids in blood and normal plasma corticotropin readily differentiate the CblC deficiency from these other diseases. The white matter changes on brain MRI of X-ALD cases are primarily localized around the posterior ventricular horns, whereas the leukodystrophy in CblC is generalized. Childhood-onset metachromatic leukodystrophy shows characteristic tigroid white matter on MRI; the leukodystrophy in CblC does not have a specific pattern. L-2-Hydroxyglutaric aciduria is associated with seizures and mental retardation but not with progressive mental deterioration. Pyramidal signs predominate the neurological examination. The brain MRI shows a centripetal leukodystrophy with loss of U-fibers.

EVALUATION. Any infant with hypotonia or with a family history of prior infantile death should be studied for CblC disease. A simple urine homocystine determination and blood panel for pancytopenia will identify the general category of metabolic derangement; when these tests are positive, urine GC/MS for methylmalonic aciduria and blood MS/MS for propionylcarnitine and hypomethioninemia should be conducted. Because phenotypic manifestations overlap with other Cbl defects, fibroblast complementation studies should also be performed.⁶⁷

Any child showing a late-onset encephalopathy should be evaluated for CblC disease. An MRI of the spinal cord is essential to document the subacute combined degeneration of the cord. Again, a positive test on the simple urine screen for homocystine justifies further workup.

MANAGEMENT. Treatment should include hydroxycobalamin injections, the active form of vitamin B₁₂, 1 mg daily. Carnitine 100 to 200 mg/kg/day should be provided

to decrease the accumulation of propionylcarnitine. Homocystinemia should be managed by betaine 100 to 200 mg/kg/day. To stimulate methionine synthetase, folic or folinic acid must be given.

PROGNOSIS. In a young infant, unless homocystinemia can be managed, the disease will be lethal with hemolytic-uremic syndrome and kidney, liver, or respiratory failure. The prognosis in a late-onset disease varies.⁶⁷ When patients respond well to treatment, regression of neurological findings occurs rapidly. In other similarly treated subjects, no ameliorative response has been observed, presumably due to more complete metabolic derangements or involvement of pathways unaffected by available treatment agents.

Methylenetetrahydrofolate Reductase Deficiency

PATHOGENESIS AND PATHOPHYSIOLOGY. MTHFR (EC 1.5.1.20) deficiency is an inborn error of metabolism of folic acid. MTHFR catalyzes the reduction of methylenetetrahydrofolate to methyltetrahydrofolate. The latter is one of the two cofactors for methionine synthetase (MeS), the enzyme that re-methylates homocysteine produced from the hydrolysis of S-adenosylmethionine (SAH). The SAH in turn is the end product of S-adenosylmethionine (SAM) used for several anabolic reactions of methylating nucleic acids and proteins. The remaining homocysteine residue must be methylated again and converted into methionine, which is used to synthesize SAM, and thus the cycle is completed. The MeS that catalyzes this reaction plays a pivotal role in the body, particularly in the brain, assuring a steady supply of methionine for protein synthesis and nucleic acid methylation. MeS requires two cofactors: methyltetrahydrofolate and methylcobalamin. Deficiency of methionine occurs either when the enzyme is deficient (very rare) or more commonly when there is a defect in the metabolism of folic acid or vitamin B₁₂. Among these latter possibilities, the absence of MTHFR causes a very severe neurological disease in an infant. A defect with similar consequences was discussed in the errors of vitamin B₁₂ metabolism. The partial deficiency of MTHFR in an adolescent or young adult has been implicated in homocystinuria leading to strokes, miscarriages, and neural tube defects. While a low methionine arrests brain growth, hypermethioninemia can occur without any neurological symptoms.

EPIDEMIOLOGY AND RISK FACTORS. Absence of MTHFR is panethnic and has been described in different populations. The partial deficiency is due to a thermolabile mutation in MTHFR and is observed frequently in many populations, especially Koreans. The disease process caused by such a mutation and its consequences in the young adult or adolescent populations are not included in this section. The severe infantile form is encountered frequently among Arabs in the Middle East.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. The phenotypic expression of this disorder varies from severe early infantile to late infantile forms. The severe early infantile presentation includes intractable hiccups, central hypotonia, myoclonic seizures associated with frequent apneic attacks, early onset microcephalus, microphthalmia, and retinitis.⁶⁸ This acute encephalopathy is

rapidly progressive, leading to cessation of crying and swallowing. Because absent folic acid function also impairs leukocyte function, intercurrent fungal and bacterial infections are common. These complications as well as the severe encephalopathy lead to death by 3 to 4 months of age if the disease is untreated. The family history may include previous early infantile deaths with a similar presentation. The later-onset infantile form is more indolent and has such nonspecific symptoms as seizures, progressive pyramidal and cerebellar signs, and cognitive decline.^{69,70} No associated disorder was observed in four consanguineous families encountered in Saudi Arabia.

DIFFERENTIAL DIAGNOSIS. The early infantile form may be confused with nonketotic hyperglycinemia, 4-hydroxybutyricaciduria, multiple acyl-CoA dehydrogenase deficiency, molybdenum cofactor or sulfite oxidase deficiency, and peroxisomal and early-onset oxidative phosphorylation diseases. Rapid biochemical testing is available to identify MTHFR deficiency.

In MTHFR deficiency, there will be neutropenia and homocystinuria, both readily detectable in a clinical biochemistry laboratory. In contrast to classic homocystinuria due to a deficiency of cystathionine synthetase, in MTHFR deficiency, cystathioninuria and cystathioninemia occur. In nonketotic hyperglycinemia, which can be confused because of the constellation of hiccups, severe hypotonia, and early myoclonic seizures, the CSF glycine will be elevated. In 4-hydroxybutyricaciduria, the urine GC/MS assay for organic acids will identify the disease. Multiple acyl-CoA dehydrogenase deficiency usually presents as a devastating metabolic disease of the newborn with acidosis and hypoglycemia. In sulfite oxidase or molybdenum cofactor deficiency, the blood uric acid will be very low and the brain MRI reveals subcortical cysts. In early-onset mitochondrial diseases such as cytochrome-*c* oxidase deficiency, there will be involvement of other systems such as heart and liver with prominent lactic acidosis. Finally, in neonatal forms of peroxisomal diseases, there will be hepatomegaly, patellar x-ray stippling, and brain ultrasound abnormalities showing corpus callosum hypogenesis and brain cysts.

EVALUATION. A complete blood count (CBC) for neutropenia and a homocystine screening test in the urine must immediately be secured in any newborn with evolving encephalopathy. If either of these tests is abnormal, an MS/MS or an amino acid profile should be obtained to detect hypomethioninemia. MS/MS is a unique procedure among all other screening tests because it can detect low levels of amino acids, including methionine.⁶⁸ Blood homocystine level must be determined because the renal threshold for homocystine is approximately 50 μM . Furthermore, blood MS/MS will indicate elevated propionylcarnitine in the case of a vitamin B₁₂ metabolic defect; this elevation is not observed in MTHFR deficiency. If needed, urine GC/MS tests should be performed for methylmalonic and methylcitric acids to rule out a vitamin B₁₂ defect. If other disorders are considered, additional studies should be performed as needed. If available, positron-emission tomography (PET) brain scans with ¹⁸F-fluoro-2-deoxyglucose are advisable⁶⁸ and reveal absent cerebral and cerebellar glucose uptake. The metabolic pattern returns to normal gradually after appropriate treatment

with methionine. The white matter changes on MRI are nonspecific.

MANAGEMENT. The two management goals are to provide enough methionine for adequate brain growth and to reduce homocystine levels in blood. These goals are achieved by providing 100 to 150 mg betaine/kg/day and 200 to 300 mg/kg/day methionine. The blood methionine level must be closely monitored biweekly to achieve a level of 200 to 400 μM .⁶⁸ Some physicians hesitate to use methionine for fear of producing high levels of homocystine in the blood, but in the authors' experience, if enough betaine is used, hyperhomocysteinemia is not a major problem. On general principles, to stimulate a defective enzyme activity to an appreciable level, weekly injections of folinic acid 15 mg and vitamin B₁₂ 1 mg may be added.

PROGNOSIS AND PREVENTION. The outcome depends on early detection and early, aggressive treatment. Unless an aggressive treatment is given, the infant will develop microcephaly. When the above protocol is not applied, the infant will likely suffer severe neurological crippling and will expire. With appropriate treatment, however, the child will develop normally or within near-normal limits. The authors are aware of three such normal children 1 to 5 years of age.

MITOCHONDRIAL ENZYME DEFECTS

Mitochondrial DNA (mtDNA) was first discovered in 1963, and in the following 20 years the basic principles of mitochondrial genetics were established.⁷¹ These are maternal inheritance, replicative segregation, threshold expression, high mtDNA mutation rate (compared with nuclear DNA genes), and accumulation of somatic mutations with aging and oxidative stress. Diseases such as Kearns-Sayre syndrome, Leber's hereditary optic neuropathy, and chronic progressive ophthalmoplegia have been described for several decades, but the genetic basis, specifically the identified mutations on the mtDNA chromosome, for them was not proved until the late 1980s and early 1990s.

For all practical purposes, the only mtDNA that is inherited is from the mother. Although sperm cells have mitochondria surrounding the tail, any paternal mtDNA that enters the ovum is inactivated. Therefore, the mtDNA of the mother is transmitted to all her children through the egg cytoplasm, containing 200,000 to 300,000 mtDNAs. The number of mitochondria increases a hundredfold, whereas the mtDNA copy number per mitochondrion decreases from 2 to 10 to 1 to 2 mtDNAs during oogenesis. After fertilization, the early embryo goes through nuclear DNA replication and cell cleavage without significant increase in number of mitochondria or mtDNAs. The mtDNA copy number per mitochondrion varies according to cell type, with an inverse relationship between mitochondrial density and copy number. The highest mtDNA copy number is in brain mitochondria. Mutations in cellular mtDNAs result in mixed intracellular populations of mutant and normal genomes, a situation called heteroplasmy. When heteroplasmic cells (those with mixed populations of wild mtDNA and mutant mtDNA) divide, different mtDNAs partition randomly into daughter cells

(replicative segregation), resulting in variation of cell genotypes.

The oxidative phosphorylation (OXPHOS) molecular system is embedded in the lipid bilayer of the mitochondrial inner membrane. It consists of two mobile electron carriers, coenzyme Q₁₀ and cytochrome *c*, and five multi-subunit protein complexes (complex I–V). The mitochondria itself comprises over 800 nuclear-encoded gene products. The mitochondrial DNA contains 37 genes, 13 of which encode for some of the subunit components of complexes I, III, IV, and V, as well as the two rRNAs and 22 tRNAs required for mitochondrial protein synthesis. The remainder of the OXPHOS system, including the majority of the subunit components of complexes I, III, IV and V, as well as all four subunits of complex II is encoded by the nuclear DNA. With few exceptions all human nuclear cDNA's/genes' encoding structural OXPHOS subunits have been characterized. The mtDNA mutations account for less than 5% of the OXPHOS defects in the pediatric age group. Most OXPHOS defects occur in nuclear subunits or in the enzymes required to assemble the complexes that make up the electron transport chain.⁷²

The mtDNA is a 16,569 base pair double-stranded circular molecule with two strands: heavy (H) and light (L). It encodes seven subunits of complex I, one subunit of complex III, three subunits of complex IV, two subunits of complex V, 22 tRNAs, and 2 rRNAs. The nuclear gene component consists of at least 40 genes for complex I, four for complex II, 10 for complex III, and 10 each for complexes IV and V. They are randomly distributed over the genome with no clustering on any one chromosome or portion of a chromosome. Mitochondrial DNA has two different promoters involved in the expression of its 13 structural genes. Transcription of mtDNA generates two large polycistronic mRNAs. As a consequence mRNAs coding for 12 of the 13 mtDNA subunits are transcribed stoichiometrically. Only the ND6 gene of the L strand is transcribed independently. However, under pathological conditions only few transcripts change. Very likely post-transcriptional mechanisms, including mRNA stability, play a role.⁷³

Nuclear transcription is not coordinated by mitochondrial transcription. However, the transcription of all nuclear genes (i.e., nuclear OXPHOS gene expression) is finely co-regulated. The transcriptions of nuclear genes are regulated by several transcription factors such as NRF1 or NRF2, Oxbox, Rebox, and Mt family factors.⁷⁴ Some of these factors may serve as nuclear signals to control mitochondrial gene expression.

The clinical phenotype a mitochondrial disease expresses depends on the specific mtDNA mutation, the percentage of mutant mtDNAs, and the differing energy requirements and reserve of tissues. The organs most affected share the fact that they are primarily all postmitotic at birth as well as have a high energy demand per gram of tissue. Each tissue requires a different minimum level of mitochondrial adenosine triphosphate (ATP) production (a threshold) to sustain normal cell function. In a family with heteroplasmic mtDNA mutations, different family members can inherit different percentages of mutant mtDNAs and therefore present with different clinical symptoms. The phenotypical effect of the mutations depends on the severity of the damage to the protein the gene encodes.

Cells with the lowest potential to replicate, like neurons, appear to be the ones most susceptible to degenerative changes in proteins, lipids, nuclear DNA, and mtDNA. Which neurons accumulate mtDNA mutations is proportional to the metabolic rate. Thus, cerebral cortex, which in PET shows a high glucose utilization rate, and basal ganglia, which also have dopaminergic neurons that generate hydrogen peroxide and oxygen radicals, are the brain areas most susceptible to accumulation of mtDNA damage. Accumulation of mtDNA mutations is also known to occur after events such as a myocardial infarction, suggesting that anoxia itself, or the oxidative damage caused by anoxia, may promote further mitochondrial injury.

Among the many disorders of oxidative phosphorylation, clinical classifications that focus on the most severe organ system presentations are misleading.⁷¹ Because the expression of mtDNA defects of oxidative phosphorylation depends on the quantitative principles stated earlier, complete phenotypes are rarely exhibited. Biochemical classifications have the same shortcomings because the type and severity of the enzyme defect varies with the percentage of mutant mtDNA in heteroplasmic families. A molecular genetic classification is therefore the most useful. It includes four categories: class I, nuclear DNA mutations; class II, mtDNA point mutations; class III, mtDNA deletions and duplications; and class IV, genetics not yet defined. In keeping with the previous section of aminoacidopathies and organic acidopathies, major diseases are listed in Table 31-6 by order of most likely age presentation. Table 31-7 lists OXPHOS diseases by respiratory complexes involved.

Subacute Necrotizing Encephalomyelopathy (Leigh's Disease)

PATHOGENESIS AND PATHOPHYSIOLOGY. At the molecular level, Leigh's disease (LD) can be caused by both mendelian (autosomal recessive nuclear coded DNA) and mtDNA defects.^{72,75} Areas affected are primarily the basal ganglia, brain stem, and cerebellum. The cerebral cortex and retinal pigment are less involved. Pathologically, there is spongy degeneration, demyelination, gliosis, necrosis, relative sparing of neurons, and capillary proliferation. It is suggested that the common final pathway that leads to Leigh's disease is a deprivation of ATP at critical developmental stages. Several enzyme complexes involved in mitochondrial respiratory metabolism show defects, singly or in combination. These are in cytochrome-*c* oxidase (COX; complex IV), NADH dehydrogenase (complex I), pyruvate dehydrogenase complex (PDHC), and pyruvate carboxylase. The most commonly reported defect is within the ATPase 6 gene at mtDNA position mt8993, a T to G or T to C mutation, resulting in severe defects of ATP production.⁷⁶ This is the same gene defect that causes the NARP syndrome (neuropathy, ataxia, and retinitis pigmentosa) in adults, and in many instances the mothers of infants with these mutations may go on to later develop the NARP syndrome. Most pathogenic mtDNA mutations cause disease only at high mutant loads, usually greater than 90%. A new ND5 mutation, G13513A, was found in three unrelated patients with complex I deficiency and LD was present at mutant loads of 50% or less in all tissues, including

TABLE 31-7

OXPHOS Diseases: Genes Involved and Clinical Presentations in Various Disorders of OXPHOS Complexes

| DEFECT IN COMPLEX | GENE INVOLVED | CLINICAL PHENOTYPE |
|-----------------------------------|--|---|
| Complex 1 | NDUF4, NDUF7, and NDUF8 | Leigh's or Leigh-like disease |
| Complex 1 | NDUFV1 (at Xq24) | Leukodystrophy, macrocephaly, and myoclonic epilepsy |
| Complex 1 | G4.5 (at Xq28) | Barth syndrome (ccardiomyopathy, cyclic neutropenia) |
| Complex 2 | Fp | Leigh's or Leigh-like disease |
| Complex 3 | Nuclear genes are OK Cyt b unit of MtDNA | CNS hypotonia, intrauterine growth retardation, growth failure, cardiomyopathy, deafness, retinopathy, and acidosis |
| Complex 4 | SURF1 | Leigh's syndrome |
| Complex 4 | SCO1 | Encephalopathy, hepatic failure |
| Complex 4 | SCO2 | Cardioencephalomyopathy |
| Complex 4 | COX10 | De Toni-Fanconi syndrome |
| Complexes 1 and 4 combined | Hep60 | Combined clinical features of complexes 1 and 4 |
| Complex 5 | F ₀ , F ₁ , ATP synthetase, mtDNA subunit 6 and 9 | Ataxia, retinitis pigmentosa when heteroplasmic, also severe lactic acidotic and lethal when homoplasmic |
| Mitochondrial transport defect | DDP gene | Mohr-Tranebjerg syndrome, transport of protein between outer and inner membrane; dystonia, sensorineural hearing loss, optic atrophy, dementia, and psychosis |

muscle and brain, and disrupted complex I assembly or turnover. This new mutation can cause disease at unusually low mutant load and may act dominantly.⁷⁷ SURF-1, one of the four proteins responsible for assembly of the COX complex, is deficient in LD.^{77,78}

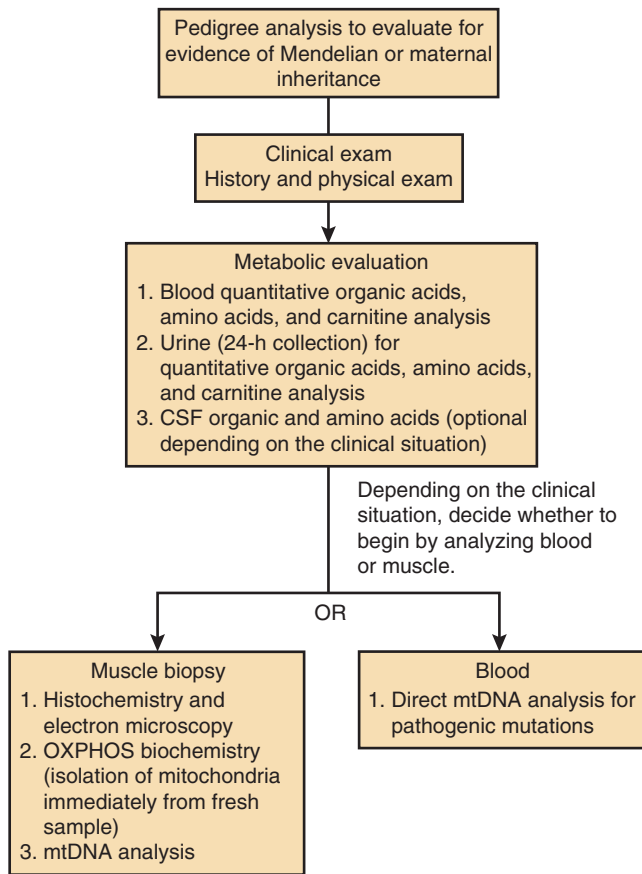

EPIDEMIOLOGY AND RISK FACTORS. LD is a relatively common neurometabolic disease. About one half of patients are diagnosed in the first year of life, usually before age 6 months; in a fourth, the onset is early in the second year of life. Males are predominantly affected, which may in part be due to the fact that pyruvate dehydrogenase deficiency, an X-linked disorder, most often presents as Leigh's syndrome in boys. There is a juvenile and an adult forms of Leigh's syndrome.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. The usual age at onset is before the age of 1 year, with death usually occurring before age 5 years. A previously healthy, normal infant exhibits a progressive encephalopathy, with an early characteristic central hypoventilation syndrome. Central hypotonia is prominent early and may later be followed by spasticity. Brain stem findings are shown as poor feeding, sucking, and swallowing and as nuclear or supranuclear ophthalmoplegia. There may be optic atrophy but also pigmentary degeneration of the retina. If the onset occurs after the infant has obtained some upright posture, ataxia becomes evident. Seizures occur in the early-onset form, particularly when due to PDHC deficiency or the NARP mt8993 mutation. Movement disorders may occur later in the course and consist often of multifocal myoclonus. Serial CSF lactate and pyruvate levels are elevated. The diagnosis can usually be made by the combination of a typical course, elevated CSF lactate and pyruvate, and typical lesions on MRI.

DIFFERENTIAL DIAGNOSIS. Included is any infantile-onset chronic or subacute progressive encephalopathy, but particularly the organic acidurias that present as progressive encephalopathy: glutaricaciduria type 1, biotinidase deficiency, and bipterin-dependent phenylketonuria. Other mitochondrial disorders such as the primary lactic acidosis, atypical peroxisomal disorder, and infantile neuraxonal dystrophy should be considered.

EVALUATION. (Fig. 31-5) The most useful ancillary study is brain MRI and magnetic resonance spectroscopy (MRS). On T₂-weighted sequences of brain MRI images, areas of increased intensity are seen in brain stem, cerebellum, and basal ganglia, more or less symmetrically. Brain MRS shows an elevated lactate peak. In LD blood amino acid screening may show nonspecific aminoaciduria. Blood and, more definitively, CSF lactate and pyruvate levels are elevated, with lactate/pyruvate ratios not always at 25:1, but are made unnecessary by demonstrating elevated tissue lactate in brain MRS. Blood ammonia and glucose values are usually normal, as are those of urine organic acids. Other useful tests include serum biotinidase determination, blood sampling for very long chain fatty acids and red blood cell catalase, and pipercolic acid determination for excluding peroxisomal disorders. An EEG may show only background slowing consistent with a nonfocal encephalopathy. Specific cause is investigated by enzyme analysis for COX and PDHC activity in cultured skin fibroblasts or muscle biopsy, and muscle biopsy is performed for mtDNA analysis (see Fig. 31-5).

MANAGEMENT. Supportive and symptomatic management includes nasogastric tube or gastrostomy for feeding problems to prevent aspiration, tracheostomy and ventilatory support for respiratory failure, prompt treatment of infections, frequent changes of position in bedridden patients to prevent skin ulceration, and the use of antiepileptic and antispastic drugs when appropriate. Metabolic treatment can be attempted, even while waiting for a definitive diagnosis, by starting with broad-spectrum cofactor supplementation therapy. This assumes that if the patient has a treatable mitochondrial disease, it will respond to factors that increase mitochondrial ATP production. Biotin (50 mg/day or more) and thiamine (300 mg/day or more) can be given in megadoses, in combination with the multivitamins. At least a 2-month trial should be given to determine therapeutic efficacy, although this approach is difficult to assess because of the phenotypical and genetic heterogeneity of these diseases. Dichloroacetate is available for lowering of lactic acid levels in research protocols, and it is hoped that it will soon be approved by the Food

Consider establishing cell lines (lymphoblasts or myoblasts) for more detailed biochemical and genetic analyses. This may be useful in investigating further whether an OXPHOS defect is caused by nuclear DNA mutations or mtDNA mutations.

Figure 31-5. Algorithm for general approach to the investigation of diseases of oxidative phosphorylation. (Reproduced with permission from The McGraw-Hill Companies, from Scriver C [ed]: *The Metabolic and Molecular Bases of Inherited Disease*, 7th ed. New York, McGraw-Hill, 1995, p 1579.)

and Drug Administration. Doses of 15 to 200 mg/kg/day have been used in infants and children, with about a 20% fall in lactic acid levels. Coenzyme Q₁₀, vitamin K, and vitamin C may also be tried, but their effectiveness has not been demonstrated in controlled trials. Patients with PDHC deficiency will often respond to the ketogenic diet, which essentially generates acetyl-CoA by β -oxidation of fats and bypasses the PDHC (which generates acetyl-CoA by the decarboxylation-activation of pyruvate).

PROGNOSIS AND FUTURE PERSPECTIVES. The prognosis for Leigh's disease is grave: death is inevitable. The course at times may spontaneously remit, and therapies may seem to arrest the disease for periods of time. Death usually occurs by respiratory failure or complications such as sepsis.

Progressive Infantile Poliiodystrophy (Alpers' Disease)

PATHOGENESIS AND PATHOPHYSIOLOGY. Alper's syndrome, also referred to as Alpers-Huttenlocher

syndrome is a progressive illness characterized by neuronal degeneration and liver disease. The main clinical features are psychomotor regression, seizures (often *epilepsia partialis continua*) and liver failure. The CNS locations affected by Alpers' disease are the same as those of Leigh's syndrome but in reverse order: with the gliosis most severe in cerebral cortex, then cerebellum, basal ganglia, and brainstem. Lesions show diffuse neuronal degeneration, characteristic spongiform or microcystic degeneration, and, in common with Leigh's syndrome, gliosis, necrosis, and capillary proliferation.⁷⁹ The biochemical abnormalities reported in Alpers-Huttenlocher syndrome have not been specific, and have included decreased pyruvate dehydrogenase activity, decreased utilization of pyruvate and NADH (substrates that donate reducing equivalents into complex I of the respiratory chain), and tricarboxylic acid cycle dysfunction. Until recently, until recently the genetic abnormality and mechanism of transmission was unknown, and it was even disputed whether Alpers' disease was a mitochondrial disease at all. However, increasing numbers of cases of classic Alpers-Huttenlocher syndrome have been attributed to mutations in POLG1, the gene encoding the catalytic subunit of DNA polymerase gamma (pol- γ A), the only polymerase that is used by the mitochondrial DNA to replicate. There is no one specific allelic mutation that causes Alpers-Huttenlocher syndrome. Although many cases are due to inheritance of identical mutations in the same gene, in some cases complex heterozygosity may play a role in this syndrome. Different mutations cause a clear differential alteration of function in terms of decreased catalytic activity (mutation affecting the C-terminus) or accuracy in nucleotide selectivity (the N-terminus), which explains the different syndromes associated with mutations in this gene. In addition to AHS, mutations are known to cause autosomal recessive progressive external ophthalmoplegia, ataxia-epilepsy syndromes and SANDO (sensory atactic neuropathy with dysarthria and ophthalmoplegia).

EPIDEMIOLOGY AND RISK FACTORS. Alpers first described the syndrome of infantile poliiodystrophy in the early 1930s, and in 1976 Huttenlocher and associates described a syndrome with an identical neurologic pathology and pathophysiology to Alpers' syndrome but with associated hepatic necrosis.⁸⁰ This has become known as both the Huttenlocher variant as well as Alpers-Huttenlocher syndrome, but it is not clear if there is a difference in terms of etiology or genetics. Certainly with the advent of improved medical care, many children may live longer to develop the hepatic complications. Valproate has been implicated in the rapid development of liver failure in children with AHS.⁸¹

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Age at onset and duration are similar to those of Leigh's disease. However, there is usually psychomotor delay before the abrupt onset of seizures.⁸² The seizures may be focal status epilepticus and *epilepsia partialis continua*, but they evolve into multifocal myoclonus. Areflexia and hypotonia are initially present, with some signs of spasticity later. Ataxia and nystagmus may worsen, with all other neurological signs and symptoms, during infections. Approximately 40% of patients in older historical

series have associated hepatic dysfunction, but the use of valproate may induce the rapid development of liver failure. The course is rapidly progressive after onset of seizures. Blindness and optic atrophy occur late.

DIFFERENTIAL DIAGNOSIS. This includes any of the infantile or late infantile progressive encephalopathies with primary involvement of cortical gray matter and presentation with refractory epilepsy. Probably the most common of these diseases is neuronal ceroid lipofuscinosis (Jansky-Bielschowsky or Batten-Spielmeyer-Vogt presentations), which can be ruled out by looking for appropriate inclusion bodies in skin, conjunctival, or full-thickness rectal (ganglion cell) biopsy specimens with electron microscopy. Another mitochondrial disease with severe epilepsy is the myoclonic epilepsy and ragged red fibers (MERRF) syndrome (see discussion later in the chapter). Other storage diseases at this age, such as atypical GM₂ gangliosidosis (Tay-Sachs disease, Sandhoff's disease), infantile sialidosis, and galactosialidosis, could be diagnosed by testing for lysosomal enzyme activity, preferably on cultured skin fibroblasts, rather than blood. Other rare causes of a progressive encephalopathy with refractory seizures at this age, but important because they are treatable and reversible, are later-onset pyridoxine dependency and nonketotic hyperglycinemia (both usually neonatal-onset diseases), biotinidase deficiency, and disorders of biogenic amine metabolism, such as folate-responsive seizures. Sulfite oxidase deficiency and Menkes' disease usually present earlier in infancy. The former can be screened for by a commercially available sulfite oxidase urine dipstick test, the latter, by measuring serum copper and ceruloplasmin. Extremely rare at this age are slow virus (subacute sclerosing panencephalitis) diseases. Within the differential diagnosis are epileptic syndromes that appear to be progressive at the onset but that usually plateau into developmental arrest and retardation. These include the syndrome of severe myoclonic epilepsy and the Lennox-Gastaut syndrome.

EVALUATION. Until recently, genetic testing was available on a research-only basis, but in the last year there a number of clinical laboratories will perform routine mutational analysis of the entire POLG1 gene. Because there is no one pathognomonic clinical sign, Alpers' disease primarily is a diagnosis of exclusion. Therefore, all rapidly progressive infantile encephalopathies need to be considered if appropriate by clinical story, followed by appropriate laboratory testing. Measurement of amino acids, organic acids, lactate, and pyruvate should be done in CSF as well as in plasma. Mitochondrial biochemical and DNA studies should be performed, looking specifically for the MERRF mutation, as well as functional neuroimaging studies (i.e., MR spectrometry, single photon emission computed tomography [SPECT], and PET if available), to garner evidence for defective energy metabolism and oxidative phosphorylation and to determine the biochemical geography. In Alpers' disease EEGs are markedly abnormal, showing a diffuse encephalopathy. A characteristic EEG pattern consists of high-voltage, very slow δ waves mixed with low-voltage polyspikes. Serial visual evoked potentials extinguish over time. Structural neuroimaging studies (CT, MRI) show progressive marked cortical atrophy. Results of liver function tests are abnormal at the onset of seizures, before clinical features of hepatic degeneration.

MANAGEMENT. There is no specific treatment. The broad-spectrum approach described earlier for Leigh's disease should be applied in order not to miss a treatable progressive encephalopathy. A trial of pyridoxine, 50 mg twice a day orally, can be done to rule out pyridoxine-dependent/deficient seizures. If the serum and CSF glycine levels are elevated, the glycine cleavage enzyme activity should be assessed by liver biopsy in a laboratory qualified to do this test; treatment should be started with dextromethorphan, leucovorin, and sodium benzoate for nonketotic hyperglycinemia. In symptomatic treatment of the seizures, valproic acid should be avoided, because the risk of accelerating the course and a resultant fatal toxic hepatitis is very high. Other treatments of refractory, nonsurgically treatable epilepsy at this age, such as corticotropin or prednisone, ketogenic diet, and intravenous IgG, are unproven and may be harmful.

PROGNOSIS AND FUTURE PERSPECTIVES. This is a fatal disease. Future treatment approaches depend on elucidation of the underlying biochemical and molecular pathogenesis. Because of the inheritance pattern, genetic counseling is recommended.⁸³

Primary Lactic Acidoses

PATHOGENESIS AND PATHOPHYSIOLOGY. The pathogenesis lies primarily with liver involvement. Three common causes often emerge as part of the evaluation: (1) cytochrome-*c* oxidase (COX deficiency, the main cause of lactic acidosis in Middle Eastern populations); (2) mitochondrial depletion syndrome, which may be due to Alpers' disease; (3) ATP synthetase 6 subunit deficiency. However, not a single mutation has been described in nuclear or mitochondrial genes in this syndrome. Other factors, such as the dialogue between nucleus and mitochondria to finely tune OXPHOS, probably are at work here. As molecular diagnostic methods improve, the actual enzymatic etiology of these cases will be clarified. However, even with the most modern investigations, at times neither a specific biochemical defect or molecular gene mutation can be identified.

EPIDEMIOLOGY AND RISK FACTORS. These diseases are rare, and their epidemiology is unknown. Because the respiratory chain is influenced by mitochondrial and nuclear genomes, inheritance is either mendelian or mitochondrial.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Presentation is usually in or shortly after the neonatal period, with marked hypotonia and weakness, failure to thrive, respiratory difficulty, and severe lactic acidosis. The hypotonia/weakness is due to a myopathy with lipid and glycogen accumulation and abnormally shaped mitochondria without inclusions but only rare, ragged red fibers. Death occurs ordinarily by 5 months, usually because of the uncorrectable lactic acidosis. Hepatic dysfunction is highly associated, with lesser involvement of kidneys (proximal tubule abnormalities and generalized aminoaciduria) and a myocardiopathy. The brain itself is rarely involved, but when it is, bilateral basal ganglial abnormalities are shown on neuroimaging.

DIFFERENTIAL DIAGNOSIS. The differential diagnosis includes other infantile causes of lactic acidosis: primary defects of pyruvate metabolism, such as pyruvate dehydrogenase deficiency, or secondary disturbances, such as in

various organic acidurias and fatty acid oxidation defects; Krebs' cycle defects; and defects of gluconeogenesis.⁸⁴ Before the serum lactic acid levels are known, the clinical picture resembles the hyperammonemia syndromes due to urea cycle defects.

EVALUATION. Important tests to order include blood levels of amino acids; urine levels of organic acids; serum and CSF levels of lactate, pyruvate, and ammonia; liver and renal function tests; blood creatine kinase (skeletal and cardiac fractions); ultrasound evaluation of the heart; neuroimaging of the brain; and EEG to document a toxic/metabolic encephalopathy.

MANAGEMENT. Supportive treatment of liver, renal, and cardiac failure is important, along with consultation with a center using experimental protocols. For respiratory chain defects, megadoses of vitamins K and C, coenzyme Q₁₀, L-carnitine, and folic acid have all been tried with controversial benefit, but there are no controlled studies available. If pyruvate dehydrogenase (PDH) deficiency is the cause, there are several patient reports demonstrating thiamine- and lipoic acid-responsive subtypes, as these are two cofactors for PDHC, so these vitamins may be therapeutic. If biotinidase deficiency or multiple carboxylase deficiency is the cause, 50 mg of biotin daily can be given. Fructose-1,6-biphosphatase deficiency and glucose-6-phosphatase deficiency, both gluconeogenic defects, respond to frequent daily and continuous nocturnal feedings to prevent hypoglycemia. There is no effective treatment for pyruvate carboxylase (PC) deficiency or partial defects of the Krebs' cycle, although ensuring proper continuous or near-continuous nutrition may retard the progression of the disease. Correction of the metabolic acidosis and lowering of serum lactic acid is most effective with sodium dichloroacetate (DCA), 15 to 200 mg/kg/day administered intravenously or orally. DCA crosses the blood-brain barrier and inhibits the PDH-specific kinase, activating the PDHC and lowering brain and blood lactate levels. The use of DCA continues to be explored in several experimental trials. Although it is effective in reducing lactic acid levels, it is not clear if this alters the course of the disease, especially in respiratory chain defects where there may be a benefit for the redox state to be shifted by the higher lactic acid levels.

PROGNOSIS AND FUTURE PERSPECTIVES. Primary lactic acidosis of the neonate usually ends in death within months. In an occasional infant, the lactic acidosis becomes less severe, and the infant will develop nearly normally until adolescence, when neurodegeneration may be observed. If definite nuclear gene mutations are identified in the future in patients with primary lactic acidosis, prenatal diagnosis using chorionic villus sampling or amniocentesis should be feasible. The prognosis of the other congenital lactic acidoses depends on the underlying biochemical defects—best with biotinidase deficiency and the gluconeogenic defects, less with PDH, PC, and Krebs' cycle defects.

Myoclonic Epilepsy and Ragged Red Fibers Syndrome

PATHOGENESIS AND PATHOPHYSIOLOGY. Eighty percent to 90% of patients with MERRF syndrome have a heteroplasmic A8344G mutation in the tRNALys gene.⁸⁵

Two other mutations, T8356C and G8363A, in the same gene account for most of the other cases of MERRF. Recently, a novel heteroplasmic G611A mutation in another gene, the mitochondrial DNA tRNA phenylalanine (tRNAPhe) gene, has been found in typical MERRF.⁸⁶ These result in protein synthesis defects involving primarily complexes I and IV, which have the greatest number of mtDNA-coded subunits. Any quantitative measure of energy metabolism—³¹P-NMR, anerobic threshold determination, or biochemical analysis of skeletal muscle—shows decreased ATP-generating capacity. When mutant mtDNAs exceed 85% in a tissue, the patient becomes symptomatic. Neuropathologic examination shows degeneration of cerebellar cortex, substantia nigra, dentatorubral and pallidoluysian systems, locus ceruleus, inferior olivary nucleus, and pontine tegmentum.

EPIDEMIOLOGY AND RISK FACTORS. The exact incidence is not known. Familial occurrence with maternal inheritance, usually before age 20, is the rule. Commonly, symptoms and signs overlap among MERRF, mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes (MELAS), and Kearns-Sayre syndrome (KSS).

CLINICAL FEATURES AND ASSOCIATED DISORDERS. The classic presentation is usually in late childhood, although it may begin in early adulthood, with progressive myoclonic epilepsy, ataxia, and action-induced polymyoclonus. Weakness and hypotonia due to a mitochondrial myopathy and a progressive dementia follow. Hearing loss may be associated. This presentation resembles the historical Ramsay Hunt syndrome of dysergia cerebellaris myoclonica. One clinical feature quite unique to MERRF is the appearance of cervical (neck) lipomatosis. As with other disorders due to mtDNA mutations, the spectrum of severity of this disorder is enormous.

DIFFERENTIAL DIAGNOSIS. MERRF is differentiated clinically from MELAS (see next section) by the lack of stroke-like episodes in MERRF. Benign essential familial myoclonus is nonprogressive. The principal differential is with other causes of progressive myoclonic epilepsy in late childhood/early adolescence. These are storage diseases—neuronal ceroid lipofuscinosis (Kufs' type) and neuraminidase deficiency (sialidosis type 1); diseases of unknown etiology—Lafora's disease, Baltic myoclonus; and slow virus and prion diseases—subacute sclerosing panencephalitis and early-onset spongiform encephalopathy.

EVALUATION. Tests to be ordered include serum and CSF lactate, pyruvate, and alanine levels; EEG and visual evoked potentials; MRI of the brain, which often shows areas of increased intensity in T₂-weighted sequences;³¹ P-NMR of muscle; muscle biopsy for biochemical tests of oxidative phosphorylation and for visualizing ragged red fibers, by light microscopy using the Gomori's trichrome stain, and by electron microscopy; and mtDNA analysis, looking for the MERRF and MELAS point mutations.

MANAGEMENT. Seizures can be symptomatically treated with valproate (using levocarnitine presymptomatically to prevent a carnitine deficiency from developing) and clonazepam. There is a dearth of data as to whether measures for refractory myoclonic epilepsy—ketogenic diet, corticotropin or corticosteroids, or L-5-hydroxytryptophan plus carbidopa—have been effective. Corticosteroids have been used for the myopathy and improvement has

been noted, but this is not generally recommended at present. Because coenzyme Q₁₀ improves electron transfer from complex I and riboflavin serves as a cofactor for electron transport in complex I (and II), these agents are reasonable to try (see Fig. 31-5). Use of vitamin K (menadione and phytonadione) has less rationale.

PROGNOSIS AND FUTURE PERSPECTIVES. The course is chronic and slowly progressive. Different family members may become symptomatic, with different phenotypes, at different ages, depending on the percentage of the mutant DNA in muscle and brain. It would be important for all maternal relatives to have blood analyses for the mutant DNA and, if negative on muscle, to determine the risk of becoming symptomatic with age. Prenatal diagnosis by amniocentesis or chorionic villus sampling for mtDNA point mutations is unreliable presently because the genotype of that tissue may not reflect that of the embryo's muscle and brain.

Mitochondrial Encephalopathy, Lactic Acidosis, and Strokelike Episodes

PATHOGENESIS AND PATHOPHYSIOLOGY. About 80% of MELAS patients exhibit a heteroplasmic A to G point mutation in the dihydrouridine loop of the tRNA^{Leu(UUR)} gene at the 3243 nucleotid position.⁸⁷ Two other mutations in the same gene, at -np3250 and -np3271, have been identified in the remaining cases, though recently a new mitochondrial DNA mutation (G12147A) has been described in a MELAS/MERRF phenotype.⁸⁸ The MELAS3243 mutation alters the dihydrouridine loop of the tRNA^{Leu(UUR)} gene and changes a nucleotide at the binding site for a nuclear DNA-encoded transcription termination factor. It is hypothesized that the mutation reduces the binding affinity of the transcription termination factor. Another possibility is that this mutation impairs protein synthesis by interfering with polypeptide chain elongation. The cerebral infarcts are nonvascular, owing to transient dysfunction of oxidative phosphorylation within parenchyma. Areas of neuronal loss, demyelination, and astrocytic proliferation are found in the infarct-like brain areas. PET studies show reduced cerebral metabolic rates for oxygen but normal glucose utilization. Mitochondrial abnormalities of endothelial cells and smooth muscle cells produce a mitochondrial angiopathy. The vascular metabolic dysfunction may cause increased production of free radicals, which could damage vasodilators such as nitrous oxide, causing vasoconstriction.

EPIDEMIOLOGY AND RISK FACTORS. The exact incidence is unknown. Most cases occur before age 20, and about a fourth of patients have a positive family history consistent with maternal inheritance.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Patients may present sporadically or in maternal pedigrees, in infancy, childhood, or adulthood. The overall course is of a progressive degenerative disease with stroke-like episodes and a mitochondrial myopathy. Various symptoms appear singly or in combination and include hemiplegia, sudden cortical blindness, hemianopia, episodes of confusion and hallucination with fever, aphasia, migraine headaches in a maternal lineage preceding stroke-like episodes, and maternally inherited diabetes mellitus

type II and deafness. Multisystem complaints and signs include myalgia, fatigability, weakness, ophthalmoplegia, pigmentary retinal degeneration, cardiomyopathy, cardiac conduction defects and block, dementia, deafness, ataxia, myoclonus, seizures, lactic acidosis, and proximal renal tubule dysfunction. Some families with MELAS seem to have only diabetes and deafness, suggesting that other mitochondrial or nuclear factors may modulate the severity of this mutation.

DIFFERENTIAL DIAGNOSIS. Conditions to exclude include any other causes of stroke in childhood, infancy, or adulthood; other mitochondrial multisystem disorders, such as MERRF or KSS/chronic progressive external ophthalmoplegia (CPEO), or other uncharacterized disorders; and any neurological disease in adulthood with an overall progressive course but relapses that leave residuals, such as multiple sclerosis or other demyelinating diseases.

EVALUATION. In the general diagnostic approach (see Fig. 31-5), the best diagnostic clues are found on CT and MRI, which show cortical infarcts that are not wedge-shaped but cut across several vascular territories, usually located in the posterior quadrants initially. Basal ganglia calcifications, in particular, occur and are seen better by CT than MRI. Ventricular dilation and cortical atrophy are also seen. With a history of strokelike episodes, these neuroimaging findings, associated with lactic acidosis and a myopathy, should strongly suggest the diagnosis. Serial MRI, EEG, and SPECT studies show a temporal and spatial progression of the strokelike lesion during the acute stage over a few weeks, which may reflect ongoing neuronal metabolic derangement with vasogenic edema, provoked by prolonged epileptic seizures.⁸⁹ Functional neuroimaging studies, such as SPECT using *N*-isopropyl-*p*-[¹²³I]-iodoamphetamine tracer can detect regional hypoperfusion when structural studies (CT, MRI) are unrevealing. SPECT is useful not only in delineating the lesion but also in following the course. Analysis of mtDNA for the known point mutations on blood and muscle confirms the diagnosis.

MANAGEMENT. Coenzyme Q₁₀ in doses up to 300 mg/day may be needed for optimal benefit, starting at 4.3 mg/kg/day. Corticosteroids and a novel quinone, idebenone, have shown some benefit. Recent evidence suggests DCA is not helpful in MELAS.

PROGNOSIS. MELAS is a progressive neurodegenerative disease with a highly variable prognosis.

Chronic Progressive External Ophthalmoplegia and Kearns-Sayre Syndrome

PATHOGENESIS AND PATHOPHYSIOLOGY. These conditions are discussed together because of a common overlap.⁹⁰ Most cases are spontaneous and have a common 5 kb deletion in the mtDNA, which is almost one third of the entire mtDNA chromosome. Over 100 different deletions have been identified; 90% occur between the large arc between the two points of replication. Deleted mtDNAs localize to distinct regions along muscle fiber, whereas normal mtDNAs are evenly distributed, resulting in a periodic respiratory deficiency along the muscle fiber. The loss of tRNAs is rate limiting in these areas, causing deficits in protein synthesis and oxidative phosphorylation.

Duplications may occur spontaneously or be maternally inherited and are detected in quiescent (muscle) and actively dividing tissue (lymphocytes). The mechanism of their generation is unclear. There is new data to suggest that many cases of CPEO are due to several mutations in the POLG1a gene, which is the gene that encodes for the DNA polymerase gamma, the polymerase required for mtDNA synthesis. This is the same gene that is responsible for many cases of Alpers' syndrome (although different mutations are responsible for CPEO).

EPIDEMIOLOGY. The exact incidence of these conditions is unknown. Most cases are sporadic.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. If ophthalmoplegia before the age of 20 years is accompanied by atypical retinitis pigmentosa, mitochondrial myopathy, along with cardiac conduction defects, a cerebellar syndrome, or elevated CSF protein (above 100 mg/dL), this constellation is termed KSS (Video 38, Facial Myopathy and Ophthalmoplegia). Chronic progressive ophthalmoplegia with onset after age 20 is termed CPEO and, if coupled with a variety of other manifestations, CPEO-plus. These manifestations are many: lactic acidemia; eye and ear findings, including pigmentary retinopathy, optic atrophy, and hearing loss; cardiac conduction defects, arrhythmias, and dilated or hypertrophic cardiomyopathies; CNS dysfunction, including dementia, seizures, and ataxias; peripheral nervous system damage, including motor/sensory neuropathies; mitochondrial myopathy; and multisystemic organ involvement in the form of diabetes mellitus, hypoparathyroidism, glomerulosclerosis, proximal renal tubule dysfunction, gastrointestinal motility problems, and respiratory failure.

DIFFERENTIAL DIAGNOSIS. Conditions to exclude include other mitochondrial diseases, primarily MERRF and MELAS; any disease causing ophthalmoplegia when that is the sole presenting symptom, especially myasthenia gravis; other diseases that cause multisystem involvement, such as collagen vascular diseases, particularly systemic lupus erythematosus; and in the appropriate setting, Lyme disease (caused by infection with *Borrelia burgdorferi*) or Whipple's disease. The diagnosis is confirmed by muscle biopsy, which will often demonstrate ragged red fibers. Southern blot on mtDNA extracted from muscle tissue will often reveal the smaller mtDNA. If the mtDNA Southern blot is normal, sequencing the POLG1 gene can be performed.

MANAGEMENT. The most treatable cause of death in patients with KSS are cardiac arrhythmias, which can be prevented with the insertion of a pacemaker before the patient develops a potentially fatal heart block. Patients may progress within months from a normal sinus rhythm to a third-degree heart block, so frequent examination and ECG monitoring is essential. No specific treatment has been proved to delay the progression of this disease, although coenzyme Q₁₀, creatine, and levocarnitine, as well as high-dose vitamin therapy, have been used. Associated endocrine abnormalities—growth hormone deficiency, diabetes mellitus, or hypoparathyroidism—can be treated medically. Hearing loss is not preventable but quality of life can be improved by the use of a hearing aid.

PROGNOSIS. Although these conditions are considered chronic, complete heart block may result in sudden death.

Leber's Hereditary Optic Neuropathy

PATHOGENESIS AND PATHOPHYSIOLOGY. Leber's hereditary optic neuropathy (LHON) was the first human disease proved to be due to an mtDNA point mutation.⁹¹ Pedigrees may be heteroplasmic or homoplasmic. Eleven different missense mutations have been identified. Approximately 80% are accounted for by mutations at bp11,778 and bp3460. Manganese superoxide dismutase and OPA-1, a dynamin-related GTPase located in the inner mitochondrial membrane have been implicated.⁹²⁻⁹⁴ There is much genetic heterogeneity, because the remaining cases reveal novel, complex mtDNA mutations that are primary or synergistic. Multifactorial etiopathogenesis probably exists.

EPIDEMIOLOGY. The exact incidence of LHON is unknown. It is maternally inherited, has variable penetrance, and has male predominance. An X-chromosome locus has not been proved, with the gender differences being explained more by gender-related physiological differences.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. LHON is essentially an optic nerve disease, though it may coexist with multisystem degeneration and as infantile bilateral striatal necrosis. Cardiac conduction defects, including Wolff-Parkinson-White syndrome, have been reported with LHON and patients should be screened by ECG. LHON presents as loss of central visual acuity in adolescence or early adulthood, acutely or subacutely, although it rarely can occur in children. Funduscopic examination shows telangiectatic microangiopathy and swelling of the nerve fiber layer around the optic disc in acute presentations and optic atrophy in subacute to chronic presentations. In addition to blindness, complex neurological features include signs suggestive of multiple sclerosis, multisystem atrophy, or MELAS. Extraparallel features like dystonia may develop with bilateral striatal necrosis.

DIFFERENTIAL DIAGNOSIS. The differential diagnosis includes other causes of optic neuropathy, multiple sclerosis, MELAS, Leigh's disease, subacute combined degeneration due to vitamin B₁₂ deficiency, Friedreich-like ataxia, and other causes of multisystem degeneration.

EVALUATION. The general paradigm should be followed, but in leukocyte/platelet analysis, for major manifestations, MTND1*LHON4160 and MTND4*LHON11778 should be assessed. For minor manifestations, MTND4*LHON11778 and MKTND1*LHON3460 and MTND6*LHON14484 are assessed. If any of these are positive, then haplotype analysis is indicated. Laboratory evaluations necessary to rule out disorders in the differential diagnosis should be done simultaneously.

MANAGEMENT AND PROGNOSIS. Up to almost one fourth of patients regain vision. Recovery from blindness depends on the mutation involved—5% in the most common and 22% in the second most common mutation.

Malignant Migraine

Various oxidative phosphorylation defects occur in the brain, although how they relate to the production of migraine is speculative. Migraine affects as much as 25% of the population and is frequently seen in maternal relatives of patients with diseases of oxidative phosphorylation. Malignant migraine refers to three situations: migraine

patients who turn out to have MELAS; migraine patients who are maternal relatives of patients with oxidative phosphorylation diseases and who are unresponsive to the usual prophylactic medications; and migraine patients who develop strokes. Blood should be tested for biochemical and mtDNA defects of oxidative phosphorylation. If the blood tests are negative, muscle biopsy should be done for routine pathology, histochemistry and electron microscopy, oxidative phosphorylation biochemistry, and mtDNA analysis to include Southern blot analysis for mtDNA rearrangements. Management is nonspecific. The prognosis is unknown and may depend on whether more specific mutations are found to be associated.

Neuropathy, Ataxia, Retinitis Pigmentosa Syndrome

The neuropathy, ataxia, retinitis pigmentosa syndrome is due to a point mutation at bp8993 in the ATPase 6 gene (MTATP6*NARP8993), which changes a highly conserved leucine at position 156 to an arginine. The exact incidence is unknown, but this is a rare illness, with variable systemic expression, adult-onset progressive disease. Presentation is with neuropathy or neurogenic weakness, ataxia, and pigmentary retinopathy. It can also be associated with dementia, generalized seizures, cerebellar and brain stem atrophy, and corticospinal degeneration. The first presentation is usually nyctalopia, followed by loss of peripheral vision. The differential diagnosis includes multisystem atrophy, familial ataxias in mid to late life; any other causes of retinitis pigmentosa, such as adult-onset neuronal ceroid lipofuscinosis; and peroxisomal disorders such as Refsum's disease. The evaluation includes specific analysis for MTATP6*NARP8993 and MTTL1*MELAS3243. Unless complex V activity is measured or a functional study of fresh mitochondria are performed by polarography, results of metabolic and muscle investigations are usually normal or slightly abnormal, with lactic acidemia only in the more severe cases. It is important to remember that a higher mutant load of the NARP8993 mutation will cause Leigh's syndrome, so finding both these syndromes in the same family is expected.

Mitochondrial Myopathies

Mitochondrial myopathies are a ubiquitous accompaniment of most diseases of oxidative phosphorylation in all classes (I to IV) but can occur as the sole symptom, owing to disorders of class I, II, and IV.⁹⁵ In class I there may be autosomal dominant or recessive presentations with tissue-specific presentations; in class II these may or may not have ragged red fibers; and in class IV the distribution of the myopathy is variable: fascioscapulohumeral, limb-girdle, generalized, with childhood, adolescent, and adult-onset forms. Class IV presents usually as singleton cases; familial cases suggest class I and II disorders. Darras and Friedman have prepared diagnostic algorithms to simplify the clinical and laboratory evaluation of mitochondrial myopathies.

Reye's Syndrome

Reye's syndrome is defined by the Centers for Disease Control and Prevention as an acute, noninflammatory

encephalopathy with altered levels of consciousness and liver dysfunction.⁹⁶ The liver disease must include either fatty metamorphosis of the liver or at least a threefold increase in alanine aminotransferase, aspartate aminotransferase, or serum ammonia.

PATHOGENESIS AND PATHOPHYSIOLOGY. A growing body of evidence suggests that Reye's syndrome may be a multiorgan disease due to diffuse mitochondrial injury of unknown origin.^{97,98} Mitochondria in hepatocytes, brain capillary endothelial cells, neurons, cardiac and skeletal muscle fibers, and pancreatic cells show histological damage. Liver mitochondrial enzyme activity is low.⁹⁹ In one study, several depressed electron transport enzymes and lowered adenosine triphosphate/adenosine diphosphate ratios were documented.⁹⁶ Epidemiological studies strongly associate three virus infections (influenza B, influenza A, and varicella-zoster (see Chapter 41) with Reye's syndrome, although the mechanism of their involvement with the pathogenesis of the condition is unclear. There is no evidence of full viral replication in the two primary organs of damage: liver and brain. It has been suggested that viral proteins are toxic, that the infection causes release of toxins, or that the viral infection plus endogenous or exogenous cofactors, such as salicylates, aflatoxins, insecticides, or certain oils, combine to damage liver and brain.

EPIDEMIOLOGY AND RISK FACTORS. Reye's syndrome occurs worldwide. In the United States, from 1982 to 1985, the incidence was approximately 0.3 in 100,000 persons, and the rate has been relatively stable since then.⁹⁶ There is no solid evidence to establish a genetic basis for Reye's syndrome, and only a few cases occur within families.¹⁰⁰ There may be two epidemiological patterns: (1) an epidemic form, not noted since the 1980s, that occurred mainly in winter and early spring, clustering in time and geographic region, and associated with outbreaks of influenza B and A, and (2) endemic Reye's syndrome with sporadic occurrence and associated with other viral infections, specifically varicella. Most Reye's syndrome cases associated with varicella occur in children between ages 5 and 9, whereas influenza type B-associated disease occurred in children aged 10 to 14. Salicylate usage has been associated with Reye's syndrome, and the reduction in cases seen in the past years has been specifically linked to reduced salicylate ingestion in children.¹⁰¹

CLINICAL FEATURES AND ASSOCIATED DISORDERS. The clinical manifestations can be divided into a prodromal phase and the syndrome itself. During the prodrome, there is an upper respiratory tract infection in 60% to 80% of cases, and most documented cases have demonstrated influenza B, influenza A, or varicella-zoster virus. During stage I of Reye's syndrome, vomiting is the primary feature. It is not known whether this effect is due to brain stem dysfunction or a systemic cause, but it is usually abrupt in onset and unremitting. The child becomes irritable and gradually lethargic. Most patients recover from this stage and never develop severe agitation and coma. With stage 2, restlessness and disorientation predominate, along with signs of dysautonomia, tachycardia, sweating, and dilated pupils. Seizures may develop, but status epilepticus is rare. With stage 3, coma ensues, with papilledema developing over 2 to 3 days but without

lateralizing signs of focal neurological damage. Seizures develop in approximately half of these patients. In stage 4, there is cerebrate posturing and respiratory dysfunction. The coma of stage 5 is associated with flaccid tone and no response to painful stimuli. Brain stem reflexes, such as cold caloric testing (see Chapter 1), are minimal or absent.

EVALUATION AND DIFFERENTIAL DIAGNOSIS. Laboratory studies during the prodromal phase are not diagnostic. Once vomiting develops, alanine aminotransferase and aspartate aminotransferase levels are often very high, often 20 to 30 times normal, but ammonia levels are in the normal range. As coma develops, ammonia levels increase threefold or more over the normal range. Other abnormalities of laboratory tests occur with increases in lactic acid and organic acids, suggesting a blend of respiratory alkalosis and metabolic acidosis, sometimes with hypoglycemia, especially in children younger than 3 years of age. Prolonged prothrombin times develop, but hemorrhaging is rare. The EEG is abnormal with diffuse slowing, and sometimes, burst suppression activity (see Chapter 24), but there is no specific pattern of diagnostic value. Liver biopsy shows highly characteristic fatty metamorphosis without inflammation. Neuroimaging with CT or MRI shows a normal brain or diffuse cerebral edema with ventricular compression. Diseases that should be excluded in the diagnosis are encephalitis and meningitis, UCDs, BCAA disorders, and other enzyme deficiency states, including propionicacidemia, glutaricaciduria, and disorders of ketogenesis. Finally, inadvertent intoxication with insecticides, salicylates, methyl bromide, margosa oil, and lead can give a combined picture of encephalopathy and hepatic damage in a young child.

TREATMENT AND PROGNOSIS. There is no specific therapy, and management is aimed at monitoring vital functions, correcting liver abnormalities, and controlling increased intracranial pressure until the disease runs its natural course. Hospitalization in an intensive care unit is recommended, because mental status and respiratory function can change abruptly. Salicylates must not be used, and serum glucose levels must be monitored. Vitamin K is often administered, and anticonvulsants are used to treat clinical seizures and sometimes subclinical epileptic activity that is evident on the EEG. Treatment of the hyperammonemia is particularly problematic because dialysis and exchange transfusions do not markedly reduce ammonia levels or improve outcome. Increased intracranial pressure is a major danger, and some centers use monitoring technology (see Chapter 26) to provide a constant assessment of shifts in pressure gradients. The goal is usually to keep intracranial pressure below 20 mmHg with a mean cerebral perfusion pressure (mean blood pressure minus mean intracranial pressure) maintained at 60 to 90 mmHg.

Overall, the mortality rate currently is 30% to 35%. Predictors of poor outcome appear to be young age, especially infants younger than 2 years old; high clinical stage at the time of hospital admission; rapid progression from vomiting to coma; maximal clinical stage; high creatine kinase levels; and ammonia levels above 300 $\mu\text{g}/\text{dL}$ at the time of hospital admission. In those surviving, hepatic recovery is full but nervous system residua are many. Behavioral problems include attention difficulties, retardation, and aggressive impulsivity. Neurological problems include

hemiparesis and quadriparesis, dysarthria, cortical blindness, and seizures. Even among children believed to have full recovery, 34% had measurable deficits in school achievement, visuomotor integration, sequencing, and problem solving.¹⁰²

FATTY ACID OXIDATION DISORDERS

Besides the mitochondrial enzyme defects characterized by disordered oxidative phosphorylation, 12 disorders of fatty acid oxidation and ketogenesis are known (Table 31-8).¹⁰³ Medium-, long-, and short-chain acyl-CoA dehydrogenase deficiencies (MCAD, LCAD, SCAD) are caused by defects of the β -oxidation spiral; the rest, except long-chain L-3 hydroxyacyl-CoA dehydrogenase (LCHAD) deficiency, are due to defects in the carnitine cycle. The mutations responsible for very long chain acyl-CoA dehydrogenase (VLCAD) deficiency have recently been described.¹⁰⁴ In this class of disorders there are three main presentations: (1) acute toxic encephalopathy with episodes of nonketotic hypoglycemia in the first 2 years of life provoked by fasting (MCAD), (2) skeletal and cardiac myopathies with weakness and low plasma carnitine levels (carnitine palmitoyl transferase [CPT] I and II deficiencies, LCAD, LCHAD, and SCAD), and (3) the syndrome of nonketotic hypoglycemia plus very low plasma carnitine levels ($<10 \mu\text{M}$) and absent dicarboxylicaciduria (carnitine transport defect).

As outlined by Treem, the clinical spectrum now also includes sudden infant death syndrome (SIDS), fulminant hepatic failure, and complications during pregnancy. Approximately 5% of 313 cases of SIDS were due to defects in fatty acid oxidation.¹⁰⁵ A careful protocol for postmortem diagnosis of fatty acid oxidation disorders has been published.¹⁰⁶ Because MCAD can be detected in asymptomatic siblings, all siblings of infants who die of SIDS should be tested for a fatty acid oxidation disorder.

Some patients with fatty acid oxidation defects can sustain severe liver injury with cirrhosis, necrosis, or liver failure, eventually leading to the need for liver transplantation.¹⁰⁷ Recent reports cite an association between fatty acid oxidation disorders and complications of pregnancy.^{108,109} All infants born of mothers with acute fatty liver of pregnancy or hemolysis, elevated liver enzymes, low platelet count (HELLP syndrome), often associated with severe preeclampsia, should be screened for fatty acid oxidation defects. A neonatal blood acylcarnitine profile analysis by MS/MS and genetic screening for the G1528C mutation in the α subunit of the trifunctional protein are available.

The diagnostic approach includes history; physical/neurological examination; routine laboratory studies, particularly including liver and urine function tests and determination of electrolytes, pH, lactate, pyruvate, ammonia, blood glucose, and urine ketones; blood free carnitine and acylcarnitines; and urine GS/MS for organic acids. These evaluations are followed by specialized techniques, including specific biochemical enzymatic analysis and molecular analysis. Because the enzymes in the β -oxidation spiral exist in different forms with chain specificities that overlap and because oxidation of unsaturated fatty acids requires

different enzymes, it is expected that other diseases of fatty acid oxidation involving enzymes in these steps will be described in the future.

Medium-Chain Acyl-CoA Dehydrogenase Deficiency

The optimal chain length specificity of MCAD is 8 carbons. The ability to oxidize fatty acids beyond medium-chain length is impaired 20% or less of control rates in cultured fibroblasts. Light microscopy of liver in acute cases shows steatosis, which disappears on recovery. The hepatic mitochondria show increased matrix density and intracristal widening, giving a condensed appearance. There may be crystalloids in the matrix. These are in contrast to the findings of Reye's syndrome, in which electron microscopy shows matrix swelling and rarefaction. MCAD is the most common mitochondrial β -oxidation disorder, with an estimated frequency being 1 in 10,000 to 1 in 20,000. Previous unexplained sibling deaths should raise MCAD as a possible diagnosis.

Most patients present between ages 3 and 15 months, rarely after 4 years. Phenotypical heterogeneity prevails, ranging from SIDS, to recurrent Reye's-like syndrome, to episodic nonketotic hypoglycemic coma. A common presentation is vomiting and lethargy, followed by fasting, associated with a prior viral respiratory or gastrointestinal infection. Presentation is usually to an emergency department as an acute toxic encephalopathy or coma, with hypoketotic hypoglycemia, hyperammonemia, and abnormal liver function tests. The serum carnitine value is low, and urine acylcarnitines are increased, with a specific profile. Enzyme assay for MCAD activity can be done on cultured skin fibroblasts, muscle, liver, or blood lymphocytes. The differential diagnosis includes other fatty acid oxidation disorders, exogenous toxic encephalopathies, and true Reye's syndrome. Specific management involves intravenous dextrose 10%, avoidance of fasting with frequent short feeds, L-carnitine 100 mg/kg/day in divided doses orally, and preventive management by neonatal screening of subsequent siblings and screening with acylcarnitine profiles of present siblings. The risk of death with the first episode (SIDS presentation) is about 20%. In delayed treatment, there is a risk for developmental retardation, speech

and language delay, behavioral problems and attention deficit disorder, muscle weakness, seizures, and failure to thrive.

Carnitine Transport Defect: Primary Generalized Carnitine Deficiency

Carnitine fails to be taken up in muscle, heart, and kidney but not liver, leading to insufficient carnitine to support fatty acid oxidation.¹¹⁰ The kidney fails to conserve carnitine by reabsorption, resulting in very low plasma carnitine levels, which then causes decreased passive diffusion into liver, impairing ketogenesis. Accumulating acyl-CoA compounds become substrates for peroxisomal β -oxidation, which produces medium-chain fatty acids and dicarboxylic acids, which do not require carnitine for mitochondrial entry. They are then completely oxidized in mitochondria, which is the reason for lack of dicarboxylicaciduria in disorders of the high-affinity carnitine transporter. Treatment with L-carnitine restores plasma levels to normal (40 to 60 μ M) but not skeletal muscle. Muscle function can be restored, however, with less than 10% normal muscle carnitine levels. This is a rare disorder, and the exact incidence is unknown. There are two major types of presentation, an early one (3 months to 2 years) with nonketotic hypoglycemia, and a later one (1 to 7 years) with cardiomyopathy. The nonketotic hypoglycemia in the early presentation is accompanied by hyperammonemia and elevated alanine and aspartate aminotransferase levels, which may present after a short fast, particularly if the patient is being fed a carnitine-free formula. The cardiomyopathy in the later presentation is progressive, with cardiac decompensation and respiratory distress, and is often accompanied by skeletal muscle weakness. Mild to moderate anemia, nonresponsive to iron, may be present. Very low plasma carnitine levels (<10 μ M) and absent dicarboxylicaciduria are practically pathognomonic of a carnitine transporter defect. The differential diagnosis includes carnitine deficiencies secondary to other disorders of the carnitine cycle, in which medium- and long-chain acylcarnitines that accumulate from the metabolic block may induce a defect in tissue uptake of free carnitine. In this primary disorder the diagnosis is established by measuring carnitine uptake by fibroblasts and leukocytes (<10% of control rates). In the nonketotic hypoglycemia presentation, management involves the intravenous use of glucose and the long-term oral administration of L-carnitine at 100 to 120 mg/kg/day in two to three divided doses. Oral L-carnitine doses can be higher in the cardiomyopathy presentation, up to 175 mg/kg/day.

Carnitine Palmitoyl Transferase II Deficiency

In CPT II deficiency, long-chain acylcarnitines are transported across the inner mitochondrial membrane but cannot be converted to their corresponding long-chain acyl-CoAs. They accumulate in the mitochondrial matrix and are transported out into plasma. These elevated levels may produce cardiac arrhythmias. Dicarboxylicaciduria is absent, because of the same explanation given for carnitine transport defect. The exact incidence is unknown, but the adult form is more common than the infantile form. Risk factors are fasting and prolonged exercise.

There are two presentations: the adult muscular form, in which prolonged exercise induces weakness and myoglobinuria, and a severe infantile form, in which nonketotic hypoglycemic coma without dicarboxylicaciduria, seizures, hepatomegaly, cardiomegaly, and cardiac arrhythmia are accompanied by low plasma and tissue levels of carnitine with increase in long-chain acylcarnitines. The classic adult form is autosomal recessive and usually affects males between 15 and 30 years of age. The serum creatine kinase value is normal between episodes, carnitine levels are usually normal in plasma and tissues, and long-term muscle weakness is rare, although lipid storage may be seen on muscle biopsy. The differential diagnosis includes other carnitine cycle disorders. Management involves supportive treatment of the renal failure and measures to remove the myoglobin from kidney and avoidance of triggering factors—prolonged exercise, exposure to cold, infections, and fasting. Presentation in the neonatal period usually ends in death. In the adult form, about a fourth of patients develop renal failure secondary to the episodic myoglobinuria.

OTHER METABOLIC DISORDERS

Various Transporter Defects

Hartnup's Disease

Hartnup's disease is an autosomal recessive transport disorder of neutral amino acids, affecting the kidney and small intestine and leading to excessive neutral aminoaciduria 5 to 20 times normal.¹¹¹ These monoamino/monocarboxylic amino acids include alanine, glutamine, histidine, serine, phenylalanine, tyrosine, tryptophan, asparagine, leucine, isoleucine, and valine but not proline. Plasma levels are normal. These same amino acids, particularly tryptophan, are retained in the gut and broken down by bacteria; their breakdown products, indolic compounds, are excreted in the urine. Because tryptophan is excessively excreted in urine and not reabsorbed in the gut, it is not available for synthesis of niacin. Many subjects are discovered to have the aminoaciduria but have no clinical manifestations (Hartnup's disorder). When the disorder is symptomatic, it is called Hartnup's disease; the main clinical manifestations are probably due to niacin deficiency, although the excessive indolic compounds may contribute to a metabolic encephalopathy. The actual carrier in the transport system or the gene responsible has not been identified. The biochemical phenotype is common, occurring in 1 in 30,000 newborns screened. However, only 10% or less actually develop the classical clinical phenotype. To develop the disease, multiple factors are probably involved—environmental, such as poor nutrition or intestinal diarrhea, and polygenic, such as low plasma amino acid levels that interact with the primary monogenic defect. Males and females are equally affected. Consanguinity in parents and affected siblings occurs not uncommonly. The disorder is worldwide and not associated with other genetic disorders.

The earliest clinical findings are photosensitive skin, leading to the pellagra-like rash in late infancy or early childhood. Later, episodic neuropsychiatric symptoms appear—intermittent cerebellar ataxia and emotional

ability to psychoses—together or separately and often triggered by poor nutrition and diarrhea, fever, or sun exposure. EEGs are nonspecific, and CSF studies are normal. Partial expressions, such as intestinal or renal tubular defects alone, may be seen. The differential diagnosis includes any cause of acute cerebellar ataxia in childhood: postinfectious cerebellitis, brain stem encephalitis, posterior fossa tumor, and vestibular neuronitis. When attacks are intermittent, particularly with the mental symptoms, episodic disturbances such as nonconvulsive status epilepticus, acute confusional migraine, other toxic-metabolic encephalopathies, or demyelinating disease should be considered. The rash with neurological signs should bring to mind other vitamin deficiency diseases, such as thiamine or biotinidase deficiency.

The evaluation involves simple urine amino acid chromatography, which will detect the neutral aminoaciduria, and oral loading tests with L-tryptophan, which will detect the indoluria. No consistent picture of abnormalities has arisen from brain CT, MRI, and PET studies. To treat symptomatic subjects, nicotinamide, rather than nicotinic acid, is given orally at 50 to 300 mg/day. Both the rash and ataxia respond. A high-protein diet may help prevent attacks in those with low plasma amino acid resting levels. Although mental retardation may occur, dementia does not. There may be learning difficulties, but most patients have normal mentation. Further specific therapy awaits elucidation of the specific membrane transport carrier system and whether the defect is of transport activation, regulation, or direct transporting, as well as mapping and cloning of the gene. As yet there are no animal models.

Menkes' Disease

Menkes' disease, an X-linked disorder in which insufficient intestinal absorption of copper leads to deficiency of copper-requiring enzymes, is now known to be due to a gene located at Xq13.3.¹¹² The gene product belongs to a highly conserved family of cation-transporting ATPases, which function in the transport of ions across cellular and intracellular membranes. The low serum copper levels, the high tissue levels (particularly intestinal mucosa, except liver), and studies from patients' cultured cells strongly suggest that the basic pathogenetic defect is the failure of a plasma membrane pump that usually extrudes copper from cells or the failure of a pump that ordinarily transports copper into an intracellular organelle-like endoplasmic reticulum. Deficient activity of copper-requiring enzymes explains the symptoms and signs. Deficiency of dopamine β -hydroxylase, critical to the catecholamine synthesis pathway, may be related to autonomic abnormalities due to decreased sympathetic adrenergic function. Cytochrome-c oxidase deficiency probably can be related to hypotonia, weakness, and the lesions similar to those seen in Leigh's disease, without severe lactic acidosis associated with complex IV respiratory chain defects. Reduced lysyl oxidase activity relates to the arterial tortuosity and other connective tissue disorders. Reduced tyrosine hydroxylase leads to lack of pigmentation. Partial loss of copper-zinc superoxide dismutase (Cu-Zn SOD) could lead to oxidant stress and cytotoxicity because of lack of defense against oxygen free radicals. The incidence is estimated

to be 1 in 100,000 to 250,000 live births, a rare condition. One third of the estimated 15 to 30 affected infants born annually in the United States are predicted to be nonfamilial new mutations.

Male infants usually present at 2 to 3 months with developmental arrest and regression, hypotonia, seizures, and failure to thrive. Seizures are an early presentation, are frequent, and are multifocal myoclonic jerks that are often stimulus-precipitated. Recurrent hypothermia and infections occur. The near-pathognomonic clinical sign is scarce, colorless, wiry, friable hair on scalp and eyebrows and, under the microscope, the characteristic appearance of pili torti (twisted hair shaft). Secondary microcephaly occurs later. A mild Menkes' disease variant occurs, with later onset and milder neurological findings. The occipital horn syndrome, another variant, has few mental or neurological signs but calcified occipital horns, changes in clavicles and long bones, and sometimes chronic diarrhea and arterial changes. The differential diagnosis includes any early infantile progressive encephalopathy presenting with seizures, such as storage disease (Tay-Sachs disease, Sandhoff's disease, infantile neuronal ceroid lipofuscinosis), aminoacidurias (nonketotic hyperglycinemia), disorders of biogenic amine metabolism (folinic acid-responsive seizures), mitochondrial diseases (Alpers' disease), sulfite oxidase deficiency, glucose transporter deficiency, or the nonprogressive infantile myoclonic epilepsies. To make the diagnosis, the clinical picture, along with typical radiological features (osteoporosis, scalloping of vertebral bodies, excessive wormian bone formation), microscopic examination of the hair, and very low levels of serum copper and ceruloplasmin after the neonatal period, is sufficient. Cultured skin fibroblasts show increased copper content. In families at risk, prenatal diagnosis and heterozygote carrier detection can be done by biochemical and mutational analysis of cultured amniocytes or chorionic villi. The therapeutic strategies must (1) bypass the block in intestinal copper absorption; (2) supply copper to intracellular enzymes that require it for a cofactor; and (3) identify and treat patients early, preferably presymptomatically. Intravenous copper histidine bypasses the intestinal block but produces no substantive neurological improvement nor increases life span. Therapy with vitamins C and E has been ineffective. Supportive care includes maximizing caloric intake, physical and occupational therapy, psychosocial support of families and, most importantly, genetic counseling. Children usually die by age 3. Future treatments might explore the principle that lipid-soluble complexes can increase copper transport through cellular membranes. Gene therapy would be difficult because of the widespread, multisystem involvement and awaits functional characterization of the transport protein and progress in developing gene delivery systems to the brain.

Glucose Transporter Type 1 Deficiency Syndrome (Devivo Disease)

The erythrocyte glucose transporter is homologous to that in the brain, with both facilitating the diffusion of glucose across lipophilic plasma membranes.¹¹³ This condition is due to defective functioning of the type 1 glucose

transporter (GLUT1) in brain microvessels at the blood-brain barrier, causing low CSF glucose (hypoglycorrachia) and therefore decreased cerebral energy metabolism and brain function. GLUT1 is coded by a gene localized to chromosome 1 and is developmentally regulated, with the messenger RNA in brain increasing with increasing cerebral metabolic rate for glucose in infancy and childhood. Symptoms occur when this rate increases in early infancy, doubling or tripling that in the neonatal and fetal periods. This is a very rare condition, originally reported as sporadic, then associated with haploinsufficiency, but recently, behaving as an autosomal dominant disorder in cases of familial epilepsy.¹¹⁴ Numerous mutations in the GLUT1 (SLC2A1) gene, which encodes the major glucose transporter in mammalian blood-brain barrier, include deletions, missense mutations, insertions, splice site, and nonsense mutations.¹¹⁵

At about age 3 months, a perfectly normal infant develops seizures—myoclonic, atypical absence, or unclassifiable—that are refractory to antiepileptic drugs. Developmental delay occurs the longer seizures are uncontrolled and the diagnosis is undiscovered, which can culminate in mental retardation and secondary microcephaly. The differential diagnosis includes any disease or condition causing refractory seizures in early infancy (see section on [Menkes' disease](#)). In this disorder, CSF glucose is 30 mg/dL or lower, with a reduced CSF/blood glucose ratio (about 0.33). CSF lactate is also low (0.97 mM/L or less). EEGs and neuroimaging studies are normal. Treatment involves seizure control with a ketogenic diet, because the diet provides ketone bodies as an alternative source of fuel for brain metabolism. The prognosis for seizure control and normal development is excellent with early diagnosis and treatment. It is likely that the defect becomes less consequential with age as the cerebral metabolic rate for glucose slows down to adult levels.

Lesch-Nyhan Disease (Hypoxanthine-Guanine Phosphoribosyltransferase Deficiency)

Lesch-Nyhan disease is an X-linked recessive disease involving abnormal purine metabolism. The disorder is due to complete deficiency of hypoxanthine-guanine phosphoribosyltransferase (HPRT), an enzyme necessary for the recycling of free purine bases and reversion into their nucleotide forms, after nucleotides are metabolized during DNA or RNA synthesis or after serving as coenzymes.¹¹⁶ Specifically, if HPRT is deficient, hypoxanthine, a free purine base, cannot be reconverted back to inosine 5'-monophosphate, from which adenosine 5'-monophosphate and guanosine 5'-monophosphate are synthesized by separate pathways. There is an acceleration of the de novo purine biosynthesis pathway, so hypoxanthine is converted by xanthine oxidase to uric acid, resulting in hyperuricemia. However, the hyperuricemia does not explain the neurological symptoms, the pathophysiology of which is essentially unknown. Based on animal models, speculation is that self-injurious behavior may be related to supersensitivity of the D₁ subclass of dopamine receptors. Autopsies have revealed no specific cerebral gross anatomical or histopathological findings.

Incidence is low, perhaps 1 in 380,000 births. The disorder occurs in many racial groups equally and is not more frequent in consanguineous populations. Patients are normal at birth, but by 6 months, developmental delay is evident. Axial hypotonia but appendicular spasticity and choreoathetoid movements appear in late infancy, and “cerebral palsy” is usually diagnosed at this time. The diagnosis is usually suspected in the toddler and early childhood years, when various kinds of compulsive self-mutilation, usually biting of lips, cheeks, or fingers, occur. Dysarthria makes communication difficult, and excitation may stimulate opisthotonus or torsion dystonia. Compulsive aggression can be directed toward anyone near the patient, including family members, and includes hitting as well as abusive language. Associated disorders are various hematological disorders, growth retardation, renal stones, and gouty arthritis if patients survive to adulthood.

Before the self-mutilating symptoms, other causes of nonprogressive or progressive extrapyramidal “cerebral palsy” should be considered, such as kernicterus, glutaric aciduria type 1, bipterin-dependent phenylketonuria, or biotinidase deficiency. Although some severely mentally retarded children of any etiology have self-abusive behaviors, such as head-banging, the relentlessness and compulsiveness of the self-injurious behavior in Lesch-Nyhan disease is extreme and unique.

The main clinical sign is self-injurious behavior resulting in tissue loss. Enzyme activity of HPRT can be assayed by radiochemical methods from dried blood spots, cultured skin fibroblasts, and hair follicle cells in probands and suspected female carriers. Biochemical analysis must be confirmed by molecular genetic analysis, particularly for female carriers. The entire HPRT locus has been sequenced, and the mutations in Lesch-Nyhan disease are extremely heterogeneous. The majority are detected by polymerase chain reaction–based techniques, usually amplification of genomic DNA and direct sequencing. In a small percentage, Southern blot analysis using HPRT complementary DNA as a probe is necessary to detect translocations or duplications.

Allopurinol, a xanthine oxidase inhibitor, decreases blood uric acid effectively but has no effect on the neurological symptoms. The following have been ineffective: folate, glutamine, magnesium, chlorpromazine, L-tryptophan, and clomipramine. Treatment with L-5-hydroxytryptophan plus carbidopa has been temporarily beneficial, but self-injurious behaviors re-emerge after discontinuing treatment or tolerance develops. Behavior modification—extinction, reinforcement of alternative behavior, or aversion therapy—shows inconsistent results. Physical restraints to prevent tissue injury are the most effective and include upper extremity splints to keep the arms straight, tying legs to wheelchairs so they cannot be brought up to the mouth, and dental guards to avoid teeth extraction as an extreme preventive measure.

Most patients are mentally retarded and do not stand or walk. Death frequently occurs during childhood. A patient with Lesch-Nyhan disease should be an ideal candidate for gene replacement therapy. The problem is to transfect an appropriate vector that would target brain cells, because neurological signs would not likely be affected by simple transplantation of infected cultured bone marrow cells into

receptive hosts. Prenatal diagnosis using mutation detection and linkage analysis can detect 100% of affected males and excludes women who are suspected carriers if that family’s HPRT mutation is known.

Congenital Disorders of Glycosylation (CDG) (Carbohydrate-deficient Glycoprotein Syndrome)

PATHOGENESIS AND PATHOPHYSIOLOGY. These disorders are clinically and biochemically heterogeneous. They result from impaired synthesis of N-linked oligosaccharides, complex multisugars attached to proteins that function in cell-to-cell recognition and glycoprotein turnover. Strokelike episodes may be due to coagulation factors and their inhibitors, many of which are N-linked glycoproteins. Decreased levels of antithrombin III and protein C and decreased activity of factor XI, protein S, and heparin cofactor II have been reported, particularly during catabolic challenges such as fever and infection. However, specific coagulopathies have not been associated with the actual strokelike episodes, and ischemia or vasculopathy have not been demonstrated by MRI/MRA. Type Ia is due to phosphomannomutase deficiency. At least 11 CDGs have been discovered.

EPIDEMIOLOGY AND RISK FACTORS. These are rare disorders with undetermined incidence and prevalence, but they have probably been underrecognized.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Affected infants develop severe CNS and other system deficits. Signs include not only developmental delay, hypotonia, failure to thrive, and mental retardation, but also oculomotor abnormalities, especially ocular bobbing, retinal pigmentary degeneration, cerebellar ataxia, and peripheral neuropathy. Systemic features are inverted nipples, female hypogonadism, abnormal fat distribution in perineal areas, and pericardial effusions without facial dysmorphism. Seizures and strokelike episodes occur in about one half of patients, often triggered by fever and infections. Recovery from stupor and coma is usually complete, but permanent residuals can occur.

EVALUATION AND DIFFERENTIAL DIAGNOSIS. Suggestive laboratory features are evidence of coagulopathy, elevated liver function tests, low albumin, and low thyroxine and thyroxine-binding globulin levels. The diagnosis is confirmed by a characteristic serum transferrin isoelectric focusing pattern measured on frozen serum. The initial differential diagnosis is wide and includes any causes of metabolic strokelike episodes and seizures. Mitochondrial oxidative phosphorylation disorders, such as MELAS and MERRF, can be excluded by normal lactate peaks on magnetic resonance spectroscopy (MRS). The decreased *N*-acetylaspartic acid peak on MRS is nonspecific, and any of the epilepsy syndromes that present with febrile seizures or febrile status epilepticus are in the differential diagnosis: severe myoclonic epilepsy syndrome of Dravet, which itself is being conceptualized as part of the familial febrile seizures; generalized epilepsy syndrome; and subtle malformations of cortical development. Various neurometabolic diseases with stuttering or progressive courses should be considered, depending on symptom presentation. In case of coma, fatty acid oxidation disorders, some organic acidurias,

and UCDs are possible. If ataxia and a small cerebellum are present, abetalipoproteinemia, ataxia-telangiectasia, or ataxia-oculomotor apraxia syndrome should be evaluated. When hypotonia and seizures occur, peroxisomal disorders such as neonatal adrenoleukodystrophy or infantile Refsum's disease are possible. Retinal pigmentary degeneration and refractory seizures may also suggest neuronal ceroid lipofuscinoses. Finally, in cases of recurrent hemiplegia, the syndromes of hemiplegic migraine or recurrent familial hemiplegia are within the differential diagnosis.

TREATMENT AND PROGNOSIS. There is no specific etiological treatment yet, except for oral D-mannose in CDG-Ib, so management is symptomatic and supportive. Such treatments include prompt defervescence of fever and treatment of infections; prevention of catabolic events; and intravenous lorazepam, fosphenytoin, and/or phenobarbital for status epilepticus or frequent repetitive convulsions. The course is usually that of a static encephalopathy from birth, punctuated by paroxysmal neurological events that may be followed by recovery or residual neurological deficit. However, normal early development with regression in infancy proceeding to severe motor and mental deficiency has been reported.¹¹⁷⁻¹¹⁹

Porphyrias

PATHOGENESIS AND PATHOPHYSIOLOGY. Porphyrias are caused by enzymatic defects in the heme pathway. There are several forms, each with similar neurological findings, highlighted by abdominal pains and peripheral neuropathy. Those with autosomal dominant inheritance include acute intermittent porphyria (AIP), due to porphobilinogen deaminase deficiency, hereditary coproporphyria (HCP) due to coproporphyrinogen oxidase deficiency, and variegate porphyria (VP), due to protoporphyrinogen oxidase deficiency. An autosomal recessive condition characterized by deficiency in δ -aminolevulinic acid dehydratase has been described.

EPIDEMIOLOGY AND RISK FACTORS. Although the crises of AIP may be spontaneous in onset, certain risk factors are identified, including infection, ingestion of alcohol, and use of a large variety of drugs, including anticonvulsant medications.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. In AIP, although the enzymatic defect is constant throughout life, neuropathic crises are interspersed between long periods of near-normal function. Abdominal pain usually is the initial symptom of a neuropathic attack, followed by a subacute motor neuropathy that may ascend from the feet, resembling Guillain-Barré syndrome. Facial, bulbar, and extremity weakness develops in most cases. In addition to these typical neuropathic signs, dysautonomia may be pronounced and lead to cardiac arrhythmias, blood pressure instability, and urinary retention. Neurobehavioral signs indicative of CNS involvement include psychotic behavior, delirium, and seizures, although the seizures are usually due to hyponatremia and inappropriate release of antidiuretic hormone.¹²⁰

EVALUATION. The diagnosis of AIP depends on the clinical presentation of intermittent painful crises, behavioral alterations, and neuropathy with excessive urinary excretion rates of δ -aminolevulinic acid and porphobilinogen. EMG

studies help in distinguishing AIP from demyelinating neuropathy, since in the former, denervation and evidence of axonal neuropathy is more pronounced than slowed conduction velocities.

MANAGEMENT. Treatment involves special dietary changes at the earliest sign of an attack. Patients must immediately increase their carbohydrate intake; if this maneuver does not abort the crisis, intravenous dextrose and hematin should be given to prevent activation of hepatic δ -aminolevulinic acid synthetase. In light of the large number of drugs associated with exacerbation of AIP crises, the control of the painful abdominal cramps is problematic, although low-dose narcotics may be used in many patients, sometimes supplemented with very low doses of benzodiazepine derivatives.¹²¹

HCP is much rarer than AIP. The neuropathic and systemic clinical manifestations of the two conditions are the same, except that a distinctive cutaneous photosensitivity occurs in one third of the HCP patients. Like AIP, HCP is punctuated with crises of neurological dysfunction that are precipitated by drugs, infections, and alcohol. HCP has a characteristic metabolic profile with elevated urinary and fecal coproporphyrins. Similar to AIP, δ -aminolevulinic acid and porphobilinogen are found in the urine, but coproporphyrin, a product not found in AIP, is also present in urine. Enzyme assays for coproporphyrin oxidase will demonstrate the deficiency, but this test is not readily available.¹²²

VP is particularly found in southern Africa. It mimics AIP and CHP clinically, and photosensitivity is common.¹²¹ In addition, a variety of skin lesions, including hyperpigmentation, hypertrichosis, vesicles, and bullae, are seen in patients with VP. Excretion patterns are similar to those of HCP, except the excreted amount of porphobilinogen exceeds coproporphyrin in VP whereas they are approximately equal in HCP. Treatment is the same as for AIP and HCP.

Finally, δ -aminolevulinic acid dehydratase deficiency is unique in being an autosomal recessive disorder. Neurological findings, as well as systemic and dermatological signs, mimic those of the other porphyrias, and the differentiation is made exclusively on the biochemical findings of enzyme deficiency and the high urinary excretion of δ -aminolevulinic acid without porphobilinogen.¹²²

Neurotransmitter-related Disorders

Normal brain function requires a bewildering complex neural circuitry in which a single nerve cell may have an enormous array of both excitatory and inhibitory inputs arising from different sources within the central nervous system. The essential feature of a normal nerve output (and therefore a normal human response) requires a meticulous balance of both excitatory and inhibitory transmission mediated by a variety of chemicals referred to as neurotransmitters. Excessive or deficient amounts of either excitatory or inhibitory neurotransmitters will result in pathology causing neurologic illness and a wide variety of clinical syndromes (Table 31-9).

One of the most important groups of neurotransmitters is the biogenic amines, which include serotonin and two catecholamines, dopamine and norepinephrine. These are major neurotransmitters within the central nervous system

TABLE 31-9

Clinical Signs and Symptoms of Neurotransmitter-related Disorders in Children

| |
|--|
| Neonatal seizures |
| Dystonia (postural or action induced)* |
| Tremor (postural or action induced)* |
| Limb rigidity (can fluctuate)* |

| Expressive speech delay |
| Oculogyric crisis |
| Convergence spasm |
| Intermittent ocular movement abnormalities |
| Autonomic symptoms (excessive sweating, temperature instability, hypoglycemia, Hypothermia, or ptosis) |

*Variation of the movement disorder can show a diurnal variation. Adapted from Hyland K: The lumbar puncture for diagnosis of pediatric neurotransmitter diseases. *Ann Neurol* 2003;54(suppl 6):S13–S17.

and enzymatic defects that interfere with their production can have a major impact on the normal functioning of the brain. The different phenotypic expressions caused by the metabolic defects in neurotransmitter synthesis have not yet been entirely defined, so the nomenclature of the so-called “neurotransmitter-related disorders” is not mature. The disorders that are referred to in this section are due to relative deficiency in a neurotransmitter, and cause a large spectrum of neurologic illness in children, with the most common symptoms related to seizures, encephalopathy, and movement disorders. Of course, the particular syndrome will often be defined by the neural pathway most affected by the abnormal level of neurotransmitter.

A number of factors make it difficult to identify those children affected by disorders of neurotransmitters. First, the rather complicated biosynthetic pathways responsible for these disorders may be overwhelming to the clinician caring for these children. Diagnosis requires a cumbersome evaluation. For the most part these disorders require cerebral spinal fluid obtained under rigid conditions and meticulously handled prior to analysis in one of a few highly specialized laboratories. A breach in technique will render results meaningless. Any comorbid state such as anoxia or seizures (which may be part of the phenotype) can result in abnormal values that make interpretation difficult. Finally the symptoms displayed by these patients overlap enormously with many static and neurodegenerative disorders including cerebral palsy, anoxic injury, the spinocerebellar atrophies, and disorders of intermediary energy metabolism.

Disorders of dopamine deficiency tend to cause parkinsonian-type symptoms, including exercise-induced dystonia, oculogyric crises, bradykinesia, hypophonia, and tremor. If the condition is due to a deficiency in tetrahydrobiopterin (BH₄) or if more than one neurotransmitter is involved, then the syndrome can be more severe and cause more severe dystonia, appendicular hypertonia, axial hypotonia, abnormal ocular movements, delayed development, and autonomic nervous system syndromes. Seizures and encephalopathy are another phenotype that may result.

As one nomenclature, Swoboda and Hyland have broken these disorders into four groups:

- Neurotransmitter deficiencies associated with hyperphenylalaninemia
- Neurotransmitter deficiency states without hyperphenylalaninemia
- Secondary neurotransmitter deficiency states
- Disorders of neurotransmitter metabolism

Pathogenesis and Pathophysiology

The synthesis of the catecholamines (dopamine and norepinephrine) and serotonin involve a complex number of metabolic steps that require the amino acids arginine, phenylalanine, tyrosine, and tryptophan; the enzymes nitric oxide synthase, phenylalanine hydroxylase, tyrosine hydroxylase, and tryptophan hydroxylase; as well as the cofactor tetrahydrobiopterin (BH₄). Tyrosine hydroxylase and tryptophan hydroxylase are the rate-limiting steps of catecholamine synthesis and both require BH₄ to function. Defects in BH₄ synthesis are now well-known to cause many of the syndromes that will be described. BH₄ itself is synthesized in a multistep process, starting with GTP. BH₄ is necessary to convert tryptophan into 5-HTP (a substrate for serotonin synthesis) and itself is converted into pterin 4a-carbinolamine, whereupon a specific dehydratase converts this to qBH₂ (quinonoid dihydropteridine) and then dihydropteridine reductase regenerates BH₄. Defects in the primary synthesis of BH₄, or its regeneration, can lead to a number of clinical syndromes. Both L-dopa and 5-HTP, formed from the decarboxylation of tyrosine and tryptophan, respectively, are decarboxylated by aromatic L-amino acid decarboxylase (AADC), which is a vitamin B₆-dependent enzyme into dopamine and serotonin, respectively. In the noradrenergic neurons the dopamine can be hydroxylated to norepinephrine. In the pineal gland, serotonin is acetylated and then methylated to produce melatonin. Dopamine is ultimately converted into homovanillic acid (HVA), serotonin into 5-hydroxyindoleacetic acid (5-HIAA), and norepinephrine into vanillylmandelic acid (VMA); all of which can be measured in the CSF.

Defects in Tetrahydrobiopterin Metabolism

BH₄ is an essential cofactor for the phenylalanine hydroxylase in the liver, the enzyme that converts phenylalanine to tyrosine. Defects in tetrahydrobiopterin will usually be detected by newborn screening programs because of elevated plasma levels of phenylalanine. If the child was not tested soon after birth by neonatal screening, these defects are often uncovered by finding elevated phenylalanine on plasma amino acid analysis. However, defects in BH₄ will not always cause elevated phenylalanine levels and elevated phenylalanine levels do not necessarily mean there is a BH₄ deficiency. Therefore, all infants and children with pathologic levels of phenylalanine should be tested for the far more common cause of hyperphenylalanine levels, a defect in phenylalanine hydroxylase, which occurs in about 1 in 14,000 infants. Between 1% and 3% of all children with hyperphenylalaninemia have a BH₄ deficiency, and in these cases identification and treatment with BH₄ can improve outcome.

In defects of BH₄ metabolism the CSF will show marked decrease in the amounts of the neurotransmitters.

The enzymes necessary for BH₄ synthesis include guanosine triphosphate cyclohydrolase, 6-pyruvoyltetrahydropterin synthase (6-PTS), sepiapterin reductase, and dihydropteridine reductase. Deficiencies in these enzymes are inherited in an autosomal recessive genetic manner. Infants with these disorders will manifest the early onset of intractable seizures, including grand mal, tonic-clonic, and myoclonic types. The clinical course also included hypotonia, poor feeding, severed developmental delays, irritability, bulbar dysfunction, oculomotor disturbance, and temperature fluctuations. In the common form of 6-PTS deficiency the infants have low levels of catecholamine and serotonin metabolites, with elevated neopterin to biopterin levels in the CSF. Most of these children do not respond well to treatment but there is a peripheral form of 6-PTS that has an excellent chance of normal development if the high phenylalanine levels are corrected with diet and supplementation with BH₄.

One disorder that deserves special mention, because it is treatable with L-dopa/carbidopa, is a dominantly inherited form of guanosine triphosphate cyclohydrolase deficiency in which the phenotype is a progressive dystonia. This disorder is often termed Segawa disease. The dystonia is dopa-responsive, and other symptoms such as seizures and developmental delay are not present. In this disorder the early development is entirely normal and a progressive gait disturbance due to dystonia develops when the child is about 5 years old. Other features that may predate the gait disturbance include torticollis, arm dystonia, and lack of coordination. These symptoms are absent or mild in the morning and worsen throughout the day. Guanosine triphosphate cyclohydrolase deficiency may also be inherited as a result of compound heterozygosity, in which case the neurotransmitter levels are low but not absent, seizures are not present and the remaining phenotypic elements are not as severe as seen in the autosomal recessive form. In general, these children have a generalized dystonia in the presence of a variable degree of developmental delay.

Tyrosine hydroxylase is the enzyme that converts tyrosine into L-dopa, and a deficiency can present soon after birth with a severe encephalopathy, parkinsonism, or spastic paraparesis, as well as generalized dystonia. Seizures are uncommon in this disorder.

The enzyme aromatic L-amino acid decarboxylase (AADC) converts L-dopa into dopamine (and 5-HTP into serotonin). In AADC deficiency the L-dopa is instead converted into 3-O-methyldopa, which will ultimately result in formation of vanillylactic acid, detectable by way of urine organic acid analysis. This is the only disorder in which levels of 3-O-methyldopa will be elevated. Levels of BH₄ will be normal in this disorder. This will usually present in the neonatal period with temperature instability, lethargy, failure to thrive, ptosis, and miosis. As the child approaches 2 months of age the temperature instability will continue, hypotonia will become apparent and new symptoms emerge including paroxysmal movements (limb extension), eye rolling, cyanosis, and severe irritability. The children will then develop myoclonic jerks, convergence spasm and oculogyric eye movements, and a variety of extrapyramidal movements. The EEG is usually normal and seizures have been rarely documented, although the movements will often be interpreted as epileptic events.

Milder variants of this disorder have been described including mild motor delay and autism. In one study, children with AADC were treated with vitamin B₆, nonselective monoamine oxidase (MAO) inhibitors to potentiate catecholamine and serotonin transmission, a dopamine agonist to potentiate dopaminergic transmission, with variable use of melatonin, anticholinergics and intranasal sympathomimetics. About one half of the group responded to the treatment with developmental progress, with a disproportionate number of boys in the treatment-responsive group and a disproportionate number of girls in the treatment-resistant group.

Dopamine β-hydroxylase converts dopamine into norepinephrine. In the newborn period children may have ptosis, hypotension, hypothermia, and hypoglycemia but develop neurologically normal, only to develop orthostatic hypotension as young adults. Seizures and other neurologic problems are not described in this disorder.

Deficiencies in monoamine oxidase A have been described in a number of disorders. MAO-A is necessary for the formation of serotonin and the catecholamines. Norrie disease is an X-linked disorder associated with deficient MAO-A levels and is the triad of blindness, hearing loss, and mental retardation of varied degrees. Other syndromes include severe mental retardation, autistic behaviors, autonomic neuropathy, and seizures.

Succinic Semialdehyde Dehydrogenase Deficiency (SSADH)

A deficiency in SSADH will result in low levels of GABA (4-gamma-aminobutyric acid). The clinical features of this disorder included global developmental delays, hypotonia, visual impairment, and intractable seizures. The use of vigabatrin has been helpful in some patients.

Serine-Deficiency Syndromes

Defects in the synthesis of the amino acid L-serine can lead to a syndrome of mental retardation, seizures and microcephaly. L-serine is a precursor for the neurotransmitters D-serine and glycine as well as for the nucleotides and phospholipids crucial for brain function. The first metabolic step in L-serine synthesis is the conversion of 3-phosphoglycerate to 3-phosphohydroxypyruvate by the enzyme 3-phosphoglycerate dehydrogenase. A deficiency in this enzyme will result in low plasma and CSF levels of serine. These children are born with microcephaly, are noted to have developmental retardation in the first few months of life, and then go on to have seizures. Treatment with serine (doses escalating to 600 mg/kg/day) often result in seizure control. In those cases in which seizures are not controlled, adding glycine at a dose of 200 to 300 mg/kg/day will often help. It is not clear if early diagnosis and treatment would be beneficial to preventing the mental retardation.

Nonketotic Hyperglycinemia

Nonketotic hyperglycinemia represents a broad group of disorders caused by defects in the various components of the mitochondrial glycine cleavage enzyme system.

The enzyme required to cleave glycine has four subunits and a defect in any of those can cause clinical disease. The most severe presentation occurs soon after birth with lethargy, hypotonia, myoclonus, and apnea. EEG shows a burst-suppression pattern. This disorder is often fatal in early infancy and those that do survive are profoundly retarded and have intractable seizures. Milder forms may present with varying degrees of mental retardation, intermittent encephalopathy, and vertical gaze palsy. Progressive spastic diplegia and optic atrophy without seizures or mental retardation are the features of the late-onset presentation. In the infantile form, CSF glycine is massively elevated to 30 times normal. The CSF-plasma ratio of glycine is also greater than 0.08.

HISTORY AND DEFINITIONS

During the past several decades, information about chromosomal abnormalities has increased rapidly. Until recently, however, identified aberrations were limited to quantitative abnormalities of increased or decreased chromosomal material. Newer techniques have enabled us to identify numerous deletions and highly specific duplications, or translocations, which ultimately result in qualitative abnormalities of genes. Recombinant DNA techniques provide powerful tools for the definition of inherited neurological diseases and allow us to identify and define regulatory events that are the basis of cellular differentiation and embryogenesis.

Cognitive impairment is the primary neurological ramification of chromosomal abnormalities; however, most early reports of this finding were based on the study of individuals who were severely retarded. These individuals may have had multiple congenital anomalies with or without associated chromosomal disorders. Furthermore, various chromosomal anomalies may occur in seemingly normal adults with no obvious intellectual deficits.

This chapter focuses first on a number of clinical syndromes in which there are conspicuous neurological sequelae of chromosomal abnormalities and then on the most common neurocutaneous syndromes.

CHROMOSOMAL ANOMALIES

Autosomal Abnormalities

Trisomy 21 (Down's Syndrome)

PATHOGENESIS AND PATHOPHYSIOLOGY. Several cytogenetic variants can produce Down's syndrome, and trisomy 21 is the most frequent. In this variant, Down's syndrome is due to an extra chromosome 21 or parts of it.¹ Trisomy of subbands 21q22.1 to 22.3 of the distal part of the long arm of chromosome 21 is the smallest component sufficient to cause Down's syndrome. In patients with trisomy 21, the genes on the extra segment of the chromosome are not found in a double dose as is normal but are tripled. In approximately 1% or 2% of cases, Down's syndrome occurs in the setting of mosaicism, in which there are two or more

cell populations. Each cell population has a different karyotype, and one has a trisomy 21. The fusion of chromosome 21 with another acrocentric chromosome, most commonly chromosome 14, 21, or 22, may also result in a clinical syndrome that does not differ from that produced by the triplication of the subband 21q22. Finally, a rare familial form of Down's syndrome has been reported that may result from familial mosaicism, maternal trisomy 21, or other cytogenetic causes. The exact method by which these chromosomal anomalies cause the clinical sequelae of Down's syndrome has yet to be determined.^{2,3}

EPIDEMIOLOGY AND RISK FACTORS. Down's syndrome is the most common autosomal chromosomal abnormality in human live births that results in structural malformations associated with developmental retardation. This disorder occurs in approximately 1 in 1000 neonates, and the frequency of trisomy 21 increases with maternal age. Although familial forms of Down's syndrome are rare, the risk of a mother having a second affected infant is approximately 0.5%. In a child with a translocation, chromosomal karyotyping should be performed in both parents since if one parent has the translocation, the risk of having a similarly affected child is much higher.

CLINICAL CHARACTERISTICS AND ASSOCIATED DISORDERS. The physical characteristics of patients with Down's syndrome are commonly recognized in the first month of life, if not in the newborn nursery. Common features include brachycephaly with a round face, Brushfield's spots, a small mouth and a large protruding tongue, small ears, epicanthal folds with upslanting palpebral fissures, and a flattened or depressed nasal bridge. Although epicanthal folds and a transverse simian palmar crease are considered characteristic of Down's syndrome, they are found in only 50% of these patients. Brachydactyly and clinodactyly of the fifth finger are observed more commonly than the simian palmar crease. There is a widened space between the first and second toes.

In addition to the typical phenotypic features of the syndrome, associated congenital cardiac and gastrointestinal abnormalities may be present. One third to one half of patients with Down's syndrome have congenital cardiac defects, of which one-third are endocardial cushion defects and the remainder are ventricular septal defects. Tetralogy

of Fallot and atrial septal defects also occur, and there is an increased incidence of moyamoya disease. More than half of patients have bilateral hearing loss, of which many cases are attributable to anomalies of the inner and middle ear. Malformations of the gastrointestinal tract, including intestinal atresia and imperforate anus, occur in approximately 5% to 7% of patients, and there is a reported increased incidence of Hirschsprung's disease. Although abnormalities of T lymphocyte function have been reported, no specific relationship of these to the infection rate has been established. Other associated abnormalities include gastroesophageal reflux, pulmonary hypertension, upper airway obstruction, obstructive sleep apnea, and an increased incidence of thyroid dysfunction, diabetes mellitus, cataracts, and leukemia.

The major neurological features of Down's syndrome are developmental delay and severe, diffuse muscular hypotonia, which affects most patients. Convulsive disorders are also more commonly present in these patients. The pathogenesis of the convulsive activity in this population is probably multifactorial and may result from a combination of medical risk factors and inherent neurological abnormalities. As individuals with Down's syndrome age, however, other neurological signs may appear (Video 262, Down's Syndrome). Approximately 20% of patients complain of neck pain or discomfort, and they may demonstrate torticollis, gait impairment, or corticospinal tract dysfunction. These features are believed to be related to atlantoaxial subluxation and instability and result in compression of the medulla and spinal cord.

By approximately the fourth decade of life, additional deterioration of cognitive function may become apparent. This deterioration has been attributed to dementia, which results from a degenerative process that has neuropathological similarities to Alzheimer's disease.² Olfactory abnormalities may also appear, and these can predate the onset of dementia by 10 to 15 years.³

DIFFERENTIAL DIAGNOSIS. It is impossible to distinguish the clinical features of Down's syndrome resulting from the "typical" trisomy 21 from those resulting from translocation. Other chromosomal abnormalities should be considered, but the phenotypic features and neurological signs generally make the diagnosis clear.

EVALUATION. The diagnosis of Down's syndrome is made by the presence of the typical physical abnormalities and can be confirmed by chromosomal karyotype. Radiological studies such as plain skull films may demonstrate a brachycephalic skull in which the anterior fontanelle and metopic suture close late. Computed tomography (CT) may show calcifications in the basal ganglia and a large opercula, whereas magnetic resonance imaging (MRI) reveals evidence of delayed myelination in some cases.⁴ Other MRI studies have demonstrated smaller hippocampal and neocortical structures in patients with Down's syndrome compared to controls.⁵ Additionally, these investigations suggest that patients with Down's syndrome develop signs associated with brain aging at an earlier age than normal; these signs include increased rates of ventricular dilatation, peripheral atrophy, and deep white matter lesions. The electroencephalogram (EEG) may be abnormal and can become progressively disorganized with the evolution of Alzheimer's type dementia. Reports of postmortem evaluations have noted the presence of a small, spherical brain and a

cerebellum that is reduced in size. Microscopic abnormalities include reduced neuronal density in cortical regions, a loss of cortical interneurons, a reduction in the number of spines along pyramidal cells, and an accumulation of undifferentiated fetal cells in the cerebellum. Abnormalities in the basal nuclei of the brain include a reduced cell count that shows a continued steady decline with age. In nearly all patients who die after reaching the age of 35, changes consistent with Alzheimer's disease are found.

MANAGEMENT AND PROGNOSIS. There is no specific treatment for Down's syndrome. Compared to the general population, these patients have increased morbidity and mortality, primarily from cardiac causes.

Trisomy 18 (Edwards' Syndrome)

Edwards' syndrome⁶ is the second most common autosomal chromosomal abnormality associated with an extra autosome. The incidence of trisomy 18 is 0.3 per 1000 live births, and females are affected more often than males (3:1). In the majority of patients, the entire chromosome 18 is trisomic, whereas other affected patients may have a mosaic state of partial trisomy. This anomaly is more frequent in the offspring of older mothers. A history of decreased in utero activity is typical, and there is an even distribution of premature, normal term, and postmature neonates with this disorder. Affected infants have a feeble cry, decreased adipose and subcutaneous tissue, and a paucity of muscle bulk. The face is generally small with a high nasal bridge, short palpebral fissures, ptosis, small mouth, narrow palate, and micrognathia. The hands are clenched, with the second finger overriding the third and the fifth overriding the fourth. The nails are hypoplastic, especially those on the fifth fingers and toes. Other commonly associated findings include rocker-bottom feet, a short sternum, small pelvis, umbilical and inguinal hernias, and diastasis recti. The skin can be redundant, and hirsutism of the head and back is notable. Cardiac malformations include ventricular and atrial septal defects and patent ductus arteriosus.

No consistent central nervous system (CNS) abnormalities are found in this disorder, but agenesis of the corpus callosum is the most common anomaly and may be associated with cerebellar or cerebral white matter heterotopias. In those individuals who survive early infancy, severe mental retardation may occur. No specific therapy is available for patients with this syndrome. Approximately half of patients die before the age of 6 months, and only 10% survive 1 year.

Trisomy 13 (Patau's Syndrome)

The incidence of this trisomic syndrome, which occurs primarily in the offspring of older mothers, is approximately 1 in 7000, and it affects mainly females.⁷ It should be noted that translocation can also result in this syndrome, but mothers of these children are usually younger. The clinical characteristics of this syndrome include multiple congenital anomalies with varying degrees of midfacial anomalies. Infants may have ophthalmic abnormalities, including anophthalmia, cycloopia, microphthalmia, and colobomas. Facial defects, such as cleft palate and lip and micrognathia, can also occur. A variety of congenital cardiac

abnormalities, such as ventricular or atrial septal defects and patent ductus arteriosus, may be present. Intestinal malrotation, Meckel's diverticulum, and a spectrum of urogenital structural abnormalities are commonly seen. Polydactyly, with the third and fifth fingers overlapping the fourth, occurs in most affected infants. Neurologically, patients have developmental retardation as well as an increased frequency of neural tube defects and microcephaly. Pathologically, the most common abnormalities include arrhinencephaly and holoprosencephaly, which can be associated with the absence of the interhemispheric fissure and the olfactory bulbs and tracts as well as with a single ventricle. Sample case reports have also noted the presence of corpus callosum lipomas and frontal cranial defects. As in infants with trisomy 18, heterotopias in the cerebellum and cerebral white matter may be observed. As is true of other trisomic conditions, no specific therapy is available. The average length of survival is approximately 9 months, and approximately 90% of affected patients die before the age of 12 months.

Prader-Willi Syndrome

The Prader-Willi syndrome is a sporadic disorder that occurs in approximately 1 in 20,000 live births and has a risk of recurrence in the same family of approximately 1 in 1000. The responsible abnormality on chromosome 15 can be documented by cytogenetic studies, and in approximately 70% of patients there is a deletion at 15q11-q13. The disorder that produces Angelman syndrome has the same gene locus. The use of cytogenetic techniques and DNA polymorphisms has made it possible to discern the origin of the parental deletion. Patients with Prader-Willi syndrome inherit the chromosomal disorder from their father, whereas patients with the Angelman syndrome inherit the chromosomal abnormality from their mother.^{8,9}

Mothers of infants with the Prader-Willi syndrome note decreased in utero fetal activity, and often these neonates are born in breech presentation. The affected individuals are of short stature and have small hands and feet and a narrowed cranial bifrontal diameter.⁹ Their eyes are almond-shaped, and they often have strabismus. The face is long, and nearly 50% of patients have hypopigmentation of the skin. Other common features include a small phallus, cryptorchidism, and hypogonadism with a small flat scrotum. Affected infants have a feeble suck and severe hypotonia, which commonly requires the use of a feeding tube. Near the end of the first year of life, however, the hypotonia may become less severe. The degree of mental retardation may seem more prominent in early life and may be correlated with the severity of the hypotonia. From 1 to 3 years of age, patients gain considerable weight and become obese because of hyperphagia. As the hypotonia becomes less severe, they also seem to be more mentally alert, yet the intelligence level usually ranges from an IQ of 40 to 60. Although the primary explanation for the short stature, hyperphagia, and hypogonadism has not been specifically defined, there is evidence that suggests the presence of primary hypothalamic dysfunction. Recent improvements in MRI scanning techniques have demonstrated anomalous cortical growth on the banks of the sylvian fissure in some children with Prader-Willi syndrome.¹⁰ These "growths"

are seen even more frequently in children with Angelman syndrome and are thought to represent misrouting of long projection axons. Electrophysiological studies and muscle biopsies have failed to reveal any clues to the cause of the severe hypotonia seen in these patients. No direct therapy is available for the neurological aspects of this disorder.¹⁰

Sex Chromosomal Abnormalities

Klinefelter's Syndrome

This syndrome, characterized by a 47XXY chromosomal karyotype, is the most common human sex chromosomal aberration and is associated with the sex chromatin-positive form of seminiferous tubular dysgenesis. The frequency of the 47XXY karyotype is reported to be 0.9 in 1000; 0.15 in 1000 have a mosaic form. Approximately half of patients with a 47XXY disorder die in utero.

Affected children have small, firm testes, and adult patients have azoospermia.¹¹ This disorder is a common cause of primary hypogonadism and male infertility. Although a male phenotype is typical, delayed or poorly developed secondary sex characteristics are present, and approximately half the patients have varying degrees of gynecomastia, androgen deficiency, and eunuchoid features. These patients tend to be tall and have long legs, and adults have an increased incidence of pulmonary disease, varicose veins, diabetes mellitus, and breast cancer. Serum levels of follicle-stimulating hormone and luteinizing hormone are increased early in the second decade, whereas testosterone concentrations are normal to low. Plasma levels of estradiol are normal or high. Affected individuals have cognitive abnormalities, including impaired auditory sequential memory with delayed language development and associated learning disorders.¹² There is a slight lowering of the mean IQ and an increased incidence of behavioral and personality abnormalities. A higher than normal prevalence of postural tremor has been reported, but the findings have not been replicated.

If androgen deficiency is present, administration of testosterone may produce an improvement in the secondary sexual characteristics and increase the general well-being of the patient. Testosterone therapy may also lessen the degree of gynecomastia, but in those patients with notable breast enlargement, surgical reduction of the breast tissue may be important for cosmetic reasons.

XYY Syndrome

The incidence of this abnormal sex chromosomal karyotype is approximately 1 in 1000 live male births. These patients have a normal male phenotype, although cryptorchidism and hypogonadism have been known to occur. Tall stature and acneiform eruptions are common characteristics. Although earlier studies suggested that affected patients had inordinately aggressive, impulsive behavior, this finding has not been reliably substantiated. Most patients have normal behavior, and their intelligence tends to be low normal. Delayed acquisition of speech and language skills may also be present. Other minor neurological findings include postural tremor and motor incoordination.¹³

Turner's Syndrome

Turner's syndrome, a form of gonadal dysgenesis resulting from a 45,X karyotype (X-chromosomal monosomy), is characterized by female phenotype, short stature, a shield-like chest, a short and sometimes webbed neck, low-set ears, high-arched palate, small mandible, and sexual infantilism.¹⁴ The frequency of 45,X in female live births is 0.1 to 0.6 per 1000. A variety of other malformations can be associated, including congenital lymphedema, particularly of the hands and feet; cardiac and renal defects; skeletal anomalies; and abnormalities of the nails. An increased number of pigmented nevi has also been reported. Other disorders have been associated with this disorder, including Hashimoto's thyroiditis, obesity, inflammatory bowel disease, and rheumatoid arthritis. Nerve deafness occurs in approximately half the patients, and olfactory as well as taste deficits have been described. Eighteen percent of patients studied in one series were mentally retarded, although this high prevalence may be due to selection bias. The absence of the X chromosome does not cause intellectual impairment per se, but the majority of these patients have right-left disorientation and defects in perceptual orientation.¹⁵

Psychological tests demonstrate that girls with Turner's syndrome perform poorly on visuospatial and intellectual measures and have difficulty with attention and social behaviors compared with age-matched controls.¹⁶ Others have reported that Turner's syndrome patients have significantly lower scores on all the Wechsler adult intelligence scale tests except verbal comprehension and reading level.¹⁷ The most significant difference is found in the visuospatial construction. Volumetric brain measures derived from MRI reveal no differences in overall cerebral or subcortical volume, yet the regional distribution of gray and white matter varies in the two groups. In general, girls with Turner's syndrome have a smaller proportion of tissue in the right and left parietal regions and a larger amount in the right inferior parietal-occipital region.^{16,17} Additional MRI studies have shown that measured volumes of the hippocampus; the caudate, lenticular, and thalamic nuclei; and the parieto-occipital brain matter bilaterally are smaller.¹⁸

Treatment of patients with Turner's syndrome is directed at facilitating growth by administering recombinant growth hormone,¹⁹ correcting associated congenital anomalies, and carefully managing hormonal replacement therapy for sexual infantilism.

Fragile-X Syndrome

Second only to Down's syndrome, the fragile-X syndrome is the most common cause of mental retardation in males and has a frequency of approximately 1 in 1500 males. It is found in all ethnic groups and has been identified in patients with other chromosomal abnormalities. The higher incidence of mental retardation in males and reports of families in which only males are affected suggest a nonspecific X-linked inheritance, termed the Martin-Bell or Renpenning's syndrome.^{19,20} No cytogenetic abnormality had been found in this heterogeneous subgroup of the mentally retarded population until a fragile site in the terminal region of the long arm of the X chromosome (Xq27.3) was demonstrated when the cells were cultured without folic acid.

The hereditary transmission of the fragile-X syndrome has been described by Tarleton and Saul, and the fragile-X gene has been isolated, cloned, and characterized.²¹ It contains a trinucleotide sequence (CGG) that repeats in the normal genome 6 to 45 times, whereas the repeat is expanded to several hundred copies in patients with fragile-X syndrome. Carriers of the fragile-X syndrome, who are asymptomatic, have approximately 50 to 230 copies of this sequence. The expansion of the CGG repeat sequence is associated with methylation-induced inactivation of a sequence (CpG island) that is contiguous but separate from the *FMR-1* gene.²² This region is thought to initiate gene transcription. The degree of methylation correlates with the number of repeats, suggesting that the fragility of the site of the fragile-X (FRAXA) is related to the triplet repeats.²³

The characteristic physical features of affected males with fragile-X syndrome include a long face, prominent mandible, large ears, and macro-orchidism with no evidence of endocrine dysfunction. All signs may not be present in prepubertal males and are not always prominent in adults. Although affected children may be unusually tall, the adult male with fragile-X tends to be shorter than average. Other associated features include joint hyperextensibility, flat feet, scoliosis, mitral valve prolapse, and dilatation of the aortic root. Although no specific abnormality of connective tissue metabolism has been identified in patients with this syndrome, abnormal elastin fibrils have been observed in skin biopsies of some patients. Some heterozygote females may also have a long face, prominent ears, and joint hyperextensibility. These features are more commonly observed in mentally subnormal females than in those with normal intelligence (Video 254, Fragile-X).

The majority of adult males with fragile-X syndrome have mental abilities that are moderately retarded, but approximately 30% have severe mental impairment. A small number of males have low-normal or mildly retarded intelligence, albeit with a variety of specific learning disabilities. There may be a delay in acquisition of speech and language skills, and older patients often have a low-pitched, somewhat hoarse voice with features of perseveration, cluttering, and staccato speech. The degree of mental impairment in females is somewhat less than that in males, with approximately one third of patients having mental abilities in the retarded range and approximately one half demonstrating specific learning disabilities. Attentional deficits, hyperactivity, and impulsive and aggressive behaviors are known to occur. Patients may additionally have macrocephaly, hypotonia, oculomotor dysfunction, and inordinate clumsiness with impairment of fine and gross motor movements.²⁴ An increased incidence of convulsive disorders may occur in nearly 25% of patients. These seizures are generally simple or partial complex seizures and tend to occur more frequently during the first 10 to 15 years of life. The seizures are usually well controlled by the administration of standard antiepileptic medications and appear to have no relationship to the degree of mental retardation. Tic disorders have also been reported in patients with fragile-X syndrome and their families.

There is no specific treatment for fragile-X syndrome other than providing special educational programs tailored to the specific disabilities of each patient. For patients with attentional deficit disorder and hyperactivity, these

behaviors are sometimes improved by the administration of CNS stimulants.

NEUROCUTANEOUS DISORDERS

The neurocutaneous syndromes comprise a group of heterogeneous disorders characterized by dysplasia and a tendency to form tumors.^{25,26} The CNS and skin are primarily involved, but other organ systems can be affected. Since the skin and nervous tissue originate from the same germ layer, the ectoderm, these disorders have been variously called congenital ectodermoses and congenital neuroectodermal dysplasias. Van der Hoeve believed that the ocular findings of neurofibromatosis and tuberous sclerosis were similar and suggested that they be classified together under the inappropriate term phakomatosis (Greek *phakos*: lentil, mole, or birthmark).²⁷ He later added von Hippel-Lindau disease and Sturge-Weber syndrome to this category, and in 1941 Louis-Bar proposed that ataxia-telangiectasia should also be considered as one of the phakomatoses.^{28–30} During the past 50 years, a wide variety of disorders, all of which are unusual and many of which lack dysplastic or

neoplastic characteristics, have been considered to belong to this heterogeneous group of disorders. The major neurocutaneous syndromes are considered herein, and others are noted in Table 32-1.

Autosomal Dominant Diseases

Neurofibromatosis (Von Recklinghausen's Disease)

PATHOGENESIS AND PATHOPHYSIOLOGY. Neurofibromatosis is no longer considered a single clinical entity and has been divided into at least two distinct forms.^{31,32} The common form, once known as peripheral neurofibromatosis (NF), is called NF-1, and the rare form, once termed central NF, is NF-2. Both are inherited as autosomal dominant traits, and the gene locus responsible for NF-1 is on chromosome 17 (17q11.2), whereas that for NF-2 is on chromosome 22 (22q11.1–22q13.1).³¹ These disorders are due to abnormalities in the development of neural crest cells that produce hyperplasia, neoplasia, and dysplasias of the neuroectodermal elements and their supporting structures. Recently, the gene for NF-1 was found to code for a large, ubiquitously expressed protein

TABLE 32-1

Selected Neurocutaneous Syndromes

| DISEASE | CLINICAL FEATURES |
|--|---|
| Autosomal Dominant Inheritance | |
| Incontinentia pigmenti achromians (hypomelanosis of Ito) | Bilateral asymmetrical areas of hypopigmented whorls ("marbling"); central nervous system, eye, tooth, skin, nail, and bone anomalies |
| Rendu-Osler-Weber disease | Multiple angiomas of skin and mucous membranes that are dilations of capillaries and venules; bleeding from any site: nose, gastrointestinal, pulmonary, and urinary systems |
| Waardenburg's syndrome (I) | Frontal patch of white hair, heterochromia iridis, lateral displacement of inner canthus and, at times, cochlear deafness |
| Waardenburg's syndrome (II) | Clinical findings are similar to type I without the lateral displacement of inner canthus; deafness is more common |
| Autosomal Recessive Inheritance | |
| Ataxia-telangiectasia | Ataxia and telangiectasias of the bulbar conjunctivae, malar eminences, ear lobes, and upper neck; increased incidence of respiratory infections, lymphomas, Hodgkin's disease, acute leukemia, and a variety of cancers; thymus gland is hypoplastic or absent; there is decreased IgA and IgG; increased chromosomal breakage and increased sensitivity to ionizing radiation of fibroblasts and lymphocytes |
| Chédiak-Higashi syndrome | Rare, partial oculocutaneous albinism, photophobia, neuropathy, and recurring infection; giant cytoplasmic organelles are observed |
| Refsum's syndrome | Retinal pigmentary degeneration, polyneuropathy, and ataxia; sensorineural deafness, anosmia, and cardiomyopathy are usually present; abnormalities of the eyes, skin (ichthyosis), and bone are often present |
| Rothmond-Thomson syndrome | Erythematous skin lesions in early life followed by telangiectasias, atrophy, hypo- and/or hyperpigmentation, ectodermal dysplasia; body hair is sparse or absent; cataracts, short stature, hypogonadism, and skeletal abnormalities are common; intelligence is normal |
| Rud's syndrome | Ichthyosis and hypogonadism are major features; microcephaly, sensorineural deafness, polyneuropathy, and hypoplastic teeth and nails are less frequent |
| Sjögren-Larsson syndrome | Congenital ichthyosis associated with mental subnormality and corticospinal tract dysfunction |
| Xeroderma pigmentosum | Defect in DNA repair results in premature aging of tissues exposed to sunlight; microcephaly, mental subnormality, ocular changes, corticospinal tract dysfunction, ataxia, and movement disorders may be present |
| X-Linked Inheritance | |
| Fabry-Anderson disease | A glycolipid lysosomal storage disease with a wide spectrum of clinical findings: angiokeratosis is a characteristic feature; lancinating limb pain is often the first symptom; joint pain may resemble that of juvenile rheumatoid arthritis; ocular, cardiac, and gastrointestinal symptoms may be present; cerebrovascular accidents can occur in young adults; neuropathy; renal disease manifests as inability to concentrate urine, urinary frequency, polyuria, and nocturia |
| Incontinentia pigmenti (Bloch-Sulzberger syndrome) | Seen almost entirely in females; characterized by skin lesions present during the first few weeks of life that are erythematous, macular, papular, vesicular, or bullous; second stage, skin lesions are variably verrucous, lichenoid, or keratotic; third stage, lesions are notable for hyperpigmentation; abnormalities of the eyes, central nervous system, hair, teeth, and bone are commonly associated |

(neurofibromin).³³ This protein has structural and functional similarity to a family of proteins that has guanosine triphosphatase activation properties. This family of proteins is involved in the regulation of the proto-oncogene *ras*. It has been speculated that the functions of the NF-1 gene product may be related to its ability to regulate *ras*-mediated cell proliferation.

EPIDEMIOLOGY AND RISK FACTORS. NF-1 occurs in approximately 1 in 4000 to 5000 individuals. Approximately half the cases appear to be sporadic, and the mutation rate has been estimated at 1 in 10,000 gametes per generation, one of the highest mutation rates in humans. Approximately 50% of patients have affected relatives, and in nearly all instances the distribution of cases is consistent with an autosomal dominant mode of inheritance. NF-1 is observed in all regions of the world and affects men and women equally. The frequency of NF-2 is not known, and its natural history has been derived from studies of a large Pennsylvania family.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. NF-1 is characterized by cutaneous pigmentation, multiple tumors within the central and peripheral nervous systems, and lesions of the vascular and other organ systems³⁴ (Table 32-2). Focal hyperpigmented areas and café au lait spots, ranging in size from a few millimeters to centimeters, are more commonly found on the trunk than on the limbs, and they are not found on the scalp, soles, or palms (Fig. 32-1). These spots are light brown and result from an aggregation of neural crest-derived pigmented melanoblasts in the basal layer of the epidermis. Café au lait spots are present at birth and become more apparent with time. The number of café au lait spots probably does not significantly increase after the first several years of life, although the degree of hyperpigmentation usually does. The presence of six or more café au lait spots larger than 15 mm in greatest diameter is required for a diagnosis of NF, a criterion that is most useful when applied to the post-pubertal patient. It should be recognized, however, that approximately 10% of the general population have café au lait spots without other stigmata of the disease. Less fre-

Figure 32-1. A 9-year-old patient with multiple café au lait spots of varying sizes, which are more common on the trunk than on the limbs.

quent cutaneous changes in NF-1 include diffuse axillary or inguinal freckling and large areas of faintly increased pigmentation (melanoderma) (Fig. 32-2).

Fibroma molluscum, soft or firm papules found in or just below the dermis that vary in size from a few millimeters to 1 or more centimeters, may also occur (Fig. 32-3). They are violaceous in color and vary in configuration from flat or sessile forms to pedunculated or lobulated forms. When compressed, these skin lesions tend to invaginate into the subcutaneous tissue. Hypopigmented spots similar to those observed in patients with tuberous sclerosis, discrete areas of skin hypoplasia, and angiomas may also be present in

TABLE 32-2

Diagnostic Criteria for Neurofibromatosis

Diagnostic Criteria for Neurofibromatosis 1

- Six or more café au lait macules over 5 mm in greatest diameter in prepubertal individuals and over 15 mm in greatest diameter in postpubertal individuals
- Two or more neurofibromas of any type or one plexiform neuroma
- Freckling in the axillary or inguinal region
- Optic glioma
- Two or more Lisch nodules (iris hamartomas)
- Distinctive osseous lesion such as sphenoidal dysplasia or thinning of long bone cortex with or without pseudoarthrosis
- First-degree relative (parent, sibling, or offspring) with neurofibromatosis 1 by these criteria

Diagnostic Criteria for Neurofibromatosis 2

- Bilateral cranial nerve VIII masses seen with appropriate imaging techniques
- First-degree relative with neurofibromatosis 2 and either unilateral cranial nerve VIII mass or two of the following: neurofibroma, meningioma, glioma, schwannoma, and juvenile posterior subcapsular lenticular opacity

Figure 32-2. Axillary and inguinal freckling, as observed in this patient, is common in patients with neurofibromatosis.

Figure 32-3. An example of fibroma molluscum, which is a soft or firm papular or polypoid lesion found in or just below the dermis and which ranges in size from a few millimeters to 1 cm or more. (Courtesy of Dr. Mary Williams, Department of Dermatology, University of California Medical Center, San Francisco).

Figure 32-4. Lisch nodules are age-dependent iridic melanocytic hamartomas that are commonly observed in patients with neurofibromatosis. (Courtesy of Dr. Creig Hoyt, Department of Ophthalmology, University of California Medical Center, San Francisco).

NF-1. All dermatological abnormalities may appear well before any neurological signs or symptoms occur.

Lisch nodules are iridic melanocytic hamartomas that are age dependent and are found in 10% of patients younger than 6 years of age, 50% of patients younger than 30 years old, and in virtually all affected patients by the age of 50 years (Fig. 32-4).³⁴ Optic gliomas, reported in 15% to 20% of patients, can present with decreased visual acuity or visual field defects. These tumors can involve the optic chiasm and hypothalamus and rarely become manifest as the diencephalic syndrome of infancy. There is some controversy about the nature of the tumor, but optic gliomas of childhood are probably congenital, indolent, and slowly growing hamartomas.^{35,36} Congenital glaucoma may also be a complication of NF-1 and is sometimes associated with neurofibromas of the superior eyelid.

Neural tumors, or neurofibromas, can involve any nerve from the dorsal root ganglia to the terminal twigs of the

Figure 32-5. An older teenage patient with numerous neurofibromas (short arrow) as well as multiple lesions typical of fibroma molluscum (long arrow).

Figure 32-6. An 8-year-old girl with a large plexiform neuroma affecting her left shoulder and arm. Note the enlargement of the left superior thorax and areola.

peripheral nerves, and any organ can be involved. Peripheral neurofibromas vary in size and occur more frequently on the trunk than on the limbs (Fig. 32-5). Plexiform neuromas are composed of an overgrowth of neural elements of tumor and connective tissue that infiltrates normal tissue. These larger tumors can be superficial, affecting the skin and subcutaneous tissue, or deep, affecting visceral and adjacent tissues (Fig. 32-6). Intracranial tumors occurring in NF-1 are primarily meningiomas and gliomas. There is an increased incidence of optic gliomas and neurofibromas in these patients, and schwannomas may also occur and may involve other cranial nerves. Intraspinous tumors can be present and are sometimes accompanied by spinal cord anomalies. Although most tumors in this

disorder are benign, some neurofibromas may undergo malignant transformation.

The diagnostic criteria for NF-2 require one or more of the following: bilateral cranial nerve VIII masses; a parent, sibling, or child with NF-2; and either a unilateral cranial nerve VIII mass or any two of the following—neurofibroma, meningioma, glioma, schwannoma, or juvenile posterior subcapsular lenticular opacity. Bilateral acoustic neuromas become manifest in more than 95% of affected individuals. Symptoms of acoustic neuromas are usually referable to pressure on the vestibulocochlear and facial nerves, and patients may complain of tinnitus, buzzing, or background noise in the head. Alternatively, the initial symptom may be unilateral loss of hearing, which is noticed when the patient uses the telephone. Typically, symptoms begin in the second or third decade, but patients may become symptomatic in the first decade or as late as the ninth. Other features of NF-2 include café au lait spots and neurofibromas, although these are less commonly observed than in patients with NF-1. Presenile lens opacities or subcapsular cataracts have been found in nearly 50% of patients and may precede the symptoms of acoustic neuromas. Patients with NF-2 may have Schwann cell tumors of other cranial nerves or spinal roots, and meningiomas, astrocytomas, and ependymomas may present in the same patient. Optic gliomas, astrocytomas, and hamartomas are usually not found in this form of NF.

Associated features of NF include mental retardation or seizures. In a controlled study of 81 children affected with NF-1 compared with 49 unaffected siblings, 81% of children with NF-1 had moderate to severe impairment in several areas of cognition. Fifty percent of affected children performed poorly in reading, spelling, and mathematics. Evidence of specific learning disabilities was demonstrated in 20% of children, and 38% had attentional deficit hyperkinetic syndrome.³⁷ Occlusive cerebrovascular disease, although rare, can sometimes be demonstrated by angiography, which shows occlusive changes of the supraclinoid segment of the internal carotid artery associated with the telangiectasiae characteristic of moyamoya disease.

Macrocephaly and short stature are reported in 10% to 40% of NF patients, and a variety of bony changes may also be present, including “ballooning” of the middle fossa, an enlarged or J-shaped sella, and dysplastic changes of the sphenoid. Patients with optic gliomas may have enlarged optic foramina, and bony defects of the orbit and other cranial bones are not uncommon. Scoliosis has been reported in 10% to 40% of patients and usually becomes manifest after the age of 6 years. Anterior meningocele, kyphosis, enlarged intervertebral foramina, bowing of the tibia and fibula, and bony overgrowth occur. Precocious puberty may occur in NF-1 patients with gliomas or hamartomas of the hypothalamus.

NF may be associated with a number of other neoplastic processes with a more than random frequency. These include leukemia, Wilms’ tumor, neuroblastoma, multiple endocrine neoplasias, and pheochromocytoma. Of patients with pheochromocytomas, 4% to 23% are reported to have neurofibromatosis, whereas fewer than 1% have pheochromocytomas. Hypertension may also result from intimal proliferation and fibromuscular changes of the media of the small renal arteries or from a pheochromocytoma.

DIFFERENTIAL DIAGNOSIS. The differential diagnosis of NF-1 is limited to the presence of a family history of the disease and the typical neurological and dermatological findings. NF-2 should be distinguished from sporadic, unilateral acoustic neuroma (SUAN). NF-2 usually presents prior to 40 years of age and is distinguished by the presence of brain and spinal tumors, café au lait spots, fibromas, and posterior capsular lens opacities. In contrast, SUAN presents after 40 years and has no associated findings.

EVALUATION. The diagnostic tests used in patients with NF should be determined by the findings in the clinical examination because most studies will not be valuable in the asymptomatic NF patient. MRI can be useful in the evaluation of patients with possible intracranial, extracranial, and nerve root neoplasms. This neuroimaging study may also demonstrate incidental “bright areas” in patients with NF-1 that are consistent with “hamartomas” that may represent focal areas of heterotopic or dysplastic tissue. These focal areas of increased signal intensity on T2-weighted images are not associated with vasogenic edema and are primarily seen in the basal ganglia, internal capsule, midbrain, cerebellum, and subcortical white matter. They are not visualized on contrast-enhanced CT. MRI findings suggestive of gliomas include the presence of vasogenic edema, mass effect, cavitation, enhancement with gadolinium, and decreased signal intensity on T1-weighted images. When optic nerve gliomas are suspected, MRI with fat suppression techniques is a useful adjunctive study. The spine of a patient with NF-1 should also be imaged with MRI if there are symptoms or signs of intraspinal or nerve root compression. Isolated neurofibromas may involve the neural foramina and spinal canal, forming the so-called dumbbell tumor. Neoplasms involving the spinal canal and cord are best demonstrated with the use of gadolinium.

Patients who are at high risk for NF-2 should undergo MRI with gadolinium of the head, paying special attention to the cerebellopontine angle and internal acoustic meatus. Careful ophthalmic assessment should be performed to document the presence or absence of posterior capsular lenticular opacities and papilledema. Tests of vestibular and auditory function as well as brain stem auditory evoked potentials should be considered in the evaluation of these patients.

If symptoms suggest the presence of a pheochromocytoma, abdominal and mediastinal imaging should be performed, and neurotransmitter metabolites should be measured. Patients who are having problems with academic achievement should undergo neuropsychological studies to detect the presence and nature of any specific learning disabilities.

MANAGEMENT. Treatment of patients with NF is supportive and symptomatic. Patients with specific learning disabilities should receive the benefit of special education programs. Patients with seizures should be treated with standard antiepileptic agents. Peripheral neurofibromas are generally indolent and do not require surgical removal unless they are subjected to repeated trauma and abrasion or show rapid growth. Plexiform neuromas may be removed for strictly cosmetic reasons. Intracranial and intraspinal tumors should be treated with neurosurgical intervention, irradiation, or chemotherapy when appropriate. Most

investigators suggest managing optic gliomas conservatively, with serial MRI scans and visual field and acuity examinations, rather than by immediate surgery or chemotherapy.^{35,36} The clinical course of patients with NF-2 may be relatively benign, and indications for acoustic neuroma surgery must be made on an individual basis. The presence of an acoustic neuroma does not inevitably lead to deafness and facial disfigurement; moreover, surgery in the region of the cerebellopontine angle is not without risk. Partial removal may be appropriate to preserve useful hearing in some cases. Counseling should address the issues of prognosis, genetics, and psychological and social adjustment.

PROGNOSIS. Neurofibromatosis is a progressive disorder that requires continuous surveillance. The overall prognosis is determined by the location, number, and severity of the tumors that are present. It is important to note that most patients with the disease retain good function.

Tuberous Sclerosis

PATHOGENESIS AND PATHOPHYSIOLOGY. Tuberous sclerosis, or tuberous sclerosis complex (TSC), is inherited as an autosomal dominant trait. The TSC is the result of mutation of two genes, namely TSC 1, which is cloned from human chromosome 9, and TSC 2, which is cloned from chromosome 16. The TSC 1 and TSC 2 encoded proteins have been named *hamartin* and *tuberin*, respectively.³⁸ Other cases have been attributed to a gene mutation. Although the genetic basis of the disease has been established, the pathogenesis remains unknown. The lesions involve cells derived from the ectoderm and mesoderm, and the cellular elements demonstrate abnormalities in number and size.

EPIDEMIOLOGY AND RISK FACTORS. Tuberous sclerosis has been identified in all races in all areas of the world. Both sexes are equally affected, and heredity is evident in 50% of cases. Prevalence is estimated at 1 in 50,000 to 1 in 300,000 people. This disorder accounts for nearly 1% of the institutionalized population in the United States and for 0.3% of patients with epilepsy.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Although Bourneville^{39,40} is credited with the first description of the disease, probably von Recklinghausen described it initially. Bourneville believed that the cerebral “scleroses” and renal tumors were associated findings, but he failed to recognize the importance of the typical facial skin lesions. Vogt⁴¹ believed that a triad of clinical findings—seizures, mental retardation, and adenoma sebaceum—were characteristic of the disease, but the criteria for diagnosis have been revised (Table 32-3). TSC is characterized by a variety of clinical findings, including seizures; varying degrees of mental subnormality; and dysplastic or neoplastic changes of the skin, nervous system, and other organ systems.

The clinical expression of the disease is dependent on which organs are affected and the extent of their involvement. Seizures, either partial or generalized, are the most common symptom of the disease, and infantile spasms are particularly frequent during the first several years of life. The early onset and severity of the seizure disorder are correlated with the degree of mental abnormality. Mental function is notably variable, however, and approximately one third of patients have normal intelligence. Some patients develop normally during

TABLE 32-3

Diagnostic Criteria for Tuberous Sclerosis Complex (TSC)

| |
|---|
| Primary Features |
| Facial angiofibromas |
| Multiple ungual fibromas |
| Cortical tuber (histologically confirmed) |
| Subependymal nodule or giant cell astrocytoma (histologically confirmed) |
| Multiple calcified subependymal nodules protruding into the ventricle (radiographical evidence) |
| Multiple retinal astrocytomas |
| Secondary Features |
| Affected first-degree relative |
| Cardiac rhabdomyoma (histologic or radiographic evidence) |
| Other retinal hamartomas or achromic patch |
| Cerebral tubers (radiographical confirmation) |
| Noncalcified subependymal nodules (radiographical confirmation) |
| Shagreen patch |
| Forehead plaque |
| Pulmonary lymphangiomyomatosis (histological confirmation) |
| Renal angiomyolipoma (radiographical or histological confirmation) |
| Renal cysts (histological confirmation) |
| Tertiary Features |
| Hypomelanotic macules |
| “Confetti” skin lesions |
| Renal cysts (radiographical evidence) |
| Randomly distributed enamel pits in deciduous or permanent teeth |
| Hamartomatous rectal polyps (histological confirmation) |
| Bone cysts (radiographical evidence) |
| Pulmonary lymphangiomyomatosis (radiographical evidence) |
| Cerebral white matter “migration tracts” or heterotopias (radiographical evidence) |
| Gingival fibromas |
| Hamartoma of other organs (histological confirmation) |
| Infantile spasms |
| Definite TSC |
| One primary feature, two secondary features, or one secondary plus two tertiary features |
| Probable TSC |
| Either one secondary plus one tertiary feature or three tertiary features |
| Suspect TSC |
| Either one secondary feature or two tertiary features |

their early years only to experience a deterioration in mental function in the latter part of the first decade.

The most common skin lesion is the hypopigmented macule, which is found in approximately 90% of patients.⁴² According to Fitzpatrick,⁴³ the most frequent shape is the polygonal or “thumb-print” lesion, followed by the “ash leaf” spot and, finally, groups of multiple “confetti-like” hypopigmented macules (Fig. 32-7). Adenoma sebaceum, which is an angiofibromatous lesion, had been generally considered the most common skin change in tuberous sclerosis, but the lesions occur in only 50% of patients (Fig. 32-8). The lesions appear in patches or in a butterfly distribution about the nose, cheeks, and chin. They are rarely apparent at birth, usually first observed between the ages of 1 and 4 years, and tend to enlarge over time. Other skin changes include the “shagreen” patch (a “leathery” plaque), which is usually found over the lumbosacral or gluteal region; café au lait spots; fibromas; and angiomas. Subungual or periungual fibromas (Koenen

Figure 32-7. A typical ash leaf-shaped area of hypopigmentation (arrows) found in most patients with tuberous sclerosis.

Figure 32-8. Adenoma sebaceum occurs as angiofibromatous lesions about the nose. The nasolabial folds and chin were also involved.

tumors) are found in approximately 20% of patients and affect the toes more commonly than the fingers. These lesions are usually first noted during adolescence. Gingival fibromas can also occur, as well as pitting of the dental enamel.

Retinal tumors, which seldom affect vision, can occur and are thought to be astrocytic hamartomas. They are nodular or mulberry-like in configuration and may be solitary or multiple; they tend to calcify. Other associated ocular findings include retinal gray-yellow glial patches, and iridic hypomelanotic spots, cataracts, and colobomas of the iris, lens, and choroid. Renal tumors occur in approximately half of patients with TSC and are primarily renal cysts or renal angiomyolipomas. These tumors can occur separately or in combination, and they are typically multiple, involving both kidneys. Although they can be symptomatic because of renal enlargement, they are usually indolent. Angiomyolipomas are also thought to be benign, yet they may result in hemorrhage and can cause serious morbidity or mortality.⁴⁴ Early onset and severe hypertension can occur in patients with numerous renal cysts, and it has been suggested that patients with TSC have an increased risk of renal cell carcinoma. Cardiac rhabdomyomas are

present in approximately half of patients and can be solitary, multiple, or infiltrative, diffusely affecting the myocardium. Newer techniques of echocardiography have facilitated early recognition of this tumor.

The lungs can also be affected in patients with TSC; they demonstrate multicystic lesions that have been shown to be similar pathologically to lymphangiomyomatosis. Pulmonary abnormalities occur almost entirely in females, presenting as dyspnea, spontaneous pneumothorax, and pulmonary hypertension. Endocrine abnormalities have also been reported.

DIFFERENTIAL DIAGNOSIS. The clinical features of TSC just described are characteristic, and although other neurocutaneous syndromes may have some similar features, it is rarely difficult to make the correct diagnosis. Infants who show developmental delay and intracranial calcifications and seizures should be evaluated for the possible presence of intrauterine infections such as toxoplasmosis and cytomegalovirus.

EVALUATION. Visualization of these hypomelanotic macules is enhanced by using a Wood light because melanin absorbs light of that frequency (360 nm), and areas deficient in melanin are visually accentuated.^{42,43} Imaging studies of affected patients can be effectively used to assist in diagnosis. Intracranial calcifications, commonly found in the region of the foramen of Monro or the periventricular region, are present in approximately 60% of skull radiographs in these patients. CT may demonstrate cerebral hamartomas, subependymal nodules, ventriculomegaly, and areas of demyelination. The calcified subependymal nodule (the tuber) is the most reliable finding on CT head scans, but periventricular calcifications can also be observed in patients with toxoplasmosis, cytomegalic inclusion disease, and Fahr's syndrome.⁴⁵ MRI demonstrates with greater specificity not only the uncalcified subependymal nodules but also the distortion of the normal cerebral cytoarchitecture.⁴⁶

Other characteristic radiographic abnormalities include cystic changes of the phalanges and metacarpals, sclerotic areas in the long bones, and areas of increased or decreased bone density in the skull. Renal changes can be demonstrated by CT, MRI, or renal angiography, and the presence of a cardiac tumor is readily demonstrated by echocardiography. Patients with rare pulmonary involvement show a fine reticular infiltrate or multicystic changes on chest radiographs. EEG and examination of the cerebrospinal fluid are of little help in establishing the diagnosis.

The tubers can be located anywhere in the cerebral hemisphere but are commonly found in the cortical gyri. Smaller nodules can be located in the region of the sulcus terminalis or the basal ganglia, protruding into the ventricle. Those tubers situated in the region of the foramen of Monro or the aqueduct of Sylvius may become large enough to obstruct the normal flow of cerebrospinal fluid, resulting in hydrocephalus. The tuber is characterized pathologically by a decreased number of neurons with large, bizarre, and sometimes vacuolated "monster" neurons. A proliferation of fibrillary astrocytes, areas of demyelination, and abnormalities of cortical cytoarchitectonics are seen. Some vessel walls may show hyaline degeneration. The subependymal nodules are fibrocellular with round or oval cells and whorls of fibrillary glial tissue. Calcium

and amyloid deposits may be present within the tuber or the subependymal nodule; cerebellar calcification rarely occurs.

MANAGEMENT. Convulsive disorders are treated by the administration of standard anticonvulsant medications; however, control cannot be ensured. The individual TSC patient with recurrent partial seizures may experience some improvement with the excision of carefully identified epileptogenic foci. No specific treatment is available for the angiofibromatous lesions of adenoma sebaceum. They may be surgically removed if subject to repeated irritation or trauma, as is true of lesions obstructing the nares. Patients with TSC must not only receive careful medical management but also should be evaluated and followed by social workers and psychologists. Genetic counseling for the family is mandatory.

Von Hippel-Lindau Disease

Von Hippel-Lindau disease, which is inherited as an autosomal dominant trait, is characterized by hemangioblastomas of the retina and cerebellum. Von Hippel thought the retinal lesion was a hemangioblastoma, but he labeled it *angiomatosis retinae*.⁴⁷ Lindau first recognized the association between the retinal and cerebellar hemangioblastomas; moreover, he was aware that patients could have other lesions, including spinal cord angiomas and cystic tumors of the pancreas, liver, and epididymis.⁴⁸ Linkage analysis has localized the gene defect to chromosome 3p25–26.^{49,50} Additional findings include cysts of the pancreas, liver, and spleen as well as renal tumors. Compared with other neurocutaneous disorders, skin lesions are not associated with the disease.⁵¹

The retinal hemangioblastoma is one of the earliest manifestations of the disease, and although it is reported to occur in childhood, it is usually found during or after the third decade. Aneurysmal dilation of the peripheral retinal vessels appears to be the earliest characteristic feature of the lesion, but, later, tortuous vessels marked by an afferent arteriole and venule leading to a raised retinal lesion appear (Fig. 32-9). Some retinal lesions are small and easily overlooked. The retinal abnormalities have been divided into three stages: first, a pinkish red vascular lesion found in the midperipheral retina with visible “feeder”

Figure 32-9. A typical elevated, round whitish-red retinal lesion as observed in von Hippel-Lindau disease. Note the tortuous artery-vein pair coursing toward the lesion.

vessels and variable exudate; second, a pale gray lesion in which the feeder vessels can be observed on fluorescein retinal angiography; and third, retinal vascular lesions that are similar to diabetic microaneurysms but have no retinal vascular connections. These peripheral retinal lesions may not result in any visual impairment; however, if the lesion involves the macula or optic disc, progressive visual loss can occur.

The diagnosis of a cerebellar hemangioblastoma is usually made during the third or fourth decade, but there are reports of its occurrence before puberty. The presenting signs and symptoms are those of cerebellar dysfunction and increased intracranial pressure. These tumors may also involve the medulla and spinal cord, and approximately 80% of patients have an associated syringomyelia. Supratentorial hemangioblastomas, although uncommon, have been reported in the region of the pituitary gland and the third ventricle as well as the cerebral hemispheres.

Associated renal lesions are found in von Hippel-Lindau disease and include benign cysts, angiomas, and hypernephromas, which are common and are a significant cause of morbidity and mortality in the disease. Benign cysts may also be found in the pancreas, adrenal gland, and epididymis; they are usually asymptomatic. There is an increased frequency of pheochromocytomas in patients with von Hippel-Lindau disease.⁵² Retinal hemangioblastomas are recognized by careful ophthalmoscopy, and fluorescein angiography can show the vascular characteristics of the lesion. CT and MRI demonstrate the lesions of the cerebellum and spinal cord. The intra-abdominal lesions are shown by abdominal CT and ultrasonography.

Some retinal lesions are recognized because of visual impairment and retinal detachment. Obliteration of these lesions has been accomplished with cryocoagulation or photocoagulation. Cerebellar hemangioblastomas are removed surgically in approximately 90% of patients, who have a risk of recurrence of approximately 15%. Small renal tumors should be judiciously removed because the presence of multiple tumors is a possibility. In patients with cystic renal disease, nephrectomy should be considered, followed by dialysis.

Autosomal Recessive Disease

Ataxia-Telangiectasia

Syllaba and Henner⁵³ first reported three adolescent patients with progressive choreoathetosis and ocular telangiectasia in 1926, but it was not until 1964 that Martin⁵⁴ recognized their clinical description as ataxia-telangiectasia (AT). A report in 1941 by Louis-Bar described a young boy with progressive cerebellar ataxia and extensive cutaneous telangiectasias; she identified the syndrome as one of the phakomatoses.³⁰ After the 1958 descriptions by Bean,⁵⁵ Boder and Sedgwick,^{56,57} and Centerwall and Miller,⁵⁸ AT became recognized as a distinct disease, and multiple reports appeared in the literature.

AT is an autosomal recessive disorder characterized by a constellation of signs and symptoms associated with progressive cerebellar dysfunction, conjunctival and cutaneous telangiectasias, severe immune deficiencies, premature aging, and a predisposition to cancer.⁵⁹ AT is inherited as

a single mendelian locus on chromosome 11q22–23. Studies have identified the mutated gene in AT, and its identification provides answers to the link between the mutated gene product in AT and the signaling pathways that regulate the cell cycle.⁶⁰ In the normal cell cycle, surveillance checkpoints are used to arrest cells during the cell cycle, allowing either completion of certain events that are required at that point or repair of damage. During these delay periods, damaged DNA can be repaired so that subsequent cycles can occur normally.⁶¹ Clinical and laboratory work has suggested that the AT gene product is involved in maintaining the integrity of chromosomal DNA and in signal transduction mechanisms that operate to regulate the cell cycle or DNA repair. The exact biochemical roles of the gene product in these processes, however, remain unknown.

AT occurs equally among the sexes and is reported in all races and in all areas of the world. The prevalence of this disorder ranges from 1 in 40,000 to 100,000 births. Although AT is a multisystem disorder, progressive neurological deterioration is the hallmark of the syndrome. The early neurological features of AT are characterized by signs indicative of a progressive cerebellar degeneration, including ataxia and dysarthric speech. Ataxia is manifested by a swaying of the head and trunk and becomes apparent soon after affected children begin to walk. It progresses and becomes severe enough to warrant the use of a wheelchair by 10 to 15 years of age. By this time, dys-synergia and intention tremor of the extremities interfere with normal activity. Speech is initiated slowly and slurred, and words are articulated poorly. Choreoathetosis can be present in older children and can even mask the ataxia. Myoclonic jerks, rigidity, dystonic posturing, muscular hypotonia, drooling, and arrest of cognitive development are also typical. These patients also have characteristic facies, described as relaxed, dull, sad, and inattentive when unstimulated. The examination also reveals oculomotor abnormalities, including slowly initiated voluntary horizontal movements of conjugate gaze with nystagmus-like jerks with fixation and refixation. The deep tendon reflexes are diminished, the plantar response is flexor, Romberg's sign is absent, and deep and superficial sensation is normal. Later neurological features may be dominated by spinal cord dysfunction, including abnormalities of position and vibratory sensation. Other patients demonstrate neuromuscular deficits with diffuse weakness, muscle atrophy, fasciculations, and absent tendon reflexes with intact sensory findings. Finally, in some patients there is a more mixed clinical picture including abnormalities of both sensory and motor function.

Non-neurological features vary and include vasculocutaneous, immunological, and neoplastic manifestations. The characteristic telangiectasias usually appear later than ataxia, typically at approximately 3 to 6 years of age in the region of the conjunctival angles of the eye (Fig 32-10). Once present, they steadily progress and spread in a symmetrical pattern across the exposed portion of the bulbar conjunctivae. These telangiectasias are bright red horizontal streaks that cause the eyes to look "bloodshot" and eventually involve the rest of the conjunctivae, eyelids, adjoining facial regions, external ears, neck, and antecubital and popliteal spaces. Rarely, the telangiectasias may

Figure 32-10. Note the typical conjunctival telangiectasias as observed in ataxia-telangiectasia disease.

be present on the dorsum of the hands and feet and on the mucosal surfaces of the palate. These abnormal vessels are not symptomatic and appear to be of venous origin, branching from subpapillary venous plexuses in the skin and dilated connecting venules in the conjunctivae.

Patients with AT also demonstrate progeric changes of the hair and skin, including early graying of the hair and atrophic, hidebound facial skin. Pigmentary changes are also frequent and consist of hyperpigmentation and hypopigmentation with cutaneous atrophy. A few patients may demonstrate partial albinism, vitiligo, and café au lait spots. Seborrheic dermatitis occurs in nearly all patients, and senile keratoses, atopic dermatitis, and eczema are also reported. Another prominent feature of AT is frequent sinopulmonary infections. These may range from infection of the ears, nose, and sinuses to chronic bronchitis and recurrent pneumonia. The latter two may result in bronchiectasis and pulmonary fibrosis. Chronic infections are typically due to common bacteria; however, they are sometimes poorly responsive to antibiotic therapy. The predisposition to infection is associated with the presence of an abnormal thymus and a marked deficiency of IgA, which is the predominant immunoglobulin in respiratory secretions. Neoplasms occur in an estimated 10% to 15% of patients with AT and are second only to pulmonary disorders as a cause of death. The most common neoplasms include Hodgkin's disease, malignant lymphomas, reticulum cell sarcoma, and histiocytosarcomas. Various other tumors have been associated with AT, including medulloblastoma, basal cell carcinoma, acute lymphocytic leukemia, and gliomas. These patients also have retarded somatic growth with dwarfing and various skeletal disorders. Endocrine abnormalities are also prominent, and female hypogonadism with sexual infantilism is found consistently. Male hypogonadism also occurs but is less prominent and is characterized by a delay in puberty, incomplete spermatogenesis, and decreased Leydig cells. Other studies report an unusual type of diabetes mellitus that appears in late adolescence as well as anterior lobe pituitary abnormalities.

The laboratory evaluation of patients with AT reveals normal results on routine studies of the urine, blood (except for lymphopenia), and spinal fluid. Although glucose

studies may reveal evidence of an insulin-resistant diabetes mellitus, thyroid function studies are normal. Elevations in serum α -fetoprotein and plasma carcinoembryonic antigen are typically, but not invariably, present and are not required diagnostic criteria. Humoral or cellular immunological defects are also helpful in the diagnosis of AT, including low or absent levels of IgA, IgG2, and IgE, yet these are not invariable. Plain films of the skull may show decreased or absent nasopharyngeal adenoidal tissue, and CT and MRI studies of the head show cerebellar atrophy. Muscle and nerve biopsies may reveal evidence of denervation atrophy and axonal degeneration, respectively.

Treatment of patients with AT is supportive and includes treatment of infections and the use of sunscreens to retard the cutaneous progeric changes. Early institution of pulmonary physiotherapy and physical therapy is important. Prenatal diagnosis is possible through the measurement of α -fetoprotein levels in amniotic fluid and the documentation of increased spontaneous chromosomal breakage of amniotic cell DNA.

Unknown Inheritance Patterns

Sturge-Weber Syndrome

Sturge⁶² is credited with the first report of this syndrome, which appeared in a 6-year-old girl who had a facial angioma, buphthalmos, and contralateral partial seizures. Sturge surmised that she had an underlying cerebral angioma, but it was not until 18 years later that a cerebral angioma affecting the leptomeninges of these patients was first described. Weber reported the presence of intracranial calcifications in skull radiographs of these patients, Dimitri noted double serpentine calcifications, and Krabbe correctly pointed out that the calcifications were located primarily in the cerebral substance rather than in the vessel walls. Van der Hoeve believed that this syndrome was the “fourth phakomatosis.”

Sturge-Weber syndrome (SWS) is characterized by a congenital facial angioma (nevus flammeus, port-wine stain) that is associated with signs and symptoms of an ipsilateral leptomeningeal angioma. The facial angioma is usually unilateral, although it can be bilateral, and involves at least the upper face, superior eyelid, or periorbital region (Fig. 32-11). Angiomas can also occur in other areas of the head, including the nasopharynx, palate, lips, gingiva, and tongue, as well as the neck, trunk, and extremities. The facial angioma conforms to the sensory divisions of the trigeminal nerve, but its configuration may be determined by the embryological facial development. Leptomeningeal angiomas can also occur in the absence of any facial angioma. In this case, although the signs are similar to those of SWS, the patients should be considered to have a different disorder referred to as leptomeningeal angiomatosis. SWS has no known recognized pattern of inheritance, but there is one report of a father and son who had facial angiomas and glaucoma.

Most patients with SWS have seizures, often beginning in infancy, that are primarily partial motor seizures, but some patients have secondary generalization. Other seizure types, such as myoclonic, tonic, and atonic seizures as well as infantile spasms, can occur less frequently. Earlier

Figure 32-11. A 14-month-old male with a facial angioma (“port-wine stain”) involving the upper face primarily in the distribution of the ophthalmic division of the left cranial nerve V. In addition, he had glaucoma of the left eye.

studies noted a seizure frequency of 70% to 90%. In a retrospective study of 102 patients, 88 patients had a leptomeningeal angioma affecting one cerebral hemisphere, and 14 patients had bilateral hemispheric involvement. Seizures occurred in 75% of these patients. Among the patients with unilateral involvement, 63 had seizures, with a mean age of seizure onset of 24 months. Thirteen of the 14 patients with bilateral involvement had seizures, with a mean age of onset of 6 months.⁶³

At least half of patients with SWS are mentally subnormal, and behavioral problems are common. As seizures of early onset increase in frequency and severity, mental function and behavior often regress. In the retrospective study noted previously, 25 of 88 patients with unihemispheric leptomeningeal involvement who did not have seizures were of average intelligence; 1 of 14 patients with bilateral hemispheric involvement was unaffected by seizures, and that patient was of average intelligence. Others have documented that SWS patients with seizures have a notably higher incidence of developmental delay and emotional and behavioral problems, and these patients need special education. These observations are important considerations in patient management. Hemisensory deficits can occur but are sometimes difficult to document reliably in very young and mentally subnormal patients. Homonymous hemianopia has been noted in approximately one third of patients, and glaucoma secondary to choroidal angioma is found in one-fourth. Other ocular abnormalities include iridic heterochromia in which the hyperpigmented iris is ipsilateral to the facial angioma, optic atrophy, and strabismus.

Electroencephalographic studies often show decreased amplitude and frequency of electrocerebral activity overlying the affected hemisphere. Other commonly noted abnormal EEG features include multiple and independent spike foci. Intracranial calcifications on skull radiographs are present in approximately 90% of patients, are usually found in the occipital or parieto-occipital region, and have a serpentine linear, parallel configuration (“tram sign”). They are rarely observed on plain skull radiographs during infancy but are present in most patients by the end of the second decade. CT of the head demonstrates intracerebral calcifications and cerebral atrophy more readily than do

plain skull radiographs, and it has documented calcific deposits during the first few months of life. MRI, however, is the neuroimaging study of choice to show the extent of structural abnormalities of SWS.

Cerebral angiography demonstrates decreased cerebral venous drainage and dilation of the deep cerebral veins.^{64,65} A variety of vascular abnormalities, including thrombotic lesions, dural venous sinus abnormalities, and arteriovenous malformations, have been observed in approximately one third of patients. Positron emission tomography (PET) can provide some measure of cerebral metabolic impairment, and serial PET scans can demonstrate the progression of the disease process.^{66,67} Moreover, PET scans can provide important information that can be used to guide careful selection of patients for focal cortical resection or hemispherectomy. Single-photon emission computed tomography can also reveal useful information about cerebral perfusion.

Characteristic pathological features of SWS include thickened hypervascularized leptomeninges, which primarily affect the occipital, parietal, or temporo-occipital lobes. Meningeal vessels are small and tortuous, producing a dark, purplish blue color. These abnormal vessels rarely enter the underlying atrophic cerebral hemisphere. Calcific deposits are primarily located in the molecular and outer pyramidal cortical layers, but small calcific spicules can be found in some small cerebral vessels. The pathogenesis of calcium deposition in the brain substance is not well understood.

Management of patients with SWS requires careful attention not only to the patient's neurological deficits but also to the associated behavioral and emotional problems. Convulsive disorders are treated by administration of standard antiepileptic drugs, but seizures in some patients may be refractory to medical management. These patients should be considered for focal cerebral resection of the affected lobes or hemispherectomy.⁶⁸⁻⁷⁰ Management of the associated problems of mentally subnormal patients or those with behavioral or emotional disturbances requires the skills not only of the physician but also of competent psychologists and social workers.

INTRODUCTION AND GENERAL DIAGNOSTIC CONSIDERATIONS

The term dementia has an intellectually constricting effect on differential diagnostic considerations and should be applied with care. A confused elderly person seen for the first time might be described as demented but may in fact be confused because of toxicity from a narcotic analgesic received postoperatively. A more generic term that is less diagnostically constricting is encephalopathy. Encephalopathy can be acute, subacute, or chronic, and there are reversible and irreversible etiologies. Dementia is a type (or types) of chronic encephalopathy that can have many causes, including irreversible degenerative and potentially reversible nondegenerative causes.

The most important diagnostic step in evaluating dementias is to determine whether a chronic encephalopathy results from a degenerative or other potentially reversible cause. Clues may exist at any level of the diagnostic ladder, although typically only a subset of clues is found in any one patient. Historical clues suggesting a reversible process include fluctuating severity, altered level of consciousness or hypersomnolence, and visual hallucinations (although fluctuating severity and visual hallucinations are also typical in dementia with Lewy bodies, which is a degenerative disease). Clues on mental status testing include finding the patient to be inattentive, disoriented, and somnolent but not particularly amnesic. Clues on physical examination include a variety of findings that may be common in elderly patients but are not part of the typical picture of Alzheimer's disease, such as ataxia, hyper-reflexia, and tremulousness.

Laboratory evaluation should be directed toward common medical ailments, and a reasonably recent complete physical evaluation should be available or obtained in all patients suspected of having a significant brain-related disease. Practice parameters from the American Academy of Neurology for the diagnosis of dementia specify thyroid function studies and serum vitamin B₁₂ levels be performed.¹ Serological tests for syphilis should be considered in the appropriate medical setting, but this is no longer routinely recommended. All patients being evaluated for

dementia should undergo structural neuroimaging with computed tomography (CT) or magnetic resonance imaging (MRI) of the brain.¹ When a nondegenerative-based chronic progressive encephalopathy is suspected, electroencephalography (EEG) may be helpful in demonstrating severe dysrhythmic slowing. Cerebrospinal fluid (CSF) examination may show evidence of a chronic meningoencephalitic process such as an elevated IgG index and synthesis rate, and occasionally oligoclonal bands, suggesting an intrathecal inflammatory reaction. Autoimmune and paraneoplastic serologies may be helpful in such patients as well. Ultimately, if suspicion remains high based on noninvasive tests for a nondegenerative cause, cerebral angiography and meningeal and brain biopsy can be considered, or in the absence of such invasive testing, an empirical therapeutic trial of prednisone could be considered for a possible steroid-responsive inflammatory meningoencephalitis. In short, encephalopathy is a serious condition that warrants a thorough diagnostic and therapeutic approach.

If a degenerative disease is ultimately diagnosed, then it must be realized that an incurable, invariably progressive, and ultimately fatal condition has been diagnosed.

Chronic progressive encephalopathies can be divided into potentially reversible and irreversible diseases. More important than remembering a few specific diseases is to keep pathophysiological categories in mind. Some reversible causes of subacute and chronic widespread progressive encephalopathy include the following:

1. Inflammatory: nonvasculitic autoimmune inflammatory meningoencephalitis (NAIM), sarcoidosis, primary and secondary central nervous system (CNS) vasculitides, CNS complications of systemic lupus erythematosus, and paraneoplastic limbic encephalitis
2. Infectious: chronic meningitis due to fungi, tuberculosis, *Listeria monocytogenes*, Lyme disease, syphilis, and CNS Whipple's disease
3. Nutritional: vitamin B₁₂ deficiency
4. Toxic: drugs (particularly prescription medications)
5. Mass lesion: subdural hematoma, communicating (normal pressure) hydrocephalus, meningioma, and other tumors
6. Complex partial status epilepticus

Some irreversible causes of chronic widespread progressive encephalopathy include the following:

1. Degenerative: Alzheimer's disease, frontotemporal lobar degeneration (FTLD), dementia with Lewy bodies (DLB), progressive supranuclear palsy (PSP), Huntington's disease (HD), and Parkinson's disease (PD)
2. Vascular: vascular dementia, disseminated intravascular coagulation, and cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy
3. Metabolic: storage diseases and leukodystrophies
4. Neoplastic: meningeal metastases and gliomatosis cerebri

With this perspective in mind, this chapter considers the subset of irreversible causes of chronic progressive encephalopathies referred to as neurodegenerative dementing diseases, which affect adults. Previous classification schemes (including our own previous editions of this chapter) have relied on the presence of clinical features that are traditionally regarded as cortical (e.g., aphasia) or subcortical (e.g., psychomotor slowing) and so categorized dementias into three broad categories: cortical, subcortical, and mixed. Essentially all neurodegenerative dementias have both cortical and subcortical pathology, but those that primarily target the cerebral cortex are clinically distinguishable from those that primarily target subcortical structures, so the distinction had both heuristic and practical value. However, progress in many different areas, including genetic, imaging, pathophysiologic, and clinical, has led us to the current point where a revision in our classification scheme is appropriate, and so will now include the three broad categories of Alzheimer's disease, parkinsonism with dementia (and related disorders), and the tauopathies. Undoubtedly, with further progress, there will be more to come.

ALZHEIMER'S DISEASE

The terms Alzheimer's disease (AD) and Alzheimer's dementia are related but not synonymous. AD is the pathologically defined disease process that ultimately results in the clinical syndrome of Alzheimer's dementia. Alzheimer's dementia has a characteristic cognitive pattern that includes specific cognitive domains and consequent disability. Early in a patient's course, AD may cause nondisabling memory loss described as "mild cognitive impairment" rather than dementia. Other patients with AD may have a pattern of cognitive or somatic deficits (e.g., progressive aphasia or progressive apraxia) that are uncharacteristic of Alzheimer's dementia and instead may mimic another degenerative dementia. Most often, however, AD causes Alzheimer's dementia.

PATHOGENESIS AND PATHOPHYSIOLOGY. AD is characterized by generalized cerebral cortical atrophy (Fig. 33-1) with widespread cortical neuritic (or senile) plaques (NPs) and neurofibrillary tangles (NFTs) (Fig. 33-2). Other typical pathological findings include neuropil threads, granulovacuolar degeneration, lipochrome accumulation, and Hirano bodies. NPs are composed of an amyloid core surrounded by dystrophic neurites, whereas

Figure 33-1. Alzheimer's disease. Note the generalized cerebral cortical atrophy. (Courtesy of J. E. Parisi, Mayo Clinic, Rochester, MN.)

Figure 33-2. Photomicrograph of entorhinal cortex in Alzheimer's disease. The neuritic plaque is composed of an amyloid core surrounded by dystrophic neurites. The dark "flame-shaped" fibrillar structures are neurofibrillary tangles, which are mainly composed of paired helical filaments. Each filament is approximately 11 to 24 nm in diameter, and periodic twists occur roughly every 85 to 93 nm (Bielschowsky silver stain, 200 \times). (Ksiezak-Reding H, et al: Ultrastructure and biochemical composition of paired helical filaments in corticobasal degeneration. *Am J Pathol* 1994;145:1496–1508; courtesy of J. E. Parisi, Mayo Clinic, Rochester, MN)

paired helical filaments are the major constituent in NFTs, neuropil threads, and dystrophic neurites. None of these histological findings individually are entirely specific for AD because NPs can be seen in clinically nondemented patients,² and NFTs can occur in other neurodegenerative and prion disorders. The current neuropathological criteria for the diagnosis of AD are based on the frequency of NP and topography of NFT.

Synapse loss appears to be the most important correlate of dementia severity,³ but the number of NPs and NFTs and the density of a β -amyloid load have each been associated with dementia severity. Mesial temporal structures, particularly the hippocampal formation, are involved early in AD, and this accounts for the amnesic syndrome in these patients. AD produces a lamina-specific pattern of damage to the entorhinal cortex that disrupts cortical input to the hippocampal formation from association and limbic cortices, and it disrupts hippocampal outflow from the

cornu ammonis (CA) sectors and subiculum to the association cortices, diencephalon, basal forebrain, and amygdala. Hence, AD effectively disconnects the hippocampus from its major input and output pathways.⁴

The plaque core in AD in isolation or occurring with Down's syndrome is composed of insoluble β -amyloid,⁵ and the gene for amyloid precursor protein (APP) has been mapped to chromosome 21. APP is normally expressed in multiple cells of neural and non-neural origin and has several putative cellular functions. APP can be processed by nonamyloidogenic and amyloidogenic pathways. The fragment of APP formed by the latter pathway, termed β -amyloid or $A\beta$, is a soluble secretory product composed of 39 to 43 residues. This pathway may generate $A\beta$ at the cell surface, in the lysosomes, or in the Golgi apparatus, and the precise mechanism of $A\beta$ processing may be cell-type specific.⁶ The form secreted in highest quantity is $A\beta$ 1–40, with lesser amounts being in the $A\beta$ 1–42 form. Each form is secreted in varying amounts in cognitively normal and abnormal individuals, and levels of each can be measured in both plasma and CSF. The insoluble $A\beta$ 1–42 form is contained in plaques. Additional amyloid-associated proteins are believed to interact with $A\beta$, which can also promote amyloid fibril formation and deposition as plaques.

Plaques, in which amyloid deposition is diffuse and distended neurites are absent, have been termed diffuse non-NPs. These plaques are present in nondemented aged and Down's syndrome patients. With the appearance of distended neurites, the plaques are then classified as diffuse NPs. Insoluble amyloid fibrils surrounded by distended neurites constitute a dense-core NP, which is equivalent to the classic NP. A "burnt-out" plaque is a dense core of amyloid without the surrounding distended neurites. The accumulated evidence favors the amyloid cascade hypothesis in the pathogenesis of AD (Fig. 33-3). This hypothesis states that the initial abnormality in AD pathogenesis is amyloid deposition in the neuropil (forming plaques) and cerebral vessels (forming amyloid angiopathy).^{6,7} This deposition is neurotoxic, leading to cytoskeletal derangement with neurofibrillary tangle formation, leading, in turn, to neuronal degeneration. Studies from several laboratories suggest that $A\beta$ 1–42 is the crucial form of $A\beta$ involved in this cascade. $A\beta$ 1–42 has been shown to form insoluble amyloid fibrils faster than $A\beta$ 1–40 in vitro. This form is deposited in the diffuse plaques of Down's syndrome patients far in advance of $A\beta$ 1–40, and this peptide is the primary form of $A\beta$ deposition in the NPs of sporadic AD. Plasma $A\beta$ 1–42 is elevated in approximately 12% of patients, and CSF $A\beta$ 1–42 is reduced in patients with clinically diagnosed AD.⁸ The reduction of $A\beta$ 1–42 presumably reflects diminished clearance and subsequent deposition. It is hoped that interfering with $A\beta$ 1–42 formation or deposition may impact AD pathogenesis.

The six human isoforms of the microtubule-associated protein tau are derived from a single gene on chromosome 17. Tau normally binds to microtubules when dephosphorylated or only partially phosphorylated. Hyperphosphorylated tau is the major component of paired helical filaments, which are the major constituents of neurofibrillary tangles, neuropil threads, and dystrophic neurites. Accumulated paired helical filaments or microtubule destabilization, or

both, may disrupt axonal transport and lead to NFT formation and neuronal death. In AD, tau concentration is elevated in the CSF.⁹

The association between the type 4 allele of apolipoprotein E (ApoE ϵ 4) and late-onset familial^{10,11} and sporadic AD¹¹ was recognized in 1993. An increased risk of developing sporadic AD and a decreased age of onset has been associated with the ApoE ϵ 4 allele, whereas risk decreases and age of onset increases with the ApoE ϵ 2 allele.¹² However, ApoE ϵ 4 does not directly cause AD because it can occur in the absence of even one copy of the ApoE ϵ 4 allele, and two copies of this allele have been documented in cognitively and neuropathologically normal individuals. Disease progression does not appear to be reliably associated with ApoE status.

The mechanism of ApoE's effect on AD susceptibility is not known. ApoE is found in the NPs, vascular amyloid, and NFTs of AD. Amyloid deposition in NPs and blood vessels has correlated with ApoE ϵ 4 dosage (i.e., whether there is one or two copies of the ApoE ϵ 4 allele), whereas the frequency of NFTs has not.¹³ ApoE promotes amyloid filament formation in vitro.¹⁴ ApoE ϵ 3, but not ApoE ϵ 4, binds to microtubule-associated protein tau, which may slow the rate of tau phosphorylation and self-assembly into parhelical filaments. More recently, it has been shown that intracellular degradation of the ϵ 4 isoform generates a toxic carboxyl fragment.¹⁵

There are four types of ApoE receptors in the brain. One type, the low-density lipoprotein receptor-related protein (LRP), is found in hippocampal pyramidal cells and dentate granule cells. It is a highly conserved protein found also in nematodes, and it functions in membrane maintenance. LRP binds and internalizes not only ApoE but also several other ligands, all of which have been associated with NP. LRP internalization of its associated ligands may be impaired in AD, thus resulting in $A\beta$ -ApoE complex aggregation and NP formation.¹⁶ The specific interactions between the various ligands and ApoE isoforms remain to be determined, but the potential may exist for developing therapeutic interventions that manipulate these interactions.

Neuropathological, clinical, and epidemiological studies have supported a role for immunological activation as an intrinsic component of the neurodegenerative process.¹⁷ The number of activated microglia is high in diffuse plaques and higher in diffuse NPs, but there are fewer microglia in more mature plaques with amyloid cores, suggesting that the inflammatory response may have a primary role in the early steps of plaque formation.

Chronic aluminum exposure was once thought to play a role in AD mainly due to encephalopathy occurring in dialysis patients who were exposed to toxic levels of aluminum. The possible mechanisms by which aluminum could lead to AD histopathology include promoting hyperphosphorylation of tau and subsequent formation of NFTs; altering processing of the APP, which would lead to the formation of NPs; and initiating the inflammatory response.¹⁸ However, aluminum exposure is not thought to be a major risk factor for AD.

The oxidative stress hypothesis of neurodegeneration holds that free radical generation from metabolism is neurotoxic, and there is evidence that $A\beta$ may promote free

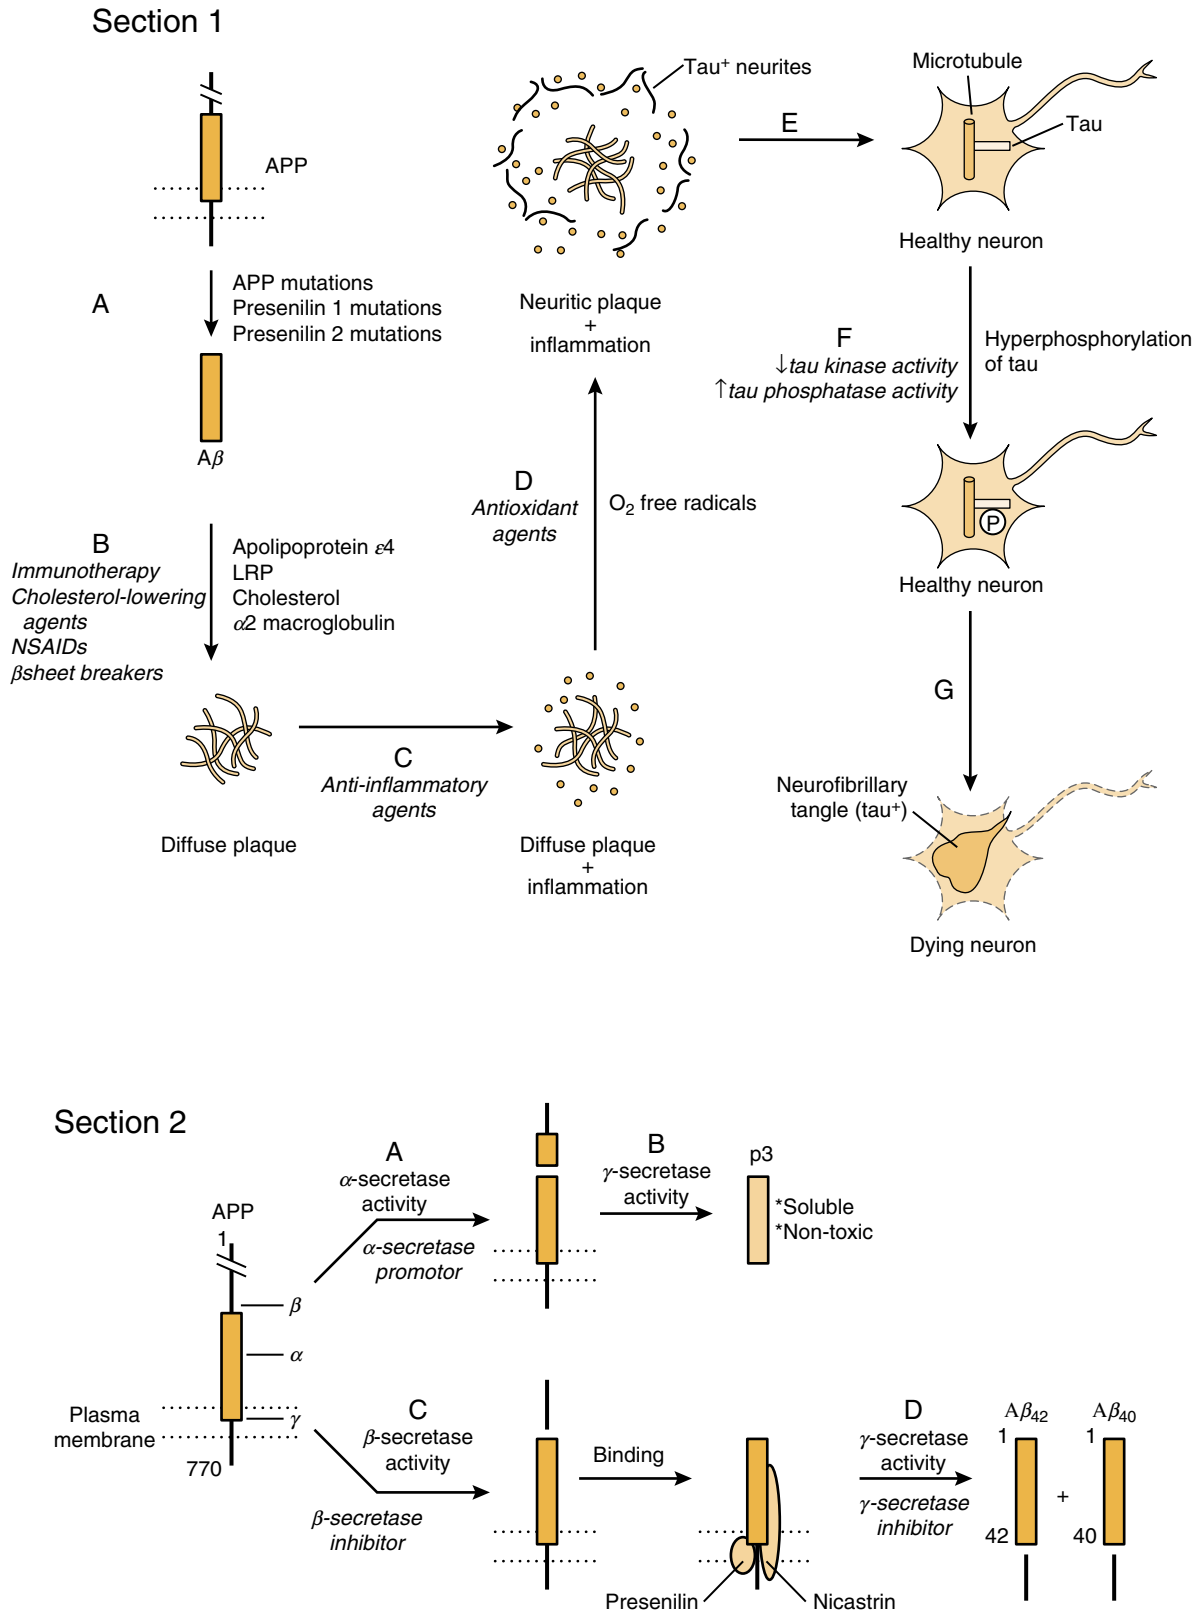

Figure 33-3. The amyloid cascade hypothesis of Alzheimer’s disease (AD) pathogenesis and potential therapeutic targets. The amyloid precursor protein (APP) is a 770-amino acid protein whose normal physiologic function has not been defined. The APP can be cleaved by the enzymes α-, β-, and γ-secretase (1A, 2A–2D). Presenilin likely requires nicastrin to allow γ-secretase activity to occur (2D). The APP is cleaved into p3 by α-secretase; p3 is

a soluble and nontoxic form of amyloid (2A, 2B). β - and γ -secretase activity cleaves APP into β -amyloid ($A\beta$), which fibrillizes, aggregates, and deposits in the brain (2C, 2D). The 42-amino acid fragment ($A\beta_{42}$) tends to deposit in the brain parenchyma and is the major constituent of amyloid plaques; the 40-amino acid fragment ($A\beta_{40}$) tends to deposit in blood vessels and cause amyloid angiopathy, thereby increasing friability and the tendency to hemorrhage. Mutations in APP, presenilin-1, and presenilin-2 all act to increase production of $A\beta$ (1A). $A\beta$ interacts with apolipoprotein $\epsilon 4$, lipoprotein-related protein, cholesterol, α_2 macroglobulin, and other compounds to increase aggregation and/or decrease clearance of amyloid or diffuse plaques (1B). The plaques presumably lead to microglial activation and the associated inflammatory response and free radical formation (1C, 1D). Tau-positive neurites then develop around the amyloid core resulting in neuritic plaques. The amyloid cascade hypothesis posits that the series of events described here affects healthy neurons to degenerate (1E); the mechanisms underlying this process have not been adequately characterized. The microtubule-associated protein tau becomes hyperphosphorylated (1F), causing impaired intracellular processing and neurofibrillary tangle formation (1G). The affected neurons degenerate, ultimately causing dementia.

Several steps in this cascade could potentially be manipulated to affect AD pathogenesis. β - and γ -secretase inhibitors may decrease $A\beta$ production and potentially prevent the development, delay the onset, and delay the rate of progression on AD (1A, 2C, 2D). Promoters of α -secretase activity (2A) could decrease the proportion of APP that is processed via steps 2C and 2D. Immunotherapy (i.e., amyloid vaccine), cholesterol-lowering agents, and β -pleated sheet breakers may decrease amyloid plaque development and/or increase amyloid clearance (1B). Epidemiologic studies have suggested that nonsteroidal anti-inflammatory drugs (NSAIDs) are protective against AD, which has been presumed to be due to their anti-inflammatory properties (1C). Data indicate that certain NSAIDs actually decrease $A\beta$ levels independent of their anti-inflammatory properties (1B). There is continued hope that NSAIDs and other agents with anti-inflammatory properties may decrease the inflammatory response to amyloid plaques (1C). Free radical scavengers such as α -tocopherol and selegiline have been shown to delay the rate of progression in patients with AD, presumably by affecting free radical formation (1D). The complex interactions between amyloid and tau processing could be manipulated (1E). Decreasing tau kinase activity and/or increasing tau phosphatase activity could decrease development of neurofibrillary tangles (1F, 1G).

radical formation.¹⁹ This has led some to propose the use of antioxidants clinically and in experimental trials in patients with clinically diagnosed AD.¹⁷

Levels of acetylcholine, noradrenaline, serotonin, γ -aminobutyric acid (GABA), glutamate, somatostatin, neuropeptide Y, and substance P have all been documented to be reduced in the brains of AD patients. However, reductions in acetylcholine and choline acetyltransferase are the most profound, and therefore they have been thought to be the most important. Such reductions are due to neuronal loss in the basal forebrain, which is the major region from which cholinergic projections originate.²⁰ Only modest improvements in cognitive functions have been achieved with cholinergic agonists, presumably due to neuronal loss in the cortical targets that receive cholinergic input.

Pathological variants of AD include limbic AD, plaque-only AD,²¹ and DLB (in which AD pathology coexists with neocortical and subcortical Lewy bodies).

There are four genetic variants of AD. AD1 results from a mutation in the APP gene on chromosome 21, resulting in increased amyloid formation and deposition in the brain and cerebral vasculature, causing autosomal dominantly inherited familial AD, as well as amyloid angiopathy. AD2 is genetic subtype of late-onset familial AD reflecting the type 4 allele of ApoE located on chromosome 19.¹⁰ AD3 is a form of early onset familial AD (EOFAD) resulting from mutation of an integral membrane protein (presenilin-1) gene located on chromosome 14. Mutations in this gene may be responsible for more than 75% of cases of EOFAD with a mean onset before age 50 years.²² Finally, AD4 is another early onset familial form of AD related to a mutation of another transmembrane protein (presenilin-2) located on chromosome 1 in seven related families of Volga German ancestry (and one Italian kindred) with autosomal dominant AD.²³ Evidence suggests that presenilin is the major component of γ -secretase. Additional loci on chromosome 10 and 12 have been associated with late-onset AD, but the specific genes have not been identified.^{24,25} The genetic variants of

AD1, AD3, and AD4 seem to exert their pathogenetic effect through increased production and deposition of insoluble β -amyloid.

EPIDEMIOLOGY AND RISK FACTORS. AD is the most common cause of dementia overall, accounting for more than half of all cases, and it increases in frequency with advancing age. Epidemiological age-specific estimates of incidence and prevalence vary by region and study due to differences in diagnostic criteria and population demographics. Figures 33-4 and 33-5 show the incidence and prevalence rates for dementia (all causes) and AD in particular in Olmsted County, Minnesota.²⁶ There is an exponential increase in both with advancing age at least through the ninth decade. Whether this trend continues into the tenth decade is unknown. The prevalence of severe dementia over the age of 60 years is estimated at 5%, and over the age of 85 years it is estimated to be between 20% and 50%. The lifetime risk of developing AD is estimated to be between 12% and 17%.^{26,27}

Following age, ApoE status is the second most important risk factor. In both familial late-onset¹⁰ and sporadic¹¹ cases, the ApoE $\epsilon 4$ allele increases risk and the $\epsilon 2$ allele decreases risk.¹² The lifetime risk of AD in people without a family history increases from 9% without an ApoE $\epsilon 4$ allele to 29% with one copy of the ApoE $\epsilon 4$ allele.²⁸ ApoE $\epsilon 4$ homozygotes comprise approximately 2% of the population, but approximately 83% are estimated to develop AD in their lifetime,²⁹ similar to the 91% reported in familial late-onset cases.^{10,11} In limited populations, other genetic factors play a determining role, such as Down's syndrome (trisomy 21)³⁰ and EOFAD kindreds.

Other purported risk factors are weaker and some are more controversial in that not all well-controlled epidemiological studies have found them to be significant. These risk factors include limited education, depression, gender, estrogen replacement therapy, use of vitamin E, head trauma, use of anti-inflammatory drugs, and a history of thyroid disease.

Figure 33-4. Incidence rates of dementia (all causes) and Alzheimer's disease in Olmsted County, Minnesota, by age for five quinquennial periods (1960–1984), pyrs, person years. (From Kokmen E, Beard CM, O'Brien PC, Kurland LT: Epidemiology of dementia in Rochester, MN. Mayo Clinic Proc 1996;71:275–282 with permission of the author and the publisher.)

CLINICAL FEATURES AND ASSOCIATED DISORDERS

Mild Cognitive Impairment. The clinical symptoms and signs of AD reflect the underlying topography of the disease. Memory loss is a cardinal feature of Alzheimer's dementia but it is not the only abnormality in most patients. Early in the course of AD, patients may not yet be functionally impaired. The diagnostic term *mild cognitive*

impairment (MCI) was originally introduced to define a progressive monosymptomatic amnesic syndrome, and many patients present in this fashion.³¹ The criteria for the diagnosis of MCI are shown in [Table 33-1](#). The memory loss in these patients should be distinguished from the milder memory problems of normal aging. MCI has the same profile of risk factors as AD, including advanced

age and ApoE,³² and patients who have come to autopsy often prove to have AD. Such patients also have radiologically demonstrable hippocampal atrophy. More than half of patients who present with MCI develop features of dementia over a 4- or 5-year period.³² The practice parameter on MCI suggests that patients with forgetfulness should be evaluated and monitored.³³ Recognition of patients with MCI will become increasingly important as many agents will be tested to potentially delay the rate of progression of MCI to AD.

MCI has evolved by consensus into an entire classification scheme for early, nondisabling cognitive disorders.³⁴ These constitute amnesic MCI (single domain), amnesic MCI-multiple domains, nonamnesic, MCI-single domain, and nonamnesic MCI-multiple domains. Each MCI subtype can then be classified according to the presumed etiology—degenerative, vascular, psychiatric, etc. Amnesic MCI is the originally conceived monosymptomatic amnesic form and is often applied to those with a presumed underlying degenerative etiology. Nonamnesic MCI-single domain refers to monosymptomatic syndromes other than memory loss, such as anomia, visual disorders, apraxia (Video 40, Apraxia), executive disorders, or essentially any deficit that can be considered to be confined to a single cognitive domain. Finally, amnesic and nonamnesic MCI-multiple cognitive domains refer to patients with impairment in multiple cognitive domains with and without memory impairment. MCI-amnesic is the most specifically correlated with AD,³⁵ but it may be less prevalent overall than MCI-multiple cognitive domains.³⁶ The utility of MCI as a diagnostic category, particularly amnesic MCI, is that it has been used operationally to define a “pre-dementia” state amenable to therapeutic interventions whose efficacy can be defined by “conversion rate” of MCI to dementia.

Longitudinal studies of patients with MCI have shown a conversion rate to dementia of approximately 10% to 15% per year,^{32,37} although conversion rates vary considerably between studies in part due to different operational definitions of MCI. After 5 years, approximately half of all patients with MCI will meet the criteria for dementia, par-

ticularly AD, and after a 10-year period, most will have AD or another dementia syndrome. At autopsy, approximately 80% of patients originally diagnosed with MCI prove to have AD.³⁷ Other diagnoses that have been found include cerebrovascular disease, frontotemporal lobar degeneration, argyrophilic grain disease, and a variety of less common diseases.³⁸ Thus, in most cases, amnesic MCI can be regarded as an early clinical stage of AD.

Although MCI has gained widespread acceptance, challenges remain. The most glaring is the absence of a uniform quantitative or systematic definition of functional impairment. The Clinical Dementia Rating Scale³⁹ has been used in research studies and has proven to be a valuable instrument for the definition of functional impairment. However, it is too long and cumbersome for practical clinical application. Also, because of the relatively recent redefinition of MCI, our understanding of the incidence, prevalence, and conversion rates to AD of the various subtypes is currently in flux as new studies are designed to address these new definitions.

Alzheimer’s Dementia. The clinically defined syndrome, Alzheimer’s dementia, has been considered the paradigm of a cortical dementia syndrome. The hallmarks of cortical dementia include not only memory loss, which is common to most dementia syndromes, but also elements of aphasia, apraxia, and agnosia (Video 101, Dissociation Apraxia). Furthermore, there is an absence (or lack of prominence) of subcortical features, particularly parkinsonism. Some patients with pathologically proven AD, however, also exhibit features of mild parkinsonism, emphasizing that diagnostic boundaries are relative, not absolute.

Table 33-2 shows the National Institute of Neurological and Communicative Disorders and Stroke and the Alzheimer’s Disease and Related Disorders Association (NINCDS-ADRDA) Work Group’s diagnostic criteria for AD.⁴⁰ Definite AD is defined by tissue confirmation. Probable AD is defined by the clinical picture of dementia in the absence of certain atypical features such as focal neurological abnormalities and for which another cause cannot be found. Possible AD is defined by the clinical picture of dementia, but with either atypical features in the course of the illness or with a second potentially contributory disease not believed to be the primary cause. In the absence of histological confirmation, therefore, the clinical picture of dementia is the most important diagnostic feature.

Dementia is not a homogeneous clinical syndrome. It is defined as disabling impairment of multiple cognitive domains. Hence, memory loss alone does not equal dementia, even though it may be the heralding symptom of a dementing illness and is the most commonly impaired cognitive domain among all dementia syndromes (cortical and subcortical). Degenerative dementia further implies disease progression over time. The pattern and evolution of cognitive deficits defines the syndrome of Alzheimer’s dementia, even though pathologically defined AD may rarely not present in this way. Nonetheless, the overall clinical-pathological correlation of Alzheimer’s dementia with AD at experienced centers is now approximately 87%.⁴¹

Most clinical studies are in agreement that the earliest clinical sign of AD is memory loss, which precedes the actual dementia. Abnormal cerebral metabolism, demonstrated by positron emission tomography (PET), may pre-

TABLE 33-2

NINCDS-ADRDA Criteria for the Diagnosis of Alzheimer's Disease*

- I. Clinical Diagnosis of Probable Alzheimer's Disease
 1. Dementia established by clinical examination and mental status testing and confirmed by neuropsychological testing
 2. Deficits in at least two cognitive domains
 3. Progressive cognitive decline, including memory
 4. Normal level of consciousness
 5. Onset between ages 40 and 90 (most common after 65) years
 6. No other possible medical or neurological explanation
- II. Probable Alzheimer's Disease Diagnosis Supported by
 1. Progressive aphasia, apraxia, and agnosia
 2. Impaired activities of daily living
 3. Family history of similar disorder
 4. Brain atrophy on CT/MRI, especially if progressive
 5. Normal CSF, EEG (or nonspecifically abnormal)
- III. Other Clinical Features Consistent with Probable Alzheimer's Disease
 1. Plateau in course
 2. Associated symptoms: depression; insomnia; incontinence; illusions; hallucinations; catastrophic verbal, emotional, or physical outbursts; sexual disorders; weight loss; during more advanced stages increased muscle tone, myoclonus, and abnormal gait
 3. Seizures in advanced disease
 4. CT normal for age
- IV. Features That Make Alzheimer's Disease Uncertain or Unlikely
 1. Acute onset
 2. Focal sensorimotor signs
 3. Seizures or gait disorder early in course
- V. Clinical Diagnosis of Possible Alzheimer's Disease
 1. Dementia with atypical onset or course in the absence of another medical/neuropsychiatric explanation
 2. Dementia with another disease not felt otherwise to be the cause of dementia
 3. For research purposes, a progressive focal cognitive deficit
- VI. Definite Alzheimer's Disease
 1. Meets clinical criteria for probable Alzheimer's disease
 2. Tissue confirmation (autopsy or brain biopsy)
- VII. Research Classification of Alzheimer's Disease Should Specify
 1. Familial?
 2. Early onset (before age 65)?
 3. Down's syndrome (trisomy 21)?
 4. Coexistent other neurodegenerative disease (e.g., Parkinson's disease)?

*National Institute of Neurological and Communicative Disorders and Stroke and the Alzheimer's Disease and Related Disorders Association Work Group's report summarizing the criteria for a diagnosis of Alzheimer's disease.

CSF, cerebrospinal fluid; CT, computed tomography; EEG, electroencephalogram; MRI, magnetic resonance imaging.

cede even mild memory loss.⁴² A few studies have correlated other relative cognitive inefficiencies occurring much earlier in life with the subsequent development of dementia, although interpretation of these findings has been a source of controversy.

Recent memory is easier to assess reliably than remote memory and is thought to be disproportionately severely involved. Nonetheless, remote memory is also abnormal, and there is a gradient effect regarding recall over a retrograde time interval: The oldest memories appear to be the best preserved, with proportionately greater forgetting as the retrograde interval shortens.⁴³ In contrast, procedural memory appears to be relatively spared. Alzheimer's patients are able to learn simple skills as easily as

normal controls and better than patients with subcortical patterns of dementia or patients with various types of sensorimotor deficits.⁴⁴ Although apraxia is one of the defining features of cortical dementia, it is rarely severe in mild to moderate stages of AD and can be very difficult to distinguish from impaired comprehension in these patients. One very important skill that needs to be addressed clinically is driving. Despite the relative preservation of procedural memory, patients with mild Alzheimer's dementia have a higher rate of collisions and moving violations than age-matched controls,⁴⁵ although estimates of risk vary, especially during the first 2 years of the disease. Whether this actually results from impaired procedural memory, attentional factors, other cognitive aspects, or a combination is unclear, although visual tracking, memory, and Mini-Mental State score all correlate with a laboratory-based driving score.

Aphasia, apraxia, and agnosia are the other categories of cognitive impairment that typically occur in cortical dementia syndromes and particularly in AD (Video 103, Conceptual Apraxia). In Alzheimer's dementia, these aspects do not usually dominate the clinical picture, but they can in variant syndromes. A patient with a predominant aphasic syndrome (progressive aphasia) should not be assumed to have AD, although some do (see section on Tauopathies). Rather, these aspects of cognitive pathology occur in discrete apportionments that define the dementia syndrome as typical Alzheimer's dementia. In patients with such an apportionment, clinicopathological correlation rates are high.⁴¹ In mild to moderate stages of dementia, anomia is prominent and readily detectable with neuropsychological testing using a variety of naming tests (see Chapter 27). However, patients are fluent and may have relatively good comprehension, so clinical detection is not always easy. As the disease progresses, the predominantly anomnic aphasia gives way to a more fluent, or Wernicke's, type of aphasia with impaired comprehension (Video 96, Conduction Aphasia). Nonfluent aphasia does not generally occur in AD, although preterminally patients become mute (see Chapter 6). This should not be the case in a patient who is still ambulatory, however.

Apraxia can be confused with impaired comprehension in mild to moderate stages of Alzheimer's dementia (Video 103, Conceptual Apraxia). Patients have difficulty performing tasks at which they were previously adept, such as repairing a household appliance or doing carpentry work. They also have difficulty learning new procedures, such as operating a new car, new appliance, or remote control device. They have some difficulty pantomiming gestures in the office setting but also have constructional apraxia (Video 40, Apraxia). In moderately advanced stages, patients have trouble dressing and performing other activities of daily living. Patients with clinically evident apraxia typically also have significant perceptual difficulties (see later discussion in Asymmetric Cortical Degeneration Syndrome section) and definitely should not be driving a motor vehicle (Video 102, Ideomotor Apraxia).

Anosognosia, the failure to recognize illness, is a cardinal feature of Alzheimer's dementia and is typically present, even in mild stages of the disease. It is a useful sign to distinguish progressive amnesic syndromes from Alzheimer's dementia. A typical patient with AD is brought or sent for evaluation rather than coming of his or her own accord,

although appreciation of memory impairment may still be preserved in those with amnesic MCI. In AD, he or she may deny significant memory problems and will actively try to explain away the observations of concerned family members and friends, even to the point of becoming hostile and accusative. This is one of the most difficult aspects of the disease because such patients often should not be driving or managing their own finances but will do so anyway, sometimes to their detriment.

In moderate to advanced stages, patients exhibit other so-called agnosic types of disturbances. Arguably, the difficulty such patients have in recognizing familiar people reflects prosopagnosia, save that they are not reliably benefited by voice recognition either. Difficulty finding their way could be compared with topographagnosia, another visual agnosic syndrome, but again this is not occurring in the pure form given the wealth of other cognitive problems accompanying it. Rarely, patients with histologically documented AD present with a disabling, primarily visual syndrome termed simultanagnosia, in which there is an inability to view all parts of a complex visual scene in a single coherent time-space frame. Such patients fail to see a target object that is right in front of them, especially if it is surrounded by potentially distracting stray objects.⁴⁶ Strictly speaking, this is not an agnosic disorder but, rather, another type of complex visual disturbance that resembles agnosia and can occur in this setting. It is rarely the presenting feature. More commonly, it is a mild accompanying feature.

Psychiatric symptoms include both affective and psychotic disturbances. Depression interferes with a person's functional status and an accurate cognitive assessment, erroneously leading to the diagnosis of dementia; such is the nature of pseudodementia, which has been estimated to account for 4% or 5% of dementia cases.⁴⁷ More commonly, depression may complicate the course of AD and other dementing illnesses. Antidepressant therapy should be strongly considered in such patients. Psychotic symptoms most commonly involve paranoid delusions and, less commonly, hallucinations. AD should be in the differential diagnosis of an elderly patient presenting *de novo* with an organic delusional syndrome or hallucinosis. Common paranoid themes involve infidelity and stealing. Hallucinations are generally complex, involving people (familiar or unfamiliar), animals, or both. The combination of anosognosia, paranoid delusions, and mild cognitive decline is potentially dangerous and very difficult to manage, especially if such individuals live alone, yet a significant minority of AD patients have exactly that combination.

Sleep-wake cycle disturbances are common and may be present even during relatively mild stages of the illness. They become more common and more severe during moderately severe stages. There are two aspects to the sleep-wake cycle disturbance. The first is the so-called *sundowning* effect, which means that the patient becomes more confused, agitated, and difficult to manage during the evening hours. The second regards not sleeping at night, waking up during very early hours, or going to sleep very early in the evening. Sleep becomes fractionated into shorter segments throughout the 24-hour period. As the disease progresses to more advanced stages, patients may become generally less active, sleep more, and eventually,

in terminal stages, are bedbound with little apparent conscious activity. Weight loss is common during the latter stages as well. Incontinence (both urinary and fecal) is uncommon in mild stages but becomes increasingly frequent as the disease progresses and is universal in late stages. Early on, it may inadvertently result from voiding in the "wrong place" rather than actual sphincter control problems, but in later stages, sphincter control is lost.

Late and preterminal stage AD ensues after approximately a 5- to 10-year course but is highly variable and can be shorter or longer. In very advanced stages, patients are no longer ambulatory, become mute and incontinent, and are totally dependent on their caregiver or nursing attendant. Eventually, dysphagia signals the terminal phase, and unless a feeding tube is placed, patients eventually die from inanition or aspiration or both. Death can also result from urosepsis and pulmonary embolism. Few patients live to these latter stages, with death resulting from intercurrent illnesses in most.

Down's syndrome has a strong association with AD. If a patient with Down's syndrome (trisomy 21) lives beyond the age of 40 years, it is a near certainty that there will be neuropathological evidence of AD at autopsy.³⁰ Clinical dementia increases with age and peaks at approximately 40% to 75% over the age of 60 years.³⁰ Analysis of the amyloid plaques has shown that trisomy 21 predisposes to larger plaques, presumably reflecting increased production of A β , in contrast to ApoE ϵ 4, which leads to greater numbers of plaques presumably reflecting increased probability of senile plaque initiation.⁴⁷

DIFFERENTIAL DIAGNOSIS. AD is one disease among many, both degenerative and nondegenerative, that can produce the categorical syndrome of a chronic progressive encephalopathy. All-encompassing, indiscriminant differential diagnostic inclusion of 100 conditions encompassed by this broad category is inefficient and impractical. So, too, is the reflex assumption that memory loss in an elderly individual equals dementia equals AD. Simply determining that a disease is degenerative already accomplishes the most important goal of excluding any possible or more effectively treated etiology.

Reversible forms of dementia are truly chronic encephalopathies and often cause one or several of the following: hypersomnolence, acute or subacute deterioration, fluctuating severity, severe electroencephalographic abnormalities, visual hallucinations, tremulousness, or unsteadiness. It may be accompanied by non-neurological symptoms as well. Such symptoms may occur within the context of another disease process known to sometimes cause neurological problems, such as hypothyroidism, or may occur in specific circumstances such as immunosuppression. Irreversible forms of dementia are generally more slowly progressive (more than 1 or 2 years), fluctuate much less, do not occur within the context of another potentially causative disease, have recognizable clinical and cognitive profiles, and are not accompanied by many of the aforementioned clues of a reversible chronic encephalopathy. When analyzed in this way, a more realistic differential diagnosis of AD includes (1) other degenerative diseases, such as Pick's disease, dementia lacking distinctive histopathology, frontotemporal dementia, and DLB; and (2) vascular dementia resulting from small vessel disease due either to atherosclerotic small vessel disease or amyloid angiopathy. In mild

to moderate stages, clinical cognitive patterns can be very helpful in distinguishing various dementing illnesses. In late stages, however, patients are more diffusely impaired both cognitively and somatically, making it difficult to distinguish one degenerative brain disease from another.

EVALUATION. Because the recognition of distinctive clinical cognitive patterns can be difficult, a practical approach must take into account some of the chronic encephalopathic causes as well as degenerative and related causes. Neuroimaging is essential. MRI is preferred, if possible, but CT is generally adequate. Structural processes such as chronic (or subacute) subdural hematomas, tumors (frontal lobe meningiomas and temporal lobe gliomas in particular), cerebrovascular lesions, prior traumatic encephalomalacia, relevant focal atrophy (see tauopathy section), and meningeal enhancement are among the many important diagnostic clues that mitigate against a diagnosis of AD. Bilateral medial temporal or more generalized atrophy may be discernible, but this is nonspecific, and in the absence of quantitation it is difficult to use for diagnostic purposes. Physiological neuroimaging is not recommended for routine evaluation of patients suspected of having AD but may be helpful in patients with focal or asymmetric cortical degeneration syndromes such as Alzheimer variants and tauopathies. Nonetheless, single-photon emission computed tomography (SPECT) and PET have shown bilateral temporoparietal and posterior cingulate hypometabolism and hypoperfusion in AD, and in some cases they are now accepted by third-party payors as indicated for the assessment of AD.

Cognitive examination is essential, but whether formal neuropsychological assessment is required depends on the examining physician's skill in clinical cognitive assessment. In general, neuropsychological assessment is highly desirable in mild to moderate stages of dementia for both qualitative description of the dementia pattern (which has diagnostic significance) and quantitative estimation of cognitive disability. Although variable, a typical neuropsychological profile will show severe learning and memory impairment, anomia, and impaired semantic fluency. Frequently, there is also evidence of impaired aural comprehension, a generally reliable indicator of significant cognitive disability. Psychomotor speed is generally preserved, although with longitudinal assessment, it also declines.

Basic laboratory and general health measures are also essential. Cognitive decline has very different implications in a smoker with active lung cancer, severe anemia, or disseminated intravascular coagulation, for example, than in a previously healthy octogenarian. Recent chest x-ray study, electrocardiogram, urinalysis, complete blood counts, and a chemistry profile (which should include electrolytes, calcium, fasting blood glucose, and renal and liver function tests) are not specifically neurological but can be very relevant if they disclose a severe abnormality. Thyroid function tests and vitamin B₁₂ should be assessed. The actual frequency of B₁₂ deficiency-related dementia is questionable, however. In patients with severe vitamin B₁₂ deficiencies, anemia and combined systems disease with prominent myelopathic features seem to predominate. Cognitive decline in such a setting should certainly prompt consideration of B₁₂ deficiency, but in cases of mild B₁₂ deficiency without accompanying features, its significance is doubtful

(see Chapter 40). CNS syphilis has become rare but again should be screened with rapid plasma reagin or other syphilitic serological tests. The erythrocyte sedimentation rate is an arguably useful screening test for a variety of diseases that result in a systemic inflammatory response, and when the rate is highly elevated, it may be an important diagnostic clue.

The previously mentioned laboratory measures are the core tests to consider in essentially all patients. Additional tests that may not be necessary in every patient include EEG, spinal fluid examination, overnight oximetry, psychiatric evaluation, small bowel biopsy, Lyme disease serology, human immunodeficiency virus serology, various connective tissue disease serologies, and paraneoplastic serologies. Ultimately, invasive testing including cerebral angiography and meningeal or brain biopsy also have their place in the diagnostic armamentarium for chronic progressive encephalopathy but not when AD is the leading diagnostic consideration.

Degenerative diseases other than DLB and depression are rarely accompanied by severe EEG disturbances. In contrast, EEG abnormalities are often severe (and usually nonspecific) in toxic, metabolic, inflammatory, infectious, and neoplastic encephalopathies. Complex partial status epilepticus and Creutzfeldt-Jakob disease may produce pathognomonic patterns. When in doubt, an EEG is a simple, noninvasive screening test for a wide variety of diseases, many of which are reversible. Patients suspected of having a chronic encephalopathy, perhaps reinforced by a severely abnormal EEG, should undergo spinal fluid examination, and tests should include immunological indices such as IgG index, IgG synthesis rate, and oligoclonal bands. Although these tests are nonspecific, they are markers of intrathecal inflammation, which does not generally occur in AD or any other degenerative neurological diseases. Other tests, including cytology, cultures for fungi and mycobacteria, and routine tests such as total protein, glucose, cell count, and syphilis serology, should also be obtained when a spinal tap is performed. Quantification of neuron-specific enolase (NSE) and the 14-3-3 protein may also be helpful in the assessment of those with suspected prion disease, although importantly, values are not entirely sensitive nor specific for Creutzfeldt-Jakob disease. Opening pressure should be recorded, especially in patients suspected of having communicating, normal pressure hydrocephalus.

Overnight oximetry is a useful screening test for obstructive sleep apnea, a common cause of hypersomnolence with secondary inattentiveness and mild memory impairment. Psychiatric evaluation should be considered if depression is suspected and if psychotic symptoms complicate the clinical picture. Small bowel biopsy should be considered if CNS Whipple's disease is suspected. Various serological tests should be considered for specific infectious diseases (e.g., Lyme disease, particularly if a patient is from an endemic area), autoimmune diseases, and paraneoplastic conditions in patients with prior or known provocative malignancies (especially oat cell lung cancer and ovarian cancer).

MANAGEMENT

Prevention. To date, there have been no reproducible studies demonstrating the efficacy of any putative primary

prevention therapy for AD. Studies of putative agents that have concluded more harm than good include those of steroids, NSAIDs, and estrogen. Studies that have shown little to no benefit include those of vitamin E, ginkgo, and hydergine. Ongoing studies include statins and B vitamins (to lower homocysteine levels).

Intellectual Decline. Two classes of drugs have shown modest cognitive enhancing effects in AD. The first are centrally acting acetylcholinesterase inhibitors that are thought to partially reverse the decline in cortically projected acetylcholine that results from degeneration of the cholinergic basal forebrain. The first of this class to be released was tacrine, although its use has declined in favor of newer agents (donepezil, rivastigmine, and galantamine) that have been less toxic and less complex to titrate despite similar efficacy. The symptomatic benefits of all of these drugs are modest, but rate of cognitive decline seems to slow somewhat as well for reasons that are not well understood, so their use has been advocated even in the absence of overt symptomatic benefit. Nonetheless, they can result in functionally important gains in some patients and should be particularly considered in patients with mild to moderate stages of the disease. There is accumulating evidence, however, that modest gains can occur in more advanced stages of disease, although their use in such patients remains controversial. Relatively common side effects include gastrointestinal upset such as nausea, anorexia, and diarrhea. More severe side effects are less common but generally reflect systemic cholinergic effects. They should either not be used or be used with caution in patients with cardiac conduction defects, liver disease, or seizures. Another drug of a different class that boasts modest cognitive efficacy is the *N*-methyl *D*-aspartate (NMDA) receptor antagonist memantine. Memantine has been approved for use in patients with moderate to severe dementia, and therapeutic endpoints have included simple activities of daily living, including dressing, bathroom use, and eating. Although not approved for patients with MCI or mild dementia, memantine is nonetheless used in many such patients either alone or together with a cholinesterase inhibitor with uncertain benefit.

Behavioral Disorders. Three very broadly defined treatable categories of behavioral disturbance that affect dementia patients are psychosis, depression, and anxiety. Paranoid delusions and other psychotic symptoms are disruptive, pose extraordinary obstacles to effective caregiving, and are probably the most common reasons patients are sent to nursing homes. Small doses of neuroleptic medications may produce sufficient relief as to permit caregivers to continue to keep the patient at home, and these medications should be part of the therapeutic armamentarium. Haloperidol at doses ranging from 0.5 to 2 mg a day is often sufficient, but sometimes higher doses are required. Extrapyramidal side effects, however, can become dose-limiting problems (Video 51, Parkinsonism in Alzheimer's Disease). Due to the severe neuroleptic sensitivity often present in those with DLB, conventional neuroleptics such as haloperidol and chlorpromazine should be avoided. There are no agents that have received Food and Drug Administration (FDA) approval for the specific treatment of agitated, delirious, psychotic elderly patients with dementia. In the absence of definitive clinical trials, anecdotal experience

and meta-analysis⁴⁸ have suggested that atypical antipsychotic agents (e.g., quetiapine, olanzapine, and risperidone) may be the preferred agents, especially in patients with parkinsonism, because they can be effective and because they are less likely to cause or exacerbate extrapyramidal syndromes. They currently lack FDA approval for such an indication, however, so clinical judgment is essential. Furthermore, the FDA recently required a black box warning label on the use of atypical antipsychotics in the treatment of elderly patients with dementia because of unpublished data suggesting an increased risk of mortality (www.fda.gov/cder/drug/advisory/antipsychotics.htm). Alternate recommendations were not given, and in the absence of a clear alternative, many clinicians continue to believe that these medications remain an important therapeutic option for managing severe behavioral problems. A more recent analysis suggested mortality associated with neuroleptic use in the older dementia population is more frequent in those treated with conventional neuroleptics compared to the newer atypical neuroleptics.⁴⁹ Therefore, use of atypical neuroleptics can be justified, provided that the patient's family and other physicians involved in a patient's care believe the benefits outweigh the risks.

Regarding depression, antidepressants with anticholinergic side effects, including all the tricyclic antidepressants, often exacerbate the confusion in these patients and are generally not recommended. Rather, selective serotonin reuptake inhibitors (SSRIs), such as fluoxetine, sertraline, and citalopram, can enhance energy levels (and possibly attentiveness as a result in some patients) and have antidepressant effects without the risk of anticholinergic side effects. They should not be used, however, in agitated patients or in patients with psychotic symptoms because SSRIs can exacerbate these behaviors. For anxiety, buspirone, although it is generally less effective than benzodiazepines, has much less risk of paradoxical agitation and should be tried first. Atypical neuroleptic agents can also be considered for anxiety in some patients, especially if there are accompanying psychotic symptoms.

Sleep. Sedative hypnotic agents can be used in patients in whom sleep-wake disturbances are disrupting their home care. Agents that have few side effects or risks of exacerbating confusion and agitation include zolpidem, zaleplon, and chloral hydrate. Trazadone is sometimes used as a longer acting agent, especially in the presence of comorbid depression. Many patients fall asleep without difficulty but awaken at an early hour. In such instances, the sleeping aid may be given when they waken rather than at bedtime. These medications help patients fall asleep, but they will not reliably keep them asleep for prolonged periods, which is in part why they are more advisable than longer acting agents. There is insufficient clinical experience, and no published controlled trials, to know the safety and efficacy of newer agents such as eszopiclone, ramelteon, and sodium oxybate for management of sleep-wake disturbances in this population.

Abrupt Decline. A sudden decline in cognitive status or other neurological function, such as ambulation, in a patient with AD generally implies a secondary disease process, often one that is non-neurological, such as a urinary tract infection, pneumonia, and fluid and electrolyte disturbances. Medication side effects (particularly those

associated with tricyclic antidepressants, benzodiazepines, and narcotic analgesics) or complications from improper medication administration should be sought, especially if the patient has continued to administer his or her own medications without adequate supervision. Common neurological causes include subdural hematoma, stroke, and complex partial seizures. The differential diagnosis is extensive and is that of an acute encephalopathy.

Driving Cessation. One of the more difficult lifestyle changes for patients with dementia to accept is not driving. The Clinical Dementia Rating (CDR) is a widely utilized clinical tool for grading the relative severity of dementia with scores that range from 0 (no impairment) to 3 (severe impairment).³⁹ Patients with MCI typically have a CDR of 0.5 and comprise an identifiable subgroup of patients who can be distinguished from those with significant functional impairment or with impairment of multiple cognitive domains that include but are not confined to memory. According to the Practice Parameter of the Quality Standards Subcommittee of the American Academy of Neurology, patients with MCI and CDR of 0.5 should be cautioned, but in the absence of overt driving impairment reported either by the patient or by a reliable observer, there is no absolute restriction that must be placed on them. However, the practice parameter advises they be reassessed periodically (every 6 months) until they have declined to a CDR of 1.0 (or the equivalent), and at that point, the standard changes to no driving. Therefore, according to the practice parameter, a patient with mild AD and a CDR of 1.0 is to be advised not to drive.⁵⁰

There are many simple reasons why patients with dementia may not be able to drive. Patients with visual variant AD have disabling visual impairment. Patients with progressive apraxia related to corticobasal degeneration have severe motor impairment, and some additionally have visual impairment. Patients with primary progressive aphasia are sometimes capable of driving but due to the speech disturbance occurring within the context of a dementing degenerative brain disease would be ill equipped to explain themselves in the event of a mishap and legally would be difficult to defend if challenged. (Hence, it is probably best that they not drive.) Impaired attention, inability to “multitask,” and other cognitive disturbances in addition to memory loss all impair driving skills, as shown on actual road tests⁴⁵ as well as on driving simulation tests,⁵¹ resulting in a two- to eightfold increase in rate of collisions in patients with AD who continue driving.⁵⁰

Simply telling a patient with dementia not to drive often is not sufficient, and many continue to drive even after they develop evident driving impairment despite admonitions not to drive.⁵² Patients may take a driving test, and when they do, 40% to 60% fail,⁵³ but losing their license only makes it illegal for them to drive. The most effective way to stop a patient from driving is to remove their access to car keys or the car. This is not always easy to accomplish and has caused some patients to become belligerent, so care must be used in managing this very difficult but important issue.

Weapon Storage. There has been relatively little written about proper handling of weapons in dementia households,⁵⁴ save that the issue exists and would seem to pose a serious risk. One study found that gun ownership was prevalent

in 60% of “dementia households,” and that the guns were known to be deliberately kept in an unloaded state in only 17% of those households with guns. Common sense would argue that weapons should be addressed at least as consistently as driving, and perhaps with even greater sensitivity. Secured storage sites, unloading the weapons, and similar measures should be considered.

Assisted Living and Skilled Nursing Facilities. Patients with dementia require assistance with activities of daily living, behavioral supervision, assistance with medication use, and essentially assistance with every aspect of daily life. This is a 24-hour per day job and one that is taxing on a caregiver so that caregiver burnout and depression is a common comorbidity of dementia.⁵⁵ Support groups and adult day care can provide some emotional support and respite but are often not enough. As long as a caregiver or family is able to cope with a patient’s needs, there are few absolute reasons that mandate placement of a patient into a supervised assisted living or nursing home setting. However, as might be anticipated, predictors of such placement include increasing severity of dementia, increased burden of need, and reduced availability of caregivers.⁵⁶ Someone living alone is at very high risk and thus most likely to require placement, whereas a patient with multiple family members who are available to help with nighttime as well as daytime behaviors are least likely to require placement. Some studies have shown that treatment with cholinesterase inhibitors delays nursing home placement by between 1 and 2 years.⁵⁷

Other important lifestyle issues include living wills, power of attorney, and legal guardianship. These provide for the disposition of care in the absence of current patient competency, the protection and management of a patient’s estate, and the ability of a trusted caregiver to become the legal guardian of the patient.

PROGNOSIS AND FUTURE PERSPECTIVES. AD, like all degenerative neurological diseases, is relentlessly progressive. Because the patients are elderly, and susceptible to a variety of other disease processes, AD is not the most common cause of death. However, if no other disease process supervenes, death usually ensues approximately 6 to 10 years after onset (there is great variability).

Increasing emphasis has been placed on early diagnosis in anticipation of preventive or retardant therapy. At the extreme of this approach is the fact that those individuals destined for AD have measurable differences throughout their lives,⁵⁸ and one such study correlated certain aspects of verbal skills at the mean age of 22 years with the subsequent development of AD 50 to 60 years later.⁵⁸ The prevailing paradigm, however, is that AD is a disease that begins in later life, but that various types of cognitive⁵⁹ and metabolic⁴² derangements can be measured at least several years in advance of clinically evident cognitive decline. Possible strategies for preventive and retardant therapy include

- interfering with a critical step in the amyloid/tau/ApoE pathway that results in plaque formation or in the pathway that results in the hyperphosphorylation of tau leading to cytoskeletal disruption. Early phase trials of secretase inhibitors, particularly those affecting β -secretase, to decrease formation of

β -amyloid, are under way. Other agents that affect plasma A β levels and/or the amyloidogenic cascade of presumed pathophysiology are also in progress.

- administration of ApoE ϵ 2 or analog to promote whatever salutary effect it appears to have in preventing AD.
- use of a large family of growth factor compounds that normally function during embryogenesis, some of which promote neuronal growth and retard neuronal death.
- use of antioxidants to interfere with the generation of free radicals that cause cellular damage.
- immunologic therapies such as vaccination against a key antigen such as β -amyloid.
- other ongoing primary and secondary prevention trials, including statin and B vitamin trials.

Until a very effective treatment or cure is found, another important agenda item for the future lies in the realm of public policy. How to deal with the burgeoning elderly population and the growing number of AD patients, many of whom require expensive chronic institutional care, will be issues of increasing societal and political focus.

PARKINSONISM AND DEMENTIA

Dementia with Lewy Bodies

PATHOGENESIS AND PATHOPHYSIOLOGY. Lewy bodies are intracytoplasmic fibrillar aggregates of α -synuclein and ubiquitin, a signature feature of PD, and a defining feature of DLB.⁶⁰ Neuropathological studies have shown that cortical Lewy bodies are a common feature in patients with PD (32% with hematoxylin and eosin [H&E] stains, up to 76% with ubiquitin stains) and a defining feature in the setting of concurrent parkinsonism and dementia.⁶⁰

Distinctions currently made between Parkinson's disease with dementia (PDD) and DLB are based on the duration of parkinsonism preceding the onset of cognitive symptoms, but neuropathological findings are similar whether dementia occurs as an early or late feature. Dementia correlates with cortical Lewy body burden whether or not there is concurrent AD pathology.⁶¹ Distinguishing the relative contributions to DLB and AD pathology in PDD and DLB patients is difficult. More than half of patients with clinically diagnosed DLB have AD pathology in addition to neocortical Lewy bodies at autopsy,⁶² and among patients with clinically diagnosed AD, neocortical Lewy bodies are found in 15% at autopsy.⁶³ ApoE ϵ 4, a major genetic risk factor for AD, does not correlate with risk for sporadic PD, but some studies have suggested a correlation with dementia in patients with PD⁶⁴ (possibly reflecting concurrent AD in these cases). Conversely, ApoE ϵ 4 also correlates with neocortical Lewy body burden in patients with AD.⁶⁵ Therefore, ApoE status, as a genetic risk factor for AD, may also be identifying a population at risk for DLB due either to its primary association with AD or its influence on Lewy body pathology.

Between 20% and 30% of brains of patients with a degenerative dementia have concomitant AD and PD changes, therefore making Lewy body-related pathology the second most common histopathology after AD. A much

smaller percentage have neocortical Lewy bodies without AD changes. Therefore, the dementing disorders associated with Lewy bodies can be categorized into three groups: PD without cortical Lewy bodies or AD changes, PD with cortical Lewy bodies but not concomitant AD changes, and PD with cortical Lewy bodies and AD changes. The McKeith consensus criteria led to dementia with Lewy bodies as the preferred term for patients with cortical Lewy bodies and dementia with or without concurrent pathological evidence of AD⁶⁶ (the published revision of the original criteria is described later in the chapter). Numerous data indicate that PD and AD have distinctly separate clinical, pathological, pathophysiological, and genetic correlates. However, there is a significant proportion of patients with combinations of the classic features of PD and AD, which suggests that there is a pathophysiological relationship between them.

Pathologically, the gross appearance of the brain is normal to slightly atrophic. The substantia nigra is pale. In the LBV of AD, there are sufficient numbers of NPs to apply the neuropathological diagnosis of AD. NFT counts are more variable. Lewy bodies, if present in the cortex, are almost invariably also present in the brain stem. The Lewy bodies in the brain stem are easily seen on sections stained with hematoxylin-eosin, where they tend to reside in the substantia nigra, locus caeruleus, and raphe nuclei. Cortical Lewy bodies often lack the surrounding halo that is typical of those in the brain stem, and they are more difficult to visualize unless immunostains for ubiquitin or α -synuclein are used (Fig. 33-6). The locations of maximal numbers of cortical Lewy bodies include the cingulate gyrus, insular cortex, and parahippocampal gyrus. Ubiquitin- and synuclein-positive neuritic changes are also present in the CA2/CA3 region of the hippocampus, whereas Lewy bodies are rarely found in the hippocampus. The degree of neuronal loss in the hippocampal CA subfields is variable in LBV and DLB. These findings suggest that the type of ubiquitin- and synuclein-positive changes may be site specific. The cholinergic neurons in the nucleus basalis are markedly depleted.

As noted previously, a subgroup of AD cases with primarily plaque-only changes were found to have numerous extranigral Lewy bodies.²¹ In those cases with more typical NPs and NFTs, the number of NFTs tends to be less in AD plus PD brains than in AD-only brains. All of these cases had sufficient numbers of NPs to apply the neuropathological diagnosis of AD. However, because frequent NPs have also been observed in cognitively normal individuals, debate has surrounded the issue of whether these cases represent a variant of AD (thus the name LBV of AD) or a distinct entity (thus the name DLB) with coexisting AD changes.

Katzman and colleagues⁶⁷ provided several lines of evidence supporting the LBV of AD concept: (1) The clinical features of AD and LBV are similar, (2) the LBV has been observed in several familial AD1 cases, (3) the LBV has also been observed in rare Down's cases, and (4) the LBV is frequently observed in ApoE ϵ 4 carriers. Other investigators have observed an association between ApoE ϵ 4 dosage and PD-related changes, but interestingly, the severity of ubiquitin-positive neuritic changes in the hippocampus correlated with ApoE ϵ 4 dosage, whereas the

Figure 33-6. Photomicrograph of cortical Lewy bodies using an anti-ubiquitin immunostain. The core is composed of 7- or 8-nm filaments (hematoxylin and eosin, 400 \times). (Courtesy of J. E. Parisi, Mayo Clinic, Rochester, MN.)

frequency of cortical Lewy bodies did not.⁶⁸ It has been suggested that the LBV of AD may represent the result of a coexistent gene that promotes LB rather than NFT in degenerating neocortical neurons.⁶⁷

The cardinal features of DLB involve dementia and mild to moderate parkinsonism. The extrapyramidal symptoms reflect basal ganglia and nigral degeneration. The nature of cognitive impairment in DLB is likely multifactorial. The degree of neurofibrillary degeneration is less than in pure AD. Although supportive data are lacking, the presence and frequency of cortical LB may be a contributor, and the effects of LB and AD changes may be additive. Subcortical degenerative changes underlie the psychomotor slowing. Prominent hallucinations, delusions, illusions, and behavioral dyscontrol are also characteristic clinical features (Video 89, Hallucinations). It is unclear whether the neuropsychiatric features reflect unique qualities of cortical Lewy bodies themselves; the topographic distribution of LB or cortical degeneration or both; or neurochemical abnormalities.

The nucleus basalis atrophy and marked cholinergic deficiency in brains affected by LBV and DLB mirror those noted in brains affected by AD only. Choline acetyltransferase activity has been found to be lower in patients with LBV than in those with AD only.⁶⁹ The brains of

patients with AD plus PD changes have also been found to have reduced levels of dopamine and homovanillic acid compared with normal brains and those affected by AD only.

EPIDEMIOLOGY AND RISK FACTORS. The synucleinopathies are a group of disorders that include PD, DLB, and multiple system atrophy (MSA).⁶⁰ Dementia commonly occurs within the context of parkinsonism but is an infrequent accompaniment of MSA. PD is the second most common degenerative brain disease after AD, and it is the most common presenting phenotype of the synucleinopathies.⁶⁰ The estimated prevalence of PD is 107 to 187 per 100,000,⁷⁰ with a lifetime risk that is greater in men (2%) than women (1.3%).⁷¹ Prevalence estimates of the co-occurrence of dementia and parkinsonism vary widely between studies but average approximately 20% to 30%, and annual incidence rates of dementia in established parkinsonism also vary but average approximately 5% or 6% per year.⁷² Following AD, dementia within the context of parkinsonism is the second most common form of dementia.⁷³

The relationship among DLB, AD, and PD is debated because there is evidence to support all points of view—that is, DLB is related to AD and to PD and can be a distinct entity unrelated to either. Hence, it is unclear whether epidemiological data that relate to AD and PD are relevant for DLB. There are no large epidemiological studies, but autopsy series suggest that the mean age of onset of DLB is 57 years, that it affects men more often than women (male-to-female ratio, 1.7:1), and that death ensues after approximately 10 to 15 years.⁷⁴ In this series, there were 20 patients who died with PD and 8 who died with DLB, suggesting that the prevalence of DLB is, very roughly, 30% that of PD.⁷⁴ Extrapyramidal findings occur with increasing frequency as AD progresses (in approximately 30% of patients),⁷⁵ but how often this reflects Lewy body-related pathology is uncertain. In an autopsy series of AD, 15% of patients had some type of Lewy body-related pathology.⁷⁶ The relationship of ApoE to DLB depends on how closely DLB is related to AD, and although ApoE genotype appears relevant, the relationship is weaker than that for AD.⁷⁷

CLINICAL FEATURES AND ASSOCIATED DISORDERS. AD and PD are both part of the nosological spectrum of DLB, which seems to bridge the cortical and subcortical degenerative dementias. Parkinsonism adds to the severity⁷⁸ and cost of care of dementia patients.⁷⁹ Either parkinsonian or cognitive symptoms can present first, and both are important components.

The proposed core features of DLB include fluctuating cognition, visual hallucinations, and parkinsonism⁸⁰ (Table 33-3; Video 232, Dementia with Lewy Bodies); two features are required for the diagnosis of clinically probable DLB and one is required for the diagnosis of clinically possible DLB. In the new criteria, rapid eye movement (REM) sleep behavior disorder and neuroleptic sensitivity are now considered “suggestive” clinical features, meaning that the presence of either feature plus only one (or more) of the core features warrant the diagnosis of clinically probable DLB (see Table 33-3). In general, the clinical picture of a mild parkinsonian syndrome with a more severe dementia and prominent visual hallucinations and paranoid delusions should prompt consideration of DLB. Although the parkinsonism is typically levodopa

TABLE 33-3

Diagnostic Criteria for Dementia with Lewy Bodies (DLB)

| |
|---|
| Central Feature |
| Progressive cognitive decline of sufficient magnitude to interfere with normal social and occupational function |
| Prominent or persistent memory impairment may not necessarily occur in the early stages but is usually evident with progression |
| Deficits on tests of attention, executive function, and visuospatial ability may be especially prominent. |
| Core Features (two core features essential for a diagnosis of probable, one for possible DLB) |
| Fluctuating cognition with pronounced variations in attention and alertness |
| Recurrent visual hallucinations that are typically well formed and detailed |
| Spontaneous features of parkinsonism |
| Suggestive Features (one or more present in addition to one or more core features is sufficient for a diagnosis of probable DLB, and in the absence of any core features is sufficient for possible DLB) |
| REM sleep behavior disorder (which may precede onset of dementia by several years) |
| Severe neuroleptic sensitivity |
| Abnormal (low uptake) in basal ganglia on SPECT or PET dopamine transporter scans |
| Supportive Features (commonly present but not proven to have diagnostic specificity) |
| Repeated falls and syncope |
| Transient, unexplained loss of consciousness |
| Severe autonomic dysfunction (e.g., orthostatic hypotension and urinary incontinence) |
| Hallucinations in other modalities |
| Systematized delusions |
| Depression |
| Relative preservation of medial temporal lobe structures on CT/MRI scan |
| Generalized low uptake on SPECT/PET perfusion scan with reduced occipital activity |
| Abnormal (low uptake) MIBG myocardial scintigraphy |
| Prominent slow-wave activity on EEG with temporal lobe transient sharp waves |
| A diagnosis of DLB is <i>less likely</i> : |
| In the presence of cerebrovascular disease evident as focal neurologic signs or on brain imaging |
| In the presence of any other physical illness or brain disorder sufficient to account in part or in total for the clinical picture |
| If parkinsonism only appears for the first time at a stage of severe dementia |

CT, computed tomography; EEG, electroencephalogram; MIBG, metaiodobenzylguanidine; MRI, magnetic resonance imaging; PET, position emission tomography; SPECT, single-photon emission computed tomography.

responsive, levodopa may exacerbate the psychosis, and in the early to middle stages the neuropsychiatric disturbance is generally the more disabling feature. As the disease progresses, however, both components worsen, and the patient may eventually develop severe parkinsonian symptoms and become wheelchair bound. Rest tremor is less frequent (approximately 29% of patients)⁷⁴ than in PD, but bradykinesia is a predictable feature. The quality of the dementia resembles the subcortical pattern, with pronounced psychomotor slowing; the absence of severe aphasia, agnosia, or apraxia; and concurrent parkinsonism. Atypical features, including impaired vertical gaze and progressive spasticity, have been described further, highlighting the clinicopathological overlap that occurs among many of the degenerative dementias. Importantly, approximately 20% to 30% of cases with autopsy-proven neocortical-predominant Lewy body

disease failed to exhibit any parkinsonism in life, so the absence of parkinsonism should not dissuade one from making a DLB diagnosis if the other core \pm suggestive features are present.

Clinically, the AD and DLB components may be separable in some cases. We reported a patient with autopsy-confirmed mixed DLB-AD in whom the first 6 years were dominated by progressive aphasia (caused by the AD component) and the final 3 years by new-onset psychosis and parkinsonism (caused by the LB component).⁸¹ It is therefore possible to distinguish the clinical contributions of each pathological component in some cases.

Evidence suggests that REM sleep behavior disorder (RBD) is a frequently associated feature of DLB (as well as PD and MSA) but is rarely present in AD and the tauopathies.⁸²⁻⁸⁴ RBD is a parasomnia manifested by dream enactment behavior, in which the normal paralysis REM sleep is lost and patients appear to “act out their dreams” (Video 241, REM Behavioral Disorder). Clinicians can usually elicit a history suggesting RBD by simply asking spouses whether their bed partners have repeatedly acted out their dreams, even if such behavior was more frequent and severe years or decades earlier. The underlying neurologic substrate for RBD clearly localizes to the brain stem, but which specific neuronal networks are involved is not known. The Braak staging system for the neuropathologic characterization of Lewy body pathology posits an ascending pattern of synuclein deposition, beginning in the medulla (and olfactory structures) and then pons, midbrain, limbic, and neocortical structures.⁸⁵ This schema is therefore consistent with the tendency for RBD to be present for years or decades, followed by the variable degrees of parkinsonism and/or dementia.

DIFFERENTIAL DIAGNOSIS. The differential diagnosis of DLB is particularly broad because of its overlap with cortical and subcortical degenerative dementias, as well as the clinical similarities with nondegenerative dementing illnesses. Dementia and mild parkinsonism is perhaps the most common presenting symptom complex of small vessel-type multi-infarct dementia (another, and perhaps the most common, cause of subcortical dementia). Prominent visual hallucinations can be an important clinical feature of certain reversible chronic progressive encephalopathies, including chronic inflammatory meningoencephalitis, chronic meningitides occurring on infectious or neoplastic bases, and many toxic-metabolic encephalopathies (Video 41, Carbon Monoxide Intoxication Parkinsonism). Although they do occur in other degenerative dementias, including AD and PD, they are less frequent and should not be considered typical early features.

EVALUATION. The neuropsychological pattern of impairment in DLB is quite different from that of AD, with significantly worse mental speed, visual perceptual organization, sequencing, and letter fluency but significantly better confrontation naming and verbal memory.^{86,87} When diagnostic clarification for the diagnosis of RBD is necessary, particularly when the risk for injury is high, polysomnography (PSG) with simultaneous video-PSG monitoring is warranted. In addition to the usual tests for dementia evaluation (MRI, neuropsychological testing, and laboratory studies, as described in the section on AD), the EEG is particularly useful. Many reversible chronic progressive

encephalopathies produce severe dysrhythmic slowing, whereas most degenerative diseases, at least in early stages, produce mild or no dysrhythmic slowing. Although a severely abnormal EEG can occur in DLB, it should prompt strong consideration of more exhaustive laboratory studies searching for unusual autoimmune causes and other systemic medical causes of encephalopathy, as well as a CSF examination. CSF tests should include microbiological, cytological, and immunological studies (including IgG index, IgG synthesis rate, and oligoclonal bands). These immunological studies may provide evidence of an intrathecal immunological response that, although nonspecific, may be more sensitive than fungal cultures or cytology and therefore may be the only sign of an autoimmune process. If the patient has a so-called psychotic delirium with minimal parkinsonian features, a severely dysrhythmic EEG, and a CSF profile that suggests an inflammatory-mediated process, in the absence of another obvious cause, meningeal and brain biopsy should be considered, observing for NAIM, CNS vasculitis, CNS infection, and meningeal carcinomatosis. Because NAIM is very steroid responsive, an empirical trial of corticosteroid therapy could be considered, especially if there is reticence to perform a brain biopsy.

MANAGEMENT. As noted previously, treatment of the parkinsonian syndrome may exacerbate the neuropsychiatric disorder, and treatment of the neuropsychiatric disorder may exacerbate the parkinsonian syndrome. Therefore, a decision must first be made regarding whether treatment is necessary at all and, if so, what symptoms warrant treatment. Generally, the neuropsychiatric syndrome is the most disabling aspect in mild to moderate stages, and selective neuroleptic therapy with quetiapine should be considered as a first choice. Treatment of the parkinsonian syndrome is similar to that of PD, generally beginning with Sinemet at a very low dose and gradually titrating the dose to symptoms and side effects. Other nonpharmacological aspects of caregiving are similar to those described for AD except that physical and occupational therapies are of greater importance at an earlier stage due to the extrapyramidal syndrome. However, benefits are generally modest.

PROGNOSIS AND FUTURE PERSPECTIVES. As noted previously, the mean age of onset of DLB is 57 years, and death ensues after approximately 10 to 15 years.⁷⁴ Treatment and caregiving are especially difficult because of the psychosis and parkinsonism.

DLB is an important nosological entity because it appears to occupy an intermediate position between AD and PD, two common degenerative diseases that are generally thought to have little in common. Therefore, understanding the genetics and disease mechanisms of DLB may provide important insights into its more frequent cousins as well. Also, this group of patients will be an important testing ground for newer antipsychotic agents with greater selectivity. Since RBD is often associated with DLB, and the onset of RBD often precedes the onset of cognitive impairment or parkinsonism, isolated RBD may represent the earliest clinical manifestation of DLB (or PD or MSA). Thus, the presence of RBD may be particularly relevant early in the course of a neurodegenerative disease when intervention may be most critical; treatment of patients with isolated RBD could potentially delay or prevent the development of cognitive impairment or parkinsonism.

Parkinson's Disease with Dementia

Many considerations regarding PDD have been discussed previously. The primary distinction between PDD and DLB is simply one of the duration of delay between the onset of parkinsonism and the subsequent appearance of dementia. If dementia occurs more than 1 year after the onset of parkinsonism, the term PDD is used. Neuropathological findings are the same in each. It is therefore unclear whether they are two different diseases or variations of the same disease.

In familial cases of PDD, genetic defects and pathological changes differ between kindreds, so it is difficult to generalize to sporadic PD. In each case of PD, however, when dementia is described, it is most consistent with a "subcortical pattern" to distinguish it clinically from typical Alzheimer's dementia (Video 67, Parkinsonian Rest Tremor).

PATHOGENESIS AND PATHOPHYSIOLOGY. Cognitive performance in nondemented and demented patients with PD is qualitatively different,^{86,87} suggesting that cognitive impairment in nondemented and demented PD patients reflects different anatomical or neurochemical systems or separate pathogenetic processes. Histological components of the Parkinson's dementia picture include both Parkinson- and Alzheimer-type pathology. Therefore, one must consider the roles of cortical Lewy bodies, concomitant AD pathology, and cholinergic deficiency in the pathogenesis of dementia in PD (see the section on DLB). Studies using ubiquitin staining in previous pathologically diagnosed PD demonstrate that 76% of cases have neocortical Lewy bodies compared to only 32% of cases studied only with routine hematoxylin-eosin stains.⁸⁸ Concomitant AD changes meeting diagnostic criteria for AD diagnosis have been found in up to 50% of patients with PD dementia. Immunostaining with α -synuclein is more sensitive and specific than ubiquitin, and α -synuclein immunocytochemistry has rapidly become viewed as essential in the neuropathological characterization of demented individuals.

PD is characterized by nigral degeneration with Lewy bodies in the pigmented brain stem nuclei, but the contribution of medial substantia nigra neuronal loss, the most consistent pathological finding in PD, to dementia is unclear. The basal ganglia interfaces with the limbic system through a subset of structures collectively referred to as the ventral striatum and ventral pallidum. Cortical input to the ventral striatum is from the hippocampal formation through the precommissural fornix, and dopaminergic input comes from the ventral tegmental area (part of the mesocorticolimbic dopaminergic system). Analogous to the concept that the dorsal or neostriatum and its neocortical targets are part of a so-called motor loop, so too have the ventral striatum and its allocortical or paralimbic targets been termed a cognitive loop.⁸⁹ However, the role of the cognitive loop remains speculative, and it is unknown whether any cognitive alterations in PD or dementia reflect this loop.

EPIDEMIOLOGY AND RISK FACTORS. Considering the heterogeneity of parkinsonian syndromes, potential co-occurrence of AD, and the cognitive side effects of anti-parkinsonian treatment, estimates of dementia prevalence in PD vary considerably. Most range between 20% and 30%.⁹⁰

One population-based study found that almost 80% of PD patients develop dementia within 8 years.⁹¹ Based on autopsy studies, approximately half (or more) of demented parkinsonian patients have coincident AD pathology.⁹²

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Although PSP was the original model for subcortical dementia, this model is applicable to PD, which is much more common than PSP. The concept was intended to distinguish subcortical dementia from the cortical dementia of AD. Subcortical dementia-related memory impairment benefits more by cuing than the memory disturbance of cortical dementia. Patients have equal or greater difficulty learning new material but have relatively less difficulty retrieving it, possibly due to disturbed frontal or frontostriatal function involved in attending to and organizing the memory task. Subcortical dementia is not usually accompanied by aphasia, apraxia, and agnosia. However, it is accompanied by psychomotor slowing, an early feature of Parkinson's dementia.^{86,87} Patients perform disproportionately poorly on timed tests whether the tests use motor responses (e.g., the digit symbol substitution subtest of the Wechsler Adult Intelligence Scale-Revised) or whether they are purely cognitive (e.g., the controlled oral word association test). PD results in disproportionately poor performances on visuospatial tasks, although this aspect does not seem to be a major source of clinical disability, and the cause is debated. Depression is more common in PD with or without dementia than in AD. Finally, the noncognitive (motor) parkinsonian features make distinction from AD and related cortical degenerative syndromes generally possible. The distinction has clinical value, despite overlap with cortical dementia on both clinical and pathological grounds that blur nosological boundaries. For example, a subset of patients with AD have mild extrapyramidal features, and there is important subcortical pathology in the basal forebrain of AD. The coincidence of Alzheimer's pathology in patients with PD with so-called subcortical dementia was alluded to previously. There are certain kindreds in which a parkinsonian syndrome is invariably accompanied by severe dementia. Nondegenerative quasiparkinsonian syndromes in which cognitive impairment is present can have many etiologies, including multi-infarct dementia, normal pressure hydrocephalus, and postencephalitic parkinsonism.

DIFFERENTIAL DIAGNOSIS. The differential diagnosis of PD is extensive, and dementia can occur in many of the conditions discussed in the section on PD. Some of the differential diagnoses that are of particular note that are also degenerative include PSP, MSA, DLB, and corticobasal degeneration (CBD). Occasionally, frontal lobe disorders may be mistaken for parkinsonian syndromes with dementia, including both degenerative etiologies, such as Pick's disease, and nondegenerative etiologies, such as frontal lobe meningiomas. Other progressive, nondegenerative diseases that have loosely fitting parkinsonian features include multi-infarct dementia and normal pressure hydrocephalus. Occasionally, parkinsonian features occur in patients with AD (see the sections on AD and DLBD).

EVALUATION. MRI is generally preferable to CT, in part because of the multifocal areas of increased T2 signal (often missed or poorly defined by CT) in periventricular, basal ganglia, and other locations that may signify a small

vessel multi-infarct state. Evaluation is similar to that described for AD except that response to therapy offers additional diagnostic information.

MANAGEMENT. Dopaminergic therapy is discussed in the section on PD, but special considerations apply here. First, dopaminergic therapy is more likely to cause hallucinations and delusions in parkinsonian patients with dementia, as well as in patients with related parkinsonian syndromes, than in those with uncomplicated PD. Second, neuroleptic therapy is more likely to cause an exacerbation of parkinsonian symptoms. Third, so-called on-off motor fluctuations may be accompanied by mild fluctuations in cognitive status as well. There are no perfect solutions, and antipsychotic therapy with atypical agents such as quetiapine, which produce fewer parkinsonian side effects than standard agents, will need to be tried cautiously if absolutely required (although note FDA warnings described for AD). Cholinesterase inhibitors could be considered given the frequency of Alzheimer-type pathology, including cholinergic deficiency, although again there is at least the theoretical risk that increasing central cholinergic tone could mildly exacerbate the parkinsonian syndrome (rarely seen in clinical practice).

PROGNOSIS AND FUTURE PERSPECTIVES. Prognostic considerations are similar to those discussed for AD except that the combination of parkinsonism and dementia is a more difficult management problem, and because dementia is usually a late complication of PD, it may signify a shorter lifespan than for patients with either uncomplicated PD or AD.

There is ongoing development of more highly selective neuroleptic agents with less toxicity than clozapine. One report suggested that selective serotonin receptor blockade may offer one such strategy. See the section on movement disorders.

Vascular Dementia

Cerebrovascular disease and its relationship to dementia is covered more fully in the chapters on cerebrovascular disease, but we focus here on the intersection between vascular and degenerative mechanisms in patients with the syndrome of vascular dementia.

PATHOGENESIS AND PATHOPHYSIOLOGY. Cognitive decline has been linked to cardiovascular disease and atherosclerotic risk factors, including diabetes mellitus, hypertension, and high blood pressure. Various genetic and nongenetic factors known to increase the risk of vascular disease, including ApoE and angiotensin I converting enzyme 1 genotypes, total cholesterol, lipoprotein A, diabetes mellitus, atrial fibrillation, hypertension, serum ApoE levels, and atherosclerosis, have been evaluated as risk factors for AD and vascular dementia.⁹³

Vascular mechanisms of cognitive loss include the direct consequences of brain infarctions, hemorrhages, and global hypoxia-ischemia. The two major subtypes of vascular pathology in patients with vascular dementia are multiple large artery territory infarctions (and/or hemorrhages) and small vessel cerebrovascular disease caused either by arteriosclerosis or by amyloid angiopathy. In the large artery type, clinically evident strokes occur with consequent accrual of deficits. This is not a slowly progressive disease

but one of defined events. An ongoing controversy, however, is whether AD develops at an accelerated rate following (and, by implication, as a result of) cerebral infarction (or hemorrhage).^{94,95} Investigations have also established that risk factors for atherosclerotic vascular disease are also risk factors for AD, and that there is a statistically significant association between AD and atherosclerosis of major intracranial arteries.⁹⁶

Small vessel cerebrovascular disease, however, is more subtle, often with no defined events (or with few as a minor component). Within this context, a mixed pathological picture with both vascular and AD is common whether the underlying vasculopathy is atherosclerotic⁹⁷ or amyloid based.⁹⁸

EPIDEMIOLOGY AND RISK FACTORS. Incidence and prevalence rates of vascular dementia are affected by the definition used. For example, the prevalence of post-stroke vascular dementia ranged from 11.3% using the NINDS-AIREN criteria to 20.1% using the ICD-10-NA criteria, and the incidence ranged from 2.6% with the ADDTC to 5.2% with the ICD-10-NA.⁹⁹ In one longitudinal population-based study, among patients with MCI who progressed to dementia, 60% progressed to AD and 33% to vascular dementia.¹⁰⁰ Others have found that midlife hypercholesterolemia and hypertension increased the risk for AD,^{101,102} whereas physical exercise such as walking reduces the risk.¹⁰³ The incidence rate of AD is higher among individuals with prevalent cardiovascular disease (34.4 per 1000 person-years) than among those without it (22.2 per 1000 person-years).¹⁰⁴

CLINICAL FEATURES AND ASSOCIATED DISORDERS. There are multiple proposed diagnostic criteria for the diagnosis of vascular dementia, with poor agreement among them.^{105–107} Patients have a more subcortical pattern of dementia with psychomotor slowing, a poor learning curve, and relative preservation of naming and other language skills.^{108,109} The degree of impairment, however, correlates better with the degree of neurofibrillary pathology than with cerebrovascular pathology at autopsy (Video 233, Vascular Parkinsonism).¹¹⁰

DIFFERENTIAL DIAGNOSIS. There is a broad range of cerebrovascular disorders that may result in cognitive impairment. Multiple large artery territory infarctions and hemorrhages may result in more extensive physical disability and cortical cognitive signs such as aphasia. Non-atherosclerotic forms of cerebrovascular disease may have their own disease associations that, in turn, may influence cognition. For example, amyloid angiopathy may cause subcortical small vessel territory infarctions, recurrent lobar hemorrhages in posterior hemisphere locations (resulting in severe visual impairment), and be associated with AD. Cerebral vasculitis may present as a rapidly progressive fulminant encephalopathy, a subacute course of recurrent cerebral infarctions (and/or hemorrhages), or a more chronic dementia-like course. Finally, given the frequent finding of small vessel disease on brain imaging, essentially any cause of cognitive impairment and dementia in an elderly patient should be considered in the differential diagnosis of vascular dementia.

EVALUATION. Considerations are the same as for AD except that causes of cerebral infarction also need to be included.

MANAGEMENT. Considerations are the same as for AD except that treatment for causes of cerebral infarction and the physical as well as cognitive disabilities produced also need to be included.

PROGNOSIS AND FUTURE PERSPECTIVES. Perhaps more than any other form of dementia, basic clinicopathological correlation studies are still important in deciphering the prevalence of “pure” vascular dementia and the contributory role played by concomitant cerebrovascular disease in patients with other primary forms of dementia such as AD.

Other Extrapyramidal Disorders with Dementia

Multiple System Atrophy

This is an uncommon and heterogeneous group of disorders generally characterized by atypical, relative dopamine-unresponsive parkinsonism with variable degrees of cognitive impairment. MSA includes olivopontocerebellar atrophy (OPCA), striatonigral degeneration, and parkinsonism with orthostatic hypotension and dysautonomia (Shy-Drager syndrome) (Video 235, Multiple System Atrophy, Striatum-Nigral Degeneration).

PATHOGENESIS AND PATHOPHYSIOLOGY. Neuropsychological studies in both sporadic and familial cases of OPCA have demonstrated frontostriatal dysfunction.¹¹¹ A similar profile of frontostriatal impairment occurs in MSA with predominantly striatonigral degeneration features, which is qualitatively different from PD and PSP.¹¹² Therefore, it appears that the cognitive impairment in the various forms of MSA results, at least in part, from frontostriatal dysfunction. Cerebellar dysfunction may play an additional role in OPCA.

EPIDEMIOLOGY AND RISK FACTORS. Of five clinical subtypes of OPCA that have been described on both genetic and sporadic bases, mild to moderate decline has been described in types III, IV, and V.¹¹¹ Approximately 60% of familial and 35% of sporadic cases have accompanying cognitive impairment.¹¹³

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Patients with dominantly inherited OPCA (type IV) have frontal lobe-related cognitive impairments,¹¹¹ but the apparent mild intellectual decline in most OPCA cases may be related more importantly to motor impairment and depression without actual dementia and without evidence of aphasia, agnosia, or apraxia (Video 234, multiple System Atrophy, Cerebellar Type).¹¹⁴ MSA of the Shy-Drager variety has been less studied. Given the clinical similarities to other parkinsonian syndromes, as well as its clinical heterogeneity, mild “subcortical” patterns of cognitive impairment are possible, but it should not be regarded as a cause of severe dementia.

MANAGEMENT. Considerations are similar to those discussed for Parkinson’s dementia, but additional consideration must be given to symptomatic orthostatic hypotension and other autonomic disturbances.

Huntington’s Disease

PATHOGENESIS AND PATHOPHYSIOLOGY. The cognitive impairment in HD, like other subcortical dementias,

primarily reflects frontostriatal dysfunction, and there is evidence of both subcortical and cortical pathology. Grossly, the cortical gyri appear normal to slightly atrophic. Coronal sections reveal striking caudate greater than putamen and pallidum atrophy. Neuronal loss and gliosis follow the same regional distribution. The medium-sized spiny type I striatal neurons are preferentially affected, whereas the aspiny type I neurons that contain somatostatin and neuropeptide Y are unaffected. Several neurotransmitters are decreased in the striatum, most notably GABA and acetylcholine. Glutamic acid decarboxylase and choline acetyltransferase are also diminished.

Milder degenerative changes occur in the neocortex and thalamus. Cross-sectional areas within the frontal, temporal, and parietal lobes were decreased compared with controls, with atrophy in HD being greater than in PSP.¹¹⁵ Quantitative analysis in HD patients compared with that of controls has revealed moderate to severe neuronal loss in the cortex and striatum, which was differentially distributed in the cortical laminae in primary sensory and association cortices.¹¹⁶ Ubiquitin-reactive dystrophic neurites were identified in all cortical but no subcortical areas,¹¹⁷ and these neurites have been hypothesized by some to correlate with dementia. Evidence exists for excitotoxic damage and mitochondrial DNA mutations and oxidative stress¹¹⁸ in the pathogenesis of cortical pathology in HD.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Lieberman and associates⁹⁰ found that 90% of patients were demented by a mean age of 48.3 years, and that dementia preceded the onset of chorea in 24% (Video 15, Facial Chorea). There are discrepant studies with regard to the existence of preclinical cognitive abnormalities, although preclinical metabolic abnormalities are detectable with PET.¹¹⁹ Whether or not it is the critical determinant of cognitive decline, cognitive decline correlates pathologically and radiologically with degree of caudate atrophy¹²⁰ and hypometabolism.¹²¹ Three areas of particular interest in the dementia of HD are frontal lobe-related or frontostriatal-related neuropsychiatric deficits, declarative memory impairment, and motor learning difficulties. Visuospatial disturbances have been demonstrated in some studies. With regard to frontostriatal neuropsychiatric deficits, patients may present initially with either primarily psychiatric or cognitive disturbances, although both may occur together. Regarding cognitive disturbances, prospective study of cognitive decline in early cases has shown that psychomotor slowing is a characteristic early feature,¹²² and memory impairment, although present early on, does not deteriorate as rapidly, or correlate as well with caudate atrophy, as does psychomotor speed.¹²² Patients with HD have greater perseveration and less initiation than AD patients, and they have greater problems with concentration and sustained attention. The overall pattern of frontal lobe-related deficits nonetheless appears qualitatively distinct from purely frontal cortical damage and has instead been attributed to frontostriatal dysfunction.

Regarding declarative memory impairment, much work has focused on the qualitative differences between HD and amnesic patients, including both AD and Korsakoff's patients. HD causes memory loss, but it appears to be less severe compared with that of AD at matched stages of dementia severity, although this factor has been more con-

sistent at milder stages of dementia. Most studies have found that patients with HD have greater difficulty learning a task (e.g., a list of words), but they benefit more by cued recall or recognition compared with free or unassisted recall. This has been thought to reflect greater impairment of retrieval than storage mechanisms, and it affects remote memory retrieval as well as more recently learned material.⁴³ There are many similarities in the memory disturbance between HD and PD, suggesting similarities between the subcortical dementia illnesses, but overlap is imperfect. For example, patients with HD have greater impairment of learning and free recall, better recognition memory, and more perseveration than PD patients.¹²³

In contrast to the mild impairments of verbal learning, motor learning is severely impaired. There is a "double dissociation" between the performance of AD and HD patients on tests of these two memory systems: AD patients do poorly on verbal and well on motor learning, and HD patients do well on verbal and poorly on motor learning.⁴⁴ Demented PD patients perform poorly on both,⁴⁴ which is interesting to consider in light of known overlap with AD pathology in a large subset of these patients. The most likely anatomical substrates, supported by the overlap with PD, are the basal ganglia, their frontal lobe connections, and related motor structures.

DIFFERENTIAL DIAGNOSIS. See Chapter 34. In the absence of chorea, the family history is critical in reaching a diagnosis. In the absence of both chorea and a family history, the differential diagnosis is that of other subcortical dementias and chronic progressive encephalopathies.

EVALUATION. The clinical examination may provide compelling evidence for HD, which can be confirmed genetically. Ancillary tests include MRI or CT to ascertain caudate atrophy, and (optionally) SPECT or PET to ascertain caudate hypoperfusion or -metabolism. Neuropsychological assessment is useful to document the nature and severity of cognitive decline, particularly in mild to moderate stages of the illness.

MANAGEMENT. See Chapter 34. Pharmacological management of dementia and chorea often involves dopaminergic antagonists including neuroleptic drugs but is far from adequate.

PROGNOSIS AND FUTURE PERSPECTIVES. Death occurs within 10 to 20 years after onset, although suicide is more prevalent in at-risk and early onset HD patients. Aspiration and inanition result from severe dysphagia, as well as from an apparent increased metabolic demand in patients with HD.

ASYMMETRIC CORTICAL DEGENERATION SYNDROMES AND THE TAUOPATHIES

This is a clinically heterogeneous group of disorders that produce distinctive cortical syndromes, including aphasia, apraxia, and agnosia, and that have a more focal appearance than Alzheimer's dementia. They can be roughly localized by the more focal features, although only a small subset are truly focal. The frontotemporal lobes degeneration (FTLD) syndromes reflect this asymmetry as regards frontal and temporal cortices.

TABLE 33-4

Asymmetric Cortical Degeneration Syndromes

| SYNDROME | MAJOR TOPOGRAPHY | MAIN PATHOLOGY | COGNITIVE SIGNS | OTHER EARLY NEUROLOGICAL SIGNS |
|----------------------------|-------------------------------------|-------------------|---------------------------|--|
| Progressive Aphasia | | | | |
| Nonfluent | Dominant frontal operculum | FTLD/Pick | Nonfluent aphasia | Dysarthria, reflex asymmetry, memory loss |
| Fluent | Dominant temporal | FTLD/AD | Fluent aphasia | Acalculia, apraxia, other parietal signs, memory loss |
| Anomic-semantic dementia | Dominant anterior temporal | FTLD/Pick | Anomia | Abulia and other frontal lobe signs, memory loss |
| Mixed | Dominant perisylvian | FTLD/AD | All aspects of speech | Memory loss, dysarthria, acalculia, apraxia |
| Perceptual-Motor | | | | |
| Visual | Asymmetric bilateral P-T-O | AD | Asimultanagnosia | Alexia, memory loss |
| Motor | Asymmetric parietofrontal | CBD/PLS/PSP | Apraxia/spasticity | Hemiakineti-rigid syndrome/spasticity, psychomotor slowing |
| Mixed | Asymmetric P-F and P-O | CBD/AD variant | Asimultanagnosia, apraxia | Memory loss, aphasia, and any of the above |
| Frontotemporal | | | | |
| Neuropsychiatric | Bilateral prefrontal, orbitofrontal | FTLD/Pick | Abulia, disinhibition | Memory loss, anomia, anosognosia |
| Semantic dementia | Dominant anterior temporal | FTLD/Pick | Anomia | Abulia and other frontal lobe signs, memory loss |
| Spasticity | Bilateral paracentral | Nonspecific (PLS) | Psychomotor slowing | Spasticity, dysarthria |
| Mixed | Bilateral frontal | PSP | Spastic-dementia syndrome | Dysarthria |
| Bitemporal | | | | |
| Amnesia | Bilateral mesial temporal | AD | Amnesic MCI | |
| Semantic dementia | Dominant anterior temporal | FTLD/Pick | Anomia | Abulia and other frontal lobe signs, memory loss |
| Prosopagnosia | Right inferior temporal (bilateral) | FTLD/Pick/other | Prosopagnosia | Memory loss, alexia |
| Neuropsychiatric | Nondominant anterior temporal | FTLD/Pick/other | Anomia, amnesia, abulia | Psychomotor slowing, anosognosia |

AD, Alzheimer's disease; CBD, cortical basal ganglionic degeneration; F, frontal; FTLD, frontotemporal lobar degeneration; MND, motor neuron disease; O, occipital; P, parietal; PLS, primary lateral sclerosis; T, temporal.

There are four primary categories, each with several subtypes: progressive aphasia, progressive frontal lobe/frontotemporal dementia (FTD) syndromes, progressive perceptual-motor syndromes, and progressive bitemporal syndromes (Table 33-4). Since this original clinical classification, many of the individual asymmetric cortical degeneration syndromes (ACDS) have been shown to be genetically and pathophysiologically related to each other reflecting tau-based cytoskeletal pathology and so leading to the new term, the "tauopathies." Not all members of the ACDS group are tauopathies, however, but both tau- and non-tau-based entities are presented here to preserve the heuristic value of the ACDS classification scheme.

PATHOGENESIS AND PATHOPHYSIOLOGY. Despite the semiological and pathological diversity of the ACDS group, there is a common clinicopathological theme among all members: Clinical presentation is dictated by the topographical distribution of degeneration. Routine H&E staining reveals nonspecific degenerative changes consisting of neuronal loss, gliosis, and vacuolation of neuropil predominantly affecting superficial cortical laminae (Fig. 33-7) that are common to all clinical subtypes. These nonspecific changes with and without ubiquitin-positive inclusions probably account for the overall majority of pathological findings in ACDS. Tauopathy-

based cases also stain for intracytoplasmic hyperphosphorylated neurofilaments.

PROGRESSIVE APHASIA

Nonfluent Aphasia. This is now recognized as one of the member syndromes of frontotemporal lobar degeneration and is generally tauopathy based. The degenerative focus centers on anterior perisylvian language cortices (Broca's area). Neuropathology of progressive aphasia has included (1) nonspecific degenerative changes, including increased neuronal lipofuscin,¹²⁴ neuronal loss, astrogliosis, and perineuronal microvacuolation in superficial laminae with or without occasional amyloid plaques¹²⁵; (2) tau-positive neuronal and/or glial pathology and nonspecific degenerative changes with focal accumulations of achromatic neurons¹²⁶; and (3) unusual combinations of Pick/Alzheimer¹²⁷ and Alzheimer/Pick/Lewy body disease type pathology in one family (without Pick bodies).¹²⁷ The hippocampal formation is involved by the asymmetrical degeneration, but the nucleus basalis is spared.¹²⁶ Additionally, pigmented brain stem nuclei may be affected.¹²⁶

Fluent Aphasia. The degenerative focus is more posteriorly placed, including Wernicke's area, although usually the entire left temporal lobe appears atrophic. Neuropathology is similar to that of nonfluent aphasia, including nonspecific degenerative changes with moderate spongiosis of superficial

Figure 33-7. Photomicrograph of frontal cortex demonstrating nonspecific histology. Note the neuronal loss and gliosis, with spongiosis involving the superficial cortical layers (hematoxylin and eosin, 25 \times). (Courtesy of J. E. Parisi, Mayo Clinic, Rochester, MN.)

cortical layers and involvement of the amygdala,¹²⁶ but some patients have been found to have AD.¹²⁷

Semantic Dementia and Anomic Aphasia. This is also one of the member syndromes of FTLN and thus one of the tauopathies. The responsible degenerative focus is in the left anterior temporal lobe. Neuropathologically, Pick's disease may cause generalized atrophy that is more severe in the left hemisphere, particularly the left anterior temporal lobe and insula, with sparing of the nucleus basalis of Meynert.¹²⁸

Mixed Aphasia. Again, the degenerative focus appears to involve the left perisylvian cortices, particularly the left temporal lobe diffusely. Neuropathological findings include nonspecific degenerative changes with focal spongiosis of superficial cortical layers¹²⁹ and AD.¹³⁰

FRONTOTEMPORAL LOBAR DEGENERATION SYNDROMES

Frontotemporal Dementia and Pick's Disease. Arnold Pick originally introduced the concept of a lobar atrophy with relevant progressive focal symptoms in his description of a patient with progressive aphasic dementia, who at autopsy had, in addition to generalized cortical atrophy, focally accentuated atrophy of the left temporal lobe. The

specific histological findings were later appreciated by Alzheimer in 1911, who observed distinctive intraneuronal inclusions, which were termed "Pick bodies." Swollen, ballooned, and poorly staining (chromatolytic) neurons were subsequently called "Pick cells."

During the following decades, most investigators have included three pathological varieties of Pick's disease: lobar atrophy with swollen chromatolytic neurons (SCN) and Pick bodies (Pick's disease type A), lobar atrophy with SCN but not Pick bodies (Pick's disease type B), and lobar atrophy without SCN or Pick bodies (Pick's disease type C or nonspecific degeneration).¹³¹ Whether the findings in Pick's disease types B and C are indeed variants of Pick's disease or different disease processes is debated, although Pick's type B may represent what we now term cortico-basal degeneration and type C likely represents FTLN \pm ubiquitin positive inclusions.

The cardinal pathological changes in Pick's disease type A are lobar atrophy with corresponding neuronal loss that is most apparent in the first three cortical layers (Fig. 33-8). The maximally involved cortical gyri are very thin, and they are often described as walnut or knife-edge in appearance. When the temporal lobe atrophy is focally accentuated, the posterior one-third of the superior temporal gyrus appears relatively preserved. Marked caudate and hippocampal atrophy are also typical findings. Variable degrees of coexisting subcortical gliosis and degeneration of other subcortical nuclei can occur as well, although the basal forebrain tends to be spared. Pick bodies are argentophilic, eosinophilic, rounded cytoplasmic masses that appear densely black on silver stains (Fig. 33-9). They are composed of 10- to 20-nm straight filaments that share antigenic properties with neurofilaments. Pick bodies tend to predominate in the most severely atrophic cortical regions and in the hippocampi. Pick cells also immunostain positively to neurofilaments, but they are not regarded as diagnostic of Pick's disease because similar-appearing cells have been observed in several other disorders. The nucleus basalis is spared or only mildly affected in both Pick's disease and in FTD.¹³²

Pick's disease usually involves the frontal and anterior temporal lobes, but rare cases with preferential parietal

Figure 33-8. Pick's disease. Note the circumscribed frontotemporal cortical atrophy with relative sparing of the posterior one-third of the superior temporal gyrus. The marked gyral thinning is often described as "walnut" or "knife-edge" in appearance. (Courtesy of J. E. Parisi, Mayo Clinic, Rochester, MN.)

Figure 33-9. Photomicrograph of frontal cortex in classic Pick's disease (Pick's type A). The argentophilic, rounded cytoplasmic masses are Pick bodies, which are principally composed of 8- to 20-nm straight filaments (Bielschowsky silver stain, 200 \times). (Courtesy of J. E. Parisi, Mayo Clinic, Rochester, MN.)

lobe atrophy have also been described. Therefore, patients with Pick's pathology have exhibited FTD, semantic dementia, progressive aphasia syndrome,¹²⁸ and progressive perceptual-motor syndrome (CBD).¹³³ There are a few kindreds with autosomal dominant Pick's disease with mutations in tau.¹³⁴

Progressive Spasticity (Primary Lateral Sclerosis). Primary lateral sclerosis (PLS) is primarily a motor syndrome rather than a cause of dementia. Nonetheless, there are some cognitive changes that occur in PLS that conform to the frontal lobe spectrum and therefore are included here with FTD syndromes. Neuropathologically, there is highly circumscribed atrophy of the precentral gyrus with loss of Betz cells, decreased numbers of pyramidal neurons, and laminar gliosis in the external and internal pyramidal cell cortical layers.¹³⁵ No lower motor neuron abnormalities are typically found in hypoglossal or spinal gray nuclei, and the substantia nigra is generally unaffected.¹³⁵

PROGRESSIVE PERCEPTUAL-MOTOR SYNDROMES

Visual. Neuropathological studies of patients with dorsal visual syndromes have generally shown senile plaques and neurofibrillary tangles, which is typical of AD.⁴⁶ The topographic distribution, however, differs from that seen in Alzheimer's dementia, with heaviest involvement of primary and association visual cortices in the occipital lobes and, to a slightly lesser degree, in the parietal lobes. The nucleus basalis is involved in these cases. Other pathologies include nonspecific degenerative changes (gliosis, neuronal loss, and vacuolation of superficial cortices), Creutzfeldt-Jakob disease (Heidenhain variant), and CBD.¹³⁶ To date, one published pathological study of a patient with progressive prosopagnosia revealed argyrophilic grain disease,¹³⁷ but impaired facial recognition is common among patients with asymmetric right greater than left bitemporal degeneration, one of the FTLN variants.

Motor. This syndrome has been most typical of CBD with neuronal achromasia (one of the tauopathies) or nonspecific degenerative changes (see section on CBD). Other histological patterns have included Pick's disease,¹³³ AD

with involvement of the nucleus basalis,¹³⁸ and PSP.¹³⁹ There is generalized but asymmetrical atrophy, with the most severe focal degeneration generally occurring in superomedial frontoparietal regions, primary motor cortex, and parietal convexity cortex; however, other cortical regions, including Wernicke's area, sometimes can be severely involved as well. The substantia nigra is also involved, but the nucleus basalis is spared in the absence of AD.¹⁴⁰

Mixed. Pathological findings include CBD and AD.

PROGRESSIVE BITEMPORAL SYNDROMES

Progressive Amnesia. See Alzheimer's Disease, Mild Cognitive Impairment section.

Progressive Prosopagnosia. See Progressive Visual Syndromes section.

Progressive Bitemporal Neuropsychiatric Syndromes. Patients usually have either Pick's disease or a related FTLN variant, and they often have concurrent prosopagnosia.

EPIDEMIOLOGY AND RISK FACTORS. There are no incidence and prevalence studies of this group of disorders, but clinical experience (at a tertiary care referral center) suggests that they are, as a group, perhaps a tenth as common as AD. Although many cases appear to be sporadic, studies of familial cases, some occurring in association with parkinsonism, have been associated with mutations of the tau gene on chromosome 17, and the term tauopathy has since been coined. Kindreds can be quite complex and include diverse phenotypes.¹⁴¹ Of the ACDSs, frontotemporal degeneration, progressive aphasia, CBD, and PSP (which can mimic CBD) are all part of the tauopathy spectrum.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. There are four broad categories of ACDS, each of which can be further subdivided, and topographical and pathological correlations could be made for each (see Table 33-4). In most cases, there are three properties of the atrophy topography that are radiologically discernible: (1) There is a lateralized major atrophic focus, (2) there is a contralateral area of focal atrophy in the homologous region that is less severe than the primary focus, and (3) there is milder generalized atrophy. Metabolic abnormalities reflect this pattern as well.¹⁴²

Several types of ACDS are associated with amyotrophic lateral sclerosis (ALS), including progressive aphasia,¹⁴³ frontotemporal dementia,¹⁴⁴ and bitemporal syndromes¹⁴⁵ (all of which are part of the FTLN spectrum). In such cases, longevity is determined by the ALS component. Occasional patients with apparent PLS may have mild lower motor neuron abnormalities, and they appear to have a slower course than typical ALS. Finally, subtypes of ACDS may occasionally overlap in the same patient, such as progressive aphasia and a progressive perceptual-motor syndrome.

PROGRESSIVE APHASIA. Although original credit should probably go to Arnold Pick for correlating lobar atrophy with aphasic dementia,¹⁴⁶ Mesulam's 1982 report of progressive aphasia¹²⁴ essentially refocused modern neurology on the relationship of focal cortical degeneration to a progressive cortical syndrome. Because most patients are left hemisphere dominant for language, most patients have left-sided asymmetrical atrophy. However, occasional patients are found who are left handed and who have right hemisphere asymmetrical atrophy accompanying progressive aphasia. Cognitive deficits other than those directly

Figure 33-10. Progressive nonfluent aphasia. MRI (top) and SPECT (bottom) showing left frontal opercular atrophy. (Adapted from Caselli RJ, Jack CR Jr: Asymmetric cortical degenerative syndromes: A proposed clinical classification. *Arch Neurol* 1992;49:770–780.)

attributable to language may also occur, especially memory impairment and constructional apraxia.

Nonfluent progressive aphasia is part of the FTLN spectrum and generally reflects anterior perisylvian cortical degeneration (Fig. 33-10). It should be readily distinguished from typical AD. Speech is effortful, halting, and sometimes dysarthric. Naming ability is marked by phonemic paraphasic errors (e.g., “calicopter” for helicopter), repetition is generally severely impaired, and although writing sometimes is easier than speaking, it is also usually abnormal. Aural and reading comprehension are less impaired in mild to moderate stages but deteriorate in most patients with disease progression. Some patients have orofacial apraxia but not gestural or limb apraxia. Verbal memory tests are difficult to administer, but verbal memory is typically impaired. The criteria for the clinical diagnosis of progressive nonfluent aphasia are shown in Table 33-5.

Fluent aphasia involves degeneration of temporal and posterior perisylvian cortices. Contiguous involvement of neighboring cortices may complicate the clinical picture, making it difficult to distinguish a focal left temporoparietal syndrome (with aphasia, amnesia, apraxia, and acalculia) from a so-called diffuse cognitive disorder, or Alzheimer’s dementia. The nonlanguage impairments, however, are much less disabling than the language impairment in progressive fluent aphasia. Fluency, articulation, and prosody are normal, but comprehension and naming are impaired. Sentence repetition appears to be impaired less consistently. The characteristic naming errors are semantic paraphasias, but phonemic paraphasias occur as well. Typically, a patient may recognize and describe the object or action he or she cannot name (e.g., “something that flies” for a helicopter) or give a generic descriptor. Spelling errors are frequent.

Semantic dementia is another of the FTLN syndromes, and it presents as a progressive anomic aphasia due to degeneration of anterior temporal cortices. Anomia results initially from a dissociation of lexical and semantic knowledge, but in later stages there is a frank loss of seman-

tic knowledge (associated with more posterior extension of degeneration and visualized atrophy). Patients are fluent, comprehend well, and can repeat, read, and write with minimal difficulty. However, their speech lacks semantic precision. They substitute generic terms for specific words (e.g., “machine” for computer) and make semantic paraphasias (e.g., “staple” for paper clip). Anomia is a

TABLE 33-5

Clinical Diagnosis of Progressive Nonfluent Aphasia

Core Features

- Insidious onset and gradual progression
- Disorder of expressive language dominant feature initially and throughout the disease course
- Nonfluent spontaneous speech with at least one of the following: agrammatism, phonemic paraphasias, anomia
- Other aspects of cognition intact or relatively well preserved

Supportive Features

- Speech and language
 - Stuttering or oral apraxia
 - Impaired repetition
 - Alexia, agraphia
 - Early preservation of word meaning
 - Late mutism
- Behavior
 - Early preservation of social skills
 - Late behavioral changes similar to frontotemporal dementia
- Physical signs
 - Late contralateral primitive reflexes, akinesia, rigidity, and tremor
- Investigations
 - Neuropsychology: nonfluent aphasia in the absence of severe amnesia or perceptuospatial disorder
 - Electroencephalography: normal or minor asymmetrical slowing
 - Brain imaging (structural and/or functional): asymmetrical abnormality predominantly affecting dominant (usually left) hemisphere

Data from Neary D, Snowden JS, Gustafson L, et al: Frontotemporal lobar degeneration: A consensus on clinical diagnostic criteria. *Neurology* 1998;51:1546–1554.

TABLE 33-6

Clinical Diagnosis of Semantic Dementia and Associative Agnosia**Core Features**

Insidious onset and gradual progression
 Language disorder characterized by
 Progressive, fluent, empty spontaneous speech
 Loss of word meaning, manifest by impaired naming and comprehension
 Semantic paraphasias
and/or
 Perceptual disorder characterized by
 Prosopagnosia: impaired recognition of identity of familiar faces
 Associative agnosia: impaired recognition of object identity
 Preserved perceptual matching and drawing reproduction
 Preserved single-word repetition
 Preserved ability to read aloud and write to dictation orthographically regular words
 Autobiographical memory intact or relatively well preserved

Supportive Features

Speech and language:
 Press of speech
 Idiosyncratic word usage
 Absence of phonemic paraphasias
 Surface dyslexia and dysgraphia
 Preserved calculation
 Behavior
 Loss of sympathy and empathy
 Narrowed preoccupations
 Parsimony
 Physical signs
 Absent or late primitive reflexes
 Akinesia, rigidity, and tremor
 Investigations
 Neuropsychology
 Profound semantic loss, manifest in failure of word comprehension and naming and/or face and object recognition
 Preserved phonology and syntax, and elementary perceptual processing, spatial skills, and day-to-day memorizing
 Electroencephalography: normal
 Brain imaging (structural and/or functional): predominant anterior temporal abnormality (symmetrical or asymmetrical)

Data from Neary D, Snowden JS, Gustafson L, et al: Frontotemporal lobar degeneration: A consensus on clinical diagnostic criteria. *Neurology* 1998;51:1546-1554.

common feature of both AD and Pick's disease, but verbal memory is usually impaired even in the absence of dementia (Video 260, Memory Testing). Hodges first applied the term *semantic dementia* to patients with prominent anomia associated with focal anterior temporal lobe atrophy; the criteria for the diagnosis of semantic dementia are shown in Table 33-6.

Mixed progressive aphasia is a more nonspecific pattern involving degeneration of left temporal and perisylvian cortices. Patients with this condition have impairment of all aspects of language, making classification into a single taxonomic category impossible. They are nonfluent, with impaired comprehension, naming, repetition, writing, and reading.

PROGRESSIVE PERCEPTUAL-MOTOR SYNDROMES. Although many patients have a mixed sensorimotor syndrome (including visual or somatosensory systems or both), there are a few patients who have a pure sensory (typically visual) or pure motor syndrome (typically a hemiakinetically rigid syndrome).

Progressive visual syndromes involve degeneration of parieto-occipital or parietotemporal visual association cortices or both. Visual association cortices can be broadly divided into dorsal (occipitoparietal) and ventral (occipitotemporal) pathways, and disorders of visual association cortices reflect this dichotomy. The occipitoparietal pathway is more concerned with localizing an object in space (where), and the occipitotemporal pathway is more concerned with object identification (what). Two broad types of complex visual disturbance have been described with ACDS. The more commonly reported is progressive simultanagnosia, reflecting dysfunction of the dorsal cortical visual pathway. Patients cannot integrate the numerous components of an ordinarily complex scene into a coherent whole. When viewing a street scene, for example, they might describe a car or a person or a lamppost but overlook the fact that it is an inner city rush hour. Occasional associated problems that also reflect posterior parietal and temporal involvement include alexia, acalculia, right-left disorientation, and mild deficits of memory and language (fluent aphasia). Eventually, patients may be found to have inferior quadrantanopia, although typically visual field testing produces inconsistent responses.

The second type of complex visual disorder resulting from ACD is visual agnosia, of which there are fewer reported examples.¹⁴⁷ Visual agnosia results from dysfunction of the ventral cortical visual pathway. Some patients have been described with progressive prosopagnosia, which is a failure to recognize familiar faces.¹⁴⁷ Rarely, patients may describe progressive topographagnosia, the inability to recognize familiar places. In later stages, both ventral and dorsal visual pathways become involved, and a more globally encompassing visual agnosia results.

The term *posterior cortical atrophy* has also been applied to cases with dysfunction in the occipitoparietal pathway, and those with more occipitotemporal dysfunction have been coined *associative agnosia* (Table 33-7).

PROGRESSIVE MOTOR SYNDROMES. See also section on CBD. Progressive motor syndromes are marked by two major clinical characteristics, both slowly progressive in onset, that make this disorder distinctive and easily recognized. The first is lateralized somatic deficits, including hemiparesis, hemiparesis, hemisensory impairment (usually in the form of astereognosis or tactile agnosia with less consistent impairment of more basic somatosensory modalities), and myoclonic jerks. Some patients may have a hemirigid or hemidystonic syndrome with tremor. The second is severe and disabling apraxia, including limb apraxia (inability to use the limb in a meaningful way, such as to use a comb), gestural apraxia (inability to pantomime or imitate symbolic movements), dressing apraxia, constructional apraxia, and apraxic agraphia. If the lateralized limb defects reflect dominant hemispheric dysfunction, then a mild fluent aphasia may be present that is milder than that seen in progressive fluent aphasia. When the lateralized limb defects reflect nondominant hemisphere dysfunction, it is uncommon (but possible) for a hemineglect syndrome to result.

Additional clinical abnormalities may include acalculia, psychomotor slowing, aphasia, and supranuclear oculomotor disturbances. Although patients with severe apraxia, psychomotor slowing, and mild aphasia may appear demen-

TABLE 33-7

Proposed Diagnostic Criteria for Posterior Cortical Atrophy

| |
|---|
| Core Features |
| Onset of signs/symptoms is insidious and course is progressive |
| Absence of primary ocular dysfunction that could account for visual impairment |
| Two or more of the following symptoms |
| Unable to follow lines while reading |
| Poor depth perception |
| Often fails to appreciate objects in direction of gaze |
| Unable to navigate in stores, while driving, in own home |
| Illusions |
| Hallucinations |
| Misidentification errors |
| Micropsia |
| Macropsia |
| Metamorphopsia |
| Two or more of the following signs |
| Quadrant or hemifield defect |
| Achromatopsia in quadrant or hemifield |
| Hemispacial neglect |
| Constructional dyspraxia |
| Simultanagnosia |
| Ocular apraxia |
| Optic ataxia |
| Cortical blindness |
| Supportive Features |
| Relatively preserved visual acuity early |
| Preserved insight and expressive language functioning |
| No significant behavioral abnormalities or memory impairment early in course |
| Absence of focal motor findings, parkinsonism, or frontal release signs early in course, although parkinsonism and/or motor neuron disease can evolve later in course |
| Investigations |
| Neuropsychologic deficits referable to parietal and/or occipital regions |
| Focal or asymmetric atrophy in parietal and/or occipital regions on CT or MRI |
| Focal or asymmetric hypoperfusion/hypometabolism in parietal and/or occipital regions on SPECT/PET |

CT, computed tomography; MRI, magnetic resonance imaging; PET, position emission tomography; SPECT, single-photon emission computed tomography.

ted according to neuropsychological testing, they are usually rational, insightful, and upset by their condition. In late stages, patients can barely move or speak despite preserved consciousness. This constellation of clinical features is termed *corticobasal syndrome* by some, and criteria for the diagnosis have been proposed.¹⁴⁸

Many patients have both a sensorimotor and a visuospatial disorder, combining features of both of the previously mentioned groups (Fig. 33-11).

FRONTOTEMPORAL LOBAR DEGENERATION

SYNDROMES. The three main syndromes of the FTL spectrum that are popularly recognized include nonfluent aphasia (considered under progressive aphasia), semantic dementia (also considered under progressive aphasia), and frontotemporal dementia. However, it seems appropriate to include as well progressive spasticity (primary lateral sclerosis), and the right hemisphere equivalent of semantic dementia (sometimes called progressive prosopagnosia, or right greater than left bitemporal variant) because they are both equally part of the anatomical and pathological FTL spectrum.

The progressive neuropsychiatric syndrome is the best known example of this group and has been referred to as frontal lobe or frontotemporal dementia (Fig. 33-12). Pick's disease is prominently represented in this group. Brun¹⁴⁹ and Gustafson¹⁵⁰ have described a similar clinical syndrome in the absence of Pick bodies. The proposed criteria for the diagnosis of frontotemporal dementia are shown in Table 33-8. Although the clinical picture is characteristic, many clinicians have difficulty distinguishing these patients from those with Alzheimer-type dementia. Another common misdiagnosis is depression. The errors made by these patients tend to be omissions rather than commissions, and the term that describes this condition is *abulia*. They fail to change their clothes, to brush their teeth, to pursue their former interests, and to initiate many activities that constitute a normal day. Just as they fail to start something new, they may fail to stop what they are doing and perseveratively fixate, in a seemingly idiosyncratic fashion, on some particular activity, such as going to the bathroom, sorting through their wallet, or watching television. Some patients have greater disinhibition and emotional lability, crying at the least provocation or laughing loud and long. They may complain that they are hungry yet be unmoved to fix themselves a snack. Some may perseveratively want to eat repeatedly. Memory and language (especially naming) are typically impaired. Despite their sometimes reduced temporal latency in responding to the examiner (they may start answering a question before the physician has finished asking it), their answers are brief and often consist of "I don't know." Patients with FTD may stay close to their caregiver and generally cause fewer disruptions than patients with AD, particularly in mild to moderate stages (although there are notable exceptions).

Associated clinical abnormalities reflect dysfunction of other frontal lobe functions, including spasticity and non-fluent aphasia. Because Pick's disease has a predilection for the temporal as well as the frontal lobe, some patients also develop signs referable to the temporal lobe, particularly anomia.

The syndrome of progressive spasticity has been termed PLS, and historically, the nosological focus has been on its relationship to ALS (see Chapter 36) rather than other frontal lobe degenerations. PLS reflects degeneration of the precentral gyrus and primary motor cortex.¹³⁵ Cognitive impairment is minimal but can include emotional lability, mild frontal lobe-related cognitive deficits, and mild memory impairment.¹⁵¹

Some patients present early in their course with a combination of both spasticity and FLD/FTD. One of our patients was found at autopsy to have PSP, but further cases are needed for study.

PROGRESSIVE BITEMPORAL SYNDROMES. The three syndromes in this category are progressive amnesia (amnestic MCI), progressive prosopagnosia, and progressive neuropsychiatric syndrome. MCI is discussed in the section on AD, and progressive prosopagnosia is discussed in the section on progressive visual syndromes. Patients with a progressive neuropsychiatric syndrome due to bitemporal degeneration (Fig. 33-13) have severe anomia and amnesia, relative indifference to their condition, and mild perseverative behaviors that are shared with patients in the FTD group. Psychomotor speed is normal or only mildly

Figure 33-11. Progressive perceptual-motor syndrome. MRI (*top*) and SPECT (*bottom*) showing right greater than left parietal atrophy. (Adapted from Caselli RJ, Jack CR Jr: Asymmetric cortical degenerative syndromes: A proposed clinical classification. *Arch Neurol* 1992;49:770–780.)

Figure 33-12. Progressive frontotemporal dementia. MRI (*top*) and SPECT (*bottom*) showing right greater than left frontal and anterior temporal atrophy in a patient with autopsy documented Pick's disease. (Adapted from Caselli RJ, Jack CR Jr: Asymmetric cortical degenerative syndromes: A proposed clinical classification. *Arch Neurol* 1992;49:770–780.)

impaired. Neuroimaging shows bilateral severe anterior temporal atrophy (typically worse on the right) and hypoperfusion with relative sparing of the frontal lobes.

DIFFERENTIAL DIAGNOSIS. The two broad categories to consider are nondegenerative structural focal brain lesions, such as a slowly growing tumor, and other degenerative conditions. Regarding the first, a slowly progressive neurological syndrome that can be reasonably localized could be neoplastic, whether malignant or benign. Rarely, high-grade arterial stenoses cause stuttering infarction mimicking a slowly progressive degenerative cortical syndrome. Other

pathological processes that could occur focally, including infection or abscess and demyelinating or vasculitic conditions, should also be considered. Other degenerative illnesses include Creutzfeldt-Jakob disease in rapidly progressive cases and the wide variety of degenerative pathologies discussed previously in the section on pathogenesis and pathophysiology (Video 33, Spinal Muscular Atrophy; Video 50, Myoclonus in Creutzfeldt-Jakob Disease). For example, a patient suspected of CBD may have AD at autopsy. Among the frontal lobe, aphasic, and bitemporal varieties of ACDS, an association with ALS must also be considered.

TABLE 33-8

Clinical Diagnosis of Frontotemporal Dementia (FTD)**Core Features**

Insidious onset and gradual progression
 Early decline in social interpersonal conduct
 Early impairment in regulation of personal conduct
 Early emotional blunting
 Early loss of insight
 Instrumental functions of perception, spatial skills, praxis, and memory intact or relatively well preserved

Supportive Features

Behavioral disorder
 Decline in personal hygiene and grooming
 Mental rigidity and inflexibility
 Distractibility and impersistence
 Hyperorality and dietary changes
 Perseverative and stereotyped behavior
 Utilization behavior

Speech and language
 Altered speech output
 Spontaneity and economy of speech
 Press of speech
 Stereotype of speech
 Echolalia
 Perseveration
 Mutism

Physical signs
 Primitive reflexes
 Incontinence
 Akinesia, rigidity, and tremor
 Low and labile blood pressure

Investigations

Neuropsychology: significant impairment on frontal lobe tests in the absence of severe amnesia, aphasia, or perceptuospatial disorder
 Electroencephalography: normal on conventional EEG despite clinically evident dementia
 Brain imaging (structural and/or functional): predominant frontal and/or anterior temporal abnormality

Data from Neary D, Snowden JS, Gustafson L, et al: Frontotemporal lobar degeneration: A consensus on clinical diagnostic criteria. *Neurology* 1998;51:1546–1554.

EVALUATION. The most important diagnostic test is adequate structural neuroimaging. MRI is preferable to CT, but either will generally suffice to evaluate the possibility of a tumor. In addition to excluding nondegenerative structural abnormalities, a magnetic resonance angiographic study could be included, if available, to search for a potentially relevant high-grade arterial stenosis. Patients with ACDS usually, but not invariably, have radiologically discernible focal atrophy in the symptomatic region. It is often subtle and of insufficient severity to permit blinded diagnosis of ACDS. However, in a patient with progressive anomic aphasia, for example, focal left anterior temporal atrophy should be considered important not only because of the absence of a tumor but also because it shows the responsible lesion to be an atrophic one, presumably degenerative. Formal neuropsychological assessment can be helpful to assess quality and severity of cognitive impairment to a greater extent and usually demonstrates a pattern that is not typical for Alzheimer's dementia. It is also useful for monitoring disease progression. Other laboratory studies are less helpful because of the apparent focal nature of the ACDS. Metabolic encephalopathies do not usually cause the syndrome of slowly progressive aphasia, which is difficult to confuse with a diffuse encephalopathy. Nonetheless, it is still reasonable to make certain that basic laboratory data are normal, as was discussed for AD.

MANAGEMENT. Considerations similar to those discussed for AD are applicable here with minor additions. First, patients with ACDS are usually aware of their limitations and are not likely to get themselves in trouble unwittingly by wandering, refusing medications, and so forth. They require nursing home placement less often if there is a caregiver. Physical therapy is important for patients with CBD and PLS, especially because of the complications resulting from altered muscle tone and gait unsteadiness. Occupational therapy is particularly important for ACDS

Figure 33-13. Progressive bitemporal neuropsychiatric syndrome: MRI (top) and SPECT (bottom) showing right greater than left anterior temporal atrophy. (From Caselli RJ: Focal and asymmetric cortical degeneration syndromes. *The Neurologist* 1995;1:1–19.)

patients with apraxia and spatial disorders to assist with dressing, eating, and other activities of daily living. Speech therapy is appropriate to consider for progressive aphasia not only because of the aphasia but also because of dysphagia, particularly in later stages of nonfluent aphasia. Late-stage complications are similar for AD but perhaps are most severe for CBD. In this condition, because all avenues of communication are lost, including speech and praxis, and because muscle tone contorts them into painful dystonic postures with contracture formation, there remains relative preservation of insight, perhaps compounding their suffering further. Trials of carbidopa and levodopa (Sinemet) in CBD should be considered, even though it is usually of minimal efficacy at best. In patients with CBD with severe myoclonus, small doses of clonazepam can also be considered. Finally, in cases with severe dystonic posturing, especially hand closure, selective botulinum toxin injection can be considered to accomplish limited goals, such as allowing the hand to be opened for maintenance of skin hygiene and to retard contracture formation.

PROGNOSIS AND FUTURE PERSPECTIVES. All of the ACDSs are progressive and follow a similar time course to AD. Most patients have a more generalized cortical degenerative process that becomes more significant in later stages, but occasionally patients have a highly focal process with minimal evidence of generalized decline, even at the time of their death. Prognosis is better in the group with the highly focal process. Otherwise, ACDSs of all types, like AD and other degenerative brain diseases, result in death after relentless progression.

The following question is begged by this group of disorders: What determines the topographic distribution of neurodegeneration? Indeed, this is a question shared by all neurodegenerative diseases. If the determinants of selective neuronal vulnerability could be identified, so too might novel prevention and therapeutic strategies be formulated.

ALS-DEMENCIA COMPLEX

PATHOGENESIS AND PATHOPHYSIOLOGY. The nosological distinction between FTD, FTD with motor neuron disease (MND), and classic MND has been debated, with some arguing that FTD with MND is a distinct disorder and others suggesting each represents a phenotype along a continuum of the same disease.¹⁵² The histological findings do not clarify nosology because in the majority of cases they are nonspecific: neuronal loss, gliosis, and microvacuolation or spongiform changes predominantly affecting the superficial cortical layers and subcortical white matter. Degeneration is usually greatest in frontotemporal regions and, less commonly, in perisylvian language cortices. The nucleus basalis of Meynert appears normal, as do cortical levels of choline acetyltransferase and somatostatin.¹⁵³ Variable degrees of degeneration also occur in the amygdala, hippocampus, thalamus, caudate nucleus, and substantia nigra.

EPIDEMIOLOGY AND RISK FACTORS. Some degree of cognitive impairment can be demonstrated in most individuals with ALS, although this is often mild and nondisabling. Frank dementia rarely occurs in patients with ALS, although known associations include the Parkinson-ALS-dementia

complex of Guam, which occurs in the indigenous Chamorro population,¹⁵⁴ and familial and sporadic cases. Pathogenesis in most patients is uncertain, and histopathological features are generally nonspecific.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Frontotemporal dementia is the most common dementia pattern, followed by aphasic dementia. Bulbar symptoms are typically prominent. Among patients presenting with FTD, some studies have suggested that between 10% and 15% may have or develop ALS, and among patients with ALS, approximately one-third have subtle signs of frontal lobe-based cognitive impairment with a similar pattern of frontotemporal atrophy.¹⁵⁵ Pathological criteria that emphasize biochemical analysis of insoluble tau and ubiquitin immunohistochemistry to define motor neuron disease type inclusions continue to find overlap between ALS-dementia patients and other degenerative syndromes (Video 236, ALS-Parkinsonism Dementia).¹⁵⁶

DIFFERENTIAL DIAGNOSIS. Certain types of the ALS-dementia complex may be rapidly progressive, with anarthria within 1 year and death within 2 years. Given the severity, rapid progression, and sometimes paucity of limb abnormalities, Creutzfeldt-Jakob disease should be considered. In rapidly progressive cases, carcinomatous meningitis can also cause encephalopathy and polyradiculopathy, which might be mistaken for ALS-dementia complex, so CSF evaluation can be useful. Head and neck tumors, particularly carcinoma of the posterior tongue with CNS metastases, can cause severe dysarthria and mental status changes, and they should not be overlooked, particularly when dysarthria is the main finding. Finally, neuromuscular weakness due to ALS, myasthenia gravis, acid maltase deficiency, myotonic dystrophy, and any other disease of sufficient severity to compromise ventilatory capacity may lead to a hypoxic encephalopathy that, in the absence of a corroborating history, might be mistaken for ALS-dementia complex, so arterial blood gases should be considered in some cases.

EVALUATION. Both the nature of the neuromuscular disorder and the cognitive disorder must be established. Electromyography is important for the neuromuscular disorder and an essential diagnostic step but may not be conclusive, especially in bulbar cases. Further evaluation of the ALS aspect of this disorder is considered in the section on ALS but may include acetylcholine receptor antibody and creatine phosphokinase, among other tests. Regarding the cognitive disturbance, formal mental status assessment is the first step, and if there is any doubt, formal neuropsychological assessment focusing particularly on frontal lobe and language function should be performed. Evaluation of the dementia should then proceed with similar considerations, as discussed for AD, with particular attention to neuroimaging. In this context, MRI is preferable to CT because imaging of lower brain stem structures in particular is better accomplished by MRI. In selected circumstances, additional consideration should be given to EEG, CSF examination, consultation with an otolaryngologist, and arterial blood gas evaluation.

MANAGEMENT. Treatment considerations overlap those for ALS. Caregiving for the demented patient was discussed in the section on AD. This is a particularly difficult

condition because of the combination of neuromuscular, bulbar, and cognitive problems that confront the patient.

PROGNOSIS AND FUTURE PERSPECTIVES. As with other neurodegenerative diseases, progression is inevitable and generally more rapid than in AD, with death occurring within 3 to 5 years in typical cases. Unlike uncomplicated ALS, in which the mind is preserved, causing some individuals to opt for feeding tubes, external ventilatory support, and other life-sustaining measures, ALS-dementia complex also produces severe intellectual decline, making justification of such measures difficult.

Ongoing refinement of molecular and neurochemical techniques promises to further resolve nosological distinctions between patients within the FTLD spectrum.

PROGRESSIVE SUPRANUCLEAR PALSY

PATHOGENESIS AND PATHOPHYSIOLOGY. PSP is another of the tauopathies. Although the anatomical substrates underlying the parkinsonian and oculomotor disturbances are relatively well understood (see Chapter 34), those underlying the cognitive symptoms are not. In addition to mesocorticolimbic dopaminergic alterations (see the section on Parkinson's disease dementia), there is evidence of more pronounced frontal lobe dysfunction than in other subcortical dementias on the basis of neuropsychological tests^{157,158} and PET.¹⁵⁹ These findings have been attributed to primary striatal damage, which disrupts normal processing in the frontostriatal "cognitive" circuit such that frontal deafferentation occurs.¹⁵⁷ Striatal damage could also explain disruption in the anterior cingulate attention and lateral-orbitofrontal social affect circuits (Video 55, Supranuclear Gaze Paresis).¹⁵⁷

Rarely, patients with PSP have variable degrees of aphasia, anomia, alexia, apraxia, or hemineglect, and some have had a frank progressive perceptual-motor syndrome similar to CBD.¹³⁹ Anatomical distribution of degeneration is atypical in such cases and may be maximally present in the parietal cortex. All 10 cases in another report had neocortical tangles and neuropil threads; the density of tangles was highest in Brodmann's area 4.¹⁶⁰ Pronounced transentorhinal and entorhinal cortical degeneration resulting in hippocampal-isocortex disconnection similar to that occurring in AD has rarely been observed in PSP with severe dementia.

In summary, the typical subcortical pattern of dementia probably reflects substrates that are similar to those found in Parkinson's dementia with greater physiological disruption of frontal lobe function, but atypical cases have presented as definite cortical patterns of dementia due to predominantly cortical patterns of pathology.

EPIDEMIOLOGY AND RISK FACTORS. The incidence of PSP is approximately three new cases per million per year, and the prevalence is 1.5 cases per million, making it approximately 1% as common as PD.¹⁶¹ Median survival after symptom onset is approximately 6 or 7 years.¹⁶¹

CLINICAL FEATURES AND ASSOCIATED DISORDERS. In addition to the extrapyramidal and oculomotor abnormalities that characterize PSP (Video 55, Supranuclear Gaze Paresis) (see Chapter 34), certain cognitive features occur

that led to the characterization of subcortical dementia and are discussed in the section on Parkinson's dementia. In addition, there are frontal lobe features that appear to be more prominent than in other types of subcortical dementia.¹⁵⁸

DIFFERENTIAL DIAGNOSIS. PSP is part of the differential diagnosis of the patient with atypical parkinsonism with dementia and is usually distinguished clinically on the basis of the oculomotor disturbance and levodopa unresponsiveness. PSP should also be considered in the differential diagnosis of other tauopathies, such as FTD and CBD. Also, PSP can present in atypical ways, such as FTD and nonfluent aphasia.^{162,163}

EVALUATION. In addition to the evaluation outline for PD and AD, SPECT and PET may show frontal and basal ganglia hypometabolism.

MANAGEMENT. Severe dementia and psychosis is less common in PSP than in PDD, although treatment considerations are otherwise similar for Parkinson's dementia.

PROGNOSIS AND FUTURE PERSPECTIVES. Disease progression is similar (relentless) to that of other neurodegenerative conditions. Median survival after symptom onset is 6 or 7 years, and patients are typically wheelchair bound at least 1 year before death.

CORTICOBASAL DEGENERATION

PATHOGENESIS AND PATHOPHYSIOLOGY. The characteristic pathological changes in CBD include asymmetrical frontoparietal cortical atrophy with corresponding neuronal loss and gliosis, substantia nigra degeneration, swollen achromatic neurons, and tau-positive neuronal and glial pathology.^{164,165} Variable degrees of degeneration in other subcortical nuclei also occur. The achromatic neurons immunostain positively to neurofilaments (Fig. 33-14). Some have regarded these neurons to be related to Pick cells, although immunohistochemical and ultrastructural analyses suggest that CBD can be differentiated from Pick's disease, PSP, and AD.¹⁶⁵ CBD is a diffuse cytoskeletal process characterized by the accumulation of pathologic tau proteins. Impaired neurofilament phosphorylation, transportation, or degradation or distal axonal damage may be involved in the pathophysiology of neuronal achromasia. Neuronal achromasia may therefore represent the end result of one or more pathophysiological processes.

The profile of cognitive impairment reflects dysfunction predominantly of frontal and parietal cortices, including apraxia, psychomotor slowing, and visuoperceptual disturbances. Memory is also impaired. However, CBD pathology has also been observed in occasional patients with FTD and progressive aphasia.

EPIDEMIOLOGY AND RISK FACTORS. CBD was originally described in 1967 by Rebeiz and colleagues.¹⁶⁶ There are few data regarding epidemiology or risk factors, although clinical experience suggests that the prevalence may be similar to that of PSP or approximately 1% that of PD. There has been little evidence of a familial tendency.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. The vast majority of cases have exhibited a progressive

A

B

Figure 33-14. Photomicrographs of achromatic neurons typical of cortical-basal ganglionic degeneration using hematoxylin and eosin (H&E) (A) and an immunostain for phosphorylated neurofilaments (B). Note the swollen and pale appearance on H&E. The filaments in CBD are 13 to 28 nm in width, with periodic twists occurring every 169 to 202 nm (Part A, H&E, 400 \times ; Part B, monoclonal anti-neurofilament protein (2F11) stain [DAKO Corporation], 400 \times). (Both courtesy of J. E. Parisi, Mayo Clinic, Rochester, MN.)

perceptual-motor syndrome, and the terms progressive asymmetrical rigidity and apraxia syndrome and corticobasal syndrome (CBS) have been proposed (Video 231, Cortical Basal Degeneration).^{148,167} Less common presentations

with a similar histology include frontotemporal dementia and progressive aphasia. Asymmetrical hyper-reflexia, postural instability, frontal release signs, oculomotor impairment, and hypokinetic dysarthria commonly occur. Dysphagia begins insidiously in the latter stages of the disease, and eventually aspiration pneumonia and death ensue.

Characteristic CBD histological findings have been reported to coexist with Pick's disease, PSP, and AD, and alternate presentations with the same histology have included FTD and progressive aphasia, as noted previously.

DIFFERENTIAL DIAGNOSIS. See the section on ACDS. The most common misdiagnoses are stroke, PD, PSP, and perhaps AD. CBD falls within the spectrum of ACDS, and clinicopathological correlations are far from perfect, as previously discussed. Other degenerative histologies underlying a progressive apraxic or perceptual-motor syndrome include nonspecific degeneration, AD, Pick's disease, and PSP.

EVALUATION. Neuroimaging is the most important aspect in evaluating any focal-appearing cerebral syndrome, as discussed in the section on ACDS. A fairly consistent finding on CT and MRI is asymmetrical cortical atrophy, which is predominantly parietal with variable involvement of contiguous regions in patients with a progressive perceptual-motor syndrome. The laterality of atrophy correlates with the laterality of clinical impairment.

Asymmetrical cortical (and subcortical) hypoperfusion on SPECT is usually more extensive than the MRI appearance of atrophy. Asymmetrical fluorodeoxyglucose cortical hypometabolism and asymmetrical striatal fluorodopa hypometabolism on PET are also found in this disorder, but these tests should be regarded as ancillary.

The neurological and neuropsychological pattern of deficits is distinctive and should not be mistaken for an Alzheimer- or Parkinson-type pattern of dementia.

MANAGEMENT. Pharmacotherapy generally provides minimal if any improvement in most symptoms,¹⁶⁸ but an empirical trial of levodopa is nonetheless reasonable and will occasionally result in modest symptomatic amelioration of rigidity. Clonazepam may yield modest improvement in myoclonus, but it may cause sedation with worsening of balance and cognitive function. Botulinum toxin injection can permit a clenched dystonic hand to be opened for hygiene maintenance (Video 231, Cortical Basal Degeneration). Pharmacotherapy should be supplemented with physical, occupational, and speech therapies. Passive range of motion exercises may retard the development of contractures. Ambulation becomes impaired in all individuals at some point, hence the need for gait assistance devices. Apraxia is often the most debilitating feature of the disorder (Video 40, Apraxia). A home assessment by an occupational therapist can aid in determining which changes can be made to facilitate functional independence, although experience to date has been disappointing. Speech therapy and communication devices can optimize communication when dysarthria, apraxia of speech, or aphasia is present, although they are generally of minimal benefit. Therapists also counsel patients and families on swallowing maneuvers and food additives to minimize aspiration when dysphagia evolves. Decisions regarding placement of feeding gastrostomy tubes should be discussed before dysphagia becomes problematic.

PROGNOSIS AND FUTURE PERSPECTIVES. Most patients succumb to the disease in 7 to 10 years. Death usually results from aspiration pneumonia or urosepsis.

The nosology of CBD¹⁶⁷ and its relationship to other tauopathies remains a point of controversy that may be further clarified by ongoing molecular and neurochemical strategies.¹⁵⁶

HIPPOCAMPAL SCLEROSIS DEMENTIA

PATHOGENESIS AND PATHOPHYSIOLOGY. In a subset of elderly individuals with dementia, hippocampal sclerosis (HS) is the only remarkable autopsy finding.¹⁶⁹ The cause of HS associated with dementia (HSD) is unknown; there is rarely a history of seizures or of a global cerebral hypoxic-ischemic event, which are known causes of HS in other settings. It has been suggested that HSD is due to occult hypoxic/ischemic episodes or limbic encephalitis. A large subset of HSD cases have a distinctive cerebral neuronoglia tauopathy¹⁷⁰ that suggests that this condition should be classified as neurodegenerative.

EPIDEMIOLOGY AND RISK FACTORS. The frequency of HS in autopsy series of elderly demented people has been reported to be as low as 0.4% and as high as 26%.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. During life, these cases are usually diagnosed as AD since they typically present with memory loss that progresses to dementia. To date, antemortem distinction of HSD from AD has not been reliable, even with extensive neuropsychologic test batteries.¹⁷⁰ Some patients have been thought to resemble FTD as well.

DIFFERENTIAL DIAGNOSIS. Alzheimer's disease and FTD currently appear to be the most similar clinically, but so little is known that further refinement should be expected in the future.

EVALUATION. As for Alzheimer's disease.

MANAGEMENT. As for Alzheimer's disease.

PROGNOSIS AND FUTURE PERSPECTIVES. Basic clinicopathological correlation is probably most needed at this early stage. With increasing numbers of well-studied cases, the clinical characteristics of this condition will be more clearly defined.

Movement Disorders

Joseph Jankovic

HISTORY

HYPOKINETIC MOVEMENT DISORDERS

Parkinson's Disease
 Parkinsonism-Plus Syndromes
 Stiff-Person Syndrome

HYPERKINETIC MOVEMENT DISORDERS

Huntington's Disease
 Other Forms of Chorea
 Primary Dystonia
 Other Forms of Primary Dystonia
 Neurodegeneration with Brain Iron Accumulation (Hallervorden-Spatz Disease)
 Gilles de la Tourette Syndrome and Other Tic Disorders

Other Stereotypies
 Restless Legs Syndrome
 Painful Legs-Moving Toes Syndrome
 Action Tremors
 Wilson's Disease
 Hemifacial Spasm
 Essential Myoclonus
 Startle Syndromes

HISTORY

Because they attract visual attention, movement disorders have been described in both medical and nonmedical historical material for hundreds of years. Early etiological explanations reflected the knowledge and prejudices of their times, with various life forces and demonic possession being cited as common causes. The original clinical descriptions of these disorders, however, extend far beyond historical interest and are important documents rich in details of phenomenology and natural history. Gilles de la Tourette syndrome, although not named until the 19th century, was vividly described in the *Malleus Maleficarum* (1489), and Paracelsus described various forms of chorea in careful detail. Parkinson's disease, the prototypical movement disorder, was first reported by James Parkinson in 1817, and his succinct and vibrant description of the disease in the context of the pollution of London during the industrial revolution not only covered the major clinical features of the disease but also suggested the possibility of a causative role of environmental toxins. Specifically, in the United States, the country practitioner George Huntington extensively described Huntington's chorea in the 1800s, basing his description on his and his father's experiences with a large New York kindred. Clear phenomenological descriptions occupied primary attention during the 19th century, largely steered by the supervision of Charcot and other European neurologists. In the first half of the 20th century, a clearer focus was placed on the basal ganglia due to early histological and biochemical studies. The molecular, biological, and physiological bases of both hypokinetic and hyperkinetic disorders have received primary attention during the past "decade of the brain."

HYPOKINETIC MOVEMENT DISORDERS

Parkinson's Disease

PATHOGENESIS AND PATHOPHYSIOLOGY. Pathological findings of Parkinson's disease (PD) include

depigmentation and neuronal loss in the substantia nigra (SN) and the presence of Lewy bodies and pale bodies (Fig. 34-1). Because the degenerating cells in the SN normally synthesize the neurochemical dopamine, the pathophysiological hallmark of PD is dopaminergic underactivity at the site of these cells' axonal projection—that is, the striatum (caudate nucleus and putamen) (Fig. 34-2). Lewy bodies are eosinophilic inclusions composed of neurofilament, tubulin components, α -synuclein, and ubiquitin. Pale bodies are composed of neurofilament interspersed with vacuolar granules. Besides the substantia nigra, they are also present in the basal ganglia, cortex, brain stem, spinal cord, and even in the sympathetic ganglia, myenteric plexus, and cardiac plexus. Although characteristic of PD, Lewy bodies are also seen in Alzheimer's disease, neurodegeneration with brain iron accumulation (Hallervorden-Spatz disease), ataxia-telangiectasia, and, rarely, in patients without clinical neurological disease.

The mechanism of Lewy body formation and cell death in PD is not known, but the degenerative process is highly localized at the beginning of the illness. Anatomical studies have found that the area first affected in the disorder is the pars compacta in the ventrolateral SN (SNpc), with its fibers projecting to the putamen. Neurochemical changes resulting from this selective neurodegeneration consist mainly of loss of dopamine (DA), and it is estimated that 60% to 85% of nigral neurons and striatal DA is lost prior to the development of PD symptoms. The traditional view that the pathological process in PD starts with degeneration of dopaminergic neurons in SNpc has been challenged by Braak and colleagues,¹ who proposed a six-stage pathological process. During the presymptomatic stages 1 and 2, the Lewy bodies remain confined to the medulla oblongata and olfactory bulb. In stages 3 and 4, the SN and basal forebrain become involved, and in stages 5 and 6, the pathological process encroaches upon the telencephalic cortex. Although the Braak staging has gained widespread popularity, no cell counts have been done to correlate with the described synuclein pathology.

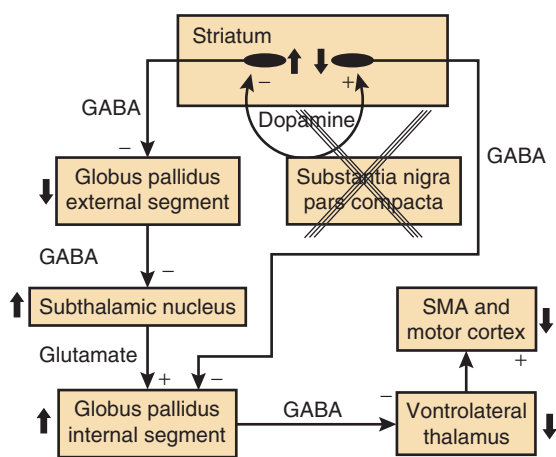

Figure 34-2. Basal ganglia circuitry relevant to pathogenesis of PD. GABA, γ -aminobutyric acid; SMA, supplementary motor area.

The most actively studied hypothesis of the origin of PD has focused on the possibility that the natural proteasomal activity in the brains of patients with PD may be impaired, thus leading to abnormal protein aggregation. Postmortem

studies of brains of patients with PD have provided evidence that proteasomal function is selectively impaired in the SN.² Aggresomes, centrosome-associated structures that sequester proteasomal components, normally localize in the perinuclear area presumably to guard the nucleus and protect other organelles from exposure to the potentially toxic proteins, but in PD the normal aggresome formation is impaired and therefore these cells do not benefit from the potentially cytoprotective response. This finding is one piece of growing evidence that inhibition of the ubiquitin-proteasome pathway leads to altered protein handling and Lewy body formation. Thus, as a result of an age-related or disease-related impaired proteasomal system, both normal and abnormal proteins accumulate and aggregate to form Lewy bodies. Although Lewy bodies were once considered to be toxic, they are now thought to actually serve a protective role by absorbing the unwanted proteins. The neuronal loss in PD is presumably due to a failure of ubiquitination and proteasomal degradation resulting in accumulation of aggregated proteins that promote oxidative stress, disrupt intracellular processes, and induce apoptosis. Metabolic pathways for DA generate numerous by-products that include hydrogen peroxide, superoxide anions, and hydroxy radicals. Interaction between these chemicals and membrane lipids leads to lipid peroxidation, membrane disruption, and, potentially, cell death. In support of this hypothesis, several observations are pertinent: (1) Glutathione peroxidase, a tripeptide normally present in brain that is reduced with oxidative stress, is markedly reduced in the SN of patients with PD; (2) elemental iron, which can facilitate the formation of free radicals in the nervous system, is increased in the brains of PD patients; (3) the iron-chelating protein ferritin is decreased or of normal concentration in PD so that compensatory increases to handle elemental iron do not occur; and (4) specific enzymatic activity defects in complex 1 of the mitochondrial respiratory chain appear to occur in the SN of the brains of patients with PD. Although all these events develop and probably reflect or provoke oxidative stress in the SN, the actual precipitant, whether genetic, environmental, dietary, or multifactorial, remains to be determined.

Although the cardinal motor signs of PD, such as tremor, bradykinesia, rigidity, and postural instability, are primarily related to dopaminergic deficiency, many of the other motor and nonmotor signs that do not respond to levodopa are probably mediated through other neurotransmitter systems.³ Thus, norepinephrine and serotonin deficiency resulting from degeneration of the lower brain stem nuclei, locus caeruleus and dorsal raphe, respectively, may be associated with depression and anxiety, whereas cholinergic deficit may lead to cognitive impairment.⁴

EPIDEMIOLOGY AND RISK FACTORS. Population-based surveys in the United States, Portugal, and Italy have reported that the prevalence of PD ranges from 107 to 187 per 100,000 population.⁵ A community study of the elderly in a suburb of Boston, however, found parkinsonian features in 159 of 467 (34%) individuals aged 65 years or older.⁶ This study suggests that at least one-third of the elderly exhibit some evidence of PD or other parkinsonian disorders.

Although both environmental and inherited factors have been implicated in the pathogenesis of PD, no specific

cause has been found. Case-controlled studies have documented an increase in risk for PD associated with a family history of PD, insecticide exposure, herbicide exposure, rural residency at the time of diagnosis, well water exposure, and nut or seed eating 10 years prior to diagnosis.⁷ Study of time trends over 15 years in the incidence of parkinsonism in Olmsted County, Minnesota, found no evidence of major environmental risk factors for PD.⁸ Exposure to hydrocarbon solvents has been associated with earlier onset of symptoms and more severe PD and other forms of parkinsonism.^{9,10} In one study, welders with PD were found to have their onset of PD an average of 17 years earlier than a control population of PD patients, suggesting that welding, possibly by causing manganese toxicity, is a risk factor for PD.¹¹ Critical review of the literature, however, provides no evidence that welding is associated with an increased risk of PD.¹² Numerous reports suggest the possibility that the frequency of PD is decreased in patients with a history of cigarette smoking and caffeine consumption.^{13–15} The best studied model of parkinsonism is that produced by 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), a meperidine analogue first developed during the production of an illicit drug. This compound, when injected intravenously, produces parkinsonism in humans and animals.¹⁶

Twin studies and other family studies suggest that genetic predisposition plays an important role in the development of some forms of PD.¹⁷ The original gene locus in one autosomal dominant pedigree was isolated to chromosome 4q21.23 and was later found to involve Ala53Thr substitution in the α -synuclein gene.¹⁸ It has been hypothesized that this and other mutations cause the natively unfolded α -synuclein protein to alter its secondary structure, ubiquitinate, and self-aggregate.¹⁹ The application of quantitative real-time polymerase chain reaction amplification of the α -synuclein gene exons showed results consistent with whole gene triplication in a large family with autosomal dominant, young-onset parkinsonism, dysautonomia, cardiac denervation, dementia, with Lewy bodies and glial cytoplasmic inclusions at autopsy.²⁰

In addition to mutations in the gene coding for α -synuclein, there is a growing number of parkinsonian disorders associated with specific genetic defects. For example, one of the most common causes of young-onset parkinsonism is an autosomal recessive form of PD (ARPD) due to mutations in the gene called Parkin (PARK2) on chromosome 6q25.2–27. This 500-kilobase, 12-exon gene encodes a 465-amino acid protein containing an N-terminal ubiquitin-like motif and C-terminal RING finger motif. Multiple mutations have been identified in this gene among families with this levodopa-responsive form of PD.²¹ Parkin, the protein product of the Parkin gene, is expressed in SN and other brain regions as well as in Lewy bodies of patients with PD.²² Normal parkin is thus involved in ubiquitination and subsequent degradation of certain proteins, but mutated parkin protein loses this activity and thus may lead to an accumulation of proteins yet to be identified. This process could cause a selective neural cell death without formation of Lewy bodies. In contrast to typical PD, patients with ARPD often present with a dystonic gait during early adulthood. The mean age at onset of this variant is 25 years, but the disease may not present until age 58. Parkin gene

mutation phenotypes range from dopa-responsive dystonia to young-onset PD with early levodopa-induced dyskinesias and to otherwise typical PD. In one study, 36 of 73 (49%) families with PD onset at 45 or younger had a mutation in the Parkin gene: 10 of 13 (77%) patients with onset at 20 or before and 2 of 64 (3%) patients with onset at 30 or later.²³ Another gene locus for PD has been found on chromosome 2p13.²⁴ This locus (PARK3) was detected in a group of European families with a mean age at onset of 59 years. Although some members of the kindreds had prominent dementia, the autopsy in some cases confirmed the typical pathological features of PD, including Lewy bodies. An autosomal dominant, levodopa-responsive Lewy body parkinsonism has been mapped to chromosome 4p15.7 (PARK4).²⁵ The haplotype also occurred in members of the family who did not have any clinical evidence of parkinsonism but, rather, exhibited postural tremor phenomenologically identical to essential tremor (ET). This finding and other data provide further evidence that PD and ET may be associated and genetically related.²⁶ The finding of a mutation in the deubiquinating enzyme ubiquitin carboxy-terminal hydrolase L1 (UCH-L1) gene on 4p14 in one German family with autosomal dominant PD (PARK5)²⁷ further supports the concept that an impairment of normal protein degradation is an important mechanism of neurodegeneration in PD. Two loci on chromosome 1 have been found to be associated with autosomal recessive, early onset parkinsonism: 1p35–36 (PARK6)²⁸ and 1p36 (PARK7).²⁹ Mutation in the PTEN-induced kinase 1 (PINK1) gene, chromosome 1p36, was identified in three consanguineous, autosomal recessive families with early onset parkinsonism (PARK6).³⁰ The PINK1 gene codes for a putative serine-threonine kinase, located in the mitochondria, thus providing further support for the role of oxidative stress in the pathogenesis of PD. Patients with PINK1 mutation may be indistinguishable from those with typical PD or from those with Parkin mutations.^{31,32} Although located in the same chromosomal region, 1p36, another autosomal recessive form of PD has been identified and found to be caused by a mutation in the DJ-1 gene. This form of PD, designated as PARK7, is manifested by a range from slow progression and mild hypokinesia to severe parkinsonism, dementia, motor neuron disease, and levodopa-induced motor fluctuations and psychiatric disturbances.^{33,34}

Another locus, mapped to 12p11.23-q13.11 (PARK8), has been identified in a Japanese family with typical PD inherited in an autosomal dominant pattern with incomplete penetrance.³⁵ This novel gene, called LRRK2 (leucine-rich repeat kinase 2), belongs to the ROCO protein family and includes a protein kinase domain of the MAPKKK class and several other major functional domains.³⁶ The gene product, a protein called “dardarin” (from the Basque word *dardara*, meaning tremor), is a novel protein that probably functions as a cytoplasmic kinase involved in phosphorylation of proteins, such as α -synuclein and tau. Dardarin protein contains 2527 amino acids (AA) (in contrast to α -synuclein protein, which contains only 140 AAs) encoded by 51 exons. The course of the disease is relatively benign, usually presenting with unilateral hand or leg tremor without cognitive deficit; patients respond well to levodopa. Other clinical phenotypes have included parkinsonism with dementia or amyotrophy or both and otherwise typical

essential tremor.³⁷ An autopsy examination of some patients with this mutation demonstrated variable pathology, ranging from Lewy body and neurofibrillary tangle pathology to no pathological changes.³⁶ Other postmortem findings show brain stem dopaminergic degeneration consistent with Lewy body PD, diffuse Lewy body disease, nigral degeneration without distinctive histopathology, progressive supranuclear palsy-like pathology, and even β -amyloid deposits in anterior horn cells. This mutation has been found to be particularly frequent in people with PD of North African origin and in approximately one third of familial PD cases of Ashkenazi Jewish origin.^{37–39} Also known as the Kufor-Rakeb syndrome (PARK9), this levodopa-responsive parkinsonism has also been associated with spasticity, dementia, supranuclear gaze palsy, and globus pallidus atrophy on imaging studies. The disorder has been linked to chromosome 1p36, but no gene has been identified.⁴⁰ These genetic discoveries have important implications for genetic counseling.⁴¹

In addition to these parkinsonism-related gene loci, there may be multiple genetic factors important in the pathogenesis of PD and other parkinsonian disorders. In a complete genomic screen of 174 families with multiple individuals diagnosed with PD involving a total of 870 family members (378 with PD), Scott and colleagues⁴² found LOD scores ranging from 1.5 to 5.47 indicative of linkage to the following five chromosomal regions: 6 (in the Parkin gene), 17q (in the Tau gene), 8p, 5q, and 9q.

CLINICAL FINDINGS AND ASSOCIATED DISORDERS.

The cardinal features of PD include resting tremor, rigidity, bradykinesia, and postural instability. Many movement disorder specialists consider a good response to levodopa or dopamine agonists useful in clinically supporting the diagnosis. The rest tremor usually consists of an oscillatory movement of 4 to 7 Hz frequency that involves the limbs, jaw, face, and tongue but almost never involves the head (Video 59, Rest Tremor). The tremor of the forearm is often pronating and supinating, whereas the hand tremor has been described as “pill-rolling” (Video 67, Parkinsonian Rest Tremor). Early in the course of the disease, the tremors and other signs are usually asymmetrical but eventually become bilateral. In addition to the rest tremor that is so distinctive of PD, most patients also have a postural tremor, which is evident with the hands extended or in action. This postural tremor probably represents re-emergence of rest tremor or coexistent ET (see later discussion). Tremor in patients with ET, in contrast to PD, often involves not only the hands but also the head and voice, rarely affects the legs, and improves frequently with alcohol, propranolol, or primidone. Some PD patients or their relatives have an associated postural tremor that appears as ET and precedes the onset of PD symptoms by several years or decades, suggesting a possible link between the two conditions, at least in some families.

Bradykinesia (slowness of movement) or hypokinesia (poverty of movement) is manifested by slowing of activities of daily living, such as dressing, feeding, brushing teeth, and bathing (Video 61, Bradykinesia). Other features of bradykinesia or hypokinesia include masked facies (hypomimia), hypokinetic dysarthria, drooling, and slow and small handwriting (micrographia). On examination, rapid alternating movements are performed slowly and with decreasing amplitude. In more advanced stages, frequent

arrests of movement, called “freezing” or “motor blocks,” may be seen. These are manifested by an interruption in finger tapping or hand clapping, start hesitation such as an inability to initiate gait or other movements, and freezing when turning or walking through narrow passages (Video 90, Freezing of Gait).

Postural instability also often occurs in the more advanced stages of the disease. This gait and postural difficulty is frequently accompanied by small steps and festination, a tendency when standing or walking to propulse involuntarily or to retropulse and fall. In the distinctive “pull test” the examiner stands behind the patient and tugs briskly on the shoulders; the PD subject takes several small steps backward, possibly falling into the examiner’s arms (Video 68, Postural Reflex Impairment).

Most of the other signs of PD represent variations of these cardinal characteristics: sialorrhea, dysphagia, difficulty in turning in bed, and ambulatory problems that become progressively worse. Sleep disruption is common in PD patients, who demonstrate fragmented sleep and frequent awakenings. Studies suggest that a distinctive sleep aberration, rapid eye movement behavioral disorder (see Chapter 54), may be a frequent early element of PD. Additionally, akathisia, an uncomfortable feeling that drives the patient to move, can be a prominent and poorly appreciated aspect of untreated PD, and this behavior may be related to dopaminergic dysfunction. Besides motor symptoms, PD patients may also exhibit several behavioral changes, including depression in at least one-third of patients and dementia in an equal proportion. Frontal release, or “cortical disinhibition” signs, may be seen, but they are not specific for PD. Pain, burning, coldness, numbness, and other sensory symptoms, often wrongly attributed to bursitis or arthritis, are reported by approximately half of patients. Joint deformities, known as striatal hand or striatal foot, and other skeletal deformities, such as scoliosis and campocormia, are also often attributed to arthritic or orthopedic problems (Fig. 34-3).^{43,44} Seborrhea, particularly that involving the face, and constipation are examples of systemic involvement in PD.

The mean age of clinical onset of PD is the mid-50s, but the range is very wide, and some patients present in their 20s and 30s, whereas others show no signs until their 80s. Although there are many exceptions, young patients often present with tremor-predominant disease and elderly patients with gait dysfunction and akinesia. Juvenile PD is a childhood and adolescent disease, presenting with parkinsonism and dystonia, and has a different histological appearance than PD.

DIFFERENTIAL DIAGNOSIS. In addition to PD, there are many other causes of parkinsonism (Table 34-1). The second most common group is the parkinsonism-plus syndromes (12%), a conglomerate term for a large number of degenerative disorders in which parkinsonism is one of several neurological features (Video 58, High-Amplitude Tremor). Drug-induced parkinsonism (8%) and hereditary degenerative conditions, such as juvenile Huntington’s disease, are less frequent. Cyanide intoxication and carbon monoxide poisoning associated with bilateral pallidal necrosis are examples of an acute cause of parkinsonism,¹³ and other toxins such as carbon disulfide and manganese can also produce parkinsonism, the latter often preceded

Figure 34-3. Typical striatal hand deformity in the right hand with marked flexion of fingers in the left hand resulting in severe flexion-contraction. (Reproduced from Ashour R, Tintner R, Jankovic J: “Striatal” hand and foot deformities in Parkinson’s disease. *Lancet Neurol* 2005;4:423–431.)

by psychiatric difficulties (“manganese madness”) (Video 41, Carbon Monoxide Intoxication Parkinsonism). Reversible parkinsonism is caused by drugs, especially neuroleptics and metoclopramide, and lesser known agents such as α -methyl dopa, reserpine, amiodarone, and certain calcium channel blockers must also be considered in the differential diagnosis. Finally, patients in whom PD is suspected should be screened for potential illicit narcotic exposure, a travel history, or an underlying medical illness such as acquired immunodeficiency syndrome that would predispose them to opportunistic infections including abscesses. A family history of neurological disorders should be obtained as well. A past medical history of stroke or hypertension may suggest a subcortical vascular encephalopathy presenting with parkinsonian features, and old meningitis or head trauma could suggest normal pressure hydrocephalus presenting with freezing, festination, and a gait disorder sometimes confused with parkinsonism (Video 54, Normal Pressure Hydrocephalus; Video 233, Vascular Parkinsonism).

EVALUATION. When all four cardinal characteristic signs are present, and the patient shows a brisk response to dopaminergic therapy, the diagnosis is straightforward. Part of the workup usually includes a magnetic resonance imaging (MRI) scan searching for evidence of alternate diagnoses such as stroke, intoxications, or other degenerative disorders.⁴⁵

MANAGEMENT. The large array of drugs used in the treatment of PD is outlined in Table 34-2 with standard doses and side effects. Treatment of symptomatic PD is based primarily on restoring a deficiency of DA due to a loss of dopamine-producing cells in the SN.⁴⁵ This neurotransmitter is synthesized from the amino acid tyrosine. The conversion of tyrosine to levodopa is facilitated by the rate-limiting enzyme tyrosine hydroxylase; levodopa is in turn converted into dopamine by the nonspecific enzyme dopa-decarboxylase. These dopaminergic neurons synapse with cholinergic interneurons and γ -aminobutyric acid (GABA)-ergic outflow neurons in the striatum.

Five subtypes of DA receptors have been identified; the D₁ and D₂ receptors are most prominent in the striatum, and the D₃, D₄, and D₅ receptors are present in the limbic

system and other dopaminergic pathways. The D₁ receptor is linked to adenylate cyclase. In contrast, the D₂ receptor is activated by DA and DA agonists. The different roles of D₁ and D₂ receptors in regulation of striatal function have not been fully defined, but the D₂ receptor appears to be more important in mediating the parkinsonian symptoms. In the brain in PD, the D₁ receptors in the striatum appear to be reduced (downregulated), whereas the D₂ receptors are increased (upregulated).⁴⁶ As a result of nigrostriatal deficiency, activation of the indirect D₂-mediated, inhibitory (GABA) striatopallidal pathway is increased, resulting in disinhibition of the subthalamic nucleus and the globus pallidus internus (GP_i), the main output nucleus from the basal ganglia. The increased activation of the GP_i is further enhanced by disinhibition of the decreased activity of the direct D₁-mediated, inhibitory (GABA) striatopallidal pathway (see Fig. 34-2).

The most effective treatment for the symptoms of PD is levodopa, but the chronic use of levodopa is complicated by the development of two motor problems, namely, fluctuations and dyskinesias in approximately half the patients after 5 years of therapy. Fluctuations are irregular and clinically unpredictable responses to medications, and dyskinesias are involuntary, usually choreic but sometimes dystonic movements that are drug induced (Video 250, Levodopa-Induced Dyskinesias). Levodopa is absorbed in the small intestine via a large neutral amino acid transporter system and is then converted to DA by the ubiquitous enzyme dopa-decarboxylase. Conversion to DA outside the blood-brain barrier activates the area postrema and is largely responsible for some of the early side effects of levodopa, particularly nausea and vomiting. The addition of dopa-decarboxylase inhibitors that do not cross the blood-brain barrier (e.g., carbidopa or benserazide) minimizes DA formation in the periphery and greatly improves patient tolerance to therapy. This is the concept behind the use of the carbidopa-levodopa combination (e.g., Sinemet), which is prescribed as a ratio of carbidopa to levodopa (25/100, 25/250, or 10/100) and has become available in a controlled-release formulation (CR 50/200 or CR 25/100). Approximately 100 mg of carbidopa per day is needed for effective

TABLE 34-1

Classification of Parkinsonism

| |
|---|
| I. Primary parkinsonism |
| Parkinson's disease |
| Juvenile parkinsonism |
| II. Multiple system degenerations (parkinsonism-plus syndromes) |
| Progressive supranuclear palsy (PSP) |
| Multiple system atrophy (MSA) |
| Striatonigral degeneration (SND) |
| Olivopontocerebellar atrophy (OPCA) |
| Shy-Drager syndrome (SDS) |
| Lytico-Bodig or parkinsonism-dementia-ALS complex of Guam (PDACG) |
| Cortical-basal ganglionic degeneration (CBGD) |
| Progressive pallidal atrophy |
| III. Hereditary parkinsonism |
| Hereditary juvenile dystonia-parkinsonism |
| Autosomal dominant Lewy body disease |
| Huntington's disease (HD) |
| Wilson's disease (WD) |
| Hereditary ceruloplasmin deficiency |
| Hallervorden-Spatz disease (HSD), also known as neurodegeneration with brain iron accumulation type I (NBIA-I) |
| Olivopontocerebellar and spinocerebellar degenerations (OPCA and SCA) |
| Familial amyotrophy-dementia-parkinsonism |
| Disinhibition-dementia-parkinsonism-amyotrophy complex |
| Gerstmann-Strausler-Scheinker disease |
| Familial progressive subcortical gliosis |
| Lubag (X-linked dystonia-parkinsonism) |
| Familial basal ganglia calcification |
| Mitochondrial cytopathies with striatal necrosis |
| Ceroid lipofuscinosis |
| Familial parkinsonism with peripheral neuropathy |
| Parkinsonian-pyramidal syndrome |
| Neuroacanthocytosis (NA) |
| Hereditary hemochromatosis |
| IV. Secondary (acquired, symptomatic) parkinsonism |
| Infectious: postencephalitic, AIDS, SSPE, Creutzfeldt-Jakob disease, prior diseases |
| Drugs: dopamine receptor-blocking drugs (antipsychotic, antiemetic drugs), reserpine, tetrabenazine, α -methyl dopa, lithium, flunarizine, cinnarizine |
| Toxins: MPTP, CO, Mn, Hg, CS ₂ , cyanide, methanol, ethanol |
| Vascular: multi-infarct, Binswanger's disease |
| Trauma: pugilistic encephalopathy |
| Other: parathyroid abnormalities, hypothyroidism, hepatocerebral degeneration, brain tumor, paraneoplastic diseases, normal pressure hydrocephalus, noncommunicating hydrocephalus, syringomesencephalia, hemiatrophy-hemiparkinsonism, peripherally induced tremor and parkinsonism, and psychogenic disorders |

peripheral blockade. Although carbidopa is useful in preventing the “peripheral” side effects of levodopa, the motor side effects of fluctuations and dyskinesia as well as psychiatric reactions, such as confusion, delusions, and visual hallucinations, are not prevented or ameliorated by its addition to levodopa. Despite the theoretical concern that dopamine is neurotoxic, this is not supported by a large, multicenter study, the ELLDOPA trial, evaluating the effects of levodopa on progression of PD in 361 patients with no prior anti-PD treatment and not requiring symptomatic therapy. These patients were randomized to placebo or levodopa at 150, 300, or 600 mg/day for 40 weeks, followed by a 2-week washout (extended to 4 weeks for a subset of patients).⁴⁷ This study is consistent with other *in vivo* studies that have found no evidence that levodopa is toxic.

As patients continue to take levodopa, they often begin to report a “wearing-off” or end-of-dose deterioration in mobility, which is thought to result from a reduced duration of therapeutic plasma and brain levels of levodopa.⁴⁸ A typical patient may also notice dyskinesias or involuntary movements related to peak plasma levodopa levels (“peak dose dyskinesia”). Most patients have this pattern of response characterized by improvement-dyskinesia-improvement (IDI). Approximately 15% of patients who are treated chronically with levodopa experience initial dyskinesia within a few minutes after ingestion of levodopa; this is followed by an improvement in parkinsonian symptoms for 2 to 4 hours and then by subsequent recurrence of dyskinesia, usually in the form of dystonia. This diphasic dyskinesia pattern of dyskinesia-improvement-dyskinesia is referred to as the DID response. Treatment of these motor fluctuations is based on “smoothing out” the plasma concentration curves by giving more frequent smaller doses of levodopa, converting to the controlled-release form of levodopa, or, in the patient with markedly advanced disease, titrating the medication by having the patient sip very small quantities of Sinemet dissolved in water or juice every 30 or 60 minutes throughout the waking day.⁴⁹ In patients with advancing disease who have had prolonged levodopa therapy, more complex and less predictable (“on-off”) motor fluctuations occur. For instance, patients may change from relatively normal function to a frozen akinetic state in as few as 15 seconds (sudden on-off), or they may develop severe dyskinesia at both the peak effect of the levodopa dose and the end of the dose (biphasic dyskinesia). The mechanism of these motor fluctuations and dyskinesias is not well understood, but there is a growing body of evidence supporting the notion that some of these problems arise from the combination of loss of presynaptic DA storage capacity and postsynaptic receptor alterations.⁵⁰

In the 1980s, the monoamine oxidase-B (MAO-B) inhibitor deprenyl (selegiline) was reported to delay the clinical progression of PD. In a large multicenter trial, the Deprenyl and Tocopherol Antioxidative Trial of Parkinson's Disease (DATATOP), deprenyl but not tocopherol delayed the need for levodopa by approximately 9 months.⁵¹ Whether this is due to deprenyl's beneficial effect on the parkinsonian symptoms or to a putative neuroprotective action is a subject of continued debate. Other MAO-B inhibitors, such as lazabemide, have been evaluated in PD as well, but long-term protocols aimed at defining neuroprotective mechanisms have not been carried out.

In the early stages of PD, anticholinergic (e.g., trihexyphenidyl) therapy may provide moderate improvement. This strategy is based on the neurochemical competition between DA and acetylcholine in the striatum. Amantadine, an antiviral agent, has mild dopaminergic activity and possibly anticholinergic action as well. Amantadine and anticholinergic agents may produce dry mouth, nausea, vomiting, blurring of vision, visual hallucinations, and other mental changes. Because of the anticholinergic side effects, patients with glaucoma, prostatic hypertrophy, and dementia may experience exacerbations of these conditions with these agents. Amantadine may also cause pitting edema and livedo reticularis, a purplish-reddish mottling of the skin, particularly the skin below the knees; it should be avoided in patients with impaired renal function.

TABLE 34-2

Medications for Parkinson's Disease

| MEDICATION | DOSAGE | SIDE EFFECTS |
|---|--|---|
| Dopaminergic Drugs | | |
| Precursor amino acid: levodopa Carbidopa/levodopa | 10/100, 25/100, 25/250, 100–1000 mg/day | Nausea, hypotension, confusion, hallucinations, dyskinesia |
| Controlled release | 25/100, 50/200, 200–1400 mg/day | |
| Dopamine agonists | | |
| Bromocriptine | 2.5–60 mg/day | Somnolence, confusion, hallucinations, hypotension |
| Pergolide | 0.25–6.0 mg/day | |
| Pramipexole | 0.25–6.0 mg/day | |
| Ropinirole | 0.25–6.0 mg/day | |
| Monamine oxidase B inhibitor | | |
| Selegiline (deprenyl) | 5–10 mg/day | Sleep disturbance, lightheadedness, hallucinations |
| Rasagiline | 1 mg/day | |
| Indirect agonist | | |
| Amantadine | 100–300 mg/day | Hallucinations, dry mouth, livedo reticularis, ankle swelling, myoclonic encephalopathy in setting of renal failure |
| Catecholamine- <i>O</i> -methyl transferase inhibitor (used in conjunction with levodopa) | | |
| Tolcapone | 300–600 mg/day | Dyskinesia, lightheadedness, diarrhea, orange urine |
| Entacapone | 200 mg, 2–8 times/day with each dose of carbidopa/levodopa | |
| Other Drug Classes | | |
| Anticholinergics | | |
| Trihexyphenidyl | 2–15 mg/day | Confusion, sleepiness, blurred vision, constipation |
| Biperidine | 1–8 mg/day | |
| Novel neuroleptics: used for psychosis and unusual tremor | | |
| Clozapine | 12.5–100 mg/day | Fatal neutropenia, somnolence |
| Quetiapine | 12.5–100 mg/day | Somnolence, potential aggravated parkinsonism |
| Miscellaneous | | |
| Amitriptyline: used for sleep fragmentation | 10–50 mg/day at bedtime | Dry mouth, forgetfulness, blurred vision, constipation |
| Baclofen: used for dystonic cramps | 10–80 mg/day | Sleepiness, dizziness |

Since the introduction of bromocriptine and pergolide, DA agonists, which are agents that stimulate dopamine receptors, have played an increasingly important role in the treatment of PD. Because these medications have a relatively long half-life, they are used most frequently to prolong the effects of levodopa and thus smooth out motor fluctuations. Whereas some movement disorder specialists advocate the use of DA agonists in the early phases of pharmacological therapy, others introduce DA agonists after the dose of levodopa has reached 300 to 600 mg/day or when levodopa-related fluctuations emerge. Side effects associated with DA agonists include nausea, drowsiness, confusion, hallucinations, orthostatic hypotension, exacerbation of dyskinesias, erythromelalgia, and, rarely, pulmonary fibrosis. The latter two side effects have been attributed to the ergot structure of pergolide and bromocriptine, and they almost never occur with the non-ergoline DA agonists pramipexole and ropinirole. Although gambling and compulsive shopping have been attributed to dopamine agonists, this adverse effect may be a nonspecific dopaminergic effect.⁵²

As a result of new findings suggesting levodopa sparing and possibly neuroprotective effects of DA agonists, their role in the management of PD has shifted from being primarily used late in the disease in conjunction with levodopa (adjunctive therapy) to being also used as early

symptomatic treatment. Several studies have demonstrated that when introduced in early stages of PD, dopamine agonists provide adequate symptomatic benefit and delay the need for levodopa, thus minimizing the risk of levodopa-related dyskinesias and motor fluctuations.^{53,54} A 4-year follow-up of patients initially randomized to receive levodopa or pramipexole (the CALM-PD study) found that (1) initial treatment with pramipexole was associated with a significant reduction in the risk of developing dyskinesias (24.5% vs. 54.0%; hazard ratio, 0.37; $P < 0.0001$) and wearing off (47.0% vs. 62.7%; hazard ratio, 0.68; $P = 0.02$), but there was no difference between the two groups in disabling dyskinesias; (2) initial levodopa treatment resulted in a significant reduction in the risk of freezing (25.3% vs. 37.1%; hazard ratio, 1.70; $P = 0.01$); (3) the improvement in mean total UPDRS was greater with levodopa than with pramipexole (2.0 ± 15.4 vs. -3.2 ± 17.3 points, $P = 0.003$); (4) pramipexole treatment was associated with a higher risk of somnolence (36% vs. 21%, $P = 0.005$) and edema (42% vs. 15%, $P = 0.001$); and (5) there was no difference in quality of life.⁵⁵ This study, coupled with the ELLDOPA study, has resulted in some modification of the strategy to delay the use of levodopa as long as possible and many clinicians are now using levodopa in early treatment of PD, particularly in elderly patients or in patients who may be slightly cognitively

impaired and may be at a high risk for levodopa-induced hallucinations and other psychiatric side effects.

Among DA agonists, apomorphine is the only short-acting compound. As an injectable DA agonist, it can be useful in “rescuing” some PD patients from sudden, unpredictable off periods. Because of the strong emetic response with this agent, however, coadministration of the peripheral DA receptor-blocking drug domperidone is usually necessary.

Another new class of drugs is the catechol-*O*-methyltransferase (COMT) inhibitors such as entacapone and tolcapone. By limiting DA metabolism, they increase levodopa bioavailability, prolong the “on” response to levodopa, reduce motor fluctuations effectively, and allow a reduction in daily levodopa dosage.⁵⁶

Of particular interest in PD during the past several years has been the use of various surgical procedures, which have capitalized on a growing knowledge of basal ganglia anatomy and physiology (see Fig. 34-2).⁵⁷ The traditional ablative procedures have given way to newer strategies, particularly deep brain stimulation (DBS); this procedure has markedly improved the function and quality of life of many patients with advanced PD.⁵⁸ Besides lower risks associated with surgery, DBS has the advantage of customizing the stimulating parameters to the needs of the individual patient. In a multicenter, prospective, double-blind, cross-over study in 143 patients with advanced PD who received bilateral high-frequency stimulation of SN or GP_i, the Unified Parkinson’s Disease Rating Scale (UPDRS) motor scores improved by 49% ($P < 0.001$) and 37% ($P < 0.001$), respectively, in comparison to the nonstimulated state.⁵⁹ Furthermore, 6 months following implantation compared to baseline, the percentage of time “on” without dyskinesias increased from 27 to 74 ($P < 0.001$) and 28 to 64 ($P < 0.001$) with SN and GP_i DBS, respectively. Adverse events included intracranial hemorrhage in seven and lead displacement in two. Although the levodopa dosage remained unchanged in the GP_i group, the daily levodopa dose equivalents were reduced by 37% in the SN DBS group ($P < 0.001$). Two double-blind trials of fetal graft transplantation for advanced PD showed no lasting benefit and approximately half of the implanted patients experience “off” dyskinesias even without levodopa, requiring DBS.^{60,61}

Because of the remarkable array of options in the treatment of PD, it is reasonable to approach the treatment of each patient with a basic algorithm (Table 34-3). For all patients, education, exercise, and good nutrition are considered useful. If patients have no significant functional impairment in terms of independent living, consideration of a mild dopaminergic drug with a putatively neuroprotective strategy in the form of deprenyl can be considered. If additional symptomatic relief is needed, most movement disorder specialists add a DA agonist and later, when symptoms need urgent treatment to protect the patient’s safety or job security, levodopa is introduced. If symptoms can be treated more slowly, the use of anticholinergic drugs in young patients with tremor-predominant PD is often helpful, and amantadine can be used as a mild dopaminergic drug to delay the need to start levodopa in other patients. In patients who are just starting levodopa/carbidopa, the controlled-release form is often selected to minimize the number of doses needed each day. As the disease progresses, combinations of drugs are usually needed, and most patients will

TABLE 34-3

Algorithm for Managing Parkinson’s Disease at Different Phases

For All Patients

Education, physical or exercise therapy, good nutrition

For Patients with No Clinically Significant Disability

Consider selegiline.

Consider referral to study centers for trials of new neuroprotective strategies.

For Patients with Clinically Significant Disability

Job security threatened or health endangered

Levodopa, usually controlled-release formulation

Job security NOT threatened and health NOT endangered

Young and tremor-predominant disease: anticholinergic drugs, amantadine, selegiline

Older patients: amantadine, dopamine agonists

Elderly patients or cognitively impaired: levodopa

Above Patients with Progressive Disability

Add levodopa either as controlled-release or standard formulation

Once on levodopa, if added prolongation of effect is needed, add selegiline if patient is not currently taking it or, in the future, catechol-*O*-methyl (COMT) transferase inhibitors may become available.

Patients with Specific Complications

Patients on levodopa who develop motor fluctuations

More frequent, small doses of levodopa or liquid Sinemet

Selegiline agonists (or COMT inhibitors)

Consider deep brain stimulation of the subthalamic nucleus.

Patients with unremitting tremor

Deep brain stimulation

Patients with hallucinations

Reduce medications. Stop all drugs except Sinemet.

Consider Quetiapine, atypical neuroleptic

require both an agonist and levodopa/carbidopa within the first 7 years of therapy. However, in elderly patients, especially those with hallucinations or dementia, levodopa/carbidopa alone, usually in the regular formulation, is often the most practical regimen because of its relative simplicity.

One particularly difficult problem in managing PD patients is hallucinosis. Patients who are treated chronically with dopaminergic drugs develop visual hallucinations that can become frightening and severely disabling to the patient and caregiver. In this situation, the drug dosage should be reduced, and most patients are best managed on levodopa/carbidopa alone. In some instances, atypical neuroleptics with few extrapyramidal side effects can be used. Clozapine has been successful in abating hallucinations and psychotic behavior in PD patients, but it is an expensive drug and is associated with the potentially lethal side effect of agranulocytosis.⁶² Other atypical antipsychotic drugs, particularly quetiapine, are often used to control drug-induced psychosis without aggravating underlying parkinsonism. Whenever a neuroleptic agent is introduced, however, careful monitoring is needed to ensure that parkinsonism is not exacerbated.

PROGNOSIS AND FUTURE PERSPECTIVES. Survival of patients with PD has greatly improved since the development of levodopa. Prior to the advent of levodopa, mortality among PD patients was three times the normally expected rate. However, with the advent of levodopa and other medications, the life span of PD patients is almost the same as that of an age-matched control population

without the disease.⁶³ Some studies have suggested that PD patients are more likely to die from infection than from cancer, compared to an age-matched group of controls. Early, even presymptomatic, detection of disease is paramount to early intervention, and major efforts are currently aimed at identifying biological markers for both the presence of disease (trait marker) and disease activity (state marker).

Parkinsonism-Plus Syndromes

In addition to PD, parkinsonism is one of the major clinical features in several other primary neurodegenerative conditions. However, because they all have additional features not typical of Parkinson's disease and share an overall worse prognosis and poorer response to antiparkinsonian therapy, they are often grouped together under the conglomerate term parkinsonism-plus syndromes. Within this group, each condition has distinctive characteristics that must be recognized and distinguished from one another and from PD.

Progressive Supranuclear Palsy

PATHOGENESIS AND PATHOPHYSIOLOGY. Progressive supranuclear palsy (PSP) is the most common and best recognized entity among the parkinsonism-plus syndromes. PSP is an idiopathic condition with no known precipitant or strong genetic component. Postmortem analysis of the brains of PSP patients shows neuronal loss, gliosis, and neurofibrillary tangles composed of straight and paired helical filaments.⁶⁴ The SN, subthalamic nucleus, globus pallidus, superior colliculus, pretectal area, and substantia innominata are the sites of maximum involvement. Dopaminergic, cholinergic, and adrenergic neurotransmitter systems are affected, provoking a far more diffuse degenerative process than that seen in PD.¹⁶ There is a growing body of evidence that PSP is due to an alteration in the gene on chromosome 17 coding for the tau protein.⁶⁵ Several studies have provided evidence for an increase in the 4R tau isoform mRNA in PSP, which contributes to overexpression of neurofibrillary tangles in brain stems of patients with PSP. Although a tau gene mutation has been associated with early dementia and PSP-like syndrome,⁶⁶ in most cases of PSP no specific tau mutation is present, but the H1 haplotype appears to be associated with PSP.⁶⁷

EPIDEMIOLOGY AND RISK FACTORS. A medically based survey in central New Jersey found that the age-adjusted prevalence of PSP was 1.38 per 100,000 population, and men appeared to be slightly more frequently affected than women.⁶⁸ Most patients experience the initial symptoms during their sixth and seventh decades. No clear geographic, occupational, or temporal clusters of PSP have been found. Although PSP is not considered a genetic disorder, rare familial clusters have been reported.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. PSP shares some clinical features with PD, such as bradykinesia, rigidity, dysarthria, dysphagia, and dementia. However, PSP patients rarely exhibit tremor and usually have much more profound postural instability. In addition, axial rigidity is more prominent than limb rigidity. Some patients with PSP also develop severe palilalia, emotional

incontinence, and other evidence of bilateral frontal lobe dysfunction.⁶⁴ One characteristic sign of frontal lobe dysfunction in PSP the "applause sign," manifested by persistence (perseveration) of clapping after the patient has been instructed to clap three times.⁶⁹

The best known feature of PSP, vertical ocular gaze paresis, may be overcome by passive head movement, which activates the oculocephalic reflexes (hence the designation supranuclear) (Video 55, Supranuclear Gaze Paresis). Riley and colleagues⁷⁰ reported five patients who presented with "pure akinesia" of gait, speech, and handwriting without rigidity, tremor, dementia, or eye movement abnormalities on clinical examination. None of the patients responded to levodopa, and four demonstrated subtle changes in vertical saccades on eyelid movement recordings (Video 206, Postural Instability).⁷⁰ The diagnostic criteria for PSP have been recently refined as a result of careful clinical-pathological correlative studies, and the greatest diagnostic confidence is placed in the combined clinical features of early frequent falls within the first year of clinical disease and vertical downward supranuclear paresis on examination.⁷¹

DIFFERENTIAL DIAGNOSIS. Whereas PSP is idiopathic, the same clinical syndrome has been associated with Alzheimer's disease, multiple strokes, multiple system atrophy (MSA), posthypoxic encephalopathy, and Whipple's disease. Parkinson's disease and the other parkinsonism-plus syndromes, including corticobasal ganglionic degeneration (CBD), Lewy body dementia (Video 232, Dementia with Lewy Bodies), normal pressure hydrocephalus (Video 54, Normal Pressure Hydrocephalus), and "multi-infarct parkinsonism," must also be considered. Rarely, other conditions, such as dentato-rubro-pallidolusian atrophy, neuroacanthocytosis, progressive external ophthalmoplegia, Whipple's disease, and hydrocephalus, may present with oculomotility disorders that are suggestive of PSP (Video 110, Facial Myokymia).

EVALUATION. MRI should be performed in patients in whom PSP is suspected to rule out a multi-infarct state or hydrocephalus. Single-photon emission computed tomography (SPECT) and positron emission tomography (PET) demonstrate prefrontal hypoactivity and show evidence of severe involvement of the dopaminergic terminals as well as the postsynaptic DA receptors in the striatum.⁷²

MANAGEMENT. Although PSP is associated with loss of multiple neurotransmitters, pharmacological therapies remain disappointing. Levodopa ameliorates the bradykinesia and rigidity in approximately one third of cases, but the benefit rarely persists beyond 1 or 2 years. DA agonists rarely provide additional benefit. If, however, the dopaminergic drugs improve the bradykinesia but have no impact on poor balance, the medicated patient may feel more agile and independent, only to fall more frequently, leading to consequently greater disability. Anticholinergic drugs and tricyclic antidepressants with anticholinergic effects (e.g., amitriptyline) may be helpful in treating emotional incontinence. Idazoxan, a noradrenergic drug, produced modest improvement in a small number of patients, but sympathomimetic and other side effects have limited further development of this drug.⁷³ Blepharospasm, occasionally associated with PSP, responds to botulinum toxin injection, and dry eyes may be treated with topical lubricants. Although physical, occupational, and speech therapy are

of limited potential, these options may be beneficial in some patients and their families. Electroconvulsive therapy, adrenal implantation, and pallidotomy have been of no benefit.

PROGNOSIS AND FUTURE PERSPECTIVES. The median interval from onset of the initial symptom, regardless of its nature, to onset of gait difficulty is estimated at 0.3 years; to the need for gait assistance, 3.1 years; to confinement to bed or wheelchair, 8.2 years; and to death, 9.7 years.⁶⁸ In contrast to the approximately 1.5% annual decline in the Unified Parkinson's Disease Rating Scale Part III noted in patients with PD, the average annual decline in MSA-P is 28.3%.⁷⁴ The problems that most frequently cause complications or death are falls and aspiration.

Multiple System Atrophy

PATHOGENESIS AND PATHOPHYSIOLOGY. The pathogenic mechanisms of MSA remain unknown, and in contrast to PD, there is no evidence that genetic factors play a role. Recent findings link MSA to PD and related neurodegenerative disorders as “ α -synucleinopathies.”¹⁸ Whereas the initial neurodegenerative events are unclear, in well-established cases, the staining characteristics and distribution of oligodendroglial fibrillary cytoplasmic inclusions are distinctively different from the neurofibrillary tangles of Alzheimer's disease, PSP, postencephalitic parkinsonism, and others.⁷⁵ Highly variable neuronal loss and gliosis are seen in the substantia nigra, caudate, putamen, cerebellar cortex, pyramidal tract, Edinger-Westphal nucleus, locus caeruleus, inferior olives, dorsal motor nucleus of the vagus, Purkinje cells, intermediolateral cell column of the spinal cord, spinocerebellar tracts, and Onuf's nucleus. Reduced dopamine or norepinephrine levels occur in the nigra, nucleus accumbens, septum, hypothalamus, and locus caeruleus.⁷⁵

EPIDEMIOLOGY AND RISK FACTORS. In a review of autopsies of parkinsonism, Quinn reported frequencies ranging from 3.6% to 22%, with a mean of 8.2% (68/833 cases).⁷⁶ However, no study has been undertaken to determine the population prevalence of MSA. At one large referral center, 100 patients with MSA reported a median age at onset of 53 years (range, 33 to 76 years).⁷⁷

CLINICAL FEATURES AND ASSOCIATED DISORDERS. MSA encompasses three neurodegenerative syndromes, which in the past were considered clinically distinct: striatonigral degeneration (SND), olivopontocerebellar atrophy (OPCA), and Shy-Drager syndrome (SDS). All these conditions share similarities with one another and with PD. The hallmark features of MSA are parkinsonism that is poorly responsive to levodopa therapy and varying degrees of autonomic, cerebellar, and pyramidal dysfunction. SDS is diagnosed clinically when dysautonomia far outweighs the other signs, SND is designated when anterocollis and pyramidal dysfunction are prominent (Video 235, Multiple System Atrophy, Striatonigral Degeneration), and OPCA is used to characterize the patient with prominent cerebellar features of ataxia, limb dyssynergia, and kinetic tremor (Video 234, Multiple System Atrophy, Cerebellar Type). For all MSA patients, autonomic insufficiencies include orthostatic hypotension, postprandial hypotension, anhidrosis with thermoregulatory disturbances, poor lacrimation

and salivation, constipation, and impotence. Disturbances in bladder emptying and incontinence may also occur. In addition, emotional lability, pyramidal signs, supranuclear ophthalmoplegia, anterocollis, myoclonus, sleep apnea and other ventilatory dysrhythmias, respiratory stridor, polyneuropathy, amyotrophy, and dementia may be present in any of the forms.⁷¹ The variety of clinical presentations is wide, and pure autonomic failure, sleep apnea syndromes, some forms of peripheral neuropathies, and conditions that clinically resemble amyotrophic lateral sclerosis all may represent forms of underlying MSA.

DIFFERENTIAL DIAGNOSIS. Parkinson's disease, particularly in patients with prominent postural instability and gait disturbance, may be difficult to distinguish from MSA.⁷⁸ PSP and other parkinsonism-plus syndromes can be particularly difficult to separate, especially in the first 5 years of clinical illness. Vascular encephalopathies with multiple subcortical strokes may produce a similar constellation of signs, and the condition of pure autonomic failure can be difficult to differentiate from MSA in the early course of illness.

EVALUATION. MRI may be useful to rule out a multi-infarct state, normal pressure hydrocephalus, or other causes of parkinsonism. An MRI scan demonstrating marked hypointensity of the striatum and linear hyperintensity lateral to the putamen on T2-weighted images suggests iron deposition and supports the diagnosis of MSA.⁷⁶ PET scans of MSA are similar to those of PSP and usually confirm a decreased density of striatal D₂ receptors.⁷⁹ External urethral and rectal sphincter electromyography (EMG) is abnormal in almost all patients with MSA. Resting, supine, and standing norepinephrine levels are of questionable value, but supine and standing norepinephrine levels have been found to be slightly elevated in patients with MSA, whereas in those with pure autonomic failure they are usually decreased.⁸⁰

MANAGEMENT. Levodopa may provide some relief, usually short term, for the rigidity, bradykinesia, and postural instability typical of MSA.⁸¹ Patients with MSA usually require larger doses of levodopa than patients with PD, but side effects such as increased orthostatic hypotension and facial dystonia often limit the usefulness of levodopa. Patients rarely derive any meaningful benefit from DA agonists, anticholinergics, amantadine, or other anti-parkinsonian drugs. Symptomatic orthostatic hypotension can be treated with sodium and volume repletion unless the patient is at risk of congestive heart failure or renal insufficiency. Ancillary measures such as wearing elastic stockings to increase central venous volume and elevating the head of the bed 6 inches may also be attempted but often prove uncomfortable. Fludrocortisone, a mineralocorticoid, often improves orthostatic symptoms by increasing vascular volume. Some patients benefit from the inhibition of vasodilator prostaglandin synthesis brought about by indomethacin and from the use of the α -adrenergic agonist clonidine and the peripheral vasoconstrictor ephedrine. Midodrine, an α -adrenergic agonist, has benefited some patients with moderate and severe orthostatic hypotension of various causes.⁸² Urinary frequency or incontinence, if due to detrusor hyper-reflexia, may respond to peripherally acting anticholinergic agents such as oxybutynin or propantheline given at bedtime. Intranasal desmopressin at

bedtime may offer relief from nocturnal urinary frequency. Impotence may respond to yohimbine, papaverine, or a penile implant. Constipation can be treated with cisapride, stool softeners, and bulk-forming agents. Hallucinations caused by dopaminergic therapeutic agents usually respond to a lower dose of dopaminergic medications or to clozapine at bedtime.⁶² However, this latter therapy must be used cautiously in patients with hypotension. All patients receiving this drug must be monitored for agranulocytosis with weekly white blood cell counts.

PROGNOSIS AND FUTURE PERSPECTIVES. Based on autopsy-proven cases of MSA, the average survival time is expected to be less than a decade (mean survival, 8.0 years⁷⁶; median survival, 9.5 years).⁷⁷ Future studies may focus on the role of iron and oxidative stress in this disorder and the pathological hallmark of glial cytoplasmic inclusion bodies.

Other Parkinsonism-Plus Syndromes

CORTICOBASAL DEGENERATION. CBD is a distinctive parkinsonism-plus syndrome because specific cortical signs are associated with it, and it has a particular pathological picture. Autopsy in patients with CBD reveals asymmetrical, focal frontoparietal atrophy, “ballooned” and enlarged cells in the cortex, depigmentation of the substantia nigra without Lewy bodies, and diffuse neuronal loss.⁸³ There is no familial predisposition, and no environmental factors increase the risk of disease. Clinically, patients usually develop symptoms after age 60, and neurological signs of CBD include focal or asymmetrical rigidity, bradykinesia, postural and action tremor, and marked dystonia, usually predominantly in one upper extremity (Video 231, Cortical Basal Degeneration). The most characteristic symptom, however, is limb apraxia (Video 40, Apraxia), and the involved extremity can become so dysfunctional that it moves completely by itself and can be considered an “alien limb” (Video 39, Alien Hand Syndrome).⁸⁴ In most instances, the condition starts as an apparent case of PD, but the cortical sensory loss, dystonia, and apraxia are noticed quickly as distinctive. Ideomotor apraxia, possibly secondary to predominant involvement of the supplementary motor area and characterized by not knowing “how to do it” (as opposed to not knowing “what to do” with everyday objects in the ideational or conceptual apraxia), and limb-kinetic apraxia (loss of hand and finger dexterity with inability to isolate or connect individual movements) are the most typical forms of apraxia in CBD.⁸⁵ The parkinsonism can be treated with modest success in some cases by introducing levodopa or DA agonists, but the marked disability resulting from the limb dyspraxia is progressive, untreatable, and markedly disabling. Botulinum toxin can relieve elements of the dystonia. The condition usually progresses steadily, and death occurs within 10 years of diagnosis.⁸⁴

PARKINSONISM-DEMENTIA AMYOTROPHIC LATERAL SCLEROSIS COMPLEX (PDALS). This distinctive condition occurs on the island of Guam (locally known as Lytico-Bodig disease) and has been the focus of significant research because of the possibility that genetic and environmental causes may be contributive (Video 236, ALS-Parkinsonism Dementia).⁸⁶ A study of more than 2000

affected and nonaffected individuals in Guam showed that the incidence of this disorder peaked in the 1950s and has gradually declined since that time. The rapid decline in incidence of this disorder in Guam strongly supports the role of environmental factors in the pathogenesis of this disorder.⁸⁷ Early studies focusing on possible environmental dietary toxins were encouraging, but recent work has failed to identify any agent consistently, and the once-held hypothesis that native flour contains a causative neurotoxin is no longer considered tenable.⁸⁷ Pathologically, depigmentation, basophilic inclusion bodies, and cell loss in the substantia nigra are apparent in cases of PDALS. Neurofibrillary tangles without senile plaques are present in the substantia nigra, anterior horn cells, and pyramidal tracts.⁸⁷ Clinical findings in PDALS range from motor neuron disease in younger patients to parkinsonism with severe dementia in the older population. The amyotrophic lateral sclerosis (ALS) form is seen predominantly in the Chamorros, whereas the parkinsonism-dementia presentation may be seen in both Chamorro and Filipino residents. The ALS seen in Guam does not differ clinically from the motor neuron disease seen in the remainder of the world. Although no cause has been established, the coexistence of these neurodegenerative conditions in one population with overlapping signs supports the continuation of hypotheses based on a common cause. The differential diagnosis for PDALS includes Alzheimer’s disease, diffuse Lewy body disease, postencephalitic parkinsonism, PD, the parkinsonism-plus syndromes, lower body parkinsonism and other causes of parkinsonism, as well as ALS and the various forms of motor neuron disease (Video 232, Dementia with Lewy Bodies; Video 233, Vascular Parkinsonism).⁸⁷ Regardless of its form of clinical presentation, the disorder is relentlessly progressive, and death usually occurs within 10 years of diagnosis.

HEMIATROPHY/HEMIPARKINSONISM. Hemiatrophy/hemiparkinsonism (HA/HP) is an uncommon disorder that involves the onset of parkinsonism on one side of the body in association with a hemiatrophic face, arm, or leg in varying combinations (Video 243, Hemiatrophy). First described by Klawans,⁸⁸ the disease presents with unilateral parkinsonism; the hemiatrophy is completely unnoticed by the patient. In a hemiparkinsonian patient, therefore, comparative examination of the size of the hands and feet may be necessary to diagnose the condition. Compared to PD, the parkinsonism of HA/HP usually begins at a younger age and generally remains on the hemiatrophic side for several years before it sometimes becomes bilateral. Unilateral dystonic movements are a common early feature and may respond well to levodopa. The cause is unknown, but early birth injury from hypoxia or trauma has been suggested as a possibility, and there may be some relationship between this syndrome and a distinct form of dystonia termed dopa-responsive dystonia.⁸⁹ Hemiatrophy of the contralateral cortex may be seen on MRI in some patients.

Stiff-Person Syndrome

PATHOGENESIS AND PATHOPHYSIOLOGY. Stiff-person syndrome (SPS) is believed to be an idiopathic disorder in some patients and an autoimmune disorder with

functional impairment of spinal neurons due to antibodies directed against the enzyme glutamic acid decarboxylase (GAD) in others.⁹⁰ This enzyme is essential for the conversion of glutamic acid to GABA, an inhibitory neurotransmitter found throughout the central nervous system.⁹¹ In a paraneoplastic form of SPS, amphiphysin, a protein associated with synaptic vesicles, has been implicated, and this product's gene has been mapped to 7p13-14.⁹² Neurophysiological studies show continuous excessive firing of the motor unit, suggesting that the disorder is due to disinhibition of the descending pathways to the Renshaw cells or gamma motor system.⁹³ Autopsy information, albeit limited, has failed to demonstrate any abnormalities in the brain stem, spinal cord, peripheral nerve, or muscle.

EPIDEMIOLOGY AND RISK FACTORS. The disorder is more common in women and is frequently associated with other autoimmune disorders (diabetes mellitus, thyroiditis, myasthenia gravis, pernicious anemia, and vitiligo).⁹³

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Typically, SPS patients present with painful muscle cramps and severe lordosis secondary to chronic spasm of the paraspinal muscles. Although predominantly a disease of the axial muscles, cranial involvement has been reported in 25% of patients, and spread to the proximal limbs occurs. Examination reveals marked lumbar and thoracic muscle spasms. Stress or exertional activity may provoke painful spasms that may last for hours. Because of hypertonicity, the gait may resemble that of a "tin soldier" (Video 238, Stiff Person Syndrome).

DIFFERENTIAL DIAGNOSIS. Among the primary differential diagnoses are dystonia and orthostatic tremor. In both instances, patients may complain of tight cramping muscles and pain, especially when standing. Other rare conditions resembling SPS include tetanus, progressive encephalomyelitis with rigidity, and Isaac's syndrome. Tetanus secondary to infection with *Clostridium tetanii* is usually associated with a laceration injury and progresses from focal muscle spasm at the site of inoculation to bulbar and generalized spasms. Progressive encephalomyelitis usually begins with pain and sensory changes, and in these patients, a paraneoplastic disorder is possible. Isaac's syndrome is often familial and is associated with peripheral neuropathy, but most important, it usually causes more symptoms in the appendicular muscles than in the axial ones.

EVALUATION. Electromyographic demonstration of continuous motor unit activity is essential to confirm the diagnosis of SPS. The presence of reduced motor activity after benzodiazepine administration is also important. Diagnostically, spinal fluid analysis may reveal increased immunoglobulin or oligoclonal bands, and the presence of GAD antibodies is helpful in confirming the autoimmune form of this diagnosis.

MANAGEMENT. Treatment is based on controlling rigidity; diazepam (20 to 300 mg/day) is the most effective medication for this purpose. Baclofen, clonazepam, valproic acid, and clonidine have been reported to improve symptoms. The role of treatment for autoimmune conditions, such as plasmapheresis, corticosteroids, or azathioprine, has yet to be defined, but high-dose intravenous immunoglobulin has been found to be an effective, albeit costly, treatment.⁹⁴ Intrathecal baclofen and botulinum

toxin may also be beneficial, but because of the rarity of this syndrome, controlled clinical trials of these drugs for this purpose have not been undertaken. Although these patients may be in pain, extreme caution must be used in mixing narcotic medications with benzodiazepine derivatives, especially if the patient's spasms induce respiratory acidosis because of the rigidity of the diaphragmatic muscles.

PROGNOSIS AND FUTURE PERSPECTIVES. Without treatment, SPS progresses to total disability related to generalized rigidity and secondary musculoskeletal deformities. The pathogenetic autoimmune mechanisms remain to be elucidated.

HYPERKINETIC MOVEMENT DISORDERS

Huntington's Disease

This primary neurodegenerative disorder usually begins during adult life, often after the affected individuals have already borne their children. It is inherited in an autosomally dominant pattern, and the disorder has clinical manifestations that often vary among involved family members. Patients may have predominantly behavioral, cognitive, or movement disorder signs.

PATHOGENESIS AND PATHOPHYSIOLOGY. Huntington's disease (HD) is caused by a mutation on chromosome 4 consisting of an unstable expansion of CAG repeats. Normal individuals have between 11 and 34 repeats, whereas those with HD have between 37 and 86. The trinucleotide CAG codes for glutamine, and the increase in polyglutamine is thought to cause an overexpression of the gene whose protein is termed huntingtin. This product tightly binds with ubiquitin to form intranuclear inclusions and may subsequently interfere with normal mitochondrial bioenergetic mechanisms.⁹⁵ Huntingtin is associated with vesicle membranes and microtubules and as such probably has a role in endocytosis, intracellular trafficking, and membrane recycling. Mutant huntingtin fragments also accumulate in axon terminals and interfere with glutamate uptake and, similar to other polyglutamine disease, impair axonal transport.⁹⁶ It is not clear whether HD results from a toxic property of the mutant protein (gain of function) or loss of neuroprotective activity of the normal huntingtin (loss of function).⁹⁷

It is not known why the striatum is preferentially affected because the HD mRNA product has been found in all examined tissues.⁹⁸ Neuronal loss in the caudate and putamen has been correlated with a longer CAG trinucleotide repeat length, and the preproenkephalin medium spiny neuron seems to be particularly vulnerable.⁹⁹

Pathological changes in the brain of patients with HD include generalized atrophy with neuronal degeneration in the cortex and severe loss of medium spiny projection neurons with preservation of cholinergic aspiny interneurons in the caudate and putamen. Marked caudate atrophy is the pathological hallmark of the disease, and this finding can be detected on MRI scans. MR spectroscopy demonstrates changes that reflect increased levels of lactic acid, suggesting a bioenergetic defect. Additional evidence, particularly in experimental models of HD, suggests that mitochondrial dysfunction may be a possible pathogenetic mechanism of neuronal cell death.¹⁰⁰

Several important biochemical abnormalities have been noted in postmortem brain tissue, particularly in the striatum. These include decreases in choline acetyltransferase activity and acetylcholine; a reduction in the total number of cholinergic muscarinic receptors; and depletion of GAD, substance P, angiotensin-converting enzyme, cholecystokinin, enkephalin, and other peptides. In contrast, the concentrations of DA, norepinephrine, serotonin, neurotensin, somatostatin, and thyrotropin-releasing hormone are normal or increased.¹⁰⁰ The result of these changes suggests a functional overactivity of the cerebral glutaminergic and striatal dopaminergic systems and an underactivity of the GABAergic systems.

EPIDEMIOLOGY AND RISK FACTORS. The estimated prevalence of HD is 5 to 10 per 100,000 people in the United States.¹⁰¹ Because the CAG repeat length is unstable in sperm, affected fathers often transmit a very high repeat sequence, resulting in an early onset of disease in their offspring.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Gradual onset of chorea, dementia, and behavioral abnormalities in a young or middle-aged adult should suggest the possibility of HD. Slowed saccadic eye movements are usually the first detectable clinical sign, and in 85% of patients chorea is the predominant movement disorder. Movements may start as fine, irregular body jerks that have no functional significance, but coordination, gait, and balance difficulties gradually supervene (Video 15, Facial Chorea; Video 18, Limb Chorea). In the juvenile form of HD, rigidity, bradykinesia, resting tremor, dystonic postures, ataxia, seizures, myoclonus, and mental retardation are more prominent, and this presentation is termed the Westphal variant of HD. Even in patients with adult-onset and prominent chorea, bradykinesia and postural reflex compromise can occur and may be sources of significant functional disability (Video 63, Choreic Gait). In the terminal phases of HD, dysarthria, dysphagia, and respiratory difficulties become the most disabling and life-threatening problems.¹⁰⁰

Cognitive impairment is a source of major disability in these patients. Memory difficulties, concentration problems, confusion, and forgetfulness can occur (see Chapter 33) (Video 16, Luria Testing). In addition, depression and other emotional disturbances may be severe and can lead to erratic, impulsive behavior as well as suicidal ideation. Other psychiatric disturbances include delusional thoughts, paranoia, and hallucinations.¹⁰⁰ Eventually, patients become demented, and most require assistance and supervision in daily living activities.

DIFFERENTIAL DIAGNOSIS. Besides HD, other less common hereditary choreas include hereditary benign chorea and neuroacanthocytosis (see later discussion in this chapter). If a family history of choreic or psychiatric disorders is lacking, numerous other disorders should be considered, including tardive dyskinesia, central nervous system (CNS) vasculitis, Wilson's disease, Sydenham's chorea, and toxin exposure. Drugs causing chorea include oral contraceptives, levodopa, CNS stimulants, neuroleptics, phenytoin, carbamazepine, and ethosuximide (Video 71, Birth Control Pill-Induced Chorea). If the diagnosis is approached from the perspective of genetic testing, other hereditary neurodegenerative conditions with expanded

trinucleotide repeats of CAG include Kennedy's syndrome (X-linked spinal and bulbar muscular atrophy), myotonic dystrophy, spinocerebellar atrophy type 1, and DRPLA (Table 34-4).

EVALUATION. In addition to taking a complete family history, blood should be drawn for DNA testing. Careful counseling about the implications of the diagnosis is essential when working with patients who are at risk for the disease. Issues of privacy are particularly important because giving subjects positive diagnostic information reveals information about the parents' genetic makeup. MRI scans can detect the presence of caudate and cerebral atrophy. When the family history is in doubt, an assiduous search of autopsy reports on relatives can sometimes unearth the diagnosis in the genealogy.

MANAGEMENT. DA receptor-blocking agents (e.g., haloperidol and fluphenazine) and dopamine-depleting agents (e.g., tetrabenazine and reserpine) reduce the choreic movements but may not improve other symptoms of HD. Because of their potentially serious side effects, including tardive dyskinesia (neuroleptics), depression (dopamine-depleting drugs), and parkinsonism (both drug classes), the antidopaminergic drugs should be reserved for patients with disabling chorea or serious psychosis. In a multicenter, double-blind, placebo-controlled trial of

TABLE 34-4

Etiological Classification of Chorea

1. Developmental and aging choreas
 - a. Physiological chorea of infancy
 - b. Cerebral palsy—anoxic, kernicterus
 - c. Minimal cerebral dysfunction
 - d. Buccal-oral-lingual dyskinesia and edentulous orodyskinesia in elderly
 - e. Senile chorea (probably several causes)
2. Hereditary choreas
 - a. Huntington's disease
 - b. Benign hereditary chorea
 - c. Neuroacanthocytosis
 - d. Other CNS "degenerations": olivopontocerebellar atrophy, Azorean disease, ataxia-telangiectasia, tuberous sclerosis, Hallervorden-Spatz, dentato-rubral-pallido-lysonian atrophy (DRPLA), familial calcification of basal ganglia, others
 - e. Neurometabolic disorders: Wilson's disease, Lesch-Nyhan disease, lysosomal storage disorders, amino acid disorders, Leigh's disease, porphyria
3. Drug-induced choreas: neuroleptics (tardive dyskinesia), antiparkinsonian drugs, amphetamines, tricyclics, oral contraceptives, anticonvulsants, anticholinergics, others
4. Toxin-induced choreas: alcohol intoxication and withdrawal, anoxia, carbon monoxide, Mn, Hg, thallium, toluene
5. Metabolic causes
 - a. Hyperthyroidism
 - b. Hypoparathyroidism (various types)
 - c. Pregnancy (chorea gravidarum)
 - d. Hyper- and hyponatremia, hypomagnesemia, hypocalcemia
 - e. Hypo- and hyperglycemia (latter may cause hemichorea, hemiballismus)
 - f. Acquired hepatocerebral degeneration
 - g. Nutritional—for example, beriberi, pellagra, vitamin B₁₂ deficiency in infants
6. Infectious causes
 - a. Sydenham's chorea
 - b. Encephalitis lethargica
 - c. Various other infections and postinfectious encephalitides, including Creutzfeldt-Jakob disease

tetrabenazine 84 ambulatory patients with HD, tetrabenazine treatment resulted in a reduction of 5.0 units in chorea severity compared with a reduction of 1.5 units on placebo treatment (adjusted mean effect size, -3.5 ± 0.8 UHDRS units [mean \pm SE]; 95% confidence interval, -5.2, -1.9; $P < 0.0001$).¹⁰² The tricyclic antidepressants and selective serotonin reuptake inhibitors are often helpful in ameliorating the affective disorders but may precipitate myoclonus. Antiglutaminergic drugs and facilitators of mitochondrial metabolism are currently being tested in clinical trials. Psychological support, genetic counseling, long-term planning, and access to social service agencies are important elements of patient management.

PROGNOSIS AND FUTURE PERSPECTIVES. Despite advances in treatment, this disorder results in progressive functional decline and eventual death, usually within 12 to 15 years of onset. Neural transplantation with fetal striatal or other cell sources may become experimental options in the future.

Other Forms of Chorea

Senile chorea (essential chorea) begins after age 60 and is unaccompanied by any particular neurobehavioral symptoms or a family history of chorea. Whereas some patients have caudate atrophy similar to that seen in HD, others have predominant putamenal degeneration. In occasional cases, genetic detection studies in these patients reveal that the correct diagnosis is actually HD. Treatment of the chorea is similar to that for HD.

Paroxysmal dyskinesia is a chronic condition that becomes manifest by a sudden onset of transient choreo-athetosis, dystonia, or both. The familial paroxysmal dyskinesias are subdivided into kinesigenic and nonkinesigenic disorders depending on whether or not they are induced by sudden voluntary movements.¹⁰³ In the familial (autosomal dominant or recessive) kinesigenic paroxysmal dyskinesia, the movements are brief, usually lasting less than 3 minutes, and occur many times daily—sometimes up to 100 times per day.¹⁰³ Nonkinesigenic and exertional paroxysmal dyskinesias may also be transmitted as autosomal dominant disorders, and the movements in these forms tend to be more dystonic than choreic in nature (Video 20, Tonic Spasms). The episodes of dyskinesia are usually more prolonged (lasting 2 minutes to 4 hours) and less frequent (occurring three to five times per day). Attacks are precipitated by alcohol, coffee, fatigue, stress, or excitement. Kinesigenic dyskinesias respond well to anticonvulsant medications such as phenytoin, carbamazepine, or phenobarbital. In contrast, the nonkinesigenic dyskinesias respond poorly to most medical therapy, although some patients improve with clonazepam.¹⁰³ Pathophysiologically, these conditions appear to be an interface between movement disorders and epilepsy since in some conditions assiduous electrode placement over the frontal and frontocentral regions may reveal epileptic spikes and phase reversals.¹⁰⁴ Secondary paroxysmal dyskinesias may be associated with structural lesions of the premotor cortex or basal ganglia, and specific causes include multiple sclerosis and hypocalcemia.¹⁰³

Neuroacanthocytosis is a rare disorder with autosomal dominant, recessive, or even X-linked inheritance and is

manifested by chorea, tics, dystonia, parkinsonism, self-mutilatory behavior, amyotrophy, areflexia, elevated creatine kinase, and other symptoms.¹⁰⁵ One of the most distinguishing features of neuroacanthocytosis is an eating dysfunction that is due to orolingual dystonia and is manifested by expulsion of food from the mouth by a protruding tongue. Involuntary vocalizations and parkinsonism also occur. Although the mechanism of acanthocyte formation in neuroacanthocytosis is unknown, abnormal protein-to-fatty acid ratios and, in some cases, abnormal erythrocyte surface antigens have been found. It is possible that, as in the periodic ataxias, some of the paroxysmal dyskinesias represent abnormalities of the calcium channel or other channelopathies. Acanthocytes in most patients can be seen in fresh blood smears, but erythrocytes may require incubation in normal saline for 3 to 5 minutes prior to wet mount preparation. Computed tomography (CT) or MRI of the head may demonstrate cerebral or caudate atrophy. PET scans reveal 42% and 54% reductions in putamenal and caudate fluorodopa uptake, respectively, and 65% and 53% reductions in the D₂ receptor density in these areas.¹⁰⁵ Treatment may involve the use of dopamine-blocking agents in the form of neuroleptics (haloperidol and fluphenazine) or dopamine-depleting drugs (reserpine and tetrabenazine). As the disease progresses, most care is supportive. Although the course of progression varies, death usually occurs within 15 years of diagnosis.

Sydenham's chorea (also known as St. Vitus' dance) develops following exposure to the bacteria *Streptococcus pneumoniae* and, in the age of antibiotic therapy, is rare.⁹⁸ Most typically, Sydenham's chorea is associated with infection and other sequelae of rheumatic fever. Autopsy studies of patients with Sydenham's chorea reveal edema, chromatolysis, and atrophy that affect primarily the striatum, but the cortex, thalamus, and other basal ganglial nuclei may be variably involved as well.⁹⁸ The clinical picture involves a child with diffuse chorea, motor impersistence, and variable degrees of weakness. Unlike arthritis and carditis, chorea may not develop for weeks or even months after acute infection has occurred. Children are often very distressed in the midst of the chorea, rest poorly, and can develop a number of behavioral abnormalities. In addition to high titers of antistreptolysin, approximately 50% of patients have IgG antibodies that react against neurons in the caudate and subthalamic nuclei. The condition is usually self-limited, but during the period of marked chorea, dopamine-blocking or -depleting agents can be used. Because prolonged drug usage is usually not necessary, major concerns about the induction of tardive dyskinesia from neuroleptic drugs do not exist.

In the evaluation of these forms of primary choreic disorders, other secondary choreas must be considered. Chorea gravidarum and endocrine-metabolic choreas, such as birth control pill chorea, should be considered in appropriate women with hyperkinetic movements (Video 71, Birth Control Pill-Induced Chorea). Prior Sydenham's chorea may be a risk factor for these conditions. Estrogens may serve as a facilitator of dopamine pharmacology, either directly at the receptor sites or through second messengers. In pregnancy, DA receptor-blocking drugs (neuroleptics) should be avoided, particularly during the limb-geneses period of the first trimester. Benzodiazepines

may be appropriate in the second and third trimesters, but fetal respiratory depression must be avoided. Hyperthyroidism, either primary or pituitary in origin, can be associated with various movement disorders, including chorea (Video 70, Hyperthyroidism-induced Chorea).

Primary Dystonia

PATHOGENESIS AND PATHOPHYSIOLOGY. Dystonia consists of sustained, repetitive, patterned contractions of the muscles producing twisting (e.g., torticollis) or squeezing (e.g., blepharospasm) movements or abnormal postures that may be present at rest, when changing position, or when performing a specific motor activity.¹⁰⁶ The most frequently encountered form of generalized dystonia is primary dystonia, formerly referred to as dystonia musculorum deformans or idiopathic torsion dystonia. It is an autosomal dominant disorder in which the genetic defect consists of a three-base pair deletion in a gene on chromosome 9q32–34 (DYT1), coding for an ATP-domain protein called TorsinA. The mutant protein forms multiple, large inclusions composed of endoplasmic reticulum-derived membrane whorls in cultured cells.¹⁰⁷ In contrast to the traditional view that brains of patients with dystonia are usually normal, one study of four brains from genetically confirmed DYT1 dystonia patients found perinuclear inclusion bodies in the midbrain reticular formation and periaqueductal gray of the pedunculopontine nucleus, cuneiform nucleus, and griseum centrale mesencephali.¹⁰⁸ These inclusions stained positive for ubiquitin, torsinA, and the nuclear envelope protein lamin A/C. In addition, tau/ubiquitin-immunoreactive aggregates were found in the substantia nigra pars compacta and locus coeruleus. These findings support the notion that DYT1 dystonia is associated with impaired protein handling, particularly in the brain stem nuclei. Rarer forms of pure dystonia unrelated to this defect or due to enzyme deficiencies have been described (Table 34-5) but are not well delineated.

Although autopsy studies have produced no reproducible histological or biochemical abnormalities in patients with primary dystonia, the disorder is thought to be due to altered physiological control of descending pathways from the basal ganglia and brain stem. Subtle changes on MRI have been reported in patients with primary dystonia, but in most patients no discernible abnormalities can be identified on imaging tests. PET studies have also failed to reveal consistent abnormalities. Studies using blink, acoustic, and vestibulo-ocular reflex testing, however, have revealed abnormalities suggesting that the brain stem reflexes have enhanced excitability.¹⁰⁹ Changes in norepinephrine, serotonin, and dopamine levels have been found in some patients.

EPIDEMIOLOGY AND RISK FACTORS. Limited information is available about the epidemiology of primary dystonia, but data from Rochester, Minnesota, reveal a prevalence of 34 per 1 million population; specific cultural groups are more likely to develop primary dystonia than others, however, and among Jews of Eastern European ancestry the prevalence is at least double that seen in other groups.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Primary dystonia may involve the entire body (generalized dystonia) or may be confined to one body part (focal dystonia), for example, the head (cranial dystonia), neck

(cervical dystonia), or vocal muscles. Alternatively, it may involve contiguous body parts (segmental dystonia), for example, the neck, shoulder, and arm. The most common form of limb dystonia is dystonic writer's cramp (Video 48, Spasmodic Dysphonia; Video 52, Torticollis; Video 64, Generalized Dystonia).

Although primary dystonia is a highly variable condition, there are a number of important clinical patterns. First, primary dystonia, regardless of its eventual outcome (focal, segmental, or generalized), usually begins as a focal condition, and in children the legs and feet are the areas most commonly affected. Second, environmental conditions affect dystonia and, importantly, in the early stages of primary dystonia, dystonia is usually seen only during activity, for example, when walking or running (action dystonia). In addition, and related to exacerbation of disease with action, dystonic signs usually become prominent in the middle and later part of the day. This feature is most pronounced in a particular form of dystonia, termed dopa-responsive dystonia (see subsequent discussion), in which diurnal fluctuation in the gait disturbance may be so marked that the patient is almost normal in the early morning but becomes virtually crippled by late afternoon or evening. Third, the younger the age at onset, the more likely the dystonia is to become severe and spread to many body regions. Likewise, adult-onset primary dystonia is almost always focal or segmental and does not become generalized. Fourth, patients with primary dystonia often report that certain postures or sensory "tricks" or "gestes antagoniques" improve their dystonia. For example, gentle counterpressure by a hand against the chin in a patient with torticollis may enable the patient to maintain the primary or normal position of the head. Finally, one of the features in many patients with dystonia is an associated tremor in addition to the contorted posture. This tremor, termed dystonic tremor, involves the patient's attempt, conscious or not, to overcome the dystonia. It is most pronounced when the patient works maximally to resist the pull of the dystonic muscles and is least apparent when the patient permits the involved body part to drift with the dystonic spasm.

DIFFERENTIAL DIAGNOSIS. In addition to primary dystonia, the differential diagnosis of the dystonic patient (see Table 34-5) must include (1) dystonia-plus syndromes, a conglomerate term that includes other forms of primary dystonia associated with additional neurological deficits, and (2) secondary forms of dystonia, in which the dystonia is related to underlying damage from a known pathological cause. In the latter category, causes of dystonia are numerous and include exposure to DA receptor-blocking drugs ("tardive dystonia"), hypoxic encephalopathy, head trauma, encephalitis, human immunodeficiency virus and other infections, peripheral or segmental nerve injury, inherited disorders (e.g., Wilson's disease), metabolic disorders and other inborn errors of metabolism, mitochondrial disorders, and chromosomal abnormalities (Video 58, High-Amplitude Tremor; Video 66, Tardive Dyskinesia).¹⁰⁵ Unilateral dystonia (hemidystonia) is usually not part of the clinical picture of primary dystonia but is associated with a structural lesion in the contralateral striatum, particularly the putamen.

EVALUATION. The diagnosis of primary dystonia should be considered in any patient with an abnormal posture and a

TABLE 34-5

Etiological Classification of Dystonia

- I. Idiopathic (primary) dystonia
- A. Sporadic (idiopathic torsion dystonia, ITD)
 - B. Inherited (hereditary torsion dystonia)
 1. Classic autosomal dominant ITD (*DYT1* gene, 9q34)
 2. Nonclassic autosomal dominant ITD (not *DYT1* gene)
 3. Autosomal recessive tyrosine hydroxylase deficiency
- II. Secondary dystonia
- A. Dystonia-plus syndromes
 1. Myoclonic dystonia (not *DYT1* gene)
 2. Dopa-responsive dystonia (DRD, GTP cyclohydrolase I 14q22.1–q22.2 gene defect)
 3. Rapid-onset dystonia-parkinsonism (RDP)
 4. Early onset parkinsonism with dystonia (EPD)
 5. Paroxysmal dystonia-choreoathetosis
 - B. Associated with neurodegenerative disorders
 1. Sporadic
 - Parkinson's disease
 - Progressive supranuclear palsy
 - Multiple system atrophy
 - Corticobasal ganglionic degeneration
 - Multiple sclerosis
 - Central pontine myelinolysis
 2. Inherited
 - Wilson's disease
 - Huntington's disease
 - Juvenile parkinsonism-dystonia
 - Progressive pallidal degeneration
 - Hallervorden-Spatz disease
 - Hypoprebetalipoproteinemia, acanthocytosis, retinitis pigmentosa, and pallidal degeneration (HARP syndrome)
 - Joseph's disease
 - Ataxia-telangiectasia
 - Neuroacanthocytosis
 - Rett's syndrome (?)
 - Intraneuronal inclusion disease
 - Infantile bilateral striatal necrosis
 - Familial basal ganglia calcifications
 - Spinocerebellar degeneration
 - Olivopontocerebellar atrophy
 - Hereditary spastic paraplegia with dystonia
 - X-linked dystonia-parkinsonism or Lubag (pericentromeric)
 - Deletion of 18q
 - C. Associated with metabolic disorders
 1. Amino acid disorders
 - Glutaricacidemia
 - Methylmalonicacidemia
 - Homocystinuria
 - Hartnup's disease
 - Tyrosinosis
 2. Lipid disorders
 - Metachromatic leukodystrophy
 - Ceroid lipofuscinosis
 - Dystonic lipidosis ("sea blue" histiocytosis)
 - Gangliosidoses GM₁, GM₂ variants
 - Hexosaminidase A and B deficiencies
 3. Miscellaneous metabolic disorders
 - Wilson's disease
 - Mitochondrial encephalopathies:
 - Leigh's disease, Leber's disease
 - Lesch-Nyhan syndrome
 - Triosephosphate isomerase deficiency
 - Vitamin E deficiency
 - Biopterin deficiency
 - D. Due to a known specific cause
 - Perinatal cerebral injury and kernicterus: athetoid cerebral palsy, delayed-onset dystonia
 - Infection: viral encephalitis, encephalitis lethargica, Reye's syndrome; subacute sclerosing panencephalitis; Creutzfeldt-Jakob disease; acquired immunodeficiency syndrome
 - Other: tuberculosis, syphilis, acute infectious torticollis
 - Paraneoplastic brain stem encephalitis

- Cerebral vascular and ischemic injury
 - Brain tumor
 - Arteriovenous malformation
 - Head trauma and brain surgery
 - Peripheral trauma
 - Toxins: MN, CO < CS₂, methanol, disulfiram, wasp sting
 - Drugs: levodopa, bromocriptine, antipsychotics, metoclopramide, fenfluramine, flecainide, ergot, anticonvulsants, certain calcium channel blockers
- III. Other hyperkinetic syndromes associated with dystonia
- A. Tic disorders with dystonic tics
 - B. Paroxysmal dyskinesias
 1. Paroxysmal kinesigenic choreoathetosis
 2. Paroxysmal dystonic choreoathetosis
 3. Intermediate paroxysmal dyskinesia
 4. Benign infantile paroxysmal dyskinesia
- IV. Psychogenic
- V. Pseudodystonia
- Atlantoaxial subluxation
 - Syringomyelia
 - Arnold-Chiari malformation
 - Trochlear nerve palsy
 - Vestibular torticollis
 - Posterior fossa mass
 - Soft tissue neck mass
 - Congenital postural torticollis
 - Congenital Klippel-Feil syndrome
 - Isaac's syndrome
 - Sandiffer's syndrome
 - Satoyoshi syndrome
 - Stiff-person syndrome

family history of variable problems with cramps, spasms, tremors, and crippling conditions. In the initial evaluation, the clinician should gather information about age at onset, initial and subsequent areas of involvement, course and progression of disease, tremor or other movement disorders, possible birth injury, developmental milestones, and exposure to neuroleptic medications, as well as a family history of dystonia, parkinsonism, or other movement disorders. Consanguinity or Jewish ancestry should be noted as well. Since the clinical expression of primary dystonia is highly variable even within families, the history and family tree may be extremely difficult to establish with confidence. Some family members may have severe problems and require extensive assistance with activities of daily living, whereas others may show only mild symptoms (e.g., writer's cramp).¹⁰⁶ Evidence of other conditions known to produce dystonia but associated with other neurological dysfunctions (e.g., cognitive, pyramidal, sensory, or cerebellar deficits) should be evaluated along with secondary causes of dystonia. The ceruloplasmin level should be obtained in all patients in whom onset of dystonia occurs before the age of 50 since Wilson's disease is highly treatable. Other blood tests, including genetic tests, depend on the clinical setting, and the various storage and metabolic disorders should be evaluated individually. An MRI scan is important in the evaluation of structural abnormalities, and skull, neck, and spine evaluations may be needed if there is evidence of a secondary myelopathy or scoliosis due to axial dystonia.

MANAGEMENT. In treating primary dystonia, high-dose anticholinergic therapy (e.g., trihexyphenidyl in doses of up to 70 mg/day) may be effective in ameliorating dystonia, particularly in younger patients. However, many patients are unable to tolerate such high doses because loss of memory, hallucinations, blurring of vision, and other

anticholinergic side effects may occur. In addition, all patients with childhood-onset dystonia deserve a trial of levodopa, using Sinemet in doses of up to 100/1000 mg/day.¹⁰⁵ Other agents, such as oral baclofen, carbamazepine, and tetrabenazine, have been reported to be beneficial in some dystonic patients. Recent interest has focused on the use of intrathecal baclofen in patients with generalized and axial dystonia, but controlled trials of this usage have not been published.

Intramuscular injections of botulinum toxin type A or type B are the most effective treatment for focal dystonia and may be used in a limited form in patients with segmental or generalized dystonia.¹¹⁰ Because it acts at the presynaptic membrane, this botulinum toxin prevents release of acetylcholine at the nerve terminal, causing muscle weakness. Injection into dystonic muscles requires knowledge of the muscle anatomy and the site of muscle innervation, and some clinicians perform this procedure with the aid of EMG guidance. Treatment is necessary every 3 to 5 months in most patients, and this therapy has been used safely in some patients for more than 15 years. However, some patients develop resistance to the clinical response, and antibodies to the A toxin may develop. If the dose is limited to less than 300 units per procedure and the treatment is given no more frequently than every 3 months, the risk of immunoresistance is minimized.¹¹¹ Other types of botulinum toxins, namely B and F, are currently being investigated for the treatment of focal dystonia.

Thalamotomy and high-frequency thalamic or pallidal stimulation are occasionally performed in patients with otherwise medically intractable disease.^{112,113} Unfortunately, when these procedures are bilateral, patients may be left with severe dysarthria, dysphagia, and memory deficit. In this regard, pallidotomy may have some advantages. Cervical cord stimulation, peripheral nerve section, rhizotomy, and myotomy are occasionally effective.

PROGNOSIS AND FUTURE PERSPECTIVES. Prognosis in primary dystonia is highly dependent on age of onset; the younger the age of onset, the higher the likelihood of spread and progression to generalized disabling dystonia. The biological markers and pathophysiological mechanisms of dystonia remain to be elucidated. It is likely that the gene or genes for primary dystonia will be identified, and the study of the gene product may provide clues to the pathogenesis of primary dystonia. Extensive information on subthalamic nucleus deep brain stimulation is not yet available.

Other Forms of Primary Dystonia

Several other forms of primary inherited degenerative syndromes are associated with dystonia.¹⁰⁵ Like the parkinsonism-plus syndromes, the major hallmark of these dystonia-plus syndromes is dystonia, but this is accompanied by movement disorders. Dopa-responsive dystonia (DRD) is also an autosomal dominant disorder caused by a mutation in the GTP cyclohydrolase I gene on chromosome 14q, which causes a defect in dihydrobiopterin synthesis. These patients present with dystonia and parkinsonism that has a marked diurnal fluctuation. In the early morning they may be symptom-free or only mildly affected, but then a progressive gait disorder and cramping and rigidity

develop during the day. These patients are markedly sensitive to low doses of levodopa, and often doses of Sinemet as low as 25/100 mg/day are effective in obliterating clinical signs. For this reason, it is particularly important to recognize DRD, and all children with dystonia and adults with leg or trunk dystonia deserve a trial of levodopa. Another syndrome, X-linked dystonia-parkinsonism, is much rarer and is confined largely to inhabitants of the Philippines.¹⁰⁶ These patients, mostly men, develop severe axial dystonia and a hunched parkinsonian posture. Falls, dysphagia, and voice compromise follow, and these signs usually are preludes to death. In contrast, myoclonic dystonia (see later section on essential myoclonus) is a benign autosomal dominant disorder marked by a combination of dystonia and jerking myoclonic movements, usually starting in the first or second decade of life without other neurological deficits. These patients show a dramatic response to alcohol⁷⁵ and are treated with this product combined with benzodiazepines with usually excellent results.¹⁰⁷

Neurodegeneration with Brain Iron Accumulation (Hallervorden-Spatz Disease)

PATHOGENESIS AND PATHOPHYSIOLOGY. Hallervorden-Spatz disease is a rare autosomal recessive disorder associated with excessive iron deposition in the globus pallidus (GP).¹¹⁴ Because of the involvement of Hallervorden in the inhuman euthanasia program conducted in Nazi Germany, the disease has been renamed as neurodegeneration with brain iron accumulation (NBIA). The most striking autopsy finding in NBIA patients is the asymmetrical rust-brown pigmentation of the GP and zona reticulata of the SN. The iron pigmentation occurs both extracellularly and intracellularly but is predominantly found in astrocytes, microglia, and neurons. "Mulberry" concretions are also typically present in the extracellular space. Numerous and large spheroid bodies, identified by myelin staining and surrounded by pigment granules, are typically present throughout the medial GP, SN zona reticulata, cortex, and subthalamic nucleus.¹¹⁵ The spheroid bodies apparently represent degenerating myelinated axons. Linkage analyses initially localized the NBIA gene on 20p12.3-p13 and subsequently seven base pair deletion and various missense mutations were identified in the coding sequence of gene PANK2 with homology to pantothenate kinase.¹¹⁶

CLINICAL FEATURES AND ASSOCIATED DISORDERS. NBIA was initially described in one family of 12 children, 3 of whom died at birth; 8 of the remaining 9 developed athetosis, tremor, and visual difficulties. Dystonia and rigidity are the major hallmarks of this childhood illness, but other associated features include gait and posture disturbances, chorea, athetosis, tremor, dysarthria, blindness with retinitis pigmentosa, intellectual decline, spasticity, and seizures. Myoclonus is rare and usually is a preterminal sign. Although the onset usually occurs in the first decade of life, rare patients with adult-onset NBIA starting in the fourth to sixth decade and presenting as parkinsonism have been described (Video 56, Generalized Dystonia).¹¹⁵

DIFFERENTIAL DIAGNOSIS. NBIA has a wide spectrum of presentation and therefore a potentially large differential diagnosis. A disease of iron deposition in the basal

ganglia, NBIA shares some features with other disorders associated with deposition of metals, such as Wilson's disease and manganese toxicity. Other disorders with overlapping clinical features include juvenile Huntington's disease, neuroacanthocytosis, and neuronal ceroid lipofuscinosis.

EVALUATION. CT scans reveal high signal intensity in the medial GP, and MRI demonstrates decreased signal intensity in the GP on T2- or proton density-weighted images; these abnormalities are produced by iron deposition bilaterally in the pallidum.¹¹⁵ In some cases, the center is hyperintense, giving rise to the term "eye of the tiger" sign. Ophthalmological examination may be particularly helpful because it may show optic degeneration and retinitis pigmentosa.

MANAGEMENT. There is no specific treatment for NBIA. Chelation therapy to remove excess iron accumulation in the basal ganglia has not been useful. Parkinsonism in some patients has responded to levodopa and bromocriptine therapies, but anticholinergic agents have failed to improve symptoms of tremor, dystonia, or bradykinesia. The choreoathetosis may benefit from benzodiazepines, but dopamine antagonists are generally not used because of the risk of worsening parkinsonism. Antiepileptic drugs are useful for the control of seizures. Supportive care and physical, occupational, and speech therapy should also be instituted when appropriate.¹¹⁵

PROGNOSIS AND FUTURE PERSPECTIVES. The mean duration of the disease is 11 years, and 45% of patients die before reaching the age of 20 years.¹¹⁴

Gilles de la Tourette Syndrome and Other Tic Disorders

PATHOGENESIS AND PATHOPHYSIOLOGY. Tics are repetitive movements that usually involve the eyes, face, shoulders, neck, and vocal apparatus more than the rest of the body. When childhood-onset tics are multifocal, motor, and vocal, last longer than 1 year, and naturally wax and wane, the term Gilles de la Tourette syndrome (GTS) is applied.¹¹⁷ Once considered a rare psychiatric condition, GTS is now recognized as a relatively common neurological disorder with both motor and behavioral manifestations. In the majority of cases of GTS, at least one parent exhibits signs of GTS and frequently both parents are affected to some degree, suggesting bilineal transmission. A major advance in the search for the elusive TS gene or genes has been made by the discovery of a frameshift mutation in the Slit and Trk-like 1 (SLITRK1) gene on chromosome 13q31.1.¹¹⁸ These variants were absent in 172 other TS and in 3600 control chromosomes. The SLITRK1 gene has been found to be expressed in brain regions previously implicated in TS, such as the cortex, hippocampus, thalamic, subthalamic, and globus pallidus nuclei, striatum, and cerebellum, and it appears to play a role in dendritic growth. Although a significant finding, this gene mutation is probably a very rare cause of TS.

Because tics respond to dopamine-depleting drugs and DA receptor antagonists (neuroleptics), striatal DA receptor supersensitivity and developmental striatal DA terminal hyperinnervation have been proposed as possible causes of GTS symptoms.¹¹⁹ Some clinical data indicate that neurotransmitters other than DA may be involved in other

aspects of GTS.¹²⁰ Obsessive-compulsive disorder (OCD), a condition thought to be related to serotonergic neurochemistry, is present in at least half of patients with GTS, and this observation suggests that the serotonergic pathways in GTS may be altered. There is also some support for the idea that the opiate or second-messenger system may be involved in this disorder.¹¹⁹

EPIDEMIOLOGY AND RISK FACTORS. Because most children with GTS have mild and undiagnosed symptoms, past prevalence estimates may be low. One review of epidemiological prevalence data in children found that prevalence estimates ranged from 0.5 to 50 per 10,000 population.¹²¹ Kurlan¹²² reported that the frequency of tics in children ranged from 4% to 24% and that 26% of children in special education classes had tics compared to 6% of children in regular classes. These studies suggest that children requiring special education may represent a high-risk population for tics. Some worsening of tics during pregnancy has been observed. Although genetic factors are clearly the most important determinants, there is evidence that perinatal complications increase the risk of GTS.

Recent studies have emphasized the familial nature of GTS, with approximately one third of probands having a positive family history of simple tics and another third having a positive family history of the full GTS.¹¹⁹ Transmission is often bilineal, meaning that both parents are affected. Typically, the father has a history of tics that may or may not persist through adulthood, and the mother has features of OCD. This pattern suggests that GTS represents one part of a spectrum, of which the mildest manifestation is a simple or transient tic of childhood and the most severe manifestation is the full syndrome that includes motor as well as behavioral features. This clinical heterogeneity makes specific definition of GTS problematic for genetic studies.

CLINICAL MANIFESTATIONS AND ASSOCIATED DISORDERS. Tics are defined as simple or complex repetitive movements that occur out of background of normal motor activity. They are usually fast (myoclonic) but can be slow (dystonic) (Video 36, Simple Tics). They increase with fatigue and after stress and decrease with concentration.¹²³ GTS is characterized by chronic waxing and waning motor and vocal tics, usually beginning between the ages of 2 and 21 years. It affects boys more frequently than girls. Approximately half of patients start with simple motor tics, such as frequent eye blinking, facial grimacing, head jerking, or shoulder shrugging, or with simple vocal tics such as throat clearing, sniffing, grunting, snorting, hissing, barking, or other noises. Complex motor tics include squatting, hopping, skipping, hand shaking, and ritualized movements such as compulsive touching of objects, people, or self. Complex vocal tics include semantically meaningful utterances, including shouting of obscenities and profanities (coprolalia). Although coprolalia and other disturbing or socially unacceptable phenomena (copropraxia, coprographia, and mental coprolalia) can occur, these features are not necessary to the diagnosis of GTS (Video 35, Coprolalia). Of great clinical importance, tics can be voluntarily suppressed for seconds to minutes, but this suppression may be followed by a rebound burst of exaggerated abnormal involuntary movements. For this reason, tics may not be seen in the doctor's office, even though

they may be disabling at school or at home. Many patients also report a premonitory phenomenon prior to the onset of motor tic.¹²⁴ This crescendo urge, tension, or abnormal sensation in the distribution of the tic is relieved with the performance of the involuntary movement. In addition to these motor and vocal tics, many patients develop behavioral disorders, especially OCD and attention deficit hyperactivity disorder (ADHD), impulsive and self-destructive behavior, sleep abnormalities, and alterations in mood and sexual behavior. Learning disability often overlaps with hyperactivity and ADHD.

DIFFERENTIAL DIAGNOSIS. GTS is considered one end of a continuum of primary tic disorders¹²³ that includes transient tic disorder of childhood (tic or tics lasting less than 1 year) and chronic multiple tic disorder (motor or vocal tics but not both). These semantic differences probably have no pathophysiological distinction, and therefore these primary tic disorders can be considered as clinical variants of one process. In contrast, several forms of secondary tics should be excluded, including hypoxic head injury, head trauma, encephalitis, carbon monoxide intoxication, Huntington's disease, neuroacanthocytosis, and startle disorders.¹¹⁷ In these cases, tics are usually combined with other abnormal movements, often chorea, cognitive impairment, or other neurological deficits. Tics must also be differentiated from other hyperkinetic movement disorders, including myoclonus, blepharospasm, stereotypies, and hyperekplexia.¹¹⁷ It may be difficult to differentiate complex motor tics and compulsions (Video 47, Blepharospasm; Video 112, Obsessive Movements).

EVALUATION. The diagnosis of GTS is usually made by the history and can be verified by neurological observation. However, given the voluntary suppressibility of tics and the characteristic waxing and waning quality of the disease, it is possible that tics may be absent at the time of an examination. Asking the patient or the parents to bring a videotape of the movements taken during a period of relaxation and fatigue is often of greater diagnostic yield than several minutes of scrutiny in the doctor's office. Neuroimaging or other diagnostic studies are generally not required. A careful family history is critical, specifically as it relates to a history of tics, unusual habits or rituals, obsessive-compulsive symptoms, and other manifestations of GTS. Attention should be paid to the possibility of neonatal or perinatal injury and whether the child met developmental milestones appropriately. Blood tests in selected cases may include genetic testing for Huntington's disease and neuroacanthocytosis.

MANAGEMENT. Because most tic disorders are mild, the majority of patients require no pharmacological therapy. Education and identification of normal patterns of waxing and waning of symptoms are often the only interventions needed. Because of the fluctuating nature of GTS, however, at some point many patients require short-term drug therapy. In such cases, therapy should be targeted to the symptoms that are particularly troublesome for the patient, and distinctions should be made between tics, ADHD, and OCD. Tics most often respond to DA receptor blockers such as pimozide, fluphenazine, haloperidol, and risperidol. Many clinicians prefer pimozide (1 to 8 mg/day) and fluphenazine because they may be less sedating than other neuroleptic drugs. However, all neuroleptics carry a

risk of tardive dyskinesia and require regular follow-up. Tetrabenazine, a monoamine depletor and DA receptor blocker, also improves tics, and, although it is not readily available in the United States, it does not carry a substantial risk of tardive dyskinesia.¹²⁵ OCDs often respond to clomipramine, sertraline, fluoxetine, and paroxetine. Patients who have difficulty with OCD and also report problems in falling asleep or wetting the bed may be good candidates for the tricyclic antidepressant clomipramine. Clonidine, guanfacine, and methylphenidate are helpful for patients with ADHD, and lithium carbonate and carbamazepine are sometimes used for patients who have severe mood changes and impulse control problems.¹²⁶ Supportive individual or family counseling may help the patient and the family adapt to the many internal and external stresses associated with the GTS. In addition, neuropsychological testing to identify the patient's strengths and weaknesses usually allows the patient to reach his or her maximum academic potential. The local and national Tourette Syndrome Association can serve as an important resource for educational material and as a patient advocate in the school and work environment.

PROGNOSIS AND FUTURE PERSPECTIVES. Most patients show a marked improvement after adolescence and have few or no clinically significant tics as adults. Between 10% and 30% continue to be symptomatic throughout early adulthood and middle age.¹¹⁹ The pathogenic mechanism for GTS remains unknown, but current research focuses on the identification of genetic and biochemical mechanisms of this complex neurobehavioral disorder.

Other Stereotypies

Stereotyped motor behavior can occur in normal children and in children with a variety of other primary neurodegenerative conditions. Repetitive head banging, an example of stereotypic activity, is seen in 15% of normal children.¹²⁷ In addition, thumb sucking, rocking, and other ritualistic behaviors are common during childhood. Most stereotypies, however, represent evidence of underlying brain dysfunction and hence require recognition. Stereotypic movements occur in at least one third of mentally retarded patients and are a characteristic feature of various autistic disorders, such as infantile autism and Rett's, Angelman's, and Asperger's syndromes.¹⁰⁵ In all these conditions, stereotypies present as repetitive, coordinated, purposeless, involuntary movements such as chewing, lip smacking, body rocking, shoulder shrugging, marching in place, shifting of weight, and thrusting movements of the trunk and pelvis. Respiratory dyskinesia can produce grunting vocalizations, hyperventilation, and shortness of breath.

Rett's syndrome occurs only in girls and is believed to be linked to the X chromosome but is lethal in hemizygous males.¹⁰⁵ Some authors have suggested that Rett's syndrome is a result of disordered lipid metabolism, whereas others believe that these children have a derangement of the neuronal mitochondria. Typically, these children develop normally through the first 6 to 12 months of life, but then motor abnormalities (stereotypies, dystonia, and chorea) emerge, accompanied by cognitive regression. The stereotypies observed most frequently in girls with Rett's syndrome include clapping, wringing, clenching, washing, patting, and rubbing behaviors. Other hyperkinetic disorders

of movement include oromandibular dystonia, other dystonias, scoliosis, myoclonus, and choreoathetosis. All patients also have gait disturbances, and parkinsonian findings are manifest chiefly as hypomimia, rigidity, and bradykinesia.^{105,127} Rett's syndrome is thought to be due to loss-of-function mutations of the X-linked gene encoding methyl-CpG binding protein-2 (MECP2), which accounts for more than 80% of Rett cases.¹²⁸ Children with Angelman's syndrome have a jerky gait (puppet movements), a tendency to exhibit hand flapping stereotypies, and laughter with minimal stimulus. Patients with Angelman's syndrome and Prader-Willi syndrome both have a similar 15q11–13 chromosomal deletion, and parental origin of the chromosomal abnormality has been postulated to play a role. The children have psychomotor and cognitive delay and ataxia; speech is almost completely absent.¹²⁹ Seizures are present in nearly all patients, and 72% have early feeding problems. Eventually, 70% of these children learn to walk, and many are able to help with household chores. The most characteristic movement in this disorder is hand flapping with elbow and wrist flexion, but athetosis and tremulousness may also be present.

Asperger's syndrome is an autistic disorder manifested by poor reciprocal interaction, inappropriate emotional expression, impaired nonverbal communication, circumscribed interests, and repetitive activities. These children generally function at a higher intellectual level than most patients with pervasive developmental disorders. Like other autistic patients, they have stereotyped motor behavior, clumsiness, and tics.¹⁰⁵ Abnormalities in patients with Asperger's syndrome include cortical atrophy with widened sylvian fissure anomalies (the opercular sign). Increased lipofuscin is present in the brain, conjunctiva, and muscle, and the substantia nigra has reduced pigmentation.

Because many children in the preceding categories receive treatment with chronic neuroleptic agents, their primary stereotypies must be distinguished from drug-induced tardive dyskinesia. Prominent lingual-facial buccal movements are typical of the latter condition and are less characteristic of the primary stereotypies.

In all these disorders, routine laboratory data, spinal fluid analysis, and chromosomal studies are usually normal. No consistent neurochemical abnormalities have been found. Postmortem studies in patients with Rett's and Angelman's syndromes reveal microcephaly and mild neuronal loss with diffuse gliosis.¹⁰⁵ Evaluation for Asperger's syndrome by MRI may reveal some nonspecific abnormalities.¹²⁹ In all instances, therapy for patients with stereotypies is empirical and involves primarily the use of neuroleptic agents or dopamine-depleting drugs such as reserpine and tetrabenazine.

Restless Legs Syndrome

Restless legs syndrome (RLS) is one of the most common movement disorders, affecting approximately 5% to 10% of the general population.^{130,131} Clinical criteria established by the International Restless Legs Syndrome Study Group include a set of four symptoms that establish the diagnosis of RLS: (1) a desire to move the limbs, often associated with unpleasant sensations; (2) restlessness; (3) worsening of symptoms at rest and at least temporary relief

with movement; and (4) worsening of symptoms in the evening or night (Video 73, Restless Leg Syndrome).

The sensations that people feel are always unpleasant but not necessarily painful. The most common descriptions used include such words as “need to move,” “crawling,” “tingling,” “restless,” “cramping,” “creeping,” “pulling,” “painful,” “electric,” “tension,” “discomfort,” and “itching.” Despite the name, these sensations can also be felt in the arms, although the legs are almost always more severely affected. Another feature that many patients with RLS have is called periodic limb movements while asleep. These are kicking movements of the legs while patients are asleep; these movements may be irregular and simple or rhythmic and more complex, resembling bicycling movements. Several surveys have shown how prevalent RLS symptoms are, and the disorder increases with age. RLS patients often do not see a physician until mid- to later life but report subtle symptoms dating from much earlier in their lives. These symptoms typically worsen over time.

The exact cause of RLS is not known, but in most cases it appears to be inherited in an autosomal dominant pattern. Secondary RLS may be associated with neuropathy, kidney failure, iron deficiency, and pregnancy. The most consistently effective treatments for RLS are dopaminergic medications, such as levodopa or DA agonists, including pramipexole, ropinirole, pergolide, bromocriptine, and cabergoline. Ropinirole is currently the only Food and Drug Administration-approved drug for RLS.¹³² Opioids may also help RLS symptoms.

Painful Legs-Moving Toes Syndrome

Painful legs-moving toes syndrome (PLMTS) is a movement disorder associated with significant sensory symptoms. The condition is idiopathic in origin but usually develops in association with back pain and often in the context of prior back injury or surgery. No specific pathophysiological mechanisms have been elucidated, and although a spinal cord or peripheral nervous system origin has been proposed, electrophysiological studies are often normal.¹³³ Because the condition sometimes follows herpes zoster infection, primary involvement of the posterior roots and ganglia has been suggested to explain the syndrome. The movements are not a response to the pain because even after local anesthesia or sympathetic blockade the movements persist. Clinically, the condition involves continuous writhing movements of the toes and pain in the legs. The pain may range from mildly irritating to excruciatingly severe.¹³⁴ In most cases, it has a constant, boring quality, but it can be burning or crushing. It does not, however, have a shooting or electric quality like a radicular irritation. The toe movements are sinuous and crawling, usually continuous throughout the waking hours and incessantly repetitive. Unlike akathisia, the patient feels no relief in moving and instead tires from fruitless attempts to stop the movement. There is no effective treatment for PLMTS, but sympathetic blockade and anticonvulsants have been used (Video 247, Akylosing Spondylitis).¹³⁴

Action Tremors (Table 34-6)

Essential tremor (ET) is the most frequent hyperkinetic movement disorder. Its age-adjusted prevalence is 2% to

TABLE 34-6

Classification and Differential Diagnosis of Tremors

1. Rest tremors
 - a. Parkinson's disease
 - b. Other parkinsonian syndromes (less commonly)
 - c. Midbrain ("rubral") tremor: rest < postural < kinetic
 - d. Wilson's disease (also acquired hepatocerebral degeneration)
 - e. Essential tremor—only if severe: rest < < postural and action
2. Postural and action ("terminal") tremors
 - a. Physiological tremor
 - b. Exaggerated physiological tremor (these factors can also aggravate other forms of tremor)
 - i. Stress, fatigue, anxiety, emotion
 - ii. Endocrine: hypoglycemia, thyrotoxicosis, pheochromocytoma, adrenocorticosteroids
 - iii. Drugs and toxins: β -agonists, dopamine agonists, amphetamines, lithium, tricyclic antidepressants, neuroleptics, theophylline, caffeine, valproic acid, alcohol withdrawal, mercury ("Hatter's shakes"), lead, arsenic, others
 - c. Essential tremor (familial or sporadic) ?subtypes
 - d. Primary writing tremor
 - e. With other CNS disorders
 - i. Parkinson's disease
 - ii. Other akinetic-rigid syndromes
 - iii. Idiopathic dystonia, including focal dystonias
 - f. With peripheral neuropathy
 - i. Charcot-Marie-Tooth syndrome (controversial whether to call this the Roussy-Levy syndrome)
 - ii. Variety of other peripheral neuropathies (especially dysgammaglobulinemia)
 - g. Cerebellar tremor
3. Kinetic (intention) tremor

Disease of cerebellar "outflow" (dentate nucleus and superior cerebellar peduncle): multiple sclerosis, trauma, tumor, vascular disease, Wilson's acquired hepatocerebral degeneration, drugs, toxins (e.g., mercury), others
4. Miscellaneous rhythmical movement disorders
 - a. Psychogenic tremor
 - b. Orthostatic tremor
 - c. Rhythmical movements in dystonia (dystonic tremor)
 - d. Rhythmical myoclonus (segmental myoclonus—; e.g., palatal or branchial myoclonus, spinal myoclonus, limb myorhythmia)
 - e. Oscillatory myoclonus
 - f. Asterixis
 - g. Clonus
 - h. Epilepsia partialis continua
 - i. Hereditary chin quivering
 - j. Spasmus nutans
 - k. Head bobbing with third ventricular cysts
 - l. Nystagmus

Modified from Weiner WJ, Lang AE: Movement Disorders: A comprehensive survey. New York, Futura, 1989.

5%,²⁶ and, as a lifelong illness, ET may affect any age group. It has a bimodal distribution of age at onset, with two peaks, adolescence and the fourth or fifth decade of life. In many families, ET is inherited in an autosomally dominant pattern, and in these patients the term *familial tremor* can be used interchangeably with ET. Although central mechanisms are thought to be causative, no specific structural abnormality has been noted in the brains of patients with ET. Because ET can be exacerbated by hyperthyroidism and by caffeine and noradrenergic drugs, alterations in the central norepinephrine chemistry have been suggested.

In contrast to the resting tremor characteristic of PD, ET is a *postural* tremor, which is characteristically present

during maintenance of a position. This tremor is typically an alternating flexion-extension movement, whereas supination-pronation oscillation is more characteristic of Parkinson's tremor. ET is also faster (7 to 10 Hz) than the PD tremor (4 to 7 Hz), and when fully developed, it usually involves the head, neck, and voice. Tremor often interferes with handwriting, drawing, holding a spoon, using a drinking cup, and manipulating tools (Video 60, Marked Postural Tremor).²⁶ The vocal cords may be affected, resulting in a wavering voice. Although ET usually occurs in isolation, it can be associated with various other neurological conditions, including dystonia, parkinsonism, and certain inherited peripheral neuropathies (e.g., Charcot-Marie-Tooth disease). The differential diagnosis includes normal physiological tremor and the tremors associated with anxiety, thyrotoxicosis, and alcohol withdrawal as well as drug-induced tremors resulting from bronchodilator use, corticosteroids, various CNS stimulants, lithium, and sodium valproate (Video 69, Lithium-Induced Postural Tremor). ET diminishes with rest, ethanol, β -noradrenergic blockers (usual dose, propranolol 80 to 240 mg/day), primidone (25 to 750 mg/day), and benzodiazepines. In addition, some patients may benefit from gabapentin, topiramate, and injections of botulinum toxin directly into the contracting muscles.^{135,136} Thalamotomy or high-frequency thalamic stimulation (DBS) may be an option in patients with severe tremors that are refractory to other treatment.¹³⁷

Orthostatic tremor and primary writer's tremor are two particular forms of tremor that are highly dependent on posture. In the former, patients can usually walk with only mild discomfort, but when asked to stand in place for several seconds, they develop hard and cramping calves and thighs that shake uncontrollably. Although considered by some to be a variant of ET, this tremor does not respond to the usual drugs described previously, and clonazepam (1 to 10 mg/day) is usually far more effective. Baclofen can also be used. The differential diagnosis includes dystonia and stiff-person syndrome. Similarly, primary writer's tremor does not occur outside the very specific activity of writing. It is thought that the complicated posture and muscle activation of writing induces the contractions in the agonist and antagonist hand muscles that induce the tremor. Sometimes the hand cramps at the same time, suggesting the presence of an underlying dystonia. The handwriting becomes sloppy, shaky, and large. Patients may respond to the medications used for ET, but often they improve more with anticholinergic medicines, again suggesting that dystonia may underlie these tremulous movements. Importantly, changing to a large, fat pen that requires different muscles for holding and writing with it or switching to typing is often the most helpful of all therapies.

Cerebellar kinetic tremor, sometimes referred to as an intention tremor, is most apparent during a goal-directed limb movement such as that used in the finger-to-nose or heel-to-shin test. In contrast to postural tremor, the patient's greatest disability occurs at the "endpoint," when a sudden destabilization occurs with severe shaking (Video 14, Tremor with Ataxia). This tremor is usually caused by a lesion in the cerebellar outflow (dentatorubral) tracts,²⁶ and therefore it is seen most typically in patients with multiple sclerosis, cerebrovascular accidents, or primary cerebellar disorders. Likewise, rubral tremor—a tremor that mixes rest,

postural, and kinetic tremors—is generally not an idiopathic tremor and is induced by structural disease in the midbrain or fiber pathways connecting this region with the cerebellar and thalamic nuclei. Treatment of these tremors is frustrating, and no reliable pharmacological success has been reported. Because these patients are generally not weak and overshoot their targets as they move, stabilization of the involved limbs with wrist weights can reduce the amplitude and disability of the tremor.

Dystonic tremor is a prominent form of shaking that occurs as a compensation for dystonic spasms and must be recognized so that the underlying dystonia can be treated. Finally, palatal tremor, also termed *palatal myoclonus*, is characterized by continuous and synchronous contractions of the soft palate that occur at frequencies of 100 to 150 per minute (range, 20 to 600 per minute). Patients may not notice the jerking movements unless they are accompanied by persistent ear clicks caused by the repetitive opening and closing of the eustachian tubes. Concomitant contractions of other muscles, including the larynx, extraocular muscles, neck, diaphragm, tongue, and face, may be observed. These patients may have additional symptoms, including postural tremor, oscillopsia, dysphagia, and dysarthria. The movements, which generally persist throughout life with infrequent remissions, may be idiopathic or due to brain stem or cerebellar disease. The anatomical and physiological bases underlying palatal tremor involve the hypertrophic degeneration of the olivary nucleus located within the medulla oblongata. The alteration of the inferior olive develops secondary to a lesion within the Guillain-Mollaret triangle, a pathway extending from the contralateral dentate nucleus via the superior cerebellar peduncle and ipsilateral central tegmental tract. Palatal tremor is usually resistant to therapy, which is unnecessary in most patients. 5-Hydroxytryptophan, the serotonin precursor, and carbamazepine are variably effective. Others have reported success with clonazepam, tetrabenazine, and trihexyphenidyl. Surgical intervention, including perforation of the tympanic membrane and tamponade of the eustachian tubes, is unsuccessful.

Wilson's Disease

PATHOGENESIS AND PATHOPHYSIOLOGY. Wilson's disease (WD), or hepatolenticular degeneration, is an autosomal recessive disorder of copper metabolism. The specific genetic biochemical defect appears to be an abnormality of a copper-binding, membrane-associated adenosine triphosphatase-associated protein, and the allele for this protein has been localized to the long arm of chromosome 13.¹³⁸ It is postulated that most of the symptoms result from excess deposition of copper in tissues, particularly in the brain and liver.

EPIDEMIOLOGY AND RISK FACTORS. This rare neurodegenerative movement disorder occurs in approximately 1 in 40,000 people. Although the disorder may not become clinically evident until the fourth or fifth decade of life, the initial presentation most often appears in the early 20s.¹³⁸

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Clinical features are age dependent. Children with WD exhibit a typical facies (so-called sardonic smile), behavioral abnormalities, and various motor disorders.¹³⁹

These include tremor (particularly in a wing-beating position), dystonia, rigidity, postural instability, dysarthria, and ataxia.¹⁴⁰ Some patients also exhibit mental and behavioral changes and seizures. Almost all patients show evidence of hepatic dysfunction. The adult patient usually presents with parkinsonian features, dystonia, athetosis, and slow (myorhythmic) or coarse postural (so-called wing-beating) tremor (Video 58, High-Amplitude Tremor). In adults, the neurological symptoms predominate over the hepatic dysfunction, and the disorder appears to be less rapidly progressive. Approximately one third of patients present with psychiatric symptoms. These range from irritability and loss of impulse control to mania and depression, sometimes with catatonic symptoms.

The clinical hallmark of the disorder is the presence of a brownish-golden ring at the corneal rim (Kayser-Fleischer ring), which is due to the deposition of copper in the cornea. This sign is seen in almost all patients with neurological or psychiatric manifestations of WD, although slit-lamp examination is sometimes necessary to detect the copper deposition.¹³⁹ Other ocular abnormalities seen in WD include “sunflower” subcapsular cataracts, retinitis pigmentosa, optic nerve atrophy, and loss of smooth pursuit.

DIFFERENTIAL DIAGNOSIS. The differential diagnosis of WD depends on the phenotypical presentation. In children, evaluation usually centers around hepatic disorders, whereas in adults, diagnostic considerations center around the type of movement disorder seen (tremor, chorea, dystonia, or parkinsonism). Although Kayser-Fleischer rings are extremely helpful in confirming this diagnosis clinically, they are also seen in patients with silver intoxication, primary biliary cirrhosis, Addison's disease, carotinemia, and chalcosis as a result of unilateral trauma to the eye with copper-containing foreign bodies.¹⁰¹

EVALUATION. All patients should be evaluated by an ophthalmologist for the presence of the Kayser-Fleischer ring. Decreased serum ceruloplasmin (<20 mg/dL) in 90% of patients, increased urinary copper excretion (>100 µg/mL), impaired hepatic and renal function, hemolytic anemia, and aminoaciduria may also be present. In most cases, a 24-hour urinary copper screen will detect elevated urinary copper levels (>100 µg/24 hours). If these tests are not diagnostic, liver biopsy should be performed with copper measurements (copper > 200 µg/g dry weight).²⁶ T2-weighted MRI scans may show the “face of the panda” sign in the midbrain due to hypodensity of the superior colliculi and hyperdensity in the medial substantia nigra and tegmentum. Fluorodopa PET scans are abnormal in symptomatic patients, demonstrating evidence of nigrostriatal damage.

MANAGEMENT. Because good recovery of hepatic and neurological function is possible in most patients, treatment must be instituted quickly. The goal of therapy is to reduce copper intake by means of a low-copper diet and increase copper excretion. D-Penicillamine is the chelating agent most often used; its side effects are potentially serious but preventable. These include nephrotic syndrome, fever, thrombocytopenia, dermatitis, vitamin B₆ deficiency, seizures, and zinc deficiency, which causes impairment of taste and smell. Pyridoxine should be administered along with penicillamine. Some investigators suggest using tetra-thiomolybdate, a drug that both blocks copper absorption and binds to blood-borne copper, as an initial therapy. In

addition, zinc acetate may be used as a maintenance therapy because of its low potential for serious side effects other than gastrointestinal effects. Dietary education about foods containing high levels of copper should be undertaken, and specific restrictions should be placed on liver and shellfish.¹³⁹ In patients who have sustained severe liver damage at the time of treatment, liver transplantation may be considered but remains controversial.

Since the disorder is inherited as an autosomal recessive trait, it is important to screen other members of the family with a neurological examination, serum ceruloplasmin level, and slit-lamp examination of the cornea. The clinical manifestations of the disorder and progression of disease may be prevented by early institution of copper chelation therapy.

PROGNOSIS AND FUTURE PERSPECTIVES. If WD is recognized early in the course of the illness and is treated aggressively with initial and maintenance chelation therapy, it is potentially a curable disorder. Without treatment, patients progress to disability and death. The gene for WD has been identified on chromosome 13, but several mutations within the gene have been found; therefore, DNA testing is not yet practical.¹³⁹

Hemifacial Spasm

Hemifacial spasm (HFS) is characterized by intermittent twitching of the muscles supplied by one facial nerve. It is thought to result from compression of the facial nerve at its junction with the brain stem by an aberrant or ectopic posterior fossa artery. Whereas many cases are idiopathic in origin, compression by vascular structures was responsible in more than 90% of cases; other rare causes include tumors and bony or other abnormalities.¹⁴¹ The average age-adjusted annual incidence for patients of all ages is 0.78 per 100,000, and the prevalence has been estimated at 14.5 per 100,000 in women and 7.4 per 100,000 in men.¹⁴² Onset generally occurs between the second and eighth decades of life, with the average age at onset being 45 to 51 years. Onset during infancy is atypical and usually indicates an underlying tumor, anomaly, or other pathology. Women are more commonly affected than men, and Asians have a particularly high risk compared with other populations. Although familial cases have been reported, most are sporadic. Trigeminal neuralgia can be associated with the development of HFS, suggesting that ephaptic transmission may underlie the pathophysiology of these two syndromes (Video 224, Hemifacial Spasm).

Clinically, symptoms begin in the periorbital region and spread to the ipsilateral facial muscles during the next few months. Spasm occurs spontaneously, is almost always unilateral, and is exacerbated by voluntary facial movements such as lip pursing, stress, fatigue, anxiety, or a change in head position. The movements often persist during sleep. Stapedius muscle contraction frequently accompanies contraction of the muscles of facial expression and may produce ipsilateral tinnitus.¹⁴¹

HFS must be differentiated from other conditions that cause involuntary facial movements. Blepharospasm and other forms of facial dystonia are almost always bilateral. Postparalytic facial spasms generally reflect fixed contraction of the facial muscles or synkinesis or both. There is

always a history of preceding facial weakness (e.g., Bell's palsy), and spontaneous spasms are generally absent. Spastic parietic facial contracture may be confused with HFS. The involved side is weak and contracted, unlike the situation in HFS, in which the facial muscles are relaxed between twitches. Facial myokymia is characterized clinically by undulating movements of the facial muscles. Facial tics are rapid, stereotyped, and relatively well-coordinated movements that may also occur in regions distant from the face. Hemimasticatory spasm involves muscles innervated by both the facial and the trigeminal nerves.

In the patient with normal results on neurological examination, including careful attention to brain stem testing (e.g., blink reflex and extraocular motility), further workup is usually not needed. If, however, neurological abnormalities, such as facial sensory deficits or an abnormal corneal blink reflex, are present, MRI and possibly MR angiography are suggested. Specific attention to the cerebellopontine angle and brain stem is required to detect possible tumors or arteriovenous malformations.

Although some clinicians treat HFS first with clonazepam, botulinum toxin injection to the involved muscles is now the treatment of choice.¹⁴¹ The role of surgical decompression has diminished with the advent of this therapy, but surgery is still performed in some clinical settings. Endoscopic surgical correction may offer a permanent treatment with less morbidity than posterior fossa exploration. Myectomies, nerve sectioning, and phenol injections have essentially been replaced by botulinum toxin injections.

Essential Myoclonus

As with other movement disorders, myoclonus may be classified in several ways, including phenomenologically, anatomicophysiological (see Chapter 16), and etiologically. The etiological divisions are physiological, essential, epileptic, and symptomatic myoclonus. Physiological forms include benign hiccups and hypnic jerks, which are sudden movements experienced by many normal individuals when falling asleep. These two phenomena rarely require evaluation or treatment.¹⁴³ Because epileptic myoclonus and the vast array of symptomatic causes of myoclonus are described in the appropriate etiological chapters in this book, this section reviews only the hereditodegenerative (essential) forms of myoclonus.

PATHOGENESIS AND PATHOPHYSIOLOGY. Using the term paramyoclonus multiplex, Friedreich presumably was first to describe a patient with essential myoclonus. Although myoclonus has been clinically well-defined, there has been no biochemical investigation that has explained the pathophysiological mechanism underlying essential myoclonus. Cerebral blood flow studies utilizing SPECT and xenon-133 or [technetium-99m]-D,L-hexamethylpropyleneamineoxime have revealed focal asymmetries in cerebral blood flow patterns consisting of relative hypoperfusion of the left cerebral hemisphere combined with an associated crossed cerebellar diaschisis.¹⁴⁴ This pattern could result from small lesions in the brain stem or basal ganglia, with secondary deafferentation of the ipsilateral frontal lobe and contralateral cerebellum, suggesting that essential myoclonus has a subcortical origin. Electrophysiological studies also suggest a subcortical origin for this form of myoclonus.

EPIDEMIOLOGY AND RISK FACTORS. Essential myoclonus is a rare disorder; however, the overall prevalence in the population is unknown.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Since its initial description, the diagnostic criteria for this form of myoclonus have evolved to the present state (Table 34-7). The jerks in essential myoclonus are brief (50 to 200 msec) and may be generalized, multifocal, segmental, or unilateral (Video 57, Myoclonus). Myoclonic jerks mainly involve the muscles of the neck or upper body and are exacerbated by action, particularly writing or outstretching of the arms. The jerks abate during sleep and are ameliorated by alcohol. The beneficial effects of the latter are at times dramatic and nearly diagnostic; however, following withdrawal of alcohol, the condition frequently becomes worse on the rebound.¹⁴⁵

Some individuals with essential myoclonus have associated dystonic movements, including spasmodic torticollis and blepharospasm. The presence of dystonia is an exception to the diagnostic criteria, as noted previously. Further complicating these diagnostic criteria is the occurrence of myoclonus in patients with hereditary dystonia, so-called myoclonic dystonia or dystonia with alcohol-responsive lightening-like jerks. Loss-of-function mutations in the 7q21 gene for ϵ -sarcoglycan were identified in most families with the myoclonus dystonia syndrome.¹⁴⁶ Whether these entities represent different disorders remains to be elucidated by future genetic studies.¹⁴⁷

In contrast to the hereditary form, the characteristics of sporadic essential myoclonus are more heterogeneous. Patients with this disorder range in age from 2 to 64 years at onset, have normal neurological findings on examination, and have normal EEG results. The myoclonic jerks may be oscillatory, rhythmical segmental, nonrhythmical segmental, or nonrhythmical multifocal; the trunk and proximal limb muscles, followed by the muscles of the neck and face, are most affected. Generally, patients do not demonstrate marked progression of symptoms or disability.

DIFFERENTIAL DIAGNOSIS. Because essential myoclonus has no known cause, its diagnosis is one of exclusion, and other causes must be evaluated. The coexistence of myoclonus and epilepsy suggests the presence of a form of epileptic myoclonus, which may present with either focal or generalized myoclonus (Video 105, Myoclonic Seizure). In these patients, epilepsy is the dominant feature, the syndrome is generally age related, and in most cases EEG abnormalities are associated (see Chapter 52). Myoclonic syndromes associated with underlying diseases that cause a predominant encephalopathy, ataxia, dementia, or pyramidal or extrapyramidal signs as major features of

the illness are termed symptomatic myoclonias (Video 50, Myoclonus in Creutzfeldt-Jakob Disease; Video 53, Myoclonus, Positive and Negative). Syndromes comprising symptomatic myoclonus with seizures are termed progressive myoclonic epilepsies (PME) (see Chapter 52), although the seizures are generally minor or late developments. Symptomatic causes of myoclonus include a variety of disorders (Table 34-8).

EVALUATION. The evaluation of essential myoclonus relies on a detailed history and a thorough neurological examination. Neuroimaging studies (head MRI and CT) in patients with essential myoclonus are normal, but these studies are helpful in patients with alternative diagnoses, such as stroke, degenerative disorders, and trauma. Electrophysiological tools, including EMG, EEG, and somatosensory evoked potentials (SEPs), can be particularly valuable in distinguishing the levels of neural dysfunction in patients with myoclonic syndromes. In essential myoclonus, these studies are normal; however, EEG results are generally abnormal in patients with epileptic myoclonus and the PMEs, showing epileptiform discharges (Video 46, Myoclonic Epilepsy). Patients with metabolic or toxic causes of myoclonus may also show diffuse slowing on EEG. SEPs are also normal in patients with essential myoclonus, as well as subcortical and spinal forms of myoclonus, but are abnormal in those syndromes originating in the cortex, including most PMEs. Blood, cerebrospinal fluid, and tissue biopsies, although normal in patients with essential myoclonus, should be used in the appropriate clinical settings.

TABLE 34-7

Diagnostic Criteria for Essential Myoclonus

1. Onset of myoclonus in first or second decade
2. Males and females equally affected
3. Benign course
4. Dominant mode of inheritance with variable severity
5. Absence of seizures, dementia, gross ataxia, or other deficit
6. Normal EEG
7. Normal somatosensory evoked potentials

TABLE 34-8

Symptomatic Myoclonus

- I. Metabolic—endogenous
 - Hypoxia, uremia, chronic hemodialysis, hepatic failure, hypercarbia, hypoglycemia, hyponatremia, nonketotic hyperglycemia
- II. Metabolic—exogenous
 - Bismuth, cocaine, organic mercury, methylbromide, strychnine, tetraethyl lead, tetanus
- III. Degenerative
 - Dementias—Alzheimer's disease
 - Movement disorders—corticobasal degeneration, multiple system atrophy, progressive supranuclear palsy, Hallervorden-Spatz disease, Huntington's disease
- IV. Neurovascular
 - Ischemia
 - Hemorrhagic
- V. Infectious
 - Transmissible spongiform encephalopathies—Creutzfeldt-Jakob disease, kuru, viral—measles, Epstein-Barr virus, etc.
- VI. Neoplastic
 - Neuroblastoma
 - Paraneoplastic disorders—ovarian, lung, breast
- VII. Autoimmune—multiple sclerosis
- VIII. Traumatic
 - Penetrating trauma—brain, spinal cord
 - Heat stroke
 - Electric shock
 - Decompression illness
- IX. Iatrogenic
 - Medications (amantadine, etomidate, penicillin, buspirone, diclofenac, lithium, metoclopramide, tricyclic antidepressants, levodopa, dopamine agonists)
 - Procedures (water-soluble contrast media, post-thalamotomy)

TABLE 34-9

Medications for the Treatment of Myoclonus

| MEDICATION | COMMON INITIAL DOSE | USUAL MAXIMUM DOSE | CLINICAL USES |
|---|--|---|-------------------------|
| Chlorpromazine | 25–50 mg intravenously | 50 mg by mouth tid | Hiccups |
| Clonazepam | 0.5–1.5 mg/day | 20 mg/day by mouth | Most forms of myoclonus |
| L-5-Hydroxytryptophan with carbidopa | 25 mg by mouth qid 25 mg by mouth qid | 500 mg by mouth qid 50 mg by mouth qid | Posthypoxic myoclonus |
| Levetiracetam | 500 mg bid | 1500 mg bid | Cervical myoclonus |
| Metoclopramide | 10 mg intravenously | 10 mg by mouth tid | Hiccups |
| Piracetam | 7.2 g/day by mouth | 16 g/day by mouth | Cortical myoclonus |
| Tetrabenazine | 25–50 mg/day by mouth | 200 mg/day by mouth | Segmental myoclonus |
| Valproic acid | 15 mg/kg/day by mouth | 2000 mg/day | Most forms of myoclonus |

TREATMENT. Despite its nonprogressive, benign nature, essential myoclonus can significantly impair the performance of routine daily activities, and symptomatic treatment of the myoclonic jerks can result in substantial improvement in the patient's quality of life. Although alcohol has been shown to alleviate the movements in a number of patients with essential myoclonus, the limitations of this pharmacological therapy are obvious. Manipulation of brain serotonin levels, although beneficial in some forms of myoclonus, has generally been unsuccessful in the treatment of essential myoclonus. A variety of medications may be used in this and other myoclonic disorders (Table 34-9). The benzodiazepines, particularly clonazepam, are the most consistently effective medications used for the treatment of essential myoclonus. In addition, favorable treatment results have been observed with certain anticholinergic medications, including bztropine and trihexyphenidyl. Piracetam and the structurally related drug levetiracetam have been also reported to be effective in the treatment of cortical myoclonus.¹⁴⁸

Startle Syndromes

The startle syndromes are characterized by an exaggerated motor response to unexpected auditory, and occasionally somesthetic or visual, stimuli. Confusion has overtaken the classification of these syndromes as various terms have been introduced. Hyperreflexia has often been used synonymously with any startle disorder; however, the word hyperreflexia (to jump excessively) was used to describe the autosomal dominantly inherited exaggerated startle reflexes in a large Dutch kindred. Matsamoto and Hallett¹⁴⁹ have advocated the use of the proper Greek term hyperreflexia to denote any movement disorder in which there is a physiological demonstration of exaggerated startle reflexes and have incorporated this terminology in dividing the startle syndromes into five main types (Table 34-10).¹⁴⁹

The pathophysiology of hyperreflexia has been recently elucidated, and now there is general agreement that the motor response in patients with hereditary and symptomatic hyperreflexia is a pathological exaggeration of the normal startle reflex.¹⁵⁰ To elicit a startle response in normal humans, an acoustic stimulus must have a volume of approximately 100 dB and a rise time of less than 5 msec. The response to such an unexpected stimulus varies in normals, and eye blinking may be the only visible reaction.

TABLE 34-10

Startle Syndromes

- I. Hereditary hyperreflexia
- II. Symptomatic hyperreflexia
- III. Startle epilepsy
- IV. Jumping, latah, myriachit
- V. Psychogenic startle

Typically, however, facial grimacing, head flexion with shoulder abduction, elbow flexion, pronation of the forearms, and fist clenching occur. In normals, habituation (a decrease in magnitude of response with repetition of the stimulus) occurs with four or five repeated stimuli. Electrophysiologically, surface EMG recordings demonstrate a bilaterally symmetrical response composed of a blink response and activation of other craniocervical muscles with variable limb muscle recruitment. The overall pattern of muscle recruitment suggests that the normal human auditory startle reflex originates in the caudal brain stem. The audiogenic jumps seen in hyperreflexias are believed to be generated by the normal startle circuit underheightened excitability, perhaps of cerebral origin. Hereditary hyperreflexia is inherited as an autosomal dominant trait caused by mutations in the α_1 subunit of the inhibitory glycine receptor, which is localized to chromosome 5q.¹⁵¹

The hallmark of hyperreflexia is an exaggerated startle response to a sudden, unexpected stimulus. Children with hyperreflexia are born with continuous stiffness and demonstrate a flexor posture, both of which disappear with sleep. Severely affected children startle excessively to sudden stimuli, and infants characteristically flex rather than extend their arms as seen with the normal Moro response. Apnea and cardiorespiratory arrest can occur, perhaps due to stiffness of the chest wall. The increased tone gradually disappears during the first several months of life, yet the startle response can interfere with walking and may result in trauma from falls. Severely affected patients have startle attacks throughout life; they often become worse during adolescence, and variable improvement occurs later in life. Other affected individuals may have infrequent attacks that may become worse with stress or illness. Violent bilateral flexion of the legs can occur during descent into slow-wave sleep or, rarely, during the daytime. Abdominal muscle involvement has been postulated to result at times in inguinal and abdominal hernias.

Other cerebral (perinatal anoxia), diencephalic (stroke), and brain stem (inflammatory and hemorrhage) lesions have also been associated with hyperreflexia, but most reports lack the physiological investigations necessary to prove that the startle reflex was involved. Certain psychiatric diseases including post-traumatic stress disorder may be associated with evidence of hyperarousal and an exaggerated startle reflex. Others have observed increased startle reactions in catatonic schizophrenics, patients with GTS, and newborns following in utero exposure to cocaine. The majority of acquired cases of exaggerated startle, however, are idiopathic and have no identifiable cause. An additional differential diagnostic consideration in the presence of exaggerated startle is startle epilepsy. Characterized by epileptic seizures triggered by sudden unexpected stimuli preceded by a startle, this disorder has been described in patients with severe brain damage, most commonly perinatal anoxic encephalopathy, but also in those with Down's syndrome, Sturge-Weber syndrome, and Tay-Sachs disease. Finally, a group of behaviors including "jumping," latak, and myriachit have been considered to represent startle phenomena, but others suggest that these entities are merely culturally based, conditioned behaviors. As a group, individuals with these behaviors demonstrate an initial violent start in response to a sudden stimulus that is variably followed by automatic speech (echolalia, echopraxia, or coprolalia) and the exhibition of aggressive gestures or defensive postures.
