Clonazepam and other benzodiazepines are considered the drugs of choice for the treatment of hyperreflexia; when effective, they reduce the severity and frequency of the startle reactions. Valproic acid, 5-hydroxytryptophan, and pramipexole have also been successful in certain patients.

 Unknown Etiology

HISTORY AND DEFINITIONS

The degenerative and congenital ataxias comprise a wide spectrum of disorders with ataxia as the prominent symptom. The neuropathological hallmark of these diseases is degeneration or malformation of the cerebellar cortex and of the spinal pathways. In many cases, there is additional involvement of the brain stem and the basal ganglia.

Traditionally, classifications of ataxia were based on neuropathological criteria. Thus, Holmes¹ distinguished between spinocerebellar degeneration, degeneration of the cerebellar cortex, and olivopontocerebellar atrophy. More recently, a clinical classification introduced by Harding² gained wide acceptance. This classification distinguishes between congenital, hereditary, and nonhereditary ataxias. Hereditary ataxias are further subdivided into ataxias with autosomal recessive inheritance such as Friedreich's ataxia (FRDA), ataxias with X-linked inheritance, and ataxias with autosomal dominant inheritance, which are now usually named spinocerebellar ataxias (SCAs). In recent years, the causative mutations of most hereditary ataxias have been identified, allowing a rational classification of hereditary ataxias. The nonhereditary ataxias comprise diseases with unknown etiology and acquired ataxias with a known cause. The acquired ataxias, many of which are due to alcoholism or malignant disease, are discussed in Chapters 38 to 40, and 47 (Table 35-1).

CONGENITAL ATAXIAS

PATHOGENESIS AND PATHOPHYSIOLOGY. Cerebellar malformations are often part of complex malformation syndromes affecting diverse structures of the central nervous system (CNS). In addition, there are cerebellar malformations that are more or less limited to the cerebellum. In these latter forms, congenital ataxia is often a prominent clinical feature, although ataxia may be associated with other symptoms, such as mental retardation, spasticity, and seizures. In some cases of severe cerebellar malformation, ataxia is surprisingly mild (see Chapter 28).

The etiology of congenital ataxia is poorly understood. Occasional appearance of congenital ataxia in siblings suggests that it may be autosomal recessively inherited. The molecular genetic basis of congenital ataxia, however, is incompletely explored. Sporadic cases of congenital ataxia outnumber familial cases by far. Whether sporadic cases are also due to recessive mutations or whether they have other causes is unknown. Animal experimental studies show that a variety of exogenous factors, such as toxins, viral infection, hypoxia, and irradiation, may lead to cerebellar malformation.³

EPIDEMIOLOGY AND RISK FACTORS. Congenital ataxia due to cerebellar malformation is a rare condition. Precise information on the epidemiology of congenital ataxia is not available.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. *Cerebellar aplasia* seldom occurs alone. It is characterized by complete or near complete absence of the cerebellum. The clinical picture of cerebellar aplasia is variable. Life expectancy of patients with cerebellar aplasia ranges from a few weeks to a normal life span. In general, patients with cerebellar agenesis have profoundly impaired motor development and persistent motor deficits. However, there are reports of patients with subtotal cerebellar aplasia who learned to stand, walk, and run. Compensation appears to be best if intelligence is normal.⁴

Vermian aplasia is often associated with reduction in the size of the cerebellar hemispheres and anomalies of the cerebellar and olivary nuclei. As in cerebellar aplasia, survival ranges from a few weeks to a normal life span. The clinical picture of vermal aplasia is not uniform. It may be associated with a nonprogressive cerebellar syndrome, or it may be completely asymptomatic. If vermal aplasia is associated with other malformations, a neurological syndrome without features of cerebellar dysfunction may be present.

Joubert's syndrome is an autosomal recessive disorder with a distinctive clinical picture. It is genetically heterogeneous.⁵ Joubert's syndrome comprises episodes of hyperpnea alternating with apnea, abnormal eye movements, ataxia, and mental retardation. Most patients die before the age of 3 years. Neuropathologically, complete or partial vermal aplasia is found along with changes in the cerebellar cortex and dentate nucleus.⁶

TABLE 35-1

Classification of Ataxia

Congenital Ataxias

Hereditary Ataxias

Autosomal Recessive Ataxias

- Friedreich's ataxia (FRDA)
- Ataxia-telangiectasia (AT)
- Ataxia with oculomotor apraxia type 1
- Ataxia with oculomotor apraxia type 2
- Autosomal recessive spastic ataxia of Charlevoix-Saguenay (ARSACS)
- Abetalipoproteinemia
- Ataxia with isolated vitamin E deficiency (AVED)
- Refsum's disease
- Cerebrotendinous xanthomatosis (CTX)
- Marinesco-Sjogren syndrome (MSS)
- Autosomal recessive ataxia with known gene locus
- Early onset cerebellar ataxia (EOCA)

X-Linked Ataxias

- Fragile X tremor ataxia syndrome (FXTAS)

Autosomal Dominant Ataxias

- Spinocerebellar ataxias (SCA)
- Dentatorubral-pallidolysian atrophy (DRPLA)
- Episodic ataxias (EA)

Nonhereditary Degenerative Ataxias

- Multiple system atrophy, cerebellar type (MSA-C)
- Sporadic adult-onset ataxia of unknown etiology

Acquired Ataxias

- Alcoholic cerebellar degeneration
- Ataxia due to other toxic reasons (antiepileptics, lithium, solvents)
- Paraneoplastic cerebellar degeneration
- Other immune-mediated ataxias (gluten ataxia, ataxia associated with anti-GAD antibodies)
- Acquired vitamin E deficiency
- Hypothyroidism
- Ataxia due to physical causes (heat stroke, hyperthermia)

Cerebellar hypoplasia is characterized by reduced size of the entire cerebellum or parts of it. Cerebellar hypoplasia may be detected by chance in neurologically healthy individuals. Often, however, cerebellar hypoplasia is associated with congenital ataxia. In affected children, motor milestones are delayed. When the child begins to walk, the gait is ataxic with frequent falls. Limb movements and speech may be also affected (Video 108, Cerebellar Ataxia).⁷

The *Dandy-Walker malformation* is a complex malformation of the CNS characterized by partial or complete aplasia of the cerebellar vermis associated with a large posterior fossa cyst. Other abnormalities include enlargement of the posterior fossa, abnormally high placement of the tentorium, and elevation of the transverse sinuses. The Dandy-Walker malformation is almost always associated with hydrocephalus. The clinical syndrome of the Dandy-Walker malformation is related to the extent of the hydrocephalus. Despite the presence of vermal aplasia, congenital ataxia is not a typical feature of the Dandy-Walker malformation.

Chiari malformations consist of caudal herniation of parts of the cerebellum and brain stem into the upper cervical canal. Although these malformations affect the cerebellum, they do not lead to congenital ataxia.

DIFFERENTIAL DIAGNOSIS AND EVALUATION. Congenital ataxia can be distinguished from other types of early onset ataxias by the nonprogressive nature of the disorder. A clinical distinction among the various cerebellar malformations that underlie congenital ataxia is impossible.

Magnetic resonance imaging (MRI) is the method of choice for evaluation of patients with congenital ataxia. MRI clearly shows the size of the cerebellum and the presence of any associated anomalies, such as cysts and hydrocephalus.⁸ Electrophysiological investigations do not reveal consistent abnormalities.

MANAGEMENT, PROGNOSIS, AND FUTURE PERSPECTIVES. There is no specific treatment for congenital ataxia. If cerebellar malformations occur in combination with hydrocephalus, surgical shunting is required.

Congenital ataxia is a nonprogressive and benign condition. Children with normal intelligence will compensate cerebellar defects particularly well. However, the cerebellar malformations that underlie congenital ataxia are often associated with other malformations of the CNS. These may lead to mental retardation, epilepsy, disorders of breathing, and noncerebellar motor symptoms. Prognosis in children affected by complex malformation syndromes is poor, and many of them die in the first weeks of life.

HEREDITARY ATAXIAS

Autosomal Recessive Disorders

Friedreich's Ataxia

PATHOGENESIS AND PATHOPHYSIOLOGY. FRDA is an autosomal recessive disease. In most cases of FRDA, the causative mutation is a homozygous, intronic GAA repeat expansion in a gene coding for a mitochondrial protein named frataxin. Less than 4% of FRDA patients are compound heterozygotes with one allele carrying the GAA repeat expansion and the other a point mutation.⁹ FRDA patients have low frataxin mRNA levels, suggesting that reduced frataxin levels are the primary cause of neurodegeneration and cardiomyopathy in FRDA. Frataxin assembles to larger protein complexes that function as iron chaperones and iron storage proteins. Frataxin thereby protects DNA from iron-induced damage.¹⁰ Loss of frataxin has been shown to lead to mitochondrial iron overload, increased production of free radicals, and impaired utilization of iron for synthesis of iron-sulfur clusters resulting in decline of mitochondrial respiratory activity.¹¹

The first pathological changes in FRDA are thought to occur in the dorsal root ganglia with loss of large sensory neurons. In advanced cases, the neuropathological abnormalities include axonal sensory and motor neuropathy, degeneration of spinal tracts (spinocerebellar tracts, posterior columns, and pyramidal tract), and hypertrophic cardiomyopathy. There is only occasional involvement of the cerebellum with loss of Purkinje cells and moderate cerebellar atrophy.

EPIDEMIOLOGY AND RISK FACTORS. Prevalence rates of FRDA range from 0.4 to 4.7 per 100,000. As in

other recessive disorders, birth from a consanguineous marriage is a major risk factor for FRDA. In families with one affected child, each of the remaining children carries a risk of 25% to develop FRDA. Children descending from an unaffected sibling of an FRDA patient and a nonconsanguineous spouse have an estimated risk of approximately 1 out of 1000 to develop FRDA.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. FRDA usually starts before the age of 25 years, most often between ages 10 and 15 years. In most patients, ataxia of gait and stance is the first manifestation of the disease (Video 37, Friedreich's Ataxia). In others, skeletal deformities, particularly scoliosis, are present prior to the onset of ataxia. There are a number of clinical symptoms that are present from the beginning of the disease in virtually all patients. These include progressive ataxia and impaired vibration or position sense. Most patients have areflexia of lower extremities, approximately two thirds have extensor plantar responses. There is progressive weakness of the extremities, which is due to pyramidal tract dysfunction and to distal muscle atrophy. Despite pyramidal involvement, muscle tone is usually normal or decreased. However, some patients may suffer from spontaneous flexor spasms. Less than 10% of FRDA patients experience reduced appreciation of pain and light touch. Oculomotor disturbances are a frequent finding in FRDA. Typically, they include fixation instability with square wave jerks and reduced gain of vestibulo-ocular reflex. In contrast to cerebellar disease, gaze-evoked nystagmus (Video 8, Gaze-Evoked Nystagmus) is an unusual finding. In the course of the disease, all FRDA patients develop dysarthria characterized by slow, hesitating, and scanning speech. In later stages of the disease, optic atrophy with reduced visual acuity and progressive sensorineural hearing loss can occur. Bladder function is usually unimpaired, although some patients complain of frequency and urgency in late stages of the disease. There is no evidence that FRDA is associated with cognitive impairment. FRDA is associated with a number of non-neurological symptoms, including skeletal deformities, such as scoliosis and pes cavus, and hypertrophic obstructive cardiomyopathy. Ten percent of patients have diabetes mellitus.¹² The advent of molecular diagnostic tests for FRDA has allowed identification of atypical variants of FRDA. These include late-onset cases with disease onset after the age of 25 years and cases in which tendon reflexes are retained or exaggerated.

DIFFERENTIAL DIAGNOSIS. A molecular diagnosis of FRDA can be made by demonstration of homozygosity for the GAA repeat expansion by polymerase chain reaction. In patients with a FRDA phenotype who are heterozygous for the GAA repeat, a search for point mutations in the other allele should be made. A number of recessive ataxias, particularly ataxia with isolated vitamin E deficiency, may cause confusion with FRDA. In cases of suspected FRDA in which molecular genetic tests are negative, additional laboratory tests should be ordered.

Hereditary motor-sensory neuropathies (HMSN) may mimic the phenotype of FRDA, although these patients do not develop oculomotor abnormalities, dysarthria, or

cardiomyopathy. In particular, the axonal form of HMSN with motor nerve conduction velocities (MNCVs) more often than 37 m/sec may lead to considerable diagnostic confusion that requires genetic testing to resolve.

EVALUATION. Nerve conduction and evoked potential studies show abnormal conduction along peripheral and central somatosensory pathways with reduced amplitudes of sensory nerve action potentials and delay or loss of cortical responses to peripheral stimulation. In addition, motor evoked potentials (MEPs) to transcranial magnetic stimulation are abnormal in almost all FRDA patients, with loss of responses or increased central motor conduction time (CMCT) indicating pyramidal tract involvement. MRI is the method of choice to study the atrophy changes underlying FRDA. Typically, MRIs show severe atrophy of the cervical spinal cord, whereas there is little evidence of cerebellar atrophy (Fig. 35-1).¹³

Electrocardiography and echocardiography are useful to study cardiac involvement in FRDA. The most common

Figure 35-1. T1-weighted MRIs of infratentorial brain structures and cervical spinal cord in FRDA. The images show the posterior fossa in the mid-sagittal plane (*top*) and an axial slice at the level of the dens axis (*bottom*). There is severe shrinkage of the cervical spinal cord. In contrast, the cerebellum and brain stem have normal size.

electrocardiographic abnormality in FRDA is the presence of T-wave inversion. Echocardiography typically reveals interventricular septal and left ventricular wall hypertrophy.

MANAGEMENT. Since frataxin deficiency leads to increased production of free radicals, free radical scavengers are currently investigated in FRDA. The available data show that idebenone reduces cardiac hypertrophy but does not improve the neurological phenotype.¹⁴ To date, there are no other pharmacological treatments.

PROGNOSIS AND FUTURE PERSPECTIVES. FRDA is a progressive disorder. On average, FRDA patients become wheelchair-bound 10 to 12 years after disease onset. Median survival after disease onset is approximately 35 years.

Ataxia-Telangiectasia

Ataxia-telangiectasia (AT) is the second most common recessive ataxia. It is a multisystemic disorder characterized by a progressive ataxia starting in early childhood, the occurrence of oculocutaneous telangiectasia, a high incidence of neoplasia, radiosensitivity, and recurrent infections. The gene affected in AT, ATM (ataxia-telangiectasia mutated), encodes a member of the phosphoinositol-3 kinase family involved in cell cycle checkpoint control and DNA repair. AT is discussed in more detail in Chapter 32.

Autosomal Recessive Ataxia With Oculomotor Apraxia Type 1

Autosomal recessive ataxia with oculomotor apraxia type 1 (AOA1) is an autosomal recessively inherited ataxia that is caused by mutations of the aprataxin gene. AOA1 was initially described in Japan and Portugal, but it is also prevalent in other countries.¹⁵ Aprataxin is a protein of the histidine triad superfamily,^{16,17} and it plays a role in repair of single-strand DNA breaks.¹⁸ It was recently shown that AOA1 patients have severe muscular coenzyme Q deficiency.¹⁹ The mechanisms leading to coenzyme Q deficiency have not been elucidated.

AOA1 starts in children with a mean age of onset of 7 years. Besides ataxia and oculomotor apraxia, the clinical spectrum of AOA1 involves chorea, neuropathy, and mental retardation.²⁰ With progression of the disease, neuropathy becomes increasingly more disabling, whereas the oculomotor abnormalities may become less prominent. AOA1 patients survive in a severely disabled state into adulthood.

Characteristically, routine laboratory tests show hypoalbuminemia that increases with progression of the disease. A definite diagnosis of AOA1 can be made by genetic testing.

If the report on coenzyme Q deficiency is confirmed by other groups, AOA1 patients should be supplemented with coenzyme Q at a dose of at least 500 mg per day.¹⁹

Autosomal Recessive Ataxia With Oculomotor Apraxia Type 2

Autosomal recessive ataxia with oculomotor apraxia type 2 (AOA2) is an autosomal recessively inherited ataxia caused

by mutations of the senataxin gene. Senataxin is the human homologue of the yeast gene Sen1p.²¹ It has been suggested that senataxin, like aprataxin, is involved in repair of single-strand DNA breaks. The prevalence of AOA2 is unknown, but it has been suggested that AOA2 is the second most frequent recessive ataxia in Europe after FRDA.²²

The mean age of onset of AOA2 is 15 years. Clinically, AOA2 is characterized by ataxia and neuropathy. Oculomotor apraxia is not present in all AOA2 patients.^{22,23}

All AOA2 patients have increased serum α -fetoprotein levels. To differentiate AOA2 from AT patients, who also have increased serum α -fetoprotein levels, a lymphocyte radiosensitivity assay should be performed. This test is normal in AOA2. A definite diagnosis of AOA2 can be made by genetic testing.

Spinocerebellar Ataxia With Neuropathy Type 1

Spinocerebellar ataxia with neuropathy type 1 (SCAN1) is an autosomal recessive disorder that was identified in a Saudi Arabian family. It is caused by a mutation in the conserved part of the tyrosyl-DNA phosphodiesterase 1 (TDP1) gene affecting the active enzymatic site.²⁴ TDP1 is required for the repair of DNA single-strand breaks, placing SCAN1 into the group of recessive ataxias due to defects of DNA repair. Clinically, SCAN1 is characterized by ataxia in combination with sensory neuropathy.

Autosomal Recessive Spastic Ataxia of Charlevoix-Saguenay

Autosomal recessive spastic ataxia of Charlevoix-Saguenay (ARSACS) is an autosomal recessive ataxia with a distinctive phenotype that is prevalent in a restricted area in Quebec, Canada. ARSACS is due to mutations in a large, single exon gene encoding a novel protein called saccin. The most frequent mutation accounting for more than 90% of all mutations is a deletion leading to protein truncation. Saccin contains a heat-shock domain, suggesting that it subserves a chaperone function.²⁵

ARSACS is characterized by the combination of progressive cerebellar ataxia and spasticity. Muscle reflexes are exaggerated and plantar responses are extensor. With progression of the disease, the ankle jerks disappear, and distal wasting of foot muscles develops. A highly characteristic ocular sign is the presence of prominent myelinated fibers radiating from the optic disc at funduscopy.

A genetic test for ARSACS has been established at the Genetic Service of the St. Justine Hospital in Montreal (A. Richter, personal communication, 2000). ARSACS typically starts at the age of 1 or 2 years. On average, patients become wheelchair-bound at approximately the age of 40 years. There is no effective therapy for ARSACS.

Abetalipoproteinemia

Abetalipoproteinemia is a rare, autosomal recessive disorder characterized by onset of diarrhea soon after birth and

slow development of a neurological syndrome thereafter. The neurological syndrome consists of ataxia, weakness of the limbs with loss of tendon reflexes, disturbed sensation, and retinal degeneration. Abetalipoproteinemia is caused by mutations in the gene encoding a subunit of a microsomal triglyceride transfer protein.²⁶ As a consequence, circulating apoprotein B-containing lipoproteins are almost completely missing, and the patients are unable to absorb and transport fat and fat-soluble vitamins. The neurological symptoms are due to vitamin E deficiency. Management of abetalipoproteinemia consists of a diet with reduced fat intake and oral vitamin E supplementation (50 to 100 mg/kg/day) (see Chapter 30).

Ataxia with Isolated Vitamin E Deficiency

Ataxia with isolated vitamin E deficiency (AVED) is a rare, autosomal recessive disorder with a phenotype resembling FRDA. AVED patients carry homozygous mutations of the gene encoding the α -tocopherol transport protein, a liver-specific protein that incorporates vitamin E into very low-density lipoproteins.²⁷ As a consequence, vitamin E is rapidly eliminated. AVED is a frequent cause of recessive ataxia in north African countries but is rarely encountered in other areas of the world. Because there is no absorption deficit, oral supplementation of vitamin E at a dose of 800 to 2000 mg/day is recommended.

Refsum's Disease

Refsum's disease is a rare, autosomal recessive disorder due to mutations in the gene encoding phytanoyl-CoA hydroxylase that is involved in the α -oxidation of phytanic acid.²⁸ The clinical phenotype of Refsum's disease is caused by accumulation of phytanic acid in body tissues. Clinically, Refsum's disease is characterized by ataxia, demyelinating sensorimotor neuropathy, pigmentary retinal degeneration, deafness, cardiac arrhythmias, and ichthyosis-like skin changes. Whereas ocular and hearing problems are usually slowly progressive, there may be acute exacerbations of ataxia that are precipitated by low caloric intake and mobilization of phytanic acid from adipose tissue.

Refsum's disease is treated by dietary restriction of phytanic acid from the 50 to 100 mg contained in a normal Western diet to less than 10 mg per day. With good dietary supervision, ataxia and neuropathy may improve. In contrast, the progressive loss of vision and hearing cannot be prevented. In acute exacerbations, plasma exchange is effective in lowering phytanic acid levels and improving neurological and cardiac function (see Chapter 30).

Cerebrotendinous Xanthomatosis

Cerebrotendinous xanthomatosis (CTX) is a rare, autosomal recessively inherited lipid storage disorder that is due to mutations of the gene encoding sterol 27-hydroxylase.²⁹

Sterol 27-hydroxylase is responsible for the degradation of 7 α -hydroxy-cholesterol to bile acids. As a consequence of the enzymatic defect, there is reduced excretion of bile acids with feces, whereas the content of bile alcohols increases. In addition, cholesterol and 7 α -hydroxy-cholesterol are increasingly degraded to cholestanol. It is assumed that CTX is caused by the accumulation of cholestanol.

CTX is a progressive multisystemic disorder. The neurologic syndrome includes ataxia, pyramidal signs, cognitive impairment, epilepsy, and peripheral neuropathy. In addition, patients have chronic diarrhea, xanthomatous tendon swelling, and cataracts. The tendon xanthomas that gave rise to the naming of the disorder are not obligate so that their absence does not rule out a diagnosis of CTX.

CTX is treated by oral administration of chenodeoxycholate (750 mg/day). Treatment can be further improved by addition of HMG-CoA reductase inhibitors such as simvastatin or lovastatin.

Marinesco-Sjögren Syndrome

Marinesco-Sjögren syndrome (MSS) is an autosomal recessive condition characterized by cerebellar ataxia, mental retardation, and congenital cataracts. Mutations of the SIL1 gene have been shown to cause MSS.³⁰ MSS is genetically distinct from the congenital cataracts facial dysmorphism neuropathy syndrome.

Autosomal Recessive Ataxias with Known Gene Locus

In a number of recessive ataxias, the chromosomal locus has been found but the affected gene and mutations have not been identified.

Linkage to chromosome 6p was demonstrated in an Israeli family with early onset recessive ataxia. Patients subsequently developed hearing impairment and optic atrophy.³¹

Infantile onset spinocerebellar ataxia is an early onset recessive ataxia linked to a locus on chromosome 10q that has been described in Finnish families. The disease manifests at approximately 1 year of age as acute or subacute clumsiness, athetoid movements in hands and face, hypotonia, and loss of deep tendon reflexes in the legs. Ophthalmoplegia and a sensorineural hearing deficit are found by school age, sensory neuropathy and optic atrophy by the age of 10 to 15 years, and female hypogonadism and epilepsy by the age of 15 to 20 years. Most patients are wheelchair-bound by the age of 20 years.³²

Early Onset Cerebellar Ataxia

Early onset cerebellar ataxia (EOCA) denotes those ataxias with an onset before the age of 20 years in which the etiology is unknown. It is assumed that most EOCA are autosomal recessive disorders.

The most frequent form of EOCA, EOCA with retained tendon reflexes, is clinically distinguished from typical FRDA by the preservation of muscle reflexes. On MRI, these patients have cerebellar atrophy, and disease progression is slower than in FRDA.³³

A highly characteristic, clinically defined variant of EOCA is cerebellar ataxia with hypogonadism, also known as Holmes' syndrome.³⁴

X-Linked Disorders

Fragile X Tremor Ataxia Syndrome

Fragile X syndrome (FXS) is the most common inherited form of mental retardation. It is an X-linked disorder caused by a CGG expansion (>200; normal, 6 to 44) in the 5' region of the FMR1 gene resulting in hypermethylation of the FMR1 promoter, transcriptional silencing, and loss of FMR1 protein. FMR1 premutations (55 to 200) are frequent in the general population (females, 386:100,000; males, 123:100,000) and may give rise to full mutations. Female premutation carriers may have a number of health problems including premature ovarian failure and emotional problems. Expansions ranging from 45 to 54 are outside the normal range but are not definite premutations. This range is therefore called a gray area.

Fragile X tremor ataxia syndrome (FXTAS) is a unique form of clinical involvement in FMR1 older male premutation carriers characterized by progressive action tremor and cerebellar ataxia. These symptoms may be accompanied by cognitive decline, parkinsonism, neuropathy, and autonomic failure. MRIs of FXTAS patients show hyperintense signal changes lateral to the dentate nucleus extending into the middle cerebellar peduncles (Video 239, Fragile X Premutation Syndrome).³⁵

In contrast to FXS, FXTAS patients have increased levels of FMR1 mRNA and normal FMR1 protein levels. A neuropathological study showed the presence of neuronal intranuclear inclusions.³⁶

The prevalence and penetrance of FXTAS are unknown. Based on studies in FXS families, it has been claimed that FXTAS has an age-dependent but complete penetrance.³⁷ Given the high frequency of FMR1 premutations in the normal population, this would mean that FXTAS should

be a frequent cause of ataxia and tremor in older males. On the other hand, screening for FMR1 premutations in male patients with unexplained ataxia yielded variable results. In most studies, including a study of 390 ataxia patients, the frequency of the FMR1 premutation was less than 0.5%. However, one study reported a frequency of 5%.³⁸

Autosomal Dominant Disorders

Spinocerebellar Ataxias

The SCAs are a genetically heterogeneous group of autosomal dominant progressive ataxia disorders. To date, more than 25 different gene loci have been found in association with SCA. In 11, the affected genes and causative mutations have been found (SCA1 to 3, 6, 7, 10, 12 to 14, 17, and 27) (Table 35-2). In 6 (SCA1 to 3, 6, 7, and 17), the mutation is a translated CAG repeat mutation coding for an elongated polyglutamine tract within the respective protein (Fig. 35-2A). These disorders belong to a larger group of polyglutamine disorders that also includes Huntington's disease, dentatorubral pallidoluysian atrophy (DRPLA), and spinobulbar muscular atrophy.³⁹ In all polyglutamine disorders, there is an inverse correlation between age of onset and CAG repeat length (Fig. 35-2B). However, the repeat length explains only part of the variation of age of onset, implicating additional non-CAG factors.⁴⁰

PATHOGENESIS AND PATHOPHYSIOLOGY. All polyglutamine disorders share important pathogenetic features that are due to deleterious actions mediated by the elongated polyglutamine tracts. Specifically, proteins containing elongated polyglutamine tracts have a strong tendency to aggregate and to undergo abnormal interactions with other cellular proteins. Aggregations of the disease proteins form-

TABLE 35-2

Mutations and Clinical Phenotypes of Spinocerebellar Ataxias (SCA) with Known Gene Mutations

| DISORDER | MUTATION | GENE PRODUCT | CLINICAL PHENOTYPE |
|-------------------------------|-----------------------------------|--|--|
| SCA1 | Translated CAG repeat expansion | Ataxin-1 | Ataxia, pyramidal signs, neuropathy, dysphagia, restless legs syndrome |
| SCA2 | Translated CAG repeat expansion | Ataxin-2 | Ataxia, slow saccades, neuropathy, restless legs syndrome |
| SCA3 (Machado-Joseph disease) | Translated CAG repeat expansion | Ataxin-3 | Ataxia, pyramidal signs, ophthalmoplegia, neuropathy, dystonia, restless legs syndrome |
| SCA6 | Translated CAG repeat expansion | Calcium channel subunit (CACNA1A) | Almost pure cerebellar ataxia |
| SCA7 | Translated CAG repeat expansion | Ataxin-7 | Ataxia, ophthalmoplegia, visual loss |
| SCA10 | Intronic ATTCT repeat expansion | Unknown | Ataxia, epilepsy |
| SCA12 | Untranslated CAG repeat expansion | Phosphatase subunit (PP2A-PR55 β) | Ataxia, tremor |
| SCA13 | Point mutation | Potassium channel (KCNC3) | Ataxia, mental retardation |
| SCA14 | Point mutation | Protein kinase C γ | Ataxia, myoclonus |
| SCA17 | Translated CAG repeat expansion | TATA binding protein | Ataxia, dystonia |
| SCA27 | Point mutation | Fibroblast growth factor (FGF14) | Ataxia, tremor, dyskinesia |

Figure 35-2. A, Diagrammatic representation of the SCA3 gene mutation. Normals have a CAG trinucleotide repeat within one of the exons ranging from 14 to 37 trinucleotides. In patients, the repeat is expanded to 55 to 84 units. B, Relationship between age of onset and CAG repeat length in SCA3.

ing ubiquitinated neuronal intranuclear inclusions are found in affected brain areas of most polyglutamine disorders. However, research has shown that these inclusions are not required for neurodegeneration. Instead, it is assumed that the abnormal interaction of the elongated proteins with general transcription factors such as TATA-binding protein (TBP) or TBP-associated factor (TAF), which contain polyglutamine tracts, is a common and essential pathogenetic mechanism. As a consequence, there is a general suppression of gene transcription.⁴¹ Interestingly, SCA17 is due to a polyglutamine expansion in the TBP gene.⁴² In addition, there are pathogenetic mechanisms that are specific for each disorder and that are related to the specific properties of the involved proteins and their alterations through the polyglutamine expansion. This dual model explains both the overlapping and the disease-specific phenotypical features of the polyglutamine disorders.

EPIDEMIOLOGY. An epidemiological study performed in The Netherlands found a prevalence of all SCAs of 3.0:100,000. SCA1, SCA2, SCA3, and SCA6 are the most frequent mutations worldwide, accounting for 50% to 70% of all families with dominant ataxia.^{43,44}

MANAGEMENT. There is no specific treatment for any of the SCAs. Physical therapy and speech therapy are recommended. Many SCA patients are dependent on canes or wheelchairs within years after disease onset. A number of accompanying symptoms, such as parkinsonism, dystonia, or restless legs syndrome, are treated in standard manner.

SPINOCEREBELLAR ATAXIA TYPE 1

PATHOGENESIS AND PATHOPHYSIOLOGY. SCA1 is an autosomal dominant disorder with a disease locus on

chromosome 6p. In 1993, Orr and colleagues⁴⁵ isolated the SCA1 gene and showed that the mutation is an unstable CAG trinucleotide repeat expansion within a translated region of the gene. The repeat length in normals varies between 6 and 39 trinucleotides, whereas SCA1 patients have one allele within a range of 40 to 81 repeat units. The mutated SCA1 genes contain uninterrupted CAG stretches. In contrast, normal alleles have a midstream CAT interruption.

The physiological function of ataxin-1, the gene product of the SCA1 gene, remains unknown. Overexpression of normal and expanded ataxin-1 in flies produces a disease phenotype. This observation led to the hypothesis that the polyglutamine expansion causes the disease by stabilizing ataxin-1, leading to its accumulation. Ataxin-1 inactivates the transcription factor Gfi-1, which is essential for the integrity of the cerebellum. Accordingly, Gfi-1 knockout mice have an SCA1-like phenotype.⁴⁶

Neuropathological findings in SCA1 are variable. In most cases, there is olivopontocerebellar atrophy and degeneration of ascending spinal pathways with minor degeneration of the pyramidal tract. In the cerebellar cortex, Purkinje cells are primarily affected. Often, there is additional cell loss in the caudal cranial nerve nuclei.⁴⁷ In surviving neurons of the nucleus centralis pontis, the presence of ubiquitin-positive nuclear inclusions containing ataxin-1 has been demonstrated.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Disease onset in SCA1 varies and can occur between adolescence and late adulthood with features of anticipation. On average, the disease starts at approximately age 35 years. All SCA1 patients suffer from a progressive cerebellar syndrome with ataxia of gait and stance, ataxia of limb movements, dysarthria (Video 9, Dysmetria), and cerebellar oculomotor abnormalities (gaze-evoked nystagmus, saccade hypermetria, broken up smooth pursuit, reduced optokinetic nystagmus, and impaired suppression of vestibulo-ocular reflex by fixation) (Video 228, Saccadic Dysmetria). In the majority of patients, there are additional noncerebellar symptoms. Pyramidal tract signs, skeletal muscle atrophy, and pale discs are found in more than 50% of SCA1 patients. Gaze palsy, slow saccades, decreased vibration sense, and bladder dysfunction occur less frequently, whereas basal ganglia symptoms and dementia are rare symptoms in SCA1. Dysphagia is a typical feature of late disease stages.⁴⁸

DIFFERENTIAL DIAGNOSIS AND EVALUATION. Diagnosis of SCA1 is made by demonstration of CAG repeat expansion at the SCA1 locus. Clinically, SCA1 cannot be distinguished with certainty from other SCAs. However, the presence of pyramidal tract signs, pale discs, and dysphagia is suggestive for SCA1 because these symptoms are found less frequently in other SCA mutations.

NCVs are in the normal range or moderately reduced. SNAPs are reduced in almost all patients, suggesting sensory axonal neuropathy. Patients having widespread atrophy of skeletal muscles demonstrate chronic neurogenic electromyographic (EMG) features. MEPs to transcranial magnetic stimulation are abnormal in almost all SCA1

patients with loss of responses or increased CMCT indicating pyramidal tract involvement. Somatosensory evoked potentials (SEPs) due to tibial nerve stimulation are usually delayed or absent. Similarly, visual evoked potentials (VEPs) are abnormal in almost all SCA1 patients with loss or delay of P100. Abnormalities of brain stem auditory evoked potentials (BAEPs) with delay of peaks I, III, and V and increased interpeak latencies are found in approximately half of SCA1 patients.⁴⁹ MRI shows diffuse cerebellar atrophy, brain stem atrophy, and shrinkage of the cervical spinal cord.⁵⁰

PROGNOSIS AND FUTURE PERSPECTIVES. SCA1 is a progressive disorder. On average, SCA1 patients become wheelchair-bound approximately 13 years after disease onset. Median survival after disease onset is 18 to 20 years.⁵¹

SPINOCEREBELLAR ATAXIA TYPE 2

PATHOGENESIS AND PATHOPHYSIOLOGY. The mutation causing SCA2 is a translated CAG repeat expansion in a gene coding for ataxin-2. The repeat length in normals varies between 6 and 31 trinucleotides, with more than 90% of control alleles having 22 or 23 repeats. SCA2 patients have one allele within a range of 36 to 63 repeat units. Alleles with a length of 30 to 34 repeats represent an intermediate range that may give rise to expansion in the offspring. Normal alleles have CAA interruptions. Expanded alleles are unstable with a tendency to further expansion, particularly in father-to-child transmission.⁵²

Autopsy studies of SCA2 patients consistently show olivopontocerebellar atrophy with marked reduction of Purkinje cells and degeneration of the inferior olives, pontine nuclei, and pontocerebellar fibers. In most cases, there is additional degeneration of posterior columns and spinocerebellar pathways and cell loss in the substantia nigra. Ubiquitinated nuclear inclusions have not been observed in SCA2.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Disease onset in SCA2 varies, occurring between early childhood and late adulthood with features of anticipation. On average, the disease starts at approximately the age of 35 years. All SCA2 patients suffer from a progressive cerebellar syndrome with ataxia of gait and stance, ataxia of limb movements (Video 12, Dysdiadochokinesis), and dysarthria. Saccade slowing is a highly characteristic feature that is observed in the majority of SCA2 patients. Approximately half of patients have vertical or horizontal gaze palsy. Cerebellar oculomotor abnormalities are rarely found in SCA2. Typically, tendon reflexes are absent or decreased. Pyramidal tract signs are present in less than 20% of patients. Vibration sense is decreased in most patients, but sensation is otherwise normal. Dementia, basal ganglia symptoms, pale discs, and bladder dysfunction are usually absent.^{53,54} There are exceptional SCA2 patients with short expansions who suffer from levodopa-responsive parkinsonism without ataxia.

DIFFERENTIAL DIAGNOSIS AND EVALUATION. Diagnosis of SCA2 is made by demonstration of CAG repeat expansion at the SCA2 locus. Clinically, SCA2 cannot be distinguished with certainty from other SCAs. However,

the presence of slow saccades, axonal neuropathy, and severe pontine atrophy in MRI is suggestive for SCA2. Nerve conduction findings are similar to those for SCA1, with low amplitudes of SNAPs and normal or slightly reduced NCVs. In contrast to SCA1, MEPs to transcranial magnetic stimulation and VEPs are usually normal in SCA2. BAEPs reveal abnormalities in less than half of SCA2 patients. SEPs after tibial nerve stimulation are usually abnormal. MRIs show diffuse cerebellar atrophy with marked brain stem atrophy suggesting the presence of olivopontocerebellar atrophy. In addition, the cervical spinal cord is atrophic in most patients (Fig. 35-3).⁵⁰ A recent positron emission tomography study showed a significant loss of striatal dopamine terminals in ataxic SCA2 patients that almost equaled that in patients with Parkinson's disease.⁵⁵

PROGNOSIS AND FUTURE PERSPECTIVES. SCA2 is a progressive disorder. On average, SCA2 patients become wheelchair-bound approximately 15 years after disease onset. Median survival after disease onset is approximately 25 years. Patients with disease onset in childhood appear to have a worse prognosis.

SPINOCEREBELLAR ATAXIA TYPE 3

PATHOGENESIS AND PATHOPHYSIOLOGY. The mutation causing SCA3 is a translated CAG repeat expansion in a gene coding for ataxin-3.⁵⁶ The SCA3 mutation was initially found in families with the Machado-Joseph disease phenotype. Machado-Joseph disease is a historical term used to denote a dominantly inherited ataxic disorder with large phenotypic variation that was first described in patients of Azorean descent.⁵⁷ After discovery of the gene mutation, it was determined that this mutation is frequently found in ataxia families of non-Azorean origin.

Whereas the repeat length of the SCA3 gene in normals varies between 14 and 37 trinucleotides, SCA3 patients have one allele within a range of 55 to 84 repeat units (see Fig. 35-2A). Both the normal and mutated SCA3 genes contain uninterrupted CAG stretches. Expanded SCA3 alleles display intergenerational instability with a tendency to further expansion. As shown by a worldwide haplotype analysis, the majority of abnormal alleles are derived from two founder mutations that originated in Portuguese families settling on the Azores.⁵⁸

The gene product of the SCA3 gene, ataxin-3, has deubiquitinating properties and acts as a transcriptional corepressor. Overexpression of normal ataxin-3 prevents polyglutamine-induced neurodegeneration, suggesting that a loss of the physiological ataxin-3 action could contribute to the pathogenesis of SCA3.⁵⁹

SCA3 is a multisystemic disorder characterized by degeneration of spinocerebellar tracts, dentate nucleus, pontine and other brain stem nuclei, substantia nigra, and pallidum. In contrast to most other SCAs, the cerebellar cortex and the inferior olives are widely spared. Nuclear inclusions containing expanded ataxin-3 have been found in neurons of affected brain regions.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Disease onset in SCA3 varies, occurring between early childhood and late adulthood with features of anticipation.

Figure 35-3. T1-weighted MRIs of infratentorial brain structures and cervical spine cord in different types of degenerative ataxia. The images show the posterior fossa in the midsagittal plane (*top left*) and axial slices at the level of the middle cerebellar peduncles (*top right*), inferior olive complex (*bottom left*), and dens axis (*bottom right*). **A**, Normal. **B**, SCA2. There is severe cerebellar and brain stem shrinkage, suggesting the presence of OPCA. In addition, the cervical spinal cord is atrophic. **C**, SCA3. There is only mild cerebellar vermal atrophy with additional involvement of the spinal cord. **D**, MSA-C. There is severe cerebellar and brain stem shrinkage, suggesting the presence of OPCA. The cervical spinal cord has normal size.

On average, the disease starts at approximately the age of 40 years. Age at disease onset is inversely correlated with CAG repeat length (see Fig. 35-2B). The clinical picture of SCA3 is characterized by a wide range of clinical manifestations, the precise nature of which partly depends on repeat length. All SCA3 patients suffer from a progressive syndrome with ataxia of gait and stance, ataxia of limb movements, and dysarthria. Vertical or horizontal gaze palsy are frequent additional findings, which occur independently of age of onset. Saccade velocity is usually normal. Dementia, basal ganglia symptoms, pale discs, and bladder dysfunction are absent in most cases. Patients with a repeat length of more than 74 have an early disease onset, usually before 30 years, and clinical features of pyramidal tract and basal ganglia involvement. Most of these patients have increased tendon reflexes, extensor plantar responses, spasticity, and dystonia. Patients with an intermediate repeat length of 71 to 74 units have a disease onset in middle age and show mainly ataxia and gaze palsy. Patients with a repeat length of less than 71 have a later disease onset and show signs of peripheral neuropathy with loss of tendon reflexes, amyotrophy, and decreased vibration sense. However, the boundaries between these clinical syndromes are vague, and the clinical phenotype of an individual may change with progression of the disease. Therefore, we do not advocate dividing SCA3/MJD patients into clinical subtypes (Video 207, Spinal Cerebellar Atrophy III).⁵⁹⁻⁶¹

DIFFERENTIAL DIAGNOSIS AND EVALUATION. Diagnosis of SCA3 is made by demonstration of CAG repeat expansion at the SCA3 locus. Clinically, SCA3 cannot be distinguished with certainty from other SCAs.

The results of electrophysiological investigations resemble those in SCA2 with evidence for peripheral axonal neuropathy and posterior column involvement, whereas MEPs to transcranial magnetic stimulation and VEPs are normal in most patients. On MRI, the cerebellum and brain stem appear normal or only moderately shrunken. As in SCA1 and SCA2, the cervical spinal cord is atrophic in most patients (Fig. 35-3).

PROGNOSIS AND FUTURE PERSPECTIVES. SCA3 is a progressive disorder. On average, SCA3 patients become wheelchair-bound approximately 15 years after disease onset. Median survival is 25 to 30 years. Progression is faster in patients with long repeats and early disease onset.

SPINOCEREBELLAR ATAXIA TYPE 6

PATHOGENESIS AND PATHOPHYSIOLOGY. The mutation causing SCA6 is a CAG repeat expansion in the 3' translated region of the CACNA1A gene coding for the α_{1A} voltage-dependent calcium channel subunit.⁶² Calcium channels containing the α_{1A} subunit mediate P- and Q-type currents. The α_{1A} subunit is expressed throughout the brain, with highest expression levels in cerebellar Purkinje cells. In contrast to other CAG repeat mutations, the expansions causing SCA6 are relatively short, ranging between 21 and 27, and do not undergo intergenerational length changes.⁶³

The pathogenesis of SCA6 is not completely understood. One hypothesis states that SCA6 is due to a gain-of-function

mechanism resembling that of other polyglutamine disorders. On the other hand, there is evidence for altered calcium channel function in SCA6 resulting in excessive influx of calcium ions into cerebellar Purkinje cells. The view that altered calcium channel function may be sufficient to cause progressive ataxia is supported by the observation that a missense mutation in the CACNA1A gene may cause progressive ataxia without episodic features.⁶² Both pathogenetic mechanisms, polyglutamine-induced gain of function and altered calcium channel function, do not appear to be mutually exclusive.

Autopsy studies of SCA6 patients consistently show a pure cerebellar degeneration with prominent loss of cerebellar Purkinje neurons. In contrast to other polyglutamine disease, neurons do not contain ubiquitinated nuclear inclusions but, rather, cytoplasmic inclusion containing channel protein.⁶⁴

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Disease onset in SCA6 is later than in other SCAs and varies, occurring between ages 30 and 75 years. Most patients become ataxic in their 50s. SCA6 patients suffer from a progressive cerebellar syndrome with ataxia of gait and stance, ataxia of limb movements, and dysarthria. Horizontal gaze-evoked nystagmus is almost universally present, and downbeat nystagmus is found in more than half of SCA6 patients. Other cerebellar oculomotor findings are also common, such as impaired smooth pursuit and dysmetric saccades. With disease progression, some SCA6 patients have clinical evidence of noncerebellar involvement, including pyramidal signs and mild sensory disturbances.⁶⁴

DIFFERENTIAL DIAGNOSIS AND EVALUATION. Diagnosis of SCA6 is made by demonstration of CAG repeat expansion of the CACNA1A gene. Clinically, SCA6 cannot be distinguished with certainty from other SCAs. Pure cerebellar presentation and late disease onset are suggestive of SCA6.

PROGNOSIS AND FUTURE PERSPECTIVES. SCA6 is a progressive disorder leading to physical disability. Compared to the other common SCAs, however, prognosis is better and life expectancy is not shortened.

SPINOCEREBELLAR ATAXIA TYPE 7

PATHOGENESIS AND PATHOPHYSIOLOGY. SCA7 is a rare, autosomal dominant ataxia that is distinct from all other SCAs in having the constant additional feature of retinal degeneration. The causative gene mutation is a translated CAG repeat expansion in a gene coding for ataxin-7. The normal range is 7 to 19 repeats, and the pathogenic alleles range from 37 to more than 300 repeats.⁶⁵ Expanded alleles are unstable with a strong tendency to further expansion, particularly in father-to-child transmission. SCA7 patients with childhood onset have almost always inherited the disease from their fathers. Ataxin-7 is widely expressed through the brain and localized in the cytoplasm of neurons. Ataxin-7, the gene product of the SCA7 gene, is an integral part of the transcription coactivator complex, STAGA, that is directly involved in the activation of photoreceptor genes. Polyglutamine expansion of ataxin-7 inhibits activity of this complex in a dominant-negative manner.⁶⁶

Neuropathological examinations of SCA7 patients consistently revealed olivopontocerebellar atrophy. All patients have primarily macular degeneration, which then spreads to involve the retina. There is often secondary atrophy of the optic nerve.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Disease onset in SCA7 varies between childhood and late adulthood with features of anticipation. Anticipation is greater when the disease is transmitted by males. On average, SCA7 starts at approximately age 25 years. The clinical picture and the course of the disease depend on the age of onset. In patients with late disease onset after the age of 40 years, cerebellar ataxia is the first symptom. There are some exceptional cases who never develop visual problems. In most patients, however, ataxia is followed by progressive loss of vision. In approximately half of patients with late disease onset, there is no evidence of retinal degeneration or optic atrophy, suggesting that retinopathy only affects the macula. All patients with earlier disease onset before the age of 40 years have visual problems, starting either prior to or at the same time as cerebellar ataxia. The majority of these patients have retinal degeneration, and some of them also have optic atrophy. Tendon reflexes are usually absent. There are a number of additional symptoms that occur in less than half of patients and that tend to be more frequent in patients with long disease duration. These symptoms include gaze palsy, dysphagia, hearing loss, and muscle weakness. Dementia and basal ganglia symptoms are not typical features of SCA7.⁶⁷

DIFFERENTIAL DIAGNOSIS AND EVALUATION. Diagnosis of SCA7 is made by demonstration of CAG repeat expansion of the SCA7 gene. SCA7 is highly probable in patients with ataxia in combination with progressive visual loss and a positive family history suggesting autosomal dominant inheritance.

MRIs show cerebellar and brain stem atrophy suggesting the presence of olivopontocerebellar atrophy. Electroretinography may be used for early detection of retinal degeneration.

PROGNOSIS AND FUTURE PERSPECTIVES. SCA7 is a progressive disorder. Disease progression is more rapid in patients with early disease onset. On average, patients with juvenile disease onset die 5 years after disease onset, whereas patients with adult onset survive for approximately 15 years.

SPINOCEREBELLAR ATAXIA TYPE 17

PATHOGENESIS AND PATHOPHYSIOLOGY. SCA17 is a rare, autosomal dominant disorder that is caused by a CAG/CAA repeat expansion in the TBP gene. The normal range is 25 to 42 repeats, and the pathogenic alleles range from 48 to more than 60 repeats. Alleles from 43 to 48 repeats appear to be not fully penetrant. As in other polyglutamine disorders, there is an inverse relationship between repeat length and disease onset. The pathogenesis of SCA17 has not been intensively studied. However, one may assume that SCA17 is at least partly due to reduced general transcription.⁴²

Neuropathological examinations of SCA17 patients revealed degeneration of the cerebellar cortex and inferior

olives. In addition, widespread distribution of neuronal intranuclear inclusions was found.⁶⁸

CLINICAL FEATURES AND ASSOCIATED DISORDERS. SCA17 has a very variable clinical presentation that differs from that of other SCAs by frequent manifestation of psychiatric abnormalities and dementia. The neurological features include progressive ataxia, parkinsonism, dystonia, and chorea. Some patients have a clinical presentation that is difficult to distinguish from that of Huntington's disease.⁶⁸

DIFFERENTIAL DIAGNOSIS AND EVALUATION. Diagnosis of SCA17 is made by demonstration of CAG/CAA repeat expansion of the TBP/SCA17 gene.

PROGNOSIS AND FUTURE PERSPECTIVES. SCA17 is a progressive disorder. Detailed information on the rate of disease progression and evolution of symptoms is lacking.

Dentatorubral Pallidoluysian Atrophy

PATHOGENESIS AND PATHOPHYSIOLOGY. DRPLA is an autosomal dominant disease occurring mainly in Japan. DRPLA patients show an unstable expanded CAG repeat within a coding region of the gene coding for atrophin. Whereas the repeat length in normals varies between 7 and 23 trinucleotides, DRPLA patients have one allele within a range of 49 to 79 repeat units. As in other trinucleotide repeat disorders, DRPLA alleles display intergenerational instability with a tendency to further expansion. Larger expansions frequently occur with paternal transmission. There is an inverse correlation between the length of the CAG repeat and the age of onset, with the largest alleles occurring in patients with juvenile disease onset. As a consequence of the intergenerational instability of expanded repeats, age of onset is variable with features of anticipation.⁶⁹

The degenerative pathological changes seen in DRPLA mainly affect the dentate nucleus, with its projection to the red nucleus, and the external pallidum, with its projection to the subthalamic nucleus. Usually, the dentatorubral system is more severely affected. Atrophy may also be present in other basal ganglia nuclei, the thalamus, and the inferior olives. In several cases, degeneration of posterior columns and spinocerebellar tracts has been described. Involvement of the pontine tegmentum has also been found, and this appears to correlate with oculomotor abnormalities.

EPIDEMIOLOGY AND RISK FACTORS. DRPLA has been predominantly reported in Japan, but diseases with similar features have occasionally been observed in non-Japanese families. The Haw River syndrome, a hereditary disease occurring in an African American family, is genetically identical with DRPLA.⁷⁰

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Disease onset in DRPLA varies between infancy and late adulthood with features of anticipation. On average, the onset of clinical features begins at approximately the age of 30 years. The clinical picture of DRPLA is characterized by a wide range of clinical manifestations, the precise nature of which depend on age of onset and repeat length. The most constant clinical findings in DRPLA are cerebellar ataxia, dysarthria, and progressive dementia. These features are present in almost all patients, irrespective

of age of onset and repeat length. Patients with disease onset before the age of 21 years and large expansions show the clinical syndrome of progressive myoclonus epilepsy. Some of them have opsoclonus. In patients with later disease onset and shorter expansions, myoclonus and seizures are less prominent. Instead, many of these patients have involuntary choreic or dystonic movements and psychiatric abnormalities, including personality changes, hallucinations, and delusional ideas. Various oculomotor disturbances have been described, including gaze-evoked nystagmus, broken up smooth pursuit, square wave jerks, and vertical gaze palsy.⁷¹

DIFFERENTIAL DIAGNOSIS AND EVALUATION. The diagnosis of DRPLA is made by demonstration of an expanded CAG repeat at the DRPLA locus. The differential diagnosis of juvenile-onset cases presenting with progressive myoclonus epilepsy includes Unverricht-Lundborg disease, mitochondrial encephalomyopathy with ragged red fibers, neuronal ceroid-lipofuscinosis, Lafora body disease, and sialidosis. Adult-onset cases of DRPLA may be confused with Huntington's disease. Clinically, the presence of ataxia and seizures makes Huntington's disease unlikely and points to a diagnosis of DRPLA. DRPLA is distinct from SCAs in having the clinical feature of dementia. A syndrome of ataxia, myoclonus, and rapid cognitive decline similar to that in DRPLA may occur in Creutzfeldt-Jakob disease. Compared to DRPLA, however, progression is usually faster in Creutzfeldt-Jakob disease. In exceptional cases, DRPLA may be mistaken for schizophrenia.

The electroencephalographic (EEG) background activity is slowed in approximately 80% of DRPLA patients. More than half have epileptiform EEG patterns, and in approximately one-third EEG reveals photosensitivity. MRIs of DRPLA patients show atrophy of the superior cerebellar peduncles. In addition, T2-weighted images show high-intensity signals in the pallidum.⁷²

MANAGEMENT. There is no specific treatment for DRPLA. DRPLA patients with epilepsy require standard antiepileptic treatment. Phenytoin should be avoided because it may worsen ataxia.

PROGNOSIS AND FUTURE PERSPECTIVES. DRPLA is a progressive disorder. Quantitative data concerning rate of progression in DRPLA are not available.

Episodic Ataxia

EPISODIC ATAXIA TYPE 1

PATHOGENESIS AND PATHOPHYSIOLOGY. Episodic ataxia type 1 (EA-1) is an autosomal dominant disorder. EA-1 is due to a missense mutation in the potassium channel gene, KCNA1, on chromosome 12p leading to inefficient repolarization of the nerve cell membrane subsequent to an action potential.⁷³

EPIDEMIOLOGY AND RISK FACTORS. EA-1 is a rare familial disorder. Information concerning the epidemiology of this disorder is not available.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Disease onset of EA-1 occurs in early childhood. Clinically, EA-1 is characterized by brief attacks of ataxia and dysarthria. The attacks last for seconds to minutes and

may occur several times per day. They are often provoked by movements and startle. Apart from ataxia, the attacks may have dystonic or choreic features. EA-1 is associated with interictal myokymia (i.e., twitching of small muscles around the eyes or in the hands). Ataxia or gaze-evoked nystagmus are absent between attacks.⁷⁴

DIFFERENTIAL DIAGNOSIS AND EVALUATION. A routine molecular genetic test for EA-1 is not available because different point mutations within the KCNA1 gene may lead to the disorder. Clinically, EA-1 can be differentiated from EA-2 (see later discussion) by the shorter duration of the attacks, the presence of myokymia, and the absence of interictal ataxia and nystagmus. A number of rare metabolic defects of autosomal recessive inheritance may give rise to intermittent ataxia. These disorders include metabolic syndromes with hyperammonemia, aminoacidurias without hyperammonemia, and disorders of pyruvate and lactate metabolism.

Interictal EMG of muscles displaying myokymia shows spontaneous repetitive discharges that subside after nerve blockade. These abnormalities have also been termed neuromyotonia.⁷⁵ Nerve conduction and evoked potential studies do not reveal additional abnormalities. MRIs of the head are normal.

MANAGEMENT. Acetazolamide (2 × 250 mg/day) is of benefit in reducing attacks in some but not all kindreds. Anticonvulsants are used to reduce myokymia.

PROGNOSIS AND FUTURE PERSPECTIVES. EA-1 has a favorable prognosis in that attacks tend to abate after early childhood.

EPISODIC ATAXIA TYPE 2

PATHOGENESIS AND PATHOPHYSIOLOGY. EA-2 is a rare disorder caused by nonsense mutations causing truncation of the CACNA1A gene coding for the α_{1A} voltage-dependent calcium channel subunit.⁷⁵ Missense mutations of the same gene are associated with familial hemiplegic migraine, whereas a CAG repeat expansion in the 3' end of the gene causes SCA6.^{62,75}

EPIDEMIOLOGY AND RISK FACTORS. EA-2 is a rare familial disorder. Information concerning the epidemiology of this disorder is not available.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Clinical onset of EA-2 is usually during childhood, varying from 6 weeks to 30 years. EA-2 is clinically characterized by recurrence of acute attacks of ataxia of gait and stance, limb ataxia (Video 14, Tremor with Ataxia), and dysarthria. The attacks last from several hours to a day or more. Emotional stress, exercise, and fatigue, but not movements or startle, may precipitate the attacks. The frequency of attacks varies widely from several times per day to less than once per month. Neurological examination between attacks discloses mild gait ataxia and gaze-evoked nystagmus. Some patients develop progressive ataxia and dysarthria.⁷⁶

DIFFERENTIAL DIAGNOSIS AND EVALUATION. Because a genetic test for EA-2 is not routinely available, the diagnosis is based on a carefully taken history and clinical examination. Compared to EA-1, attacks in EA-2 last

longer and are not provoked by movements or startle. In addition, EA-2 patients may have mild interictal ataxia. The differential diagnosis of EA-2 corresponds to that in EA-1.

EA-2 is often associated with MRI abnormalities. In particular, patients with progressive interictal ataxia show atrophy of the cerebellar vermis.⁷⁷

MANAGEMENT. Continued acetazolamide (2 × 250 mg/day) therapy completely abolishes episodes of ataxia in EA-2. Cessation of acetazolamide usually prompts rapid recurrence of the attacks.⁷⁸

PROGNOSIS AND FUTURE PERSPECTIVES. Experience with EA-2 families treated with acetazolamide suggests that acetazolamide remains effective in reducing attacks for up to 20 years.

NONHEREDITARY, IDIOPATHIC CEREBELLAR ATAXIA

Multiple System Atrophy

PATHOGENESIS AND PATHOPHYSIOLOGY. Multiple system atrophy (MSA) is a sporadic, adult-onset disease characterized by neurodegeneration in the basal ganglia, brain stem, cerebellum, and intermediolateral cell columns of the spinal cord. MSA encompasses the former disease categories striatonigral degeneration, sporadic olivopontocerebellar atrophy, and Shy-Drager syndrome. The ultrastructural hallmark of MSA is the presence of oligodendroglial cytoplasmic inclusions. MSA patients present with various combinations of parkinsonism, cerebellar ataxia, and autonomic failure (orthostatic hypotension and urinary incontinence).⁷⁹ Cerebellar ataxia is present in more than half of MSA patients.⁸⁰ According to the prominent clinical presentation, MSA has been subdivided into a parkinsonian type (MSA-P) and a cerebellar type (MSA-C). The etiology of MSA is unknown.

EPIDEMIOLOGY AND RISK FACTORS. The age-adjusted prevalence of MSA is 4.4 per 100,000.⁸¹ There are no known genetic or environmental risk factors for MSA.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. On average, MSA starts at approximately age 55 years. MSA-C is clinically characterized by a progressive cerebellar syndrome with ataxia of gait and stance, ataxia of limb movements, dysarthria, and cerebellar oculomotor abnormalities (gaze-evoked nystagmus, saccade hypermetria, broken up smooth pursuit, reduced optokinetic nystagmus, and impaired suppression of vestibulo-ocular reflex by fixation). In addition, MSA-C patients have autonomic failure, including orthostatic hypotension, bladder dysfunction, and erectile dysfunction in males. Neurological non-cerebellar symptoms include akinetic-rigid parkinsonism, pyramidal tract signs, and myoclonus. Autonomic symptoms may be present years before manifestation of ataxia, may occur simultaneously with ataxia, or may develop later.^{82,83}

DIFFERENTIAL DIAGNOSIS AND EVALUATION. The clinical phenotype of advanced MSA-C consisting of ataxia, parkinsonism, and autonomic failure is highly characteristic and will rarely give rise to confusion with other disorders. In contrast, incomplete or beginning forms of MSA-C must be carefully distinguished from sporadic

ataxia of unknown etiology and symptomatic cerebellar ataxia. Degeneration of the cerebellar cortex with chronic cerebellar ataxia may be due to alcoholism, various toxic causes (antiepileptic drugs, cytostatic drugs, lithium, solvents, and heavy metals), remote effects of malignancy (paraneoplastic cerebellar degeneration), malabsorption with vitamin E deficiency, increased body temperature (heat shock, neuroleptic malignant syndrome, and sepsis), and hypothyroidism.

On MRI, MSA patients have olivopontocerebellar atrophy with diffuse cerebellar atrophy and additional shrinkage of the base of the pons and the middle cerebellar peduncles (Fig. 35-4A). T2-weighted images in MSA often show hypointense signal in the putamen suggesting basal ganglia involvement. In addition, there are hyperintensities in the pons and middle cerebellar peduncles reflecting degeneration and gliosis of pontocerebellar fibers (Fig. 35-4B). However, these are not early signs, and their absence does not exclude a diagnosis of MSA.⁸⁴

MANAGEMENT. There is no curative or preventive treatment for MSA. Among the cardinal symptoms of MSA—cerebellar ataxia, parkinsonism, and autonomic failure—ataxia is the most difficult to treat. As in other types of ataxias, a trial with 5-hydroxytryptophan, amantadine, or buspirone may be done, although there are no controlled trials that clearly demonstrate the efficacy of these drugs in relieving ataxia. Physical therapy is recommended. Parkinsonism and autonomic failure in MSA require adequate symptomatic treatment. Parkinsonian symptoms in MSA respond to dopaminergic medication, although the response is less robust than in idiopathic Parkinson's disease. Many patients develop urinary retention and have to be supplied with suprapubic catheters. For management of orthostatic hypotension, elastic stockings and oral treatment with mineralocorticoids are recommended.

PROGNOSIS AND FUTURE PERSPECTIVES. MSA has a poor prognosis. Patients become wheelchair-bound approximately 5 years after disease onset. Median survival after disease onset is 8 to 10 years.⁵¹

Sporadic Adult-Onset Ataxia of Unknown Etiology

In many patients with sporadic adult-onset progressive ataxia, the underlying cause remains unknown. A population-based epidemiological study performed in southeast Wales found a crude prevalence rate of 8.4:100,000 of sporadic adult-onset ataxia.⁸⁵ Cerebellar ataxia is the prominent symptom of sporadic ataxia, but more than half have clinical features suggesting additional involvement of pyramidal tracts, posterior columns, and the peripheral nervous system. Age of onset is approximately 50 years, and life expectancy is almost normal.⁸⁶

The diagnosis of sporadic ataxia of unknown etiology is made by exclusion. As in MSA, symptomatic causes of cerebellar ataxia have to be carefully excluded. Sporadic ataxia of unknown etiology is distinguished from MSA by the absence of autonomic failure and parkinsonism. In early disease stages, a distinction between MSA-C and sporadic ataxia of unknown etiology is often impossible. Most patients have isolated cerebellar atrophy with little or no involvement of the brain stem. There are no specific treatment approaches for sporadic adult-onset ataxia.

Figure 35-4. T2-weighted MRIs of the basal ganglia, pons, and middle cerebellar peduncles in MSA-C. **A,** Hypointensities of basal ganglia. *Top left,* normal. *Top right,* hypointensity at the dorsolateral margin of the putamen in the beginning MSA-C. *Bottom left,* strong hypointensity extending through part of the body of putamen in MSA-C. *Bottom right,* hypointensity extending throughout the putamen, with intensity exceeding that in globus pallidus in late-stage MSA-C. Note the hyperintensity at the lateral putamen border. **B,** Hyperintensities in the upper pons (*left*) and middle cerebellar peduncles (*right*). *Top,* normal. *Bottom,* hyperintensities of the transverse pontine fibers between tegmentum and the base of pons (*left*) and in the middle cerebellar peduncles (*right*) in MSA-C.

HISTORY AND DEFINITIONS

The disorders discussed in this chapter have been characterized over time by several generations of clinicians and scientists according to clinical presentation, muscle and nerve pathology, and electrophysiology. With the application of molecular biology techniques starting in the mid-1980s, it became possible to begin understanding these diseases at the molecular level. Several of them are clearly monogenic in origin, such as Duchenne and Becker muscular dystrophy, whereas others, such as sporadic amyotrophic lateral sclerosis, most likely result from the interaction of several genes with environmental factors. Work is rapidly progressing in identifying genes and gene products and function that will eventually lead to prophylactic as well as therapeutic intervention for these disorders.

UPPER AND LOWER MOTOR NEURON DEGENERATIVE DISORDERS

Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis (ALS), which is also called motor neuron disease, Charcot's disease, or Lou Gehrig disease, is an age-dependent and generally fatal paralytic disorder caused by the degeneration of motor neurons in the motor cortex, brain stem, and spinal cord. Approximately 10% of cases are familial (FALS) and the rest are sporadic (SALS).

PATHOGENESIS AND PATHOPHYSIOLOGY. ALS is a primary disorder of motor cells and their axons. The hallmark of ALS is atrophy, degeneration, and loss of motor neurons in the lower brain stem and anterior horn of the spinal cord, followed by astrocytic replacement and proliferation and microglial activation. There is loss of pyramidal cells from the motor cortex of the prefrontal gyrus and large myelinated fibers of the anterior and lateral columns

of the spinal cord, the brain stem, and the cerebrum. The posterior columns are usually spared in SALS. Lower brain stem nuclei are more often and more extensively involved than the upper brain stem nuclei (Fig. 36-1). Therefore, neuronal loss in the oculomotor nuclei is modest and rarely demonstrable clinically, whereas the neurons of the hypoglossal nuclei are severely affected. Previously, it was thought that Clarke's nucleus was unaffected, but it is now recognized that those neurons may also degenerate. Additionally, there is increasing attention being paid to frontotemporal involvement, ranging from mild, barely discernible executive function impairment to incapacitating behavioral manifestations.¹ In patients who have an extended disease course due to parenteral nutrition and artificial ventilation, there may be late involvement of oculomotor and sacral nuclei. Autonomic dysfunction has also been reported.² Several cytoplasmic and ultrastructural abnormalities are associated with ALS. Spheroids with a strongly argentophilic fibrillary pattern develop in conjunction with cell soma atrophy, suggesting these may be complementary processes. Ultrastructurally, the spheroids are neurofilament bundles that may contain other cytoplasmic structures, such as mitochondria. Some investigators hypothesize that the reported increase in phosphorylated neurofilaments identified using monoclonal antibodies reflects premature or excessive neurofilament phosphorylation that may be associated with impaired neurofilament transport. Other identified structures include Bunina bodies, tiny round eosinophilic structures that may be found in neuronal cytoplasm, and Lewy body-like eosinophilic inclusions found in both SALS and FALS. The latter are immunoreactive to neurofilaments, ubiquitin, and Cu/Zn superoxide dismutase (SOD1).³

Genetic linkage identified SOD1 at 21q22.1 as the cause in 20% of autosomal dominant familial cases (genetic nomenclature, ALS1). Different SOD1 mutations of ALS1 do not seem to influence age of onset, but they do influence the progression of the disease, with the A4V mutation duration averaging 1.2 years, the E100G mutation averaging

Figure 36-1. Spinal cord section from J.-M. Charcot's original presentations on amyotrophic lateral sclerosis, showing the combined anterior horn cell degeneration (f) and the sclerosis of the lateral columns (a). Anterior (c) and posterior (p) horn regions as normal anatomical landmarks inserted as reference points by Charcot. (From Charcot J-M: *Oeuvres Complètes*. Paris, Bureau du Progrès Médical, 1873.)

4.7 years, and the H46R and G37R mutations averaging 18 to 20 years.⁴

Identification of the SOD1 gene in FALS has provided the first opportunity to study a type of ALS with a proven etiology. SALS is not associated with mutations in SOD1 but it is clinically indistinguishable from ALS1 and pathologically very similar; therefore, it is postulated that there may be a common pathway involved in the two forms of ALS. Thus, the ALS phenotype may result from a variety of disruptions in the events required for motor neuron maintenance. Consequently, much research on the pathogenesis of motor neuron disease has focused on SOD1, an endogenous free radical scavenger enzyme. SOD1 normally functions as a dismutase, converting superoxide to oxygen and hydrogen peroxide, and is thought to have peroxidase and Cu sequestration properties. Superoxide is an unstable and highly active molecule that causes oxidation of cell constituents either directly or through toxic and stable derivatives. Often, there is a 35% to 75% reduction in activity of mutant SOD1 in ALS1, but there is no reduction in SOD1 activity in other forms of FALS. In most instances, loss of SOD1 enzyme activity appears to be due to structural instability, resulting in a shortened half-life of the mutant SOD1 protein.

Early on, exploration of mechanisms by which mutant SOD1 causes motor neuron degeneration focused on exaggerated or disturbed functions of SOD1. However, experiments with transgenic mice expressing different mutations suggest that it is unlikely that the disease phenotype is caused by a position effect of the mutations in the SOD1 gene. Whereas most, but not all, transgenic mice overexpressing mutant SOD1 develop ALS-like disease, mice overexpressing wild-type SOD1 or SOD1-deficient mice do not. This suggests mutant SOD1 must reach a threshold in its expression, where it then causes disease through the gain of a toxic property, a toxic mechanism that may also underlie FALS in humans.^{4,5} Although it is still not fully clear how the 100-plus SOD1 mutations gain this common toxic property, two major hypotheses have been put forth.⁶ Although normal SOD1 activity serves as an antioxidant

defense, the peroxidase, superoxide reductase, and superoxide generating properties of mutant SOD1 lead to the formation of toxic species such as peroxyxynitrite, superoxide, and decomposition products of hydrogen peroxide. The second stems from observation of mutant SOD1 aggregates in SOD1 mutant transgenic mice and ALS1 patients, aggregates that may either be toxic or may trap other proteins, preventing their normal functioning.⁷ Investigations in our laboratory with double transgenic mice established that wild-type SOD1 is recruited in the presence of mutant SOD1, not only hastening disease onset in G93A and L126Z mutant mice but also converting the otherwise unaffected A4V mutant mice into diseased mice. Analyses of spinal cord tissue of these double transgenic mice revealed this phenomenon is accompanied by conversion of both mutant and wild-type SOD1 from a soluble to an aggregated and detergent-insoluble form. This conversion, observed in the mitochondrial fraction of the spinal cord, involved formation of insoluble SOD1 dimers and multimers that are cross-linked through intermolecular disulfide bonds. The dimers may act as seed in forming toxic intermediate species with possible membrane disrupting properties. It is evident that SOD1, normally an important protein in cellular defense against free radicals, is converted to an aggregated and apparently toxic species by redox processes, demonstrating direct links between oxidation, protein aggregation, mitochondrial damage, and SOD1-mediated ALS.⁸

Rare recessive familial ALS (RFALS), which produces three different phenotypes classified according to type and timing of motor neuron involvement, has been identified in highly consanguineous families. The gene for RFALS type 3 (genetic nomenclature, ALS2) has been identified on chromosome 2. It codes for the protein alsin, which is expressed in various tissues in the body, including the brain, liver, and spinal cord. It is postulated there is a loss of normal function with an ALS phenotype occurring from mutations that affect the RCC1 domains close to the N-terminal region of ALSIN and thus usually both long and short transcripts of alsin may be nonfunctional. A milder primary lateral sclerosis (PLS) phenotype occurs from more distal mutations resulting in an intact RCC1 domain and perhaps a short protein that may allow the preservation of some function.⁹ The sequence of the putative protein alsin contains three domains with homology to motifs found in guanine-nucleotide exchange factors for GTPases, proteins with roles in axonal outgrowth, signaling cascades, and vesicular trafficking.^{9,10} This second ALS gene sets the precedent that proteins related to the function of small GTPases and proteins involved in vesicular trafficking are determinants of motor neuron viability. Mutations in the gene for dynactin have been identified in a single family with progressive muscular atrophy, a disorder without upper motor neuron signs inherited as a dominant trait with a phenotype similar to Kennedy disease,¹¹ which is of interest because dynactin is the molecular motor for retrograde axonal transport. Axonal transport is also affected in the SOD1 animal model of ALS.¹² In recent years, other putative new loci in dominant ALS have been reported. Linkage to the X chromosome was reported by our group, and that to chromosome 18q21 by others, each for one large ALS kindred with typical adult onset.^{13,14}

A second locus has been identified for FTD/ALS at 9p21.¹⁵ Work suggests that deletions of the heavy neurofilament subunit tail may be a primary, although extremely rare, occurrence in both SALS and FALS,¹⁶ although the relationship between such deletions and ALS is still unclear.

In genetic research, the risk to relatives of an affected person compared to the general population can be calculated, where greater risk corresponds to a larger genetic control over the trait. The estimated risk to siblings of ALS patients suggests that there is a significant genetic contribution. ALS1 represents a large genetic effect in a small ALS population (2.5% of ALS cases). Conversely, SALS may result from a genetic predisposition due to multiple small effects in larger ALS populations. Thus, newer applications of techniques to identify associations of common polymorphisms to SALS using the transmission disequilibrium test are being applied to SALS. Several genes have been examined in efforts to determine their roles in SALS. The apolipoprotein E (ApoE) gene polymorphisms comprising the ApoE2, ApoE3, and ApoE4 alleles have been the focus of at least six association studies with ALS,^{17–21} with the most recent suggesting the ApoE effect is on the age at onset rather than on risk of developing disease. Since E2 is associated with later onset, it is therefore protective against earlier onset.²² Vascular endothelial growth factor (VEGF) generated interest as a candidate gene when it was noted that mice with impaired expression of VEGF developed adult-onset progressive motor neuron degeneration, with neuropathological and clinical signs reminiscent of human ALS,²³ and that administration of intraventricular recombinant VEGF prolonged survival of G93A SOD1 rats.²⁴ A case control meta-analysis of three Belgian, Swedish, and British populations demonstrated an association with three polymorphisms known to affect VEGF expression. However, no association was found in a different subset of the British population,²⁵ a Dutch cohort,²⁶ or our own North American cohort.²⁷ Interestingly, in an Irish population, a single nucleotide polymorphism of the related protein angiogenin was associated with SALS.²⁸ Our own work using a family-based model of SALS suggests the paraoxanase gene cluster is a strong susceptibility variant.²⁹ Additional genes that may be involved in glutamate transporter, calcium homeostasis, apoptosis, mitochondrial dysfunction, protein degradation pathways, or intracellular protein cargo transport are reasonable candidates for evaluation.^{2,9}

A number of abnormalities in metabolism of the excitatory neurotransmitter glutamate have been identified in ALS, including alterations in tissue glutamate levels, transporter proteins, postsynaptic receptors, and indications of possible toxic agonists. Whether these are primary or secondary events and how they relate to the genesis of ALS is unclear but continues to be under investigation.³⁰

EPIDEMIOLOGY AND RISK FACTORS. Broadly, there are three types of ALS usually considered in epidemiological studies: SALS, FALS, and a variant of ALS, sometimes called Guamanian ALS, found in the Western Pacific and characterized by the occurrence of parkinsonism, dementia, or both. SALS has a worldwide incidence of 1 or 2 in 100,000 people, with fairly uniform distribution worldwide and equal representation among racial groups. The occurrence of ALS before the age of 40 years is uncommon. The incidence is greatest between the ages of 50

and 70 years, and it seems to decline thereafter. The male-to-female ratio is approximately 1.3:1. Clusters of the disease have been identified, particularly in the Kii peninsula of Japan and the Mariana Islands. The only indisputable risk factor other than age and gender is genetic susceptibility, with familial cases occurring in approximately 10% of most case series. Many isolated potential etiologies have been proposed for SALS, with the only consistent associations thus far being long-term exposure to heavy metals, particularly lead, and a family history of parkinsonism and dementia. There is evidence of association between increased dietary fat and cigarette smoking.^{31–33} Curiously, cigarette smoking is negatively associated with the development of Parkinson's disease. Electrical injury has also been reported to increase the risk of ALS.³⁴ Both enteroviruses and retroviruses have been implicated,^{35–37} but the significance of these reports is uncertain. Recent reports describe a possible twofold increase in the risk of developing ALS for Gulf War veterans.^{38,39} Although these studies had drawbacks, they do suggest the possibility that war-related exposures may affect genetically vulnerable individuals, and they raise the wider question of the deleterious effect of the modern war machine on the nervous system of combatants.

CLINICAL AND ASSOCIATED DISORDERS. ALS is a syndrome of upper and lower motor neuron dysfunction at several levels of the neuraxis without involvement of other neurological systems. There is no definitive test that can diagnose ALS. In 1994, the El Escorial criteria were developed to standardize its diagnosis for research studies (Table 36-1).⁴⁰ Although the disease may present in many different ways and in different parts of the body, generally the patient seeks attention because of symptomatic weakness. Alternatively, there may be a history of fasciculations, muscle cramping, and atrophy before weakness is apparent. A frequent diagnostic feature is the presence of

TABLE 36-1

Summary of El Escorial Criteria for the Diagnosis of Amyotrophic Lateral Sclerosis (ALS)

| | |
|---|--|
| The diagnosis of ALS requires the presence of signs of lower motor neuron (LMN) degeneration by clinical, electrophysiological, or neuropathological examination and signs of upper motor neuron (UMN) degeneration by clinical examination, and the progressive spread of these signs within a region or to other regions, together with the absence of electrophysiological or neuroimaging evidence of other disease processes that might explain these signs. | |
| Suspected ALS | LMN signs only in at least two regions |
| Possible ALS | UMN and LMN signs in only one region, or UMN signs only in at least two regions, or LMN signs rostral to UMN signs Special cases: monomelic ALS, progressive bulbar palsy without spinal UMN and/or LMN signs, primary lateral sclerosis without spinal LMN signs |
| Probable ALS | UMN signs in at least two regions, with some UMN signs above LMN signs |
| Definite ALS | UMN signs and LMN signs in bulbar region and at least two spinal regions, or UMN and LMN signs in three spinal regions |

segmental hyper-reflexia in regions of muscle atrophy and an absence of sensory disturbance in the same distribution. Limb involvement occurs more often than bulbar involvement, and upper limbs are more often affected than lower limbs in SALS; this pattern is reversed in FALS. However, the pattern of involvement is frequently asymmetrical or focal. If more upper motor neurons are affected, the symptoms will be primarily gait difficulty, clumsiness, stiffness, and fatigue, whereas lower motor neuron degeneration will present as weakness or atrophy and occasionally fasciculations. Bulbar symptoms include hoarseness, slurring of speech, choking on liquids, and difficulty initiating swallowing. Paresthesias and sensory symptoms affect up to 25% of patients, but if present, these complaints are generally mild. There is wide variation in disease progression and duration, neither of which can be accurately predicted from age or site of onset, although generally elderly patients have a shorter survival. Bowel, bladder, and sexual functioning are usually spared, with approximately 4% of patients experiencing loss of sphincter control. ALS patients have diminished skin elasticity and rarely develop bedsores, seemingly because of the accumulation of a basic protein there.^{3,41} Although fasciculations, especially of the tongue (Video 43, Tongue Fasciculations), are considered by some to be specifically associated with ALS, they may actually be seen in any disorder affecting the motor neuron or their axons. Remote effect of radiation damage to the hypoglossal nerve is a case in point.

There has been controversy throughout the years whether syndromes that are confined to one type of motor neuron are distinct from ALS or are a variant of ALS. Primary lateral sclerosis and progressive pseudobulbar palsy are both syndromes confined to the upper motor neuron, whereas progressive muscular atrophy and progressive bulbar palsy affect only the lower motor neuron. Because all of these phenotypes are sometimes produced by the same mutation in the SOD1 gene, and mutations in the gene for alsin can produce either ALS or PLS, it is generally now accepted that these phenotypes could result from similar processes.

In FALS associated with dementia (see Chapter 33), characterized by the association of frontal lobe dementia with parkinsonism and amyotrophy, the clinical symptoms of dementia vary to a remarkable extent. Whereas disinhibition and/or depression are common features, the amyotrophy may be prominent in some patients and absent in others.⁴²

Guamanian ALS first came to the attention of the medical community in the early 1950s when it was detected in a severalfold higher incidence in Guam than elsewhere (see Chapter 34). It is associated with parkinsonism and dementia in some patients. The incidence has been declining in the intervening years, but there has been an increase in the number of recognized persons with parkinsonism and dementia. This syndrome may include supranuclear gaze paresis (Video 55, Supranuclear Gaze Paresis). Its etiology is unclear. There has been interest in cycad flour as the source of an excitatory amino acid that causes a motor neuron disease in cynomolgus monkeys, but the amounts eaten by Guamanians in their flour appear insufficient to cause the disease. It has also been proposed that low levels of calcium and magnesium in the local environment may lead to chronic mild hyperparathyroidism with intraneuronal

depositions of calcium hydroxyapatite and aluminum.³¹ Although recently examination into the possible genetic origins of the syndrome has begun (see Chapters 33 and 34), attention has also been directed toward neurotoxins originating in the cycad.⁴³

DIFFERENTIAL DIAGNOSIS AND EVALUATION.

Within disorders of the motor neuron, the most difficult distinctions are among progressive muscular atrophy (PMA), proximal spinal muscular atrophy (SMA) (Video 33, Spinal Muscular Atrophy), spinobulbar muscular atrophy (SBMA or Kennedy disease), PLS, and hereditary spastic paraplegia (HSP) when there is no clear family history. Generally, progressive muscular atrophy is a progressive, asymmetrical lower motor neuron degeneration that has a later onset and can affect distal and proximal muscle, resulting in severe disability. The A4V mutation in SOD1 leads to PMA and death within 12 months. SMA usually occurs in younger people and is symmetrical (see later discussion in this chapter). SBMA may have gynecomastia and tongue atrophy. HSP may be distinguished from primary lateral sclerosis by spasticity restricted to the lower extremities and normal upper extremity function. Hyper-reflexia and the presence of extensor plantar response and brisk superficial abdominal reflexes are common to both. Generally, PLS is a disease of later onset that eventually affects all extremities and bulbar function, although disease caused by alsin mutation may cause infantile or juvenile PLS.

Electromyographic (EMG) features commonly seen include fibrillation, positive sharp waves, and complex repetitive discharges that indicate denervation. Simultaneously, reduced numbers and increased amplitude and duration of motor unit potentials indicate reinnervation. Multifocal fasciculations are also characteristic of the disease. Increased jitter on single-fiber EMG reflects immature endplates and inefficient reinnervation. Cerebrospinal fluid examination either is normal or shows mildly elevated protein (<100 mg/dL). There may be a moderate increase in creatine kinase (CK) of the muscle enzyme type.

Muscle biopsy demonstrates pyknotic nuclear clumps and small angulated fibers, small or large groups of atrophic fibers, and evidence of type grouping on ATPase staining and target fibers of NADH-TR.³

MANAGEMENT AND FUTURE PERSPECTIVES. Thus far, only the benzothiazole riluzole has been shown to extend life span, although in double-blind studies, the extension averages only 3 months and mortality rates are unaffected. In larger follow-up studies, the increase in life has been claimed to be as long as 12 months.⁴⁴ Riluzole acts to block voltage-activated sodium channels and to protect against glutamate toxicity.⁴⁴ A multicenter, double-blind, randomized, placebo-controlled trial of 400 patients demonstrated that pentoxifylline is not beneficial in ALS and should be avoided in patients treated with riluzole.⁴⁵ The life span of transgenic mice expressing mutant human SOD1 was prolonged by 22% with intrathecal administration of a caspase inhibitor,⁴⁶ and human clinical trials are planned. Although there is no truly effective pharmacological treatment yet available for ALS, a supportive multidisciplinary team can provide care and symptom management that significantly improves the patient's quality of life. Drugs such as baclofen, quinine, and phenytoin can be used to reduce cramping; anticholinergic agents can be used to

control sialorrhea. Amitriptyline or selective serotonin reuptake inhibitors may help control pseudobulbar symptoms in some patients. Occupational therapy can provide techniques and orthotics that can extend the patient's ability to function independently. A speech pathologist can provide instruction to prolong the patient's ability to communicate and swallow. Augmentative communication devices are now covered by Medicare but require formal evaluation. Durable medical equipment (e.g., power-driven wheelchairs and hospital beds) allow most patients to remain at home. Open, sympathetic discussion of feeding and ventilatory support options is required with the patient and family. Bilevel positive airway pressure may provide at least short-term symptomatic relief of respiratory fatigue and sleep apnea. Algorithms for nutritional and respiratory management are available at the Web site of the American Academy of Neurology (www.aan.com). ALS remains a fatal disease, with a mean survival of 3 years after the onset of symptoms.³

Spinal Muscular Atrophies

The SMAs are diseases of the motor neurons of the medulla and spinal cord that most often present with muscle weakness in infancy and childhood. They may present with either proximal or distal weakness from the antenatal period onward. The inheritance pattern is most commonly autosomal recessive, but there are forms that are dominant and X linked (Table 36-2).

PATHOGENESIS AND PATHOPHYSIOLOGY. Information about the molecular basis for these disorders has exploded in the past few years. Both the severe and the milder forms of autosomal recessive SMA have been linked to chromosome 5q11.3-13.1, a region that contains multiple copies of genes and pseudogenes and is characterized by instability. Deletions, truncations, or point mutations in what is now called the gene for survival of motor neurons (SMN) have been identified in SMA types I, II, and III.⁴⁷ SMN exists in two or more copies arranged in

tandem in *cis* configuration: the telomeric copy, commonly called SMN1, and the centromeric copy, generally called SMN2. SMN1 does not produce a full-length transcript most of the time. Human study and conditional knockout models of SMA show that the SMA phenotype is dependent on the dosage of SMN product: The higher the level of SMN the milder the phenotype.⁴⁸ Conditional knockout models affecting only the expression of SMN in muscle show dystrophic change correlating with increased CK and calf hypertrophy in juvenile SMA.⁴⁹ Most patients (95% to 98%) have a deletion of exon 7 of SMN1, whereas the remainder are compound heterozygotes. Two percent of patients have de novo mutations.⁵⁰ It was recognized early that there is little correlation between specific SMN1 mutations and phenotype, although affected siblings usually exhibit the same phenotype, which suggested a modifying factor at work, possibly another gene tightly linked to the pathogenic gene. It now appears that increased SMN2 copy number results in milder phenotype.⁵¹ The protein product of SMN has no known homolog and its function is not yet fully known. It appears to be associated with RNA processing/translocation in the nucleus, and it may also be involved in axonal guidance during development of motor axon-muscle connection.⁵²

EPIDEMIOLOGY AND RISK FACTORS. The autosomal recessive SMAs are the most common heritable cause of death in infancy, with incidence estimates of 1 in 10,000 to 25,000 for type I in the Western world. Similar numbers are affected with the milder forms and forms with a later onset. Distal SMA of recessive inheritance is more common with consanguineous parents, whereas the dominant form is rare. X-linked adult SMA is also rare,⁵³ usually with onset in childhood, so it should not be confused with Kennedy disease.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. The three clinical hallmarks of this disorder are hypotonia, weakness, and cranial nerve palsies (Fig. 36-2), although the facial muscles are usually spared. Generally, SMA has an insidious onset of symmetrical weakness. The weakness can be global, although generally

TABLE 36-2

Types of Spinal Muscular Atrophy

| TYPE | INHERITANCE PATTERN | AGE OF ONSET | PRESENTING SYMPTOMS | HALLMARK | PROGNOSIS |
|--|---|-------------------------------------|--|--|---|
| SMA type I (severe infantile SMA, acute or fatal SMA, Werdnig-Hoffman, Oppenheim disease, amyotonia congenita) | AR | In utero to 6 months | Hypotonia and weakness; problems with sucking, swallowing, and breathing | Never able to sit | Average life expectancy is 8 months, 95% dead before age 1 year |
| SMA type II (intermediate) | AR | Generally between 3 and 15 months | Proximal leg weakness, fasciculations, fine hand tremor | Never able to stand; facial muscles spared | Dependent on extent and timing of respiratory complications |
| SMA type III (chronic SMA, Kugelberg-Welander) | AR, AD | 15 months to teen years | Proximal leg weakness, delayed motor milestones | | Dependent on extent and timing of respiratory complications |
| SMA type IV (adult-onset SMA) | AD, AR, or very rarely X-linked recessive | Median age of onset, 37 years | Proximal weakness; variable within families; more severe in AD form | | Life expectancy not markedly reduced |
| Distal SMA (progressive SMA, Charcot-Marie-Tooth-type SMA) | AR, AD | AR: birth or infancy; AD: adulthood | Distal weakness | | Very slow clinical progression; does not alter life span |

AD, autosomal dominant; AR, autosomal recessive.

Figure 36-2. A baby with spinal muscular atrophy, showing the flaccid head lag in the supine position. (From Dubowitz V: *Muscle Disorders in Childhood*. Philadelphia, Saunders, 1995.)

proximal muscles are weakened before distal ones, and the legs become markedly weak before the arms are severely involved. Patients with the later onset forms decline less rapidly than those with earlier onset. An interesting difference between the SMAs and other neurodegenerative disorders is that in the SMAs the greatest decline in muscular power occurs at onset and then slows, implying great loss of motor neurons initially, followed by a stabilization in any remaining neurons. This phenomenon results in a large number of complications owing to greater demands on remaining strength, such as scoliosis, contractures, and disuse atrophy, as well as respiratory, nutritional, and sleep problems. Arthrogryposis multiplex congenita, a disorder characterized by congenital limitation of motion in all joints except the temporomandibular and vertebral joints, is sometimes secondary to loss of anterior horn cells. A deletion of SMN has been found in half of such cases examined thus far.⁵⁴

Progressive bulbar palsy of childhood, or Fazio-Londe disease, involves brain stem motor neuron degeneration that presents most often with stridor followed by ptosis, dysarthria, facial palsy, and dysphagia. Death generally occurs in early childhood.

An autosomal dominant scapuloperoneal SMA has been reported with fasciculations, weakness, and atrophy in that distribution. Autopsy findings included degeneration of anterior horn cells and motor neurons of cranial nerves VII, IX, and X. A few families with adult-onset, autosomal dominant facioscapulohumeral and scapulohumeral distribution SMA have been reported.⁵⁵

Kennedy disease is a spinobulbar neuropathy with mid-life onset, normal life span, and associated gynecomastia. It occurs in men only and is caused by the expansion of trinucleotide repeats in the androgen receptor (AR) gene located on the X chromosome.⁵⁶ This was a particularly important discovery because it paved the way for identification of trinucleotide repeats as the cause of several other neurological diseases. Trapping of important acetylation enzymes in aggregates of the AR may be the major cause of degeneration in the CAG repeat diseases.⁵⁷

Mutations in the vesicle-associated membrane protein/synaptobrevin-associated membrane protein B (VAPB) have been identified in autosomal dominant SMA type

IV, in which some patients have upper motor neuron involvement as well.⁵⁸

DIFFERENTIAL DIAGNOSIS AND EVALUATION. Because many disorders can mimic the clinical picture of the SMAs, it is essential to verify a neurogenic process with EMG and muscle biopsy. In children, the differential diagnosis is particularly wide (Table 36-3).

Homozygous deletion of SMN is a sensitive test for confirming the clinical diagnosis in almost all cases, including isolated cases and those with unusual features. A method

TABLE 36-3

Selected Differential Diagnosis of Motor Neuron Diseases of Children According to Some Presenting Symptoms

Hypotonia

- Hereditary motor and sensory neuropathies
- Neuromuscular transmission defects
 - Transient neonatal myasthenia
 - Congenital myasthenic syndromes
 - Infantile botulism
- Congenital myopathies with distinguishing structural abnormalities
 - Central core disease
 - Nemaline myopathy
 - Centronuclear myopathy
- Muscular dystrophies
- Metabolic myopathies
 - Glycogen storage diseases
 - Lipid storage myopathies
 - Mitochondrial myopathies
- Inflammatory myopathies
 - Dermatomyositis/polymyositis
- Connective tissue disorders
 - Osteogenesis imperfecta
 - Marfan disease
 - Ehlers-Danlos syndrome
- Metabolic diseases
 - Aminoacidopathies
 - Organicacidurias
 - Renal reabsorption defects
 - Endocrinopathies
 - Prader-Willi syndrome
 - Nutritional disorders

Progressive Muscle Weakness

- Peripheral neuropathies
- Subacute inflammatory polyradiculoneuropathy
 - Hereditary motor neuropathies
- Muscular dystrophies
- Metabolic myopathies
 - Glycogen storage diseases
 - Lipid storage myopathies
- Inflammatory myopathies
 - Dermatomyositis/polymyositis

Progressive Cranial Nerve Paralysis

- Neoplasms
 - Brain stem glioma
 - Extrinsic posterior fossa tumor
 - Nasopharyngeal neoplasm
- Neuromuscular transmission defect
 - Botulism
 - Myasthenia gravis
 - Congenital myasthenic syndromes
- Myopathies
 - Ocular myopathies
 - Ophthalmoplegia plus syndromes
- Intracranial infections
 - Tuberculosis

for preimplantation diagnosis for couples at risk has been reported.⁵⁹ After genetic testing, the most revealing studies are EMG and muscle histochemistry, both of which will confirm a neurogenic process involving muscle. Fibrillation and normal-sized residual motor units are commonly seen in the acutely denervated muscle fibers of SMA I. SMA II and III produce very large motor units and absence of spontaneous activity. Serum CK can be elevated, and it correlates positively with duration of illness.

MANAGEMENT AND FUTURE PERSPECTIVES. There is no specific treatment for any of the SMAs. Recent work suggests sodium butyrate may be helpful. In lymphoid cell lines from SMA patients, it increased the amount of SMN protein to normal. Administration to homozygous knockout transgenic SMA-like mice decreased the birth rate of the more severe type of SMA and ameliorated some symptoms.⁶⁰ Perhaps most important is work demonstrating in mice that deletion of murine SMN exon 7 directed to skeletal muscle results in ongoing muscle necrosis with a dystrophic phenotype that progresses to muscle paralysis and death, suggesting that primary involvement of skeletal muscle in SMA may contribute to motor deficits. This provides a new avenue to explore for intervention.⁶¹ The following observations indicate the possibility for intervention with small molecules: Treatment of fibroblast cultures from SMA patients with valproic acid increased the amount of complete SMN2 mRNA/protein two- to fourfold⁶²; treatment of fibroblast cultures from patients with SMA I, II, or III with 4-phenylbutyrate increased full-length SMN2 transcripts by 50% to 400%, with the greater increase found in cells from patients with the milder phenotype⁶³; and treatment of cultured lymphocytes from SMA patients also resulted in an increase of full-length SMN mRNA, SMN protein, and intranuclear gems.⁶⁴ A clinical trial of riluzole, a drug marginally effective in ALS, is under way.

A multidisciplinary approach aimed at preventing contractures, skeletal deformities, respiratory complications, and social isolation is imperative. Genetic counseling of parents of young SMA patients or SMA patients approaching childbearing age is appropriate. Prenatal testing for SMN deletion is

available only on a research basis. The prognosis varies according to type, ranging from the early fatality of SMA I to the basically unaltered life span of SMA III.

Hereditary Spastic Paraplegias

The HSPs, also known as Strümpell-Lorrain syndrome and the familial spastic paraplegias, are a broad group of genetically and clinically diverse disorders characterized by lower extremity spasticity and weakness. Generally, they are classified according to mode of inheritance and symptoms. The more common uncomplicated or so-called pure HSP indicates progressive spasticity of the lower extremities that may be accompanied by a mild decrease in proprioception and urinary sphincter dysfunction, whereas complicated HSP denotes the presence of other neurological problems.

PATHOGENESIS AND PATHOPHYSIOLOGY. Information about the genetic basis for these disorders is mushrooming. It has been well established that uncomplicated autosomal dominant, autosomal recessive, and X-linked HSPs are heterogeneous disorders. Because families with strong similarities in phenotype are linked to different genetic loci, there may be various points of disturbance in a common biochemical pathway that leads to degeneration of the most distal portions of the longest ascending and descending central nervous system (CNS) axons, particularly the corticospinal tracts from the motor cortex to the legs, the fasciculus gracilis fibers, and the spinocerebellar fibers (Table 36-4).⁶⁵⁻⁸¹ Genetic penetrance is age dependent and nearly complete.⁸²

The L1 cell adhesion molecule (CAM), found primarily in the nervous system, is one of a subgroup of structurally related integral membrane glycoproteins within the immunoglobulin superfamily that mediates cell-to-cell adhesion at the cell surface. PLP1 is one of two isoforms of the myelin proteolipid protein. They are highly hydrophobic integral membrane proteins comprising approximately half of the protein content of adult CNS myelin. Mutations in PLP1 are also associated with Pelizaeus-Merzbacher disease, and the type of mutation is associated with disease severity:

TABLE 36-4

Hereditary Spastic Paraplegia (SPG), Gene Locus, and Protein Product

| GENETIC NOMENCLATURE | INHERITANCE | GENE LOCUS | PRODUCT |
|----------------------|-------------|-------------------------|------------------------------------|
| SPG1 | X-linked | Xq28 | L1CAM ⁶⁵ |
| SPG2 | X-linked | Xq28 | Proteolipoprotein ^{66,67} |
| SPG3 | AD | 14q12-q21 | Atlastin ⁶⁸ |

| SPG17 | AD | 11q12-q14 ⁸¹ | ? |

AD, autosomal dominant; AR, autosomal recessive; L1CAM, L1 cell adhesion molecule.

Missense mutations in exons 2 and 4 produce severe disease, truncation mutations in exon 5 produce a milder phenotype, whereas splice site mutations produce spastic paraplegia.⁸³ PLP1-null mice develop progressive impairment in both anterograde and retrograde axonal transport, with increased levels of retrograde motor protein subunits associated with accumulation of membranous organelles distal to nodal complexes, as well as PLP1 loss in oligodendrocytes.⁸⁴ *Atlastin* is a GTP-ase expressed primarily in adult brain.⁸⁵ Expression of wild-type or ATPase-defective spastin in several cell types showed that spastin interacts dynamically with microtubules, with normal spastin functioning as a microtubule-severing protein and mutant spastin colocalizing with, but not severing, microtubules. Spastin and spartin share a conserved domain slightly larger than one that is a consistent element of molecules involved in endosomal trafficking, with both likely interacting with microtubules.^{86,87} This is also associated with abnormal cellular distribution of mitochondria and peroxisomes.⁸⁸ Endogenous spastin has been identified at the centrosome in a variety of cell types at all points in the cell cycle, supporting the contention that spastin plays a role in microtubule dynamics and organization.⁸⁹ Electron microscopy of paraplegin-null mice demonstrated axons filled with abnormal mitochondria well before axonal degeneration could be seen. With continued degeneration, axons accumulated organelles and neurofilaments, suggesting mitochondrial dysfunction may lead to axonal degeneration by impairing axonal transport. The authors propose aberrant cellular trafficking dynamics as the common pathologic process underlying HSP.⁹⁰ A missense mutation in *KIF5A* prevents stimulation of motor ATPase by microtubule binding. Normally, the kinesin motor drives intracellular movement of membranous organelles from the neuronal cell body to the distal end of the axon, again suggesting disruption of neuronal axoplasmic flow and subsequent axonal degeneration underlie HSP.⁹¹ *NIPA1* is highly expressed in neuronal tissues and also seems to encode a putative membrane transporter or receptor.⁹²

CLINICAL FEATURES AND ASSOCIATED DISORDERS. The patient generally presents with leg stiffness, weakness in the hip flexors, and impaired foot dorsiflexion in the second through fourth decades, although symptoms may be apparent in infancy or not until late adulthood. The gait disturbance progresses insidiously and continuously. Patients may also have paresthesia and mildly decreased vibratory sense below the knees and urinary urgency and incontinence late in the disease. On neurological examination, generally there are no abnormalities of the corticobulbar tracts or upper extremities, except possibly brisk deep tendon reflexes. In the lower extremities, deep tendon reflexes are pathologically increased and there is decreased hip flexion and ankle dorsiflexion. Crossed adductor reflexes, ankle clonus (Video 82, Cross-Adductor Reflex; Video 84, Sustained Clonus), and extensor plantar responses are present. Hoffman's and Tromner's signs, as well as pes cavus, may be present. Occasionally, slight dysmetria may be seen on finger-to-nose testing in patients with long-standing disease.

The designation *complicated HSP* indicates spasticity with additional neurological impairment, such as optic neuropathy, retinopathy, extrapyramidal disturbance, dementia, ataxia, ichthyosis, mental retardation, and deafness.⁸²

DIFFERENTIAL DIAGNOSIS AND EVALUATION. The HSPs are diagnoses of exclusion. Particular care is necessary if the family history is not revealing or if there are numerous complications or atypical features. Because HSP can mimic treatable disorders, such as vitamin B₁₂ deficiency, dopa-responsive dystonia, cervical spondylosis, early PLS, or multiple sclerosis, exhaustive evaluation is justified.⁸²

Molecular diagnosis is available clinically only for proteolipoprotein (genetic nomenclature, SPG2), whereas testing for L1 cell adhesion molecule (SPG1), *atlastin* (SPG3), spastin (SPG4), paraplegin (SPG7), HSP60 (SPG13), and spartin (SPG20) is available at some research facilities. Additional testing is available only to family members within kindreds linked to an identified locus. Electrophysiological studies are the most revealing. Somatosensory evoked potentials of the lower extremities show conduction delay in the dorsal column fibers, whereas cortical evoked potentials show reduced conduction velocity and amplitude in lumbar spinal segment muscles. Cortical evoked potentials of the arms are either normal or mildly slow. Nerve conduction studies are most often normal, although there may be subclinical sensory impairment of peripheral nerves and spinal pathways.

Magnetic resonance imaging of the brain and spinal cord as well as plasma very long-chain fatty acid analysis should be performed.⁸²

MANAGEMENT AND PROGNOSIS. There is no treatment available to address the underlying process in HSP. Treatments to combat the problems associated with chronic paraplegia can be helpful, particularly oral or intrathecal baclofen or, less commonly, oral dantrolene for the lower extremity spasticity and oxybutynin or tolterodine for bladder spasticity. Caution should be exhibited in counseling regarding the course of the disease because there is variation in severity of phenotype reported.

Although the phenotypes of the various autosomal dominant HSPs are very similar, HSP does seem to be more severe in families linked to chromosome 15q, in which more patients require wheelchairs by the fourth decade. Families with mutations in spastin show more variation, including a less common childhood onset and a relatively nonprogressive course.⁶⁸

DEGENERATIVE MUSCULAR DISORDERS

The muscular dystrophies are degenerative hereditary disorders, with the most common being the dystrophinopathies and disorders of dystrophin-associated proteins. In 1987, with the identification of a defect in the dystrophin gene as the cause of Duchenne muscular dystrophy (DMD), Monaco and Kunkel⁹³ opened the door for research into the role of dystrophin and functionally related proteins in muscle function and maintenance.

Dystrophin is controlled by a very large gene, at least 2300 kb and 79 exons, that encodes a 3685-amino acid protein product with four distinct domains. It has an I-beam shape with globular domains at each end and a rodlike segment in the middle (Fig. 36-3). At the amino-terminal end, it binds to cytoplasmic actin filaments; at the other end, it binds to a complex of proteins and glycoproteins called

Figure 36-3. Localization of dystrophin and utrophin in the muscle cell. Dystrophin is found throughout the sarcolemma, whereas utrophin is confined to the neuromuscular junction. Both proteins are associated with a glycoprotein complex that binds to the extracellular matrix. (Reprinted with permission from Campbell KP, Crosbie RH: The structure of dystrophin. *Nature* 1996;384:308. Copyright 1996 MacMillan Magazines Limited.)

dystrophin-associated proteins and dystrophin-associated glycoproteins. Transcripts, each with its own promoter, suggest that dystrophin influences a number of distinct functions. Muscle dystrophin is found on the plasma membrane surface in skeletal muscle fibers, on the surfaces of plasma membrane and transverse tubules of cardiac muscle fibers, and on smooth muscle membranes. Cortical dystrophin is found in the hippocampus, amygdala, thalamus, hypothalamus, and neocortex, and a Purkinje cell isoform is found in the cerebellum.⁹⁴⁻⁹⁶ A second protein product of the DMD gene, which is structurally different from dystrophin, has not been found in muscle, but its level in other tissues is comparable to that of dystrophin in muscle.⁹⁷

It is now known that there are at least three subcomplexes that form the glycoprotein complex involved with dystrophin in muscle support. Several components of these subcomplexes have now been identified and some of their relationships determined. The dystroglycan subcomplex consists of α -dystroglycan and β -dystroglycan functions as a connecting axis, called the dystrophin axis, between the extracellular matrix and the subsarcolemma cytoskeleton. These dystroglycans are ubiquitously expressed in various tissues. The basal lamina is a network of several components, including laminin, that surrounds each muscle fiber in fixed contact with the sarcolemma and provides protection from mechanical damage. α -Dystroglycan is an extracellular protein that binds to the laminin subunit merosin in the basement membrane, as well as to β -dystroglycan, a transmembrane protein, which, in turn, binds to the cysteine-rich and carboxyl-terminus domains of dystrophin within the cell. Then the *N*-terminus domain of dystrophin binds to actin filaments, forming the cytoskeleton of the subsarcolemma.⁹⁶ Utrophin, a dystrophin homolog, binds to actin and most likely the dystroglycan complex.⁹⁸ It is possible that utrophin and these proteins form a utrophin axis similar to the dystrophin axis.

Four other transmembrane glycoproteins, called the sarcoglycans, have been identified: α -sarcoglycan (in some sources called 50DAG, A2, and adhalin), β -sarcoglycan (43DAG, A3b), γ -sarcoglycan (35DAG, A4), and δ -sarcoglycan. It has been proposed that the sarcoglycan complex is fixed to the dystrophin axis by lateral association, although the binding site is not yet known. The sarcoglycan complex is expressed specifically in skeletal and cardiac muscle.⁹⁵

Finally, the cytoplasmic complex consists of two families of proteins—the syntrophins, which bind to the distal part of the carboxy-terminal domain of dystrophin,⁹⁵ and dystrobrevin, which co-localizes with dystrophin and DAPs.⁹⁹ The syntrophins are composed of at least three subclasses: α -syntrophin, specifically localized in muscle; β_1 -syntrophin, with a ubiquitous distribution; and β_2 -syntrophin, localized to the neuromuscular junction.

In the past few years, disruptions in these proteins and glycoproteins have been implicated in several types of muscular dystrophy (Table 36-5).

Dystrophinopathies

Different mutations in the dystrophin gene produce different allelic disorders, most commonly either the lethal DMD or Becker muscular dystrophy (BMD), a milder myopathy. Very rarely, patients with cardiomyopathy with mild weakness, dilated cardiomyopathy without weakness, exercise intolerance associated with myalgias, muscle cramps, or myoglobinuria, and asymptomatic elevation of serum CK have also been identified.¹⁰⁰

PATHOGENESIS AND PATHOPHYSIOLOGY. Large mutations in the dystrophin gene are identified in approximately 75% of patients with DMD and 87% of patients with BMD. Most large mutations are deletions, and they tend to occur in regions where the introns are longer. The deletion breakpoints seem to be at sites where recombination events

AD, autosomal dominant; AR, autosomal recessive.

occur in healthy individuals. Large deletions are also common in BMD, whereas large duplications are rare. Small mutations account for approximately 30% of DMD cases and 15% of BMD cases. Mutations that shift the mRNA translational reading frame usually produce a truncated dystrophin molecule missing the carboxy terminus, which in turn does not bind adequately to dystrophin-associated proteins at the cell membrane, resulting in severe dystrophin deficiency in the Duchenne phenotype. Either no dystrophin is made or the aborted molecule is degraded rapidly. Non-frameshifting mutations produce a dystrophin molecule with a preserved carboxy terminus in which more dystrophin remains and the phenotype is the milder form of BMD.¹⁰¹ In-frame deletions alter the clinical presentation depending on where they occur. Deletions that involve the cysteine-rich and carboxy-terminus domains required for attachment to the dystrophin-associated proteins confer the Duchenne phenotype, whereas deletions in the proximal portion of the rod domain produce a very mild phenotype.¹⁰² Deletions in the distal region present the BMD phenotype and produce 40% to 70% of the normal amount of dystrophin.¹⁰³ There are rare cases to which these generalizations do not apply: out-of-frame deletions that can result in DMD, BMD, or an intermediate phenotype and situations in which there is no correlation between the degree of dystrophin deficiency and the severity of phenotype.^{100,101}

EPIDEMIOLOGY AND RISK FACTORS. DMD is the most common neuromuscular disease of childhood, with an estimated overall prevalence of 63 cases per 1 million, whereas BMD has an overall prevalence of 24 cases per 1 million.¹⁰¹ Because dystrophin is at Xp21.1, nearly all patients are male. As many as 20% of new DMD cases and an unknown number of BMD cases are caused by gonadal mosaicism.¹⁰⁴

CLINICAL FEATURES AND ASSOCIATED DISORDERS. The hallmarks of DMD are progressive proximal muscle weakness with pseudohypertrophy of the calves. The myocardium is involved, whereas bulbar muscles are spared. There may be mild mental retardation. DMD is universally fatal, usually from either respiratory or cardiac complications.

As early as 1868, Duchenne had established criteria for the diagnosis of what would later be called DMD. These features still serve as an accurate description of the clinical picture: (1) weakness, appearing first in the lower extremities; (2) wide-based gait and stance (Video 13, Myopathic Gait), with lordosis; (3) subsequent hypertrophy of weakened muscles; (4) loss of muscle contractility with electrical stimulation; (5) intact sensation and bowel and bladder function; and (6) a progressive, deteriorating course.

Usually, the child is asymptomatic in the neonatal period, with the earliest problems perceived by caregivers being developmental delays, particularly in walking and climbing, and the appearance of enlarged calf muscles. Between the ages of 3 and 6 years, the gait becomes waddling and lordotic. Gower's sign appears (Video 99, Gower's Sign), in which the child stands from a prone position by a process of climbing up the legs, using the hands first on the knees and then on the thighs to support herself or himself (Fig. 36-4). Usually by the age of 6 years, there is enlargement of calf, gluteal, lateral vastus, deltoid, and infraspinatus muscles, and weakness is readily apparent, with the proximal extremities more severely affected than the distal extremities, and lower extremities and torso more severely affected than the upper extremities (Fig. 36-5). Weakness of the arms may be present but is not obvious without careful examination. The strength of limb and torso muscles continues to decline steadily from ages 6 through 11 years.

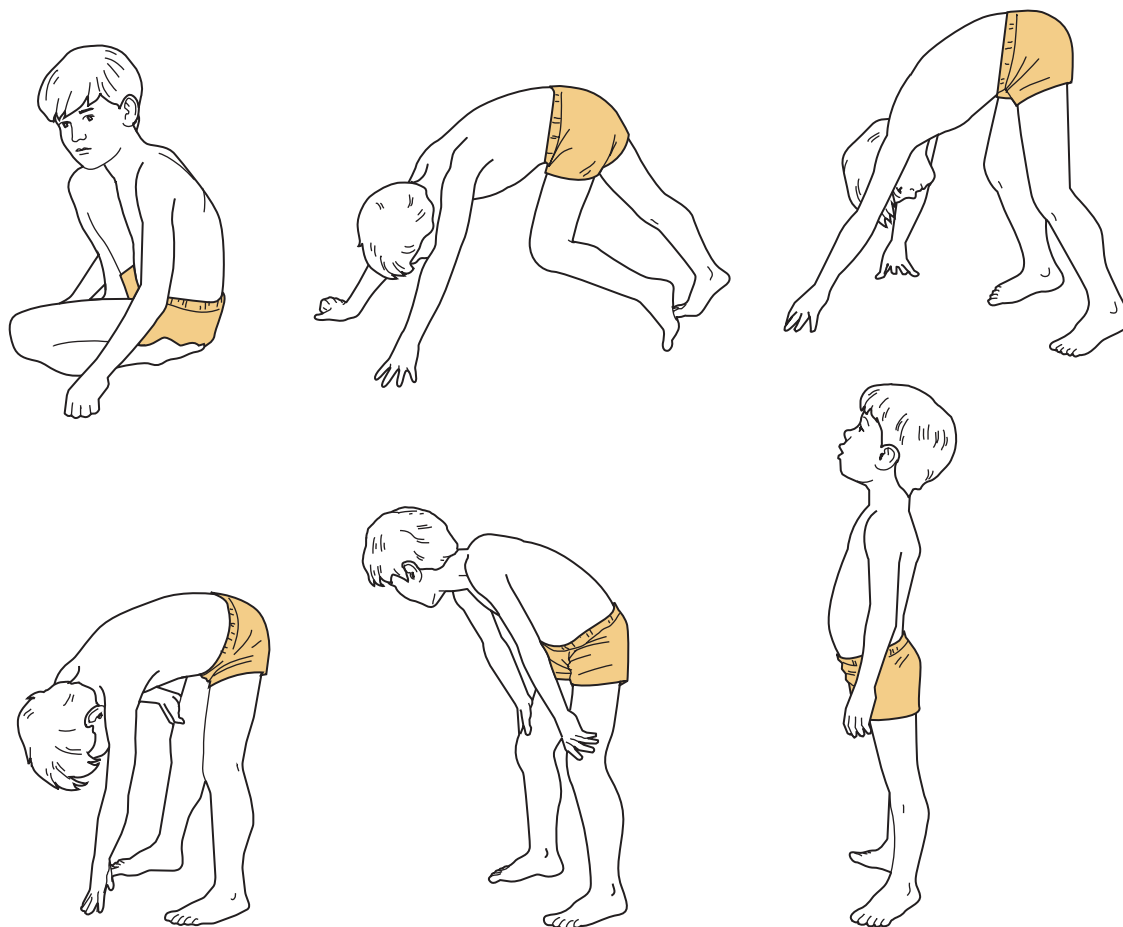

Figure 36-4. Gower's sign. (From Seigel IM: *Muscle and Its Diseases: An Outline Primer of Basic Science and Clinical Method*. Chicago, Yearbook Medical, 1986.)

Proximal muscles continue to be more severely affected than distal muscles, with neck flexors becoming more involved than extensors, wrist extensors more than flexors, biceps and triceps more than deltoid, quadriceps more than hamstrings, and the tibialis posterior and peroni more than the gastrocnemius, soleus, and tibialis anterior. Tendon reflexes decrease and disappear as muscle weakness progresses. By the age of 10 years, 50% of patients have lost biceps, triceps, and knee reflexes, in contrast with the ankle reflex, which remains in one-third of patients even in end-stage disease. Significant contractures of the iliotibial bands, hip flexors, and heel cords are present in 70% of patients by the age of 10 years. Patients tend to have relatively mild functional impairment until they are approximately 8 years old, when they then decline more rapidly during the next 2 or 3 years. The second decade brings progressive kyphoscoliosis from weakened paraspinal muscles and decreased vital and total lung capacities and maximal inspiratory and expiratory pressures from weakened respiratory muscles. These problems first appear between the ages of 8 and 9 years and progress as functional status deteriorates.

The mean age of death in a survey of 176 patients who died between 1970 and 1984 was 18.3 ± 3 years. It was slightly increased to 20 ± 3.9 years in the subset of 48 patients who died between 1980 and 1984. Approximately 40% died of respiratory failure, and 10% to 40% died of

cardiac complications. Although cardiac rate, rhythm, and conduction defects occur in up to 90% of DMD patients, they tend to be stable or slowly progressive problems.¹⁰⁰

In BMD, disease is later in onset and slower in progression. As early as the mid-1950s, Becker proposed that these cases represented a variation of DMD. Now that it is known that DMD and BMD are allelic disorders, it is apparent that BMD phenotypes range from myalgias and muscle cramps to symptoms clinically indistinguishable from DMD.

Age of onset ranges from 1 to 70 years of age, with a mean of 12 years. Ninety percent of patients are affected by age 20. Lower extremity weakness appears on average by age 11, with upper extremity weakness by age 20. Loss of ambulation generally occurs at approximately 40 years of age but can occur as early as age 12. Age at death ranges from 23 to 89 years of age, with the average being 42.

Cardiac problems similar to those associated with DMD are present in approximately half of the patients with BMD. The extent of cardiac involvement does not correlate with degree of myopathy. Myocardial pathology includes degeneration of cardiac muscle and fibrous replacement of myocardiocytes, particularly in the posterobasal region and the adjacent lateral wall of the left ventricle.

In comparison with their unaffected brothers, 10% to 79% of these patients have fertility problems, and the

Figure 36-5. Enlarged calf muscles in a patient with Duchenne muscular dystrophy. (From Fenichel GM: *Clinical Pediatric Neurology*. Philadelphia, Saunders, 1997.)

severity of infertility correlates positively with severity of phenotype. Fatty infiltration of smooth muscle may result in delayed gastric emptying with emesis, abdominal pain, and distention. Adverse reactions to succinylcholine and halothane have been reported, which ranged from marked elevation of CK in the postoperative period to cardiac arrest.¹⁰⁰

DIFFERENTIAL DIAGNOSIS AND EVALUATION. The diagnosis of DMD and BMD has become considerably more reliable with the advent of molecular genetics. When the clinical presentation, elevation of CK, muscle biopsy, EMG findings, and inheritance pattern are consistent with a dystrophinopathy, the patient's white blood cells or muscle should be examined for deletions or duplications in the dystrophin gene. Multiplex polymerase chain reaction (PCR) amplification of commonly deleted exons detects 98% of the deletions that cause more than 65% of the dystrophinopathies. Quantitative Southern blot analysis may be needed to detect partial gene duplication because it is more sensitive.^{105,106} Immunoblot analysis of muscle homogenates with dystrophin antibodies confirms abnormalities in at least 95% of DMD patients and differentiates DMD from BMD. Analysis of restriction length polymorphisms and a nonradioactive direct test based on PCR amplification provides rapid, precise carrier diagnosis in women whose relatives have a known deletion. Sisters and daughters of mothers who have given birth to boys with isolated cases of DMD or BMD should also be tested and counseled. Such mothers should also consider prenatal diagnosis because the risk for recurrence in additional sons is estimated at 7%. Prenatal diagnosis can be performed as early as 8 weeks' gestation.¹⁰⁷

The EMG changes seen are those common to all myopathic disorders. Motor units fire at a relatively high rate for the degree of effort, with a higher number activated than would be in a muscle of comparable strength in a neurogenic problem. As the disease progresses, increasingly fewer motor units can be activated. An increased number of motor unit potentials are polyphasic with one or more late components, as well as components reduced in duration. Fibrillation potentials are often observed. Nerve conduction velocities are normal.

Similar pathological changes are present in BMD and DMD, particularly necrotic and regenerating fibers, branching fibers, abnormal fiber size, and endomysial fibrosis. Generally, there are more necrotic, hypercontracted, and regenerating fibers with a more severe phenotype. Additionally, inflammatory cells are evident at perivascular, endomysial, and perimysial sites in DMD. Plasma membrane defects that lead to segmental fiber necrosis and eventual regeneration are observed with electron microscopy. Extensive discussion of morphological and electron microscopy studies is available in Engel and colleagues.¹⁰⁰

Serum CK is the most useful of the serum enzyme tests, with CK increased up to two orders of magnitude during the first 3 years when it peaks and then declines exponentially by approximately 20% annually. Myoglobinemia is roughly correlated with elevations in CK. Ambulatory DMD patients have diurnal fluctuations in myoglobin and CK, with increases corresponding to physical activity.¹⁰⁸ In the cerebrospinal fluid, protein fractions are increased in most dystrophies and γ -globulin is decreased. Because excretion of total creatinine declines with decreasing functional muscle mass, urinary creatinine is 40% to 90%

TABLE 36-6

Cardiac Manifestations in the Muscular Dystrophies

| DISORDER | MANIFESTATION | RECOMMENDATIONS |
|--------------------|--|---|
| Duchenne | Hypokineses Dilated cardiomyopathy May progress to severe cardiac failure Female carriers at risk | ECG and cardiac echo at diagnosis, every 2 years until age 10, annually thereafter ACE inhibitors first, add beta blockers |
| Becker | Cardiomyopathy May be more severe than skeletal muscle disease Female carriers at risk | ECG and cardiac echo at diagnosis Cardiac echo at least every 5 years |
| LGMD1A | Uncertain | |
| LGMD1B | Dilated cardiomyopathy with conduction defects | |
| LGMD1C | Uncertain | |
| LGMD2C, 2D, 2E, 2F | Dilated cardiomyopathy similar to Duchenne Allelic disorders; cardiomyopathy and sudden death | Same as Duchenne |
| LGMD2B | One case of cardiomyopathy reported | |
| LGMD2I | Dilated cardiomyopathy similar to Duchenne | Same as Duchenne |
| Emery-Dreifuss | Conduction defects Atrial flutter, first-degree heart block, atrial paralysis Female carriers at risk Cardiomyopathy uncommon | For AD-ED: implantable defibrillator For X-ED: pacemaker |

below normal.¹⁰⁸ Urinary creatinine excretion is approximately twice normal between ages 6 and 11 years, and it increases with age.

It is essential to evaluate the heart. Ninety percent of patients with DMD have myocardial fibrosis, revealed by elevated right precordial R waves and deep Q waves in left precordial and limb leads on electrocardiography (ECG).¹⁰⁹ Persistent or labile sinus tachycardia, sinus arrhythmias, and interatrial conduction defects are also common abnormalities. Echocardiography demonstrates small internal ventricles, hypokineses of the posterobasal ventricular wall, and slowed ventricular relaxation. For cardiac evaluation guidelines see Table 36-6.¹¹⁰ Examination of dystrophin can prevent misdiagnosis in patients with disorders that mimic the clinical presentation of DMD and BMD, particularly the SMAs, congenital muscular dystrophy, acid maltase deficiency, and Emery-Dreifuss muscular dystrophy (ED MD). Dystrophin should also be evaluated in males with dilated cardiomyopathy, even in the absence of muscle weakness, and in girls with symptoms of DMD.

MANAGEMENT AND PROGNOSIS. Thus far, the only medication to improve functioning of boys with DMD when evaluated in carefully controlled trials is a regimen of alternate-day prednisone with a dosage range of 0.75 to 1.5 mg/kg/day. Improvement began approximately 1 month after beginning treatment and peaked by 3 months, with significant and sustained benefits still evident at 3 years. With treatment, the progressive decrease in muscle strength and increase in muscle mass were slower than expected, and the extent of disability was less. Side effects included those common to all steroids: altered behavior, cushingoid appearance, gastrointestinal disturbance, rashes, and hirsutism.¹¹¹ A randomized, cross-over, controlled trial of 0.75 mg/kg/day of prednisone administered the first 10 days of each month for 6 consecutive months compared to placebo demonstrated prednisone slowed deterioration of muscle while side effects did not negatively affect quality of life.^{110,113} Current recommendations are to start treat-

ment as soon as the diagnosis is made, from ages 2 to 5 years.¹¹⁴ Practice parameters of the American Academy of Neurology and Child Neurology Society provide detailed guidelines.¹¹⁵ One study reported delayed onset and progression of left ventricular dysfunction when DMD children were treated with 2 to 4 mg/day of perindopril.¹¹⁶ Effective gene therapy remains elusive. A carefully controlled study determined that injecting normal myoblasts into affected muscle did not increase muscle force generation or the amount of dystrophin in muscle.¹¹⁷

Much of the management of the dystrophinopathies remains supportive, and there is controversy regarding appropriate active exercise regimens in the dystrophinopathies. The review by Spenser and Vignos¹¹⁸ provides a balanced discussion of the role of active exercise in DMD. In one short-term controlled study, resistance exercises neither hastened physical deterioration, as has been proposed, nor maintained strength any better than free exercises. More clearly, passive exercises and joint stretching are important in delaying the onset of contractures. Maintaining ambulation as long as possible is crucial because its loss is associated with contractures and scoliosis, which, in turn, is associated with restrictive respiratory syndrome. Release of hip and ankle contractures by subcutaneous tenotomy while the patient is still ambulatory has been shown to preserve ambulation for approximately 2 additional years.¹¹⁸

Inspiratory resistive exercises have been shown to increase endurance of respiratory muscles but not vital capacity.¹¹⁹ When indicated, intermittent ventilatory assistance ameliorates symptoms of hypoventilation but does not slow the deterioration of respiratory function. If assisted ventilation is employed when vital capacity falls below 10% of normal, it can prolong survival by 3 or 4 years.¹²⁰

Bregman¹²¹ outlined strategies that families can employ in managing childhood neuromuscular disorders: (1) maintaining a regular schedule of activities for both the affected child and other family members, (2) providing interesting

activities appropriate to the degree of disability that enhance the affected child's experiences, (3) assisting the affected child in setting realistic goals, (4) encouraging as much independence as possible in the affected child, (5) employing stress-reduction strategies, (6) including all family members in decision making, and (7) maintaining active relationships with the primary physician and support groups in the community.

Data indicate that DMD patients are living somewhat longer than they used to, probably because of more aggressive respiratory and cardiac care, but as yet, nothing reverses the basically relentless course of either the Duchenne or Becker phenotype.

FUTURE PERSPECTIVES. Work suggests that a disruption of basement membrane organization occurring in rare homozygotes for a null allele of dystroglycan may be the common feature of muscular dystrophies associated with the dystroglycan complex.¹²² Effective treatment may involve either replacement of dystrophin or upregulation of a related protein, such as utrophin. The development of adenoviral vectors from which protein-producing genes have been removed may allow transport of more DNA while eliminating proteins that trigger the host response.^{123,124} Although upregulation of utrophin theoretically could occur pharmacologically, high expression of the utrophin transgene in skeletal and diaphragmatic muscle of the dystrophin-deficient mdx mouse has markedly reduced dystrophic pathology.¹²⁵ It has been demonstrated that transgenic mice with premature stop codons in syntrophin produced normal dystrophin in muscle and had less muscle degeneration when treated with aminoglycosides than untreated mice with the same mutation, which may open an avenue for treatment.¹²⁶ It has been proposed that introduction of particular antisense oligoribonucleotides to modify the processing of dystrophin pre-mRNA may reduce the severity of symptoms. It has been demonstrated in transgenic mice that upregulation of the protein alpha 7 integrin may compensate for dystrophin and utrophin deficiency.¹²⁷ Bone marrow transplantation in the mdx mouse demonstrated that bone marrow or muscle stem cells appear to provide a means for systemic repair of muscle.¹²⁸ Chaubourt and colleagues¹²⁹ proposed the use of nitric oxide donors as a palliative treatment in combination with gene and molecular therapy. Genetic therapy restoring the reading frame in myotube cultures from two DMD patients induced skipping of exon 46 in approximately 15% of mRNA, which led to normal amounts of properly localized dystrophin in at least 85% of myotubes—a strategy that could be applied in more than two-thirds of DMD mutations.¹³⁰ Continuing in the same mode of antisense rescue, when specific skipping of a targeted exon was induced in cultured muscle cells from six DMD patients with different deletions and a nonsense mutation, dystrophin synthesis was restored in more than 75% of cells for at least 1 week. Additionally, there was restored membrane expression of four associated proteins of the dystrophin-glycoprotein complex.¹³¹

Limb Girdle Muscular Dystrophies

The limb girdle muscular dystrophies (LGMDs) are being reclassified on a genetic basis as their underlying pathologies are unraveled. The genes and their products or

actions identified thus far again point to disturbances in the structural support system of muscle, particularly of the sarcoglycan complex. It may be that a disturbance in the sarcolemma-extracellular matrix interaction is the molecular basis for muscle fiber necrosis (see Table 36-5).¹³²⁻¹⁴⁹ Emery estimates LGMD prevalence to be 1 in 100,000. As early as 1960, Morton proposed that homozygosity at either of two loci could produce LGMD and that approximately 1.6% of the normal population is heterozygous for an LGMD gene.¹⁵⁰

With the exception of gamma-sarcoglycanopathy, previously known as severe childhood autosomal recessive muscular dystrophy (SCARMD) found primarily in North Africa, the LGMDs all fall within a clinical spectrum that includes weakness of proximal lower extremities, which is usually symmetrical, appearing any time from the first decade until middle age, generally followed by weakness in the shoulder girdle region. Occasionally, shoulder girdle weakness may precede the pelvic girdle weakness. Facial muscles are uninvolved. The progression is generally slow, with loss of ambulation occurring 10 to 30 years after onset. Cardiac involvement has been reported in several types, including 1B, 2B, 2C, 2D, 2E, 2F, and 2I (see Table 36-6). The features of gamma-sarcoglycanopathy have been well described by Ben Hamida and associates.¹⁵¹ Pelvic girdle weakness precedes pectoral girdle weakness, with onset occurring between ages 3 and 12 years. Abdominal, neck flexor, and intercostal muscles are often affected, whereas external ocular, facial, lingual, and pharyngeal muscles are spared. Seventy-five percent of patients are unable to walk by their 30s. Contractures form and reflexes are lost as the disease progresses. Cardiomegaly and ECG abnormalities are common by the intermediate stages of the illness. There is no cognitive impairment.

If sufficient informative family members are available, linkage analysis can provide a genetic diagnosis if the patient has one of the previously linked types of LGMD. SCARMD can be diagnosed by a negative sarcolemmal immunostain for adhalin.¹⁵²

There are several nonspecific findings associated with the LGMDs. Serum CK is mildly to moderately elevated, except in SCARMD, in which the levels may rival those of DMD.¹⁵² Creatinuria and hypocreatinuria are nonspecific indicators of muscle destruction that may be present. The EMG shows nonspecific myopathic changes, including short duration, low-amplitude motor unit potentials, increased proportion of polyphasic potentials, and rapid recruitment. Fibrillation and positive sharp waves may occur with denervation caused by muscle fiber necrosis. Muscle biopsy pathology also is nonspecific, with morphology like that of other myopathies.¹⁵⁰

The LGMDs have relatively common and nonspecific clinical and laboratory findings that may be seen in other neuromuscular disorders. Therefore, care must be taken in evaluation. For example, in a Japanese series, 17% of patients with clinically diagnosed LGMD actually had a dystrophinopathy when muscle dystrophin content was analyzed, which emphasizes the need for examination of dystrophin protein and gene studies for accurate diagnosis (Table 36-7).¹⁵³ Protein testing by immunostaining of muscle tissue can establish the diagnosis of sarcoglycanopathy, calpainopathy, dysferlinopathy, and telethoninopathy.

TABLE 36-7

Differential Diagnoses in Limb Girdle Muscular Dystrophy

| |
|-------------------------------------|
| Acid maltase deficiency |
| Becker muscular dystrophy |
| Carnitine deficiency |
| Central core disease |
| Centronuclear myopathy |
| Congenital fiber-type disproportion |

| Nemaline rod disease |
| Reducing body myopathy |
| Sarcotubular myopathy |
| Scapuloperoneal dystrophy |
| Spinal muscular atrophy |

Mutation studies of the corresponding genes are so far available only on a research basis.

There are no specific treatments for any of the LGMDs. The physician's goal is to preserve as much function for as long as possible through the use of physical and occupational therapy and psychological support.

Research into the pathogenesis of these disorders is proceeding rapidly. A missense mutation in myotilin, a sarcomeric protein that binds to α -actin associated with the Z line, does not disrupt α -actin binding but does result in Z line streaming.¹³² Missense mutations in the caveolin gene lead to an accumulation of caveolin in the Golgi apparatus, an example of a dominant-negative effect.¹⁵⁴ The sarcoglycanopathies involve four different genes that encode proteins which form a tetrameric complex at the muscle cell plasma membrane. Its function is to stabilize the association of dystrophin with the dystroglycans and stabilize the plasma membrane cytoskeleton. Mutations in each sarcoglycan gene are consistent with complete or partial loss of the complex.¹⁵⁵ Congenital muscular dystrophy has the pathological appearance of far-advanced dystrophinopathies. In half of those cases, the laminin merosin is absent, which makes some sense in that merosin forms a connection between the DAG and the basal lamina.¹⁵⁶ As the relationships and workings of the genes and complexes become better understood, it may be possible to offer a rational treatment for these disorders.

Facioscapulohumeral Muscular Dystrophy

Facioscapulohumeral muscular dystrophy (FSH MD), or Landouzy-Dejerine muscular dystrophy, is slowly progressive degenerative myopathy that affects particular facial, torso, and extremity muscles. Deletions in polymorphic fragments of the FRG1 gene at 4q35 cause FSH MD in the majority of families, with fragments of less than 35 kb clearly associated with disease. This area contains a transcriptional

silencer, without which there is overexpression of genes located upstream.^{157,158} A mouse model overexpressing FRG1 has been developed in which the mice develop muscular dystrophy with features similar to FSH MD. Muscle examination of these mice as well as patients reveals aberrant alternative splicing in particular pre-mRNAs.^{159,160} There are still approximately 15% of other clinically indistinguishable families for whom no gene has been identified.¹⁶¹ Although isolated cases have been identified, generally with careful evaluation of the family there is a clear autosomal dominant inheritance pattern with a penetrance of 95% by the time the individuals reach their 20s. Prevalence is approximately 1 in 20,000.¹⁶²

Onset has been reported from infancy until middle age. There is significant variability in severity of symptoms within families, with some individuals having symptoms that are so mild that they are unaware they have the disease until other family members are diagnosed. Generally, the patient first notices asymmetrical weakness in an upper extremity, although facial weakness may have been present for some time. The facial weakness appears insidiously in the orbicularis oculi, zygomaticus, and orbicularis oris muscles. The weakness generally progresses slowly and in a descending pattern from facial muscles to shoulder girdle to upper arms and then pelvic girdle muscles (Fig. 36-6). One report suggests that mental retardation and epilepsy may occur in patients with very early onset.¹⁶³ There may be plateaus and even occasional arrest of the disorder.

Munsat recommends that four criteria be present for the diagnosis of FSH MD: (1) onset in facial and shoulder muscles, with sparing of extraocular, pharyngeal, lingual, and cardiac muscles; (2) autosomal dominant inheritance pattern; (3) facial weakness in half or more of affected family members; and (4) myopathic changes, including polyphasic motor units of low amplitude and short duration on EMG and variation in fiber diameter, centrally located nuclei, and moth-eaten fibers on muscle biopsy. The unevenness of the disease process may extend to individual muscles.¹⁶⁴

Several other problems have been identified in FSH MD, particularly in patients with early onset and relatively rapid progression. Hearing loss in the 4000- to 6000-Hz range and retinal capillary abnormalities (Coat's disease) have been reported. Although it is not usually clinically apparent, abnormal atrioventricular node or intranodal conduction also occur.¹⁶⁵

There is no definitive treatment for FSH MD. Steroids may provide transient benefit if there are inflammatory changes on the muscle biopsy. Physical and occupational therapy are useful for maintaining optimal functioning. Orthotics and bracing may be helpful, as may surgical stabilization of the scapulae. Early photocoagulation of retinal abnormalities is recommended.¹⁶⁴ Large families who have been linked to the chromosome 4 locus may have their diagnosis verified by genetic testing. The course is relatively benign; most patients remain ambulatory, and life span is not significantly decreased.¹⁶⁵

Scapuloperoneal Syndromes

The scapuloperoneal syndromes (SPSs) are heterogeneous disorders characterized by weakness of both shoulder

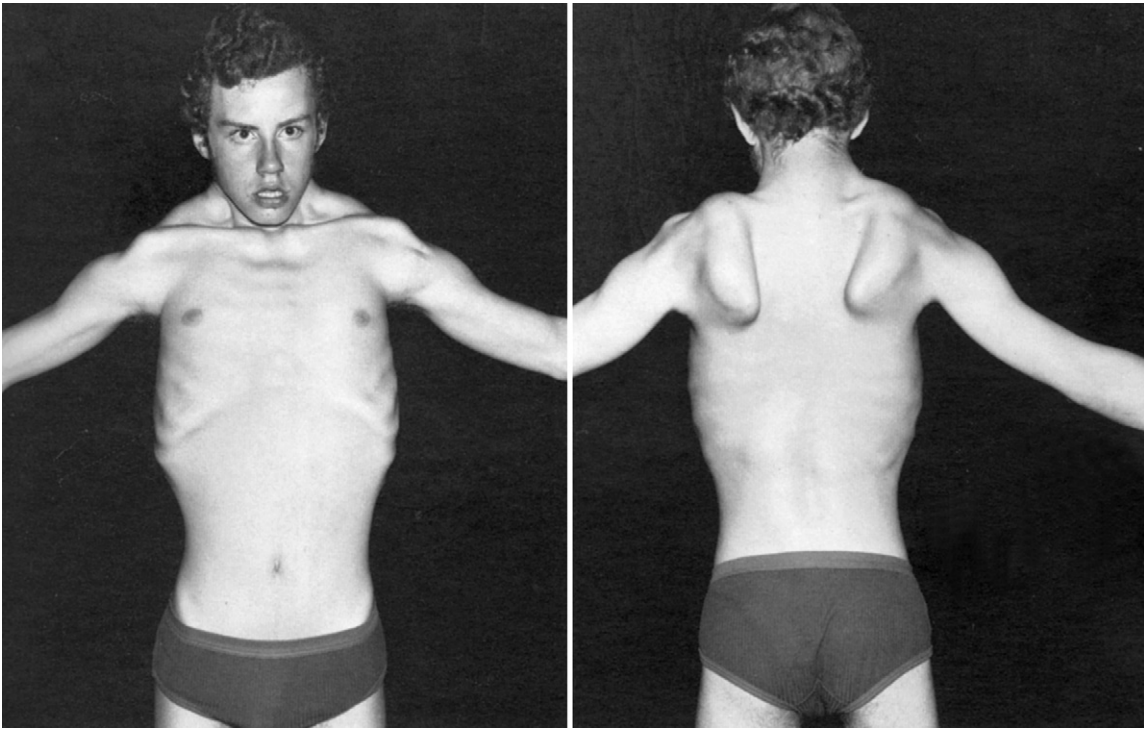

Figure 36-6. Facioscapulohumeral dystrophy in a 15-year-old boy. There is marked facial weakness on frontal view and dramatic scapular winging with arm abduction on the posterior view. (From Dubowitz V: *Muscle Disorders in Childhood*. Philadelphia, Saunders, 1995.)

girdle and peroneal muscles. Both a neurogenic form (scapuloperoneal spinal muscular atrophy [SPSMA]) and a myopathic form (scapuloperoneal muscular dystrophy [SPMD]) have been identified. The neurogenic SPSMA was linked to chromosome 12q24.1-q24.31, which is a region approximately 20 cM telomeric to the location of the gene for the myopathic SPMD.¹⁶⁶

These are uncommon disorders, with heated debate as to whether the SPSs are all distinct entities. Autosomal dominant, autosomal recessive, and sex-linked recessive patterns of inheritance have been reported, as well as sporadic cases. Genetic studies will undoubtedly eventually clarify the situation.

The clinical features of both the myopathic and the neurogenic types are similar. Age of onset ranges from infancy to adulthood, most commonly late childhood or young adulthood. The usual presentation is weakness in shoulder girdle muscles, progressing to weakness in the anterior tibial muscles, followed by weakness in pelvic girdle muscles. When facial involvement occurs, it is mild and late in onset.

Although there are a few neuromuscular disorders that may present with weakness in the scapuloperoneal distribution, particularly Charcot-Marie-Tooth disease and FSH MD, a comprehensive neuromuscular workup based primarily on EMG and muscle and nerve biopsies screens out most of them.

Davidenkow's syndrome, which includes scapuloperoneal weakness, may be confused with the SPSs. However, it also has pes cavus deformities and progressive distal sensory loss with early depression of reflexes, as well as impaired sensory and motor nerve conduction velocities.¹⁶⁷

ED MD may also produce weakness in the scapulohumeral distribution, but it has characteristic contractures and

cardiac conduction abnormalities not present in the SPSs. The weakness tends to progress very slowly, and patients become only mildly disabled. It generally does not affect the life span.¹⁶⁸

Myotonic Dystrophy

Myotonic dystrophy I (DMI), or Steinert's disease, is an autosomal dominant multisystem degenerative disease characterized by myotonia, progressive muscular weakness, gonadal atrophy, cataracts, and cardiac arrhythmias. Myotonic dystrophy II (DMII), also called proximal myotonic myopathy, or PROMM, is also dominantly inherited, with myotonia typically appearing in the third or fourth decade of life and mild proximal weakness appearing in the fifth decade or later. Although DMII is also a multisystem disorder with variable severity, it is generally considered to be more benign than DMI.

PATHOGENESIS AND PATHOPHYSIOLOGY. The molecular basis of DMI is an unstable trinucleotide repeat sequence—cytosine, thymine, and guanidine (CTG)—in the protein kinase-encoding gene (DMK) located at 19q13.3. The repeat is present 50 to several thousands of times in patients with DM, compared to 5 to 30 times in the normal population. The size of the repeat is correlated roughly with severity of symptoms, with more affected patients having greater numbers of repeats.¹⁶⁹ The repeat expansion also may account for the anticipation seen in families with DMI, in which the severity of symptoms increases and the age of onset decreases with subsequent generations.¹⁷⁰ It was demonstrated that the DMK protein is localized to the postsynaptic side of the neuromuscular junction in skeletal muscle and the intercalated discs in cardiac muscle in humans.

Figure 36-7. Myotonic dystrophy with typical myopathic facies, frontal balding, and sunken cheeks. (From Dubowitz V: *Muscle Disorders in Childhood*. Philadelphia, Saunders, 1995.)

Additionally, DMK protein is present in specific structures in rat brain, supporting the hypothesis that it may have selective actions in the CNS.¹⁷¹ There have been widely conflicting results in the effort to unravel the precise effect of the expanded repeats; some data support the theory that there is a loss of function of the mutant allele, whereas other data favor increased expression of the allele. Recent work supports a new interpretation of the data. Both normal and expanded DMK genes are transcribed in patient muscle, but the expanded RNA has a dominant effect on RNA metabolism by preventing transport of poly(A)+ RNA out of the nucleus.¹⁷²

DMII is caused by a CCTG expansion in intron 1 of the zinc finger protein 9 gene on chromosome 19. Expanded alleles have 75 to approximately 11,000 CCTG repeats, with allele expansions averaging approximately 5000 repeats.¹⁷³

EPIDEMIOLOGY AND RISK FACTORS. There is an estimated prevalence of 3 to 5 per 100,000 population and an incidence of 1 in 8000 live births, making it the most common adult muscular dystrophy. Although a few isolated populations have an exceptionally high prevalence, DM has been found in all racial groups.¹⁷⁴

CLINICAL FEATURES AND ASSOCIATED FINDINGS. The phenotype is correlated with the length of the CTG repeat and thus is widely variable, ranging from the single manifestation of cataracts that present in the middle years to severe neonatal hypotonia that can lead to death if respiratory support is not provided. Traditionally, these different types of symptoms have resulted in the designation of either congenital or noncongenital DM.

The classic presentation of noncongenital DM, which is well described by Harper and Rudel,¹⁷⁴ includes marked weakness in the face, jaw, and neck muscles and milder distal extremity weakness (Fig. 36-7). Weakness of the extremities is often the first problem perceived by the patient, even when a careful evaluation may reveal a clear history of myotonia (sometimes termed muscle stiffness or cramping by patients), facial weakness, and nasal speech. Patients frequently seem unaware of their illness and symptoms, both in themselves and in family members. Using a percussion hammer, myotonia can be elicited in patients

with DM with a brisk tap on the thenar muscle, causing flexion-opposition of the thumb with slow relaxation.

The person with advanced DM has a characteristic appearance: a long, thin face with sunken cheeks due to temporal and masseter wasting, a so-called “swan neck” because of sternocleidomastoid wasting, and ptosis, with relatively strong muscles in the posterior neck and shoulder girdle.

Congenital DM presents a distinctive picture that is different from other disorders. Facial diplegia (Video 23, Cranial Nerve VII, Facial Diplegia) and jaw weakness without concomitant extremity weakness are hallmarks. Weakness of the respiratory muscles with respiratory distress is present in at least 50% of patients and is the most common cause of death in these infants. Hypotonia is present in severely affected neonates, but it may disappear within weeks. Clinical myotonia is generally absent and is usually detectable only by EMG.¹⁷⁴

A prospective study followed patients of both types for 10 years, with the conclusion that muscle weakness was relatively mild in both types, although it was progressive in the noncongenital form. Weakness was generalized in both types, with no significant differences found in distribution. Additionally, 75% of the noncongenital patients and 81% of the congenital patients had cardiac abnormalities, primarily conduction defects, demonstrated on ECG. Intellectual function was frequently and severely impaired in the congenital type, whereas only approximately one-third of the noncongenital patients were mildly impaired.¹⁷⁵

It cannot be overemphasized that DM is a multisystem disorder. The heart is prominently involved, and the severity of cardiac symptoms does not correlate with severity of other symptoms in this disorder. All patients with DM need to undergo ECG evaluation because sudden death is well documented, and as many as 90% of patients have conduction defects, particularly first-degree heart block and atrial arrhythmias. Both the diaphragm and the intercostal muscles may be myotonic and weak, which leads to alveolar hypoventilation. In addition, there are smooth muscle abnormalities throughout the gastrointestinal system. Particularly important are the delayed relaxation of the pharynx

and reduced motility in the esophagus that may lead to aspiration, constipation, and anal sphincter abnormalities in children.

Central nervous system involvement includes generalized atrophy and ventricular dilatation, but structural changes in the brain do not seem to be common, even in patients with congenital disorders. However, there are well-known behaviors associated with DM that range from apathy and inertia, with concomitant lower socioeconomic status, to hypersomnolence that is often present without detectable respiratory problems. In addition, numerous endocrinological abnormalities have been reported, several with clinical importance. Hyperinsulinism and reduced numbers of insulin receptors are common, but diabetes is not. Elevations of pituitary follicle-stimulating hormone and luteinizing hormone occur frequently.

In males, testicular atrophy, Leydig cell hyperplasia, and slightly reduced serum testosterone are common. In females, no consistent ovarian problems have been documented, but the spontaneous abortion rate is high. Fertility in both sexes seems to be reduced to approximately 75% of normal. Finally, in the ocular system, cataracts with characteristic multicolored crystalline subcapsular opacities have been documented since the recognition of DM as an entity. Retinal degeneration, low intraocular pressure, and saccadic eye movement defects have been reported.¹⁷⁴

EVALUATION AND DIFFERENTIAL DIAGNOSIS. The condition most clinically similar to DM is proximal myotonic myopathy, a multisystem disorder with predominantly proximal weakness, myotonia, and cataracts with autosomal dominant inheritance and a normal number of CTG repeats in the DMK gene.¹⁷⁶ Facioscapulohumeral dystrophy may have the same distribution of weakness, but there is no myotonia. More rarely, some of the LGMDs may have a similar distribution of weakness, again without myotonia. Molecular analysis can distinguish DM from these disorders, as well as those with marked myotonia, such as myotonia congenita and paramyotonia.

Sometimes the clinical presentation of DM is so distinctive that the experienced clinician uses tools only to confirm a diagnosis already made. EMG should be employed in suspected DM when myotonia is clinically equivocal or absent. The typical pattern is of long-lasting runs with declining frequency and amplitude, with the distal muscles of the upper extremities and the orbicularis oris most often being involved. A careful slit-lamp evaluation will ascertain characteristic posterior lenticular opacities and should be performed on any patient suspected of having this condition. Muscle biopsy may show a constellation of abnormalities, including increased central nuclei, nuclear chains, ringed fibers, sarcoplasmic masses, atrophy of type I fibers, increased numbers of fibers in spindles, and increased arborization at the terminal.¹⁷⁴ Nerve biopsy shows increased arborization. Other conditions associated with myotonia, such as myotonia congenita (see Chapter 37) and drug-induced myotonia (see Chapter 55), need to be considered.

MANAGEMENT AND PROGNOSIS. Because there is no cure for DM, current management focuses on treatment of the myotonia and associated systemic problems, monitoring of pregnancy, and genetic counseling. Because patients frequently do not perceive their myotonia as being

problematic, they may not follow a treatment plan. However, 100 mg of phenytoin taken three times daily is effective in reducing myotonia and does not produce the cardiosuppressive complications of either quinine or procainamide. Anesthesia should be used for these patients only when it cannot be avoided. Myotonia may be increased by the depolarizing relaxants used for inducing anesthesia or the anticholinesterases used to terminate relaxation, although the barbiturates, benzodiazepines, and opiates may produce apnea. Cases have been reported in which the diagnosis of DM has been made only after the patient experienced postoperative apnea. Harper and Rudel¹⁷⁴ provide a comprehensive discussion of anesthetic management in DM. A bracelet that identifies the patient as having DM may be helpful.

Because cardiac complications may be life threatening, careful evaluation, including a His bundle electrogram, must be performed to ascertain conduction defects that need pacemakers. Some respiratory problems may be avoided by upright positioning during meals and by spacing meals well ahead of bedtime.

There is increased risk of spontaneous abortion in myotonic mothers, as well as complications during labor and delivery. There may be incoordination of contractions during labor that prolong the first stage, a retained placenta, and postpartum hemorrhage, as well as the previously cited anesthetic sensitivity.

Presymptomatic and prenatal genetic counseling, including a discussion of the increased risks of pregnancy to an affected or carrier mother as well as to the fetus, the phenomenon of anticipation, and congenital DM, should be provided to families with a history of DM. It should be remembered that although a significant number of people with DM are mentally impaired, some who are not may be perceived as such because of facial weakness.

Oculopharyngeal Muscular Dystrophy

Oculopharyngeal muscular dystrophy is a disorder of late adult onset characterized by progressive ptosis and dysphagia. It is caused by short GCG expansions in the poly(A)-binding protein gene on chromosome 14. Most often, the disease is dominant, with a more severe phenotype observed in compound heterozygotes for the GCG 9 mutation and the GCG 7 allele. Homozygosity for that same allele may produce recessive disease.¹⁷⁷ The highest prevalence of oculopharyngeal muscular dystrophy continues to be in Quebec, Canada, but families have now been identified in more than 20 countries.

Asymmetrical weakness of the levator palpebrae and pharyngeal muscles is the initial presentation, generally after the age of 50 years. Eventually, all extraocular muscles may become involved. There is no cardiac involvement. The EMG shows myopathic changes. Muscle biopsy reveals changes found in other muscular dystrophies: loss of muscle fibers, variation in fiber size, increased numbers of nuclei and internal nuclei, and increased fibrous and fatty connective tissue. On histochemistry, there are small angulated fibers that react strongly for oxidative enzymes and "rimmed" vacuoles, particularly in type I fibers from extremity muscles rather than extraocular muscles. On electron microscopy, there are unique intranuclear tubular filaments.¹⁷⁸

Oculopharyngeal muscular dystrophy can be distinguished from inclusion body myositis which presents as dysphagia. It also has rimmed vacuoles, but the filaments seen are larger and are present in the cytoplasm as well as the nucleus; there are no ocular palsies. Ocular myasthenia gravis without waxing and waning of symptoms may produce weakness in the same distribution as oculopharyngeal muscular dystrophy, but it generates demonstrable neuromuscular junction transmission defects on EMG and neuromuscular junction abnormalities on morphological studies. Although late onset of the mitochondrial myopathy, Kearns-Sayre syndrome, or oculocraniosomatic disease may present with ptosis, histochemical and ultrastructural studies of muscle show biochemical defects in the respiratory chain and mitochondrial DNA deletions.

Interventions, such as eyelid crutches to alleviate the ptosis and a feeding tube to provide adequate nutrition, are palliative. If the patient does not receive a feeding tube, the dysphagia will lead to early death by malnutrition and starvation.

Emery-Dreifuss Muscular Dystrophy

ED MD, which is characterized by early contractures and cardiomyopathy, was first identified as a distinct form of muscular dystrophy in a large Virginia family in 1966.¹⁷⁹ Generally, it is X-linked recessive, although there are rare autosomal dominant and autosomal recessive cases caused by mutations in the lamin A/C gene on chromosome 1q.¹⁸⁰ The incidence of the X-linked type is estimated to be approximately 1 in 100,000. One of 10 new X-linked cases may be a new mutation.¹⁸¹

In 1994, the gene for the X-linked ED MD was identified as STA at Xq28.¹⁸⁰ It codes for emerin, a serine-rich protein of 254 amino acids, which resembles membrane proteins of the secretory pathway involved in vesicular transport.¹⁸² Several different mutations have been reported that result in lack of emerin in skeletal and cardiac muscle.^{183,184} Although the lack of emerin seems to cause the disease, the pathway remains to be established. In 1999, mutations in the lamin A/C gene on chromosome 8, which encodes for two proteins of the nuclear lamina, were identified in dominantly inherited ED MD.¹⁸⁵ This was the first time mutations in a component of nuclear lamina had been implicated in an inherited muscle disorder. There is a report of an individual with ED MD with a homozygous mutation in this same gene. His heterozygous parents are totally asymptomatic, which demonstrates that heterozygous mutations produce a broad range of phenotypes.¹⁸⁶

The classic symptoms of ED MD include (1) contractures of elbows, Achilles' tendon, and postcervical muscles before weakness is present; (2) slowly progressive weakness and muscle wasting, generally starting in the humero-peroneal muscles; and (3) a cardiomyopathy that frequently presents as heart block. LGMD1B is allelic to the dominant form of ED MD.¹⁸⁷

The early contractures and heart conduction block are features that are helpful in distinguishing this from other muscular dystrophies that may have weakness in the same distribution and the same pattern of inheritance. The main features of the cardiac involvement are impairment of

impulse-generating cells, variable sinoatrial and atrioventricular conduction defects, increased atrial and ventricular heterotopia, and functional impairment of the myocardium. Rigid spine syndrome can be confused with ED MD but occurs sporadically, has contractures that are limited to the spinal musculature, and usually does not involve cardiac problems.¹⁸⁸

In ED MD, the muscle biopsy has nonspecific myopathic or dystrophic changes, including variation in fiber size and fiber necrosis, and endomysial and perimysial fibrosis. Unlike DMD and BMD, there is no alteration in dystrophin.¹⁸⁹

The care provided to the patient is similar to that for the other muscular dystrophies, with the notable exception of cardiac intervention. Emery documented that up to 40% of patients with ED MD die suddenly, many of them without any preceding cardiac symptoms. Therefore, a thorough cardiac evaluation is essential. Asymptomatic female carriers should be evaluated because they may also have cardiac abnormalities.¹⁹⁰ Recent recommendations include pacemakers for X-ED patients and implantable defibrillators for AD-ED patients, who are more likely to exhibit ventricular dysrhythmias (see Table 36-6).

One study suggests that the small size of the STA gene and its housekeeping pattern of expression may make gene therapy possible in ED MD.¹⁹¹ The function of emerin is unknown and efforts to make an emerin-deficient mouse have not produced a model with overt pathology. However, these mice do exhibit abnormalities in cell cycle parameters and delayed myogenic differentiation, which in turn disrupt transcriptional pathways regulated by the retinoblastoma and MyoD genes.¹⁹² Motsch and coworkers¹⁹³ report two ED-causing lamin A mutations relocated exogenous lamin A from the nuclear envelope to the cytoplasm, disrupting nuclear envelope reassembly following cell division and altering protein composition of the midbody. In contrast, exogenously expressed mutant lamin C constructs were inserted into the nuclear lamina if coexpressed with any lamin A construct except one with the T150P mutation. The T150P, R527P, and L530P mutations reduced the capacity of lamin A, but not lamin C, to bind with emerin.¹⁹³ Another report suggests emerin-deficient mouse embryo fibroblasts exhibit normal nuclear mechanics even though they have impaired expression of mechanosensitive genes in response to strain, suggesting emerin mutations may act via altered transcriptional regulation rather than by increasing nuclear fragility.¹⁹⁴

Distal Myopathies

The distal myopathies are a rare heterogeneous group of disorders characterized by progressive muscular weakness and atrophy beginning in the hands or feet (Table 36-8).¹⁹⁵⁻²⁰¹ Several types of distal myopathies have been differentiated clinically, distinguished either by site of onset or mode of inheritance or by differences seen on muscle biopsy, but as their genetics emerge, reclassification is taking place on that basis.

The late adult-onset distal autosomal dominant myopathy that first appears in the hands, also called Welander distal myopathy or Swedish-type distal myopathy, has been linked to chromosome 2p.¹⁹⁵ It has a mean onset of 47 years (range, 20 to 77 years), with weakness in the hands

TABLE 36-8

Distal Myopathies: Distinctions in Different Types

| AGE OF ONSET | TYPE | SITE OF ONSET | GENE/GENE LOCUS | INHERITANCE |
|-----------------------------------|--------------------|---|--------------------------|-------------|
| Late adulthood | Welander | Hands | 2p13 ¹⁹⁵ | AD |
| | Finnish | Legs | TTN ¹⁹⁶ | AD |
| | Markesberry-Griggs | Legs | ? | AD |
| Early adulthood | Type I: Nonaka | Anterior compartment of legs | GNE ¹⁹⁸ | AR |
| | Type II: Miyoshi | Posterior compartment of legs | Dysferlin ¹⁹⁹ | AR |
| | Type III: Laing | Anterior compartment of legs, distal weakness with sternocleidomastoid weakness | MYH7 ²⁰⁰ | AD |
| Childhood (ages 5 to 15 years) | Desmin storage | Distal weakness with respiratory, and bulbar involvement | Desmin ²⁰¹ | AD |
| | Juvenile | Feet, then hands | | AD |
| Infancy (<2 years) | Infantile | Hands and feet | | AD |

AD, autosomal dominant; AR, autosomal recessive; GNE, UDP-*N*-acetylglucosamine-2-epimerase/*N*-acetylmannosamine kinase; MYH7, slow skeletal muscle fine myosin heavy chain; TTN, titin.

that generally presents as clumsiness in the thumb and forefinger that spreads to other fingers. Eventually, patients develop distal leg weakness, more often in the extensors. Fewer than 20% of patients develop proximal extremity weakness, whereas more than 90% complain of vasomotor disturbances, primarily a sensation of cold, in the hands and feet. Another late adult-onset autosomal dominant disease found in Finland first involves weakness in the anterior tibial muscles, followed by weakness of the long toe extensor muscles and proximal leg weakness in approximately half of patients. There is no weakness in the hands. It caused by mutations in the gene encoding the skeletal muscle protein titin.¹⁹⁶ Yet another late-onset autosomal dominant distal myopathy, known as Markesberry-Griggs myopathy, has been described in which proximal weakness is also common and the intrinsic foot muscles are affected. Cardiomyopathy in non-Scandinavian middle-aged adults can also occur.¹⁹⁷

The early adult-onset autosomal recessive myopathies begin with leg weakness. Type I, Nonaka myopathy, starts in the anterior compartment, usually presenting with foot-drop, and is caused by mutations in the gene encoding UDP-*N*-acetylglucosamine-2-epimerase/*N*-acetylmannosamine kinase (GNE).¹⁹⁸ Type II, Miyoshi myopathy, starts in the gastrocnemius muscles and is caused by mutations in the gene encoding dysferlin.¹⁹⁹ Dysferlin-null transgenic mice demonstrate subsarcolemmal vesicle accumulations and their muscle fibers were defective in calcium-dependent sarcolemma resealing.¹⁹⁹ There are two other early adult-onset forms that are autosomal dominant. Laing myopathy, caused by mutations in the slow skeletal muscle fiber myosin heavy chain gene, includes facial and shoulder weakness in addition to distal weakness.²⁰⁰ Desmin storage myopathy has respiratory, cardiac, and bulbar musculature involvement as well as prominent hand and foot involvement. The gene that codes for desmin, a muscle-specific subunit of the cytoskeletal elements of the intermediate filaments, has been identified on chromosome 2.²⁰¹

Two early onset forms have also been described in Dutch and British families. The infantile-onset form spreads from the feet to the hands but does not progress after age 18 years. The juvenile-onset form starts simultaneously in the hands and feet and slowly progresses until approximately age 50 years.¹⁹⁷

The differential diagnosis includes myopathies and neuropathies. Whereas most myopathies predominantly affect proximal muscles, a few that can present distally include various metabolic myopathies and inclusion body myositis. Laing myopathy can resemble FSH MD. Although distal weakness may suggest neuropathic disorders, EMG and muscle studies establish the myopathic changes. Serum CK activity is markedly increased, often 50 times the normal value. Electrical studies demonstrate signs of myopathy in the involved areas of weakness, where nerve conduction studies are normal. Muscle biopsy shows dystrophic changes of variable severity. Rimmed vacuoles are frequently observed, suggesting a link between distal myopathies and inclusion body myositis. Patients with Welander's disease also show angulated fibers, whereas desmin storage is typical of the early adult-onset form with respiratory muscle involvement. DM can present without clinically apparent myotonia, and the neuronal late-onset type of Charcot-Marie-Tooth disease (CMT) may look similar.¹⁹⁷

Thus far, no medical interventions have improved these conditions. Appropriate orthotics and physical and occupational therapy provide the most assistance. By and large, these are slowly progressive disorders that sometimes plateau, and they are not life threatening.

DEGENERATIVE NEUROPATHIES

Hereditary Sensory and Motor Neuropathies

In general, the hereditary sensory and motor neuropathies are peripheral neuropathies that affect autonomic nerves, sensory nerves, motor fibers, or a combination thereof. The molecular genetics of these disorders is being ardently pursued, and the mechanisms underlying them are rapidly being unraveled. However, to date there is overlapping terminology used when they are described (Table 36-9). This discussion is organized according to the classification that is emerging based on genetics (Table 36-10).²⁰²⁻²³⁵ CMT is the most common hereditary sensory and motor neuropathy, and CMT type 1A is the most common form of CMT, accounting for more than 50% of all CMT cases.

PATHOGENESIS AND PATHOPHYSIOLOGY. Pathological changes seen in CMT include loss of myelinated fibers and sclerosis in the posterior column of the spinal

TABLE 36-9

Types of Hereditary Sensory and Motor Neuropathy

| TYPE | OTHER NAMES | PARTICULAR CHARACTERISTICS |
|----------|------------------------|--|
| HSMN I | CMT 1 | Hypertrophic demyelinating neuropathy |
| HSMN II | CMT 2 | Axonal neuropathy with normal or near-normal nerve conduction velocities |
| HSMN III | CMT 3, Dejerine-Sottas | Severe hypertrophic demyelinating neuropathy with onset in infancy |

CMT, Charcot-Marie-Tooth.

cord, particularly in the fasciculus gracilis in its upper regions. Peripheral nerves show fewer myelin sheaths, with the extent of the decrease correlating with the severity of clinical disease. There is also loss of large axons and an increase in transverse fascicular area, especially in the auricular and sural nerves. Onion bulbs, made up of circumferentially directed Schwann cells and their processes, can be seen at myelinated internodes, demyelinated internodes, or former sites of myelinated fibers.

There has been considerable controversy throughout the years whether the primary defect in CMT originates in the neuron and its axon or in the Schwann cell. The primary histopathological changes involve demyelination, whereas the clinical picture of muscle weakness and atrophy is evidence of muscle denervation and axonal loss and of axons with calibers reduced out of proportion to the extent of myelin loss.²³⁶

The gene defects and their products associated with the CMTs are beginning to resolve this question. Peripheral myelin protein 22 (PMP22), which has been implicated in several of the CMTs (see Table 36-10), is present as a protein in all myelinated fibers of the peripheral nervous system and is localized to compact myelin. Studies in the trembler mouse, an animal model that also has a gene defect in PMP22, indicate that Schwann cells can modulate axon caliber, neurofilament phosphorylation, and neurofilament density within the axoplasm. Therefore, abnormal expression of PMP22 could account for both the neuronal and the Schwann cell alterations seen in CMT.²³⁷ The progesterone antagonist onapristone reduced overexpression of PMP22, improved motor performance, and maintained large axons in CMT1A rats with extra copies of PMP22. PMP22 mRNA was reduced by 15% in the treated animals, suggesting reduced PMP22 transcription may have a reduced disease severity.²³⁸ Administration of ascorbic acid in mice overexpressing PMP22 resulted in amelioration of the CMT1A phenotype with a 1-fold decrease in PMP22 in the sciatic nerve.²³⁹ Myelin protein zero (MPZ) is the major component of peripheral nervous system myelin. It is an integral membrane glycoprotein, and its expression is confined to myelinated Schwann cells. A major role of the protein zero extracellular domain is compaction of peripheral myelin, whereas the cytoplasmic domain is thought to interact with a component of the opposing membrane of the compact myelin, holding these membranes together.²⁴⁰ LITAF has been found in the cytoplasm of sciatic nerve Schwann cells, as well as in adipocytes, mast cells, endothelial cells, and vascular smooth muscle cells,²⁴¹ where it may play a role in protein degradation.²⁰⁴ MNFN2, mitofusin, is necessary for mitochondrial fusion.²⁴² Connexin 32 is a gap junction protein. Before its identification as a gene for X-linked CMT (CMT X1), it was not known that there were gap junctions in human peripheral nerve. It has now been detected at the nodes of Ranvier and the Schmidt-Lanterman incisures, which may mean it forms intracellular gap junctions between the folds in Schwann cell cytoplasm.²²⁷

EPIDEMIOLOGY AND RISK FACTORS. The hereditary sensory and motor neuropathies occur worldwide, with an estimated prevalence ranging from 4.7 to 36 per 100,000 and an approximate incidence of 1 in 25,000 people. Autosomal dominant, autosomal recessive, and X-linked dominant and recessive inheritance patterns have been reported (see Table 36-10).

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Although there is wide intrafamilial variability in phenotype, it is generally accepted that clinical presentations of CMT 1A and 1B are similar, although they are distinguishable, and CMT 1A may have a milder clinical course than 1B. Age of onset ranges from childhood to early adulthood, with symmetrical insidious weakness and atrophy of the intrinsic foot and peroneal muscles occurring first, associated with varus deformity of the feet and a step-gait (Video 34, Charcot-Marie-Tooth Disease). Calf, intrinsic hand, and thigh muscles may be involved later (Fig. 36-8). Atrophy tends to occur at the distal ends of the gastrocnemius, soleus, and quadriceps muscles. Cramps and fasciculations are often reported after exercise. Stretch reflexes disappear first in the gastrocnemius and soleus, then the quadriceps, and, finally, the arms.

Although patients generally do not report sensory disturbances, a careful examination reveals abnormalities in all modalities. Pes cavus and hammertoes are present in up to two-thirds of patients. Decreased skin temperature over the distal leg is common, and decreased sweating has been reported. Enlargement and hardening of nerves, particularly those between the shoulder and elbow, have been observed in up to one-fourth of patients. Pain, primarily in the feet, is reported by 20% to 30% of CMT 1 patients.²⁴³

Hereditary neuropathy with liability to pressure palsies, also called “tomaculous neuropathy,” is a syndrome characterized by a tendency toward the development of recurring

sensory and motor nerve palsies brought on by mild pressure or trauma to a particular peripheral nerve bundle (Video 217, Anterior Interosseous Neuropathy, Pinch Sign; Video 218, Ulnar Neuropathy, Wartenberg Sign). Some of these patients have a deletion of PMP22.²⁴⁴ An insult from which a normal person would quickly recover results in residual nerve damage that may take days or even months to resolve. Some of these patients go on to develop CMT, whereas other family members may have only the HNPP phenotype.

Dejerine-Sottas syndrome, sometimes called progressive hypertrophic neuropathy, is a more severe form of peroneal muscular atrophy with presentation in infancy of progressive generalized muscle weakness, severe sensory loss, limb ataxia, and marked hypertrophy of peripheral nerves. Both dominant and recessive inheritance patterns have been reported. Molecular genetic studies indicate that Dejerine-Sottas syndrome is a variation of CMT with a generally more malignant phenotype.

Approximately 10% of cases of CMT are X-linked, in which primarily male family members are affected through maternal transmission. Again, there is intrafamilial variation in severity, but generally onset occurs in childhood, with slowly progressive distal weakness and sensory disturbance that tends to be more severe than that seen in CMT 1. Carrier females may have mild, variable clinical disease.

In Roussy-Levy syndrome, peroneal muscular atrophy is associated with essential tremor. Although originally described as a separate disorder, it has been shown to be a phenotypic variant of CMT 1A.²⁴⁵

DIFFERENTIAL DIAGNOSIS AND EVALUATION. Other mixed polyneuropathies of nutritional, infectious, toxic, autoimmune, and vasculitic origin should be considered. Both axonal and demyelinating neuropathies need to be included in the differential diagnosis. At present, genetic confirmation of this disorder is available for CMT 1A, 1B, 1C, 1D, and 1F; CMT 2A, 2B, 2B1, 2D, 2E, 2F, 2I, 2J, 2K; CMT X; CMT 4A, 4E, and 4F; and hereditary neuropathy with liability to pressure palsies. CK is normal. On EMG, nerve conduction velocities are slowed in peripheral nerves. The extent of velocity reduction is no longer an accepted criterion for diagnosing the type of CMT. On nerve biopsy, there is a moderate increase in epineurium and perineurium and a variable decrease in the number of myelinated fibers that correlates with the severity of disease. Onion bulb formation is visible around myelinated and demyelinated internodes.²³⁶

MANAGEMENT. There is no cure or effective treatment for these disorders. Physical therapy, occupational therapy, and orthotic devices can help maintain optimal function. Genetic counseling is an obvious and important component of care for these patients.

PROGNOSIS AND FUTURE PERSPECTIVES. Although large studies are not available, several series conclude that life expectancy is not reduced in CMT 1 and that generally those with CMT 1A remain ambulatory throughout their lives. A 20-year follow-up study of a family with CMT 1B demonstrated that patients remained ambulatory with a normal life span. Autopsy studies included a 92-year-old family member.²⁴⁶ Approximately twice the incidence of anomalies, postpartum bleeding, and caesarean delivery and three times the incidence of forcep delivery characterized 108 births in 49 Norwegian mothers with CMT. This

TABLE 36-11

Hereditary Sensory and Autonomic Neuropathies

| TYPE | HALLMARK | INHERITANCE PATTERN |
|---|--|---|
| HSAN I (hereditary sensory radicular neuropathy) | Insensitivity to pain in feet and ensuing tissue complications | Primarily autosomal dominant |
| HSAN II (congenital sensory neuropathy) | Early onset of loss of sensation in all modalities | Autosomal recessive |
| HSAN III (familial dysautonomia, Riley-Day) | Early onset, predominantly autonomic symptoms, absence of fungiform papillae on the tongue | Autosomal recessive, predominantly Jewish (gene on D9S58) |
| HSAN IV (familial sensory neuropathy with anhidrosis, congenital insensitivity to pain) | Mild mental retardation, episodes of fever related to environment rather than infection | Rare |
| HSAN V (congenital sensory neuropathy with selective loss of small myelinated fibers) | Congenital insensitivity to pain in extremities, normal strength and tendon reflexes, abnormality of nociception | Fewer than 10 cases reported |

may reflect CMT in the fetus and adrenergic-mediated uterine atony in the mother.²⁴⁷ A double-blind, randomized, placebo-controlled study demonstrated that subcutaneous injection of neurotrophin-3 resulted in sensory improvement and peripheral nerve regeneration in 4 CMT 1A patients compared to 4 untreated patients. A similar effect was observed in PMP22 duplication and PMP22 point mutation transgenic mice with improved Schwann cell survival and differentiation.²⁴⁸

Hereditary Sensory and Autonomic Neuropathies

The hereditary sensory and autonomic neuropathies (HSANs) are conditions in which primary sensory and autonomic neurons either fail to develop or undergo system atrophy and degeneration. Dyck proposes the comprehensive subdivision shown in Table 36-11. These disorders have been called by a large variety of names because their symptoms were described by various investigators. Types I, II, and III are discussed here. Within this classification, there are two large divisions: HSAN I is a progressive disorder with symptom onset usually occurring in the second decade or later with primarily lower extremities affected. HSANs II to V are static congenital disorders that are more generalized. A common thread among all the types is insensitivity to pain.²³⁶

Hereditary Sensory and Autonomic Neuropathy Type I

HSAN I is a disorder in which sensory disturbances and associated tissue complications outweigh its motor and autonomic manifestations. HSAN I is a rare disorder that is usually autosomal dominantly inherited, although recessive and X-linked pedigrees have been identified.²³⁶ There is chronic axonal atrophy, myelin remodeling, and axonal degeneration with sparing of the CNS and non-neural tissues. HSAN I is caused by missense mutations in the SPTLC1 gene at 9q22. These mutations increase de novo glucosylceramide synthesis in lymphoblast cell lines, which triggers apoptosis, causing massive cell death during neural tube closure, which may be the mechanism of neural degeneration seen in HSAN I.²⁴⁹

Although there are different phenotypes, typically the disorder presents in one of the following ways: (1) foot complications, such as plantar ulcers, recurring paronychia of toes, stress fractures of foot bones, recurrent cellulitis, and resorption of foot bones; (2) spontaneous pain, either burning or aching of the feet that is worsened with weight bearing and decreased at night, or disabling lancinating

pain in deep tissues of the feet, legs, or shoulder; or (3) symptoms of sensory and autonomic neuropathy.

The complications of HSAN I may be of sudden, overwhelming onset, with ulcers first developing over pressure points on the foot. When these ulcers are neglected, they do not heal and are associated with the complications previously described. Phenotypes have been reported in which HSAN is associated with deafness, leg weakness and atrophy, burning feet, restless legs, and neuropathic atrophy. HSAN is a slowly progressive disorder that does not seem to decrease the life span. It cannot be emphasized enough that proper foot care can prevent complications that can lead to foot amputation and sepsis.

HSAN I may be distinguished from other varieties of HSAN because it starts later, usually in the second or third decade; is slowly progressive; and preferentially affects lower limbs. It is closest in presentation to HSAN II, although in that condition, the motor and autonomic symptoms outweigh the sensory symptoms and deficits of type I. Spinocerebellar degeneration can be distinguished from HSAN I because of its kinesthetic and mechanoreceptor loss, cerebellar ataxia, and relatively less small fiber sensory and autonomic dysfunction. Familial amyloidosis may include sexual and sphincter dysfunction, which are not found in HSAN I, and porphyria with neuropathy has a more acute onset associated with changes in mental status.

Typically, touch-pressure threshold, thermal discrimination, and nociception are abnormally elevated in the foot and leg, although they may be altered in the arm and hand as well. Paresthesias are not present. Loss of sweating in the distal leg is common. Sural nerve amplitudes are reduced, with small myelinated fibers being primarily affected. A decrease in the Achilles tendon reflex is common, followed most often by a decrease in the quadriceps reflex.²³⁶

There is no effective treatment. The main goal is the prevention of foot ulcers. The feet should be inspected regularly for signs of pressure points, soaked daily, and treated with petrolatum lotion applied to seal in moisture. Shoes should be chosen carefully to avoid pressure points. Any ulcers should be treated promptly with cleaning and debridement, if necessary. The appropriate antibiotic should be used for cellulitis or septicemia. Genetic counseling should include information about phenotypic variation and degree of risk.

Hereditary Sensory and Autonomic Neuropathy Type II

HSAN II is characterized by an early onset of loss of sensation in all modalities. This is a rare disorder, in which

Figure 36-9. Child with hereditary sensory neuropathy type II showing destruction of tongue tissue due to insensitivity to pain. (Courtesy of Dr. J. Sarlangue, Hôpital Pellegrin Enfants, Bordeaux, France.)

cases reported are either sporadic or within a sibship, suggesting an autosomal recessive pattern of inheritance. There is profound loss of myelinated fibers in cutaneous nerves, especially the sural nerve. Dyck proposes that the degenerative process begins in utero or in infancy.²³⁶ There are fewer nerve fibers at the ankle than the midcalf, marked denervation of the extensor digitorum brevis, evidence of segmental demyelination and remyelination, and electron microscopic abnormalities within axis cylinders.²³⁶ Lafreniere and associates²⁵⁰ identified three truncating mutations in the HSN2 gene at 12p13.33 in five families from eastern Canada. This gene consists of a single exon within intron 8 of the PRKWINK1 gene and is transcribed from the same strand. They postulate the HSN2 protein may play a role in development and maintenance of peripheral sensory neurons or Schwann cells.

Symptoms first appear in infancy or early childhood and may be widespread. Paronychia, whitlows, ulcers of the fingers and feet, and previously undetected fractures of the foot and hand are common and result directly from underlying sensory disturbance (Fig. 36-9). There have been pedigrees reported with HSN II and other dysautonomic features, as well as retinitis pigmentosa or tonic pupils. There is sensory loss affecting all modalities in the lower and upper limbs and sometimes in the trunk. Tendon reflexes are generally absent or diminished in all limbs. There is loss of sweating over acral parts. However, there is no prominent muscle weakness, postural hypotension, or sphincter disturbance.

Generally, there are no sensory nerve action potentials elicitable in the ulnar, median, or sural nerves, whereas the conduction velocities of motor fibers of the same nerves are at or just below the lower end of normal. Minimal fibrillation may be found in the extensor digitorum brevis, which has a decreased number of motor unit potentials, a large number of which are polyphasic.²³⁶

Complications are much more difficult to prevent in HSN II owing to its early onset at an age when patients cannot understand the problem or cooperate with preventive regimens. In addition, complications are frequent because the hands are so seriously affected. Preventive

care, which is similar to that of HSN I, needs to be as aggressive as possible because complications may be life threatening. Special attention should be given so that these children have adequate educational opportunities to develop their intellectual potential despite severe physical handicaps. Genetic counseling should be provided.

Hereditary Sensory and Autonomic Neuropathy Type III (Riley-Day Syndrome, Familial Dysautonomia)

HSAN III is present almost exclusively in Ashkenazi Jews. Some investigators argue that those who are not Jewish in fact have a different type of neuropathy. The gene frequency has been estimated at 0.01 per 100,000 Jews in the United States.²⁵¹ Mutations in the gene that codes for IKAP, a scaffold protein and regulator for three different kinases involved in proinflammatory signaling, have been identified. The most common causative mutation, located at the donor splice site of intron 20, produces a truncated protein.²⁵² Postmortem studies have varied widely; some have shown no nervous system lesions at all, whereas others have shown extensive damage, particularly in the brain stem reticular formation, the cortex, and the long tracts of the cord. There is a marked decrease in the number of unmyelinated fibers of the cutaneous nerves.²³⁶

Usually, HSN III presents at birth. Axelrod²⁵³ proposes that it should be suspected in a child of Eastern European Jewish extraction with breech delivery, meconium staining, poor suck, hypotonia, or hypothermia. There is difficulty feeding and a failure to thrive, along with unexplained fevers, lack of tearing, paroxysmal hypertension, increased sweating, cold hands and feet, erythematous blotching of the skin, and drooling. There is also a lack of fungiform papillae on the tongue, a feature that is highly distinctive of this disorder. Although there is overlap between symptoms and signs of this and other types of HSN, examination of the tongue leads to the exclusion or inclusion of this diagnosis. If the disorder presents later, it may be observed as delayed development or stunted growth with decreased pain sensation and ataxia. Abnormalities in cutaneous temperature discrimination and nociception are present in most patients, whereas fewer have abnormalities in joint position and vibratory sensation.

Recurrent vomiting is common in the early years. Several gastrointestinal abnormalities have been identified: megaesophagus, pylorospasm, gastric ulcer, jejunal distention, and megacolon. Corneal abrasions may occur secondary to corneal insensitivity, whereas neuropathic or Charcot's joints may occur secondary to pain insensitivity. Approximately half of patients develop kyphosis, scoliosis, or both. Pulmonary complications, profound hypotension, and prolonged respiratory depression from the administration of anesthesia have been reported.²³⁶

Clinical and laboratory diagnosis may be based on the presence of five signs: (1) lack of the normal flare after intradermal injection of histamine, (2) the absence of fungiform papillae on the tongue, (3) miosis of the pupil after conjunctival instillation of 2.5% methacholine chloride, (4) absent deep tendon reflexes, and (5) diminished tear flow. Sural nerve biopsy shows markedly decreased unmyelinated fibers, no active fiber degeneration, and fewer Schwann cell cytoplasmic clusters than other types of

neuropathy. Nerve conduction velocity studies have found mixed nerve velocities within the normal range.²⁵³

Aberrant splicing of IKAP mRNA in patient fibroblasts has been corrected using epigallocatechin gallate (EGCG) to downregulate expression of HNRPA2B1, a transactivating factor that encourages the use of intron-distal 5' splice sites, resulting in generation of more exon 20 containing IKBAP transcript. Synergistic production of correctly spliced transcript and IKBKAP protein was observed when patients' fibroblasts were treated with EGCG and tocotrienol, a vitamin E isoform that upregulates transcription of the IKABKAP gene, suggesting that EGCG may be a potential therapy.²⁵⁴ Generally, however, treatment remains supportive and is best provided by an interdisciplinary team that includes a genetic counselor. Prenatal diagnosis is available for informative families.²⁵⁵ Most patients do not survive to adulthood, succumbing to either recurrent infections or hyperpyrexia. The oldest surviving patient in one series was 38 years old, with one-third of the patients in that series being 20 years or older.²⁵⁶

Hereditary Sensory and Autonomic Neuropathy Type IV

This rare condition, in which there is a sensory neuropathy accompanied by unexplained fevers, congenital insensitivity to pain, anhidrosis, and mental retardation, generally causes death from hyperpyrexia by age 3 years.²⁵⁷ Mutations in the NTRK1 gene, which codes for the tyrosine kinase nerve growth factor receptor, have been identified as the cause,²⁵⁸ which suggests this factor plays a crucial role in the development and function of the nociceptive reception system as well as thermal regulation.

Hereditary Sensory and Autonomic Neuropathy Type V

Homozygous mutations in the gene encoding nerve growth factor-beta have been identified in a large consanguineous Swedish family with loss of pain perception, impaired temperature sensitivity, ulcers, some cases of self-mutilation, severe reduction of unmyelinated nerve fibers, moderate loss of thin myelinated nerve fibers, and variable autonomic involvement.²⁵⁹

Autonomic Neuropathy of Multiple System Atrophy (Shy-Drager Syndrome)

In 1960, Shy and Drager first described the combination of progressive autonomic failure and multiple system atrophy that manifested as orthostatic hypotension, akinesia, and rigidity that led to incapacity in a few years (see Chapter 34). In the ensuing years, conditions including striatonigral degeneration and forms of olivopontocerebellar atrophy have been combined with Shy-Drager syndrome under the larger category of degenerative processes called multiple system atrophy. This discussion focuses on the phenotype with prominent dysautonomia that was described by Shy and Drager.

Shy-Drager syndrome affects men more often than women, most often in middle age or later. A Japanese series calculated the prevalence to be 0.3 per 100,000.²⁶⁰ There have been reports of families with autosomal dominant inheritance. A genetic basis was postulated in 1983 when an association

was found between HLA antigen Aw32 and autonomic failure.²⁶¹ Thus far, no gene has been identified. Recent work with α_1 -B-adrenergic receptors (α_1 -BARs) in transgenic mice that overexpress either wild-type or constitutively active α_1 -BARs produced granulovacuolar degeneration similar to that seen in Shy-Drager syndrome.^{262,263} There is degeneration of both pigmented catecholamine-containing cells in the brain stem and cholinergic cells in the intermediolateral columns, along with distal ganglionic and postganglionic degeneration. The abnormality in sympathetic function leads to depressed circulating norepinephrine responses to standing and exertion. There is enhanced blood pressure response to norepinephrine administration, along with evidence of increased α - and β -receptor concentrations, which correlates to supersensitivity to norepinephrine. Basal norepinephrine levels are normal. Generally, catecholamine is depleted in sympathetic nerve endings around blood vessels.²⁶⁴

Often in the male, the first symptom is impotence and loss of libido, with disturbance in micturition being common in both sexes. The characteristic orthostatic hypotension may be seen either as so-called drop attacks or as a gradual loss of consciousness over approximately 1 minute that is often associated with a neckache that radiates to the occiput and shoulders. Generally, there is at least partial loss of thermoregulatory sweating. Respiratory disturbance occurs as involuntary gasping, cluster breathing, and laryngeal stridor that may lead to obstructive sleep apnea and even death, or to central sleep apnea.

On neurological examination, abnormalities of the pupil, including Horner's syndrome, alternating anisocoria, and abnormal responses to drugs, may be seen. Mild parkinsonian features or cerebellar ataxia may accompany the condition, but dysautonomia is the predominant dysfunction. In the striatonigral degeneration variant, or multiple system atrophy, rigidity with little tremor, progressive loss of facial expression, limb akinesias, anterocollis, and gait instability predominate (see Chapter 34). There is difficulty walking, standing, turning, and feeding oneself, and the speech is faint and slurred. With pyramidal lesions, there may be an increase in tone, along with impaired rapid hand and foot movements and exaggerated deep tendon reflexes and bilateral extensor responses. Primitive reflexes may be present, and amyotrophy is common. Dementia is not seen more often than would be expected by chance owing to the age of this population. When the olivopontocerebellar variant is present, ataxia and limb tremor develops.²⁶⁵

DIFFERENTIAL DIAGNOSIS. Pure autonomic failure (Bradbury-Eggleston syndrome) may present with the same autonomic disturbance as Shy-Drager syndrome, but it does not have any other neurological symptoms. Amyloidosis may also look similar but generally is associated with a greater degree of bowel involvement and pain. Familial dysautonomia (Riley-Day syndrome or HSAN III) presents in children and therefore is distinguishable from Shy-Drager syndrome.

MANAGEMENT. Several general actions may help the patient avoid aggravation of orthostatic hypotension: maintenance of adequate blood volume with fluid intake of 2 to 2.5 L/day, sleeping in a semirecumbent position, and rising slowly to standing. In addition, patients should avoid excessive warmth (in bathing and climate); do moderate

rather than vigorous exercise; eat small, frequent meals; and avoid vasodilators, such as alcohol and nitroglycerin. Mechanical support may be provided by Jobst's stockings in combination with abdominal binding. Severe orthostatic hypotension has been successfully managed with an air force anti-gravity suit.²⁶⁴ The most common pharmacological agent used is fludrocortisone, which increases blood volume and maintains venous return to the heart. Second-line drugs are the vasoconstrictors, such as phenylephrine and ephedrine, with the prostaglandin inhibitors being the next choice, followed by β_1 agonists. There is a report of a single patient responding favorably to octreotide, a splanchnic venoconstrictor.²⁶⁶ Early tracheostomy for laryngeal stridor may prevent premature death. A Japanese study found that 90% of patients were alive 3 years after their first symptoms and 54% were alive after 6 years. Earlier onset of more extensive autonomic disturbance was associated with a poorer prognosis.²⁶⁷

Hereditary Nondegenerative Neuromuscular Disease

Michael Rose and Robert C. Griggs

MUSCLE CHANNELOPATHIES
(MYOTONIAS AND PERIODIC
PARALYSIS)
Sodium Channelopathies
Chloride Channelopathies
Calcium Channelopathies
Potassium Channelopathies
Possible Muscle Channelopathy:
Schwartz-Jampel Syndrome

CONGENITAL MYOPATHIES
Nemaline Myopathy
Myotubular/Centronuclear Myopathy
Central Core and Multi-Minicore
Disease
Other Congenital Myopathies
Congenital Fiber-Type Disproportion
CONGENITAL MYASTHENIAS
MALIGNANT HYPERTHERMIA

BRODY'S DISEASE
FAMILIAL AMYLOID
POLYNEUROPATHY
FAP Type 1 (Portuguese)
FAP Type 2 (Indiana)
FAP Type 3 (Iowa)
FAP Type 4 (Finnish)
GIANT AXONAL NEUROPATHY
ISAAC'S DISEASE

MUSCLE CHANNELOPATHIES (MYOTONIAS AND PERIODIC PARALYSIS)

The neurological channelopathies are disorders of ion channels that result in abnormal excitability of cellular membranes in either the central or the peripheral nervous system. A disturbance of ion channel function may result in either muscle membrane hyperexcitability leading to myotonia as the dominant feature or, alternatively, muscle membrane hypoexcitability leading to the episodic weakness seen in periodic paralysis. The muscle channelopathies can be grouped into sodium, chloride, calcium, and potassium channel disorders. Additional diseases are likely to be channelopathies but have not been firmly established to belong to this class (Table 37-1). Although the focus of this chapter is on the inherited channelopathies, acquired, usually autoimmune, channelopathies also result in nerve and muscle disease.

Traditionally, the myotonias have been divided into dystrophic and nondystrophic disorders. The dystrophic myotonias have myotonia as one of several muscle symptoms, and muscle atrophy and weakness are prominent. They are an expanding group of disorders that can now be defined genetically. Classical myotonic dystrophy (Steinert's disease) is linked to chromosome 19q and is now designated DM 1, whereas proximal myotonic myopathy (PROMM) and proximal myotonic dystrophy (PDM) are linked to 3q and are designated DM 2. Other types of DM not linked to either 19q or 3q are known and will be designated when their genetic basis becomes known.¹ For both DM 1 and DM 2, the myotonia is due to the effects of the primary gene mutation on chloride channel function.² By contrast, nondystrophic myotonias have myotonia as their most prominent symptom with little or no atrophy and weakness. These nondystrophic disorders result from a primary gene defect in a muscle channel protein.

In the past, the periodic paralyses were divided on the basis of phenotype into those associated with a high or normal serum potassium (i.e., hyperkalemic periodic paralysis) and those associated with a low serum potassium concentration (hypokalemic periodic paralysis). In fact, serum potassium concentration is clearly the consequence rather than the cause of the periodic paralysis. Nevertheless, early genetic studies supported the traditional nosological separation because hypokalemic periodic paralysis is in most cases a calcium channel disorder (but in a few can be a sodium channel disorder), and hyperkalemic periodic paralysis is a sodium channel disorder. The suggestion that potassium channel gene mutations could also result in periodic paralysis has been refuted,^{3,4} but potassium channel mutations do account for Andersen's syndrome, a condition that includes periodic paralysis.

The two clinical hallmarks of channelopathies are myotonia and periodic paralysis. Disorders of sodium, chloride, calcium, and potassium are described in this section, with attention not only to clinical descriptions but also to disease-specific genetic and pathophysiological mechanisms. After the various individual channelopathies are described, later sections will deal with them again collectively, discussing differential diagnosis, evaluation, and management of the two symptoms—myotonia and periodic paralysis.

It is difficult to obtain precise incidence figures for these conditions. They are undoubtedly underdiagnosed because patients with mild symptoms may be misdiagnosed or may not seek medical attention. Finnish and Danish studies of hypokalemic periodic paralysis give an incidence of between 0.4 and 1.25 per 100,000.⁵ For autosomal dominant myotonia congenita (Thomsen's disease), an incidence of between 0.25 and 4.0 per 100,000 has been reported.⁶

TABLE 37-1

Skeletal Muscle Channelopathies

| CHANNEL/DISEASE | CHROMOSOME |
|---|------------|
| Skeletal Muscle Sodium α Subunit | |
| Hyperkalemic periodic paralysis | 17q23–25 |
| With myotonia | |
| Without myotonia | |
| With paramyotonia congenita | |
| Hypokalemic periodic paralysis | 17q23–25 |
| Paramyotonia congenita | 17q23–25 |
| Sodium channel myotonia | 17q23–25 |
| Myotonia fluctuans | |
| Myotonia permanans | |
| Acetazolamide-responsive myotonia | |
| Skeletal Muscle Calcium Channel α1 Subunit (DHP sensitive) | 1q31–32 |
| Hypokalemic periodic paralysis | |
| Skeletal Muscle Chloride Channel | 7q32 |
| AD myotonia congenita (Thomsen's disease) | |
| AR myotonia congenita (Becker's disease) | |
| Potassium Channel | |
| Andersen's syndrome | 17q23 |
| Periodic paralysis | 11q |
| Potential Channelopathy | |
| Schwartz-Jampel syndrome | |

AD, autosomal dominant; AR, autosomal recessive.

Sodium Channelopathies

Disorders of the α subunit of the muscle sodium channel result in four major distinct disorders: hyperkalemic periodic paralysis, hypokalemic periodic paralysis, paramyotonia congenita, and sodium channel myotonias. There is some phenotypic overlap of the sodium channelopathies, suggesting that they may be a continuum of disorder rather than rigidly demarcated clinical entities. Previous literature also includes normokalemic and myotonic periodic paralyzes in this category, but since most, if not all, of these are potassium sensitive in exactly the same way as hyperkalemic periodic paralysis, it is likely that they represent sodium channel disorders.

Most, if not all, of the preceding disorders result from allelic point mutations in the same sodium channel gene that is situated on the long arm of chromosome 17. More than 25 different point mutations have been found that result in amino acid substitutions in conserved portions of the gene. Strict phenotypic-genotypic correlations for these point mutations are not yet defined because many have variable phenotypic expression. Physiologically, these mutations result in reduced inactivation of the sodium channel, resulting in either increased muscle excitability with myotonia or increased muscle inexcitability with hyperkalemic periodic paralysis. In cases of hyperkalemic periodic paralysis, this physiological abnormality is accentuated by increasing the extracellular potassium concentration; in paramyotonia congenita, it is sensitive to cooling, thus accounting for the worsening of symptoms with these factors. It remains unclear how the sodium channel mutations may result in hypokalemic periodic paralysis.⁷

Paramyotonia Congenita

This disease is autosomal dominant, inherited with complete penetrance. The predominant symptom is paradoxical myotonia, usually present from birth and persisting throughout life. The myotonia is paradoxical because unlike classical myotonia, it increases with repetitive movements. Cold temperature exacerbates myotonia and can cause weakness. The myotonia particularly affects the face, neck, and forearm. Typically on relief of the myotonia, either spontaneously or on warming, there is a variable degree of weakness that persists for several hours. In a warm environment, patients may have no symptoms at all. In some families with this disorder, there is a tendency for attacks of paralysis to occur independently of the myotonia. In many patients, these attacks are precipitated by potassium ingestion, in much the same way as hyperkalemic periodic paralysis. Occasional patients, usually adolescents, are weakened by hypokalemia.

Hyperkalemic Periodic Paralysis

As with paramyotonia congenita, hyperkalemic periodic paralysis normally appears in infancy or early childhood with frequent episodes of paralysis that are generally brief and mild, lasting between 15 minutes and 4 hours. Attacks are often precipitated by rest following exercise, by ingestion of potassium-rich foods, or by administration of potassium compounds. They commonly start in the morning before breakfast. Stress tends to make the attacks more easily provoked. Weakness is mainly proximal, but distal muscles can be involved. There is usually no ocular or respiratory muscle weakness. Examination of a patient during a severe attack reveals a flaccid tetraparesis with absent reflexes and normal sensory examination. The potassium may rise during the attack but not necessarily above the upper limit of normal range and rarely to levels that cause cardiac arrhythmia. Generally between attacks, patients maintain normal strength, but in a few cases there is persistent mild weakness. The frequency of attacks may decline as the patient gets older. In some families with hyperkalemic periodic paralysis, there is coexistent mild myotonia. In these patients, cooling may provoke weakness as seen in paramyotonia congenita, but it does not worsen myotonia.

Hypokalemic Periodic Paralysis

Clinically, cases of hypokalemic periodic paralysis associated with sodium channel mutations have identical signs to those with the more common calcium channel-related hypokalemic periodic paralysis. The clinical features are therefore given later under Calcium Channelopathies.

Sodium Channel Myotonias

This group of myotonias is related to sodium channel gene mutations but do not have the features of paramyotonia congenita or episodes of periodic paralysis. In some cases, the myotonia is worsened by the cold but without associated weakness and the myotonia is responsive to acetazolamide.⁸ In other families, myotonia fluctuates on a daily basis and is provoked by exercise, termed "myotonia fluctuans."⁹

Another sodium channel myotonia causes permanent and very severe myotonia, termed “myotonia permanans.”¹⁰

Chloride Channelopathies

Two similar forms of myotonia congenita are now known to be due to disorders of the chloride channel. One is inherited as an autosomal dominant disease (Thomsen’s disease) and the other as an autosomal recessive disease (Becker’s disease).

In both forms of myotonia congenita, the characteristic feature is that of a reduced muscle membrane chloride conductance, which results in muscle membrane hyperexcitability with afterdepolarization and repetitive firing leading to the myotonia. This abnormal physiology can be reproduced by chloride channel blockers or the substitution of impermeable ions for chloride. These diseases are linked to chromosome 7q32 in a region that encodes a chloride channel gene (CLC9I). Thomsen’s and Becker’s diseases are allelic disorders, with nearly 50 mutations having been described so far. However, these mutations only account for 30% to 40% of cases, and undoubtedly other chloride channel mutations will emerge.¹¹

Autosomal Dominant Myotonia Congenita (Thomsen’s Disease)

The main symptom of this channelopathy is painless generalized myotonia, perceived as muscle stiffness, that usually appears in the first and second decades of life. It is provoked by exertion following rest and thus can be demonstrated by asking the patient to rise from a seated position after a period of repose. The myotonia improves with exercise. Patients have well-developed muscles with particular hypertrophy of the lower limbs, with a resultant athletic appearance. Muscle strength can be normal, possibly even stronger than normal, giving subjects advantage in power sports in which speed is not a requisite. They have normal reflexes. Eyelid, grip, and percussion myotonia can usually be demonstrated.

Autosomal Recessive Myotonia Congenita (Becker’s Disease)

This disorder is very similar to Thomsen’s disease. The myotonia comes on later in the first decade but can be more severe than in Thomsen’s disease. In addition to severe myotonic stiffness, patients can also have disabling transient weakness that is not seen in Thomsen’s disease. After rest, their muscles are initially weak, and it takes a period of activity before full strength returns. At times, this weakness is so severe that patients require assistance to start ambulation; persistent weakness may occur. As in Thomsen’s disease, there may be muscle hypertrophy, particularly of the legs and buttocks, with some hyperlordosis of the spine.

Calcium Channelopathies

Mutations of the skeletal muscle dihydropyridine receptor (part of the calcium channel) cause primary hypokalemic periodic paralysis. An identical hypokalemic periodic paralysis, however, can result from a sodium channel

mutation. Secondary causes for hypokalemic periodic paralysis are more common than the hereditary form (see [Differential Diagnosis](#)).

In hypokalemic periodic paralysis, the weakness results from an abnormality of muscle membrane excitability. An influx of potassium into the muscle fiber occurs, with an accompanying influx of extracellular water. There is increased sensitivity to the effect of insulin on the movement of potassium into cells independently of the glucopenic action of insulin. This influx of potassium may account for the precipitation of hypokalemic periodic paralysis with large carbohydrate meals. In contrast to normal muscle fibers, the influx of potassium in hypokalemic periodic paralysis causes the muscle fibers to become depolarized and inexcitable. Calcium channel-related hypokalemic periodic paralysis is due to mutations of a gene on chromosome 1q coding for a skeletal muscle dihydropyridine receptor α_1 subunit, which functions as a calcium channel (CACNL1A3). Three CACNL1A3 mutations account for more than 50% of cases of hypokalemic periodic paralysis, and these mutations are all in a highly conserved region of the gene that codes for the voltage sensor region of the channel.¹² The dihydropyridine receptor has a primary role in electrocontraction coupling with opening of the calcium channels of the sarcoplasmic reticulum allowing an influx of calcium into the muscle sarcoplasm and the triggering of muscle contraction. Although the mutations described in calcium channel-related hypokalemic periodic paralysis lead to loss of function of the dihydropyridine receptor, the precise relationship between receptor function failure and the abnormal response of muscle fibers to insulin, and consequent hypokalemia and weakness, remain unclear.

Primary hypokalemic periodic paralysis due to calcium channelopathy is an autosomal dominant disorder but is more common in males and has variable penetrance in females. Attacks of episodic weakness usually start by adolescence and invariably before the age of 30 years. They often occur at night so that patients awake with weakness. Attacks may be precipitated by carbohydrate or alcohol intake, rest after exercise, or emotional stress. The frequency of attacks is generally less than that seen in hyperkalemic periodic paralysis and can vary from daily or only one or two in a lifetime. Typically, attacks last between 1 and 4 hours, but occasionally they can persist for up to 3 days. Prodromal symptoms of muscle stiffness, heavy limbs, or sweating may occur followed by proximal lower limb weakness that spreads to tetraparesis. There is rarely ocular or bulbar involvement. Fatalities are rare and usually result from injudicious treatment, especially in the case of hypokalemia-induced cardiac arrhythmias. Oliguria is typical during attacks and results from the sequestration of water intracellularly.

In younger subjects the only detectable interictal abnormality is eyelid myotonia, seen in approximately 50% of patients. In older subjects, attacks frequently decrease, but patients may have persistent weakness. During severe attacks, patients are flaccid, paralyzed, and areflexic.

Potassium Channelopathies

Andersen’s syndrome, with a triad of periodic paralysis, cardiac arrhythmias, and dysmorphic features, is a potassium

channelopathy due to mutations of the *KCNJ2* gene on 17q coding for the Kir 2.1 potassium channel with expression studies confirming the pathophysiological effects of these mutations.¹³ Of interest is the recognition that fixed skeletal defects such as seen in Andersen's syndrome may result from channel gene mutations. Heretofore, the main effects of channelopathies appeared to be restricted to excitable tissues (e.g., muscle and nerve).

The periodic paralysis of Andersen's syndrome does not neatly fit into the hypo- or hyperkalemic classification. During attacks of periodic paralysis, the potassium may rise, fall, or remain normal in these patients. The attacks may be provoked by either hyperkalemic or hypokalemic challenges or by neither. In some, the attacks have been unrecognized, with the cardiac features being more prominent. Many cases show mild proximal weakness even between attacks. Cardiac involvement can be severe and result in episodes of syncope or cardiac arrest. A variety of ventricular arrhythmias may occur, including a long QTc interval and bidirectional ventricular tachycardia, but at times the electrocardiogram (ECG) is normal. Asymptomatic family members, however, may harbor a long QTc interval and be at risk of cardiac arrhythmia. The dysmorphic features of Andersen's syndrome are subtle and often need an index of suspicion for recognition. They may include facial features of broad forehead and nose, low-set ears, small mouth and jaw, a broad neck, and hand features such as clinodactyly or syndactyly.¹⁴

Possible Muscle Channelopathy: Schwartz-Jampel Syndrome

Schwartz-Jampel syndrome (SJS) is a rare autosomal recessive myotonic disorder with an unknown etiology. Previously described autosomal dominant cases of SJS probably have a sodium channel mutation and represent cases of myotonia permanans.¹⁰ Autosomal recessive SJS is genetically heterogeneous, with some cases having mutations in the *HSPG2* gene on chromosome 1p35–36.1.^{15,16} This gene encodes for perlecan, a ubiquitous protein that constitutes 50% of the extracellular matrix of all tissues. It is speculated that loss of function mutations in perlecan result in abnormal development of cartilage and also affect muscle excitability perhaps because there is faulty distribution of acetylcholinesterase.¹⁶

Symptom onset is before the age of 3 years, with severe continuous motor activity and muscle stiffness particularly in the face and in the thighs. Patients have an unusual masklike face with blepharospasm (Video 47, Blepharospasm) and continuous motor activity of the chin and lips. Hypertrophy of the thigh muscles occurs. They have radiological evidence of osteochondrodysplasia, often resulting in reduced stature, kyphoscoliosis, bowing of the diaphyses, and irregular epiphyses.¹⁷ When all the preceding features are present, then mutations in the perlecan gene are more likely to be found. This is not the case with neonatal onset or when osteochondrodysplasia is absent.¹⁶

DIFFERENTIAL DIAGNOSIS

Myotonia. The principal symptom of myotonia is that of muscle stiffness and an inability to relax contracted muscle (Video 255, Myotonia). In most cases, myotonia is painless, although occasionally sodium channel-related myoto-

nia causes discomfort. Stiffness can be confused with spasticity or rigidity. Muscle cramps are often a feature of a peripheral nerve disorder and are readily differentiated on electromyography (EMG). Dystonia results in abnormal posture and is the result of abnormal discharge of whole motor units rather than individual muscle fibers. Painless, electrically silent contractures may be a feature of metabolic myopathy such as McArdles' disease. Pseudomyotonia or impaired muscle relaxation without electrical evidence of myotonia occurs in acid maltase deficiency and Brody's disease. True myotonia may be part of a generalized disorder as in dystrophia myotonia, but in such disorders myotonia is not usually the presenting symptom. The different nondystrophic myotonias are usually distinguished clinically, but sometimes gene analysis is needed to make a final diagnosis.

Periodic Paralysis. The differential diagnosis of periodic paralysis must include other causes of a flaccid areflexic tetraparesis without sensory signs. Metabolic causes such as hypercalcemia, hypocalcemia, hypophosphatemia, hypomagnesemia, and rhabdomyolysis need to be excluded. Diseases such as Guillain-Barré syndrome, myasthenic syndromes, and acute poliomyelitis can also produce a similar clinical picture. In many cases, the history and associated features will point to the correct diagnosis. Secondary hypokalemic periodic paralysis usually results from intracellular potassium depletion from renal, endocrine, gastrointestinal, or drug-induced mechanisms (Table 37-2). Usually these underlying conditions are obvious, but in less clear cases the recurrent episodes of transient weakness can be difficult to distinguish from primary hypokalemic periodic paralysis. Late-onset hypokalemic periodic paralysis raises strong suspicions of secondary rather than primary periodic paralysis. Thyrotoxic periodic paralysis results from alteration of muscle membrane permeability and is much more prevalent in Japanese, Chinese, and other Asian populations, although it occurs in Caucasians. The clinical presentation is often indistinguishable from hypokalemic periodic paralysis but with the additional, sometimes subtle, evidence of hyperthyroidism.¹⁸ Paralytic episodes may precede the occurrence of any other clinical feature of hyperthyroidism.

TABLE 37-2

Secondary Causes of Hypokalemic Periodic Paralysis

Endocrine

Primary hyperaldosteronism (Conn's syndrome)
Thyrotoxic periodic paralysis

Renal

Juxtaglomerular apparatus hyperplasia (Bartter's syndrome)
Renal tubular acidosis
Fanconi's syndrome

Gastrointestinal

Laxative abuse
Villous adenoma
Gastrointestinal fistula

Drug-Induced

Amphotericin B
Licorice
Corticosteroids
p-Aminosalicylic acid
Carbenoxalone
Potassium-depleting diuretics

EVALUATION OF CHANNELOPATHIES

Myotonia. Creatine kinase (CK) is usually normal, but there may be two- to fivefold elevations in Thomsen's and Becker's diseases, perhaps reflecting the degree of muscle hypertrophy. EMG shows spontaneous myotonic discharges, but in paramyotonia congenita, provocation by cooling of the examined limb may be required to demonstrate this phenomenon. There is also decrement in the compound motor action potential (CMAP) with exercise or with high-frequency 30-Hz stimulation, particularly in cases of myotonia congenita.^{19,20} The decrement in the CMAP is particularly marked in Becker's disease, and this is presumably the cause of the transient weakness seen in that condition.²⁰ In SJS, the EMG shows continuous spontaneous motor activity with little of the fluctuation of the frequency and amplitude that is seen with other myotonias and may be myogenic or neurogenic in origin. In phenotypically similar cases in which the electrical activity does more closely resemble myotonia, the diagnosis may be that of myotonia permanans.¹⁰ Muscle biopsy may show little abnormality. Variation in fiber size with fiber hypertrophy and increased central nuclei may be found. In paramyotonia congenita with hyperkalemic periodic paralysis, vacuolated fibers and necrotic fibers may be seen. In myotonia congenita, there may be a lack of 2B fibers. Study of family members may be valuable since there may be clinical or EMG evidence of disease in apparently asymptomatic individuals, which clarifies the mode of inheritance.

Periodic Paralysis. During an episode of weakness, serial blood tests should be taken for potassium, calcium, magnesium, phosphate, and CK to exclude the other previously mentioned causes of weakness. Since the potassium level may be normal during hyperkalemic periodic paralysis and occasionally in hypokalemic periodic paralysis, the potassium level needs to be checked sequentially every 15 to 30 minutes in order to determine the direction of change at a time when muscle strength is either worsening or improving. An ECG may show changes consistent with hypo- or hyperkalemia and may also forewarn of cardiac complications. EMG shows reduced CMAP proportionate to the degree of weakness. Nerve conduction studies are normal. The neurophysiology also serves to exclude other causes of paralysis, such as the Guillain-Barré syndrome or myasthenia gravis (Video 86, Ice Pack Test in Myasthenia Gravis).

Patients who are seen between attacks need investigation to exclude causes of secondary hypokalemia. EMG may be helpful in showing evidence of myotonia, which would favor hyperkalemic periodic paralysis. In those patients in whom fixed weakness has developed, the EMG may be myopathic. Even in those with an initially normal EMG, there may be an exaggerated increment followed by decline of the CMAP with high-frequency 30-Hz stimulation or following repetitive muscle contraction.²¹ Muscle biopsy is often abnormal between attacks of hypokalemic periodic paralysis, with pathognomonic changes of large central vacuoles and occasional necrotic fibers. In hyperkalemic periodic paralysis, smaller vacuoles may be present and tubular aggregates may be seen. Provocative testing may be required to confirm the diagnosis. This must be performed with careful supervision, including monitoring

of the potassium and the ECG. Hypokalemic challenge can be performed by giving intravenous glucose with or without insulin.²² Hyperkalemic challenge can be performed by giving repeated doses of oral potassium.²² Where available, genetic testing may be the preferred investigation, but its effectiveness depends on the screening strategy employed.

MANAGEMENT OF CHANNELOPATHIES

Myotonia. Myotonia can be exacerbated by some muscle relaxant drugs and by anticholinesterase drugs, and anesthesia for these patients needs to be planned accordingly. Potassium administration can exacerbate myotonia, and thus potassium supplementation should only be given where necessary and with caution. The treatment of myotonia congenita relies on membrane-stabilizing drugs such as procainamide and quinine; these can be used intermittently on an as-needed basis. Phenytoin is more useful for chronic administration and is less likely to have cardiac side effects. Occasional cases of myotonia are responsive to acetazolamide, and mexiletine is useful for both the myotonia and the weakness associated with paramyotonia congenita.

Periodic Paralysis. Attacks of hypokalemic periodic paralysis may be partially prevented by a low-carbohydrate and low-sodium diet. Where hypokalemic periodic paralysis is secondary to thyrotoxicosis, this needs to be treated. In the interim, the paralytic attacks and persistent weakness can be very effectively treated with β -adrenergic blocking agents. During acute attacks, emergency treatment may be required, but the preference is very much in favor of oral potassium since potassium concentration usually declines with parenteral potassium because of the diluents employed. The ECG should be carefully monitored during attacks for cardiac arrhythmias.

In hyperkalemic periodic paralysis, attacks are usually mild but are still worth treating to prevent the onset of permanent weakness. Thiazide diuretics are effective treatment. During acute attacks, treatment is seldom needed, but carbohydrate-containing food and fluid may aggravate the weakness and potassium-containing foods should be avoided. Inhaled β -adrenergic agonists such as salbutamol are effective treatments but may be contraindicated if there is a coexisting cardiac arrhythmia.

Both acetazolamide and dichlorphenamide can prevent paralytic attacks and may improve residual weakness between attacks.²³

CONGENITAL MYOPATHIES

PATHOGENESIS AND PATHOPHYSIOLOGY. The initial definition of the congenital myopathies implied the onset at birth of a nonprogressive primary myopathy that could not be explained on the basis of a dystrophic or metabolic abnormality. However, in some morphologically and genetically identical cases, symptoms are not present at birth and are of later onset. Furthermore, some cases of congenital myopathies, such as nemaline myopathy and centronuclear myopathy, show progressive weakness with a fatal outcome. The assumption that all of these congenital myopathies have no metabolic basis reflected ignorance as to their etiology. The various congenital myopathies continued to be diagnosed in most instances on the basis

of their morphological characteristics as seen in muscle biopsy. In some of these, there is a large body of literature that defines a clear phenotype, but in others only one or two case reports have been described, and the lack of morphological specificity casts doubt on their validity as separate disease entities. The recent descriptions of the gene lesion for most of the disorders are rapidly changing their classification.

EPIDEMIOLOGY. All of the congenital myopathies are rare, with an incidence of less than 1 per 100,000.

CLINICAL FEATURES. The diagnostic label implies that there is muscle weakness present at birth, but some of them are of late childhood or adult onset, as specified in the following sections (Video 13, Myopathic Gait). Presentation may be in utero with reduced fetal movements. There may be delayed second stage of labor and a higher incidence of assisted delivery with its consequent complications resulting from fetal hypotonia. The most common presentation is that of a floppy baby who has delayed motor milestones. In school, these individuals usually have difficulty keeping up with their peers, either in sporting activities or simply in running or walking. Early weakness may manifest as difficulty rising from a chair or the floor and in managing stairs. In some congenital myopathies, as specified in the following sections, there is facial weakness and ophthalmoplegia. The muscle weakness can give rise to skeletal defects causing dysmorphic features, kyphoscoliosis, and pes cavus. Diaphragmatic or chest wall involvement can give rise to respiratory weakness with carbon dioxide retention, particularly at night, causing morning headaches or daytime somnolence. Such respiratory weakness is usually a late feature in the congenital myopathies, but nemaline myopathy is a notable exception for its early onset. As a rule, the congenital myopathies are stable or only slowly progressive, and many patients are remarkably active despite their weakness. Specific clinical features of the individual congenital myopathies will be highlighted, and differential diagnosis, evaluation, and management will be considered collectively afterward.

Nemaline Myopathy

This particular congenital myopathy is defined on the basis of the presence of rods in the muscle biopsy. These are seen as red-staining structures using the Gomori trichrome stain, and it is their threadlike appearance that gives this condition its name, *nema*, being Greek for thread.

The usual picture is one of mild and progressive myopathy present from birth. However, there are some more severely affected individuals, with early fatalities. In addition, some adult-onset cases appear to have profuse rods on muscle biopsy but without the usual clinical phenotype. Typical cases usually have generalized reduction of muscle bulk, generalized limb weakness, and mild facial weakness but no ocular involvement. Cardiac involvement is unusual. The facial appearance is characteristic, with high arched palate and a long thin face. Respiratory failure due to involvement of the diaphragm is an early feature that can have a major impact on the prognosis.

Electron microscopy shows that the rods represent an abnormal deposition of Z band material. The etiology of

this and its relevance to the subsequent development of nemaline myopathy are unknown. Rods are not exclusive to nemaline myopathy and can be seen as an occasional feature in other muscle disorders, including polymyositis, HIV-related myopathy, and in muscle injured by tenotomy. There are many sporadic cases, but autosomal dominant cases have shown mutations of a tropomyosin (TPM3) on chromosome 1q21,²⁴ and autosomal recessive cases and some sporadic cases have shown mutations of three further genes: the nebulin gene on chromosome 2q21–22,²⁵ the skeletal muscle alpha-actin gene (ACTA 1) on chromosome 19q42,²⁶ and the slow skeletal muscle troponin T gene (TNNT1) on chromosome 19q13.4.²⁷ The last of these mutations was found in a form of nemaline myopathy common in the Amish population. Other genes will undoubtedly be found because cases of nemaline myopathy exist that show no linkage to any of these chromosome loci.

Myotubular/Centronuclear Myopathy

The key morphological abnormality is the presence of central nuclei that occupy between 25% and 80% of the muscle fibers, more often in the type 1 fibers, which usually predominate. There is often a halo around the central nuclei, which shows increased oxidative enzyme activity and glycogen staining with reduced amounts of ATPase staining. The original term, *myotubular myopathy*, was based on the resemblance of these morphological abnormalities to that of myotubules. The later and preferred term of *centronuclear myopathy* is more descriptive and avoids assumptions about the etiology of the abnormality.

Prominent ptosis and ophthalmoplegia distinguish this disease from the other congenital myopathies. Cardiac involvement is not common. A variety of skeletal malformations occur, resulting in a Marfanoid habitus with a long narrow face and high arched palate. A more severe X-linked variety is recognized with in utero and neonatal presentation and severe generalized weakness with bulbar and respiratory involvement but less ptosis and ophthalmoparesis.²⁸ With intensive initial support, some improvement may occur, but patients remain severely disabled and prone to sudden death due to aspiration. A late childhood- or adult-onset variant is seen, which presents with mild limb weakness without ptosis, ophthalmoparesis, or dysmorphic features.

Because of the resemblance to myotubules, these diseases are believed to represent a maturational arrest with failure of the normal peripheral migration of nuclei during differentiation. However, the morphological similarities with myotubules are only superficial, and central nuclei can appear after infancy. Many of these cases are hereditary, and autosomal recessive, autosomal dominant, and X-linked varieties have been described. The X-linked variety has been shown to be due to mutations in the myotubularin gene (*MTM1*) with the number of known mutations into triple figures, although three mutations occur in 17% of X-linked cases.²⁹ In 11 families, autosomal dominant, recurrent and de novo missense mutations were found in the gene dynamin 2 (*DNM2*, 19p13.2), which encodes a protein involved in endocytosis and membrane trafficking, actin assembly, and centrosome cohesion.³⁰

Central Core and Multi-Minicores Disease

In central core disease (CCD), the morphological abnormality is the presence of central or eccentric cores that have sharply defined borders and that do not stain for glycogen or oxidative enzymes but sometimes for ATPase. The cores run the length of the fiber and are exclusive for type 1 fibers that are the predominant fiber type on biopsy. Distinguishing clinical features of central core disease are the lack of cranial involvement, apart from occasional mild facial weakness, the frequency of congenital dislocation of the hip, and the occasional coexistence of malignant hyperthermia. Anesthetic precautions are required to avoid the risk of hyperthermic crises in this disease. The etiology is unknown. The resemblance of cores to target fibers suggests that central core disease may be a disorder of innervation. Cases are autosomal dominant or occasionally sporadic. This disease may be allelic, with malignant hyperthermia also having point mutations of the ryanodine receptor (RYR1) on chromosome 19q13.1.³¹

In multi-minicores disease (MmD), the key morphological abnormality is that of minicores that run along the long axis of the muscle fibers either centrally or eccentrically in both type 1 and type 2 fibers. These cores represent areas of mitochondrial depletion and sarcomere disorganization that therefore do not stain for glycogen or oxidative enzymes but do sometimes stain for ATPase. Four phenotypes are described: classical MmD predominant axial muscle weakness with severe scoliosis and respiratory compromise; a moderate form consisting of generalized muscle weakness especially affecting the pelvic girdle, with frequent and prominent hand weakness, amyotrophy, and hyperlaxity but only mild scoliosis or respiratory involvement; and two variations of the classic form with ophthalmoplegia or antenatal onset with arthrogryposis as the distinguishing features. Cardiac and brain involvement is not characteristic of MmD.^{32,33} They are genetically heterogeneous, with mutations in the ryanodine receptor type 1 gene (RYR1) and the selnprotein N gene (SEPN1) described.³⁴

Other Congenital Myopathies

There are a variety of other morphological abnormalities that have been described in cases with a presentation typical of congenital myopathy with names to match, such as finger print body or zebra body myopathy. There are too few case reports of these myopathies to discern a distinctive or diagnostic phenotype for each and to be sure that each necessarily represents a distinct myopathy.

Congenital Fiber-Type Disproportion

This description arose from a survey of congenital myopathies by Brooke,³⁵ who found several subjects in whom the type 1 fibers were at least 12% smaller than the type 2 fibers. This finding was isolated in some cases; in others, it coexisted with other more striking pathological abnormalities. Later workers have suggested a tightening of the pathological criteria to include normal or increased size of type 2 fibers so that this diagnosis can be separated from mild spinal muscular atrophy.³⁶ Even with these require-

ments, there remains considerable doubt as to whether this entity represents a distinct form of congenital myopathy.

There are no specific clinical features to define the condition, and the severity can be quite variable. Initially, it was suggested that these pathological appearances had some prognostic value in that all the cases in Brooke's original series showed no progression of their weakness beyond 2 years of age, and some even improved. This pattern, however, has not been borne out by subsequent studies. No specific pathophysiological explanation has been advanced for the pathological picture, and there is no genetic marker for it.

DIFFERENTIAL DIAGNOSIS OF CONGENITAL MYOPATHIES. The differential diagnosis of congenital myopathy includes all causes of a floppy infant, including central, neurogenic, and myopathic. The neurogenic causes are usually central, although hereditary neuropathies causing dysmyelination or hypomyelination and anterior horn disease (i.e., spinal muscular atrophy) also present similarly. Central nervous system disorders may show upper motor neuron features, seizures, or intellectual impairment, but recognition of some of these features may be difficult. Of the myopathic causes, a distinction needs to be made between the congenital muscular dystrophies, congenital myotonic dystrophy, congenital myasthenia (see later discussion), and the metabolic myopathies.

EVALUATION OF CONGENITAL MYOPATHIES. CK level is normal or only mildly elevated, in distinct contrast to many early onset muscular dystrophies. Neurophysiology tests allow exclusion of the neuropathies and myasthenias. Nerve conduction studies are normal, and the EMG may show mild nonspecific myopathic features. The pattern of muscle involvement as seen on MRI scans can be helpful in suggesting certain congenital myopathies.³⁷ The definitive diagnosis of a congenital myopathy rests on the morphological characteristics seen at muscle biopsy. These morphological abnormalities need to be present in reasonable number in order to make the diagnosis because any of them may be nonspecific findings in other neuromuscular disorders. In some cases of congenital myopathy, the muscle biopsy may show only minor nonspecific myopathic features. This pattern may reflect a selectivity of muscle involvement, and when other causes have been excluded, a label of "nonspecific congenital myopathy" may be applied.

MANAGEMENT. There is no specific treatment for any of the congenital myopathies. The association of CCD with malignant hyperthermia makes it prudent to avoid precipitating factors. Otherwise, the management of the congenital myopathies is supportive, with particular regard to the prevention of secondary complications such as contractures and progressive kyphoscoliosis. Bracing may be an effective means of maintaining ambulation but is usually unsatisfactory. Respiratory and cardiac function needs to be regularly assessed and appropriate support given.

CONGENITAL MYASTHENIAS

The onset of myasthenic symptoms at birth, especially in the presence of a family history, makes congenital forms of myasthenia a diagnostic possibility. With the advent of the acetylcholine receptor (AChR) and calcium channel

TABLE 37-3

Classification of the Congenital Myasthenias

Preynaptic Defects

Defect of ACh resynthesis or packaging
Paucity of synaptic vesicles and reduced quantal release

Pre- and Postsynaptic Defects

Endplate AChE deficiency

Postsynaptic Defects

Kinetic abnormalities of AChR with AChR deficiency
Classic slow channel syndrome
Epsilon subunit mutations
AChR deficiency and short channel open time
Kinetic abnormalities of AChR without AChR deficiency
High-conductance fast channel syndrome
Syndrome attributed to abnormal interaction of ACh with AChR

Partially Characterized Syndromes

Other AChR deficiencies
Congenital myasthenic syndrome resembling LEMS
Congenital myasthenic syndrome with facial malformations
Familial limb girdle myasthenia

ACh, acetylcholine; AChE, acetylcholinesterase; AChR, acetylcholine receptor; LEMS, Lambert-Eaton myasthenic syndrome.

antibody tests as markers for myasthenia gravis and Lambert-Eaton myasthenia, it has become apparent that congenital myasthenia, like the congenital myopathies, may also present later in life and, occasionally, without a family history.

PATHOGENESIS AND PATHOPHYSIOLOGY. Congenital defects of the neuromuscular junction can be divided into presynaptic, synaptic, and postsynaptic defects (Table 37-3). Presynaptic defects include defects in the synthesis of acetylcholine or in the packaging of acetylcholine into the presynaptic vesicles, thereby reducing the amount of acetylcholine available for release. Synaptic defects include deficiency of acetylcholinesterase. Postsynaptic defects consist of abnormal function or altered numbers of acetylcholine receptors. Not all of the congenital myasthenic syndromes have a well-defined cause. Some appear to be sporadic, but of the inherited cases, autosomal recessive inheritance is most common. The slow channel syndrome is inherited as an autosomal dominant.

EPIDEMIOLOGY AND RISK FACTORS. Precise incidence data are not available, but the congenital myasthenias represent a minority of patients with myasthenia, making them rare diseases. There are undoubtedly cases of myasthenia that mistakenly remain undiagnosed as congenital when presumed to be serologically negative cases of autoimmune myasthenia, particularly when they respond well to anticholinesterase treatment.

CLINICAL FEATURES. Only the broad clinical features of the congenital myasthenias are described here. The individual syndromes are listed in Table 37-3, and further details can be found in several reviews.³⁸⁻⁴¹ The presentation of congenital myasthenias can be similar to that of congenital myopathies, with a floppy baby, showing difficulties with feeding, delayed motor milestones, and persistent or sometimes progressive limb weakness. Skeletal abnormalities can result from this weakness. Ocular, bulbar, and respiratory weakness may occur, but some of the syndromes are notable for lack of ocular involvement. Other

syndromes characteristically have a later onset, typically in the second or third decade. The distinguishing feature of the weakness is its fluctuating nature, usually worsening with activity such as feeding, crying, or moving. With some of the myasthenic syndromes, episodic exacerbations occur with fever, with emotional upset, or for no obvious reason. The autosomal recessive inheritance of most of these syndromes means that there may not be a family history. Examination is characterized by fatigable weakness. Fixed weakness is usually generalized, but very selective weakness is described. Delayed pupillary responses occur in some cases. Reflexes are generally but not invariably preserved.

DIFFERENTIAL DIAGNOSIS. The differential diagnosis is the same as that for congenital myopathies. Clinical distinction from mitochondrial myopathy may be difficult because the latter can also present with fatigable weakness. Neonatal botulism needs to be excluded. Once the diagnosis of a myasthenic syndrome has been made, differentiating congenital from acquired autoimmune myasthenia may be required, particularly in late-onset cases lacking a family history. Neonatal myasthenia from passive placental transfer of AChR antibodies usually occurs in the offspring of obviously affected AChR antibody-positive mothers.

EVALUATION. A positive AChR antibody test excludes congenital myasthenia, but because there are cases of AChR antibody-negative myasthenia gravis, a negative test is not specifically diagnostic. A positive edrophonium test confirms a myasthenic syndrome but does not differentiate congenital myasthenia from myasthenia gravis. A negative test occurs in some cases of congenital myasthenia when there is a deficiency of acetylcholinesterase. EMG studies may show a decrement in the compound muscle action potential to repetitive stimulation but at 10 Hz rather than the usual 3 Hz. Single-fiber EMG may show excess jitter and blocking. Morphological, immunostaining, and immunohistochemical techniques and in vitro neurophysiological analysis on intercostal muscle containing motor endplates are research methods for confirming and characterizing the nature of a congenital myasthenia.^{38,41} Genetic analysis may show mutations of genes encoding for subunits of AChR.⁴¹

MANAGEMENT. Respiratory and bulbar complications require appropriate supportive measures. Depending on the precise nature of the congenital myasthenia, some cases may respond to chronic anticholinesterase treatment. Those who do not respond to anticholinesterase therapy may gain benefit from treatment with 3,4-diaminopyridine.⁴²

MALIGNANT HYPERTHERMIA

Malignant hyperthermias are hereditary skeletal muscle diseases characterized by a hypercatabolic reaction of muscle to anesthetic agents or to physical or emotional stress.

PATHOGENESIS AND PATHOPHYSIOLOGY. The central event appears to be an increase in the calcium concentration that results in continuous activation of the actin-myosin contraction apparatus and sustained muscle contraction. This increase in calcium level is due to an increased release of calcium from the sarcoplasmic reticulum of the muscle together with a reduction in calcium reuptake. The continuous muscle activity results in muscle rigidity, muscle necrosis, hyperpyrexia, and hypermetabolism. Linkage has been

found to chromosome 19q13.1. A ryanodine receptor gene in this region has been shown to have mutations in 50% of cases.³¹ The ryanodine receptor is a calcium-release channel involved in calcium homeostasis. Linkage has also been found to chromosomes 7q and 3q and to chromosome 17q1.2–24, which codes for the α subunit of the sodium channel.^{43,44}

EPIDEMIOLOGY. Malignant hyperthermia has a worldwide distribution with an incidence of 1 in 12,000 anesthetic incidents in children and 1 in 50,000 anesthetic events in adults.⁴⁵ However, many mild cases probably go unrecognized being mistaken for alternative anesthetic complications. Males are more affected than females and there is a peak incidence at age 30 years. Thereafter, the incidence declines such that cases are virtually unheard of after the age of 75 years.⁴⁵

CLINICAL FEATURES. The most common precipitating event is that of halothane general anesthesia. The muscle relaxant succinylcholine is a milder trigger of attacks when used alone but a more potent one when combined with halothane. The likelihood of triggering an attack with these agents is increased if the patient has been exercising vigorously beforehand or is under stress at the time of anesthetic induction.

In between attacks of malignant hyperthermia, patients rarely have any muscle symptoms, although some muscle diseases are associated with attacks of malignant hyperthermia (see later discussion). In 50% of cases, patients may have had previous anesthesia without any complications.⁴⁵ Attacks often start with jaw spasm followed by generalized muscle spasm and rigidity. Associated findings include hyperventilation, tachycardia, and an unstable blood pressure. A mottled, flushed, and cyanotic skin rash may appear, and after an interval of 15 or 16 minutes, the body temperature may start to rise precipitously. Metabolic and respiratory acidosis, hypoxemia, generalized vasoconstriction, and an increased cardiac output occur. The serum potassium may rise and the CK may increase 100-fold. Consequent complications of myoglobinuria and disseminated intravascular coagulation may occur, leading to renal failure. During recovery, patients may have a further relapse.

DIFFERENTIAL DIAGNOSIS. The condition most closely resembling malignant hyperthermia is the neuroleptic malignant syndrome, an abnormal response to dopamine blocking agents. Patients develop rigidity with hyperthermia and share many of the biochemical features seen in malignant hyperthermia. Neuroleptic malignant syndrome usually occurs in the setting of psychiatric disease with the use of neuroleptic drug treatment. Acute dystonic reactions to drugs such as neuroleptics or antiemetics can produce a similar picture of rigidity. Patients with myotonia may develop rigidity with depolarizing agents during anesthetic induction.

EVALUATION. During the acute illness, the main emphasis of the evaluation is monitoring possible hyperkalemia and cardiac, respiratory, and renal complications so that appropriate measures can be taken. Evaluation of well patients thought to be at risk of developing malignant hyperthermia can be difficult. Only a few have a raised CK. The genetic heterogeneity and the fact that even the recognized point mutations only cover a small percentage of the

patients mean that genetic testing needs careful consideration.^{46,47} The recognized screening test is the *in vitro* caffeine and halothane contracture test, which detects an exaggerated response to caffeine or halothane in freshly isolated muscle. This test is performed only in specialized centers, and because the threshold for the test has to be set to avoid the danger of missing at-risk cases, there is an inevitable false-positive rate.⁴⁸

MANAGEMENT. Preventive measures include the avoidance of precipitating agents, namely halothane and succinylcholine, but many other agents have some risk in susceptible subjects. Patients with known malignant hyperthermia should be advised to wear medical alert bracelets to warn of their susceptibility. Narcotics, barbiturates, benzodiazepines, nitrous oxide, and nondepolarizing muscle relaxants are generally safe to use. Acute management consists of the removal of the triggering agents and supportive measures as required. Body cooling may be required in response to the hyperthermia that aggravates the metabolic derangement. Dantrolene is the mainstay of treatment and, when given intravenously, results in reversal of the abnormalities. Mortality has decreased since its regular use.

PROGNOSIS. The improved recognition of this complication, better supportive measures, and widespread availability of dantrolene have resulted in a dramatic decrease in mortality from 65% to 2%.

BRODY'S DISEASE

This disorder, first described by Brody in 1969,⁴⁹ clinically resembles myotonia, but the EMG of affected muscle does not show any myotonic discharges.

PATHOGENESIS AND PATHOPHYSIOLOGY. The pseudomyotonia is thought to be the result of abnormalities in sarcoplasmic reticulum Ca^{2+} ATPase, a transmembrane protein responsible for extruding calcium out of the cytoplasm and into the sarcoplasmic reticulum. This 100-kDa protein is coded on chromosome 16 and is deficient in amount or activity, particularly in the type 2 muscle fibers.⁵⁰ Genetic heterogeneity was suggested by reports of variable patterns of inheritance, including autosomal dominant, recessive, and X-linked. This heterogeneity has been confirmed by the fact that some cases with recessive inheritance have mutations in the ATP2A1 gene encoding SERCA1, the fast-twitch skeletal muscle sarcoplasmic reticulum Ca^{2+} ATPase, whereas others do not.^{51–54}

EPIDEMIOLOGY. This is a rare disorder and only approximately 20 cases have been recorded in the literature.⁵⁰

CLINICAL FEATURES. The disease usually begins in childhood. Patients often have difficulty keeping up with their peers in physical activities. They develop poor relaxation of muscles, initially in the limbs but then in the face and the trunk. This pseudomyotonia is worsened by exercise and cold weather. In some, myoglobinuria occurs. On examination, they have eyelid and grip, but not percussion, myotonia. There may be mild muscle atrophy and weakness in the final stages of the disease.

DIFFERENTIAL DIAGNOSIS. The differential diagnosis of Brody's disease is that of myotonia and pseudomyotonia as detailed for the preceding myotonias.

EVALUATION. CK may be normal or slightly elevated, particularly in patients with associated myoglobinuria. Muscle biopsy shows type 2 A and B atrophy with angulated fibers. EMG shows electrical silence during the time of apparent myotonia. Biochemical and immunological assays of sarcoplasmic reticulum Ca^{2+} ATPase may be employed to make the diagnosis.

MANAGEMENT. Empirical treatment with dantrolene and calcium channel blockers has been used with varying success.

PROGNOSIS. The disease is slowly progressive or stationary over years, but in some individuals exercise-induced pseudomyotonia worsens as they get older.

FAMILIAL AMYLOID POLYNEUROPATHY

In amyloidosis, extracellular deposition of amyloid occurs in a variety of organs, such as the heart, intestinal tract, liver, and kidneys. In amyloid neuropathy, the peripheral nerve deposition predominates. Amyloid neuropathy may be due to acquired, usually immunoglobulin-derived, amyloid, or it may be hereditary, as in familial amyloid polyneuropathy. Amyloid is a class of glycoproteins that have a fibrillar β sheet structure likely derived from a variety of precursor proteins. In familial amyloid polyneuropathy (FAP) the dominant form of amyloid is derived from transthyretin (TTR), but amyloid formed from apolipoprotein A1 and gelsolin is also seen. Initially, FAP was described on a clinical basis, with four types recognized. Despite overlap with the increasing discoveries of specific mutations, this original classification is still useful (Table 37-4).

PATHOGENESIS AND PATHOPHYSIOLOGY. All of these amyloid neuropathies result from the deposition of amyloid, derived from various precursor proteins, within the substance of the nerve. More than 80 mutations of the TTR gene have been described as well as mutations of the apolipoprotein A1 and gelsolin protein genes. All are autosomal dominant conditions with reduced penetrance. Most individuals are heterozygous for the given mutation. Some homozygous individuals for the Met30 TTR mutation have been described but without any difference in the clinical phenotype from the heterozygous individuals. The Met30 mutation has arisen spontaneously in different areas of the world.⁵⁵ By contrast, the Ala60 TTR mutation, which was first described in a family in the Appalachian region, has been found to be due to a founder effect with its origin in Ireland.⁵⁶

The deposition of amyloid may occur within the nerve without being derived from circulating amyloid. In the TTR-associated FAP with the Met30 mutation, axonal loss occurs first in the small and later in the large unmyelinated fibers. Although axonal degeneration is the predominant pathological finding, there is also evidence of segmental demyelination. The amyloid may be either diffusely or patchily distributed, making a standard distal nerve biopsy of little diagnostic value in cases with involvement restricted to proximal nerves. Amyloid deposition can occur in the connective tissue of the peripheral nerves, in the endoneurial tissue, and in the vasa nervorum.

The mechanism by which amyloid deposition leads to neuropathy is unclear. Some have argued that the neuropathy results from a generalized metabolic disorder and that amyloid deposition is a secondary event. Deposition within the endoneurial vessels might result in ischemic nerves but would not fully explain the selectivity of small fiber involvement. The endoneurial blood vessel deposition of amyloid might alter vascular permeability with consequent endoneurial edema, contributing to the compressive damage on the nerves. Compressive damage may also result from the deposition of amyloid in the connective tissue surrounding the peripheral nerve. Although the presence of segmental demyelination favors a compressive etiology, this finding is not the dominant feature of the disorder and so likely is not a primary mechanism of neuropathic change.

EPIDEMIOLOGY. The most common FAP is the TTR-associated form with a Met30 mutation described in 500 Portuguese families. The gelsolin-derived FAP has been described in 200 Finnish families. By contrast, some FAP mutations have been confined to a single family.⁵⁷

FAP Type 1 (Portuguese)

TTR-derived FAP was originally described in Portugal but has since been found in a wide variety of countries, including Scandinavian and Mediterranean regions as well as North and South America and Japan. The age of onset varies with the ethnic origin; the Portuguese develop symptoms in their 20s and 30s, whereas the Swedes and the French generally develop symptoms in their late 50s. The initial symptom is painful dysesthesia with attacks of stabbing pain in the lower limbs. Early small fiber involvement causes loss of pain and temperature sensation, making patients prone to foot ulcers, osteomyelitis, Charcot joints, and trophic skin changes. The neuropathy slowly progresses

TABLE 37-4

Classification of Familial Amyloid Polyneuropathies (FAP)

| FAP TYPE | CLINICAL PHENOTYPE | AMYLOID PRECURSOR | COMMON MUTATION |
|--|--|------------------------------------|-----------------------------------|
| Type 1 (Portuguese) (Irish/Appalachian) | Lower limb neuropathy | Transthyretin | Met30 (plus others) |
| Type 2 (Indiana) | Upper limb neuropathy | Transthyretin | Ala 60 |
| Type 3 (Iowa) | Lower limb neuropathy Nephropathy Gastric ulcers | Transthyretin Apolipoprotein A1 | Ser84, His58 plus others Arg26 |
| Type 4 (Finnish) | Cranial neuropathy Corneal dystrophy | Gelsolin | Asp187, Tyr187 |

with the eventual involvement of all nerve fiber types and all sensory modalities. Subsequent motor involvement results in muscle wasting and weakness with loss of reflexes. Months or years after lower limb involvement, the upper limbs can become impaired. Carpal tunnel syndrome may occur but is rarely a presenting feature. Autonomic neuropathy is frequent and can be severe, with postural hypotension, impotence, gastrointestinal upset, urinary difficulties, and dry skin. Cardiac amyloid deposition may be asymptomatic but can result in arrhythmias and either a restrictive or a hypertrophic cardiomyopathy. Occasionally, renal involvement is severe.

The majority of cases with this clinical picture have the common TTR Met30 mutation, but there are a large number of other point mutations in the TTR gene that give rise to a similar clinical picture. The Ala60Thr TTR point mutation gives rise to an Irish/Appalachian variant of FAP with the distinguishing features of later onset (the sixth and seventh decade), prominent motor and large fiber sensory involvement, and more severe and symptomatic cardiac involvement.

FAP Type 2 (Indiana)

This was originally described in families of Swiss origin in Indiana and families of German origin in Maryland. Patients present in middle life, commonly with bilateral carpal tunnel syndrome and vitreous opacities. Some patients, particularly men, may develop a mild and generalized neuropathy with motor features appearing first in the upper limbs and then spreading to the lower limbs. Autonomic neuropathy can also occur. Regardless of its form, neuropathy is rarely disabling. Hepatosplenomegaly may occur. The vitreous abnormalities can cause severe visual impairment. The original cases had a Ser84 or His58 TTR point mutation, but a variety of other mutations have been described.^{58,59}

FAP Type 3 (Iowa)

This form of amyloidosis has many features in common with FAP type 1. Upper and lower extremities are affected, but usually carpal tunnel syndrome does not occur. The peripheral neuropathy can be severe, but the autonomic neuropathy is less prominent. Systemic signs include peptic ulceration and renal involvement that often results in hypertension and uremia. Amyloid deposition also occurs in the liver, adrenal glands, and testes. This type of FAP is associated with apolipoprotein A1-derived amyloid, and a substitution of arginine for glycine has been found in nucleotide 26 of the gene.

FAP Type 4 (Finnish)

This form was first described in a Finnish family but has since been identified in Dutch, Japanese, and Irish-American families. Corneal dystrophy may begin in the fourth decade but is usually asymptomatic. A progressive cranial neuropathy then usually occurs with the facial nerve most frequently affected, although the trigeminal, hypoglossal, and vestibular nerves can also be involved. The facial skin becomes initially thickened and then atrophic.

A mild generalized sensory and autonomic neuropathy ensues. Although cardiac deposition of amyloid occurs, patients only rarely have symptoms of cardiac disease. In this disorder, the amyloid precursor protein is gelsolin, and mutations have been described in this gene.^{60,61}

DIFFERENTIAL DIAGNOSIS OF FAP. Differential diagnosis of FAP varies with the presentation and is wider when there is no family history. Presentation with a painful distal mainly sensory neuropathy of small fiber type poses considerations of leprosy, diabetes, vasculitis, or paraneoplastic-associated neuropathies. Familial small fiber neuropathies include type 1 hereditary sensory neuropathy and the neuropathy associated with Tangier's disease. Presentation with carpal tunnel syndrome raises the diagnostic possibilities of hypothyroidism, diabetes, osteoarthritis, and acromegaly. Carpal tunnel syndrome may also occur in patients undergoing hemodialysis with deposition of β -microglobulin-derived amyloid. Presentation with prominent autonomic symptoms may require differentiation from other hereditary diseases, such as familial dysautonomia (Riley-Day syndrome), dopamine β -hydroxylase deficiency, and Fabry's disease.

EVALUATION OF FAP. Hematological and biochemical tests may reflect hepatic, renal, or gastrointestinal infiltration with amyloid. In isolated cases of amyloid neuropathy, a careful search for monoclonal antibodies is required to exclude acquired amyloidosis. Urine and serum should be screened with special attention to γ -chains, the predominant monoclonal species.⁴⁸ ECG may show evidence of cardiac involvement, including heart block, other conduction defects, and widespread Q-wave and T-wave repolarization changes. Echocardiography may show either a restrictive or hypertrophic cardiomyopathy. Autonomic function tests may reveal abnormal responses of blood pressure and heart rate to postural change and other provocative measures. Neurophysiology studies show evidence of an axonal neuropathy, but in the early stages when only small-diameter fibers are involved, sensory nerve actual potentials may be preserved. Sensory and motor conduction velocities are usually normal or only slightly reduced. EMG shows evidence of chronic partial denervation in long-standing cases. In FAP type 4, EMG shows evidence of both axonal degeneration and demyelination with slow nerve conduction velocities and prolonged distal motor latencies. The diagnosis of amyloid requires pathological demonstration of amyloid deposition detected by staining with Congo red and demonstrating the characteristic green birefringence with polarizing filters. Electromicroscopy can also demonstrate the characteristic fibrillar appearance of the protein. For biopsy, rectal tissue is the most accessible tissue to sample. Immunohistochemistry can usually characterize the nature of the amyloid, although there may be technical difficulties when only small amounts of amyloid are present. TTR antibody immunohistochemistry will be negative in some cases if TTR is not the precursor for the amyloid. It is also possible to detect variant TTR in the blood using autoimmune assay and enzyme-linked immunosorbent assay techniques. Screening for the common TTR mutations is available; if these tests are negative but a high index of suspicion remains, sequencing the entire TTR gene may be justified.

MANAGEMENT. Treatment is supportive in terms of autonomic, renal, gastrointestinal, and vitreous complications. Plasma exchange intending to remove the circulating amyloid protein has not been successful. Because more than 90% of TTR is synthesized in the liver, some patients have undergone liver transplantation. This treatment is associated with a significant decline in the circulating TTR levels with some stabilization of symptoms, including those linked to neuropathy.⁶² However, neurological benefit may not be accompanied by an arrest or slowing in the progression of the cardiomyopathy.⁶³ Liver transplantation remains a hazardous procedure, particularly in those with autonomic involvement.^{64,65} Mortality may reach 20%, usually in the first 6 months from infection and rejection. The risk/benefit ratio may be acceptable if transplantation is performed early in the course of the disease.

PROGNOSIS. The different forms of FAP vary in their prognosis. In FAP type 1, death from sepsis and systemic disease occurs approximately 15 years after onset; in late-onset cases, the disease progression may be slower. In FAP type 2, the peripheral neuropathy and the autonomic involvement are not severe, and individuals may survive as long as 35 years with only modest disability. However, the vitreous disposition may lead to severe visual loss. In FAP type 3, peripheral neuropathy becomes disabling over the course of 10 years, and death is the result of renal failure.

FUTURE PERSPECTIVES. Further experience with liver transplantation will define the success rates and phenotypic features most predictive of good surgical outcome.

GIANT AXONAL NEUROPATHY

Most cases with this rare condition occur spontaneously, but occasional autosomal recessive inheritance has been documented.⁶⁶ Symptoms begin in childhood with a slowly progressive peripheral motor and sensory neuropathy. Patients often have very tight, curly black hair. There may be associated central nervous system involvement with intellectual impairment, optic atrophy, cerebellar ataxia, nystagmus, and corticospinal disturbance. Death usually occurs in adolescence. Investigations may show mildly reduced motor conduction velocities and sensory nerve action potentials. Diagnosis is made by nerve biopsy, where there is evidence of axonal loss with focal swellings along the nerve seen on electron microscopy to contain neurofilament accumulations.

Intermediate filaments in a variety of cell types suggest that the abnormality is not confined to axons and hair. Decreases in disulfides and increases in thiol groups have been noted in hair samples from patients.⁶⁷ In some cases, mutations have been described in the giant axonal neuropathy gene (GAN) on chromosome 16q24.1 encoding for a novel, ubiquitously expressed cytoskeletal protein called gigaxonin.^{68,69}

The differential diagnosis is that of an axonal neuropathy not necessarily having a family history but with the abnormal kinky hair being the distinguishing feature.

The management is supportive; there is no specific treatment.

ISAAC'S DISEASE

The hallmark of this disorder is neuromyotonia or hyperexcitability of peripheral nerves that result in spontaneous and continuous muscle electrical activity. Although some cases are inherited, the majority are acquired. The syndrome is rare, and assessment of its frequency and of its definitive clinical features is hampered by variable names given to it in the past.

Typical patients have muscle stiffness, cramps, and myokymia, with some having generalized weakness and sweating. Onset can be any time during life, and the condition tends to be chronic. Motor features are most prominent in the limbs and trunk. Respiratory muscle involvement can cause breathing difficulties, and laryngeal involvement can cause stridor. Examination may reveal mild weakness with reduced or absent tendon reflexes and evidence of myokymia with occasional muscle hypertrophy as a result.

The continuous discharges may originate anywhere along the length of the peripheral nerve. The acquired autoimmune disease may be associated with antibodies against potassium channels.⁷⁰ In hereditary cases, there is a likely genetic defect in the potassium channel, an assumption clinically strengthened by the coexistence of myokymia in another condition with a well-established potassium channel defect, autosomal dominant episodic ataxia type I.⁷¹

Myokymia can arise from peripheral nerve damage (Video 110, Facial Myokymia). It is also a feature of autosomal dominant episodic ataxia type I. The features of cramps and stiffness raise the differential of Brody's disease, stiff-person syndrome, and the myotonias.

EMG gives confirmation of the diagnosis in showing doublet, triplet, or multiple spontaneous motor unit discharges that may be present even in the absence of visible myokymia. Nerve and muscle biopsies show nonspecific features. In a few cases, oligoclonal IgG has been found in the cerebrospinal fluid.⁷²

MANAGEMENT. Anticonvulsant medications such as phenytoin and carbamazepine have been the primary treatment. Plasma exchange may be appropriate when an autoimmune etiology is considered probable. In some of these latter cases, immune suppression with corticosteroids and azathioprine has been tried.⁷²

Sodium Disorders

Although dietary intake varies, body fluid composition and volume remain fairly constant, a reflection of multiple compensatory mechanisms. Although it is frequently cited that total body water (TBW) constitutes approximately 60% of body weight, the percentage varies with age, gender, and body habitus from 42% (obese, elderly female) to 75% (infant).¹ The cell membrane serves as an interface between the intracellular fluid and extracellular fluid (ECF) compartments; their ratio is roughly 2 to 1. Approximately three-fourths of ECF is interstitial, whereas the remaining one-fourth is intravascular (blood volume). The blood volume consists of plasma and formed elements, with plasma volume being approximately 95% water and 5% macromolecules (e.g., albumin). The interface between the interstitial and intravascular compartments is the capillary, which does not permit crossing of macromolecules. For that reason, the interstitial fluid is an ultrafiltrate of the plasma, and therefore their electrolyte concentrations are similar.

Starling forces determine the direction of water flow between compartments. Because the cell membrane is water permeable, whenever an intercompartmental osmolal gradient develops, water passively moves down its concentration gradient from an area of lower osmolality to one of higher osmolality, thereby maintaining osmolal equilibrium. Solutes that are freely permeable across the membrane (e.g., urea and ethanol) are referred to as ineffective osmoles because they do not form significant osmolal gradients across the membrane. Conversely, membrane impermeable solutes (e.g., glucose, sodium [Na], mannitol, and glycerol) are referred to as effective osmoles because they do create osmolal gradients across the membrane.¹ Translocational hyponatremia is most commonly caused by hyperglycemia.² Because the different fluid compartments are in osmolal equilibrium, the serum osmolality is a good reflection of the intracellular osmolality and can be approximated using the following formula³:

$$\text{Serum osmolality} = 1.86\text{Na} + \text{BUN}/2.8 + \text{Glucose}/18 + 9$$

where Na concentration is expressed in milliequivalents per liter (mEq/L), and blood urea nitrogen (BUN) and glucose concentrations are expressed in milligrams per deciliter (mg/dL). A discrepancy between *calculated* and *measured* osmolality indicates the presence of other serum osmoles. When sufficient amounts of ineffective osmoles are present, hypo-osmolal hyponatremia can be associated with normal or even high serum osmolality. In this setting, the risks of hypo-osmolality are the same because the solutes are ineffective osmoles.² By monitoring the osmolality and volume of the ECF, the body maintains its fluid composition and volume fairly constant.^{4,5}

Hyponatremia

PATHOGENESIS AND PATHOPHYSIOLOGY. Hyponatremia reflects an excess of water, relative to Na, and is defined as plasma Na below 135 mEq/L. Because Na is an effective osmole, intercompartmental Na imbalances must be corrected by water movement. This can produce brain edema, which, in turn, may produce pulmonary edema, central diabetes insipidus (DI), cerebral infarction, cortical blindness, persistent vegetative state, respiratory arrest, and coma.¹ Hyponatremic patients can be subdivided into hyperosmolal, normo-osmolal, and hypo-osmolal types. The hypo-osmolal type is the most frequent category and is usually further subdivided, based on ECF volume, into hypervolemic, normovolemic, and hypovolemic (Table 38-1).

The neurological symptoms associated with hyponatremia primarily reflect central nervous system (CNS) involvement (e.g., encephalopathy and seizures) and are related to the rapidity of the onset of the lowered Na level. Brain cell compensatory mechanisms exist to counter hyponatremia (see [Clinical Features and Associated Disorders](#)) but require time to occur. When hyponatremia occurs acutely, water passively flows down its concentration gradient, resulting in its entry into the brain cells, thereby producing cerebral edema. The causes of peripheral neurological symptoms and signs (cramping, muscle twitching,

TABLE 38-1

Major Causes of Hyponatremia

| |
|--|
| Iatrogenic |
| Factitious (blood drawn proximal to hypotonic infusion) |
| Hyperosmolar (glucose, mannitol, radiocontrast) |
| Normo-osmolar (hyperlipidemia, hyperproteinemia) |
| Hypo-osmolar |
| <i>Hypervolemic</i> (decreased cardiac output, increased vascular compliance, water shift) |
| <i>Normovolemic</i> (SIADH, drugs, hypothyroidism) |
| <i>Hypovolemic</i> (renal, extrarenal [e.g., gastrointestinal, cutaneous, hemorrhage]) |

and fasciculations) are most likely related to altered ion conductances and abnormal discharges of the peripheral nerves.

EPIDEMIOLOGY AND RISK FACTORS. Among hospitalized patients, the incidence of hyponatremia is approximately 1% and its prevalence is approximately 2.5%.^{6,7} Postoperative patients account for roughly 25% of all hyponatremic episodes.⁸ It is important to note that although the incidence of hyponatremia is similar between the sexes, premenopausal women have a significantly greater incidence of brain damage than do men or postmenopausal women.¹ This is a reflection of Na/K-ATPase pump inhibition (which blocks the first line of defense against hyponatremia) and antidiuretic hormone (ADH) release stimulation (which contributes to water retention) by the sex hormones.¹ Another significant risk factor for hyponatremia-induced brain damage is hypoxia, a reflection of its inhibitory effect on Na/K-ATPase transport activity, which therefore compromises the brain's ability to compensate for the hyponatremia.¹ Other high-risk populations are patients with acquired immunodeficiency syndrome, syndrome of inappropriate antidiuretic hormone (SIADH; pulmonary disease, intracranial disease, drug-induced), adrenal insufficiency, and isotonic fluid loss (emesis and diarrhea).⁸ Hyponatremia has been increasingly recognized as an important cause of race-related mortality and morbidity among marathon runners. Of the 488 runners of the 2002 Boston Marathon who provided usable blood samples, 62 (13%) had hyponatremia.⁹ Among pregnant patients, the misuse of oxytocin is the most common cause of hyponatremia.¹⁰ Severe, symptomatic hyponatremia can result when procedures requiring large quantities of irrigant solutions (e.g., transurethral prostatectomy) are performed using irrigant solutions that do not contain sodium.²

CLINICAL FEATURES AND ASSOCIATED DISORDERS. The most common clinical features of hyponatremia are gastrointestinal (GI) (e.g., nausea, vomiting, and anorexia) and neurological, with CNS abnormalities predominating. The CNS symptoms reflect cerebral edema due to the passive movement of water from the hypo-osmolar ECF into the brain cells. Initial water entry into the cell stimulates solute extrusion, initially by the Na/K-ATPase pump, which limits the amount of water entry required to restore osmotic equilibrium and may render the patient asymptomatic.¹ The most common CNS manifestation is encephalopathy,

ranging from mild confusion to coma, depending on the degree of cerebral edema, its rapidity of onset, and its absolute magnitude. Sodium levels above 125 mEq/L are usually associated with GI symptoms, whereas seizures, coma, and permanent neurological sequelae are typically only observed with levels below 115 mEq/L. Neurological features due to hyponatremia of slow onset may be much less apparent, although impaired cognition is typical with Na levels below 120 mEq/L.³ Asterixis, ataxia, and multifocal myoclonus may also be observed in acute hyponatremic encephalopathy but are less frequent than in uremic encephalopathy (UE).³ Focal neurological features may also be seen and usually remit with correction of the hyponatremia. These findings may represent underlying focal pathologies with a resultant lower threshold for clinical expression. Other reported neurological features of hyponatremia include headache, respiratory depression, bizarre behavior, nystagmus, increased tone, and hallucinations. Opisthotonic posturing, respiratory arrest, and fixed and dilated pupils suggest cerebral herniation.⁸ Muscle cramping may occur, but fasciculations, tremor, and twitching are uncommon.¹¹ An associated disorder related to hyponatremia, or rather its treatment, is central pontine myelinolysis.

DIFFERENTIAL DIAGNOSIS. The principal causes of hyponatremia include primary dilutional hyponatremia, SIADH, diuretic usage, and water intoxication. Dilutional hyponatremia can be seen in edematous states, such as cirrhosis, nephrosis, and congestive heart failure, as well as with excessive water intake in the presence of renal failure (RF), Addison's disease, myxedema, and nonosmotic ADH secretion. The possibility of adrenal insufficiency must always be excluded in the presence of hyperkalemia. Among hospitalized patients, the most common cause of acute hyponatremia is iatrogenic overhydration (e.g., excessive intravenous [IV] fluid administration) in the presence of impaired water elimination.⁶ SIADH occurs with oat cell carcinoma of the lung, a variety of CNS and pulmonary disorders, the Guillain-Barré syndrome, and acute intermittent porphyria, and it may also be idiopathic. The differential diagnosis also should include drug intoxications, infections, endocrinopathies, and other electrolyte disorders.

EVALUATION. When hyponatremia is identified, the possibility of an error, either by the laboratory or by the phlebotomist (e.g., sampling proximal to a hypotonic fluid infusion), should be considered. If hyponatremia is verified, the patient's past medical history and medication profile should be reviewed because they may suggest the cause. A careful physical examination should be performed and, if possible, the ECF volume status should be ascertained, along with serum electrolytes, BUN, creatinine (Cr), and osmolality. Uric acid is inversely proportional to the volume status and, therefore, may be helpful in determining hypervolemic and hypovolemic states. The serum osmolality should be calculated and compared with the measured osmolality, and if a discrepancy exists, the presence of an unidentified serum osmole (e.g., mannitol) is suggested. Other studies to consider include thyroid functions, adrenal studies, and the evaluation of urine Na, fractional excretion of Na, osmolality, and pH.

MANAGEMENT. Management is aimed at raising the Na level (decreasing water intake and increasing water loss), replacing the Na deficit (and other deficits, such as K),

and correcting the underlying disorder. In all cases of hyponatremia, the underlying cause must be identified and treated and iatrogenic hyponatremia prevented (e.g., avoidance of free water and hypotonic solutions in postoperative patients). Initial management is based on the type of symptoms, their rapidity of onset, and the underlying etiology. Thus, mild, asymptomatic hyponatremia typically does not require treatment, whereas acute-onset hyponatremia, which is usually associated with a marked increase in brain water and a risk of cerebral herniation, requires rapid treatment. This is especially true when seizures or a decreased level of alertness is present. Untreated, acute hyponatremia is nearly always fatal. Unfortunately, a lack of consensus regarding the optimal treatment of symptomatic hyponatremia remains.² Water restriction in acute hyponatremia is never indicated, and hypertonic saline is given in an intensive care setting. In patients with chronic hyponatremia, however, hypertonic saline is not always indicated and may even be dangerous. Its management should be based on the presence of symptoms. Asymptomatic patients with volume depletion require repletion (with NS), and those with hormone deficiency (e.g., hypothyroidism and adrenal insufficiency) require hormone replacement. Patients with drug-induced hyponatremia require discontinuation of the offending agent. Water restriction may be appropriate for some patients with asymptomatic hyponatremia. Demeclocycline, a tetracycline antibiotic that produces nephrogenic DI, can be used for the long-term management of patients with stable asymptomatic hyponatremia (e.g., SIADH).¹²

Hyponatremic-induced seizures can be treated with IV 3% hypertonic saline at a dose of 4 to 6 mL/kg body weight.¹³ This dosage rapidly raises the serum Na level by approximately 3 to 5 mEq/L and avoids the risk of respiratory embarrassment associated with benzodiazepines and phenobarbital. Hyponatremic-induced seizures are more commonly associated with acute hyponatremia, in which

case rapid normalization to a level of 120 to 125 mEq/L can be accomplished without risk of neurological complications. The serum Na concentration need not be corrected to normal to obtain seizure control, and overcorrection can be harmful. Therapy with hypertonic saline should be discontinued when the patient becomes asymptomatic or the plasma Na concentration increases by 20 mEq/L or reaches a value in the range of 120 to 125 mEq/L.¹ To avoid potential complications, the plasma Na should never be acutely elevated to normonatremic levels and should not be increased by more than 25 mEq/L during the first 48 hours of therapy.¹⁴ One of the most recent recommendations is that the elevation be limited to 8 mEq/L on any day of treatment (e.g., 1 or 2 mEq/L per hour over 4 hours with severe symptoms) and be cautiously exceeded only when severe symptoms do not respond since, at that point, the risk of hyponatremia would outweigh the potential risk of osmotic myelinolysis.² In the setting of chronic hyponatremia, seizures are less common. Loop diuretics (e.g., furosemide) result in solvent loss greater than solute loss (i.e., net water loss) and can be used, in addition to the hypertonic saline, to raise the serum Na concentration.

Central pontine myelinolysis refers to the demyelinating lesions noted in the pons of patients with hyponatremia, which were previously believed to occur when the serum Na concentration was corrected too rapidly (Fig. 38-1; Video 113, Pontine Myelinolysis). Because myelinolysis also occurs outside of the pons, the term *osmotic myelinolysis* is also used by some physicians.¹⁵ Central pontine myelinolysis was first described in 1959¹⁶ in malnourished alcoholics and was later noted in hospitalized patients undergoing hydration.¹⁷ In 1980, Leslie and colleagues¹⁸ suggested that central pontine myelinolysis was due to rapid correction of hyponatremia. This led some physicians to suggest that the rate of hyponatremia correction should not exceed 12 mEq/L per day.¹⁹

Figure 38-1. A 30-year-old woman with a history of alcoholism presented with confusion and disorientation following a seizure. The patient's serum sodium was 99 mmol/L, and she was treated with an infusion of normal saline. This resulted in a sodium value of 125 mmol/L 24 hours later. The patient initially had dysarthria and slow response on finger-to-nose testing and was interactive on examination. On day 7 of admission, the patient became unresponsive and had new Babinski's signs. Brain magnetic resonance imaging demonstrated central pontine myelinolysis with a region of low signal intensity on a sagittal T1-weighted image (A) and high signal intensity on an axial T2-weighted image, which is marked by the arrows (B). The arrowheads in part B show the relative preservation of the corticospinal tracts. (From Hart BL, Eaton RP: Images in clinical medicine—Osmotic myelinolysis. *N Engl J Med* 1995;333:1259.)

Others have suggested that the magnitude of correction determines whether or not neurological complications occur.¹⁴ Based on several prospective studies, Griggs proposed that cerebral demyelination is not a manifestation of the rapid correction of acute hyponatremia,³ and studies have not confirmed that the demyelination associated with hyponatremia is related to rapid correction.²⁰ In fact, the majority of brain lesions observed among patients with symptomatic hyponatremia result from a delay in the initiation of therapy, which, in turn, results in respiratory insufficiency.²¹ Cerebral demyelinating lesions also occur with improper therapy, but they are unrelated to its rate of correction.¹⁴ It has been reported that cerebral demyelination occurs only when patients with hyponatremia are overcorrected (i.e., patients are made hypernatremic), have an absolute increase in plasma Na concentration exceeding 25 mEq/L during the first 24 to 48 hours of therapy, suffer a hypoxic event, or have underlying severe liver disease.¹ A review on myelinolysis suggested that chronic hyponatremia should be corrected at a rate below 10 mEq/L during any 24-hour period.²² Even water restriction must be monitored closely. For example, when patients with primary polydipsia are treated with water restriction and vasopressin suppression produces a brisk water diuresis, the underlying hyponatremia may be corrected at too rapid a rate.

PROGNOSIS AND FUTURE PERSPECTIVES. The prognosis is much better for patients with chronic hyponatremia than for those with acute hyponatremia. Acute hyponatremia is associated with substantial morbidity and mortality, with a mortality rate of 50% in one series.³ In addition to a higher mortality, patients with hyponatremia-induced seizures frequently show persistent neurological deficits.³ Diuretic-induced hyponatremia, hypoxia, alcoholism, malnutrition, liver disease, and female gender are risk factors for a poor neurological outcome.⁴ Because volume-induced ADH release occurs with significant blood volume reductions, treatment of hypervolemic hypo-osmolal hyponatremia carries an ominous prognosis.⁴ In the future, the treatment of central pontine myelinolysis—a disorder currently not correctable—may include reinduction of the hyponatremic state.²³

Hypernatremia

Hypernatremia is defined as a serum Na concentration above the normal range (135 to 145 mEq/L) and represents a relative increase in total body Na relative to TBW. This may be caused by either water loss or Na gain and is usually encountered when water losses exceed Na losses (i.e., hypo-osmolal fluid loss) along with decreased water intake (e.g., limited access to water and loss of thirst).

PATHOGENESIS AND PATHOPHYSIOLOGY. The primary cause of hypernatremia is water loss—renal, extrarenal, or both—along with limited water intake (e.g., decreased thirst or a comatose or debilitated condition). Disorders causing renal water loss include DI, osmotic diuresis, hypokalemia and hypercalcemia (which may impair the concentrating capacity of the kidney), and renal parenchymal disease (e.g., sickle cell anemia). Those disorders causing nonrenal water losses include excessive sweating and other insensible losses, diarrhea, and disordered thirst. Central DI (i.e., pituitary deficiency of ADH)

most commonly results from pituitary region tumors, their surgical treatment, and cranial trauma²⁴ and less frequently from infiltrative disorders (e.g., sarcoidosis). Impaired ADH synthesis is the underlying problem in some patients, whereas others have impaired ADH release in response to osmotic stimuli. Nephrogenic DI (renal ADH unresponsiveness) is usually acquired (e.g., drugs such as amphotericin B, lithium, and fluorocarbon anesthetics), and a transient form of DI can be seen in late pregnancy and tends to remit postpartum. Less common etiologies include excessive Na intake with limited water access (seen with water loss due to peritoneal dialysis), high dietary Na, seawater consumption, and iatrogenic errors in IV fluid delivery or total parenteral nutrition formulation. Essential hypernatremia has also been attributed to an impaired osmoreceptor set point.

Although the pathophysiology of hypernatremia is similar to that of hyponatremia (the movement of water along its concentration gradient to restore osmolal equilibrium), the pathology is different (cerebral dehydration occurs rather than cerebral edema). When the hypernatremia develops slowly, brain cells may be able to compensate by increasing the influx of electrolytes across the cell membrane, decreasing the intracellular electrolyte binding, and increasing the intracellular amino acid concentration.^{24–26} In doing so, the brain increases its intracellular osmolality to avoid water loss (dehydration).

EPIDEMIOLOGY AND RISK FACTORS. The incidence of hypernatremia among hospitalized adults ranges from 0.7% to 2.3% and is even greater among children.⁸ It is usually seen among patients at the extremes of age, in whom it is most frequently caused by gastroenteritis (infants) and limited water intake due to debilitation.¹¹ Common causes of hypernatremia among the elderly include surgery (21%), febrile illness (20%), infirmity (11%), and diabetes mellitus (11%).⁸ The elderly are at further risk because they have a diminished capacity for urine concentration and a depressed thirst response.^{8,27}

Closed head injury is also a risk factor for the development of DI and hypernatremia, with an incidence of 2% after severe closed head injury; the incidence is greater if the sella turcica region is involved.²⁴ Also, hypernatremia is often induced by IV mannitol, which is used to decrease intracranial pressure (ICP); when mannitol therapy is discontinued, fluid therapy quickly restores the Na concentration.²⁸

CLINICAL FEATURES AND ASSOCIATED DISORDERS. The most common neurological manifestations reflect CNS involvement and range from mild confusion to coma, with the severity typically correlating with the degree of hypernatremia and the rapidity of its onset. A history of a strong sense of thirst and signs of dehydration should be sought.⁸

When the onset of hypernatremia is acute, early symptoms typically occur at an osmolality of 320 to 330 mOsm/kg body water, whereas coma and respiratory arrest more commonly occur at values exceeding 360 mOsm/kg body water.⁴ As with hyponatremia, seizures are usually seen with acute-onset hypernatremia and tend to be generalized. Focal neurological features likely reflect focal dysfunction. In the setting of rapid brain dehydration, tearing of the bridging veins may result in subdural hemorrhages. Subarachnoid hemorrhage and intraparenchymal hemorrhages may also occur. Similar to other metabolic

encephalopathies, myoclonus, asterixis, and tremor occur and muscle cramping is frequently reported (Video 57, Myoclonus). Seizures are infrequent in chronic hypernatremia, except when it is too rapidly corrected.

DIFFERENTIAL DIAGNOSIS AND EVALUATION.

With the clinical syndrome of confusion or coma, other disorders in addition to hypernatremia should be considered in the differential diagnosis, including other electrolyte abnormalities, endocrinopathies, drug or toxin exposure, stroke, cerebral masses, trauma, and infection. The underlying cause of the hypernatremia should be identified and treated. In the case of nonrenal water losses, the etiology should be obvious, and the urine should be concentrated and of low volume. A history, thorough physical examination, and the same laboratory tests used in the evaluation of hyponatremia should be obtained. The presence of a hypotonic urine in the face of dehydration and hypernatremia is diagnostic of DI, either central or nephrogenic. In nonketotic hyperosmolar hyperglycemia (NKH), the serum osmolality and glucose are markedly elevated, ketone bodies are absent, and the patient is dehydrated (see [Hyperglycemia](#)). Because focal neurological findings may be produced by intraparenchymal, subdural, or subarachnoid hemorrhages, brain neuroimaging with computed tomography (CT) should be considered. In this setting, other etiologies associated with focal neurological signs should be contemplated, including stroke, arteriovenous malformation, and post-traumatic sequelae.

MANAGEMENT. Management necessitates identification of the underlying cause and correction of the hypertonic state (stopping ongoing water loss and correcting the water deficit). After the patient is stabilized, water replacement is usually the initial management. Importantly, free water cannot be given IV because the rapid lowering of plasma osmolality at the injection site causes massive hemolysis. D₅W is roughly isotonic with plasma, but isotonic saline solutions offer several advantages, including quicker correction of hypovolemia and a less rapid correction of serum Na concentration. A patient with a fixed urinary concentrating defect due to central or nephrogenic DI will develop the excretion of free water and worsening of hypernatremia when isotonic saline is administered. The amount of water deficit can be estimated by the following formula:

$$\text{Water deficit} = \text{TBW}(\text{Na} - 140)/140$$

where TBW is in liters, and Na concentration is in mEq/L. However, Adrogue and Madias²⁹ recommended that this approach be abandoned because, although it adequately estimates the water deficit in patients with hypernatremia secondary to pure water loss, it underestimates the deficit in patients with hypotonic fluid loss and, in addition, it is not useful when both Na and K must be administered. In their review, they provide formulas to estimate the effect of 1 L of infusate on serum Na based on the Na concentration of the particular infusate. In acute hypernatremia, the risk of tissue dehydration (e.g., brain) is significant and fluid replacement should begin immediately. The risk of cerebral edema is not a concern because the brain rapidly extrudes any accumulated electrolytes and, consequently, a rate of reduction of 1 mEq/L/hour is acceptable. Importantly, among patients with chronic hypernatremia,

correction should occur over a 48-hour period and not exceed a rate of 0.5 mEq/L per hour; otherwise, seizures or cerebral edema might be precipitated.⁴ This reflects the increased hyperosmolality of brain cells brought about via compensatory mechanisms to avoid dehydration. When hypernatremia is aggressively treated with hypotonic fluids, cerebral edema occurs; subsequent seizures, coma, or death may result.

PROGNOSIS AND FUTURE PERSPECTIVES. Hypernatremia, either acute or chronic in onset, is associated with a high rate of mortality and severe morbidity.⁴ Among children with severe hypernatremia, an initial mortality rate of 20%, as well as an incidence of permanent brain damage exceeding 33%, has been reported.^{10,30} The mortality rate from hypernatremia in hospitalized adults is approximately 50%,⁸ although the existence of severe concomitant disease makes it difficult to determine the exact cause of the mortality.

Potassium Disorders

The total body content of potassium (K) is approximately 3500 mEq,³¹ and approximately 98% is intracellular, two thirds of which is intramuscular.¹¹ Because cell membranes are more permeable to K than to Na and Cl, K is primarily responsible for the resting transmembrane potential and is therefore critical to the function of excitable tissue.

Hypokalemia

Hypokalemia, the most frequent electrolyte disorder encountered by the clinician, is defined as a plasma K concentration below the normal range (3.5 to 5.5 mEq/L).

PATHOGENESIS AND PATHOPHYSIOLOGY. Whenever K losses exceed intake, total body K decreases and hypokalemia results ([Table 38-2](#)). Each 1 mEq/L decrement in the plasma K level roughly correlates to a total body K decrease of 100 to 300 mEq. K influx increases intracellular positivity, thereby producing a mild depolarization. This lessened state of electrical excitability underlies the muscle weakness and hyporeflexia that can be seen clinically.

EPIDEMIOLOGY AND RISK FACTORS. Approximately 2% of normal adults, 21% of hospitalized patients, 25% of patients taking 50 mg of hydrochlorothiazide daily, and nearly 100% of patients taking more than one class of diuretic have hypokalemia.³¹ Although acute hypokalemia is an uncommon cause of weakness, certain scenarios increase its risk of development, including rapid correction of systemic acidosis (e.g., hyperventilation and bicarbonate

TABLE 38-2

administration), postoperative patients unable to take food by mouth (because K excretion cannot be stopped), and the chronic use of β_2 agonists (e.g., asthmatics).

CLINICAL FEATURES AND ASSOCIATED DISORDERS. The clinical features of hypokalemia are predominantly muscular and occur more frequently when the extracellular K level changes rapidly. The magnitude is also influential.¹¹ K levels of 3 to 3.5 mEq/L are associated with weakness, myalgias, and easy fatigability; those of 2.5 to 3.0 mEq/L are associated with more pronounced weakness; and those below 2.5 mEq/L (and especially if below 2.0 mEq/L) are associated with structural muscle damage (rhabdomyolysis and myoglobinuria). Areflexic quadriplegia and respiratory insufficiency may also occur at these lowest levels. The cranial musculature is rarely involved. Tetany may be observed in some hypokalemic patients, especially those with concomitant systemic alkalosis. Because hypokalemia can mask the tetany of hypocalcemia, tetany may appear as the hypokalemia is corrected.¹¹ Sensory disturbances and encephalopathic features are not expected in hypokalemia and, when present, should prompt a search for an underlying cause. Because hypokalemia can increase renal ammonia production, it can aggravate a preexisting hepatic encephalopathy.³²

DIFFERENTIAL DIAGNOSIS AND EVALUATION. Although the cause of hypokalemia frequently is apparent by history, a full general and neurological examination, with particular emphasis on muscle strength and deep tendon reflexes, is necessary. The possibility of Cushing's syndrome or hyperaldosteronism is suggested by hypertension, and the presence of thyrotoxic periodic paralysis (TPP) is indicated by evidence of hyperthyroidism. Laboratory evaluation should include Na, K, Cl, bicarbonate, BUN, Cr, glucose, calcium (Ca), and magnesium (Mg), as well as an arterial blood gas (ABG) and an electrocardiogram (ECG). Thyroid function tests (TFTs) identify the rare TPP, and muscle biopsy may demonstrate vacuolar change but generally is not indicated. With hypokalemia due to skin or GI losses, as well as to remote vomiting or diuretic usage, urine K excretion should be less than 15 mEq/day. When this value is exceeded, renal K loss is suggested. (The latter also is suggested when the transtubular K concentration gradient exceeds 4.) Plasma renin and aldosterone levels can be used to help identify the various causes of hyperaldosteronism. Mg is checked because low Mg may cause hypokalemia.

MANAGEMENT. Therapy includes correction of the underlying cause, replacement therapy, and prevention of life-threatening complications (e.g., arrhythmias and hepatic encephalopathy). Replacement therapy is usually recommended once the K level is below 3.5 mEq/L. For safety reasons, oral supplementation is preferred, although IV supplementation may be required when GI dysfunction exists or when the K deficiency is severe (with arrhythmias and neuromuscular manifestations).

PROGNOSIS AND FUTURE PERSPECTIVES. Although respiratory failure and death can occur when hypokalemia goes unrecognized, complete recovery is expected when K replacement can be provided and the underlying disorder corrected. For disorders that cannot be corrected (e.g., aldosterone-secreting tumors), the prognosis is related to the underlying disorder.

Hyperkalemia

PATHOGENESIS AND PATHOPHYSIOLOGY. Hyperkalemia may result from increased entry of K into the ECF, intracellular K efflux, or decreased K output (Table 38-3). Of these three processes, intracellular K efflux and decreased K output predominate. Because the renal capacity for kaliuresis adapts to increasing K intake, hyperkalemia usually is not seen unless a massive amount of K is ingested, parenteral replacement is provided too rapidly, or coexistent adrenal or renal dysfunction exists. Even in the setting of complete RF, the rise in serum K is slow, ranging from 1 mEq/L per week to 0.5 mEq/L per day.³³ In the setting of hyperkalemia, the intercellular gradient for K efflux is lessened and, therefore, intracellular positivity increases. This results in a minimal depolarization that, in turn, makes the tissue less excitable by causing a reduction in Na influx.

EPIDEMIOLOGY AND RISK FACTORS. Among hospitalized patients, the incidence of hyperkalemia approaches 10%, one fifth of which is above 6.0 mEq/L.³¹ Risk factors for the development of hyperkalemia include renal or adrenal insufficiency, K supplementation at rates and quantities above the suggested values, situations resulting in tissue destruction (e.g., induction of chemotherapy), and the use of β_2 antagonists (e.g., propranolol) or other medications known to cause hyperkalemia (e.g., heparin, K-sparing diuretics, and ACE inhibitors). (Heparin causes elevated K by blocking adrenal gland synthesis of aldosterone, β -adrenergic blockers both by blocking the stimulatory effects of the sympathetic nervous system on renin release and by interfering with the cellular uptake of K through reduction in Na-K-ATPase activity.³⁴)

CLINICAL FEATURES AND ASSOCIATED DISORDERS. The usual manifesting feature of hyperkalemia is cardiac toxicity.¹¹ ECG features include peaked T waves, increased PR (atrioventricular block) and QRS (interventricular block) intervals, and arrhythmias. Cardiac arrest represents the major problem and may be the initial symptom.³¹ Like hypokalemia, the major neurological manifestations of hyperkalemia are peripheral. Hyperkalemia may cause loss of strength and deep tendon reflexes, although this is observed less commonly than with hypokalemia. Muscle cramping is not uncommon, and both paresthesias³¹ and focal neurological signs³⁵ have been reported.

Data from Singer GG, Brenner BM: Fluid and electrolyte disturbances. In Fauci AS, et al (eds): Harrison's Principles of Internal Medicine, 15th ed. New York, McGraw-Hill, 2001.

DIFFERENTIAL DIAGNOSIS AND EVALUATION. Systemic acidosis and adrenal or renal insufficiency are the more frequently encountered etiologies of hyperkalemia. Other causes include increased intake (rare), iatrogenic (overzealous replacement), pseudohyperkalemia (hemolysis and marked leukocytosis), transcellular shift (metabolic acidosis), and decreased renal excretion. Once hyperkalemia is noted, an ECG must be obtained, followed by continuous cardiac monitoring until causes of pseudohyperkalemia are excluded. This requires a complete blood count (CBC) with smear for the presence of red blood cell hemolysis, thrombocytosis ($>500,000/\mu\text{L}$), or leukocytosis ($>50,000/\mu\text{L}$). Tourniquet-induced stasis and forearm exercise may also produce hyperkalemia.³

MANAGEMENT. Depending on the degree of elevated K and the presence of ECG changes, the treatment of hyperkalemia includes addressing its cardiac manifestations, reversing the underlying disorder, decreasing the K input, increasing the intracellular influx of K, and increasing K excretion.

Calcium Disorders

Ninety-nine percent of total body Ca is contained in bone, making the skeleton a Ca reservoir; the remaining 1% is distributed in the intracellular and ECF compartments. Because 1% of skeletal Ca is freely exchangeable with the ECF, it can help buffer acute changes in the serum Ca, whereas the kidney regulates calciuresis.³⁵ Among normal adults with average calcium intake, urinary calcium excretion ranges between 100 and 400 mg/day.³⁶ Total serum Ca reflects dietary intake, GI absorption, calciuresis, and transfer from the bone to the ECF. Parathyroid hormone (PTH), 1,25-dihydroxycholecalciferol (DHCC), and calcitonin regulate both Ca absorption from the gut and calciuresis. PTH causes tubular cells to reabsorb calcium and stimulates renal parenchymal cells to hydroxylate vitamin D into its active form (DHCC).³⁶ PTH is released whenever the serum ionized Ca level falls; conversely, hypercalcemia suppresses the release of PTH. In addition to the nearly instantaneous changes in PTH secretion brought about by shift in serum Ca concentration, Marx³⁷ emphasized that changes in PTH mRNA (over a period of hours) and changes in the size of the parathyroid glands (days to months) also contribute to the regulation of the serum Ca level. Because PTH promotes the synthesis of 1,25-DHCC, it indirectly influences GI absorption.

Hypocalcemia

Although ionized Ca is the physiologically active form, total serum Ca is the laboratory parameter usually measured. This value reflects the ionized (unbound, 50%), the bound (mostly to albumin, 40%), and the chelated (10%) fractions. In the presence of normal serum protein levels, hypocalcemia exists when the total serum Ca value is below the normal range of 8.8 to 10.4 mg/dL. However, in the setting of hypoalbuminemia, although the measured total serum Ca is low, the patient is asymptomatic because the physiologically active, ionized fraction is normal.³⁸ Although the total serum Ca value may be corrected for hypoalbuminemia (e.g., by adding 0.8 mg/dL to the measured Ca value

for every 1.0 g/dL decrement in the serum albumin value), this correction formula may be inaccurate in critically ill patients.³⁹ For that reason, it is best to measure the ionized Ca value in this patient population.

PATHOGENESIS AND PATHOPHYSIOLOGY. Hypocalcemia may be caused by PTH or 1,25-DHCC deficiency, as well as by end-organ resistance to their actions and other conditions (Table 38-4). In the setting of chronic renal failure, decreased renal synthesis of 1,25-DHCC and hyperphosphatemia cause hypocalcemia with resultant secondary hyperparathyroidism. Ionized Ca is important for presynaptic neurotransmitter release and stabilization of nerve and muscle membranes (divalent cations stabilize the cell membranes of nerve and muscle).⁴⁰ Thus, it is not surprising that disturbances of ionized Ca result in neuromuscular manifestations.

Neurologically, both the peripheral nervous system (PNS) and the CNS may be involved. Tetany, a PNS manifestation, is thought to be caused by repetitively generated nerve fiber action potentials, possibly related to the spontaneous depolarization of the nerve cell membrane in the setting of hypocalcemia. When the rate of sequential muscle fiber depolarization does not permit Ca reuptake by the sarcoplasmic reticulum, tetany occurs. The instability of the neuromuscular membranes may explain why the clinical features of hypocalcemia are positive in nature (e.g., perioral and acral paresthesias, and muscle spasms).

EPIDEMIOLOGY AND RISK FACTORS. Except in neonates and patients with RF, hypocalcemia is relatively rare. The most likely cause of hypocalcemia among patients presenting to an emergency room is hypomagnesemia.⁴⁰ Risk factors include past thyroidectomy, neck trauma, a family history of hypocalcemia, malabsorption syndromes, antiepileptic drug usage, severe liver or kidney disease (decreased 1- α -hydroxylation of vitamin D), and pancreatitis. The incidence of postsurgical hypoparathyroidism (usually thyroidectomy) varies with the expertise of the surgeon.⁴¹ The decrease in total serum Ca during pregnancy reflects dilutional hypoalbuminemia and, for that reason, the ionized Ca concentration is unchanged.⁴²

CLINICAL FEATURES AND ASSOCIATED DISORDERS. The clinical features of hypocalcemia are primarily neuromuscular, regardless of the underlying disorder, and are dependent on its rapidity of onset and magnitude. The earliest PNS symptoms include perioral and acral paresthesias, as well as tetany (tonic muscle spasms), the most characteristic and frequently recognized sign of hypocalcemia.¹¹ Tetany can be overt or latent, and provocative tests may be necessary to elicit latent tetany. Provocative tests

TABLE 38-4

include Chvostek's sign, the contraction of ipsilateral facial muscles in response to light percussion over the facial nerve (just anterior to the ear), and Trousseau's sign, carpal spasm in response to ischemia (e.g., 3-minute application of blood pressure cuff maintained just above systolic pressure). The carpal spasm produced is first preceded by acral paresthesias, followed by sensations of spasm, and then carpal spasm, paralleling the sequence of development of tetany.⁴³ Latent tetany may also become overt in the setting of alkalosis (e.g., hyperventilation or Na bicarbonate administration), a reflection of increased binding between ionized Ca and albumin. When tetany is severe, lower extremity and pedal spasms, as well as laryngeal stridor, may be observed. Opisthotonos may occur if spasms involve the trunk. A history of preceding muscle cramps, or generalized muscle aching, is frequently obtained.

CNS manifestations include irritability, delirium, delusions, hallucinations, depression, and dementia. When the onset of hypocalcemia is slow and insidious, dementia may be the initial manifestation. Seizures may occur and can be the presenting sign when hypocalcemia is severe. They are usually generalized but may be focal.⁴³ Intracerebral calcifications, seen most frequently with idiopathic hypoparathyroidism and pseudohypoparathyroidism, are usually asymptomatic. Although the basal ganglia are frequently affected, parkinsonism, athetosis, and chorea have been reported only rarely.⁴⁴ When the condition is persistent, cataract formation may occur. Congestive heart failure (CHF) and papilledema with increased ICP (idiopathic intracranial hypertension) are rarely observed.⁴¹

DIFFERENTIAL DIAGNOSIS. The etiologies of hypocalcemia are listed in Table 38-4. The most common cause of hypoparathyroidism is surgical (e.g., thyroidectomy) and is usually transient, becoming permanent in less than 3% of patients. Severe hypomagnesemia may cause hypocalcemia by inducing deficient PTH secretion and causing end-organ resistance to PTH. This explains why hypomagnesemia causes many of the same clinical manifestations as hypocalcemia.

EVALUATION. Serum electrolyte, BUN, Cr, Ca (total and ionized), Mg, phosphorus, alkaline phosphatase, and albumin levels should be determined. An ABG identifies whether a hyperventilation syndrome is present. ECG and continuous cardiac monitoring may be required. More specific tests for intestinal malabsorption may also be necessary. In osteomalacia or rickets, the serum alkaline phosphatase is elevated. CT imaging of the head may reveal intracranial calcifications, especially in the basal ganglia region. When hypocalcemia and hyperphosphatemia coexist in the presence of normal renal function, the diagnosis of hypoparathyroidism is strongly suggested and the appropriate laboratory evaluation is required. Hypocalcemia coupled with a normal or low serum P level suggests vitamin D deficiency, malabsorption, or another cause of secondary hypoparathyroidism. Steatorrhea is frequently associated with hypomagnesemia and may serve as a clue to its presence.

MANAGEMENT. Acute, symptomatic hypocalcemia requires emergency treatment with IV Ca until symptoms resolve. Hypertension, bradycardia, cardiac conduction block, and digitalis toxicity may be precipitated if the infusion is provided too rapidly, and so monitoring is required.²⁴

Because this form of treatment lasts only a few hours, it must be repeated, or the patient must be provided with a continuous infusion. In less urgent settings (e.g., postsurgical hypocalcemia), elemental Ca may be given as a continuous infusion over 4 to 10 hours and Ca monitored. In the setting of mild hypocalcemia, treatment with oral Ca replacement alone may suffice. Ca carbonate, up to 1200 mg orally three times daily, may safely be given.²⁴ Definitive resolution of hypocalcemia, however, requires identification and treatment of the underlying disease. For patients requiring long-term Ca supplementation, monitoring for evidence of toxicity is required (e.g., hypercalcemia and hypercalciuria). When present, low Mg levels must be treated to correct hypocalcemia.

Hypercalcemia

PATHOGENESIS AND PATHOPHYSIOLOGY. Hypercalcemia occurs when serum Ca entry (from bone resorption and GI absorption) exceeds calciuresis. In the presence of normal serum proteins, hypercalcemia exists when the serum Ca concentration is above the normal range. However, physiological hypercalcemia is present only when the ionized Ca is above its normal range. The ionized Ca value can be calculated, based on the serum albumin level, or directly measured in most laboratories. In the setting of hypoalbuminemia, although the total serum Ca value may be normal, ionized Ca may be significantly elevated and require emergent treatment. In addition to serum protein binding, consideration of chelation (anions) and acid-base status is also important.

EPIDEMIOLOGY AND RISK FACTORS. Approximately 40% of hypercalcemic patients develop neurological manifestations.^{11,45} Nearly all patients with hypercalcemia have a malignancy or hyperparathyroidism or are using thiazide diuretics (Table 38-5). Malignancies are most common among hospitalized patients, and hyperparathyroidism is common among ambulatory patients.⁴⁶ The incidence of primary hyperparathyroidism in the United States is approximately 25 cases per 100,000 people and increases significantly when only the elderly population is considered; approximately 50,000 new cases present annually.³⁶ Malignancy-induced hypercalcemia occurs predominately

Data from Olinger ML: Disorders of calcium and magnesium metabolism. *Emerg Med Clin North Am* 1989;7:795-822; Spiegel AM: The parathyroid glands, hypercalcemia, and hypocalcemia. In Bennett JC, Plum F (eds): *Cecil Textbook of Medicine*, 20th ed. Philadelphia, Saunders, 1995, pp 1364-1373; Lipsky MS: Hypercalcemia. In Rakel RE (ed): *Saunders Manual of Medical Practice*. Philadelphia, Saunders, 1996, pp 663-664.

in patients with bone metastases, such as lung (especially squamous cell), breast, ovarian, renal, hematological, head and neck, and GI cancers.^{40,47} Through increased calciuresis, the majority of these patients do not develop hypercalcemia. However, in the setting of renal dysfunction, hypercalcemia is readily provoked. Disorders that result in prolonged immobilization (paralysis, coma, or trauma) can cause hypercalcemia, especially in patients undergoing bone remodeling (normal growth in a young patient, osteoporosis in the elderly, and Paget's disease). Infrequently, humoral hypercalcemia of malignancy (i.e., PTH-related peptide excretion by the tumor) is observed. This topic has been reviewed.⁴⁸

CLINICAL FEATURES AND ASSOCIATED DISORDERS. The presentations of hypercalcemia vary with the patient's age, underlying disorder, magnitude of hypercalcemia, albumin level, and rapidity of onset. Individuals with mild hypercalcemia are frequently asymptomatic (identified by routine blood testing), whereas those with severe hypercalcemia may present in coma and rapidly progress to death. General features may reflect the underlying disorder, such as weight loss and cachexia with malignancy, or abdominal pain with acute pancreatitis. Less specific features include dehydration, polyuria, polydipsia, nocturia, hypercalciuria, urolithiasis, nephrolithiasis, nephrocalcinosis, renal impairment, GI disorders (anorexia, constipation, ileus, nausea, and vomiting), pruritus, hypertension, and soft tissue deposition.

Neurologically, CNS symptoms predominate and can include headache, fatigue, apathy, depression, agitation, insomnia, hallucinations, psychosis, confusion, lethargy, obtundation, coma, and, rarely, seizures. The mental status changes are directly related to the degree of hypercalcemia and are more frequent at Ca levels exceeding 14 mg/dL. All CNS signs are reversible with treatment. PNS manifestations reflect decreased neuromuscular excitability, and although they are common, these manifestations are nonspecific. Weakness is generally subjective, with few objective signs.⁴⁶

DIFFERENTIAL DIAGNOSIS AND EVALUATION. Before the realization that the observed clinical features reflect hypocalcemia, other etiologies must be considered. The particular cerebral manifestations, such as seizures and encephalopathic features, also dictate specific evaluation. The differential diagnoses of these central manifestations are lengthy and not addressed here (see Chapter 52). In the clinical setting of tetany, consideration should be given to disorders associated with cramping such as congenital myopathies and dystrophies (e.g., Duchenne's muscular dystrophy), cramp-myalgia syndrome (a dystrophinopathy), benign cramp syndrome (pseudotetanus), disorders producing contractures (e.g., McCardle's disease), and disorders producing continuous muscle activity (neuromyotonia).

The differential diagnosis of hypercalcemia is extensive. Frequently, the history, physical examination, initial laboratories, and routine radiographs identify the cause of hypercalcemia. A thorough examination may disclose features indicating the underlying disorder (e.g., breast mass and lymphadenopathy). Important laboratory evaluations include serum PTH level, urine Ca, CBC, chemistries (total and ionized serum Ca, Mg, P, and alkaline phosphatase), urinalysis, stool for occult blood, ECG, and chest x-ray

study. Other considerations include tests of adrenal and thyroid function, serum and urinary immunoelectrophoresis (for myeloma), vitamin D metabolite levels, and immunoassay for PTH-related peptide. A bone scan may be required in some patients, including those with suspected multiple myeloma (e.g., abnormal serum protein electrophoresis, anemia, and increased plasma cells on blood smear). Also, 24-hour urinary excretion of calcium can be measured when familial hypocalciuric hypercalcemia (rare) is suspected.³⁶

MANAGEMENT. Prevention of hypercalcemia in immobilized patients includes early mobilization and hydration, which increases calciuresis and dilutes the urine. High Ca-containing dietary products should be avoided. Although the underlying cause is the most important consideration for definitive treatment, the initial management of hypercalcemia depends on its magnitude and symptoms and may need to be initiated without a specific diagnosis. The major treatment modalities act by decreasing bone resorption, decreasing GI absorption, and increasing calciuresis. Mild hypercalcemia (<11.5 mg/dL) may require only recognition of the underlying disorder, recommendations to increase fluid intake, and careful follow-up. Conversely, in the setting of severe hypercalcemia (>15 mg/dL or severe clinical signs), urgent treatment is usually required and, in the setting of normal renal function, typically consists of volume replacement using IV normal saline, furosemide, and careful monitoring of therapy. For patients with chronic renal failure who develop secondary hyperparathyroidism, cinacalcet, a calcimimetic drug that decreases parathyroid hormone release, can be used.^{49,50}

PROGNOSIS AND FUTURE PERSPECTIVES. The prognosis for patients with hypercalcemia is related to the underlying disorder resulting in the hypercalcemia. Although cancer patients with hypercalcemia have a poor prognosis and usually die within a few months (50% within 30 days), hypercalcemic treatment usually improves their quality of life.^{51,52}

Magnesium Disorders

Although magnesium is the fourth most common cation in the body, less than 0.5% is present in the serum,⁵³ of which approximately 30% is protein bound, 15% is chelated to serum anions, and 55% exists in the ionized (physiologically active) form.⁴⁰ The amount of protein-bound Mg is directly proportional to the serum albumin concentration and the pH and is inversely proportional to the serum anion concentration. In addition, transcellular shifting between the intracellular and extracellular compartments can occur. Although the Mg contained in bone is not readily exchangeable with that present in the serum, a shift of Mg from the ECF to the intracellular fluid occurs with insulin administration⁵⁴ and the correction of acidosis.⁴⁰ Intracellular Mg functions as an essential cofactor in hundreds of important enzymatic reactions. Mg balance is regulated by the GI tract and the kidney, which maintains the serum Mg concentration between 1.6 and 2.1 mEq/L. An interrelationship exists between Mg and Ca, as evidenced by the development of hypocalcemia in response to Mg depletion.⁵⁵ In fact, Mg depletion is the most common cause of hypocalcemia in a general hospital population.⁵⁶ An interrelationship also

exists between Mg and K, and although the mechanism is unknown, it may be related to the Mg requirement of the Na/K-ATPase enzyme system.⁵⁷

Hypomagnesemia

Because the serum Mg concentration contributes less than 0.5% of total body Mg, the terms hypomagnesemia and Mg deficiency are defined separately. Hypomagnesemia refers to a serum Mg concentration below the normal range, whereas Mg deficiency refers to a decrease in the total body or intracellular Mg contents. In the clinical setting of severe tissue Mg deficiency, the serum Mg may be normal or even elevated. Conversely, in the setting of normal tissue stores, hypomagnesemia may be present.

PATHOGENESIS AND PATHOPHYSIOLOGY. Mg affects both the PNS and the CNS. Peripherally, Mg has a curare-like action at the neuromuscular junction, an action counteracted by acetylcholinesterase inhibitors and Ca.⁴³ Mg is both a Ca channel antagonist (opposes Ca) and a membrane stabilizer (acts synergistically with Ca).⁴⁰ Centrally, Mg has a depressant effect (interestingly, hibernating animals are hypermagnesemic), which is opposed by pentylenetetrazol (Metrazol).⁴³

EPIDEMIOLOGY AND RISK FACTORS. Among hospitalized patients, the prevalence of hypomagnesemia is approximately 10%; it is approximately 20% when only intensive care unit patients are considered.⁵⁶ Because Mg deficiency is more common than hypomagnesemia,⁴⁰ the true incidence of Mg deficiency must exceed 10%. Risk factors for the development of hypomagnesemia include chronic diarrheal disorders, ketoacidosis, loop diuretic or digitalis usage, and alcoholism (Table 38-6).⁴⁰ Among patients with steatorrheic states, the prevalence of Mg depletion is approximately one-third; the correlation between fecal Mg and fat content suggests that Mg depletion may be due to formation of a complex between Mg and fat. The recommended daily allowance of Mg (1200 mg) for pregnant and lactating women is 50% greater than that for nonpregnant women.⁵⁸

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Hypomagnesemia may be asymptomatic, yet when it is

symptomatic, the neurological manifestations include agitation, tremor, myoclonus, seizures (rarely), confusion, coma, paresthesias, muscle fasciculations, weakness, the presence of Chvostek's and Trousseau's signs, tetany, and hyper-reflexia.^{24,56,59,60} In addition, a cardioskeletal mitochondrial myopathy has been described in association with chronic hypomagnesemia.⁶¹ Athetoid and choreiform movements have also been reported during hypomagnesemia, although these signs may have reflected coexistent liver disease.⁴³ Unfortunately, the association of hypomagnesemia with hypokalemia, hypocalcemia, and other metabolic disorders makes it difficult to state with certainty which manifestations truly reflect hypomagnesemia. Importantly, the efficacy of Mg repletion in relieving manifestations of neuromuscular irritability may reflect its curare-like action (i.e., a therapeutic effect rather than reversal of deficiency symptoms). When the clinical manifestations of Mg deficiency are determined by induction of deficiency in human volunteers, GI features (anorexia, nausea, and vomiting), CNS features (lethargy, weakness, and personality change), PNS features (positive Trousseau's and Chvostek's signs and carpopedal spasm), tremor, and muscle fasciculations may be observed. Unfortunately, these features correlate with the development of hypocalcemia and hypokalemia.

DIFFERENTIAL DIAGNOSIS AND EVALUATION. Although the differential diagnosis of hypomagnesemia is long, it most commonly reflects an inadequate intake superimposed on impaired renal reabsorption or GI absorption. The two major problems in diagnosing Mg deficiency are that the serum Mg content represents only 0.5% of the total body content and that the relationship between the serum level and the intracellular and total body content is poor. Thus, it is not uncommon to suspect hypomagnesemia and be faced with a normal serum Mg level. In this situation, a Mg loading test has been suggested.⁵⁴ The presence of either hypokalemia or hypocalcemia, especially when it is resistant to treatment, makes the likelihood of symptomatic hypomagnesemia even greater, and for that reason, the concentrations of these two electrolytes should be determined. A urine Mg level helps differentiate renal from nonrenal etiologies.

Mg, like Ca, affects both the CNS and the PNS. Because Mg functions as a membrane stabilizer (synergistic with Ca), hypomagnesemia (like hypocalcemia) produces membrane instability. For that reason, it should always be considered in the neurological differential diagnosis of hypocalcemia, especially when hypocalcemia is unresponsive to treatment. Diagnostic considerations to entertain vary with the clinical manifestations; they parallel those of hypocalcemia.

MANAGEMENT. The treatment of Mg deficiency depends on the underlying disorder, the clinical status of the patient, and the degree of deficit. In an emergency setting (e.g., seizure), Mg sulfate heptahydrate solution may be infused.⁵⁶ In the nonemergent setting, when hypomagnesemia is severely decreased, treatment may be IV or intramuscular. The intramuscular route is safer and preferred, when possible. Because serum Mg equilibrates with intracellular Mg slowly, rapid replacement may cause transient hypermagnesemia. Consequently, total body Mg repletion may require several days of treatment. Finally, in

nonemergent settings when the degree of hypomagnesemia is not severe, oral replacement therapy can be undertaken using Mg oxide. In mild, asymptomatic cases, dietary modification to include high Mg-containing foods (e.g., dried fruits, grains, legumes, green leafy vegetables, and unprocessed cereals) may suffice. During Mg replacement therapy, the serum Mg level should be monitored frequently and treatment continued until a normal serum Mg level is achieved. Because Mg is a neuromuscular depressant, tendon reflexes should be monitored for evidence of overtreatment (diminished reflexes); the infusion should be discontinued if either hypermagnesemia or hyporeflexia is observed.⁴³ When Mg is replaced intravenously, Ca gluconate should be on hand to counteract transient hypermagnesium-induced problems, such as apnea caused by respiratory muscle paralysis.¹¹ Since hypermagnesemia is associated with hyporeflexia, serial tendon reflex assessments can be helpful.

Hypermagnesemia

Because the kidney is the major regulator of serum Mg levels, hypermagnesemia is frequently observed in patients with renal impairment, especially when the condition is combined with increased Mg intake. By blocking the presynaptic Ca channels, Mg acts to limit depolarization-induced Ca influx. Because exocytosis of acetylcholine-containing vesicles is Ca dependent, neuromuscular depression occurs. Symptomatic hypermagnesemia is infrequently encountered.

In contrast to the neuromuscular irritability observed with hypomagnesemia, the neurological manifestations of hypermagnesemia are characterized by nervous system depression. The predominant neuromuscular manifestation is muscle weakness (or paralysis) due to neuromuscular junction transmission blockade.⁶² The manifestations of hypermagnesemia, both neurological and non-neurological, have been studied in experimental animals and human patients and reflect the degree of elevation of the serum Mg level. In general, patients are asymptomatic until the serum Mg level exceeds 4 mEq/L.⁵⁶ Blood pressure depression begins at levels between 3 and 5 mEq/L,⁶³ at which time the reflexes may be slightly depressed⁵⁶ and responsiveness may be slightly impaired.⁴³ As the serum Mg level increases further, hypotension becomes more pronounced. At levels between 7 and 10 mEq/L, the reflexes diminish and weakness and ataxia appear.⁴³ At this level, lethargy and confusion have been reported,¹¹ although this is controversial. In one study, levels as high as 12.4 mEq/L resulted in profound paralysis without significant changes in level of consciousness.⁶⁴ Possible explanations for the mental decline observed in patients with hypermagnesemia include chronicity, which permits the CNS Mg level to rise; hypermagnesemia-induced hypoxic-ischemic encephalopathy; or neuromuscular junction blockade mistaken for mental status decline.⁴⁰ At 10 mEq/L, respiratory impairment appears with resultant hypoxia and hypercapnia.⁴³ At levels of 10 to 15 mEq/L, reflexes disappear and a flaccid quadriplegia may develop,⁵⁶ and as respiratory embarrassment worsens, CNS narcosis results in coma and death. Other symptoms associated with hypermagnesemia include nausea, lethargy, dilated pupils, bradycardia, and, rarely, complete heart block and cardiac arrest.⁵⁶

The underlying cause of the hypermagnesemia, as well as its neurological and cardiovascular manifestations, should be identified. Respiratory, cardiac, and renal status should be determined. In the setting of hypermagnesemia, sources of Mg should be identified and discontinued. In asymptomatic patients with normal or mildly impaired renal function, this action alone may suffice. Because natriuresis enhances urinary Mg excretion, furosemide may be administered and the urine volume replaced.⁵⁶ Of course, this may induce hypocalcemia. In life-threatening situations, Ca salts (e.g., 10% calcium gluconate) can be administered to counteract the neuromuscular blockade and cardiotoxicity. Hemodialysis, using an Mg-free dialysate, is the most effective way of reducing serum Mg levels.⁵⁶

OXYGEN AND CARBON DIOXIDE ABNORMALITIES

Conditions causing hypoxemia include a low inspired oxygen (O₂) concentration, ventilation-perfusion mismatch, right-to-left shunting, impaired diffusion, and hypoventilation; those causing hypercapnia include the breathing of a carbon dioxide (CO₂)-containing gas, ventilation-perfusion mismatch, and hypoventilation. Because neuromuscular dysfunction produces hypoventilation, which, in turn, produces both hypoxemia and hypercapnia, distinguishing which neurological features are related to which condition is difficult. Although isolated hypoxic encephalopathy is seldom seen in humans⁶⁵ (e.g., mountain sickness), an understanding of its pathophysiological basis is important. Thus, this section is divided into three parts: hypoventilation, hypoxia, and hypocapnia.

Hypoventilation

The respiratory system consists of the lungs and chest wall and has two functions: ventilation and gas exchange. Ventilation refers to the movement of air into and out of the lungs and is required for effective gas exchange. Ventilation requires the synchronized activities of both nervous and muscle tissue. The muscles of respiration (and their innervation) are typically divided into the inspiratory group (diaphragm [C3–C5], external intercostals [T1–T12], and scalenes [C4–C8]) and the expiratory group (abdominals [T7–L1] and internal intercostals [T1–T12]). During quiet breathing, the inspiratory muscles are active, with the diaphragm generating most of the tidal volume, and expiration is predominantly passive. When quiet breathing is unable to keep pace with the metabolic demands of the body (e.g., during exercise or respiratory muscle failure), the accessory muscles of inspiration (trapezii, sternocleidomastoids, serrati, pectorals, levator scapulae, and the costal levators) are recruited and expiration becomes active; thus, ventilation increases.

All levels of the neuraxis are involved in respiration, and for the most part, it occurs without voluntary effort (i.e., it is automatic). Automatic respiration occurs via two neuronal groups located within the brain stem: One is situated near the floor of the fourth ventricle (the medullary center), and the other is located within the pons (the pontine pneumotaxic center). The medullary neurons have inherent automaticity, and the pontine neurons help coordinate the

cyclical respirations. Through synapses with motor neurons innervating respiratory muscles, these neurons are responsible for spontaneous respiration. Voluntary respiration, which involves corticospinal tract innervation of the same respiratory motor neurons, can override automatic breathing. In normal circumstances, respiratory regulation reflects the Paco_2 and pH and, to a lesser extent, the PaO_2 . Chemoreceptors within the carotid and aortic bodies transmit this information to the respiratory centers in the brain stem (via cranial nerves IX and X, respectively), and respiration is adjusted accordingly.

The term *hypoxic encephalopathy* refers to the neurological findings resulting from impaired gas exchange or ventilation (e.g., anoxic anoxia, anemic anoxia, and histotoxic anoxia) and differs from the term *hypoxic-ischemic encephalopathy*, which refers to neurological dysfunction related to cerebral hypoperfusion (i.e., ischemic anoxia). With hypoxic-ischemic encephalopathy, in addition to hypoxia, there is loss of substrate (e.g., glucose) and impaired waste removal. Anoxic anoxia refers to reduced PaO_2 (e.g., at high altitudes), whereas anemic anoxia relates to reduced hemoglobin availability for O_2 transport (e.g., in anemia and carbon monoxide intoxication). Histotoxic anoxia occurs when, in the setting of adequate O_2 availability, the tissue's ability to use O_2 is impaired (e.g., cyanide toxicity).

PATHOGENESIS AND PATHOPHYSIOLOGY. Ventilatory failure results in hypercapnia as well as hypoxemia, a combination that causes cerebral vasodilation, increased cerebral blood flow (CBF), and, occasionally, increased ICP. Although hypoxemia probably contributes to the observed neurological features, the degree of CO_2 retention is more closely correlated.⁶⁵ Acute, moderate hypercapnia (5% to 10% CO_2 in the inspired air) increases arousal and excitability. At higher levels of CO_2 , an anesthetic effect occurs, followed by a convulsant effect at the highest levels.^{65,66} Because CO_2 freely crosses the blood-brain barrier (BBB), thereby producing a cerebrospinal fluid (CSF) acidosis, respiratory acidosis is more neurologically disabling than is metabolic acidosis. Fortunately, several compensatory mechanisms exist to enhance the nervous system's tolerability of respiratory insufficiency. The CNS compensates by increasing O_2 extraction, CO_2 release, and CBF. These processes arise in conjunction with systemic alterations at the level of the kidney and with polycythemia.⁶⁷ Should compensatory mechanisms fail, hypoxia, hypercapnia, and acidosis develop and produce neurological sequelae. Sustained hypoxia produces brain edema and cell death—abnormalities that can precipitate cardiac arrhythmias and hypotension. Again, isolated hypoxic encephalopathy is seldom seen in humans.⁶⁵

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Pulmonary disease causes both hypoxemia and hypercapnia, and distinguishing which neurological features are related to which state is difficult. The clinical features observed reflect the body's ability to compensate and the acuteness of the situation. The neurological manifestations are most closely related to the rapidity of onset and degree of hypercapnia, although hypoxia and cerebral edema may also contribute.⁶⁸ Compensatory mechanisms may render individuals asymptomatic, even in the setting of significant degrees of hypoxia and hypercapnia. When these mechanisms cannot keep pace, clinical features of respiratory

insufficiency manifest. Initially, patients with respiratory insufficiency may complain of sleep disturbances, daytime somnolence, and early morning headache, a reflection of nocturnal hypoventilation with resultant CO_2 retention and vasodilation; however, these symptoms are nonspecific and can occur with CHF or respiratory muscle weakness.⁶⁹ Mental status changes are common early and include drowsiness, forgetfulness, and inattentiveness. Later, lethargy, obtundation, and coma may appear.⁶⁷ Tremor and asterixis are frequently seen, whereas myoclonus and seizures are uncommon and are observed only with severe and prolonged respiratory insufficiency.⁶⁸ Tendon reflexes may be brisk or depressed, upper motor neuron features may be present, and papilledema occurs in up to 10% of patients.⁶⁹

DIFFERENTIAL DIAGNOSIS AND EVALUATION. Respiratory impairment may be caused by dysfunction of gas exchange or ventilation (Table 38-7). Differentiation between these two categories is important and is usually afforded by a thorough history, physical examination, and laboratory evaluation. Unlike motor unit disorders that produce hypoventilation, CNS disorders produce abnormal respiratory patterns, such as Cheyne-Stokes (forebrain and diencephalic damage), central neurogenic hyperventilation (hypothalamic and midbrain damage), apneustic (inspiratory breath holding related to pontine tegmental damage), cluster (irregular bursts of rapid breathing alternating with apneic periods), and ataxic (irregular breathing related to medullary damage) breathing patterns. The respiratory impairment associated with spinal cord disorders is predominantly a reflection of its location. Lesions at C3 affect diaphragmatic and intercostal function and spare only the

TABLE 38-7

Major Causes of Respiratory Insufficiency

Extrapulmonary Causes

Central nervous system (parenchymal disorders, increased intracranial pressure, sleep apnea)
 Neuromuscular disorders
Spinal cord: Tetanus, trauma
Anterior horn cell: Amyotrophic lateral sclerosis, poliomyelitis, rabies
Nerve: Guillain-Barré syndrome, diphtheria, porphyria, ciguatoxin, saxitoxin, tetrodotoxin, thallium intoxication, acute hyperkalemic paralysis, buckthorn polyneuropathy
Neuromuscular junction: Myasthenia gravis, congenital myasthenic syndromes, botulism, hypermagnesemia, organophosphate poisoning, tick paralysis, snake bite
Muscle: Polymyositis, inclusion body myositis, myotonic dystrophy, limb girdle muscular dystrophies, hypophosphatemia, stonefish myotoxin, nemaline myopathy, centronuclear myopathy, rhabdomyolysis
Other: Kyphoscoliosis, ankylosing spondylitis, chest trauma, extreme obesity, pleural diseases

Pulmonary Causes

Chest bellows (non-neurological)
Primary muscle fatigue
Secondary muscle dysfunction: electrolyte disturbances, malnutrition, reduced respiratory drive: metabolic alkalosis, sedation
 Other (e.g., pulmonary parenchymal or airway disorders, cardiac failure)

Modified from Jozefowicz RF: Neurologic manifestations of pulmonary disease. *Neurol Clin* 1989;7:605–616; Bennett DA, Bleck TP: Diagnosis and treatment of neuromuscular causes of acute respiratory failure. *Clin Neuropharmacol* 1988;11:303–347.

accessory muscles of inspiration innervated by cranial nerve XI. Lesions at C4 or C5 produce lesser degrees of diaphragmatic impairment. Low cervical and high thoracic lesions spare the diaphragm but affect the intercostal and abdominal muscles, thereby limiting full inspiration and active expiration. Midthoracic lesions affect only the abdominal muscles and therefore interfere only with active expiration. Respiratory impairment due to diaphragmatic weakness is worse in the supine position and improved in the erect position, a reflection of the effect of gravity on the abdominal contents. These features should be sought on physical examination. The electroencephalographic (EEG) changes associated with pulmonary encephalopathy are nonspecific and similar to those observed in patients with other forms of metabolic encephalopathy (i.e., diffuse slowing and slowing of the posterior dominant rhythm).

It is important to determine whether or not respiratory impairment reflects neurological dysfunction. Helpful studies for this discrimination include an ABG, pulmonary function tests, and electromyographic examination. Neuromuscular system dysfunction impairs ventilation and is associated with both hypercapnia and hypoxemia. Non-neurological mechanisms of respiratory insufficiency (e.g., impaired gas exchange) initially produce hypoxemia without hypercapnia. This reflects the nonlinear hemoglobin dissociation curve of O₂ versus the essentially linear loading curve of CO₂. Thus, high-ventilation areas of the lung are able to compensate for low-ventilation areas until pulmonary disease is severe. In summary, hypoxemia in the presence of a normal or decreased PaCO₂ is indicative of a parenchymal process. Neurological versus non-neurological respiratory impairment may also be differentiated by determining the A-a gradient (i.e., the gradient between alveolar [A] and arterial [a] O₂ tensions), a value that is easily determined. The PaO₂ and PaCO₂ are obtained from the ABG, and the PAO₂ is obtained from the following equation:

$$PAO_2 = [(PB - 48) \times FiO_2] - PaCO_2/R$$

where PB is the barometric pressure (760 mmHg at sea level), FiO₂ is the fraction of O₂ in the inspired air (0.21 in room air), and R is the respiratory quotient (0.8). On room air, an A-a gradient above 20 to 30 mmHg always indicates intrapulmonary pathology, whereas an A-a gradient below 10 mmHg suggests extrapulmonary causes of hypoxemia (e.g., hypoventilation). Pulmonary function test parameters indicative of respiratory muscle weakness include reduced vital capacity, reduced maximum voluntary ventilation, and increased residual volume. Of these parameters, only the vital capacity can be measured outside of the pulmonary function test laboratory. Maximum expiratory and inspiratory pressures are better parameters for identifying respiratory muscle weakness⁷⁰; maximum expiratory pressure is the most sensitive indicator for patients with neuromuscular disease. Although it is less useful for identifying respiratory muscle weakness, forced vital capacity is useful for the serial assessment of patients with known neuromuscular disorders. When the vital capacity decreases below 25 mL/kg body weight, the ability to cough is impaired and oropharyngeal secretion accumulation occurs. Thus, the risk of aspiration pneumonia is significantly increased. Routine nerve conduction studies (NCS) (including phrenic

NCS), repetitive nerve stimulation, and needle electrode examination (including the diaphragm) can be of great assistance in identifying both the nature (e.g., demyelinating neuropathy) and the site (e.g., nerve, neuromuscular junction, or muscle) of the underlying disorder.

MANAGEMENT. If the condition is left untreated, encephalopathy related to pulmonary dysfunction may lead to coma and death. The mainstays of treatment are to improve gas exchange and ventilation. In patients with chronic hypercapnia, in whom hypoxia-stimulated respiratory drive exists, high-concentration O₂ administration may produce clinical deterioration due to CO₂ retention. The O₂ affinity of hemoglobin and cytochrome is not as great as the affinity for carbon monoxide (CO) and cyanide, respectively. For that reason, CO and cyanide toxicity may require hyperbaric O₂ therapy.⁷¹⁻⁷³

PROGNOSIS AND FUTURE PERSPECTIVES. Because cerebral O₂ delivery depends on the mean arterial blood pressure and autoregulation, and because compensatory mechanisms exist, it is difficult to determine the severity of hypoxia a patient has experienced. When there is no loss of consciousness, there is rarely, if ever, any permanent nervous system damage.⁷¹ When hypoxia induces hypoperfusion (e.g., cardiac arrest) and hence ischemic anoxia, the prognosis worsens.

Hypoxia

Hypoxia increases CBF, glucose use, and brain lactate concentration, whereas energy metabolite (e.g., adenosine triphosphate [ATP], adenosine diphosphate [ADP], and adenosine monophosphate [AMP]) levels remain close to normal, even during severe hypoxia.⁷⁴ Breathing 10% O₂ for 15 to 30 minutes increases the CBF by 35%, whereas breathing 7% O₂ (PaO₂ 35 mmHg) for 15 minutes increases CBF by 75%.⁷⁴ Once the PaO₂ drops below 25 mmHg, ATP decreases, AMP and ADP increase, and the EEG is markedly slowed or nearly isoelectric.⁷⁴ In addition, changes in ion homeostasis are induced by hypoxia. Unlike ischemic anoxia, in which Ca uptake is increased, hypoxia diminishes Ca uptake, thereby decreasing Ca-dependent acetylcholine release; this can be overcome by agents that enhance Ca uptake at the nerve terminals.⁷⁵ Finally, neurotransmitter metabolism is also affected by hypoxia. Acetylcholine synthesis is O₂ dependent, and brain acetylcholine levels are decreased in the setting of hypoxia. However, because acetylcholine release in some brain regions is Ca dependent, the lowered brain acetylcholine levels may reflect the effect of hypoxia on Ca metabolism. Changes in amino acid, catecholamine, and serotonin neurotransmitter levels, as well as adenosine, cyclical nucleotides, and fatty acids, have also been reviewed.⁷⁴

Compensatory physiological mechanisms (e.g., increased erythropoiesis and O₂ dissociation curve shifts) permit adaptation to hypoxia, thereby making the effects of hypoxia time dependent and necessitating separate discussions for acute and chronic hypoxic states. Healthy human volunteers subjected to rapid decompression hypoxia (analogous to acute hypoxia, clinically) demonstrate an association between the PaO₂ level and the neurological features observed.⁶⁵ New skill learning and the processing of complex information are the most vulnerable to hypoxia.⁷⁴ At a

Pao₂ of 80 mmHg, impaired dark adaptation is noted; at 55 to 45 mmHg, impaired learning and short-term memory occurs, whereas measures of selective attention are normal; at 40 to 30 mmHg, loss of judgment, euphoria, delirium, and muscular incoordination occurs; additionally, twice as much light is required for visual perception; below 25 to 20 mmHg, consciousness is rapidly lost.^{65,74} High altitude sickness begins soon after ascending above 10,000 feet and is characterized by headache, decreased concentration, sleep disturbances, anorexia, nausea, and lassitude (see Chapter 51).

The clinical features of acute CO toxicity include prominent headache, nausea, vomiting, and encephalopathic features. The cherry-red lip appearance often described with this disorder is only present at high CO levels in comatose patients (see Chapter 39).

Several posthypoxic neurological syndromes have been described, including myoclonus, delayed anoxic encephalopathy, parkinsonism, and cerebral palsy. Global cerebral hypoxia of any etiology can result in myoclonus, as well as other neurological deficits. Posthypoxic myoclonus presents in two different clinical forms. Immediately following the hypoxic event, while the patient remains comatose, myoclonic jerks can appear. This acute form is transient and characterized by spontaneous jerks that involve the face predominately, yet may be generalized. Little is known about the electrophysiological properties of this acute posthypoxic myoclonus, but the prognosis associated with this sign is poor. In those patients who survive the hypoxic event and regain consciousness, a second type of delayed posthypoxic myoclonus may develop. Lance and Adams⁷⁶ described this delayed form in patients demonstrating stimulus-sensitive intention or action myoclonus (posthypoxic action myoclonus [PHAM]) following cardiac or respiratory arrest. The characteristic feature of PHAM (Video 53, Myoclonus, Positive and Negative) is the occurrence of myoclonus, both positive and negative, with voluntary movement, especially walking and movements requiring precision. Patients may be unable to walk when negative myoclonus occurs during ambulation. Fahn⁷⁷ summarized the clinical findings of 88 patients (permanent in 87) with PHAM. All were acutely comatose with a median duration of unconsciousness of 4 days (range, 1 to 120 days). The duration of coma did not correlate with the subsequent severity of the action myoclonus. Anesthesia-related mishaps were the single most common cause of cerebral hypoxia, with other etiologies including myocardial damage, drug overdose, and airway obstruction. Other neurological abnormalities, including cerebellar dysfunction, spasticity, dementia, and cortical blindness, were observed in these patients following the resolution of coma. EEG recordings may reveal generalized symmetrical or asymmetrical sharp waves, or spikes with slow waves may be detected. Alternatively, moderate- to high-voltage fast activity, occurring centrally, can be observed. Other patients have slowing of the background or even normal EEGs. Somatosensory evoked potentials in patients with PHAM may initially be enlarged, yet decrease in size following initiation of therapy. The pathophysiological basis of PHAM is a matter of conjecture. Only a few pathological investigations exist and are not significantly helpful in the understanding of the pathophysiology of

PHAM. 5-Hydroxytryptophan (5-HTP), the serotonin precursor, has been shown to be beneficial in PHAM and has generated considerable interest in the possible role of brain serotonin in this form of myoclonus. 5-HTP alone and with carbidopa has been effective in reducing the amplitude of the myoclonic jerks. 5-HTP is started at 100 mg/day in four divided doses and is increased by 100 mg every 3 to 5 days, slower if side effects occur. Maximum daily dosage ranges from 1000 to 2000 mg. Carbidopa is given at 25 to 50 mg four times daily and should not be stopped before the discontinuation of 5-HTP. Lower doses of 5-HTP (400 to 500 mg) may suffice when administered with either fluoxetine or paroxetine, serotonin uptake inhibitors, and carbidopa. Despite the use of carbidopa, systemic side effects are nearly universal and frequently necessitate 5-HTP dose reduction or discontinuation. Common side effects include diarrhea, nausea, vomiting, abdominal pain, euphoria, insomnia, and blurred vision. Other medications with some utility in the treatment of PHAM, either alone or in combination, include valproate, piracetam, and clonazepam. The other benzodiazepines, phenobarbital, and phenytoin are usually of no benefit.

Postanoxic encephalopathy is an unexplained phenomenon that is observed during recovery (1 to 4 weeks) from an anoxic insult. It is characterized by irritability, confusion, apathy, and, occasionally, agitation or mania.⁷⁸ Although most patients with this disorder survive for a period, serious mental and motor disturbances are reported, and many patients develop diffuse rigidity, spasticity, weakness, a shuffling gait, incontinence, coma, and death after 1 or 2 weeks.⁷⁸ At autopsy, the major pathological finding is widespread cerebral demyelination.⁷¹ Uncommonly, rigidity, muteness, and helplessness develop over a period of weeks to months, and in these cases, autopsy reveals the basal ganglia to be more affected than the cerebral white matter and cortex.^{71,79}

Parkinsonism following cerebral anoxia is usually accompanied by a large number of other neurological sequelae, a reflection of the cerebral structures most susceptible to anoxic insult (i.e., Sommer's sector of Ammon's horn, Purkinje's cells, the cerebral cortex [especially layer 3], the striatum, and the globus pallidus). For that reason, a "pure" parkinsonian syndrome is unexpected (Video 41, Carbon Monoxide Intoxication Parkinsonism). It has been reported in CO intoxication, in both acute and chronic settings.⁸⁰

Cerebral palsy refers to a syndrome of acquired, non-progressive perinatal encephalopathy due to a variety of insults, including anoxia, hypoperfusion, trauma, vascular events, congenital abnormalities, and kernicterus (less common today). Asphyxia accounts for only a minority of cases, with the most common cause reflecting prenatal factors that are difficult to identify with certainty.⁸¹ Cerebral palsy may be classified based on the type of motor impairment, and its distribution is segregated into spastic types and hypotonic types. Spastic types include spastic diplegia (legs more involved than arms), which is more common in premature infants; spastic hemiplegia, which is the most common form acquired after birth; and spastic quadriplegia (usually asymmetrical with arms more involved than legs), which is sometimes termed *double hemiplegia*. The hypotonic types include athetoid (predominant basal

ganglia development) and ataxic (predominant cerebellar involvement). The spectrum of intellectual and motor deficit ranges from normal intelligence with mild motor deficits to severe retardation without the ability to walk.

Hypocapnia

Hyperventilation is defined as breathing in excess of metabolic demands and, therefore, is purely a respiratory disturbance. It produces hypocapnia, respiratory alkalosis, cerebral vasoconstriction (which, in turn, reduces the CBF), a reduction in the availability of O₂ peripherally (through shifts of the O₂ dissociation curve), a reduction in the level of ionized serum Ca, and, when sustained, significant hypophosphatemia.⁶⁷ Thus, neurological features are frequent, and patients with hyperventilation disorders are frequently referred to neurologists. Symptoms associated with hyperventilation vary widely and include lightheadedness, acral and perioral paresthesias (which may be painful), syncope, and, less commonly, carpopedal spasms, muscle cramps, blurred vision, headache, dyspnea, and chest pain.^{66,67} Other reported symptoms include sweating of the hands, cold extremities, giddiness, ataxia, tremor, tinnitus, hallucinations, epigastric pain, a bloated feeling, vomiting, and unilateral somatic symptoms, which may result in the misdiagnosis of cerebral ischemia, seizure, or complicated migraine.⁸² Once it is induced, hypocapnia can be maintained with only an occasional sigh, thereby making its visual recognition difficult.⁸³ These symptoms probably arise from a reduction in CBF and are associated with significant cerebral hypoxia.⁸² For every 1 mmHg drop in PaCO₂, the CBF drops by 2%.

Disorders associated with hyperventilation can be subdivided into psychogenic (e.g., anxiety, panic, sighing, air hunger, or factitious disorders), organic (usually multifactorial including respiratory disease, CNS disorders, pain, and aspirin overdose), and physiological (progesterone ingestion, prolonged conversation, hypoxic stimulation of chemoreceptors at high altitude, and pyrexia).⁸² Hyperventilation is frequently reported in anxious individuals without any identifiable systemic disease.⁶⁷ However, because isolated anxiety (i.e., in the absence of hyperventilation) has no effect on CBF, it should not produce these symptoms.⁸⁴ Patients with organic disorders (e.g., asthma) can present with hyperventilation. Additionally, disorders producing anxiety (e.g., angina) can cause hyperventilation. Thus, the identification of hyperventilation should never be considered synonymous with anxiety, nor should these patients be taken less seriously. For that reason, whenever hyperventilation is recognized, organic etiologies should be excluded and treatment initiated.

ENDOCRINE ABNORMALITIES

Interdependence exists between the endocrine and nervous systems, as demonstrated by the influence of hormones on the nervous system and the requirement of an intact nervous system for endocrine activity. Endocrine disorders may initially present with signs and symptoms of neurologic disease, whereas preexisting neurologic disorders may worsen in the setting of endocrine dysfunction. In the past,

when early screening was not commonplace and treatment was not an option, the neurological features ascribed to endocrine dysfunction were much more pronounced. However, because these disorders are now diagnosed earlier, the clinical features are often much more subtle. The early recognition of endocrine-related neurological dysfunction is important because the condition is frequently reversible.

Thyroid Disorders

The thyroid gland synthesizes and secretes tetraiodothyronine (T₄) and, in much smaller quantities, triiodothyronine (T₃), which is at least two to four times more potent than T₄. Both of these hormones regulate tissue metabolism. Iodine is bound to tyrosine residues of thyroglobulin in the thyroid gland (organification), and these iodinated residues are then coupled to form T₄ and T₃. Both protein-bound (inactive) and unbound (active) thyroid hormone fractions exist in serum. In the periphery, T₄ is deiodinated to T₃, accounting for approximately 80% of T₃ production⁸⁵; otherwise, it is converted into reverse T₃ (rT₃), a metabolically inactive product.

Hypothyroidism

PATHOGENESIS AND PATHOPHYSIOLOGY. Hypothyroidism is the most common disorder of thyroid function and can be caused by thyroid gland dysfunction (i.e., primary hypothyroidism), a disturbance outside of the thyroid gland (i.e., central hypothyroidism), or by peripheral resistance to thyroid hormone.⁸⁶ Mechanisms of thyroid gland dysfunction include parenchymal destruction (viral or autoimmune), chronic inflammation with lymphocytic infiltration (Hashimoto's thyroiditis), cell death (radiation damage), or defective hormonogenesis. Defective hormonogenesis may occur due to inadequate iodine intake (i.e., endemic goiter), excessive ingestion of goitrogens (e.g., turnips), intrinsic defects in thyroid hormone production (e.g., rare enzymopathies), as well as medication-induced thyroid hormone synthesis disturbance (e.g., lithium, thionamides, and amiodarone). In some patients, iodine loading may cause significant hypothyroidism (Wolff-Chaikoff effect). In addition, the hypothalamic-pituitary-thyroid axis can be disturbed following head injury⁸⁷ or pituitary apoplexy.⁸⁸

Although the pathogenesis and pathophysiology of many of the peripheral neurological manifestations of the hypothyroid state are known, most of the CNS manifestations are unexplained. Although hypothyroid-induced seizures may be related to hyponatremia, coma likely represents a multifactorial process.⁸⁹ Direct metabolic effects or entrapment by adjacent tissue (e.g., myxedematous infiltration) may cause peripheral and cranial mononeuropathies.^{85,86} Persistent percussion-induced local muscle contraction is referred to as myoedema and is caused by delayed Ca reuptake by the sarcoplasmic reticulum, thereby prolonging the contraction.⁹⁰ A reduction in myosin ATPase activity contributes to slowed contraction, and delayed reuptake of Ca by the sarcoplasmic reticulum contributes to delayed relaxation.⁹¹ Also, a shift in muscle fiber type distribution from fast twitch to slow twitch may contribute to slowed muscle contraction and relaxation.⁹² In addition, a reduction

in muscle mitochondrial oxidative capacity and β -adrenergic receptors, as well as the induction of an insulin-resistant state, may contribute to weakness, fatigue, and exertional pain.⁹² The pathophysiology of the muscle enlargement, a feature more commonly observed in children (Kocher-Debré-Sémélaigne syndrome), is uncertain, although work hypertrophy related to prolonged contraction is suspected.⁹¹

EPIDEMIOLOGY AND RISK FACTORS. The incidence of primary hypothyroidism is much greater in women than in men,^{85,93} especially among women between the ages of 40 and 60 years. Central hypothyroidism (e.g., hypothalamic and pituitary-related), on the other hand, is more commonly observed among the neurosurgical population.²⁸ Primary hypothyroidism is much more common than secondary hypothyroidism, accounting for more than 90% of cases, and is usually caused by autoimmune destruction (e.g., Hashimoto's thyroiditis), irradiation, or surgically treated hyperthyroidism. Pituitary and hypothalamic disease contribute less than 10% of cases of hypothyroidism.⁸⁹ Myxedema coma is extremely rare, and its incidence is higher in elderly women, especially those older than 60 years.⁸⁶ Risk factors for myxedema coma include noncompliance with levothyroxine therapy, infection, surgery, drugs, hyponatremia, and the winter months.^{86,89} Although complex changes in thyroid function occur during pregnancy, the normal pregnant woman is euthyroid,⁹⁴ and the incidence of hypothyroidism is not influenced by pregnancy.⁴²

CLINICAL FEATURES AND ASSOCIATED DISORDERS.

Clinically, the onset of hypothyroidism may range from subtle and insidious findings to florid psychosis. The general examination features of hypothyroidism are numerous (Table 38-8). CNS features include forgetfulness, inattention, apathy, and slowing of speech, movement, and mentation. These features may mimic depression. Seizures, personality changes, psychotic states, coma, and dementia may also be clinically apparent (Video 22, Delusional Thinking). Cerebellar ataxia is seen in 5% to 10% of patients⁹⁵ and may be the presenting sign (so-called myxedema staggers); its pathophysiology remains unknown. A psychotic presentation (myxedema madness) characterized by agitation, disorientation, delusions, hallucinations, paranoia, and restlessness is observed in approximately

3% to 5% of patients.⁸⁵ Myxedema coma is extremely rare, and its characteristic features include extreme hypothermia, seizures (the presenting manifestation in nearly 20% of patients),⁸⁹ respiratory depression, and areflexia. Death can occur when early recognition and prompt treatment are lacking. Dementia may develop when hypothyroidism is severe. Except for the marked increase in the number of hours these patients remain asleep or resting, the clinical features of the dementia are similar to those secondary to other causes.⁹⁶ The pathophysiology of Hashimoto's encephalopathy is unknown but may reflect an inflammatory vasculitis of the CNS. As emphasized by Doherty,⁹⁷ its clinical features include rapidly progressive dementia, seizures, extrapyramidal rigidity, myoclonus, and, occasionally, focal CNS features. It and the EEG features associated with it may mimic a prion disease. Often, the patient is biochemically euthyroid with elevated thyroid peroxidase antibodies as the only marker.^{97,98}

Peripheral neuromuscular features include cranial and peripheral neuropathies, prolonged reflex relaxation time (up to 85% of hypothyroid patients),^{85,86} and myopathy. Visual field defects can occur when pituitary enlargement causes hypothyroidism with concomitant chiasmal compression. A facial mononeuropathy, due to nerve entrapment in the fallopian canal of the temporal bone, may rarely occur.⁹⁹ Although sensorineural hearing loss has been reported to correlate with the degree of hypothyroidism and has a high incidence among patients with congenital hypothyroidism,⁹⁶ its reported incidence among adult hypothyroid patients varies.¹⁰⁰ Minor evidence of polyneuropathy, such as distal lower extremity sensory dysfunction and absent ankle jerks (Video 98, Romberg Sign), is observed in approximately 10% of patients,⁹¹ and, rarely, a moderately severe sensorimotor polyneuropathy has been described. Carpal tunnel syndrome (i.e., median mononeuropathy at the wrist) occurs in 15% to 30% of hypothyroid patients, is usually bilateral, and is the most common mononeuropathy encountered (Video 217, Anterior Interosseous Neuropathy, Pinch Sign).

Myopathy can be a feature of hypothyroidism and manifests with proximal muscle weakness.¹⁰¹ Regardless of the cause of the hypothyroidism, weakness is observed in approximately one third of these patients.⁹⁰ Increased muscle size and firmness, which is most obvious in the limb musculature, as well as slowed muscle contraction are important features to identify. Exertional pain, stiffness, and cramps may be noted, and myoedema may be observed. Hoffman syndrome is a myopathic syndrome characterized by firm, large, well-developed muscles and prominent myotonia that can be seen in adults with hypothyroidism. Myoedema, a mounding of the muscle in response to direct percussion, is painless and electrically silent and occurs in one-third of hypothyroid patients.⁹⁰ Difficulty relaxing the hand grip and exacerbation by cold weather may suggest myotonia. However, unlike myotonia, hypothyroid myopathy involves a slowness of muscle relaxation and contraction and resolves with correction of the hypothyroid state.⁹⁶ In patients with newly detected hypothyroidism, skeletal muscle is less frequently affected, despite the fact that 25% of patients with hypothyroidism have muscle symptoms. Although sleep apnea is usually of the obstructive type, other possibilities include a central abnormality,

TABLE 38-8

General Features of Hypothyroidism

| SUBJECTIVE | OBJECTIVE |
|--|---|
| Fatigue, somnolence, cold intolerance, syncope, exertional dyspnea, weight gain, arthralgias, nausea, anorexia, indigestion, constipation, menstrual abnormalities | Bradycardia, hair changes (sparse, coarse, dry, brittle), puffy face, loss of lateral aspects of the eyebrows, periorbital edema, macroglossia, voice deepening and hoarsening, skin changes (scaly, thick, doughy, coarse, dry, carotenemia), brittle nails, nonpitting edema, galactorrhea, effusions |

Data from Mitchell JM: Thyroid disease in the emergency department: Thyroid function tests and hypothyroidism and myxedema coma. *Emerg Med Clin North Am* 1989;7:885-902; Mazzaferrri EL: Adult hypothyroidism: I. Manifestations and clinical presentation. *Postgrad Med* 1986;79:64-72; Myers L, Hays J: Myxedema coma. *Crit Care Clin* 1991;7:43-56; Kaminski HJ, Ruff RL: Neurologic complications of endocrine diseases. *Neurol Clin* 7:489-508.

chest muscle weakness, and blunted responses to hypoxia and hypercapnia.⁸⁵ Reports have associated hypothyroidism with SIADH,²⁸ idiopathic intracranial hypertension,¹⁰² and myasthenia gravis.

DIFFERENTIAL DIAGNOSIS. The differential diagnosis of hypothyroidism includes nonthyroidal illness (i.e., decreased T₃ or T₄ or both, without clinical hypothyroidism), euthyroid hypothyroxinemia (decreased T₄ caused by decreased thyroid-binding globulin), and drugs that inhibit T₄ binding (salicylates, phenytoin, and phenobarbital). Once hypothyroidism has been diagnosed, the most important clinical distinction is between primary and secondary hypothyroidism. The clinical and laboratory similarities between myxedema coma and other life-threatening causes of the comatose state may make its diagnosis extremely difficult. Regarding hypothyroid myopathy, the muscular appearance, stiffness, and exacerbation by cold may suggest a mild form of myotonia congenita, which can present in adulthood. Although the stiffness noted in patients with pyramidal and extrapyramidal diseases may appear similar to that of hypothyroid myopathy, the characteristic history, appearance, and laboratory studies usually permit the diagnosis of hypothyroidism.

EVALUATION. The combination of a low T₄ level and an elevated thyroid-stimulating hormone (TSH) level is virtually diagnostic of primary hypothyroidism because TSH elevation does not occur in central hypothyroidism. Further delineation between primary and secondary hypothyroidism is dependent on history, examination, and other laboratory studies. In addition to TFTs, other laboratory abnormalities have been described, including anemia (normocytic-normochromic, microcytic-hypochromic, or macrocytic) and hyponatremia (factitious due to hyperlipidemia or secondary to impaired free water excretion), as well as elevated serum creatine kinase (CK), myoglobin,⁹² and prolactin. Although elevated CK levels are frequently observed in patients with hypothyroidism, when patients with predominantly subclinical and mild hypothyroidism are studied, elevated CK levels are much less frequent (approximately 3%). Because of the possibility of concomitant adrenal insufficiency, a serum cortisol level should also be obtained. The EEG may show slowing of the posterior dominant rhythm and a generalized voltage decrease, as well as triphasic waves that disappear with replacement therapy.¹⁰³ CSF analysis may reveal an elevated protein content that may exceed 100 mg/dL.

MANAGEMENT. The treatment of hypothyroidism, regardless of cause, consists of thyroid hormone replacement. Thyroxine dosages may need to be increased when females with hypothyroidism are placed on estrogen therapy.⁹⁸ Even in the setting of hypothyroid-induced seizures, achievement of the euthyroid state facilitates control.⁹⁵ Precipitants of myxedema coma (e.g., infection, cold exposure, certain drugs [phenothiazines, narcotics, sedative-hypnotics, phenytoin, and rifampin], and other stressors [surgery and trauma]) require correction.⁸⁵

PROGNOSIS AND FUTURE PERSPECTIVES. With early recognition and treatment, as well as improved intensive supportive care, the mortality rate of myxedema coma has decreased from approximately 50% to 70% to approximately 15% to 20%.¹⁰⁴ Without early recognition and prompt institution of replacement therapy, the prognosis is grave.¹⁰⁵

Hyperthyroidism

PATHOGENESIS AND PATHOPHYSIOLOGY. Thyroid hormones affect mitochondrial oxidative capacity, protein synthesis and degradation, tissue sensitivity to catecholamines, muscle fiber differentiation, and capillary growth.¹⁰⁶ Excess thyroid hormone produces accelerated muscle protein catabolism and enhanced lysosomal protease activity and interferes with the anabolic effects of insulin on muscle.⁹⁰ Despite this understanding, the exact pathophysiology of thyrotoxic myopathy remains unknown. CNS observations include elevated rates of cerebral circulation, faster posterior dominant rhythms, alterations in the sensitivity of some brain enzymes and neurotransmitter systems, and altered metabolic responses.¹⁰⁶ The specific pathophysiological processes causing these manifestations remain unknown. It has been proposed that alterations in central and peripheral β-adrenergic tone may be responsible for hyperthyroid-related tremor and chorea and that brisk tendon reflexes may reflect faster muscle contraction and relaxation times. Graves' disease is caused by thyroid-stimulating antibodies that activate the thyrotropin receptor on thyroid cells, causing thyroid hypersecretion, hypertrophy and hyperplasia of thyroid follicles, and the characteristic diffuse goiter.¹⁰⁷

EPIDEMIOLOGY AND RISK FACTORS. Hyperthyroidism is more common in women than in men (10:1 ratio) and often shows a strong familial predisposition. During pregnancy, hyperthyroidism occurs more commonly than hypothyroidism, with an incidence ranging from 0.05% to 0.2%, most commonly related to Graves' disease, acute (i.e., subacute) thyroiditis, toxic nodular goiter, and toxic adenoma.^{42,94} The incidence of low-birth-weight infants is significantly increased, and neonatal mortality is slightly increased.⁹⁴

CLINICAL FEATURES AND ASSOCIATED DISORDERS. The general clinical features of thyrotoxicosis are numerous (Table 38-9). Neuropsychiatric signs include impaired attention, concentration, and memory, as well as emotional lability, nervousness, hypervigilance, lethargy, depression

TABLE 38-9

General Features of Thyrotoxicosis

| SUBJECTIVE | OBJECTIVE |
|---|---|
| Impaired concentration and memory, emotional lability, nervousness, irritability, palpitations, heat chorea, intolerance, increased sweating and appetite, weight loss, frequent defecation, menstrual abnormalities, insomnia, headaches | Impaired attention span and memory, hypervigilance, systolic flow murmurs, skin changes (warm, moist, smooth), ECG changes (sinus tachycardia, atrial fibrillation), psychiatric problems (depression, mania, bipolar disorder, manic psychosis), thyrotoxic periodic paralysis, thyroid storm, ocular features |

Data from Weiner WJ, Lang AE (eds): Movement Disorders: A Comprehensive Survey. New York, Futura, 1989; Kaminski HJ, Ruff RL: Neurologic complications of endocrine diseases. *Neurol Clin North Am* 1989;7:489–508; Abend WK, Tyler HR: Thyroid disease and the nervous system. In Aminoff MJ (ed): *Neurology and General Medicine*, 2nd ed. New York, Churchill Livingstone, 1995, pp 333–347; Shahar E, Shapiro MS, Shenkman L: Hyperthyroid-induced chorea: Case report and review of the literature. *Isr J Med Sci* 1988;24:264–266.

(i.e., apathetic hyperthyroidism), mania, psychosis, insomnia, and agitated delirium.⁹⁵ Apathetic hyperthyroidism most frequently occurs in the elderly, lacks the usual hyperadrenergic features, and may easily be confused with depression or dementia.

Although new-onset adulthood seizures are rarely related to hyperthyroidism, the seizure incidence among thyrotoxic patients ranges from 1% to 9% (Video 70, Hyperthyroidism-Induced Chorea).⁹² Movement disorders, such as tremor (usually enhanced physiological tremor) and choreoathetosis, as well as upper motor neuron signs, including spasticity, hyper-reflexia, clonus, and Babinski's signs, may also be observed (Video 203, Babinski Sign).^{80,108}

Peripheral neurological features include cranial and peripheral neuropathies, as well as neuromuscular junction and muscle disturbances (Fig. 38-2). Ocular features include lid lag, stare, widened palpebral fissures, extraocular muscle dysfunction with diplopia, and optic nerve compression with visual impairment. Eyelid retraction manifests in several ways: (1) Stellwag's sign, a staring expression with infrequent blinking; (2) Dalrymple's sign, a widened palpebral fissure due to retraction of both the upper and the lower lids; (3) von Graefe's sign, a larger than normal portion of visible sclera with downward eye movement; (4) Joffroy's sign, a lack of frontalis muscle contraction with upgaze; and (5) Möbius' sign, sympathetic overactivity-induced exophthalmos with resultant limited convergence.⁹⁵ Although reports of a distal sensorimotor polyneuropathy in thyrotoxic patients are rare, improvement of the neuropathic features with attainment of the euthyroid state indicates that these features are manifestations of

hyperthyroidism.¹⁰⁹ Myasthenia gravis (MG) can be associated with hyperthyroidism, although some reported cases may have been secondary to coincident MG.⁹² Also, when bulbar weakness responds to treatment of the hyperthyroid state, it is more likely related to hyperthyroidism.¹¹⁰ When MG coexists with thyrotoxic myopathy, the clinical findings do not differ from those in euthyroid patients, although the patients may be weaker due to the coexistence of two motor disorders. Thyrotoxic myopathy is characterized by the gradual onset of proximal limb weakness, which may be accompanied by myalgias, easy fatigability, and prominent atrophy. Although the muscular atrophy may be severe, most patients remain ambulatory. Shoulder girdle muscles can be more severely affected than the hip girdle muscles, with prominent atrophy and scapular winging.^{90,91} Distal limb muscles are also affected, the facial muscles may be affected, and, rarely, bulbar and ocular muscles are involved.^{91,106} Thyroid-associated ophthalmopathy refers to the exophthalmos and ocular muscle dysfunction associated with thyroid disease. It is seen in most patients with Graves' disease but is also seen in 5% of patients with Hashimoto's thyroiditis. It is not correlated with the onset of Graves' disease,¹¹¹ having been reported to precede (rarely), occur concomitantly with, or develop after its treatment. It also does not correlate with the level of circulating thyroid hormone and may occur in euthyroid patients or in patients with hypothyroid Graves' disease.⁹⁵ When it is prominent, thyroid-associated ophthalmopathy may cause exposure keratopathy (due to marked proptosis), as well as optic nerve compression. TPP refers to recurrent attacks of flaccid paralysis of the limbs and trunk (the oculobulbar muscles are usually spared or involved to a lesser degree) due to secondary hypokalemia.

DIFFERENTIAL DIAGNOSIS. The differential diagnosis of thyrotoxicosis includes other hypermetabolic disorders, euthyroid hyperthyroxinemia, and nonthyroidal causes. Occasionally, recognition that myopathic features are due to thyrotoxicosis can be difficult, especially if the myopathy is the presenting feature (rare), when exophthalmos is minimal, or when an apathetic state is present.¹¹² When it is present, the observation of hyper-reflexia is helpful because this feature is not observed in other metabolic myopathies. Thyrotoxic myopathy with pronounced muscular atrophy should be differentiated from progressive muscular atrophy by the presence of fasciculations and more profound weakness in the latter. When thyrotoxic myopathy involves the ocular and bulbar musculature, it must be differentiated from MG. In thyrotoxic myopathy, rapid muscle fatigue and recovery with rest is not appreciated, a response to anticholinesterases is not observed, and decrement is not apparent on EMG. In MG, ocular and bulbar muscle involvement is more pronounced and atrophy is not present.¹⁰⁶ Also, MG is painless, without orbital congestion, lid lag, lid retraction, or exophthalmos. The ophthalmoplegia is parietic, rather than restrictive, and usually there is lid ptosis, diurnal variation, and Cogan's lid twitch, as well as normal orbital imaging studies.¹¹³ Conversely, with thyroid ophthalmopathy, mild orbital discomfort, orbital congestion, lid lag, lid retraction, exophthalmos, restrictive ophthalmoplegia (often late), and absence of ptosis, diurnal variation, and Cogan's lid twitch are observed. Also, a positive forced duction test and enlarged extraocular muscles on imaging

Figure 38-2. A 40-year-old woman who presented with complaints of double vision. This brain computed tomography of the orbits demonstrates enlarged extraocular muscles bilaterally associated with Graves' ophthalmopathy. (From Kennell T, Levy JM, Stegman CJ: Radiologic case. *Western J Med* 1987;146:241. Reprinted by permission of The Western Journal of Medicine.)

studies of the orbits are characteristic.¹¹³ These two conditions may coexist. Polymyositis should also be considered and is differentiated by EMG and muscle biopsy. In the setting of episodic weakness, TPP should be considered. The latter is a sporadic disorder that is much more frequent among Asians and males, typically begins in the second decade of life, affects the lower extremities more frequently than the upper extremities, and spares the oculobulbar muscles.¹¹³ Vigorous exercise and high-carbohydrate meals may precipitate acute attacks.

EVALUATION. TFTs can confirm thyrotoxicosis, typically demonstrating an elevated free T₄, total T₄, T₃RU, free thyroxine index, free T₃, total T₃, and a suppressed (usually undetectable) TSH. A normal or elevated TSH in the face of unequivocal clinical thyrotoxicosis should raise suspicion for a TSH-secreting pituitary adenoma. Other laboratory features may include anemia, hypokalemia, hypercalcemia, and an elevated erythrocyte sedimentation rate. Approximately half of hyperthyroid patients demonstrate EEG changes, most commonly generalized slowing or excessive fast activity, both of which resolve with attainment of the euthyroid state.⁹² Magnetic resonance imaging (MRI) with gadolinium may demonstrate the characteristic features of thyroid ophthalmopathy, including multiple extraocular muscle involvement, smooth margins gradually tapering into the tendon insertions, and uniform enhancement when contrast is administered. These features are readily displayed with fat saturation techniques that de-emphasize intraocular fat. Optic nerve impingement may also be visualized with a similar approach. MRI may also be useful in ruling out orbital pseudotumor, Tolosa-Hunt syndrome, orbital lymphoma, Wegener's granulomatosis, and orbital aspergillosis (Video 227, Orbital Pseudotumor).¹¹⁴

When coexistent MG is considered, acetylcholine receptor antibodies in response to edrophonium (Tensilon) may be helpful in its evaluation. Although the Tensilon test may be normal in MG (false-negative result) and may lead to improvement of dysthyroid orbitopathy (false-positive result),⁹⁵ patients with thyrotoxic bulbar features typically do not have immunological, electrophysiological, or pharmacological evidence of MG.⁹¹

MANAGEMENT. Almost all of the clinical features of thyroid dysfunction, with the exception of thyroid-associated ophthalmopathy, resolve once the euthyroid state is achieved.^{106,115} Medical (definitive and symptomatic) and surgical approaches to treatment of thyrotoxicosis include β -blockers; antithyroid, anti-inflammatory, and immunosuppressive drugs; radioactive iodine-131; iodine-containing compounds; and subtotal thyroidectomy. β -Blockers, in addition to decreasing the β -adrenergic-mediated features of thyrotoxicosis, may decrease the peripheral conversion of T₄ to T₃. β -Blockers are also useful in the prophylactic treatment of TPP while attainment of the euthyroid state is awaited. A typical dosage regimen is propranolol, 40 mg four times daily.⁹¹ Prophylaxis against further attacks includes avoidance of identified precipitants and acetazolamide until restoration of the euthyroid state is achieved. In hyperthyroid patients with coexistent MG, β -blockers should be used cautiously because of their neuromuscular blocking properties.⁹¹ Higher grade orbital features typically require systemic corticosteroids (with or without cyclosporine), irradiation, or

orbital decompression,¹¹⁶ yet some believe surgery is rarely indicated because the dysthyroid orbitopathy usually spontaneously arrests before a serious degree of ophthalmopathy has been reached.¹¹⁷ One of the most frequent complications of thyroid surgery is recurrent laryngeal nerve paralysis.¹¹⁸ A more limited surgery involving partial lid suturing may be required to protect the cornea. When an undetectable serum thyrotropin concentration is identified in the presence of normal serum T₃ and T₄ concentrations, the term *subclinical hyperthyroidism* is applied. Toft¹¹⁹ provided recommendations on its management. Significant depression can be associated with subclinical hyperthyroidism. Transient thyroiditis (e.g., subacute and postpartum thyroiditis) may only require symptomatic therapy (e.g., β -blockers).

Parathyroid Disorders

See the sections on [hypocalcemia](#) and [hypercalcemia](#).

Adrenal Disorders

Hypoadrenalism

PATHOGENESIS AND PATHOPHYSIOLOGY. The adrenal gland is the effector organ of the hypothalamic-pituitary-adrenal (HPA) axis and secretes cortisol in response to stimulation by pituitary-derived corticotropin (adrenocorticotropic hormone [ACTH]). Pituitary function, in turn, is under the control of corticotropin-releasing hormone from the hypothalamus. Dysfunction anywhere in the HPA axis may result in adrenal insufficiency. Primary adrenal insufficiency (PAI) is due to bilateral adrenal gland destruction, and secondary adrenal insufficiency (SAI) results from hypothalamic or pituitary dysfunction. Although brain injury affects the HPA axis, the most frequent cause of adrenal insufficiency is iatrogenic SAI following the withdrawal of exogenously administered steroids.⁸⁷ The fatigue and weakness associated with hypoadrenalism reflect the associated hypotension as well as the water and electrolyte disturbances. The role of glucocorticoids in catabolic energy mobilization likely also contributes.

EPIDEMIOLOGY AND RISK FACTORS. PAI is relatively rare, may occur at any age, affects both sexes equally, and is most often due to autoimmune adrenalitis.¹²⁰ Acquired immunodeficiency syndrome, histoplasmosis, and active tuberculosis are significant risk factors for PAI. Major risk factors for SAI include prior administration of exogenous corticosteroids, especially prolonged, high-dose courses, and any destructive lesion of the pituitary or hypothalamus.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. The clinical features of adrenal insufficiency are influenced by the site of dysfunction because PAI affects all of the adrenocortical hormones, whereas SAI only affects glucocorticoids. Thus, hyperpigmentation, salt craving, and hyperkalemia are unique to patients with PAI. Patients with adrenal insufficiency may present acutely or as a chronic condition. Acute adrenal insufficiency is a medical emergency (so-called Addisonian crisis) characterized by mental status changes, fever, hypotension, volume depletion, arthralgias, myalgias, and abdominal pain that may mimic an acute abdomen.¹²¹ Chronic adrenal insufficiency may present more insidiously with fatigue, weakness, GI

symptoms, amenorrhea, decreased libido, salt craving, arthralgias, and hypoglycemic symptoms. Neurological manifestations can include confusion, apathy, depression, psychosis, paranoia, and myalgias, as well as hypoglycemic symptoms.¹²² In addition, a past medical history of cancer, recent tuberculosis exposure or steroid usage, immunosuppression, a history of treated Cushing's syndrome, features of hypothalamic/pituitary disease, or other endocrine deficiencies, as well as a family history of a sex-linked recessive disorder, should be sought.

DIFFERENTIAL DIAGNOSIS. In the industrialized world, approximately 70% of cases of PAI are autoimmune in etiology (due to the polyendocrine deficiency syndrome), 20% are related to tuberculosis (most common cause worldwide), and the remaining 10% are due to other causes (Table 38-10).¹²¹ SAI commonly follows exogenous steroid withdrawal and the surgical treatment of Cushing's syndrome; it is uncommonly related to hypothalamic or pituitary lesions.¹²¹ The neurological differential diagnosis relates to the rapidity of onset of the hypoadrenalism. In the setting of acute adrenal insufficiency (i.e., Addisonian crisis), the differential diagnosis of acute-onset encephalopathy must be entertained in addition to those disorders that produce septic shock. With a more chronic presentation, the differential diagnosis varies with the clinical manifestations and includes those disorders associated with encephalopathy, fatigue, weakness, or myalgias.

EVALUATION. The evaluation of patients with suspected adrenal insufficiency serves to determine the adequacy of cortisol production and to localize the process within the HPA axis (i.e., PAI versus SAI). Tests to assess cortisol production include serum cortisol level, short cosyntropin (Cortrosyn) stimulation test, insulin tolerance test, and the metyrapone test. The plasma ACTH level is the principal localizing test,¹²³ and in severely stressed patients with normal adrenal function, serum cortisol levels range from 20 to 120 µg/dL.¹²¹ In unstressed patients, the normal cortisol level overlaps with that observed in patients with adrenal insufficiency, making random cortisol testing less useful in this group.

MANAGEMENT. In patients receiving exogenous glucocorticoids, the prevention of HPA axis suppression is aided

by using the lowest possible dosage, shortest duration, and an every-other-day dosing schedule, when possible. The treatment of adrenal insufficiency is hormone replacement. In general, in acute adrenal insufficiency, IV hydrocortisone is administered and fluid, Na, and glucose are replaced. In chronic adrenal insufficiency, the preferred replacement glucocorticoid is also hydrocortisone because it has a short half-life and is therefore less likely to produce Cushing's syndrome or osteoporosis.¹²² A typical regimen is hydrocortisone, 20 mg in the morning and 10 mg in the evening. Mineralocorticoid replacement may be required in PAI and is usually provided by fludrocortisone (Florinef), 0.05 to 0.1 mg/day, along with the recommendation for a high-Na diet. Pituitary apoplexy, an uncommon endocrine emergency, requires a multidimensional treatment plan.⁸⁸ Patients should be informed about the need for steroid adjustment during disease and should always wear a medical bracelet.

Hyperadrenalism

Hyperadrenalism refers to hypersecretory disorders of the adrenal medulla (e.g., pheochromocytoma) and cortex (e.g., aldosteronism and Cushing's syndrome). *Pheochromocytomas* are catecholamine-secreting tumors of neural crest (neuroectoderm) origin that may be sporadic or familial. In adults, approximately 10% of these tumors are malignant, 10% are extra-adrenal (i.e., 90% occur within the adrenal glands), and 10% are bilateral.¹²⁴

The major clinical features of pheochromocytoma are headaches, palpitations, diaphoresis, hypertension, hypotension, pallor, weight loss, chest pain, and abdominal pain.¹²⁴ Other features include dizziness, anxiety, nausea, vomiting, diarrhea, mydriasis, tachycardia, pulmonary edema, and CHF.¹¹⁷ A more serious neurological feature is intracranial hemorrhage. *Pheochromocytoma multisystem crisis* is a serious and rare presentation that is characterized by encephalopathic features, multiple organ failure, fever, and labile blood pressure.¹²⁵ Pheochromocytoma can be associated with multiple endocrine neoplasia type II, neurofibromatosis, and von Hippel-Lindau disease.¹¹⁷

The differential diagnosis of hypertension associated with hyperadrenergic symptoms is extensive and includes thyrotoxicosis, anxiety and panic disorders, hypoglycemia, diencephalic epilepsy, acute myocardial infarction, abrupt clonidine withdrawal, and drug usage (e.g., monoamine oxidase inhibitors, cocaine, and decongestants). Although pheochromocytoma is rare, its life-threatening status requires consideration and exclusion whenever hypertension is associated with suggestive symptoms, especially the triad of headache, palpitations, and diaphoresis.

A total plasma catecholamine (epinephrine plus norepinephrine) level, drawn 30 minutes after supine rest, can be diagnostic. Values higher than 2000 pg/mL are pathognomonic for pheochromocytoma, whereas those less than 1000 pg/mL exclude pheochromocytoma. Twenty-four-hour urine studies (metanephrines, normetanephrines, and vanillylmandelic acid) and clonidine suppression testing are required when values between these levels are obtained.¹²⁴ Twenty-four-hour urine studies are diagnostic in up to 90% of patients with pheochromocytoma.¹¹⁷ Once the diagnosis of pheochromocytoma is confirmed,

Modified from Loriaux DL: Adrenocortical insufficiency. In Becker KL, Bilezikian JP, Brenner WJ, et al (eds): Principles and Practice of Endocrinology and Metabolism, 2nd ed. Philadelphia, Lippincott, 1995, pp 682–686; Rone JK: Adrenal insufficiency. In Rakel RE (ed): Saunders Manual of Medical Practice. Philadelphia, Saunders, 1996, pp 653–656.

tumor localization becomes the priority and is best evaluated by abdominal CT.

For neurologists, it is important to consider pheochromocytomas in patients with headaches and other suggestive symptoms. Serious morbidity and mortality may occur when these patients present with headache and β -blocker therapy is begun, which allows unopposed α -adrenergic stimulation. This may result in CHF, myocardial or cerebral infarction, malignant hypertension, or death. When pheochromocytoma is considered to be a diagnostic possibility, referral to an endocrinologist for further evaluation and treatment is appropriate. With the widespread availability of imaging (CT and MRI) and biochemical assays, the incidence of undiagnosed pheochromocytoma has decreased significantly.¹²⁴ With surgery, most pheochromocytomas are cured. However, 10% are malignant and current treatments for widespread metastases are unsatisfactory.

Aldosteronism results from the overproduction of aldosterone by the adrenal cortex and can be primary or secondary. Primary aldosteronism refers to aldosteronism related to adrenal gland disorders such as aldosterone-secreting adrenal adenomas (Conn's syndrome) and functional overactivity of both adrenal glands (idiopathic hyperaldosteronism). Secondary aldosteronism refers to stimulation of aldosterone production by extra-adrenal influences, such as occurs in CHF, cirrhosis, volume depletion (or other conditions of decreased effective renal perfusion), and Bartter's syndrome, a rare disorder characterized by hyper-reninemia, hypokalemia, and normal blood pressure. Aldosteronism, both primary and secondary, results in hypokalemia and metabolic alkalosis, which, in turn, may cause neurological symptoms. Primary aldosteronism is approximately twice as common in women, occurs between the ages of 30 and 50 years, and is found in approximately 1% of hypertensive patients.¹²⁰ It is the most common endocrine cause of secondary hypertension.

Aldosteronism-induced hypokalemia may trigger episodic attacks of severe muscular weakness (similar to periodic paralysis), tetany, paresthesias, polyuria, and hypertension.¹²⁶ The episodic attacks of weakness are similar to both the familial and the thyrotoxic forms of periodic paralysis, although respiratory paralysis is more common.⁹¹ Unlike the familial form, hypokalemia and alkalosis may be present between attacks.⁹¹ In addition to episodic weakness, a subacute or chronic myopathy may develop. In this setting, serum creatinine kinase may be moderately elevated and EMG examination discloses myopathic features that are often accompanied by fibrillation potentials.⁹¹ Rarely, rhabdomyolysis and myoglobinuria occur. Laboratory features include an inability to concentrate the urine, hypernatremia, hypokalemia, metabolic alkalosis, and hypokalemic-induced ECG changes. The plasma renin activity should be measured because this factor allows the differentiation between primary (suppressed) and secondary (elevated) aldosteronism.

The etiology dictates the treatment. In idiopathic hyperaldosteronism, medical therapy is primary, whereas hyperaldosteronism due to an adenoma is typically treated by surgical excision, although medical treatment with spironolactone (an aldosterone antagonist) and dietary Na restriction may be effective (antihypertensives may also be required).

Cushing's syndrome is the clinical expression of chronic excess adrenal corticosteroids (i.e., hypercortisolism) and can be classified into ACTH-dependent and ACTH-independent etiologies.¹²⁷ Disorders belonging to the ACTH-dependent category overproduce cortisol in response to excessive ACTH release, whereas those in the ACTH-independent category produce cortisol without ACTH stimulation. ACTH-dependent causes account for 80% of the cases of endogenous Cushing's syndrome and include ACTH-producing pituitary tumors (Cushing's disease; 65%) as well as both ACTH-producing (15%) and corticotropin-releasing hormone-producing (rare) ectopic tissue.¹²⁸ ACTH-independent etiologies account for 20% of the cases of Cushing's syndrome and include adenoma and carcinoma of the adrenal gland, nodular hyperplasia, and cortisol-secreting tumors.¹²⁸ In addition to these endogenous etiologies, prolonged administration of exogenous glucocorticoids can cause a nearly identical syndrome.

The clinical features of Cushing's syndrome vary with the underlying etiology and are dependent on the amount of ACTH, cortisol, and other adrenocortical steroids secreted (Table 38-11). Neuropsychiatric manifestations can include irritability, emotional lability, depression, and psychotic episodes.^{92,117} Approximately 50% of patients with Cushing's disease have muscle weakness.⁹¹ Other possible neurological signs are mental status changes and visual field defects as well as optic neuropathy when pituitary adenomas extend beyond the confines of the sella turcica. Rarely, the accumulation of fat epidurally can result in the development of a myelopathy. An association with idiopathic intracranial hypertension has also been reported (see Chapter 53).

Cushing's syndrome must be differentiated from disorders producing secondary hypercortisolism (e.g., obesity, major depression, and alcoholism). Initial (screening) evaluation usually includes an overnight dexamethasone suppression test or a 24-hour urine collection for free cortisol. Free cortisol typically exceeds 90 $\mu\text{g}/\text{day}$ in Cushing's syndrome. The overnight dexamethasone suppression

TABLE 38-11

The Clinical Features of Cushing's Syndrome and Disease

| CUSHING'S SYNDROME | CUSHING'S DISEASE |
|--|---|
| Hypertension, diabetes, hyperphagia, central obesity, moon facies, dorsocervical fat deposition (buffalo hump; may cause myelopathy), hirsutism, acne, menstrual disorders, evidence of protein catabolism (e.g., easy bruising, myopathy, osteopenia), cutaneous lesions (hyperpigmentation; wide, purple striae), psychiatric manifestations | Mental status changes, idiopathic intracranial hypertension, visual field defects, optic neuropathy |

Data from Layzer RB: Neuromuscular manifestations of endocrine disease. In Becker KL, Bilezikian JP, Bremner WJ, et al (eds): Principles and Practice of Endocrinology and Metabolism, 2nd ed. Philadelphia, Lippincott, 1995, pp 1762-1770; Scheingart DE: Cushing syndrome. In Becker KL, Bilezikian JP, Bremner WJ, et al (eds): Principles and Practice of Endocrinology and Metabolism, 2nd ed. Philadelphia, Lippincott, 1995, pp 667-682.

test assesses the patient's ability to suppress cortisol production in response to dexamethasone. Typically, 1 mg of dexamethasone is administered at 11 PM, and a blood sample for serum cortisol is drawn at 8 AM. Serum cortisol is suppressed to less than 5 µg/dL in normal individuals, whereas it is higher than 10 µg/dL in patients with Cushing's syndrome. If either test is abnormal, then a low-dose (0.5 mg) dexamethasone is required for further differentiation. False-positive results may be noted with physiological stress, estrogen or phenytoin use, RF, and endogenous depression.¹²⁸

Basic laboratory studies may identify glucose intolerance, leukocytosis with lymphopenia, polycythemia, and hypokalemia. Hypokalemia is unusual in Cushing's disease (10%) but is much more common in the ectopic ACTH syndrome (60%).¹²⁸ An MRI scan of the pituitary is the procedure of choice for the identification of pituitary adenomas. Abdominal CT scanning for the presence of an adrenal tumor is indicated in ACTH-independent syndromes. The treatment of endogenous Cushing's syndrome depends on the underlying etiology.

Growth Hormone Disorders

Growth hormone (GH; somatotropin) is secreted by the anterior pituitary in response to hypothalamic GH-releasing hormone (GHRH). GH promotes linear growth and has both anabolic and catabolic effects. Hypersecretion of GH causes gigantism when it occurs before epiphyseal closure and acromegaly when it begins afterward. Hyposecretion causes short stature in childhood and possibly a chronic fatigue-like syndrome in adults. GH acts indirectly through insulin-like growth factors (IGFs; somatomedins), with IGF-1 (formerly somatomedin C) being the most important for growth. Prolonged exposure to elevated levels of GH and IGF-1 results in the insidious onset of skeletal and soft tissue overgrowth, the latter of which is most pronounced in tissues containing large amounts of cartilage proteoglycans.¹²⁹ Cortical bone density is increased and trabecular bone (e.g., vertebral) density is decreased, probably because of coexistent hypogonadism.¹²⁹ Soft tissue hypertrophy may result in compression neuropathies, radiculopathies, and, rarely, myelopathy.⁹⁰

More than 98% of cases of acromegaly are due to GH hypersecretion by a pituitary adenoma.¹³⁰ Rare etiologies include increased hypothalamic production of GHRH, ectopic pharyngeal pituitary tissue, and ectopic hormone (GH and GHRH)-secreting tumors (e.g., hypothalamic gangliocytoma and breast, stomach, and lung tumors).¹²⁹ GH-secreting pituitary adenomas are relatively rare, with an incidence of 3 or 4 per 1 million and a prevalence of 50 to 70 per 1 million.¹³⁰ There is no sexual predilection, and the majority of patients are diagnosed in their fourth or fifth decade, after a mean delay of 8.7 years.¹³¹

If it is present, an enlarging pituitary adenoma may produce headaches, visual changes (e.g., bitemporal hemianopia due to optic chiasm compression), and hypopituitarism (e.g., decreased ACTH or TSH levels due to anterior pituitary destruction), as well as DI (posterior pituitary involvement) and diplopia (due to cavernous sinus invasion). The lack of correlation between headache and tumor size reported in some series¹³¹ suggests that headache may also be a feature of GH hypersecretion.

The hypersecretion of GH produces various forms of disfigurement and other physical changes (Table 38-12).

TABLE 38-12

General Features of Growth Hormone Hypersecretion

Growth Hormone Hypersecretion

Musculoskeletal: Increasing hat, glove, or shoe sizes; prognathism; prominent supraorbital ridges; coarsening of facial features (e.g., large bulbous nose, thick lips, separated teeth)

Endocrine: Hyperhidrosis, fatigue, exercise intolerance, hoarseness, sleep apnea (peripheral and central)

Cardiopulmonary: Hypertension, hyperlipidemia, cholelithiasis, carbohydrate intolerance, overt diabetes, heart disease (e.g., arrhythmias, congestive heart failure, coronary artery disease)

Other: Arthralgias, slight kyphosis, visceromegaly, reproductive problems (women: amenorrhea, galactorrhea, anovulatory problems; men: decreased libido, hypogonadism), hyperprolactinemia, adenomatous polyps and colon cancer, esophageal and gastric cancer, parathyroid and pancreatic islet cell adenomas (MEN-I syndrome)

Pituitary Gland Enlargement

Headaches, visual changes (e.g., bitemporal hemianopsia due to optic chiasm involvement), hypopituitarism, diabetes insipidus, diplopia

MEN-I, multiple endocrine neoplasia type I.

Data from Kissel JT: Endocrine myopathies, In Update on Neuromuscular Disease. Course 423 of the AAN Annual Meeting, Washington, DC, May, 1994, pp 34–35; Maugans TA, Coates ML: Diagnosis and treatment of acromegaly. *Am Fam Phys* 1995;52:207–213; Molitch ME: Clinical manifestations of acromegaly. *Endocrinol Metab Clin North Am* 1992;21:597–614; Grunstein RR, Ho KY, Sullivan CE: Sleep apnea in acromegaly. *Ann Intern Med* 1991;115:527–532.

Central sleep apnea has been reported in one-third of acromegalic patients with sleep apnea.¹³² Importantly, the presence of sleep apnea increases the risk for hypertension, myocardial infarction, and stroke, as well as accident susceptibility due to daytime sleepiness.¹³⁰ Mononeuropathies, especially compression neuropathies such as carpal tunnel syndrome (CTS), may be noted. CTS occurs in 50% of patients and is noted in 75% when EMG testing is performed.⁹¹ Objective weakness, in a myopathic pattern, is observed in approximately 40% of acromegalic patients.⁹¹ The weakness typically has an insidious onset and is a late manifestation, correlating best with the duration of acromegaly.⁹⁰ Polyneuropathies, nerve root and spinal cord compression, headaches, and visual changes have also been described.⁹⁰

The most sensitive and specific screening test for acromegaly is the plasma IGF-1 level. The pulsatile nature of GH secretion may result in a randomly high GH level being obtained in a normal person, as may physical stressors, making this a less useful test. All patients with elevated IGF-1 levels should have an oral glucose tolerance test, the gold standard for acromegaly. MRI can confirm the suspicion of a pituitary adenoma. When MRI is negative in an acromegalic patient, consideration should be given to the rarer etiologies of acromegaly.

The prevention of many of the sequelae of disorders associated with acromegaly (e.g., hypertension, cardiovascular disease, stroke, sleep apnea, diabetes, and arthropathy) requires early identification and treatment. The management of acromegaly includes the identification of the source of the excess GH secretion and its excision, irradiation, or medical suppression. The somatostatin analog octreotide is a highly effective pharmacological means of controlling GH secretion¹¹⁷ while awaiting the effect of irradiation in those cases related to a pituitary adenoma incompletely responsive to transphenoidal resection.

Glucose Metabolism Disorders

Hypoglycemia

PATHOGENESIS AND PATHOPHYSIOLOGY. Unlike other body tissues, the CNS relies almost exclusively on glucose as an energy substrate. CNS features that promote its vulnerability to hypoglycemia include its low glucose level (approximately 25% of the serum glucose value), its inability to store significant glucose as glycogen, and the high cerebral metabolic rate (5 mg/100 g brain tissue/minute) for glucose.¹³³ Thus, for a 1400-g brain, the glucose requirement is 70 mg/minute. The brain's dependence on glucose, coupled with its limited glycogen stores, results in rapid CNS dysfunction when hypoglycemia occurs and permanent neurological sequelae if it is prolonged. The glucose level at which CNS dysfunction occurs depends on its rapidity of onset, the current level of CNS activity, the quantity of CNS glycogen, and the availability of alternative fuels. The immediate cause of CNS dysfunction is unknown. Although it was initially believed to be due to tissue energy depletion, high-energy organic phosphates are normal during the early stages of symptomatic hypoglycemia.⁶⁵ Alternative explanations include accumulation of metabolic by-products of nonglucose metabolism, impaired acetylcholine synthesis, and changes in neurotransmitter levels, such as those of glutamate, aspartate, and γ -aminobutyric acid.⁶⁵ When glucose slowly decreases, the CNS can use nonglucose substrates, especially ketoacids and glucose metabolism intermediaries,⁷¹ as well as several amino acids.⁶⁵

EPIDEMIOLOGY AND RISK FACTORS. Hypoglycemia is a common problem without predilection for any age, gender, or ethnic group. Although excessive insulin administration is the most common cause of hypoglycemia,⁶⁶ excessive use of oral hypoglycemic agents is another common cause. The major risk factor for the development of reactive hypoglycemia (infrequent) is GI surgery (e.g., vagotomy and pyloroplasty, gastrectomy, or gastrojejunostomy).

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Symptoms of hypoglycemia can be divided into adrenergic and neuroglycopenic (low CNS glucose). The adrenergic symptoms (e.g., diaphoresis, tachycardia, and enhanced physiological tremor) are inversely correlated to the rate of development of hypoglycemia, being most pronounced with acute onsets. Hunger, visual disturbances, and altered temperature perceptions are other possible adrenergic features. The neuroglycopenic features include headache, malaise, impaired concentration, confusion, disorientation, irritability, lethargy, stupor, coma, generalized seizures, myoclonus, and psychiatric disturbance. Focal CNS dysfunction, including focal seizures, hemiplegia, paroxysmal choreoathetosis, and patchy brain stem and cerebellar involvement mimicking basilar artery thrombosis, have also been reported.¹³⁴ With subacute onset, drowsiness, lethargy, decreased psychomotor activity, and confusion may be observed,⁷¹ and when chronic, the insidious onset of memory, personality, and behavioral disturbances may suggest dementia.¹³⁵ The medullary phase of hypoglycemia, characterized by deep coma, pupillary dilatation, shallow breathing, bradycardia, and hypotonicity, occurs at a blood glucose level of approximately 10 mg/dL.⁷¹

| Idiopathic |
| Artificial (lymphoproliferative disorders) |

Data from Bleck TP: Metabolic encephalopathies. In Weiner WJ (ed): Emergent and Urgent Neurology. Philadelphia, Lippincott, 1992, pp 27-57; Lockwood AH: Toxic and metabolic encephalopathies. In Bradley WG, Daroff RB, et al (eds): Neurology in Clinical Practice, 2nd ed. Boston, Butterworth-Heinemann, 1996, pp 1355-1372; Yealy DM, Wolfson AB: Hypoglycemia. Emerg Med Clin North Am 1989;7:837-848.

Adrenergic features, when present, precede neurobehavioral features, thereby functioning as an early warning system. However, when sympathetic dysfunction (e.g., diabetic autonomic neuropathy) exists or when adrenergic blockers are being used, these features may be inapparent.

DIFFERENTIAL DIAGNOSIS AND EVALUATION. Hypoglycemia may be divided into fasting (the overwhelming majority), reactive (uncommon), and artificial (Table 38-13). Fasting hypoglycemia is usually the result of exogenous insulin or oral hypoglycemic administration by diabetic patients. Drug-induced hypoglycemia can be caused by pentamidine, nonsteroidal anti-inflammatory drugs, salicylates, sulfonamides, clofibrate, phenytoin, rifampin, thyroid hormone, anabolic steroids, and probenecid. Enzyme defects causing hypoglycemia are rare and typically begin in childhood. By prolonging the half-life of insulin and oral agents, RF may result in hypoglycemia. Liver disease may also cause hypoglycemia in this way while also impairing glucose production and glycogen storage. Disorders of fatty acid utilization increase the need for glucose and may rapidly result in hypoglycemia. Reactive hypoglycemia is most commonly caused by surgical procedures (iatrogenic) that result in rapid gastric emptying, which, in turn, stimulates excessive insulin release, thereby causing hypoglycemia.¹³⁶

The neurological symptoms associated with hypoglycemia primarily reflect CNS involvement (e.g., encephalopathy and seizures) and are related to the rapidity of onset. Diagnostic considerations of patients with hypoglycemia depend on the presenting manifestations (e.g., disorders known to produce seizures, when hypoglycemia is associated with such, or disorders known to produce encephalopathy, when hypoglycemia is associated with confusion).

EVALUATION. Whipple's triad (hypoglycemic features, laboratory confirmation of a low serum glucose, and resolution of symptoms with glucose replacement) is diagnostic of hypoglycemia. To identify the underlying cause of hypoglycemia, other studies, including serum studies for C-peptide, proinsulin and insulin levels, antibodies to insulin or its receptor, and sulfonyleurea levels, may be required in addition to routine laboratories. Abdominal imaging (CT or MRI) and arteriography, for tumor localization, may be useful. In the evaluation of related neurological symptoms, the EEG reveals generalized slowing, unless the degree of hypoglycemia is mild. In this setting, hyperventilation-induced slowing may persist after hyperventilation is

discontinued. In the setting of symptomatic hypoglycemia, the confusional state correlates with EEG slowing. Additionally, seizure activity may be observed. As the glucose level drops further, the comatose state supervenes and burst-suppression activity is demonstrated on the EEG. Intravenous administration of glucose can reverse hypoglycemic seizure activity and coma.

Regarding symptom resolution with glucose replacement, although catecholamine-mediated features usually respond within minutes, the CNS-related features may require longer for resolution.¹³⁶ If the CNS features do not resolve within 1 hour, permanent CNS damage may have occurred. In addition, the possibility that the hypoglycemia is related to another disorder should be considered.

MANAGEMENT. Prevention of serious morbidity and mortality requires early recognition of hypoglycemia and prompt glucose replacement, regardless of etiology. To avoid masking of the autonomic (warning) features of hypoglycemia, β -blockers should be avoided in patients taking hypoglycemic agents. To prevent the development of Wernicke-Korsakoff syndrome in alcoholic and malnourished patients, thiamine supplementation (1 mg/kg) should also be administered before giving glucose (Video 229, Wernicke's Encephalopathy). Malnourished patients should also receive niacin to prevent pellagra. Depending on the etiology, more specific therapies may be indicated (e.g., corticosteroid replacement for adrenal insufficiency).

PROGNOSIS AND FUTURE PERSPECTIVES. Hypoglycemia is associated with a substantial morbidity, primarily related to accidents (e.g., vehicular) and seizures with resultant injuries.¹³³ In the setting of hypoxic encephalopathy, premature prognostication should be avoided, given that slow improvement may continue for 1 or 2 years.⁷¹ When glucose is replaced before the medullary phase is reached, the features may be reversible. After this point, especially if treatment was delayed, recovery may be protracted or incomplete.⁷¹ The potential risk of glucose administration to euglycemic and hyperglycemic patients is small compared to the potentially substantial benefit. However, the possibility of cerebral ischemia must be considered because hyperglycemia at the onset of brain ischemia worsens the postischemic outcome, whereas hyperglycemia occurring after experimental cerebral infarction does not.^{66,137}

Hyperglycemia

Diabetic ketoacidosis (DKA) and NKHH, two hyperglycemic syndromes occurring among patients with diabetes, can both present with encephalopathy. In addition, patients with NKHH frequently present in coma or with new-onset seizures. Moreover, in the setting of acute myocardial infarction, intensive care unit admission, and acute brain injury (e.g., acute ischemic stroke, intracerebral hemorrhage, and cerebral trauma), hyperglycemia is associated with increased morbidity and mortality.¹³⁸

PATHOGENESIS AND PATHOPHYSIOLOGY. Although the brain tolerates hyperglycemia better than hypoglycemia, encephalopathic features still develop, usually as a reflection of cerebral dehydration (e.g., intravascular hyperosmolality) or cerebral edema (e.g., too rapid correction of the hyperglycemia). A correlation between the de-

gree of encephalopathy and the serum osmolality exists, the pathophysiology of which has been discussed (see [Hyponatremia](#)). In addition to osmotic effects, intravascular coagulation related to hyperviscosity may occur.⁶⁸

The primary problem in DKA is insulin deficiency. This results in an increased ratio of glucagon to insulin, accelerated gluconeogenesis, enhanced glycogenolysis, and reduced glucose clearance, thereby producing hyperglycemia.¹³⁹ In addition, insulin deficiency leads to increased fatty acid mobilization, and the increased glucagon-to-insulin ratio induces fatty acid oxidation.¹³⁹ Therefore, lipolysis and ketone body formation occur. Once the renal threshold is exceeded, glucosuria occurs,¹³³ which promotes polyuria, due to osmotic diuresis, and polydipsia. In the setting of NKHH, insulin production is usually sufficient to inhibit lipolysis (i.e., nonketotic) but insufficient to prevent hyperglycemia. As the serum osmolality slowly rises, cerebral idiogenic osmole formation occurs (to prevent dehydration), thereby making the patient susceptible to cerebral edema during rehydration.

EPIDEMIOLOGY AND RISK FACTORS. The major risk factor for the development of hyperglycemia is diabetes mellitus, with a prevalence of approximately 1% in the United States. NKHH accounts for 10% to 20% of all cases of severe hyperglycemia,¹⁴⁰ a value that is decreasing due to earlier detection of uncontrolled hyperglycemia.¹⁴¹ Because of the high glucose content of total parenteral nutrition, patients receiving this type of therapy are also at risk of developing hyperglycemia. The incidence of gestational diabetes (carbohydrate intolerance that is present only during pregnancy) ranges from 1% in predominantly rural areas to 12% in racially mixed urban areas.¹⁴²

CLINICAL FEATURES AND ASSOCIATED DISORDERS. The general medical features of hyperglycemia include polyuria, polydipsia, and anorexia. Patients with DKA tend to be younger, type I diabetics, with a symptom onset measured in days. At onset, the mental status varies from normal (20%) to comatose (10%) and correlates most to the level of hyperosmolality.¹³⁹ DKA is frequently precipitated by infection or noncompliance with insulin therapy. Patients with NKHH tend to be older, type II diabetics with more pronounced dehydration. Unlike patients with DKA, focal neurological abnormalities, seizures (both focal and generalized), and coma are commonly observed. The most common precipitants of NKHH are infection, chronic renal insufficiency, GI bleeding, pancreatitis, stroke, burns, and certain medications.¹⁴¹

DIFFERENTIAL DIAGNOSIS. Although patients who present with encephalopathy may easily be diagnosed with hyperglycemia as the cause, diagnostic difficulty arises when encephalopathic patients present without a history of diabetes. Blood glucose determinations must be performed on all encephalopathic patients, and when they are shown to be hyperglycemic, DKA and NKHH, in addition to uremia, hepatic failure, toxin ingestion, starvation ketosis, alcoholic ketoacidosis, lactic acidosis, and other causes of encephalopathy, must be excluded. A history of ethanol abuse and, typically, a lack of hyperglycemia help differentiate alcoholic ketoacidosis. Evidence of renal dysfunction and the absence of ketones help differentiate uremia, and starvation ketosis is not associated with hyperglycemia.

EVALUATION. In evaluating patients with hyperglycemic-induced encephalopathy, precipitating factors and secondary disturbances should be sought, including electrolyte disturbances (hypokalemia, hypophosphatemia, and hypomagnesemia), infection (leukocytosis, urinalysis, CXR, and blood and urine cultures), and hypokalemic-induced ECG changes. In addition, ABGs and serum osmolality, as well as renal and hepatic function, should be assessed. Hyperamylasemia, seen in nearly 80% of patients with DKA, may result in an incorrect diagnosis of pancreatitis.¹³⁹ Typical laboratory features in patients with DKA include blood glucose above 400 mg/dL, arterial blood pH below 7.2, bicarbonate below 10 mEq/L, and an elevated serum osmolality (usually below 350 mOsm/L). Ketone bodies and β -hydroxybutyrate are elevated in the blood and urine, and there is a marked glycosuria.¹³³ In patients with NKHH, the blood glucose level is usually above 800 mg/dL and the osmolality above 350 mOsm/L.⁶⁸

MANAGEMENT. If encephalopathic features are noted in a known diabetic, 25 g of dextrose should be administered intravenously because hypoglycemia is the most common cause of mental status changes and this dosage will not cause harm in the setting of DKA.¹⁴³ The primary treatment of DKA is insulin replacement, which facilitates glucose uptake and glycogen formation and reduces the rate of ketone body formation. Volume repletion initially requires NS because most patients have TBW deficits of approximately 5 L.¹³⁹ This also lessens the degree of cerebral edema. Half-normal saline can be substituted once the orthostasis resolves, and 5% dextrose can be added after the glucose decreases to 250 mg/dL or less. Although cerebral edema is a concomitant of treatment, a malignant increase in cerebral edema may occur, with resultant increased ICP, rapid deterioration, and death.¹³³ In this setting, aggressive treatment of cerebral edema must be undertaken, typically with hyperventilation, mannitol administration, and ICP monitoring. Because the major problem in patients with NKHH is dehydration, the primary treatment is rehydration, followed by insulin therapy and correction of underlying illnesses. Normal saline is the fluid of choice, and once blood glucose levels reach 250 mg/dL, 5% dextrose is provided to avoid hypoglycemia.

Seizure control requires normalization of serum osmolality and glucose. Standard antiepileptic drugs are ineffective; furthermore, some antiepileptic drugs, such as phenytoin, can inhibit the release of endogenous insulin.¹⁴⁰ In the setting of acute brain injury, hyperglycemia increases the risk of serious neurologic outcomes. However, whether hyperglycemia is an epiphenomenon of the underlying disorder or an independent contributor to its morbidity and mortality is unclear.^{138,144,145} In DKA, the rate of patient mortality remains significant (6% to 9%), with most deaths related to cardiovascular or cerebral complications or the precipitating factor.¹³³ Mortality rates as high as 40% to 70% are reported for NKHH.

Diabetes

The neurological complications of diabetes were first recognized in 1798, and until 1864 diabetes was considered an effect of neuropathy.¹⁴⁶ For discussion purposes, the

neurological complications of diabetes can be divided into CNS, cranial nerve, and PNS disturbances, of which PNS disturbances predominate. These disorders involve different parts of the nervous system and therefore produce different clinical manifestations.

Central Nervous System Complications of Diabetes

The brain, although not frequently discussed as a target of the complications of chronic diabetes, is nonetheless affected by this disorder. In addition to the neurological complications of glycemic extremes previously discussed (see [Hypoglycemia and Hyperglycemia](#)), patients with diabetes have an increased stroke incidence, increased stroke severity, and, possibly, a chronic encephalopathy.¹⁴⁷ Regarding stroke, diabetes increases the risk of large, medium, and small vessel atheroma, as well as arteriolar and capillary microangiopathy, even after other concomitant risk factors (e.g., hypertension) are excluded.¹⁴⁸ In addition, studies have shown that the presence of hyperglycemia at the time of stroke results in more severe brain injury and, hence, a poorer stroke outcome (see [Hyperglycemia](#)). Even among individuals without diabetes, sustained hyperglycemia may be an independent risk factor for stroke, with relative risks similar to those reported for coronary heart disease.¹⁴⁹ CNS abnormalities reported in patients with diabetes include increased P-300 latency, abnormal psychometric tests, and, among children with diabetes, lower school achievement test scores.¹⁴⁸ Potential causes for encephalopathy in patients with diabetes include vascular (e.g., stroke, altered BBB function, and cerebrovascular reactivity), metabolic (e.g., altered glycemia, ketosis, hypoxia, electrolyte changes, and neurotransmitter changes), and the coexistence of other disorders (e.g., hypertension and RF).¹⁴⁷

Spinal cord abnormalities include infarction and pseudotabes diabetica. Pseudotabes diabetica reflects dorsal root ganglia disease, which, in turn, causes posterior column degeneration. Thus, this actually represents a disorder with a PNS onset resulting in secondary distal axon degeneration (i.e., the dying back phenomenon) causing posterior column degeneration.

Cranial Nerve Complications of Diabetes

The cranial mononeuropathies complicating diabetes primarily involve the oculomotor nerves (i.e., oculomotor [CN III], trochlear [CN IV], and abducens [CN VI]). Facial neuropathy and anterior ischemic optic neuropathy are only briefly discussed because these items are reviewed elsewhere in this text. Although peripheral nerve infarction has been the presumed mechanism of cranial mononeuropathies among diabetic patients, microinfarction-induced fascicular disruption within the brain stem parenchyma has been identified in many of these patients.¹⁵⁰ Diabetic oculomotor cranial mononeuropathies primarily involve CN III, followed by CN VI; CN IV is uncommonly affected alone. Clinically, patients notice the onset of eye pain or headache, followed by diplopia. The ophthalmoplegia reflects muscle weakness in the distribution of a single oculomotor nerve. Typically, in the setting of CN III involvement, pupillary sparing is noted. This likely reflects the peripheral location of the pupillomotor fibers, which

are therefore supplied by external larger vessels rather than internal smaller vessels. However, this is not always the case. Pupillary involvement is found in 10% to 20% of patients with vasculopathic (e.g., diabetes) cranial mononeuropathies, and pupillary sparing is found in 8% to 15% of patients with aneurysms.^{151,152} Concerning the latter, pupillary involvement usually appears within 3 to 5 days.¹⁵² Even patients with complete paralysis tend to recover without residual weakness, usually within 3 months.¹⁴⁶ Among patients with diabetes, facial mononeuropathies occur with increased frequency and a poor outcome may be observed.¹⁴⁶ Thus, the facial mononeuropathy associated with diabetes may be secondary rather than idiopathic. Differences noted in diabetic patients with facial mononeuropathies support this statement and include (1) normal taste (argues for a different lesion site), (2) more frequent recurrent or bilateral facial nerve involvement, and (3) more frequent axon loss as the underlying pathophysiology rather than demyelinating conduction block,¹⁵³ which explains the poorer outcome. Clinically, patients with CN II involvement and an anterior ischemic optic neuropathy suffer acute visual loss, visual field defects (usually inferior altitudinal), or both. Ophthalmologically, a pale and swollen optic disc (usually superiorly), accompanied by flame-shaped hemorrhages within the optic disc or the peripapillary retina, is observed. In addition, most of these patients have a small optic disc, no central cup, and anomalous branching patterns of the optic disc vessels—a triad referred to as the *disc at risk*.¹⁵¹ Importantly, there is a 40% chance of a similar episode in the contralateral eye and a 2% to 4% chance of a recurrent episode in the same eye.¹⁵¹ Among this patient population, the occurrence of diabetes mellitus is increased (20%).¹⁵¹ However, this may reflect the increased prevalence of hypertension among the diabetic population.

Peripheral Nervous System Complications of Diabetes

A great variety of PNS disorders are observed among patients with diabetes, and these disorders can be divided into focal, segmental, and generalized.

FOCAL PERIPHERAL NERVOUS SYSTEM DISORDERS. The focal PNS disorders include focal myopathies and mononeuropathies. The etiologies of focal myopathies include traumatic (associated with insulin injection injury) and vascular (related to thigh muscle infarction). Mononeuropathies may be divided into those affecting the cranial nerves and those affecting the somatic nerves. Somatic mononeuropathies result from entrapment or compression and nerve infarction. Entrapment and compression tend to occur in the same nerves and at the same sites as among the nondiabetic population—median mononeuropathies at the wrist (i.e., CTS), ulnar mononeuropathies at the elbow, and common peroneal mononeuropathies at the fibular head (Video 218, Ulnar Neuropathy, Wartenberg Sign; Video 237, Foot Drop). The prevalence of CTS among diabetics, as among the nondiabetic population, increases in the presence of polyneuropathy.¹⁵⁴ An increased incidence of ulnar neuropathy also exists, whereas the occurrence of a common peroneal mononeuropathy at the fibular head is likely coincidental.¹⁵⁴ Concerning the lower extremity, although femoral mononeuropathies

are the most frequently reported lower extremity mononeuropathies among diabetic patients, they are extremely rare. The initial publications on diabetic femoral neuropathies likely represent mislabeled diabetic amyotrophy, and in subsequent publications these authors noted that the lesions were located more proximally.¹⁵³ Thus, common peroneal mononeuropathies are the most common lower extremity mononeuropathy. These lesions occur unilaterally or bilaterally and can be caused by either compression or nerve infarction.¹⁵³ In patients with nerve infarction, the onset is acute and painful, the pathophysiology reflects axon loss, and recovery is often slow and suboptimal. The poor outcome reflects several features, including the following: (1) The lesions tend to be complete, and robust collateral sprouting cannot occur; (2) the lesions tend to involve the nerve trunks proximally or in their midportion, and the distance required for proximodistal regeneration is greater; and (3) the lesions tend to occur in elderly patients.¹⁵³ Unlike nerve infarction, which produces solely axon loss, compressive lesions may produce demyelinating conduction block, axon loss, or a combination of the two; therefore, it is not unexpected that, in general, patients with compressive lesions tend to have a better outcome. Except for an attempt to control the serum glucose concentration better, the mononeuropathies occurring among diabetic patients are treated in the same manner as those occurring among nondiabetic patients.

SEGMENTAL PERIPHERAL NERVOUS SYSTEM DISORDERS. The diabetic polyradiculopathy syndromes belong to this category. The term *diabetic myelopathy* was introduced by Bruns in 1890 and was displaced by Garland in 1955 when it became clinically and pathologically apparent that the disease process was not a myelopathy.¹⁴⁶ Garland suggested the intentionally nonlocalizing term *diabetic amyotrophy*. Several years later, Sullivan¹⁵⁵ suggested the term *asymmetrical (motor) proximal neuropathy*, variations of which appear in most current discussions. Historically, at least 20 synonyms for this entity have been used, which is a reflection of its varied presentations.¹⁵³ The term *diabetic thoracoabdominal neuropathy* (discussed later) has at least 10 synonyms.¹⁵³ In 1981, Bastron and Thomas¹⁵⁶ proposed the more general term *diabetic polyradiculopathy* for all of the diabetic neuropathies other than distal symmetrical polyneuropathy, thereby incorporating several of the various diabetic polyradiculopathy syndromes into a single entity (e.g., diabetic amyotrophy and diabetic thoracoabdominal neuropathy). In addition, they coined the term *territorial extension* to describe the cephalad, caudal, or contralateral progression of this process from one root region to another. Based on this framework, Wilbourn¹⁵³ drew several important conclusions: (1) The root level is primarily attacked; (2) single or contiguous roots are attacked most severely; (3) territorial extension occurs in approximately two-thirds of patients; (4) some root regions are more likely to be affected than others; (5) when uncommon root regions are involved, they generally follow involvement of the more typical root region; (6) the predominant pathophysiology is axon loss; and (7) the majority of patients have coexisting diabetic distal symmetrical polyneuropathy (DDSPN). Thus, the commonly observed diabetic amyotrophy reflects

isolated root involvement of the L2–L4 root levels, whereas diabetic thoracoabdominal neuropathy reflects isolated root involvement of the mid- to lower thoracic root levels. Also, when patients with diabetic amyotrophy develop foot drop, it most likely reflects territorial extension into the L5 level, and should it progress more caudally, global leg muscle involvement will develop. Bilateral shoulder girdle weakness is occasionally observed.¹⁵³

GENERALIZED PERIPHERAL NERVOUS SYSTEM DISORDERS. Disorders included in this category are DDSPN and diabetic autonomic neuropathy. DDSPN is the most common form of diabetic neuropathy and resembles the polyneuropathies caused by numerous other disorders. Different diagnostic criteria and methods of detection, applied to patients with diabetes of varying duration (i.e., patient selection bias), have led to a wide variation in its reported incidence and prevalence. Typically, paresthesias and numbness begin in the toes and ascend proximally in a stocking-like distribution (Video 5, Sensory Ataxia). When the ascent reaches the upper tibia, the hands begin to become involved. Once involved, the upper extremity disturbance also progresses proximally in a glove-like distribution. This distribution pattern, in which the longest nerves are first affected, is often referred to as a dying-back neuropathy. At this time, diminished or absent ankle reflexes and foot intrinsic muscle weakness are evident. Even anhidrosis follows this pattern, which typically begins in the foot and predisposes patients to foot ulcers. The electrodiagnostic abnormalities also show a distal to proximal gradient. The most sensitive NCS are the plantar mixed NCS, followed by the superficial peroneal and sural sensory NCS and the upper extremity sensory NCS. The motor NCS abnormalities and needle electrode examination abnormalities follow this same pattern. When one considers that a nerve is made of sensory, motor, and autonomic axons ranging in size from small to large, it is easy to envision the range of clinical symptoms this disorder produces. Small fiber sensory disruption causes loss of pain and temperature perception, as well as more prevalent features of dysautonomia. Large fiber sensory involvement impairs proprioception, vibratory perception, gait (sensory ataxia), and reflexes. Motor axon dysfunction produces weakness, and autonomic axon involvement produces various dysautonomic features. Occasionally, patients present with disproportionate small fiber or large fiber sensory involvement or autonomic involvement. As noted by Dyck and colleagues,^{146,154} a continuum of fiber involvement is most common, with the disproportionate cases representing the extremes of a normal distribution. Thus, diabetic autonomic neuropathy can present in isolation, although uncommonly, and the symptoms reflect the wide distribution of autonomic fibers: pupillary (miotic pupils with sluggish light reflex), cardiovascular (resting tachycardia and orthostatic hypotension), GI (constipation), genitourinary (impotence and reduced vaginal lubrication), and sudomotor (distal anhidrosis) systems.¹⁴⁸ The symptoms, evaluation, and management of diabetic autonomic neuropathy have been reviewed.¹⁵⁷ Hyperglycemic polyneuropathy refers to transient, distal paresthesias or dysesthesias occurring just before the diagnosis of diabetes or following ketoacidotic coma. The treatment of painful diabetic neuropathy is often the major management problem and can be chal-

lenging. For mild cases, simple analgesics may suffice, as may cold water soaks and the use of support stockings for evening pain. The potential for nephrotoxicity limits the usefulness of chronic nonsteroidal anti-inflammatory drugs, and the potential for addiction (as well as the occurrence of tolerance) limits the utility of narcotics, although controlled-release oxycodone may be effective for the treatment of moderate to severe pain related to diabetic polyneuropathy.¹⁵⁸ Tricyclic antidepressants, such as amitriptyline and nortriptyline, desipramine, carbamazepine (perhaps the drug of choice if the pain is lancinating or paroxysmal), gabapentin, topiramate, and mexiletine have been shown to be of value.¹⁵⁹ Anticholinergic side effects associated with tricyclic antidepressants limit their utility for patients with accompanying autonomic dysfunction. These agents, as well as others, have been reviewed.¹⁴⁸

ORGAN FAILURE

Hepatic Failure

Because of the complexity of liver metabolism, patients with liver disease may develop many complications, including neurological dysfunction. This problem can be expected, considering the important role the liver plays in both nutrient metabolism (glycolysis and nutrient biosynthesis) and detoxification. The term *hepatic encephalopathy* (HE) refers to diffuse cerebral dysfunction occurring secondary to liver disease. When HE develops acutely in patients with liver disease of less than 8 weeks' duration, the term *fulminant hepatic failure* (FHF) is used, whereas the term *portal-systemic encephalopathy* (PSE) is used when HE develops in patients with chronic liver disease. This differentiation has therapeutic implications because a number of treatments exist for patients with PSE, whereas no specific form of treatment has been proven beneficial in FHF, except urgent liver transplantation.

PATHOGENESIS AND PATHOPHYSIOLOGY. Although neither the responsible toxin nor the pathogenesis of HE is known, it is believed to result from impaired hepatic degradation of neurotoxic substances arising from the GI metabolism of nitrogenous compounds. Normally, these GI products are delivered to the liver by the portal vein. There are two mechanisms by which hepatic impairment may result in the systemic accumulation of these gut-derived substances: (1) direct entry of portal vein-derived blood into the systemic circulation (shunting) secondary to the formation of portal-systemic collaterals (e.g., PSE) and (2) impaired detoxification secondary to hepatocyte dysfunction (e.g., FHF). HE results in increased BBB permeability, which, in turn, enhances the entry of these substances into the CNS, facilitating the development of HE. This may explain why patients with liver disease can become symptomatic with only minimal hyperammonemia and their sensitivity to precipitation by ammonia-producing processes.¹⁶⁰ Normally, the brain removes ammonia by converting it to glutamine. If glutamine accumulates rapidly, the increased intracellular osmolality of the brain can cause cerebral edema.¹⁶¹

A variety of substances have been implicated in the pathogenesis of HE, including ammonia, endogenous

benzodiazepines, Na/K-ATPase inhibitors (e.g., glutamine, short-chain fatty acids, aromatic amino acids, and mercaptans), false neurotransmitters (e.g., octopamine), and γ -aminobutyric acid.¹⁶² The leading hypothesis relates to the effects of ammonia and states that HE results from its systemic accumulation. The following findings support this hypothesis: (1) Patients with HE usually have elevated arterial ammonia levels, (2) the degree of hyperammonemia correlates with the depth of coma, (3) ammonia metabolites (α -ketoglutarate and glutamine) are elevated in the brains and CSF of patients with HE, (4) the BBB permeability increases for ammonia, (5) the cerebral metabolic rate increases for ammonia, (6) experimental administration of ammonium salts results in reversible HE, (7) ammonia-forming compounds in the GI tract (e.g., protein meals and blood) reproducibly precipitate coma, (8) all proven treatments reduce blood ammonia levels, and (9) patients with urea cycle enzyme defects develop hyperammonemia and encephalopathy in the setting of normal liver function.^{160,161,163} A second hypothesis is the false neurotransmitter theory. This theory suggests that the increased ratio of aromatic to branched-chain amino acids occurring in liver failure causes an increased entry of aromatic amino acids into the brain (i.e., less competition). The enhanced entry of aromatic amino acids, in turn, increases the synthesis of serotonin and false neurotransmitters (e.g., octopamine). The increased quantities of false neurotransmitters could theoretically competitively inhibit the normal function of true neurotransmitters. However, although false neurotransmitters do accumulate in PSE, there is no evidence that they are responsible for the encephalopathy. Because the pathogenesis of HE is probably not due to the accumulation of any single cerebral toxin, a multifactorial process is more likely, with the accumulation of multiple substances synergistically contributing to its development.

EPIDEMIOLOGY AND RISK FACTORS. FHF is rare, with an incidence of approximately 2000 cases per year in the United States.¹⁶⁴ Viral hepatitis, usually hepatitis B or hepatitis C, is the most common cause of FHF in the United States and accounts for approximately 75% of cases.¹⁶⁴ Among patients with hepatitis B, approximately 1% develop FHF. Drug-induced liver dysfunction is second in frequency.¹⁶¹ Abnormalities associated with liver disease, such as hypoxia, acid-base disturbances, and electrolyte abnormalities, predispose patients to the development of encephalopathy. Retrospective epidemiological studies have shown a correlation between intracranial hemorrhage and hepatic disease, with the relative risk for intracranial hemorrhage increased approximately fivefold among patients with liver disease.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. The neurological manifestations of HE range from subtle psychomotor abnormalities to coma and death. The exact clinical picture depends on the rapidity of onset, the degree of liver dysfunction, and the degree of portal-systemic shunting. PSE, the much more commonly encountered form, is mostly observed among patients with chronic liver disorders (e.g., cirrhosis). In addition to the neurological features, these patients may have numerous other clinical findings (Table 38-14). PSE is typically precipitated by ammonia-producing processes, such as GI bleeding, increased dietary protein, constipation, and

TABLE 38-14

Clinical Features of Chronic Liver Disease

| SUBJECTIVE | OBJECTIVE |
|-------------------|---|
| Anorexia, fatigue | Jaundice, scleral icterus, Kayser-Fleischer rings (Wilson's disease, primary biliary cirrhosis), fetor hepaticus (musty, sweet breath odor), spider nevi, gynecomastia, caput medusa (dilation of the umbilical vessels), splenomegaly, ascites, xanthomas, palmar erythema, Dupuytren's contractures of the hands and feet |

azotemia. Other known precipitants include infection, hypokalemia, hypoglycemia, hypoxia, and medications (e.g., sedative-hypnotics and analgesics).¹⁶³ Usually, the onset of encephalopathy is slow and insidious, often beginning with anxiety, altered sleep patterns and mood, agitated delirium, or a decreased attention span. Eventually, lethargy progresses to stupor and coma.¹⁶³ Asterixis is almost always present (Video 57, Myoclonus), and as the encephalopathy progresses, increased muscle tone, hyper-reflexia, and extensor plantar responses are commonly noted. As part of the coma, decorticate and decerebrate posturing may also be observed. Unless a superimposed acute event occurs, cerebral edema is uncommon in these patients.¹⁶² Unlike uremic encephalopathy, seizures are infrequent and suggest the presence of a coexistent disorder.

The onset of FHF is much more rapid and is typically associated with severe liver disease. Mental status changes, such as agitation, inappropriate behavior, and impaired judgment, appear early and may quickly progress to stupor and coma. Unlike PSE, cerebral edema with increased ICP is common and may result in cerebral herniation and death. Seizures and focal neurological signs are uncommon and suggest a coexistent process (e.g., subdural hematoma [SDH]).

In addition to developing encephalopathy, some patients with chronic liver disease develop hepatocerebral degeneration, a slowly progressive and irreversible neurodegenerative syndrome associated with extensive portal-systemic shunting. It is characterized by tremor, rigidity, bradykinesia, ataxia, dysarthria, choreoathetosis, and dementia. Studies have shown a selective loss of dopaminergic D₂ (postsynaptic) receptors in the globus pallidus of patients with PSE, suggesting that these extrapyramidal signs may reflect dopaminergic neuronal dysfunction.¹⁶³ Rarely, spinal cord degeneration (hepatic myelopathy), characterized by spastic paraparesis, hyper-reflexia, and extensor plantar responses, is observed.¹⁶⁵ The presence of polyneuropathy has been variably reported. When they are present, these signs are typically mild or asymptomatic. It is not known whether these neuropathic changes are directly related to hepatic dysfunction (e.g., from toxin accumulation) or to the disease process causing the liver impairment (e.g., alcohol abuse and hemochromatosis).

DIFFERENTIAL DIAGNOSIS AND EVALUATION. Any disorder resulting in liver failure may cause HE. Viral hepatitis is the most common cause of FHF in the United States, followed by drug-induced liver dysfunction (e.g., acetaminophen, isoniazid, rifampin, methylidopa [Aldomet], and halothane), fatty infiltration, Reye's syndrome, infiltrative diseases, and less common causes.^{155,164}

Figure 38-3. A 58-year-old patient with hepatic encephalopathy. The patient's EEG demonstrates classic triphasic waves that are more prominent anteriorly. (From Lüders HO, Koechter S: *Atlas und Klassifikation der Elektroenzephalographie*. Baden, Germany, Verlag CIBA-Geigy, 1994, p 118.)

The diagnosis of HE is clinical and depends on the identification of precipitating factors and the observation of a good response to empirical treatment.¹⁶⁶ Unfortunately, there are no pathognomonic features of HE, and all of its typical features may be noted with encephalopathies of other etiologies. Patients suspected of having HE require a thorough neurological examination. Laboratory studies help exclude alternative etiologies of encephalopathy and identify other complications related to hepatic disease. Potentially helpful laboratory studies include a CBC, electrolytes, BUN, Cr, glucose, Ca, drug screen, vitamin B₁₂ level, ABGs, and liver function tests. There is no correlation between the degree of HE and the degree of liver function test abnormality. In fact, liver function tests may be normal in the setting of severe, chronic liver disease. An arterial blood ammonia level should be drawn, placed on ice, and immediately assayed. Venous samples are unacceptable because tourniquet-induced muscle ischemia can result in the release of ammonia from muscle (possible false-positive result), and muscle can take up variable amounts of ammonia, producing false-negative results.¹⁶⁰ Although infrequent, a normal value does not exclude HE, especially in the fasting state.^{162,166} Although its absolute value does not correlate with the degree of HE, the ammonia level is useful in following the individual patient's course and response to therapy.

The EEG typically reveals generalized slowing, and triphasic waves may also be seen. Triphasic waves, although characteristic of HE, are not specific for this disorder and can be observed in a wide variety of encephalopathic states and structural processes (Fig. 38-3). Because the degree of slowing is proportional to the severity of encephalopathy, serial EEGs allow for the assessment of the subsequent clinical course and response to treatment. If the patient is febrile or if meningismus is observed, CSF analysis should be cautiously performed because increased ICP or a coagu-

lopathy may also be present in this patient population. The opening pressure should be recorded and routine CSF studies obtained. In HE, the CSF protein may be mildly elevated, and glutamine levels are usually elevated. The glutamine level has been cited as the biochemical parameter most closely correlated to the degree of HE.^{161,167}

Once HE is diagnosed, the degree of impairment should be clinically graded and used as a baseline for future comparisons. Daily handwriting samples, number connection tests (e.g., trail making), and mental status examinations are helpful in the daily assessment of patients with HE.¹⁶² The most widely used grading system categorizes patients into one of four stages, based primarily on alterations in mentation and the EEG.¹⁶¹ Stage I is characterized by subtle changes in thought processes and personality, such as dyscalculia, poor handwriting, impaired construction of simple figures, difficulty connecting a series of numbers, and sloppiness. At this stage, any abnormalities on the EEG are subtle. In stage II, more obvious changes in thought processes, such as confusion, inappropriate behavior, decreased attention, drowsiness, and abnormal sleep patterns, are noted. Asterixis and hyper-reflexia are usually present, and clonus as well as extensor plantar responses may also be observed. The EEG shows generalized slowing. In stage III, further worsening of thought processes occurs, with confusion and an even shorter attention span. The patient is unable to perform fine motor movements and remains asleep most of the time. Asterixis is present, and the EEG shows more pronounced slowing; in addition, triphasic waves may be observed. In stage IV, the patient is comatose. Brain stem reflexes persist until the deepest stages of coma are reached. The EEG shows generalized delta frequency slowing. ICP monitoring can be helpful in the management of patients in stages III and IV by guiding therapy, facilitating the early detection of rising ICP, and identifying patients with sustained ICP elevations so

that they may be excluded from emergency liver transplantation procedures.¹⁶¹ When ICP monitoring cannot be performed, the patient must be followed closely for evidence of cerebral herniation so that treatment can be provided at a time when the process may be reversible.

In HE, focal neurological features are unexpected and suggest a coexistent structural abnormality (e.g., SDH) or focal metabolic abnormality (e.g., postictal state). In these cases, CT or MRI studies of the head are warranted. In patients with hepatocerebral degeneration, reversible MRI abnormalities, which are most pronounced in the globus pallidus, may be seen. Proton magnetic resonance spectroscopy can be used to detect specific metabolic abnormalities in this region of the brain, thereby constituting an early marker of metabolic alteration.¹⁶⁸

MANAGEMENT. Prevention is an important aspect of treatment among patients with chronic liver disease. Known precipitants of HE should be avoided and, if they are identified, reversed. Because the onset of PSE is slow, insidious, and often subclinical, patients with chronic liver disease should undergo periodic psychometric testing.¹⁶⁹ As many as 70% of patients with cirrhosis and without evidence of an overt encephalopathy have significant impairment when tested.¹⁶⁰ Because the visuospatial sphere is the most frequently affected, the Reitan Trials A and B, Block Design, and Symbol-Digit subtests of the Wechsler Adult Intelligence Scale-Revised, as well as the Purd Pegboard test, are frequently employed and commonly found to yield abnormal results.¹⁶⁰

In the patient with HE, empirical therapy should be initiated while causes of encephalopathy are being excluded and precipitating factors are being sought. Thiamine hydrochloride, 100 mg IV, is administered and should be followed by a daily dosage of 50 mg PO to prevent Wernicke-Korsakoff syndrome.

General measures in the treatment of HE include maintaining adequate nutrition, good renal function, and acid-base status, as well as reducing colonic ammonia production. Because normal brain pH is 6.95 and blood pH is 7.4, there is a tendency for ammonia to enter the brain. By minimizing the interaction between enteric bacterial flora and nitrogenous substances, colonic ammonia production is reduced. Dietary protein restriction, avoidance of constipation, and GI tract evacuation are helpful in this respect. The GI tract is evacuated through the use of cathartics (e.g., lactulose) and enemas. Lactulose is a synthetic disaccharide capable of reducing arterial ammonia levels. In the colon, it is converted into acidic metabolites, which create a pH gradient across the intestinal wall. Colon acidification was thought to select for bacteria that did not contain urease. Instead, colon acidification decreases blood ammonia by trapping it in the acidified feces, thereby making it unavailable for absorption.¹⁷⁰ In addition, the pH gradient causes movement of ammonia into the colon. The dosage is usually titrated to yield two or three soft bowel movements per day, typically requiring 30 to 40 g four times daily. If the patient is comatose, hourly doses of 20 to 30 g are provided until a catharsis is produced, after which the dosage can be reduced.¹⁶⁰ Some patients do not tolerate lactulose, presumably because of the associated contaminants, such as lactose, galactose, and other carbohydrates. Lactitol, another synthetic disaccharide, is better tolerated. It is purer than

commercial lactulose and therefore has fewer adverse effects, such as nausea, diarrhea, and intestinal cramping. Unfortunately, it is more expensive and is not available in the United States. Neomycin, a nonabsorbable antibiotic, kills colonic bacteria and thereby decreases both the bacterial nitrogen content and the synthesis of urea. Compared with lactulose, it has more side effects without increased efficacy. In addition, there is evidence that aminoglycosides contribute to the development of hepatorenal syndrome, and for that reason they are rarely used today. In the setting of neomycin resistance, metronidazole is an alternative. Dietary protein restriction (less than 1 g/kg dry weight of high biological value protein) and the administration of multivitamins, folate and thiamine supplements, vitamin K, and at least 2000 calories per day should be provided.^{164,169} Therapies considered to be nonbeneficial include branched-chain amino acid solutions, serotonin reuptake inhibitors, L-dopa, and bromocriptine.¹⁶³ Sodium benzoate was also shown to reduce blood ammonia levels in a double-blinded and randomized trial of 38 patients with PSE.¹⁷¹ Improvement within 1 to 3 days of starting empirical therapy is expected. Failure to respond suggests the wrong diagnosis, a missed precipitant, multiple causes of the encephalopathy, or, the most common cause, a missed nosocomial infection.¹⁶⁶ In addition to the general measures listed previously, more specific treatments may be required. Orthotopic liver transplantation (OLT) represents an alternative for patients with little chance of recovery.¹⁷² Even in the setting of minimal hepatic encephalopathy, liver transplantation leads to improvement in cognitive functioning, especially attention and memory functions.¹⁷³ Neurologic complications have been reported in 26% of liver transplant recipients (more than 40% when the underlying disorder was alcoholic liver disease or primary biliary cirrhosis).¹⁷² The most common complications are diffuse encephalopathy (11%) and seizures (6%). Other neurologic sequelae include reversible posterior leukoencephalopathy syndrome, osmotic myelinolysis, central nervous system infection, cerebrovascular complications, sensorineural hearing loss, hemorrhagic nerve compression, critical illness myopathy, severe quadriplegia, perioperative mononeuropathies, and herpes zoster-related radiculopathies.¹⁷⁴ The majority of new-onset seizures following OLT were related to immunosuppressive treatment, did not require antiepileptic drug (AED) therapy for favorable long-term outcome, and were not as ominous as previously thought.¹⁷⁵ Viral hepatitis may recur following successful liver transplantation, and although recurrent hepatitis B viral infection can be prevented, recurrent hepatitis C viral infection cannot.

PROGNOSIS AND FUTURE PERSPECTIVES. The mortality rate for patients with FHF, despite aggressive therapy, is approximately 85%.¹⁶⁰ Age, etiology, and degree of encephalopathy influence survival in FHF. Younger patients have a more favorable outcome, with the discriminatory age between 30 and 50 years.¹⁷⁶ Recovery from FHF is expected when the condition is due to hepatitis A and acetaminophen hepatotoxicity, yet the rate is only 40% when it is associated with hepatitis B and 20% when it is associated with hepatitis C or drug-induced hepatitis. When FHF is associated with Wilson's disease, recovery almost never occurs.^{161,177} The recovery rate approaches

75% for patients who do not progress beyond stage II, whereas less than 20% of patients reaching stage IV survive.¹⁶¹ In patients with FHF, death is commonly caused by complications involving other organ systems, two-thirds of which are neurological.¹⁶⁴ OLT has increased the survival rate significantly (50% to 90%) and, in the case of patients with cirrhosis, can normalize their neuropsychiatric status. Ultimately, the prognosis is related to the ability of the liver to regenerate or the availability of livers for transplantation. Regarding the latter, new procedures (e.g., split liver and partial live donor transplants) are increasing liver availability.

Typically, patients with PSE have a good prognosis for full recovery, especially if a precipitating factor can be identified and reversed. When the cause cannot be reversed, continuous therapy is required (e.g., surgical portacaval shunts). Still, the underlying etiology, the occurrence of secondary complications, and the degree of encephalopathy affect survival. Favorable prognosticators include an identifiable and treatable precipitant, mild encephalopathy, and lack of secondary complications.¹⁶⁰

Renal Failure

The kidney is one of the principal homeostatic organs of the body and is involved in the regulation of water, electrolyte, and acid-base balance; the excretion of metabolic waste products; and the synthesis of erythropoietin, renin, and 1,25-DHCC. This section focuses on the neurological manifestations of renal failure, both acute (ARF) and chronic (CRF), and the neurological complications of its treatment.

PATHOGENESIS AND PATHOPHYSIOLOGY. Uremic encephalopathy (UE) regularly occurs when the glomerular filtration rate falls below 10% of normal, regardless of whether it occurs with ARF or CRF.¹⁷⁸ The fact that dialysis can rapidly clear UE suggests that the responsible molecules causing UE are water soluble and small to moderate in size. However, because renal insufficiency causes a spectrum of biochemical abnormalities, the individual significance of any single abnormality is indeterminable.

Although water, osmolality, acid-base, and electrolyte abnormalities are commonly observed in patients with RF, they do not appear to contribute substantially to the development of UE. The brain water content in uremic patients is normal,¹⁷⁹⁻¹⁸¹ and an absence of brain edema in animals with acute uremia¹⁸⁰ further argues against water toxicity as the cause of UE. Although the increase in brain osmolality (from 310 to 350 mOsm/kg water) noted in ARF patients is due to urea, this compound is nontoxic, even at high concentrations.⁶⁵ Among CRF patients, urea constitutes only half of the osmotically active particles, with the unidentified remainder referred to as idiogenic osmoles.¹⁸² The lack of a significant gradient between the blood, CSF, and brain urea concentrations¹⁸³ also argues against osmolality variability as the primary cause of UE.

The accumulation of toxic organic acids in the CNS has been proposed as a possible mechanism of UE.⁷² However, studies of CSF acidity in uremic patients¹⁸⁴ and of acid-base balance in the CSF, blood, brain, and skeletal muscle of uremic dogs¹⁸⁵ have been normal. Although the permeability

of the BBB is increased toward insulin and sucrose, its permeability toward weak acids is decreased.⁶⁵

Cooper and associates¹⁸¹ studied the brains of 10 patients who had died of uremia and noted the brain content to be normal for K, Cl, and Mg; slightly decreased for Na; and approximately doubled for Ca. In experimental uremia, increased brain Ca levels have been associated with an increase in the PTH level.¹⁸¹ In addition, the increase coincided with the onset of EEG abnormalities, with both appearing approximately 2 days after onset of the RF. In a study of 20 dialysis patients with EEG slowing, a direct correlation was noted between the plasma concentration of the N-terminal fragment of PTH and the degree of EEG slowing.^{186,187} Administration of PTH to normal dogs produces EEG changes similar to those seen in uremic animals. The EEG abnormalities, as well as the increased brain Ca, can be prevented by performing a parathyroidectomy before the induction of RF.⁶⁵ PTH accumulation probably affects the Ca pump,¹⁸⁸ suggesting that this hormone is a uremic toxin.¹⁸⁹ Although more recent studies have corroborated the relationship between PTH and brain Ca content abnormalities,¹⁹⁰ the fact that this hormone is not dialyzable argues against it as the uremic toxin responsible for UE. Ca content may be affected by other system abnormalities.

Uremic neuropathy (UN) is the most common neurological manifestation observed among CRF patients. It is pathologically characterized by axon loss. Its pathogenesis is unknown but, like UE, improvement occurs following dialysis, suggesting that the responsible substances are dialyzable. Because some patients experience neuropathic improvement only when their dialysis time is increased, it is postulated that the responsible substances are larger than urea (because larger molecules require more time to cross dialysis membranes). Hypotheses concerning the role of PTH and Ca metabolism in UN have been advanced and are supported by the following features: (1) PTH increases the Ca content of nerve, (2) increased nerve Ca content slows its conduction velocity, (3) the observed slowing is prevented by performing parathyroidectomy before the administration of PTH, and (4) the PTH level is inversely related to the nerve conduction velocity in uremic patients. Like UE, the strongest argument against PTH as the mediator of UN is its nondialyzability. Also, hyperparathyroidism is not typically associated with a neuropathy.

EPIDEMIOLOGY AND RISK FACTORS. In the United States, although the frequency of ARF is low (approximately 30 patients/1 million/year),¹⁹¹ the prevalence of end-stage renal disease increased from 45,000 in 1977 to greater than 165,000 in 1990.¹⁹² In the United States, hypertension and diabetes are the leading causes of CRF.¹⁹² The most important risk factors for the development of UN are the duration and severity of the RF.¹⁸⁶ In recent years, the appearance of neuropathy in chronic hemodialysis patients has become rare,¹⁹³ which is the result of earlier treatment, more intensive dialysis, and technical improvements in dialysis membranes (thinner, with greater clearance properties).¹⁹⁴

CLINICAL FEATURES AND ASSOCIATED DISORDERS. The clinical features of UE are similar to those of other metabolic encephalopathies. The typical progression of clinical features begins with inattentiveness, impaired

concentration, fatigue, apathy, and irritability, which is usually accompanied by motor manifestations (e.g., tremor, asterixis, and myoclonus). Tetany, seizures (focal and generalized), focal neurological signs, and meningeal features are also common.^{133,195} One or more of these features may predominate, and symptom fluctuation is typical. Without treatment, coma develops and Kussmaul breathing may be followed by Cheyne-Stokes breathing. Simultaneous evidence of CNS depression (lethargy, obtundation, and coma) and excitation (agitation, myoclonus, and seizures) are important features of UE.¹⁸⁶ In CRF patients, personality changes and features of polyneuropathy may be the earliest features because the encephalopathic manifestations may not appear until the process is advanced.^{66,195}

Asterixis, first described by Adams and Foley¹⁹⁶ in patients with PSE and later noted by Tyler¹⁹⁷ in uremic patients, is a nonspecific feature of metabolic encephalopathies typically present once higher cortical function is affected.^{198,199} In patients incapable of voluntarily maintaining a posture (e.g., comatose patients), the examiner can position the ankles of a supine patient near the buttocks and observe for abduction-adduction movements at the hip joints (Video 57, Myoclonus).²⁰⁰ Myoclonus is often multifocal and is more common in the deeper stages of encephalopathy.^{194,198} Uremic twitching (severe asterixis with myoclonus) can be continuous and evident during both wakefulness and sleep⁷¹ and may simulate a multifocal seizure disorder,¹⁹⁸ chorea, or ballismus.²⁰¹ Other motor system abnormalities include muscle cramping and tetany, which may be overt or latent.^{186,198}

Seizures, which are relatively uncommon in other metabolic encephalopathies,¹⁹⁴ occur in approximately 25% of patients with UE. The seizures are usually generalized,¹⁹⁴ although focal motor seizures may also be seen.^{186,201} Seizures occur earlier and more frequently (40%) among ARF patients than among CRF patients (10%).¹⁹⁴ In addition, seizures may occur due to dialysis disequilibrium syndrome, hypertensive encephalopathy, water intoxication, or other metabolic encephalopathies.

Unlike the flaccidity characterizing some metabolic encephalopathies, limb tone is usually increased in UE and may even be asymmetrical.^{194,198} As the disorder progresses, opisthotonic or decorticate posturing may be observed.²⁰² Cranial nerve reflexes (e.g., corneal, oculocephalic, and pupillary) are normal, unless the patient is deeply comatose.¹⁸⁶ Sensory examination abnormalities in a stocking-glove distribution and hyporeflexia suggest the presence of UN. Wernicke's encephalopathy has been reported in hemodialysis patients, which is a reflection of the water-soluble, and hence dialyzable, nature of thiamine.

UN is a symmetrical, sensorimotor, axon loss, dying-back (i.e., it has a distal-proximal gradient) polyneuropathy that is clinically indistinguishable from other polyneuropathies that have a stocking-glove distribution. Although lower extremity vibratory sensation impairment²⁰³ and loss of deep tendon reflexes¹⁹⁷ have been reported as early features, suggesting early large fiber involvement, a wide spectrum of clinical patterns has been observed. The sensory aspects of UN were studied, and paradoxical heat sensation (i.e., the perception of heat in response to low

temperature stimulation) was identified in 15 of 36 (42%) patients,²⁰⁴ more than fourfold greater than the normal population.²⁰⁵ Although burning dysesthesias have been frequently cited as a characteristic feature of UN, Asbury has reported them to be rare, a likely reflection of routine supplementation with thiamine and other water-soluble vitamins. Autonomic symptoms, such as orthostasis, impotence, diarrhea, and hyperhidrosis, are commonly reported.²⁰⁶ An acute, flaccid quadriplegia has also been reported.²⁰⁷ The restless legs syndrome (see Chapter 54) occurs in more than 40% of uremic patients^{208–210} and may be a harbinger of polyneuropathy. Although distal lower extremity cramping has also been suggested to herald polyneuropathy, cramps occur in patients without neuropathic features and are more frequent among patients with ARF.¹⁹⁴ Other features reported in uremic patients include myopathy,^{72,211} optic neuropathy, isolated mononeuropathies, flaccid quadriplegia (due to hyperkalemia), and vestibulocochlear and neuromuscular junction disturbances (due to aminoglycoside antibiotics). CTS is another manifestation of uremia that may result from the deposition of amyloid fibrils. The amyloid fibrils are composed of β_2 microglobulin, a substance that is poorly dialyzed and builds up over time in chronically hemodialyzed patients (healthy kidneys are capable of catabolizing β_2 microglobulin). Restless legs syndrome commonly occurs among uremic patients and can be severe enough to interfere with dialysis.²¹² The shoulder joints and carpal bones are frequently involved and abnormalities may be seen on plain films of these areas.

DIFFERENTIAL DIAGNOSIS AND EVALUATION. When patients with known RF present with encephalopathic features, concomitant medical problems, such as DKA, hypertensive encephalopathy, hypertensive intracranial hemorrhage, intracranial abscess, infectious meningitis, primary CNS lymphoma, and hepatic or pulmonary insufficiency, should be sought. Current medications should be reviewed for drugs that are metabolized or excreted by the kidney, especially those known to have neurological manifestations. For patients receiving dialysis treatments, determine (1) the temporal relationship between the last dialysis session and the onset of encephalopathic features, (2) the current dialysis regimen, (3) the occurrence of neurological symptoms with previous dialysis sessions, and (4) the length of time the patient has been undergoing maintenance dialysis. Initial laboratory studies should include CBC with differential, prothrombin time, partial thromboplastin time, electrolytes, BUN and Cr, glucose, liver function tests, Ca, Mg, phosphorus, and urinalysis. Finally, if infection is suspected and a source is not immediately apparent, lumbar puncture for CSF analysis should be performed.

Patients with RF who have focal neurological findings or seizures require additional evaluation with head CT or MRI to evaluate for SDH, intracerebral hemorrhage, infarction, abscess, neoplasm, or other focal processes. An EEG is also helpful and typically shows diffuse slowing (indicative of an encephalopathy), may show triphasic waves (consistent with a metabolic process), and sometimes shows paroxysmal activity that includes spikes or sharp waves.⁶⁸ Electrodiagnostic testing helps characterize an identified polyneuropathy and may be used to monitor the course of disease after dialysis has been initiated.

Secondary hyperparathyroidism should be considered in those patients noted to have proximal extremity muscle weakness and the appropriate laboratories ordered.¹⁹⁴

MANAGEMENT. Because drugs requiring renal metabolism or excretion can accumulate to toxic levels in patients with RF, medication selection is important for the prevention of neurological side effects. In this population, aminoglycoside antibiotics are commonly used but may cause cochlear, vestibular, or neuromuscular junction disturbances. The use of B vitamin supplementation in patients undergoing maintenance dialysis can help prevent UN.

UE requires definitive treatment that is directed toward correcting its cause (e.g., urinary tract obstruction), when possible. Otherwise, dialysis is required to manage fluid, electrolyte, and acid-base imbalances commonly seen in this setting. A nutritionist, to recommend dietary guidelines (e.g., salt and protein), can be very helpful. Because tremulousness, asterixis, and myoclonus tend to resolve as the UE improves, they usually do not require specific treatment. When they are severe, asterixis and myoclonus may respond to clonazepam or valproic acid.

The management of seizures in this patient population warrants separate discussion because changes in plasma protein binding and AED metabolism complicate its management. For highly protein-bound AEDs, such as phenytoin, decreased plasma protein binding increases the percentage of unbound (free, active) drug. Normally, phenytoin is approximately 90% protein bound and 10% unbound, yet in uremic patients the percentage of unbound phenytoin may approach 25% to 75%.^{133,213} Because the rate of AED diffusion into the brain is proportional to the unbound fraction,²¹⁴ the CNS concentration increases²¹⁵ and adjustments may be required. Because the therapeutic range of total phenytoin is 10 to 20 µg/mL and nonuremic patients have 10% in the unbound state, the therapeutic range of free phenytoin is 1 to 2 µg/mL. Therefore, when uremic patients require phenytoin, the required dosage is best determined by following the free phenytoin level. Because phenytoin is not dialyzable, supratherapeutic levels should be used only when necessary for seizure control. A potential for cross-reactivity between phenytoin and its metabolites exists whenever immunological methods are used to determine free phenytoin levels and can result in falsely elevated levels.²¹⁶ For any given phenytoin dose, the drug level is lower in patients with RF,²¹⁷ a reflection of the increased volume of distribution²¹⁸ and rate of metabolism.^{219,220} The rate of metabolism reduces the half-life of phenytoin to 8.1 hours in uremics.²¹⁹ The increased proportion of free phenytoin balances the greater volume of distribution and shorter half-life; thus, the same loading and maintenance doses used in nonuremic patients are used in this clinical situation. However, because the half-life is decreased, a dosage regimen of three times a day is favored over a twice-daily regimen.

Although phenobarbital is renally excreted, it is a useful AED for the treatment of epilepsy in this patient population, provided that sedation can be avoided. Because phenobarbital is only 40% to 60% protein bound, its level can be decreased by dialysis. When phenobarbital is used, a postdialysis serum phenobarbital level should be obtained and a supplemental dosage provided. Valproic acid is useful for myoclonus and generalized seizures. Seizures

occurring during or up to 8 hours after a dialysis run can be a manifestation of the dialysis disequilibrium syndrome. In these patients, prophylactic AEDs are recommended until uremia is controlled.¹⁹⁹ Also, decreasing the blood flow rate and duration of dialysis, increasing dialysis frequency, and administering hypertonic mannitol during dialysis can help with seizure control.

Treatment of the RF improves the UN, and patients with mild UN typically recover completely with maintenance dialysis. Conversely, patients with severe UN rarely recover, even after several years of treatment, and the slowed nerve conduction velocities are only mildly improved by dialysis.¹⁹⁴ Renal transplantation is much more effective at relieving neuropathic symptoms than is maintenance dialysis.^{221,222} NCS show improvement within days of transplantation,²²³ and the improvement continues with complete recovery at times.^{221,222} Neuropathic pain associated with RF can be treated as well with tricyclic antidepressants or antiepileptic drugs (e.g., gabapentin and carbamazepine; see Chapter 20). Uremic optic neuropathy causes rapidly progressive visual loss that responds to hemodialysis and corticosteroid treatment.⁷² Following successful renal transplantation, uremic restless legs syndrome also may resolve. Otherwise, levodopa or a dopamine agonist may be tried. In a small, uncontrolled trial, pramipexole was effective in 9 of 10 patients.²¹²

Neurological Complications of Dialysis

Complications associated with dialysis include dialysis disequilibrium syndrome (DDS), dialysis dementia, SDH, dialysis headaches, exacerbation of migraine headaches, muscle cramping, neurological vitamin deficiency syndromes, ischemic neuropathy due to the presence of an arteriovenous fistula, and CTS (Table 38-15).

DDS refers to a transient form of encephalopathy related to the first few dialysis treatments among profoundly uremic patients. Although its pathogenesis is unknown, it most likely results from a shift of water into the brain (i.e., cerebral edema) in response to the rapid reduction of serum osmolality occurring with dialysis. The duration of symptoms reflects the time required for the brain to decrease its own osmolality. In the predialysis state, idiogenic osmoles allowed the brain to protect itself against dehydration (i.e., it countered the increased serum osmolality). Conversely, in the postdialysis state, this previously protective feature becomes detrimental. Arieff and colleagues¹⁸³ compared different rates of hemodialysis in uremic dogs and showed that the amount of cerebral edema was greater

in the more rapidly hemodialyzed group. This hypothesis is further supported by the appearance of DDS during the early phases of a hemodialysis program rather than after routine maintenance dialysis has begun. This likely reflects the greater net difference between the predialysis and post-dialysis serum concentrations of dialyzable molecules occurring with the earlier dialysis treatments. The onset of DDS is usually during approximately the third or fourth hour of a dialysis run (sometimes up to 24 hours after) and typically lasts several hours. Although DDS is seen in all age groups, it is more common at the extremes of age. Delirium, although infrequently precipitated, often lasts several days.²²⁴ Symptoms of DDS are usually self-limited and include headache, anorexia, nausea, emesis, hypertension, disorientation, tremors, twitching, blurred vision, fatigue, muscle cramps, restlessness, and dizziness.²²⁵ More serious neurological sequelae, such as seizures, coma, and death, were not uncommon before 1970, when aggressive dialysis was used. Uncommon features, including exophthalmos, increased intraocular pressure,²²⁶ papilledema,⁷² and increased ICP, have been reported.¹⁸⁶ If muscle cramping occurs, it may respond to quinine sulfate, 320 mg PO, at the beginning of each dialysis.

The differential diagnosis of DDS includes malignant hypertension, Wernicke's encephalopathy, UE, dialysis dementia, SDH, hyponatremia, hypercalcemia, hypoglycemia, NKHH, hypoxic-ischemic processes, copper and nickel intoxication, and excessive ultrafiltration.¹⁷⁸ DDS may respond to an extension of the dialysis period from 4 to 6 hours or switching to peritoneal dialysis.

Dialysis dementia, also called dialysis encephalopathy, is a rare, subacutely progressive, irreversible, and fatal encephalopathy that was initially described in 1972 in chronic hemodialysis patients.²²⁷ The disorder usually begins with memory problems and dysarthric, stuttering, hesitant speech, progressing to mutism, asterixis, myoclonus, dementia, coma, and death.⁶⁶ The speech disorder is initially intermittent, appearing during and just after dialysis, but eventually becomes permanent.^{71,198} Other features include personality and behavioral changes and occasionally apraxia of speech.⁷¹ Delusions, hallucinations, gait disturbances,⁷² and focal neurological abnormalities¹⁹⁸ may also be seen. Seizures are common and usually multifocal.²²⁸

It is now strongly suspected that dialysis dementia is caused by high brain aluminum content. In 1976, Alfrey and co-workers²²⁹ reported that the brain aluminum content was greater in patients with dialysis dementia than it was in normal controls. Although oral P-binding drugs were initially considered to be the source of exogenous aluminum, this did not explain the geographic variation in the incidence of the disorder. Researchers discovered a difference in dialysate aluminum content among various dialysis centers,²³⁰ and epidemiological studies linked dialysis dementia to municipal water supplies with high aluminum levels.²³¹ However, unexplained sporadic cases in centers with low aluminum dialysate content have been reported.²³¹ The high blood aluminum levels in these sporadic cases suggest that the GI absorption of aluminum (oral P-binding drugs) may occasionally cause this syndrome.

In evaluating these patients, it is important to remember that dialysis dementia is rare and should always be a diagnosis of exclusion. The differential diagnosis includes DDS,

hypertensive encephalopathy, structural lesions (e.g., SDH and stroke), and metabolic encephalopathies such as drug intoxications. Trace element intoxications, decreased glucose, electrolyte disorders (increased Ca and decreased Na or phosphorus), hyperosmolar states, hyperparathyroidism, and UE should also be considered.¹⁷⁸ Changes in dialysis schedule, a change in baseline metabolic status, infection (e.g., dialysis shunt, brain abscess, and hepatitis), and treatable encephalopathies (vitamin B₁₂, folate, and TFTs) can present similarly.²³⁰ Routine laboratory studies, urinalysis, chest x-ray study, and neuroimaging, when focal neurological abnormalities are identified, are also required. If an infectious cause is suspected, CSF examination may be required. The EEG is invariably abnormal, showing characteristic bursts of frontal slowing and epileptiform spikes.

Dialysis dementia does not respond to an increase in weekly dialysis time or renal transplantation. Because deferoxamine crosses the BBB, binds aluminum with greater affinity than do plasma proteins, and results in a dialyzable complex, it can be used to treat this disorder.²³² The CSF aluminum content increases with deferoxamine treatment, a finding that correlates with deterioration,²³⁰ and it has been associated with visual and auditory disturbances.⁷² Several dosing protocols have been reported, and treatment duration has not yet been determined.^{230,233,234} Seizures are treated similarly to those in other patients with RF.

On average, dialysis dementia begins 37 months (range, 9 to 84 months) after hemodialysis is initiated and has an average survival of 6 months (range, 1 to 15 months).²³⁵ However, waxing and waning courses, several-year survivals, and transient symptoms have also been reported.^{236,237} Reports from Europe and the United States have suggested that dialysis dementia might be part of a larger syndrome, including anemia, bone disease, and a proximal myopathy.²³⁸

|---|--|----------------------------------|
| HISTORY AND OVERVIEW | Acetone, Benzene, Carbon Disulfide, and Carbon Tetrachloride | PLANT TOXINS |
| METAL INTOXICATION | GASES | Chickpea (Lathyrism) |
| Arsenic | Carbon Monoxide | Mushrooms |
| Inorganic Lead | Cyanide, Ethylene Oxide, and Nitrous Oxide | BACTERIAL TOXINS |
| Organic Lead | PESTICIDES | Diphtheria |
| Manganese | Organophosphate Insecticides | Tetanus |
| Inorganic Mercury | Organochlorine Insecticides | Botulism |
| Organic Mercury | Other Pesticides: Methyl Bromide, Picrotoxin, and Strychnine | ILLICIT DRUGS |
| Aluminum, Thallium, and Other Metals | ANIMAL TOXINS | Cocaine |
| ORGANIC SOLVENTS | Snake, Scorpion, and Spider Venoms | Amphetamine Analogs |
| Mixed Solvents | Tick Paralysis | Methylenedioxymethamphetamine |
| Methyl Alcohol | Puffer Fish Tetrodotoxin | Opioid Agonists |
| Ethylene Glycol | | Hallucinogens |
| <i>N</i> -Hexane and Methyl- <i>N</i> -butyl Ketone | | Methyl-phenyl-tetrahydropyridine |
| Toluene (Methyl Benzene) | | Phencyclidine |
| Trichlorethylene | | Cannabinol (Marijuana) |

HISTORY AND OVERVIEW

Individual cases of lead poisoning were reported as early as 200 BC. However, it was not until the 20th century that industrialization and modernization resulted in a need for medical evaluation and treatment of health effects caused by exposure to harmful chemicals. To meet this need, a new medical specialty was developed called occupational and environmental medicine. Unfortunately, the number of physicians in this specialty is too few to treat the number of patients requiring evaluation and treatment. Even in academic and workplace settings that offer this expertise, neurological input is paramount because many of the health effects due to chemical exposure are related to the central and peripheral nervous systems. Whereas some health effects such as pulmonary distress and gastrointestinal symptoms are noticed readily by the affected individual, some nervous system effects may be unrecognized. Acute, high-level exposure to a toxicant often results in clearly identifiable signs (e.g., delirium, seizures, or unconsciousness), but the residual effects, involving cognition, mood, and personality, are usually quite subtle. The most common clinical presentation is one of poor concentration, short-term memory loss, depressed mood, anxiety, restlessness, loss of interest in work and hobbies, decreased libido, irritability, headaches, weakness, and sleep disturbances ranging from insomnia to somnambulism.^{1,2} Patients may also report symptoms consistent with peripheral neuropathy.

The diagnosis of neurotoxicant-related damage is one of exclusion for most individuals. Therefore, other causes of central and peripheral nervous system dysfunction must

be ruled out, and a history of significant exposure must be substantiated. The neurological examination, electroencephalogram (EEG), computed tomography (CT) scan, and magnetic resonance imaging (MRI) scan are generally not helpful in making a specific diagnosis of toxic encephalopathy but are helpful in ruling out other causes of the patient's symptoms. In contrast, nerve conduction studies are useful in detecting peripheral neuropathies that are often associated with exposure to specific chemicals. Central nervous system (CNS) effects are best discovered with neuropsychological assessment. However, interpretation of decrements in performance on these tests is often erroneous if made by individuals who lack specific expertise in neurobehavioral toxicology. The reader is referred to Bolla³ for an in-depth discussion of the use and limitations of neuropsychological methods for the detection of alterations in the CNS following chemical exposure.

Once health effects have been detected, it can be problematic to relate these in a causal fashion to a specific chemical exposure. Because biomarkers for many chemicals are either difficult to obtain or do not exist, it is difficult to determine the intensity of current and past exposure, or even if an individual has been exposed to a toxic chemical. In instances of mass poisonings, this association can be made more readily. Also, for the evaluating clinician, knowledge of the patient's baseline neurological function prior to exposure is important to ascertain whether there has been a change in neurological status, but it is rarely available.

Evaluation of the direct toxic effects on the CNS must also be considered in the context of the emotional state and personality characteristics of the patient. Psychological disturbance may be a primary or secondary sequela of chemical exposure. Emotional reactions to exposure may be as important as the direct physiological effects of the chemicals, especially when one is considering the cause and persistence of symptoms. In addition, specific inherent personality characteristics may predispose an individual to the development of physical, cognitive, and psychological symptoms even in the absence of any direct toxic effects on the nervous system. Certain individuals' expectations about the adverse health effects of suspected chemical exposure may result in an enhanced awareness of normal bodily sensations. The degree to which an individual is hypersensitive to endogenous stimuli (normal bodily sensations) may determine the duration and intensity of the symptoms.

This chapter focuses on the clinical manifestations subsequent to exposure to specific chemicals. The reader should be aware that the clinical symptoms reported in this chapter have been described in some studies, whereas other studies have failed to find significant symptoms associated with specific chemicals. In addition, not all symptoms listed for a given chemical are observed in one individual. Therefore, the association between symptoms and exposure to a given chemical is still controversial. In this chapter, the chemicals are organized by class (e.g., metals and organic solvents). Table 39-1 lists the occupations and job-related sources associated with a number of different chemicals. As with any diagnostic process, the ability to make a differential diagnosis between neurotoxicant exposure, neurological disease, psychiatric disturbance, or malingering is based on the combined evidence taken from the occupational, medical, social, and academic histories; the physical and neurological examinations; biological monitoring; nerve conduction studies, EEG, and CT/MRI; and the neuropsychological evaluation.

METAL INTOXICATION

Arsenic

PATHOGENESIS AND PATHOPHYSIOLOGY. Although arsenic is rapidly absorbed through the mucous membranes and the skin, the most common route is ingestion. Arsenic rapidly leaves the bloodstream for storage in the liver, kidneys, intestines, spleen, lymph nodes, and bones, and within 2 weeks it is deposited in the hair, remaining there for years. It also remains in the bones for extended periods of time. Excretion through the kidneys and feces is slow. A single dose may require up to 10 days to be excreted. Pathways involved in oxidative metabolism are sensitive to arsenic toxicity. Arsenic also prevents the transformation of thiamine into acetyl-CoA, causing patients to become clinically thiamine deficient. Organic arsenicals release the poison slowly and are therefore less likely to produce acute symptoms than the elemental form. Neuropathological findings in patients with fatal arsenic encephalopathy include cerebral congestion, multiple hemorrhagic lesions throughout the white matter, and areas of necrosis. Decreased numbers of myelinated fibers are seen in the peripheral

nerves, and degenerative changes, consisting of swelling, granularity, and a reduction in the number of axons, are present.

EPIDEMIOLOGY AND RISK FACTORS. Occupational and job-related sources of arsenic are listed in Table 39-1. The National Institute for Occupational Safety and Health (NIOSH) estimates that approximately 900,000 workers have potential daily exposure to arsenic.

CLINICAL FEATURES AND ASSOCIATED FINDINGS. Acute toxicity is associated with a sudden rise in temperature accompanied by headache, vertigo, nausea and vomiting, nervousness, and apprehension. Convulsions are common. Tendon reflex changes are variable and are frequently exaggerated. Nystagmus, paralysis, or incontinence may also be observed. Kernig's sign is often positive with neck stiffness. Mee's lines (white lines in the nails) usually appear 2 or 3 weeks after acute exposure to arsenic (Fig. 39-1). Encephalopathy with marked excitement followed by lethargy and coma occur, and signs of acute peripheral neuropathy can develop within hours. In patients with fatal acute poisoning, death ensues within a few days. With subacute and chronic arsenic encephalitis, continuous progressive headaches, physical and mental fatigue, vertigo, restlessness, mild somnolence, and focal paresis develop. Spinal cord involvement leads to weakness, sphincter disturbances, motor and sensory impairment, and trophic changes. Optic neuritis manifested by cloudy vision and visual field defects may also be observed subacutely but can be delayed for as long as 2 years. Generally, a mixed sensory and motor neuropathy develops within 7 to 10 days after ingestion of toxic amounts of arsenic, and patients often complain of severe burning in the soles of the feet (Fig. 39-2). Long-standing cognitive changes have been reported.⁴

DIFFERENTIAL DIAGNOSIS AND EVALUATION. Arsenic intoxication is suggested when a patient presents with severe abdominal pain, dermatitis, painful peripheral neuropathy, and seizures. A history of arsenic exposure and toxic levels in the hair, urine, or nails confirm the diagnosis. Arsenic is poorly tolerated in the presence of alcohol. Therefore, patients with alcohol-related disease may be at greater risk for developing associated arsenic neuropathy. Although hair and nails may be useful, urinary arsenic is the major biomarker; Table 39-2 shows the threshold levels. A level of arsenic in urine (24 hour) greater than 50 µg/g creatinine is considered to be elevated. However, a high urinary level may be seen after ingestion of seafood and thus a dietary history should be obtained. If urinary arsenic is elevated and is not fractionated, wait 3 days without seafood intake and repeat. A better measurement can be obtained from the inorganic arsenic metabolites, monomethylarsonic acid and dimethylarsinic acid, in the urine. Although these screening guidelines are clinically useful, arsenic toxicity may occur even when blood and urine concentrations are normal.

MANAGEMENT. In patients with acute oral ingestion of arsenic, gastric lavage with electrolyte replacement is recommended. Also, excretion of absorbed arsenic can be enhanced by chelation using dimercaprol (British antilewisite [BAL]), D-penicillamine, or dimercaptosuccinic acid. Chelators essentially reverse or prevent the attachment of heavy metals to various essential body chemicals. Although chelation may alleviate the acute symptoms, there is no

who develop arsenic encephalopathy, vitamins should be administered to replace nutritional deficits.

PROGNOSIS AND FUTURE PERSPECTIVES. Prognosis with severe arsenic poisoning is poor, with a mortality rate of 50% to 75%, usually within 48 hours. Intoxication during pregnancy carries a particularly poor prognosis. Follow-up studies after acute intoxication are few. A cohort of eight patients with arsenic ingestion at a local festival in Wakayama, Japan, were followed for a 1-year period. A total of 67 patients were exposed to the arsenic. Arsenic intake was calculated from urinary amounts. Each patient underwent peripheral nerve testing at 1, 3, and 12 months. Six patients developed numbness and tingling of the extremities within 2 to 4 weeks. In 3 patients, symptoms were persistent at 1 year. Electrodiagnostic testing revealed a sensory neuropathy and delayed or absent F-wave responses. Motor nerve conduction velocities and compound muscle action potentials were normal. The amount of nervous system involvement was directly correlated with the amount of arsenic ingestion.⁵

Inorganic Lead

PATHOGENESIS AND PATHOPHYSIOLOGY. In the human body, inorganic lead is not metabolized but is absorbed, distributed, and excreted unchanged. The rate of absorption is influenced by nutritional status and age. The amount of lead absorbed increases significantly with iron or calcium deficiency and under fasting conditions. Once absorbed, lead travels bound by erythrocytes. It is then distributed primarily into blood, soft tissues (kidney, bone marrow, liver, and brain) and mineralized tissues (bones and teeth). In adults, approximately 95% of the total body burden of lead is contained in bones and teeth. In conditions of physiological stress, such as pregnancy, lactation, menopause, or chronic disease, lead can be mobilized from the bones, thus increasing the level of lead in the blood. The turnover rate of lead in cortical and trabecular bone is slow; although quantitative estimates of its half-life vary, there is a consensus that it is on the order of years or even decades.⁶ Measures of the bone content of lead thus reflect the integrated or chronic lifetime lead exposure.⁷ Unbound lead is excreted by the kidneys or through the biliary system into the gastrointestinal tract. In single exposed studies in adults, lead has a half-life of approximately 25 days in blood, approximately 40 days in soft tissue, and more than 25 years in bone. Therefore, although a person's blood level may begin to return to normal after a single exposure, the total body burden of lead may still be elevated. For lead poisoning to occur, significant acute exposures are not necessary. Since the body accumulates lead over time and releases it slowly, even small amounts can cause lead poisoning.

The nervous system is the most sensitive target of lead poisoning. Lead encephalopathy has been associated with softening and flattening of convolutions in the brain. Occasionally, punctate hemorrhages, dilation of the vessels, and dilation of the ventricular system are seen, especially in the frontal portions of the brain. Histologically, extensive involvement of the ganglion cells is seen. The developing brain appears to be especially sensitive to levels of lead that were once thought to cause no harmful effects.

TABLE 39-2

Symptoms Associated with Heavy Metal Exposure

| METAL | PROPOSED TOXIC MECHANISM | TISSUE ASSESSED AND TOXIC LEVELS [†] | ASSOCIATED SYMPTOMS | CLINICAL FINDINGS [†] | SPECIFIC TREATMENTS | PATHOLOGY |
|------------------------|--|---|--|--|--|---|
| Aluminum | Decrease in glucose utilization; reduction of acetylcholine | Blood 6 µg/L [†] (NC) Urine (24 hr) 20 µg/L (NC) | Respiratory dysfunction | Cognitive decline; halting speech; ataxia | Deferoxamine (DFO) | |
| Arsenic Acute | Prevents thiamine transformation into acetylcholine; affects pathways involved in oxidative metabolism | Blood, unreliable Urine (24 hr) 50 µg/g creatine (B, D, NC) | GI distress; respiratory distress; cardiac distress; elevated temperature; Mee's lines | Headache; nervousness; vertigo; paralysis, seizures; myelopathy; hyper-reflexia; neuropathy | Chelation; gastric lavage with electrolyte replacement; morphine for abdominal pain; IV fluids for dehydration | Cerebral congestion; white matter hemorrhagic lesions; demyelination of peripheral nerves; reduction in number of axons |
| Chronic | Prevents thiamine transformation into acetylcholine; effects pathways involved in oxidative metabolism | Blood, unreliable Urine (24 hr) 50 µg/g creatine (B, D, NC) | Abdominal pain; dermatitis; increased risk of cancer | Headaches; fatigue; restlessness; vertigo; cognitive decline; visual changes or optic neuropathy; seizures; painful sensorimotor peripheral neuropathy | | Cerebral congestion; white matter hemorrhagic lesions; demyelination of peripheral nerves; reduction in number of axons |
| Lead Acute Children | Changes in neurotransmitters; inhibits NMDA receptor complex | Blood 10 µg/dL [‡] (B, CW) | Respiratory distress | Lethargy; cognitive decline; gait disorder; ataxia; seizures | Removal from exposure; chelation with IV calcium disodium-EDTA, succimer (DMSA), or oral penicillamine | Unclear |
| Adults | Changes in neurotransmitters; inhibits NMDA receptor complex | Blood 30 µg/dL [‡] Urine (24 hr) 150 µg/g creatine (B, CW) Zinc protoporphyrin in blood: 250 µg/dL erythrocytes or 100 µg/dL blood | GI distress; miscarriages; joint pain | Fatigue; delirium; seizures | Removal from exposure; chelation with IV calcium disodium-EDTA, succimer (DMSA), or oral penicillamine | Unclear |
| Chronic Children | Changes in neurotransmitters; inhibits NMDA receptor complex | Blood 10 µg/dL [‡] (B, CW) | Changes in auditory threshold; behavioral problems; cognitive decline; learning disabilities; attention deficit hyperactivity disorder | Learning disorders | Removal from exposure; chelation | Unclear |
| Adults | Changes in neurotransmitters; inhibits NMDA receptor complex | Blood 30 µg/dL [‡] Urine (24hr) 150µg/g creatine (B, CW) Zinc protoporphyrin in blood: 250 µg/dL erythrocytes or 100 µg/dL blood | Miscarriage/stillbirth; arthralgia; anemia; hypertension; gout; renal effects; decreased sperm count | Scotopic visual effects; depression; irritability; sleep disturbance; decline in libido; decreased cognition (learning and memory); fasciculations; paresthesias; sensorimotor polyneuropathy; changes in auditory threshold | Removal from exposure; chelation | Punctate hemorrhages; dilation of vessels and ventricles; involvement of ganglion cells; histological changes in hippocampus and cerebellum; demyelination of peripheral nerves |

| | | | | | | |
|----------------------------|---|--|--|---|---|---|
| Manganese | Promotes formation of cytotoxic free radicals; oxidative stress; mitochondrial toxin | 24-hour urine 3 µg/L (NC); blood 2 µg/dL (NC) | Anorexia; manganese pneumonia | Headaches; apathy; fatigue; depression; hyperexcitability; dysarthria; psychotic behavior; tremor; gait disorders; micrographia; parkinsonism | Removal from exposure; for chronic movement disorders; levodopa, 5-hydroxytryptophan | Histological changes of ganglion cells; damage to substantia nigra and globus pallidus; nerve cell changes in basal nuclei, frontal and parietal cortex, cerebellum, hypothalamus |
| Mercury Inorganic Acute | Alters cell membranes; causes combination of: metabolic disturbance, disturbance of Ca ⁺ homeostasis, oxidative injury, aberrant protein phosphorylation | Blood 15 µg/L [†] Urine 35 µg/g creatine (B, NC) | Bronchial irritation; chills; gingivitis; GI distress; bloody diarrhea; brownish mouth lesions; metallic breath; respiratory distress; renal failure | Weakness; irritability; delirium; psychosis | Removal from exposure | Lesions in cerebral gray matter, cerebellum, brain stem nuclei |
| Chronic | Alters cell membranes; causes combination of metabolic disturbance, disturbance of Ca ⁺ homeostasis, oxidative injury, aberrant protein phosphorylation | Blood 15 µg/L [†] Urine 35 µg/g creatine (B, NC) | Salivary gland swelling; excessive salivation; gingivitis; renal dysfunction | Shyness; fatigue; weakness; personality changes; hyperirritability; insomnia; depression; cognitive decline; visual disturbances; intentional tremor; parkinsonism; seizures; painful paresthesias; peripheral polyneuropathy (sensorimotor axonopathy) | Removal from exposure; chelation | Neuronal loss and gliosis of the calcarine cortex; atrophy of cerebellum, especially inferior vermis |
| Organic | Alters cell membranes; causes combination of metabolic disturbance, disturbance of Ca ⁺ homeostasis, oxidative injury, aberrant protein phosphorylation | Blood 15 µg/L [†] (D, NC) Urine (24 hr) unreliable Hair 50 µg/g | Primarily affects the nervous system | Cognitive decline; neurasthenia; paresthesias; ataxia; restricted visual fields; cortical blindness; peripheral polyneuropathy; intention tremor, motor neuron disease (ALS-like) | Chelation with D-penicillamine, BAL, or DMSA; selenium; vitamin E | Damages primary visual cortex, cerebellar cortex, pre- and postcentral gyri, transverse gyrus, and putamen |
| Thallium | Affects Na ⁺ /K ⁺ -ATPase, porphyrin metabolism and SH groups | Urine (24 hr) 1 µg/g creatine (NC) | GI distress; alopecia | Irritability; fatigue; depression; confusion; movement disorder; optic abnormalities; sensory neuropathy; ascending weakness (Guillain-Barré, polioliike) | BAL; Prussian blue (potassium ferrihexacyanoferrate); combined hemoperfusion and hemodialysis | Ganglion cell changes in cortex; demyelination; axonal degeneration; segmental myelin degeneration in peripheral nerves |

B, present in significant amounts in individuals not occupationally exposed; BAL, British antilewisite; CW, correlates well with clinical symptoms. D, diet significantly influences the measurement; DMSA, dimercaptosuccinic acid; GI distress: nausea, vomiting, stomach cramps; NC, level correlates poorly with clinical symptoms.

EPIDEMIOLOGY AND RISK FACTORS. Lead poisoning has a very long clinical history.⁸ Although lead as an etiological factor was identified as early as 200 BC, it remains a common entity even today. More than 1 million workers in more than 100 different occupations have been exposed to lead (see Table 39-1). In lead-related industries, workers not only inhale lead dust and lead oxide fumes but also may eat, drink, and smoke in or near contaminated areas, increasing the probability of lead ingestion. If the worker does not properly “clean up” before leaving work, he or she can bring lead dust home on his or her skin, shoes, and clothing, thus exposing family members. Sources of lead exposure for nonoccupational populations include air, food, water, certain consumer products, surface dust, and oils. Automobile emissions have been an important source of lead exposure, especially for urban residents. However, the de-lead of gasoline has significantly altered environmental levels of lead. Periodic assessment of national blood lead levels supports this inference. From 1976 to 1978, median blood levels for adults in the United States were approximately 13 µg/dL⁹; in 1991 lead levels were estimated at 6 µg/dL (Environmental Protection Agency, National Advisory Council for Environmental Policy and Technology Committee, 1993). The current major sources of lead in the environment appear to be lead paint in homes built prior to 1950 and lead used in plumbing (which was not restricted until 1986).

Children are especially vulnerable to the effects of lead, especially before the age of 5 years. Elevated lead levels in children are due to pica (compulsive eating of nonfood items) or to the mouthing of items contaminated with lead from paint dust. In addition, children absorb and retain more lead in proportion to their weight than adults. Young children also have a greater prevalence of iron deficiency, a condition that can increase gastrointestinal absorption of lead. Lead absorption from the gastrointestinal tract appears to differ with age. For example, in adults, approximately 10% of ingested lead is absorbed. However, in children, it is estimated that 40% to 50% of ingested lead is absorbed. Fetuses are at risk because lead readily crosses the placenta. Exposure in utero can cause adverse neurological effects in the developing child.

CLINICAL FEATURES AND ASSOCIATED FINDINGS. Acute signs of lead toxicity in children include listlessness, drowsiness with clumsiness, and possibly ataxia. With very high levels of lead, convulsions, coma, and respiratory arrest may occur. Therefore, a diagnosis of lead toxicity in a child should be considered when a child presents with a change in mental status, gait disorder, or a history of seizures. Chronic low-level lead exposure in children may result in behavioral disturbances, learning disabilities, attention deficit hyperactivity disorder, or cognitive decline.

Currently, acute lead encephalopathy due to industrial lead exposure is rare. Symptoms generally include delirium, combative irrational behavior, and seizures. Early signs of lead exposure include sleep disturbances, decreased libido, increased distractibility, increased irritability, and mental status changes marked by psychomotor slowing and memory dysfunction.

Both sensory and motor peripheral nerve involvement are seen in adults with chronic lead intoxication. Sensory

complaints include paresthesias and spontaneous pain. Motor signs include local weakness, atrophy, and fasciculations. In severe cases of lead toxicity, wrist drop and foot drop have been well documented (Video 237, Foot Drop). Extensive bilateral neuropathy involving the hands, fingers, deltoids, biceps, and triceps may also occur. In individuals with predominantly motor findings, nerve conduction velocity may not be altered even after significant occupational exposure. However, in other cases mild slowing in nerve conduction velocity has been reported even in asymptomatic lead workers.

Anemia may be seen in patients with chronically elevated lead levels. Long-term lead exposure may have a direct effect on kidney function¹⁰ and may be associated with hypertension and gout. An association has also been found between lead and homocysteine levels, suggesting that homocysteine could be a mechanism by which lead affects the cardiovascular and central nervous systems.¹¹ Increased frequencies of miscarriage and stillborn births have been documented in women working in the lead trades. Low prenatal lead exposure may produce low birth weight and premature birth. Lead affects the male reproductive system by reducing sperm counts and sperm motility.

In one series of studies, an association was found between the body burden of lead, corresponding to blood lead levels of 25 to 55 µg/dL, and a drop in mean verbal IQ score of 4.5 points in exposed children.^{12,13} In another study of total body burden, primary schoolchildren with high lead levels in teeth but no known history of lead poisoning had larger deficits in psychometric intelligence scores, speech and language processing, attention, and classroom performance than children with lower levels of lead. In a 1990 follow-up report of children who 11 years previously had been found to have elevated lead levels in their teeth, a sevenfold increase was noted in the odds of failure to graduate from high school, lower class standing, greater absenteeism, reading disabilities, and deficits in vocabulary, fine motor skills, reaction time, and eye-hand coordination. In studies of adults, patients with occupational exposure to lead underwent cognitive testing to determine if exposure had effects on cognitive function. A total of 535 patients with known lead exposure were compared to 188 control patients. Tibia lead levels as measured by x-ray fluorescence were directly correlated with diminished performance on tests of visuoconstructive ability, verbal memory, and learning. This study suggests that cognitive function can be affected from early exposure to neurotoxins.¹⁴ Occupational exposure to lead may also be related to longitudinal decline in neurobehavioral function.¹⁵

DIFFERENTIAL DIAGNOSIS AND EVALUATION. The laboratory pattern typical of patients with lead intoxication includes elevations in whole blood lead levels, free erythrocyte protoporphyrins (FEP), and urinary coproporphyrins. The blood lead level reflects more recent exposure to lead, whereas the FEP level tends to reflect more chronic levels of exposure. Blood lead levels greater than 10 µg/dL in children and 30 µg/dL in adults are considered elevated. FEP levels begin to rise in adults once blood lead levels reach 30 to 40 µg/dL. Once elevated, the FEP remains so for several months even after exposure has ceased and the blood lead level has fallen. The threshold blood zinc

protoporphyrin level is 100 µg/dL. Both blood lead level and zinc protoporphyria should be obtained to determine the presence of significant lead exposure. The most widely available method for measuring body burden of lead is diagnostic chelation. Urinary lead excretion is measured after infusion of 1 g calcium ethylenediaminetetra-acetic acid (EDTA). Urinary excretion of more than 600 g of lead over a period of 72 hours is considered elevated. A new noninvasive method of measuring the body burden of lead in bone is x-ray fluorescence (XRF).¹⁶ XRF promises in the future to become the noninvasive gold standard for estimating the total body burden of lead. Except for patients with acute high exposure, an EEG is not generally useful. In addition, neither CT nor MRI reveals any abnormalities. The neuropsychological evaluation may prove useful in assessing specific cognitive deficits in individuals exposed to lead. In some studies, workers with lead blood levels below 30 µg/dL have demonstrated decreased muscle strain and affective complaints as well as decrements in visuomotor integration and psychomotor speed, short-term visual and verbal memory, attention or concentration, and problem-solving skills.¹⁷⁻¹⁹ Nevertheless, it should be noted that a comprehensive review of the published literature on the neurobehavioral performance of individuals exposed to inorganic lead failed to find enough evidence to draw definitive conclusions on the negative influence of lead on human performance on neurobehavioral tests.²⁰

MANAGEMENT. In both children and adults with substantial lead levels, immediate removal from the sources of exposure to lead and administration of chelating agents comprise the treatment of choice. Specific chelating agents for lead include intravenous calcium disodium-EDTA and an oral agent called succimer (dimercaptosuccinic acid; DMSA). Chelation with oral penicillamine may be used (up to 2 g/day). Multiple chelation cycles may be necessary, and at least 24 hours of rest between cycles is suggested. Adequate hydration should be maintained because chelating agents have been associated with renal toxicity and may dramatically increase circulating levels of lead owing to their ability to unbind lead from the bones. DMSA is a relatively new oral chelating agent that is reported to be safer than EDTA and penicillamine. Common side effects are renal sequelae and hypertension. The latest guidelines for treating children suggest starting chelation therapy for children with blood lead levels above 45 µg/dL. Although chelation therapy may reduce symptoms of acute lead poisoning, amelioration of the neurological and renal sequelae of both acute and chronic lead intoxication is less likely. Prevention of lead toxicity in children includes removal of young children from contaminated environments, such as houses with peeling paints. Individuals who work in occupations in which they might be exposed to lead should use mandatory personal protective equipment. Routine monitoring for lead levels is also advised.

PROGNOSIS AND FUTURE PERSPECTIVES. As the work of Needleman and colleagues suggests,¹³ complete recovery of higher cognitive functions may not occur in children with early childhood exposure to lead. Likewise, it is unclear how much CNS function is recovered in adults because research in this area is limited.

Organic Lead

Organic lead (tetraethyl lead; TEL) is used as an antiknock agent in gasoline and jet fuels. TEL is absorbed rapidly from the skin as well as the lungs and gastrointestinal tract and is converted to triethyl lead in the body. This form of lead may be responsible for its toxic effects. Due to its highly lipophilic nature, TEL passes the blood-brain barrier readily. It is soluble in CNS structures, especially the limbic forebrain, frontal cortex, and hippocampus. Symptoms of acute high-level exposure include delirium, nightmares, irritability, and hallucinations. Chronic effects of TEL, as measured by peak tibia lead in organolead workers, were associated with poorer neurobehavioral test scores in the domains of manual dexterity, executive ability, and verbal memory.²¹ Treatment is mainly supportive, but chelation may be helpful.

Manganese

PATHOGENESIS AND PATHOPHYSIOLOGY. Inhalation is the primary source of exposure. Neuropathologically, ganglion cells, including cells of the pallidum, show histological changes. Damage to the substantia nigra has also been seen, as have nerve cell alterations in the basal nuclei, frontal and parietal cortex, cerebellum, and hypothalamus.

EPIDEMIOLOGY AND RISK FACTORS. The neurological syndrome manganism was first described in 1837. Since that time, hundreds of cases have been reported in the medical literature. Mining dust and industry are the primary sources of manganese (see Table 39-1). Like organic lead, manganese is also an antiknock additive in gasoline.

Outside the occupational setting, hospitalized patients receiving total parenteral nutrition (TPN) therapy that includes manganese can develop distinctive T1-weighted hyperintense patterns in the region of the globus pallidum. These apparent lesions disappear after cessation of TPN, but in some patients their presence correlates with clinical signs of parkinsonism and high blood levels of manganese.

CLINICAL FEATURES AND ASSOCIATED FINDINGS. The onset of symptoms is extremely variable from individual to individual and depends on the intensity of exposure, individual susceptibility, and possibly the type of ore involved. Symptoms may appear after only 1 or 2 months or after 20 years of exposure. The earliest signs of manganism include anorexia, asthenia, apathy, somnolence, headaches, and social withdrawal. Personality changes are common and consist of irritability, emotional lability, and periods of hyperexcitability (manganese psychosis). Few cognitive deficits have been substantiated. With continued moderate to high-level exposure, "Parkinson disease-like symptoms" develop, including "masked facies" and bradykinesia. Speech is affected, becoming faint, monotonous, disjointed, occasionally unintelligible, and even mute. Other symptoms include weakness and fatigue, which increase until the worker is unable to go to work. Symptoms are generally confined to the extrapyramidal system, and gait difficulties are observed as retropulsion on rising and propulsion on walking, awkwardness and fine or coarse

tremor of the hands, and gross rhythmical movements of the trunk and head. Micrographia in writing samples may also be evident. Although manganism has certain clinical features in common with idiopathic Parkinson's disease (PD), such as bradykinesia and rigidity, tremors are less prominent, response to levodopa is absent, and lesions in the globus pallidus with sparing of the dopaminergic nigrostriatal pathway make manganism distinguishable from classical PD. Whereas individuals with classic cases of severe manganism have more diffuse signs than those typical of PD, there is a major controversy as to whether chronic low or moderate exposure during occupations such as welding could be a risk factor for typical PD.²² Nevertheless, there are insufficient data supporting an association between welding fume exposure and the development of PD because there are no well-controlled case-control studies investigating the link between welding and PD. It may be difficult to link manganese exposure to PD because welding fumes contain not only manganese but also iron, aluminum, chromium, nickel, and ozone.²³

DIFFERENTIAL DIAGNOSIS AND EVALUATION. Diagnosis requires a history of exposure to manganese in combination with physical findings. Liver failure should be excluded since patients with chronic liver failure may accumulate manganese in the nigrostriatal projections and have associated neurological features of parkinsonism (Video 62, Parkinsonian Gait), gait ataxia (Video 211, Gait Ataxia) plus other neurologic findings, and cognitive and psychiatric deficits.²⁴ Approximately 43% of the body burden of manganese is in the bone. Excretion is biphasic, consisting of a rapid phase with a half-life of 4 days and a second slower phase that has a half-life of 39 days. Methods of biological monitoring are poor, and individual manganese levels in blood and urine do not correlate with either present or past exposure. Diagnostic chelation with EDTA is not useful.

MANAGEMENT. Management involves removal of the patient from exposure. The chronic movement disorder may respond to the use of levodopa and 5-hydroxytryptophan. Patients studied by Mena and colleagues²⁵ responded well to levodopa doses of more than 3 g/day, showing a marked reduction in rigidity and all other symptoms except speech disorders. Traditional chelation therapy has not proved helpful.

PROGNOSIS AND FUTURE PERSPECTIVES. Manganism is usually progressive once the syndrome develops. In the very early stages, symptoms may improve over a period of many months after the patient has been removed from exposure. This improvement is not thought to be correlated with a reduction in the concentration of manganese.²⁶

Inorganic Mercury

PATHOGENESIS AND PATHOPHYSIOLOGY. Elemental mercury is transported in blood plasma, proteins, and hemoglobin. In the appropriate conditions, mercury may be incorporated rapidly into the brain. Once incorporated into the body, mercury can be found in the urine as long as 6 years after exposure has ceased. Inorganic mercury has the greatest affinity for the kidney. Although

concentrations are lower in the CNS, they may still be significant. In the brain, animal studies have shown that the highest concentrations of mercury occur in the brain stem, followed by the cerebellum, cerebral cortex, and hippocampus.

Inorganic mercury exerts its neurotoxic effects by altering membranes. There is a paucity of information on the pathological events resulting from inorganic mercury intoxication. Very few postmortem studies have been published, and results vary from normal to slight neuronal damage with evidence of intracellular mercury.

EPIDEMIOLOGY AND RISK FACTORS. Historically, inorganic mercury compounds have been used as antiseptics, disinfectants, purgatives, and components in the industrial manufacture of felt. Mercury was also used formerly in the form of cinnabar, a red pigment used for painting and coloring. Works of art containing cinnabar can be found in ancient Egyptian and Pakistanian ruins.

By current NIOSH estimates, 65,000 workers are potentially exposed to mercury. The occupations significantly at risk for mercury intoxication are listed in Table 39-1. Mercury is also one of the most serious environmental pollutants in air and water. Between 1953 and 1956, an epidemic of methyl mercury poisoning occurred in Japan when a large number of villagers developed chronic mercurialism (Minamata disease) from ingesting fish contaminated with methyl mercury from industrial waste. There appears to be a wide range of individual susceptibility to the toxic effects of mercury; these may depend on the form of mercury involved, hygiene, diet (including vitamin deficiency), and some intrinsic differences in mercury metabolism. Metallic mercury becomes volatile at room temperature and thus generally enters the body through the inhalation of mercury vapors.

CLINICAL FEATURES AND ASSOCIATED FINDINGS. Acute mercury poisoning usually results from accidental ingestion of an antiseptic in the medicine cabinet. Symptoms of acute inorganic mercury poisoning consist of massive gastrointestinal vomiting and colitis with renal failure. The breath has a metallic odor. A brownish mercurial linear streak may be visible along the margin of the teeth. Symptoms of irritability, rapid onset of weakness in the lower limbs, psychotic episodes with delirium, hallucinations, and motor hyperactivity have been reported. The major threat to these patients is gastrointestinal hemorrhage, but after 24 hours renal failure becomes the predominant cause of morbidity.

Chronic mercury toxicity can result in tremor and weakness of the limbs or progressive personality changes. Mercury-induced tremors, also known as "hatter's shakes" or "Danbury shakes," consist of fine and regular tremors interrupted by much coarser myoclonic jerks. These tremors can be seen at rest and often diminish with activity. In the later stages of intoxication, gait and balance may be altered because of the continuous trembling. In addition, dyskinetic movements, paresis, and convulsions have been reported. Occasionally, these patients present a typical picture of parkinsonism (Video 5, Sensory Ataxia). Mercury can also cause peripheral polyneuropathy (sensorimotor axonopathy), which affects the lower extremities more than the upper ones. Paresthesias with extreme pain or peripheral

neuropathy with muscle atrophy may also occur. Cognitive decline, vertigo, nystagmus, blurred vision, narrowing of the visual fields, optic neuritis, optic atrophy, sensory ataxia with a positive Romberg's sign (Video 98, Romberg Sign), seizures, and vegetative disturbances have also been observed.

Personality changes can develop before neurological signs appear. So-called "mercurial neurasthenia" may develop for weeks or months before the patient seeks treatment. This syndrome consists of extreme fatigue, hyperirritability, insomnia, pathological shyness, and depression. The hyperirritability may become so severe that extremely violent behavior develops, possibly including homicidal acts.

Acrodynia, chronic mercury toxicity in children, is a syndrome consisting of painful neuropathy that involves significant autonomic changes. This syndrome includes redness and coldness in the hands and feet, pain in the limbs, profuse sweating of the trunk, severe constipation, and weakness. Tremors similar to those found in adults and personality changes may also occur. Case reports of children with acrodynia and a syndrome mimicking signs of a pheochromocytoma have been described in association with inorganic mercury intoxication. The mercury may interfere with the normal catabolic processing of catecholamines via the cytosolic enzyme catecholamine-*O*-methyltransferase. Catecholamine-*O*-methyltransferase requires the use of the methyl group provided by coenzyme *S*-adenosylmethionine (SAM). Mercury inactivates SAM and leads to elevated levels of norepinephrine, dopamine, and epinephrine. The elevation of catecholamines leads to the pheochromocytoma-like syndrome.²⁷

DIFFERENTIAL DIAGNOSIS AND EVALUATION.

Serum concentrations of mercury are unreliable indicators of inorganic and organic mercury toxicity because blood levels vary greatly between individuals and in the same individual. The threshold biological exposure index (BEI) for blood is 15 µg/L, and for urine it is 35 µg/g creatinine. However, urinary excretion is not a good measure of toxicity because there seems to be little correlation between symptomatology and the amount of mercury excreted in the urine. Although the early differential diagnosis might include Parkinson's disease, the tremor seen with mercurial intoxication is not solely a resting tremor and is usually coarser than that found in patients with PD. Because the signs of mercury intoxication may mimic those of some common neurological syndromes, the correct diagnosis is dependent on a detailed occupational history, clinical symptomatology, and documentation of mercury in the patient's blood, urine, or hair.

MANAGEMENT. Removal of the patient from the sources of exposure and chelation with *N*-acetyl-D-penicillamine is recommended.

PROGNOSIS AND FUTURE PERSPECTIVES. Most patients with severe mercury poisoning die within a few weeks of symptom onset. Some may survive with major neurological disability. In those with mild or moderate neurological symptoms, improvement may occur within the first 6 months, mostly in children and young adults. Isolated cases have been reported in which bedridden individuals regained the ability to walk, and some children who were totally blind regained vision.

Organic Mercury

PATHOGENESIS AND PATHOPHYSIOLOGY. Organic mercury readily crosses the blood-brain barrier, and its turnover in the brain is slow. In cases of chronic exposure, approximately 10% of the body burden localizes in the brain. Less than 3% is degraded into inorganic mercury. In a single case study, histological changes and high mercurial content were noted in the corpus callosum. Excretion occurs primarily through the gastrointestinal tract, mostly through biliary secretion, and the mercury then undergoes almost immediate gastrointestinal reabsorption into the bloodstream. Neuropathological changes noted in 10 cases included damage to peripheral neurons in the myelin sheath accompanied by glial proliferation and mobilization of phagocytes.²⁸ Anatomically, the most severe damage was found in the primary visual cortex, followed by the cerebellar cortex, the pre- and postcentral gyri, the transverse gyrus, and the putamen.

EPIDEMIOLOGY AND RISK FACTORS. Sources of organic mercury include contaminated seafood or exposure to alkyl mercury (used in antifungal treatment of seed grains). There have been reports of massive intoxications resulting from ingestion of fish containing methyl mercury or from eating homemade bread prepared from seed treated with methyl mercury fungicide. Ingestion of livestock that have been fed grain treated with mercury-containing fungicides is an additional source.

Routes of absorption of organic mercury are primarily dermal and gastrointestinal. Organic mercury is slowly excreted through the kidneys, and its half-life varies from 40 to 105 days. Organic mercury readily crosses the placenta, resulting in blood concentrations in the fetus that are equal to or greater than those in the maternal blood. There have been several reports of fetal methyl mercury poisoning in asymptomatic mothers. Methyl mercury is also secreted in breast milk.

CLINICAL FEATURES AND ASSOCIATED FINDINGS.

The clinical triad of organic mercury toxicity consists of peripheral neuropathy, ataxia, and cortical blindness. There may be a delay of 2 weeks to several months before symptoms appear after mercury exposure. The earliest symptoms may be paresthesias of the extremities, beginning distally and extending in a glove-stocking distribution. Touch and pain sensations are most impaired. Constriction of the visual fields is generally seen.²⁹

In infants born from intoxicated mothers, severe brain damage may develop, including retardation and cerebral palsy. Motor neuron disease resembling amyotrophic lateral sclerosis is another notable and prominent clinical pattern. In these patients, gradual weakness develops with features of both upper motor neuron disease (increased reflexes and prominent jaw jerk) and lower motor neuron disease (fasciculations and atrophy) (Video 45, Tongue Atrophy).

DIFFERENTIAL DIAGNOSIS AND EVALUATION. It is difficult to diagnose mercury toxicity from laboratory data because the blood and urine measurements vary widely. Although measurements in blood and hair are less variable than those in urine, these do not necessarily reflect the degree of mercury toxicity. Hair samples must be collected according to specific protocols. For example, samples must be taken close to the scalp and then washed to remove

contaminants such as hair dyes or hair treatments. The advantage of hair samples is that they provide exposure information for the past year. Hair sample levels are usually 300 to 500 times those seen in blood.

MANAGEMENT. Management of mercury toxicity depends first on eliminating the exposure. Other remedies include the use of mercury-binding chelators such as D-penicillamine, BAL, or DMSA, which may accelerate the excretion of mercury. However, because chelation mobilizes mercury from bones, it may cause the clinical symptoms to become worse and allow further deposits of mercury into the brain (especially BAL). Penicillamine may be more effective in improving the CNS effects of mercury. However, the side effects of penicillamine treatment may include hematopoietic suppression, alterations in cognitive and renal function, symptoms of myasthenia gravis (Video 42, Fatiguability), occasional hepatitis, and allergic reactions such as pruritus and swelling. With chelation, blood concentrations usually begin to decline after approximately 3 days. In asymptomatic individuals with increased blood concentrations of mercury, administration of selenium and vitamin E may prevent the development of symptoms. In patients with mild contractures, physical therapy can be helpful.

PROGNOSIS AND FUTURE PERSPECTIVES. Follow-up of the survivors with Minamata disease years after poisoning revealed decreased bilateral attenuation on CT scans in the visual cortex and diffuse atrophy of the cerebellum, especially the vermis.

Aluminum, Thallium, and Other Metals

See Tables 39-1 and 39-2.

ORGANIC SOLVENTS (Table 39-3)

Mixed Solvents

PATHOGENESIS AND PATHOPHYSIOLOGY. Organic solvents are lipophilic and very volatile. Lipophilicity influences the anatomical distribution of the solvents to organs rich in lipids (brain and adrenals). Lipophilic compounds are eliminated through the kidneys after several osmotic conversions have occurred to make them more water soluble. The resulting metabolites can be more toxic than the original compounds. Reports of synergistic effects between organic solvents and alcohol are found in the literature. Paint “huffers” show signs of acute denervation in the peripheral nervous system and show MRI evidence of brain atrophy involving the cerebellum, brain stem pontine, frontal lobe, and hippocampus.³⁰ At high dose levels, depending on the specific chemical, solvents may act as anesthetics (e.g., trichloroethylene [TCE]), convulsants (e.g., fluorothyl), anticonvulsants (e.g., toluene), anxiolytics (e.g., toluene), antidepressants (e.g., benzyl chloride), and narcotics (e.g., TCE). However, the mechanisms involved in solvent neurotoxicity are generally unknown. For many solvents, it is not known which are neurotoxins, whether or not they require bioactivation to become toxic to the nervous system, and what targets within the nervous system are critical. It is also unknown how the toxic metabolites

produce cellular changes that result in human health effects. A wide variety of mechanisms related to the effects of organic solvents have been proposed. Neurotoxicity may result from effects on neurotransmitters such as dopamine and γ -aminobutyric acid (GABA), although it is not known whether this occurs at specific receptor sites, at the bilipid layer surrounding the receptors, or at ion channels.

EPIDEMIOLOGY AND RISK FACTORS. Due to the proliferation of the plastic and chemical industries, large segments of the population have been exposed to organic solvents. NIOSH estimates that 9.8 million workers have been exposed to solvents in the United States. Since solvents are highly volatile, and volatility corresponds to the amount of solvent that becomes airborne, the respiratory system is the primary mode of solvent absorption. The amount of uptake is modified by workload, respiratory rate, use of respirators, and adequacy of workplace ventilation. Because most solvents that cause health problems are mixtures of solvents, we first discuss the neurological sequelae of exposure to organic solvents in general. Then we describe briefly some of the more highly toxic individual organic solvents. Occupational settings of potential exposure to organic solvents are numerous and are shown in Table 39-1. It appears that the number of workers suffering adverse effects from exposure to organic solvents has decreased. This is due to closer adherence by industry to appropriate levels of safe airborne concentrations as well as to the mandatory use of personal protective equipment by workers. Unfortunately, the abuse of solvents in the form of “huffing” remains a public health concern. In these cases, substances such as paint, airplane glue, and gasoline are placed in plastic bags, which are then placed over the face and inhaled to produce a “high.”

CLINICAL FEATURES AND ASSOCIATED FINDINGS. The digestive, hepatic, renal, and nervous systems are all affected by organic solvents. All solvents have nasal mucosal irritant effects. Symptoms of acute high-level exposure include headache, dysphoria, dizziness, euphoria, excitation, and exhilaration. However, with discontinuation of exposure, symptoms of acute exposure abate within hours. With extremely high levels of exposure such as those obtained during paint huffing, the later stages of intoxication include somnolence and coma followed by death.

Chronic low-level exposure is generally seen in industrial settings. In these cases, development of symptoms is insidious. Headaches are the most commonly reported symptom. Characteristically, these begin soon after arriving at work and disappear at night, on weekends, and during vacations when patients are not in the vicinity of the organic solvents. Other complaints include irritability, personality changes, depression, memory loss, poor attention or concentration, sleep difficulties, decreased libido, and pain and numbness starting in the feet and then progressing to the hands (peripheral neuropathy). Neurobehavioral findings are most notable in activities demanding manual dexterity, executive or motor functioning, and olfaction.³¹

DIFFERENTIAL DIAGNOSIS. Diagnosis of solvent encephalopathy is generally confirmed by the presence of a positive exposure history, objective findings on neurobehavioral tests, and negative findings on neurological examination with the exception of the possible presence of a

TABLE 39-3

Symptoms Associated with Organic Solvent Exposure

| ORGANIC SOLVENTS | PROPOSED TOXIC MECHANISM | TISSUE ASSESSED AND TOXIC LEVELS* | ASSOCIATED SYMPTOMS | CLINICAL FINDINGS | SPECIFIC TREATMENTS | PATHOLOGY |
|--------------------------------------|--|---|---|--|---|---|
| Mixtures | Generally unknown, acts on neurotransmission | Not available | Irritant effects; contact dermatitis | Headaches; fatigue; irritability; depression; sleep difficulties; cognitive decline; decreased olfaction; peripheral neuropathy; myopathy | Removal from exposure | Atrophy (paint huffers) |
| Acetone | Unclear | Urine 50 mg/L | GI distress; irritant effects | Nausea; vomiting; headache; dysphoria; bad dreams; vertigo | Removal from exposure | Unclear |
| Benzene | Increases levels of GABA in cerebellum and pons; increases levels of glutamic acid decarboxylase (GAD); affects porphyrin metabolism | Urine 50 µg/g creatine; exhaled air mixed: 0.08 ppm; <i>S</i> -phenyl-mecapturic acid in urine 20 µg/g creatinine; +, + muconic acid in urine 500 µg/g creatinine | Increased risk of cancer; pancytopenia | Ataxia; inebriation; muscular twitching; paralysis; seizures; unconsciousness; peripheral neuropathy in cases with associated toluene exposure | Removal from exposure; lecithin, vitamin C, pentanucleotide, folic acid, pyridoxine | Denervation and clinical atrophy |
| Carbon Disulfide | Alkylation of proteins | Urine 5 mg/g creatine | Pulmonary and dermal irritant; cardiac effects; toxic threshold lowered in alcoholism, diabetes mellitus, renal/hepatic disease | Headache; irritability; cognitive decline; psychosis; delirium; hearing loss; loss of corneal reflex; parkinsonism; peripheral polyneuropathy | Removal from exposure | Chromatolysis and vacuolation in frontal lobe, globus pallidum, and putamen; peripheral nerve myelin swelling and fragmentation |
| Carbon Tetrachloride | Unclear | Not available | GI distress; hiccups; liver and kidney damage; toxic threshold lowered in alcoholism, obesity, diabetes, liver and kidney disease | Intoxication; headaches; vertigo; delirium; seizures; parkinsonism; optic atrophy; visual difficulties | Calcium gluconate and hemodialysis | Purkinje cell damage; cerebellar venous thrombosis and hemorrhagic infarcts; brain edema; neuronal loss; astrocytosis |
| Ethylene Glycol | Metabolized to aldehydes and oxalate | 100 mL | Renal effects; cardiopulmonary effects | Restlessness; agitation; seizures; absent corneal reflexes; coma | Early dialysis to correct acidosis | Cerebral edema; vascular engorgement; hemorrhage |
| Methyl Alcohol (Methanol) | Oxidation to formaldehyde and formic acid | Urine 15 mg/L (<i>B, NS</i>); formic acid in urine 80 µg/g creatine (<i>B, NS</i>) | GI distress | Headache; weakness; incoordination; delirium; hallucinations; visual loss; stupor; seizures; parkinsonism; death | Administration of ethyl alcohol, folic acid, or bicarbonate; frequent measures of blood methanol, CO ₂ , bicarbonate, and PH; monitor serum potassium; peritoneal/hemodialysis | Shrinkage and degeneration of neurons, primarily in parietal cortex |
| Methyl- <i>N</i> -Butyl Ketone (MBK) | Metabolized to 2,5-hexanedine | No specific findings | Euphoria | Weight loss; sensorimotor polyneuropathy | Removal from exposure | Multifocal axonal degeneration; myelin thinning |

Continued

TABLE 39-3

Symptoms Associated with Organic Solvent Exposure—cont'd

| ORGANIC SOLVENTS | PROPOSED TOXIC MECHANISM | TISSUE ASSESSED AND TOXIC LEVELS* | ASSOCIATED SYMPTOMS | CLINICAL FINDINGS | SPECIFIC TREATMENTS | PATHOLOGY |
|--------------------------|--|--|---|---|-----------------------|--|
| <i>N</i> -Hexane | Metabolized to 2,5-hexanedine; inhibits glycolytic enzymes | Urine 5 µg/g creatinine (<i>NS</i>) | Euphoria | Headaches; poor appetite; mild euphoria; mostly peripheral polyneuropathy | Removal from exposure | Degeneration of peripheral nerve axons |
| Toluene (Methyl Benzene) | Toxic effects similar to benzene | Hippuric acid in urine 1.6 g/g creatine (<i>B, NS</i>); venous blood 0.05 mg/L <i>O</i> -cresol in urine 0.5 mg/L | Pulmonary effects; cardiac effects | Euphoria; fatigue; ataxia; dizziness; tremor; cognitive decline; seizures; delirium; decreased olfaction; optic atrophy; hearing loss; peripheral neuropathy (in cases w/associated <i>N</i> -hexane exposure); alcohol intolerance | Removal from exposure | Cortical and cerebral atrophy |
| Trichloroethylene (TCE) | Unknown; toxic effects potentiated by alcohol | Trichloroacetic acid in urine 100 mg/g creatine (<i>NS</i>) Trichloroacetic acid and trichloroethanol in urine 300 mg/g creatine (<i>NS</i>) Blood free trichloroethanol in blood 4 mg/L (<i>NS</i>) | Cardiopulmonary effects; toxic threshold reduced with alcohol | Headaches; insomnia; fatigue; anxiety; trigeminal nerve damage; neuro-ophthalmological findings; alcohol intolerance; cognitive decline; hearing loss; peripheral neuropathy | Removal from exposure | Myelin and axonal degeneration |

*Biological exposure indices. American Conference of Governmental Industrial Hygienists (ACGIH) values from ACGIH: Threshold Limit Values and Biological Exposure Indices 2001. Cincinnati, OH, ACGIH, 2001. *B*, present in significant amounts in individuals not occupationally exposed; *GABA*, gamma-aminobutyric acid; *NS*, nonspecific, may be observed after exposure to some other chemicals.

polyneuropathy (Video 259, Sensory Polyneuropathy). There are few reliable or easily attainable biomarkers of solvent exposure. Therefore, this diagnosis is often one of exclusion. The differential diagnosis includes other neuropathological conditions (e.g., cerebrovascular disease and tumor), heavy alcohol use, and neuropsychiatric disorders (e.g., affective disorders, anxiety, and somatoform disorders). Often, individuals who have been exposed to chemicals with strong odors misinterpret normal body sensations as pathological symptoms. Subsequently, these symptoms are misattributed to chemical exposure because of reports by the news media exaggerating the dangers of commonly encountered environmental chemicals.

EVALUATION. In 1985, an attempt was made to develop a rating classification system for individuals who were exposed to organic solvents. The following categories were proposed: Type I—Subjective nonspecific symptoms only. Patients complain of fatigue, memory and concentration difficulties, and changes in mood and sleep patterns. However, there is no objective evidence of neurobehavioral dysfunction. After discontinuation of exposure, symptoms completely disappear within 6 months to 1 year. Type Iia—Sustained personality and mood change. Affective changes are noted. These include depression, aggressiveness, fatigue, poor impulse control, and anhedonia. Neurobehavioral findings are negative. It is unclear if these symptoms are reversible. Type Iib—Impairment of intellectual function documented by objective neurobehavioral test results with possible mild neurological signs. Difficulty in concentration, memory loss, and a decline in learning capacity may be objectively detectable. After removal from exposure, these symptoms may remain stable or improve but should not become worse. Type III—Dementia, with neurological signs and/or neuroradiological findings. Neurobehavioral test results are significantly affected. Type III is related to repeated severe exposure (e.g., paint huffers). It is poorly reversible but generally does not progress once exposure is stopped.³²

Nerve conduction studies can be extremely useful because many organic solvents affect the peripheral nervous system (PNS) before the CNS. Sensory polyneuropathy, more pronounced in the feet than in the hands, is characteristic of exposure to chronic organic solvents.

MANAGEMENT. Management consists of removal from the source of exposure. In addition, the anxiety and depression typically seen in these individuals can be treated with psychotropic medications and supportive psychotherapy.

PROGNOSIS AND FUTURE PERSPECTIVES. Once removed from the source of exposure, symptoms should remain stable or improve over time. However, deterioration in function is often seen and can be attributed to psychological disorders that develop secondary to the organic solvent exposure.

Methyl Alcohol

Methyl alcohol (methanol, wood alcohol) is used as a solvent, a component of antifreeze, and an adulterant of alcoholic beverages. Although this chemical is only mildly toxic, it is oxidized to formaldehyde and formic acid, which produce severe acidosis and are responsible for the symptoms of methanol abuse. Neuropathological changes

in the form of shrinkages and degeneration of neurons, primarily in the parietal cortex, have been reported.³³ The oxidation and excretion of methyl alcohol is so slow that toxic symptoms do not develop for 12 to 48 hours, although they may last for several days. Once apparent, toxic symptoms involve the visual apparatus, CNS, and the gastrointestinal and respiratory tracts. Early symptoms include nausea, vomiting, weakness, abdominal pain, vertigo, and headache. Additional symptoms may include restlessness, uncoordination, and, in severe cases, delirium and hallucinations. Confusion and memory deficits are also reported. In severe cases, stupor, coma, tonic muscle contractions, hyperactive reflexes, visual loss, Parkinson-like extrapyramidal syndrome, and convulsions may also be seen. In the most severe cases, death occurs from respiratory failure.

Treatment involves frequent measurements of blood methanol, carbon dioxide, bicarbonate, and pH. Ethyl alcohol may be administered to retard the conversion of methanol into toxic formaldehyde and formic acid. Bicarbonate can be given to correct severe acidosis. Serum potassium levels should be monitored because bicarbonate tends to decrease potassium. Administration of folic acid may accelerate the metabolism of formic acid to carbon dioxide. Either peritoneal dialysis or hemodialysis can be used in patients with methanol blood concentrations higher than 50 mg.

Ethylene Glycol

Antifreeze is the most common source of ethylene glycol. Due to its inebriant properties, ingestion of ethylene glycol can be fatal and accounts for approximately 40 to 60 deaths per year. Although ethylene glycol is not toxic, it metabolizes to aldehydes and oxalate. The toxic dose is approximately 100 mL, and death is due to renal or cardiopulmonary mechanisms. After ingestion, symptoms may appear rapidly or may take hours to develop. Initial symptoms include restlessness and agitation, followed by somnolence, stupor, coma, and convulsions. The patient becomes cyanotic, pupils are nonreactive, and corneal reflexes are absent. In milder cases, fatigue, personality change, and depression are present. Ethylene glycol poisoning should be suspected when an apparently inebriated patient has no alcohol on the breath. Neuropathological changes have been reported and include cerebral edema, vascular engorgement, and hemorrhage. Treatment consists of correcting the acidosis and using early dialysis to remove the ethylene glycol, oxalate, and aldehyde and also treat the associated uremia. Patients with ethylene glycol intoxication who present with normal creatine levels and an absence of metabolic acidosis may benefit from administration of fomepizole without hemodialysis.³⁴

N-Hexane and Methyl-N-butyl Ketone

N-Hexane is a component of a number of glues. Therefore, exposure is likely to come from inhalant abuse. With acute exposure, N-hexane causes euphoric effects. Pronounced peripheral polyneuropathy may occur after chronic intoxication. Hexane is metabolized to 2,5-hexanedione, which is responsible for much of the neurotoxicity related to this compound.

Unlike toluene, hexane does not produce significant central neurological symptoms. Lightheadedness, headache, decreased appetite, and mild euphoria as well as occasional hallucinations may occur acutely, but seizures and delirium are not associated with *N*-hexane exposure. The predominant neurological feature of *N*-hexane exposure appears to be peripheral neuropathy. Symmetrical sensory dysfunction in the hands and feet is the usual presenting complaint. Decreased response to pin, vibration, and thermal stimulation is found on examination. Glue huffers may develop proximal weakness. The most prominent electrophysiological feature is slowing of motor and nerve conduction velocities, which occurs in proportion to the intensity of clinical disease.³⁵

More recent concerns regarding *N*-hexane and petroleum derivatives have focused on parkinsonism. Cases of well-described intoxication have been associated with rigidity, bradykinesia, tremor, and postural reflex compromise. A large cohort of patients with clinically diagnosed PD were screened for hydrocarbon exposure. Of the 990 interviewed, 188 patients reported hydrocarbon exposure, and these patients were age and gender matched to patients with no reported exposure. The patients with exposure as determined by an industrial hygienist had an earlier onset age and more motoric impairment than the control patients.³⁶ Furthermore, animal experiments demonstrate that *N*-hexane exposure lowers brain dopamine and homovanillic acid, the central metabolite of dopamine.³⁷ Because *N*-hexane is a common environmental contaminant and hydrocarbons can be by-products of endogenous metabolic pathways, these compounds are a focus of pathogenic research efforts in movement disorders. Although chemically dissimilar from carbon disulfide, *N*-hexane is metabolized to the γ -diketone 2,5-hexanedione, which induces histologic neurofilament-filled swelling in distal axons of the CNS and PNS similarly to carbon disulfide. This observation suggests that these two neurotoxins may share some pathogenic features and serve as a unifying model for the study of chemicals that adversely affect both PNS and CNS axons.

Methyl-*N*-butyl ketone (MBK) is used as a paint thinner, cleaning agent, and solvent for dye printing. Exposure to MBK is associated with sensorimotor polyneuropathy, which may begin several months after continued chronic exposure. In the later stages, axonal degeneration occurs distally.

There is no specific treatment for *N*-hexane and MBK neuropathy other than removal from the source of exposure. After removal, recovery (regeneration of peripheral nerve axons) may occur over a period of weeks.

Toluene (Methyl Benzene)

Toluene is a widely used solvent and is employed as a paint and lacquer thinner and as a cleaning and dyeing agent. It is also a constituent of motor and aviation fuels. Toluene is a major constituent of the glue used by paint huffers and has thus been implicated as the chemical responsible for the neurotoxic syndrome seen in this group of solvent abusers. Toluene's toxic effects are similar to those of benzene, although more mental status changes are seen.

With acute exposure, clinical signs include early exhilaration followed by fatigue, mild confusion, ataxia, and dizziness. With chronic use, exhilaration, euphoria, disinhi-

bition, and tremor are common. Neurobehavioral effects include declines in performance IQ, decreased memory, poor motor control, decreased visuospatial functioning, and dementia.³⁸ Toluene appears to affect the CNS more readily than the PNS. Treatment primarily involves removal from exposure.

Trichlorethylene

TCE is used extensively in dry cleaning and for degreasing metal parts and extracting oils and fats from vegetable products. It is also used as an adhesive in the leather industry and occasionally in medicine as an anesthetic. A number of workers have become addicted to the fumes since deliberate inhalation produces rapid euphoria. Fatalities resulting from bronchial constriction, pulmonary edema, and myocardial irritation have been reported.

TCE toxicity is associated with cranial and peripheral neuropathies. Mixed sensory and motor involvement of the trigeminal and facial nerves is characteristic of high-level TCE exposure. Neuro-ophthalmological findings include retrobulbar neuropathy, optic atrophy, and oculomotor disturbances. Peripheral neuropathy is common, usually mixed and predominantly distal. Neuropathological examination has revealed extensive myelin and axonal degeneration. TCE may act as a demyelinating agent because of its lipid solvent qualities. The effects of TCE appear to be potentiated by alcohol.

Clinically, a history of possible TCE exposure should be investigated in any patient with trigeminal neuralgia or trigeminal dysfunction. Long-term exposure or acute high-level exposure also produces disturbances in memory. When a human volunteer was exposed to 2, 3, and 500 ppm for more than 2 hours, his major complaint was drowsiness.³⁹ At 500 ppm, however, a pronounced decrease in neuropsychological functioning was observed. General CNS symptoms include headaches, dizziness, fatigue, alcohol intolerance, neurasthenia, anxiety, and insomnia. Neurobehavioral effects include poor concentration and memory, decreased manual dexterity and visuospatial accuracy, and a slowed reaction time. As with the other organic solvents, treatment primarily involves removal from exposure.

Acetone, Benzene, Carbon Disulfide, and Carbon Tetrachloride

See Table 39-3.

GASES (Table 39-4)

Carbon Monoxide

PATHOGENESIS AND PATHOPHYSIOLOGY. Carbon monoxide enters the bloodstream through pulmonary absorption and binds reversibly to hemoglobin. The affinity of hemoglobin for carbon monoxide is approximately 225 times greater than that for oxygen. Thus, exposure to carbon monoxide resulting in increased carboxyhemoglobin decreases the amount of oxygen carried by the red blood cell. This results in pronounced tissue oxygen deprivation. Pathoclinical correlates generally show globus pallidus lucency and atrophy on CT scan (Fig. 39-3).⁴⁰ Diffusion-

TABLE 39-4

Symptoms Associated with Exposure to Gases

| GAS | PROPOSED TOXIC MECHANISM | TISSUE ASSESSED AND TOXIC LEVELS* | ASSOCIATED SYMPTOMS | CLINICAL FINDINGS | SPECIFIC TREATMENTS | PATHOLOGY |
|-----------------|--|--|--|--|--|--|
| Carbon Monoxide | Binds to hemoglobin, creating tissue oxygen deprivation; mitochondrial toxin | Blood 3.5% of hemoglobin Exhaled air 20 ppm | None | Headaches; irritability; dizziness; cognitive decline; impaired vision; blindness; deafness; seizures; parkinsonism; coma | Removal from exposure; 100% oxygen; hyperbaric oxygen | Cerebral atrophy; globus pallidus lucency |
| Cyanide | Mitochondrial toxin | Blood 0.2 µg/L Urine thiocyanate level | Bitter almond taste; mucosal irritation; GI distress; cardiopulmonary distress | Agitation; panic attacks; headaches; dizziness; decreased consciousness | Administration of antidote; supportive ventilation | Demyelination and cellular damage in stratum cortex and cerebellum |
| Ethylene Oxide | Not known | Not established | Skin lesions; mucosal irritation; pulmonary edema; GI distress | Headaches; nausea; vomiting; decreased level of consciousness; peripheral neuropathy; axonal degeneration | Removal from exposure | Axonal neuropathy |
| Nitrous Oxide | Interferes with cobalamin-dependent enzymatic reactions | Not established | Vitamin B ₁₂ deficiency | Decline in manual dexterity; cognitive decline; polyneuropathy; axonal degeneration; gradual progressive numbness in extremities followed by weakness, gait disturbance, and loss of sphincter control | Removal from exposure; good nutrition; vitamin B ₁₂ treatment | Axonal degeneration |

*Biological exposure indices. American Conference of Governmental Industrial Hygienists (ACGIH) values from ACGIH: Threshold Limit Values and Biological Exposure Indices for 1994–1995. Cincinnati, OH, ACGIH, 1994.

Figure 39-3. CT scan from a patient with carbon monoxide intoxication showing cystic lucencies in both globus palladi. (From Klawans HL, Stein RW, Tanner CM, Goetz CG: Pure parkinsonian syndrome following acute carbon monoxide intoxication. *Arch Neurol* 1982;39:302.)

weighted imaging may be useful for early identification of pallidoreticular damage in acute carbon monoxide poisoning.

EPIDEMIOLOGY AND RISK FACTORS. Carbon monoxide is an odorless, nonirritating gas, acute exposure to which accounts for more than 3000 accidental or suicidal deaths each year and 10,000 episodes of illness. Industrial sources include portable kerosene heaters, hot water heaters, and furnaces. At home, inadequately vented fireplaces are a common source. However, the major source of carbon monoxide is automobile exhaust fumes, which have concentrations of approximately 50,000 ppm. Although cigarette smoke may be a major source of carbon monoxide, it is diluted with air, making it significantly less toxic. The threshold limit value of carbon monoxide is 50 ppm, which causes a carboxyhemoglobin saturation of 8% to 10% after an 8-hour exposure. Carboxyhemoglobin levels of more than 50% are considered threatening, and levels of 70% to 75% are usually fatal. Saturation may be obtained by either very high acute exposure or prolonged exposure to lower concentrations.

CLINICAL FEATURES. Neurological signs of mild carbon monoxide poisoning include dizziness, headache, and impaired vision. As poisoning becomes more severe, symptoms develop into severe throbbing headaches, convulsions, and coma. Persistent chronic exposure, as occurs with inadequately vented heaters in the home, leads to blindness, deafness, pyramidal signs, extrapyramidal signs, and convulsive disorders.

Mild neurological effects may be transient to persistent and may appear immediately or days to weeks following exposure.⁴⁰ Behavioral and psychiatric changes include irritability, violent behavior, personality disturbances, euphoria, confusion, and impaired judgment. Neurobehavioral

sequelae include difficulties with visual and verbal memory, spatial deficits, and declines in cognitive efficiency and flexibility.⁴¹ Parkinsonism has also been reported after acute and chronic exposure (Video 41, Carbon Monoxide Intoxication Parkinsonism).

DIFFERENTIAL DIAGNOSIS AND EVALUATION. Both clinical symptoms and a history of exposure to carbon monoxide are necessary for a diagnosis. In suspected cases of carbon monoxide exposure, blood levels of carboxyhemoglobin can be determined. However, the current level of carbon monoxide in the blood is not indicative of the severity of poisoning because carboxyhemoglobin may rapidly decline after exposure ceases. If a patient dies of carbon monoxide poisoning, however, the level of carboxyhemoglobin determined at postmortem represents the actual level of carbon monoxide at the moment of death since carbon monoxide cannot be excreted without active respiration.

MANAGEMENT. Treatment involves removal of the patient from the contaminated environment as well as administration of 100% oxygen. Hyperbaric oxygen reduces the half-life of carboxyhemoglobin to less than 25 minutes and is considered the treatment of choice for all patients with severe carbon monoxide intoxication. However, CNS oxygen toxicity is a potential risk of hyperbaric oxygen therapy. Additionally, hypothermia has been advocated to decrease the tissue demands of oxygen. Patients may be covered in ice for 8 to 12 hours at a temperature of 30°C to 32°C.

PROGNOSIS AND FUTURE PERSPECTIVES. The prognosis for patients with significant carbon monoxide poisoning varies. However, follow-up has shown the presence of neurological sequelae, consisting of cortical blindness, seizures, cognitive impairment with amnesia, polyneuropathy, and a parkinsonian syndrome. In a follow-up study performed 3 years after carbon monoxide poisoning, 43% of patients had impaired memory, 33% showed a deterioration of personality, and 13% showed neurocognitive deficits.

Cyanide, Ethylene Oxide, and Nitrous Oxide

See Table 39-4.

PESTICIDES (Table 39-5)

Organophosphate Insecticides

PATHOGENESIS AND PATHOPHYSIOLOGY. Organophosphates inhibit acetylcholinesterase and pseudocholinesterase. Insecticides that are cholinesterase inhibitors include chlorpyrifos (Dursban), diazinon, malathion, ethyl and methyl parathion, and trichlorofon.⁴² The neurotoxicity of these compounds is related to their ability to inhibit acetylcholinesterase, which occurs in the brain, spinal cord, myoneural junctions, pre- and postganglionic parasympathetic synapses, and preganglionic and some postganglionic sympathetic nerve endings. The resulting increase in acetylcholine overstimulates the postsynaptic receptors in the cholinergic system, thus differentially stimulating nicotinic receptors (skeletal muscle and autonomic ganglia) and muscarinic receptors (secretory glands and postganglionic fibers in the parasympathetic nervous system).

TABLE 39-5

Symptoms Associated with Pesticide Exposure

| PESTICIDE | PROPOSED TOXIC MECHANISM | TISSUE ASSESSED AND TOXIC LEVELS* | ASSOCIATED SYMPTOMS | CLINICAL FINDINGS | SPECIFIC TREATMENTS | PATHOLOGY |
|-----------------------|--|---|---|---|--|---|
| Methyl Bromide | | Blood 2.8 µg/dL | Pulmonary and dermal irritant; renal effects; pulmonary effects; cardiac effects; GI distress; garlic or rotten fish odor | Mania; hallucinations; delirium; headache; vertigo; cognitive decline; amnesia; aphasia; incoordination; myoclonus; tremors | Removal from exposure | Affects cortical, cerebellar, and basal ganglia structures |
| Organochlorines (DDT) | Excessive and spontaneous release of acetylcholine | | Metallic taste; thirst; burning eyes | Resembles Reye's syndrome in children; drowsiness; optic neuropathy; night blindness; tremors; seizures; mononeuropathy; polyneuropathy | Anticonvulsants for patients with seizures | With chlordecone, electron-dense particle accumulation in Schwann cells |
| Organophosphates | Inhibits acetylcholinesterase and pseudocholinesterase | Blood low cholinesterase activity (70% of baseline) | GI distress; excessive sweating and salivation; hypothermia; liver dysfunction | Headache; fatigue; dizziness; decreased consciousness; sleep disturbance; cognitive decline; blurred vision; absent pupillary response; muscular fasciculations; tremor; delayed polyneuropathy (OPIDP) | Administer atropine sulfate and pralidoxime | Axonal neuropathy and nonspecific CNS changes |
| Strychnine | Central analeptic agent; GABA antagonist; postsynaptic inhibitor | | GI distress; respiratory failure | Irritability; excitement; decreased consciousness; paresthesias; muscular stiffness; fasciculations; seizures; rigidity | Respiratory support; seizure prevention; administer diazepam; morphine and apomorphine are contraindicated | Small subarachnoid hemorrhages; capillary proliferation; demyelination |

*Biological exposure indices, American Conference of Governmental Industrial Hygienists (ACGIH) values from ACGIH: Threshold Limit Values and Biological Exposure Indices for 1994–1995. Cincinnati, OH, ACGIH, 1994. CNS, central nervous system; GABA, gamma-aminobutyric acid; GI, gastrointestinal.

EPIDEMIOLOGY AND RISK FACTORS. Organophosphate insecticides are highly toxic to insects but are relatively less so to humans and domestic animals. Although specific organophosphates, such as triorthocresyl phosphate, nipafox, and trichlorofon compounds, are obviously neurotoxic, the situation is less clear for other organophosphate pesticides. At risk are factory workers involved in the production of these compounds and agricultural workers who use them to spray crops. The occurrence of organophosphate poisoning in the United States is low, although epidemics have been reported in some Third World countries. It should be noted, however, that 3011 pesticide-related cases were reported in California and Washington between 1993 and 1998. California accounts for approximately one third of the agricultural workforce in the United States. Organophosphates are absorbed through the skin and respiratory tracts. In addition, small amounts may be ingested by eating foods that have been sprayed with organophosphates.

CLINICAL FEATURES AND ASSOCIATED FINDINGS. Clinically, patients with acute mild symptoms complain of vague fatigue, headache, dizziness, increased salivation, nausea and vomiting, diaphoresis, and abdominal cramps. Symptoms always develop within 24 hours after exposure. Difficulty with speaking or swallowing, shortness of breath, and muscular fasciculations have been reported in patients with more moderate poisoning. With increased severity of poisoning, more intense signs and symptoms can appear. These may include depressed levels of consciousness and marked myosis with no pupillary response. After initial recovery from acute severe intoxication, an organophosphate-induced delayed polyneuropathy (OPIDP) may develop. OPIDP is a distal dying back axonopathy characterized by cramping muscle pain in the legs, paresthesias, and motor weakness beginning 10 days to 3 weeks after the initial exposure. OPIDP-associated signs include foot drop, weakness of the intrinsic hand muscles, absent ankle jerk, and weakness of the hip and knee flexors.⁴³ Chronic low-level exposure has been associated with weakness, malaise, headache, and lightheadedness. Anxiety, irritability, altered sleep, tremor, numbness and tingling of the extremities, and small pupils may also be observed.⁴⁴ Neurobehavioral findings include decreased capacity for information processing, decreased memory and learning abilities, and poor visuoperceptual skills.

A cohort of 90 patients with chronic low-level exposure to organophosphates were clinically examined and found to have decreased vibratory sense compared to a matched sample group. Nine of these patients underwent electrophysiological testing, and 5 of them were found to have abnormalities consistent with a peripheral neuropathic condition. This study suggests that low-level organophosphate exposure may be particularly toxic to the PNS.⁴⁵ Five cases of acute parkinsonism following acute exposure to organophosphates have been described. Each of these patients resembled the clinical picture of PD but did not respond to levodopa. After the offending agent was removed, 4 of the patients recovered without sequelae. Upon reexposure to the organophosphate, 1 patient had reoccurrence of parkinsonian symptoms. These case reports suggest a causal link between organophosphate exposure and parkinsonism.⁴⁶

DIFFERENTIAL DIAGNOSIS AND EVALUATION. Diagnosis depends on exposure history, clinical symptoms,

and abnormally low cholinesterase activity in the blood (BEI 70% of baseline level). Serial cholinesterase levels that show a rise after removal from exposure are diagnostic of exposure. Fasciculations with miosis, although not always present, are also diagnostic of organophosphate poisoning. Also, improvement of acute symptoms can be expected after administration of atropine sulfate.

MANAGEMENT. At the time of ingestion, vomiting should be induced. The primary treatment for mild to moderate organophosphate poisoning is the administration of atropine sulfate (1 mg intravenously or intramuscularly) and pralidoxime (Protopam, 2-PAM, 1 g intravenously). However, potential complications of atropine toxicity include flushed, hot, and dry skin, fever, and delirium. Also, 2-PAM may cause dangerous increases in blood pressure.⁴² In patients with very severe organophosphate poisoning, intravenous administration of pralidoxime will restore consciousness within 40 minutes.

PROGNOSIS AND FUTURE PERSPECTIVES. Prolonged high exposure and the appearance of CNS and PNS symptoms may be associated with an incomplete recovery. However, recovery is complete within weeks to months after lower levels of exposure.

Organochlorine Insecticides

PATHOGENESIS AND PATHOPHYSIOLOGY. The neurotoxic mechanisms for dichlorodiphenyltrichloroethane (DDT) and other organochlorine insecticides is not well-defined but may involve the excessive and spontaneous release of acetylcholine. This is in contrast to the acute actions of organophosphates, which block the metabolism of acetylcholine extracellularly. Interestingly, because exposure to both organochlorines and organophosphates produces cholinergic overactivation, these chemicals can cause similar symptomatology.

EPIDEMIOLOGY AND RISK FACTORS. Chlorinated hydrocarbon insecticides are highly soluble in fats and oils. In addition, they persist for extended periods of time in the environment, thus contributing to chronic toxicity. Commonly used organochlorine insecticides include aldrin, chlordane, DDT, endrin, heptachlor, chlordecone (kepone), and lindane. Most of these insecticides have been banned or restricted in the United States because of their persistence in the food chain, which leads to deleterious effects on wildlife. DDT was banned in the United States in 1973 but is still used in the Third World. Absorption may occur through respiration or through the oral or skin route.

CLINICAL FEATURES AND ASSOCIATED FINDINGS. Clinical manifestations of organochlorine neurotoxicity have been associated with an oral dose of 10 mg/kg. With acute DDT toxicity, patients report a metallic taste in the mouth. Within 1 hour they complain of dryness of the mouth and extreme thirst. Drowsiness or extreme insomnia, burning eyes, and a gritty sensation in the eyelid are also reported. Other symptoms may include aching of the limbs, muscular spasms, tremors, stiffness and pain in the jaw, difficulty with concentration, and night blindness. Chronic exposure to these compounds can cause tremor and convulsions. Upper extremity weakness, which progresses to wrist drop, may also occur. Mononeuropathy (Video 220, Ulnar Neuropathy, Main en Griffe), optic

neuropathy, and polyneuropathy have all been described in patients with chronic exposure. In workers in industrial settings that produce DDT and other chlorinated hydrocarbon insecticides, abnormal EEGs marked by bitemporal, sharp wave activity and shifting lateralization have been reported.⁴⁷ A cohort of 59 males with chronic exposure to DDT were compared to matched controls using neurobehavioral testing. The group with chronic exposure to DDT scored consistently lower on cognitive testing and this was directly related to years of exposure. The exposure group also had more neuropsychological and psychiatric symptoms than the matched controls.⁴⁸

DIFFERENTIAL DIAGNOSIS AND EVALUATION. The diagnosis is made by the history. Although organochlorines and their metabolites can be found in the blood, this test is generally unavailable.

MANAGEMENT. Treatment is supportive. For patients with intractable seizures, diazepam and pentobarbital may be useful. Pentobarbital may also accelerate the metabolism of organochlorines. Atropine and adrenergic amines are contraindicated because they may potentiate myocardial irritability.

PROGNOSIS. With the exception of anticonvulsants in patients in whom seizures are prominent features, there are no specific antidotes for DDT.

Other Pesticides: Methyl Bromide, Picrotoxin, and Strychnine

See Table 39-5.

ANIMAL TOXINS

Snake, Scorpion, and Spider Venoms

PATHOGENESIS AND PATHOPHYSIOLOGY. Most animal neurotoxins affect the cholinergic system through either enhancement or blockade. Snake venoms are extremely toxic to cardiac muscle, coagulant pathways, and the nervous system.⁴⁹ Snake venom acts either presynaptically as a toxin that inhibits the release of acetylcholine from presynaptic cells in the neuromuscular junction or postsynaptically as an agent that produces a nondepolarizing neuromuscular block. The resulting effect is a depression of cholinergic function at the neuromuscular junction. There is little evidence that snake bites act directly on the nervous system. Spider venom causes a release of acetylcholine, producing tetanic spasms followed by paralysis.

EPIDEMIOLOGY AND RISK FACTORS. Poisonous snakes include vipers, rattlesnakes, cobras, kraits, mambas, and the American coral snake. Pit vipers are the snakes of most concern in North America. The rattlesnakes, moccasins, cottonmouths, and copperheads account for 95% of the annual snakebites in the United States.⁵⁰ Spiders such as the black widow probably account for most of the neurotoxic syndromes that occur after spider bites. Fatalities associated with spider bites occur in approximately 2.5% to 6% of cases.⁵¹ Tarantula bites are probably similar to those of the black widow spider.

CLINICAL FEATURES AND ASSOCIATED FINDINGS. The clinical presentation of people with a snakebite

includes localized pain and swelling, headache, vomiting, loss of consciousness, paresthesias, ptosis, loss of vision secondary to coagulation disturbances, and hemorrhage into the retina. Symptoms after snakebite may develop in 1 to 10 hours. Beginning signs of paralysis include difficulty with swallowing and opening the mouth. Depending on the species, scorpion stings may include both local and systemic complications. Early symptoms include pain, swelling, excessive salivation, sweating, and abdominal pain. Death may result from hypertension, peripheral circulatory collapse, and cardiac failure. Neurological sequelae are more common in children than in adults and include overexcitement, muscle rigidity, convulsions, and alteration of mental status, which is probably secondary to hypoxia. In those with spider bites, neurological sequelae include paresthesias, fasciculations, tremor, and hyperreflexia during the excitatory phase.

DIFFERENTIAL DIAGNOSIS AND EVALUATION. In patients with snakebites, it is especially important to attempt to identify the specific snake involved since a number of antivenins have been developed against specific poisons.

MANAGEMENT. Treatment of snakebites involves administration of anticholinesterases and specific antivenin as early as possible after the bite. Antivenom use carries the risk of adverse effects, including fatal anaphylaxis. To avoid this problem, pretreatment with diphenhydramine, steroids, and adrenaline has been advocated. In a prospective, placebo-controlled, randomized study of the use of 0.25 mL of adrenaline in 105 snakebite victims about to receive antivenom treatment, those patients receiving the adrenaline showed a significant reduction in adverse effects, including intracerebral hemorrhage.⁵² If these are administered prior to the development of major weakness, both pre- and postsynaptic toxic effects can be aborted. Mechanical respiration may also be warranted. During the acute stages after a spider bite, atropine can be administered to control the cardiac muscle effort; gradual recovery will occur over approximately 2 days. Treatment for scorpion bites focuses primarily on supportive respiratory and cardiac measures and attention to coagulation.⁵³

PROGNOSIS AND FUTURE PERSPECTIVES. Survival depends heavily on the control of cardiac and coagulation defects.⁵⁴ The development of effective antitoxins and more rapid access to supportive care centers may improve the prognosis.

Tick Paralysis

Tick paralysis is a flaccid ascending paralysis caused by the bite of certain female ticks, specifically in North America, *Dermacentor andersoni*, *D. variabilis*, *D. occidentalis*, *Amblyomma americanum*, and *A. maculatum*, which are found commonly in areas west of the Rocky Mountains. The toxin producing the disease is presumably excreted in the saliva of the mature female tick during engorgement. Although people of any age may be affected, small children are particularly likely to become paralyzed.⁵⁵ The head and neck are the most common sites of tick attachment, although any part of the body may be involved. There is some indication of an association between the proximity to the brain of the site of attachment and the severity of the disease. The toxin acts either by

causing a failure to liberate acetylcholine at the neuromuscular junction or by causing a generalized depression of all excitable tissues, including the neurons of the spinal cord and brain stem. The course of tick paralysis depends on how soon the tick is found and removed. If it is removed before bulbar symptoms begin, improvement occurs within hours and is complete by 1 week. If bulbar symptoms have begun, death often occurs despite intensive therapy.⁵⁶ A polyclonal dog antiserum is available, but it is expensive and effective only in the very early stages of paralysis. Recombinant veterinary vaccines based on the tick neurotoxin peptide sequences are being investigated.⁵⁷

Puffer Fish Tetrodotoxin

The puffer fish is a delicacy in Japan and has been part of the oriental cuisine for centuries. Unless the puffer fish is cleaned properly, however, intoxication by tetrodotoxin, a sodium channel blocker, can culminate in death. TTX can be found in high concentrations in the liver, ovaries, intestines, and skin of the puffer fish. Initial symptoms include ataxia, perioral paresthesia, and general weakness involving the respiratory muscles. Neurotoxic effects generally resolve within 1 week and full recovery is generally reported.

PLANT TOXINS (Table 39-6)

Chickpea (Lathyrism)

Lathyrism is related to a neurotoxin acting through the glutaminergic system. Spastic paraplegia has been observed in Europe and India following consumption of different varieties of chickpea.⁵⁸ Development of human lathyrism is associated with two potent neurotoxins found in the peas: α -amino β -oxalylaminopropionic acid and α -amino γ -oxalylaminobutyric acid.⁵⁹

Toxic neurological signs are seen when 30% or more of the diet consists of chickpeas. Men tend to be affected more than women. The onset is subtle, with pain in the

lumbar region and stiffness and weakness of the lower extremities on awakening in the morning. A slight fever may be present. Paresthesias and weakness may develop during the next several days. The legs become spastic and exhibit clonic tremor. The upper extremities may also be involved in patients with severe disease. Within 1 or 2 weeks, the pain and paresthesias usually disappear, although relapses sometimes occur. In addition to the more common spastic paraplegia, polyneuropathy and peripheral mononeuropathy may be present.⁶⁰

Mushrooms

Amanita mushrooms have strong anticholinergic effects due to their concentration of ibotenic acid, muscazone, and muscimol. Clinically, intoxication takes the form of agitation, muscle spasms, ataxia, mydriasis, and even convulsions. Additional indole compounds may account for the hallucinosis that is often seen with intoxication. The genera *Inocybe* and *Clitocybe* contain muscarine and cause cholinergic excitation at all parasympathetic nerve endings except those of the neuromuscular junctions and nicotinic sites. *Coprius atramentarius*, or Inky Cap, is a common mushroom that is generally considered edible. Its consumption in combination with alcohol, however, results in a severe toxic reaction similar to that seen with disulfiram. The syndrome includes facial flushing, paresthesias, and severe nausea and vomiting. The responsible toxin is coprine, which acts to increase acetaldehyde blood levels. *Amanita* mushrooms are responsible for approximately 95% of fatalities associated with mushroom ingestion, reaching several hundred per year globally. Although most cases are sporadic, clusters of intoxicated victims are intermittently identified. The clinical course begins 6 to 8 hours after ingestion. Symptoms include massive emesis and bloody cholera-like diarrhea. Patients often die during this phase from electrolyte imbalance, but the most dangerous phase of hepatorenal failure does not occur until after 3 to 5 days. Secondary neurologic manifestations include a gradual decline of mental status with confusion, asterixis, and eventually hepatic coma and death. Treatment is

TABLE 39-6

Botanical Toxins

| PLANT | CHEMICAL | MECHANISM OF TOXICITY | PHYSIOLOGICAL CHANGES |
|---|--------------------------------------|--|---|
| <i>Amanita muscaria</i> mushroom (fly agaric) | Ibotenic acid | Activates NMDA receptors | Marked depolarization with excitation and excitotoxicity |
| <i>Clitocybe acromelalga</i> mushroom | Acromelic acid Muscarine | Activates kainic acid receptors Activates cholinergic parasympathetic endings | Spasms, excitation, seizures Severe sweating, salivation, and hypertension |
| Cycad | Beta-N-methyl-amino-L-alanine (BMAA) | Activates NMDA receptors | Associated with ALS-Guamanian-PD-dementia complex |
| Chickpea: Lathyrus | Beta-N-oxalyl-amino-L-alanine (BOAA) | Acts as an agonist of AMPA receptors in spinal neurons | Induces spastic paralysis of lower limbs termed neurolathyrism |
| Betel nut | Arecoline | Stimulates parasympathetic receptors and causes CNS arousal | Excitation, salivation, slowed heart rate |
| Henbane | Scopolamine | Antagonizes muscarinic cholinergic receptors | Rapid heart rate, sedation and confusion, dilated pupils |
| Deadly nightshade, Jimson weed | Atropine | Antagonizes muscarinic cholinergic receptors | Rapid heart rate, sedation and confusion, dilated pupils |

ALS, amyotrophic lateral sclerosis; AMPA, alpha-amino-3 hydroxy-5-methyl-4-isoxazolepropionic acid; NMDA, N-methyl D-aspartate; PD, Parkinson's disease.

mainly supportive and includes careful regulation of fluid status and electrolyte balance, correction of hypoglycemia, and monitoring of coagulation, renal, and liver function. Additionally, hemodialysis, often with exchange transfusion or plasma phoresis, can be used, although mortality rates are 30% to 40%; when acute liver failure appears, 70% or more patients fail to survive.^{61,62}

BACTERIAL TOXINS

Diphtheria

PATHOGENESIS AND PATHOPHYSIOLOGY. Diphtheria is an acute infectious disease caused by the bacteria *Corynebacterium diphtheria*. Diphtheria is transmitted by respiratory droplets from infected people or asymptomatic carriers. There are two forms, oropharyngeal and cutaneous, and the incubation period is 1 to 4 days. The bacteria affects the respiratory tract and often the heart, kidneys, and nervous system as well. In the immediate area of the infection, usually the nose and throat, the bacteria produce a toxin that causes tissue damage and can spread via the bloodstream to other organs. Muscle and myelin are preferentially affected by this powerful exotoxin. Neurological symptoms result from either direct damage to muscle and peripheral nerve or indirect damage caused by hypoxia and airway obstruction. Fortunately, the exotoxin does not penetrate the blood-brain barrier, and therefore the CNS is not directly affected.⁶³ Pathological signs include demyelination of the ganglia of the peripheral nerves, especially the node of Ranvier, and the cranial and somatic nerves.

EPIDEMIOLOGY AND RISK FACTORS. Diphtheria is now rare in many areas of the world owing to immunization. Potential risk factors for this disease are lack of immunization, crowding, and poor hygiene. In the United States, only five cases of diphtheria were reported in 1991. However, because of a decline in routine child immunizations in the former Soviet Union, a diphtheria epidemic that included more than 50,000 cases was reported in 1993 and 1994.

CLINICAL FEATURES AND ASSOCIATED FINDINGS. The clinical course follows a predictable pattern. Between days 5 and 12 of the illness, the initial symptoms are sore throat, fever, a gray to black throat membrane, nasal voice, regurgitation, and dysphagia. At approximately this time, the trigeminal, facial, vagus, and hypoglossal cranial nerves may be affected. In approximately half the patients who have postdiphtheria neurological dysfunction, ocular involvement and paralysis of accommodation are noted in the second or third week. Mononeuropathies can also occur within 2 weeks of onset, and further peripheral neuropathy, predominantly sensory polyneuropathy, or proximal motor neuropathy extending distally are characteristic in weeks 6 and 7 of the illness. Sometimes toxic encephalopathy, consisting of a change in mental status, drowsiness, and possibly convulsions, is seen.

DIFFERENTIAL DIAGNOSIS AND EVALUATION. The diagnosis must be based on the clinical history and clinical presentation. Physical examination may show a characteristic gray membrane in the throat, enlarged lymph glands,

and swelling of the neck and larynx. In patients with a clinical picture of Guillain-Barré syndrome with visual blurring and palatal involvement, a diagnosis of diphtheria should be questioned. Diphtheric polyneuropathy can be distinguished from all other polyneuropathies by the early bulbar symptoms, unique ciliary paralysis, and subacute evolution of a delayed symmetrical sensorimotor peripheral polyneuropathy. Diagnostic testing should include Gram stain of the infected membrane, a throat culture, and an electrocardiogram, which will show evidence of myocarditis.

MANAGEMENT. There is no specific treatment for the neurological symptoms of diphtheria. Treatment generally involves administration of antitoxin within 48 hours of the earliest signs of infection, rest, and maintenance of proper airway and cardiac function. All contacts of the infected person should be immunized since protective immunity is not present longer than 10 years after the last vaccination. Diphtheria is preventable through immunization at the age of 3 months. Booster doses at 1 year and before the child enters school are suggested.

PROGNOSIS. The death rate is 10%. If the patient does not die because of respiratory distress or cardiac failure, he or she stabilizes and slowly recovers completely. Therefore, activities should be slowly resumed.

Tetanus

PATHOGENESIS AND PATHOPHYSIOLOGY. Tetanus is caused by a powerful exotoxin, *Clostridium tetani*, which produces spores. The spores can remain dormant in the soil or in animal excrement for many years until they enter the body and produce a toxin. In patients with tetanus toxicity, both the CNS and the PNS as well as the musculature are involved.⁶⁴ The major CNS effect occurs through disinhibition on gray matter gangliosides and through presynaptic antagonism of GABA. At high concentrations, tetanus toxin acts like botulism toxin in that it inhibits the release of acetylcholine at cholinergic synapses. The nervous system is infected by tetanus through retrograde axonal transport from the site of infection. The incubation period may range from 5 to 25 days but can be only a few hours. Early in the illness, pathological changes include changes in the nerve cells of the cortex and brain stem. If the illness lasts for more than 5 days, demyelination and gliosis may occur, and in the most severe cases hemorrhages can occur.

EPIDEMIOLOGY AND RISK FACTORS. In Third World countries, tetanus is still an important cause of morbidity and mortality. The bacteria can be transmitted in the anaerobic conditions of wounds, through soil-contaminated injuries, and, less commonly, by unclean needles used by drug abusers. In adults, tetanus is seen only in those who have not been immunized. Approximately 50 to 100 cases are reported in the United States each year, and 60% of those cases occur in adults older than 60 years. Although neonatal tetanus due to infection of the stump of the umbilical cord is thought to be of only historical interest, worldwide it remains the second leading cause of vaccine-preventable death among children.⁶⁵

CLINICAL FEATURES AND ASSOCIATED FINDINGS. The clinical course consists of early symptoms of chills, headache, restlessness, and pain at the site of injury.

Tightness in the jaw and mild stiffness and soreness in the neck are usually noticed within a few hours. As symptoms develop, the jaw becomes stiff and tight (lockjaw). Muscular involvement then progresses to the throat and facial muscles. Muscular rigidity may then become generalized and may include the trunk and extremities. Rigidity in the abdominal muscles can result in a forward arching at the back. The tetanic contractions occur periodically and can cause severe pain. In the most severe cases, convulsions and marked dyspnea with cyanosis can occur, terminating in asphyxia and sudden death. Mental status remains intact. However, the patient suffers from anxiety and mental and physical distress.

DIFFERENTIAL DIAGNOSIS AND EVALUATION.

A diagnosis of tetanus can be made by a positive history of a prior wound, a high titer of serum antibody to tetanus, a history of partial immunization, and clinical symptoms as previously outlined. Tetanus must be differentiated from the stiff-person syndrome and the Moersch-Woltman syndrome. Trismus is not typical of stiff-person syndrome.

MANAGEMENT. Patients should be hospitalized and external stimuli kept to a minimum. The infected wound should be debrided. Muscle relaxation can be initiated by the use of barbiturates or diazepam. Although antiserum does not neutralize the toxins fixed in the nervous system, human tetanus immunoglobulin should be given. One dose of 3000 to 6000 units given intramuscularly into three sites simultaneously is recommended. If human antitoxin is unavailable, equine antiserum can be given. Tetanus is prevented by immunization. Children should be immunized at 2 months to 6 years of age. In adults, tetanus boosters last approximately 10 years.

PROGNOSIS AND FUTURE PERSPECTIVES. The prognosis is poor. The fatality rate is approximately 65%. Death generally occurs rapidly between the third and fifth day of illness and is due to exhaustion, medullary failure, asphyxia resulting from spasm, or circulatory failure resulting from exertion on the heart. Occasionally, tetanus antitoxin produces an adverse reaction involving primarily the PNS. After 6 months, recovery is usually complete.

Botulism

PATHOGENESIS AND PATHOPHYSIOLOGY. Botulism is the most potent poison known to man. It is produced by the spores of *Clostridium botulinum*. Three distinct varieties of the disease exist. Foodborne botulism results primarily from the ingestion of contaminated home-canned fruits and vegetables. Since this type of botulinum toxin is produced by spores that are already formed and ingested, toxic signs appear rapidly, usually between 8 and 36 hours after ingestion, and an incubation period is not required. After ingestion of the botulinum toxin, neurological signs appear within hours or at most 1 week. Wound botulism is both an infection and an intoxication. The organism enters through the wound site, and the spores may germinate locally in the tissues, producing a potent exotoxin. The third form of botulism is infantile botulism, which occurs in the first 6 months of life. In this situation, spores germinate in the infant's intestine and produce the toxin in vivo. The basic pathophysiological mechanism of botulism neurotoxicity is inhibition of acetylcholine release.

EPIDEMIOLOGY AND RISK FACTORS. Each year, approximately 20 cases of foodborne botulism are reported in adults. In infants, approximately 70 to 100 cases are reported yearly in the United States.⁶⁶ Although some cases are acquired from food, most cases involve contamination of the gastrointestinal tract by ingestion of dust from environmental sources containing *C. botulinum*. Infantile botulism produces a very different clinical syndrome from that seen in adults. Interestingly, botulinum toxicity has been associated with respiratory failure and has been offered as a possible explanation for the sudden infant death syndrome (SIDS). The age distribution is the same, and 10 infants with SIDS in California in 1977 also had evidence of intestinal infection with *C. botulinum*. The introduction of botulinum toxin for the treatment of dystonia, hemifacial spasm, and spasticity raises the possibility of iatrogenic treatment as a risk factor for botulism. A botulism-like syndrome of generalized weakness has been reported after injections of botulinum toxin likely due to systemic spread of toxin.^{67,68}

CLINICAL FEATURES AND ASSOCIATED FINDINGS.

Early signs of toxicity include nausea and vomiting with abdominal pain, and diarrhea. Other symptoms include ptosis, extraocular paresis, and progressive weakness suggestive of myasthenia gravis (Video 42, Fatiguability). Cranial nerve symptoms most commonly involve the eyes. Additional symptoms include dryness of the mucous membranes, vertigo, deafness, dysphasia, swallowing difficulties, breathing difficulty that may lead to respiratory failure, speech impairment, absent or decreased gag reflex, and absent or decreased deep tendon reflexes. By the second to fourth day of the illness, muscular weakness develops. Often, muscular involvement is limited to the neck muscles, resulting in an inability of the patient to raise the head.⁶⁹ Botulism may cause sudden infant death by producing flaccidity of the upper airway or tongue muscles, leading to airway obstruction during sleep.⁷⁰ Clinical features in infants include acute bulbar dysfunction, respiratory failure, constipation, weakness with loss of muscle tone, and an alert but weak appearance.^{71,72}

DIFFERENTIAL DIAGNOSIS. Weakness can usually be differentiated from Guillain-Barré syndrome because the weakness associated with botulism toxicity is descending, so the proximal muscles are affected before the distal extremities. The progressive weakness is suggestive of myasthenia gravis; however, the pupillary dilation seen in botulism is not characteristic of myasthenia. Stimulation single fiber EMG may be particularly useful in establishing the diagnosis and monitoring clinical progression.⁷³ Botulism should be considered in cases of SIDS, when asphyxia is thought to be due to upper airway or tongue flaccidity.

EVALUATION. Confirmation of the diagnosis depends on detection of the toxin either in the patient (blood) or in the implicated food. A stool culture is often useful.

MANAGEMENT. Botulism immune globulin (BIG) was approved in October 2003. Intravenous therapy with BIG shortens the duration and reduces the complications of adverse symptoms in infants with botulism.⁷² In adults, once the patient has been admitted to the hospital, respiration should be monitored. Trivalent ABE equine antitoxin is recommended.

PROGNOSIS AND FUTURE PERSPECTIVES. In severe cases, a downward course is rapid and terminates in death.

Death occurs in 70% of untreated cases. If the patient survives, recovery begins within a few weeks.

ILLICIT DRUGS (Table 39-7)

Cocaine

PATHOGENESIS AND PATHOPHYSIOLOGY. Blockade of the uptake of monoamines into the presynaptic terminals is probably responsible for the acute effects produced by cocaine. Depending on the affected system, this blockade leads to increased levels of dopamine (DA), norepinephrine, or serotonin in the synaptic cleft. The increase in neurotransmitters is associated with overstimulation of postsynaptic receptors, activation of transcription factors, and increased or decreased expression of specific target genes.

Cocaine can cause strokes when taken intranasally, intravenously, or intramuscularly.^{74,75} The effects of cocaine on the cerebral circulation are due primarily to direct vasoconstriction, probably related to stimulation of noradrenergic receptors by increased levels of norepinephrine. This is exemplified by the markedly increased blood flow and vascular resistance that follows acute administration of cocaine. In addition, cocaine can enhance platelet response to arachidonic acid, thus promoting aggregation.

Cocaine-induced strokes may be ischemic or hemorrhagic. Cocaine-associated ischemic strokes can present as transient ischemic attacks. Infarctions in the distribution of all major arteries have been described. Cocaine-induced strokes in young patients have increased remarkably.⁷⁶ Although cerebral infarction has often been attributed to vasculitis and vasospasm, there are actually few documented examples of vasculitis in autopsied cases.^{77,78}

Intracerebral or subarachnoid hemorrhages may also be associated with cocaine use. The majority of these cases occur in the presence of saccular aneurysms or vascular malformations.

Infarctions and hemorrhages have been reported in newborns whose mothers had used cocaine prior to delivery.

The mechanisms of cocaine-related stroke are unclear. However, it has been reported that cocaine hydrochloride is more often associated with hemorrhagic stroke than with occlusive stroke, whereas hemorrhagic and occlusive strokes occur with approximately equal frequency in patients who use cocaine alkaloid (“crack”). Acute hypertension can lead to intracranial hemorrhage, especially in patients with underlying aneurysms or vascular malformations. Myocardial infarction, cardiac arrhythmia, and cardiomyopathy carry a very high risk of embolic stroke.

Acute cocaine exposure provokes cerebral vasoconstriction that may be a cause of occlusive stroke.⁷⁹ Cocaine metabolites also cause cerebral vasospasm, and these metabolites may be detectable in the chronic user’s urine for weeks. Chronic cocaine abusers show increased distal arteriolar resistance that persists after a month of drug abstinence.⁷⁹ These findings demonstrate that chronic cocaine abuse increases the risk of thromboembolic strokes independent of acute use of the drug.⁷⁹

The neuropsychological effects of chronic cocaine exposure are thought to be due to decreased DA levels in the brain. This hypothesized dopamine decrease may be secondary to long-term depletion of DA, which occurs with repeated drug administration. However, there is very little direct evidence to support this view, and other data suggest that chronic cocaine exposure may induce structural changes in neuroanatomy. A CT study has shown that habitual cocaine users (those who use the drug at least twice weekly for 2 years or more) have significant degrees of cerebral atrophy with enlargement of the lateral ventricles and widening of the sylvian fissures compared to first-time users and nonusers. Studies examining the consequences of chronic cocaine abuse in abstinent cocaine abusers have shown that cerebral metabolism in the medial orbitofrontal cortex and basal ganglia during the first week of abstinence from cocaine is higher than that in normal subjects but then falls below normal levels and remains so for at least 3 months.⁸⁰ In another positron emission tomography (PET) study, glucose metabolism in the entire cerebral cortex, thalamus, and midbrain was reduced following acute administration of cocaine.⁸¹ In an O¹⁵ PET activation study conducted after 4 weeks of abstinence, cocaine users showed less activation in the left anterior cingulate cortex and lateral prefrontal cortex bilaterally compared to controls during performance on a task aimed to activate these brain regions selectively.⁸² Because these brain regions play a role in performance monitoring⁸³ and the suppression of inappropriate responses of incorrect actions,⁸⁴ circuitry disruption could impair a drug abuser’s ability to discontinue drug-seeking behavior.

EPIDEMIOLOGY AND RISK FACTORS. Cocaine was first used by South American Indians between 2000 and 1500 BC. From the 1920s to the 1960s, recreational use of cocaine in the United States was limited to jazz musicians and the “cultural avant garde.” In the mid-1980s, the development of crack cocaine caused a marked increase in the number of new cocaine users to an estimated 5000 new users a day, 6 million regular users, and 1 million compulsive users. In 2002 and 2003, 5.9 million people aged 12 years or older had used cocaine in the past year.⁸⁵

TABLE 39-7

Summary of Neurologic Signs and Symptoms of Drug Abuse

| SIGNS OR SYMPTOMS | DRUGS |
|----------------------------|---|
| Cranial Nerves | |
| Pupils | |
| Pinpoint | Opiates |
| Dilated | Stimulants |
| Sluggish | Hallucinogens |
| Reactive | Opiate withdrawal |
| Extraocular Muscles | |
| Nystagmus | Depressants, phencyclidine (PCP) |
| Speech | |
| Slow | Opiates |
| Slurred | Depressants, opiates |
| Rapid | Stimulants |
| Motor | |
| Tremor (fine) | Hallucinogens, stimulants |
| Tremor (coarse) | Depressants |
| Reflexes | |
| Increased | Stimulants |
| Decreased | Depressants |
| Seizures | Opiates, stimulants, over-the-counter drugs |

Therefore, the epidemic of cocaine use with its associated medical and neurological sequelae makes cocaine use a major public health concern.

CLINICAL FEATURES AND ASSOCIATED FINDINGS. Cocaine produces a brief rush, which peaks at 1.5 to 2 minutes. This rush is followed by euphoria, excitability, and hypervigilance. The acute administration of cocaine causes both psychiatric and neurological symptoms. Acute psychiatric symptoms include anxiety, insomnia, paranoia, agitation, and psychosis. Neurological symptoms include stereotypy, bruxism, chorea, dystonia, myoclonus, seizures, lethargy, strokes, and coma. In addition, high doses of cocaine cause tachycardia, tachypnea, and hypertension. Parenteral cocaine users are also at risk for stroke related to infection, such as endocarditis and the acquired immunodeficiency syndrome (AIDS).

DIFFERENTIAL DIAGNOSIS AND EVALUATION. The clinical presentation of a cocaine-induced neurological disorder can mimic a number of other neurological abnormalities. However, a cocaine-related stroke or other neurological disorder can be diagnosed if a urine toxicology screen is positive for cocaine. It is important to perform the toxicology screen within the first 24 hours of presentation because of the short half-life of cocaine in the urine. However, urinary cocaine metabolites such as norcocaine and benzoylecgonine may remain positive for several days. Urine toxicology screening is indicated in all patients who present to the emergency room with an acute neurological syndrome because a very high prevalence of cocaine use exists in many communities, including suburban areas.

MANAGEMENT. Treatment of cocaine-induced neurological abnormalities depends on the clinical presentation. In patients with acute paranoia or psychosis, neuroleptics are indicated. However, it is important to note that cocaine abusers may be at increased risk for acute dystonic reaction secondary to antipsychotic drugs. In these cases, anticholinergics can be very helpful. Other complications, including strokes, are treated according to the clinical presentation.

Amphetamine Analogs

PATHOGENESIS AND PATHOPHYSIOLOGY. The pathophysiological bases for the complications associated with amphetamine use are not well understood. Amphetamine-induced cerebral vasculitides cause occlusive as well as hemorrhagic strokes. Methamphetamine use can cause necrotizing angiitis. Also, cerebral arteritis with multiple occlusions of arterioles was reported in young abusers of intravenous methamphetamine who were hospitalized because of coma or stroke.⁸⁶ Angiographic studies in such patients have shown occlusions or beading of vessels in the internal carotid, distal middle cerebral, and lenticulostriate arteries.⁸⁷

To test the role of methamphetamine in the etiology of vasculitis, monkeys were given methamphetamine intravenously and then underwent serial angiograms.⁸⁸ Some of the animals showed beading of small and large vessels that persisted or progressed over a 2-week period. Hypertension and behavioral changes were also seen. At autopsy, subarachnoid hemorrhages were found in some animals as well as brain petechiae, infarcts, microaneurysms, and

perivascular white cell cuffing. More severe vasculitides were reported in another study of monkeys that received intravenous methamphetamine three times weekly for up to 1 year.⁸⁹ Angiographic and histological changes have also been reported in monkeys given intravenous methylphenidate.⁸⁹ Sural nerve biopsy showed hypersensitivity angiitis of medium and small arteries and veins in an adolescent amphetamine abuser who presented with mononeuritis multiplex.⁹⁰

EPIDEMIOLOGY AND RISK FACTORS. Amphetamines have been used for many decades to promote weight loss. They are also used in the treatment of attention deficit disorder and narcolepsy and as an adjunctive treatment in patients with treatment-resistant depression. During the 1960s and early 1970s, amphetamines were widely abused by people involved in the so-called counterculture movement. During the 1980s and 1990s, most of these drugs were replaced by cocaine. Nevertheless, prescribed amphetamines remained a significant source of abusable drugs. More recently, drugs such as methamphetamine (“meth” or “ice”) and methylenedioxymethamphetamine (MDMA or “ecstasy”) have undergone a major resurgence among adolescents and young people in their early 20s. In 2004, an estimated 1.4 million people older than 12 years of age used methamphetamine in the past year, with 600,000 using in the past month.⁸⁵ Meth is also widely used in California and in some midwestern states, where it is synthesized in basement laboratories. In Japan, meth abuse has been rampant since the end of World War II. MDMA is used frequently at “raves” and has become a major public health issue in some communities.

CLINICAL FEATURES AND ASSOCIATED FINDINGS. The amphetamine analogues tend to produce very similar signs and symptoms. These include hyperalertness, euphoria, hyperactivity, and greater physical endurance. Higher doses of these drugs can cause dysphoria, headaches, and confusion.⁹¹ Unlike cocaine, these drugs can produce a prolonged rush when taken intravenously, and inhalation of meth can sometimes cause a more rapid rush. These responses are due to their longer half-lives; also, the psychological response to amphetamine analogs usually lasts longer than that of cocaine. In fact, meth can induce psychotic symptomatology that is often indistinguishable from that of an acute schizophrenic break. Meth-induced psychosis is quite common in Japan.

Gilles de la Tourette syndrome can be exacerbated and precipitated by amphetamine, methylphenidate, and pemo-line; it sometimes clears with discontinuation of the drug but occasionally persists.^{92,93} The bruxism and choreiform movements that develop with chronic amphetamine use may also persist after the drug has been discontinued.

Strokes are also frequent complications of amphetamine abuse. Intracerebral hemorrhages have been reported after either nasal or intravenous use of these drugs. Often, strokes are preceded by complaints of severe headaches. Blood pressure is elevated in more than half the subjects who come to medical attention; diastolic pressure has been reported to be as high as 120 mmHg. CT scans have shown intracerebral, intraventricular, or subarachnoid hemorrhage. Cerebral angiography shows irregular narrowing of the distal cerebral vessels; this is consistent with the presence of vasculitis.

MANAGEMENT. In patients who present with acute psychotic symptomatology, antipsychotic drugs may be indicated. It is very important to pay close attention to the patient's vital signs because amphetamines can cause a marked increase in body temperature. These patients may be more prone to develop the neuroleptic malignant syndrome. In such cases, it might be more beneficial to use a quiet, cool room for treatment rather than pharmacological agents. If this is not possible, anxiolytic agents are recommended. The clinical presentation of the patient should determine the exact method of management.

PROGNOSIS AND FUTURE PERSPECTIVES. Whether the amphetamines can cause permanent psychiatric or cognitive disturbances is uncertain. Ten users of amphetamines reported decreased memory or poor concentration ability after they achieved abstinence. There are also reports of lasting psychosis or dementia.

Methylenedioxymethamphetamine

MDMA is a derivative of methamphetamine. The use of MDMA in the United States has reached epidemic proportions. In 2001, more than 8 million people had used MDMA at least once in their lifetime, and in 2003, 2.1 million people reported using ecstasy in the past month.⁸⁵ Most of these users are between the ages of 18 and 25 years. Although not thought to be physically addicting, MDMA is reported to cause severe damage to the serotonergic neurons in nonhuman primates and decreases in the serotonin metabolite 5-hydroxyindoleacetic acid in the cerebrospinal fluid of humans who have abused the drug.⁹⁴ MDMA has properties similar to both stimulants and hallucinogens. It is abused by individuals who wish to intensify their emotional and sensory experiences. MDMA and a close congener, methylenedioxyamphetamine (MDA), are reported to cause individuals to become more empathic. Before MDMA and MDA were made illegal in 1985, psychiatrists experimented with these drugs to facilitate psychotherapy, especially in patients who had difficulty expressing their emotions. The Food and Drug Administration has approved a protocol to study MDMA-assisted psychotherapy for the treatment of patients suffering from post-traumatic stress disorder.

MDMA and MDA can cause increases in blood pressure and heart rate, anxiety, and locomotor hyperactivity. Mild neurological side effects include pupillary dilatation and tremors, but more serious consequences include seizures, strokes, and coma. A number of studies have shown dose-related neurobehavioral deficits in memory with heavy MDMA use.⁹⁵⁻⁹⁷ However, it is unclear if these memory problems improve with cessation of use or worsen with continued use.⁹⁸ Public education efforts have focused especially on young adults to communicate the medical and neurotoxic concerns related to memory deficits and their potential irreversibility.

Opioid Agonists

PATHOGENESIS AND PATHOPHYSIOLOGY. Opioid drugs can cause respiratory suppression because of the high density of opioid receptors in the brain stem nuclei. These receptors subserve respiration. CT studies have revealed cerebral and cerebellar white matter lucencies in patients

who present with pseudobulbar palsy and quadriparesis. MRI investigations have shown leukoencephalopathy, and T2 hyperintensities have been reported in diffuse brain regions but the most common site is the periventricular white matter of the frontal lobes.⁹⁹ Postmortem studies have also shown edema and spongiform-type changes in the white matter of heroin abusers.¹⁰⁰ It is possible that these pathological changes may be secondary to the adulterants used with these drugs, such as chloroquine. This adulterant is often used in conjunction with heroin.

A large number of heroin abusers develop AIDS. At autopsy, neuropathological abnormalities consistent with AIDS are found. Almost all have neurological symptoms and signs prior to death. Retrospective surveys of AIDS cases suggest that parenteral drug abusers are more likely than other high-risk groups to have cryptococcal meningitis and CNS toxoplasmosis. No differences were found between parenteral drug abusers and non-drug-abusing homosexuals in the prevalence of these infections or of neurological symptoms, including dementia, seizures, or peripheral neuropathy. On the other hand, Kaposi's sarcoma is rare in drug abusers. Neuropsychological studies of asymptomatic human immunodeficiency virus (HIV)-seropositive parenteral drug abusers found no evidence of significant cognitive impairment. However, in those with more advanced stages of HIV disease, there appears to be a synergistic effect of drug use and HIV disease status.

EPIDEMIOLOGY AND RISK FACTORS. The poppy has been used for its opioid content for more than a few thousand years. Opium has been available in Europe since the middle of the 16th century. By the 19th century, opium was popular in many countries as a euphoriant. After the Civil War, opioid use became widespread in the United States, and opium was present in a number of over-the-counter remedies, including Dover's powder, Godfrey's cordial, and Darby's carminative. The number of Americans reportedly addicted to opioids at the beginning of the 20th century ranges from 200,000 to more than 1 million. Most were white middle-aged women who took opium in medicines. More recently, opioid agonists have been used for their acute euphoric effects. Three milligrams of heroin is equivalent to approximately 10 mg of morphine. Until the advent of crack cocaine, heroin was probably the most common illicit drug used in many metropolitan areas. In the late 1960s, heroin-related fatalities were very common in New York City men aged 15 to 35 years. In 1985, there was a striking increase in the number of fatal heroin overdoses in New Mexico; this was attributed to the availability of Mexican "black tar" heroin. Heroin (diacetylmorphine) is metabolized to 6-acetylmorphine and morphine.

CLINICAL FEATURES AND ASSOCIATED FINDINGS. The acute effects of opiates include euphoria and drowsiness.¹⁰¹ Parenteral heroin produces a "hit" that lasts for approximately 1 minute. It is often compared to orgasm. The user then experiences a dreamlike and pleasant drowsiness. Visual hallucinations have been reported after morphine or heroin administration. Nausea and vomiting can also occur. Drug abusers often experience dryness of the mouth, pruritus, suppression of the cough reflex, respiratory depression, hypothermia, postural hypotension, and constipation. Some case accounts also report an ataxic syndrome with symmetric deep cerebellar lesions.¹⁰²

Pentazocine (Talwin) and tripeleminamine (Pyribenzamine) were widely abused in some U.S. cities in the 1970s.¹⁰³ Cerebral hemorrhages resulted from the injection of crushed oral tablets that were suspended in water and passed through a cigarette filter. Pulverized meperidine tablets have caused seizures and fundal hemorrhages. Cerebral vasculitides have also been reported in users of these drugs.

The chronic use of heroin can result in myelopathy, which is probably of vascular origin.¹⁰⁴ Acute paraparesis, sensory loss, and urinary retention usually occur soon after administration of the drug. Possible causes of spinal lesions include hypotension, embolism of foreign objects, and direct toxic effects of the drugs. Vasculitis affecting mainly the small arteries and arterioles has been reported. Also noted is an anterior spinal artery syndrome with quadriplegia that follows supraclavicular heroin injection.

A number of other neurological complications affect heroin users. Peripheral neuropathy can present as a Guillain-Barré syndrome.¹⁰⁵ The peripheral nerves may also be damaged secondary to direct injection or to pressure palsies. Ulnar and femoral neuropathies have also been observed (Video 219, Ulnar Neuropathy, Froment Sign). Painful brachial and lumbosacral plexopathies are also common; these can result from a septic aneurysm affecting the subclavian or axillary arteries. Vocal cord paralysis can follow repeated jugular vein injections.

Adulteration of heroin with chloroquine can cause headache, confusion, and visual disturbances. Spongiform encephalopathy has also been reported. In these patients, there were symptoms of apathy, bradyphrenia, dysarthria, and ataxia. There are also signs of spastic hemiparesis or quadriplegia, tremor, chorea, myoclonus, pseudobulbar palsy, fever, and blindness. Heroin use is also a risk factor for new-onset seizures independent of head injury, infection, stroke, or alcohol. Infections are a common cause of morbidity in heroin users. Osteomyelitis is associated with back or neck pain, radiculopathy, and sometimes even cord compression. Cervical infection is especially common among addicts who inject into the jugular vein. Symptoms frequently precede diagnosis by several weeks. *Staphylococcus aureus* and *Pseudomonas* are common etiological factors in these infections. Bacterial endocarditis can lead to intraparenchymal or extraparenchymal abscess of the brain or spinal cord, meningitis, cerebral infarction, diffuse vasculitis, and subarachnoid hemorrhage from rupture of septic mycotic aneurysms. Progressive neurological symptoms, including headache, fever, syncope, hemiparesis, and aphasia, are a common presentation of mycotic aneurysms.

Tetanus has been reported in skin poppers who suffer from multiple skin abscesses.¹⁰⁶ Among drug users, curarization is frequently necessary to control symptoms. Botulism with dysphagia, blurred vision, dysphonia, and descending paralysis has also occurred in parenteral heroin abusers.

Coma is a common presentation of opioid overdose. In some comatose patients, pulmonary edema is frequently present. These patients do not respond to naloxone. In milder cases, overdose of heroin can be associated with spastic quadriplegia, deafness, seizures, and dystonia. Post-anoxic encephalopathy has also been reported. Death can follow very small amounts of heroin or methadone. Some

of these complications may be due to adulterants. For example, quinine causes cardiac conduction abnormalities and ventricular fibrillation. The combination of heroin, ethanol, and quinine might synergize to cause sudden death.

MANAGEMENT. The treatment of opioid-related complications is based on the clinical presentation. Naloxone (2 mg) is initially administered for patients with respiratory depression. Increments of 2 to 4 mg can be repeated up to a total dose of 20 mg, depending on the clinical status of the patient. Higher doses are often used for those with propoxyphene, pentazocine, diphenoxylate, nalbuphine, or butorphanol toxicity. It is often necessary to administer naloxone intramuscularly or subcutaneously because of the bad veins of these patients. The clinician must be aware of the potential for precipitating withdrawal symptoms with overdosage of an antagonist. Based on the clinical status of the subject, it may be necessary to titrate a naloxone infusion because methadone and propoxyphene have long half-lives.

If heroin is taken in combination with cocaine or amphetamine, paranoid psychosis can be unmasked through the use of naloxone. Opioids taken in combination with barbiturates or ethanol can produce a coma that does not respond to naloxone.

Hallucinogens

Hallucinogens (psychedelics) have been used and abused since time immemorial. Many of these compounds, including mescaline (peyote cactus) and psilocybin (mushrooms), are used in religious ceremonies by Native Americans. These drugs were used actively during the 1960s and early 1970s. Hallucinogens are still popular, and in 1997, 4.1 million people (2%) in the United States used them in the past year.⁸⁵

The most commonly abused hallucinogen in the United States is lysergic acid diethylamide (LSD). LSD is made from lysergic acid found in the fungus, ergot, which can grow on grains. Many of the hallucinogens are structurally similar to serotonin, which suggests that this class of drugs exerts its effects by altering this neurotransmitter. LSD also alters adrenergic mechanisms in the periphery and acts as a partial dopaminergic agonist. It is the most powerful hallucinogen and produces symptoms at doses varying from 25 to 50 µg. LSD is sold in a variety of forms, including small sticky pieces of paper that contain as much as 300 µg of the drug. LSD is readily absorbable after oral administration. Its effects peak after 2 to 4 hours and may last for several hours.

Symptoms consist of euphoria, intensive arousal, panic, or even depression. Perceptual distortions are very common, as are hallucinations (Video 89, Hallucinations). Neurological abnormalities include papillary dilatation, lacrimation, and hyper-reflexia. Patients report visual changes consisting of increased intensity of colors and alterations in shapes. No toxic fatalities have been reported with LSD use. A number of LSD users have recurring episodic visual disturbances, which include flashes of color, geometric pseudohallucinations, and fleeting perceptions in the peripheral visual fields. Formerly known as “flashbacks,” these have been renamed the hallucinogen persisting perception disorder. Some chronic heavy users of LSD

have been reported to suffer from impaired memory, poor attention span, and confusion.

Users of LSD may require treatment because they experience severe anxiety, intense depression, or suicidal ideation. Therapy consists of “talking the patient down,” which is a highly effective approach. If medication is required, diazepam given orally is the drug of choice.

Methyl-phenyl-tetrahydropyridine

The first case of methyl-phenyl-tetrahydropyridine (MPTP)-induced parkinsonism was reported in 1979.¹⁰⁷ The subject later died of a drug overdose. At autopsy, destruction of the substantia nigra zona compacta was evident; other areas usually involved in PD, such as the locus ceruleus, were not affected. This article lay dormant until parkinsonism began appearing in the San Francisco Bay area among users of MPTP, sold as “synthetic heroin.” The responsible chemical was identified as a by-product of meperidine synthesis, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine.¹⁰⁸

The cerebrospinal fluid of affected patients contains decreased homovanillic acid levels similar to those observed in patients with PD.¹⁰⁹ PET using ¹⁸F-dopa of asymptomatic drug users exposed to MPTP showed decreased dopa uptake, which suggests that the numbers of DA terminals and, by extension, the nigral cell bodies were decreased. The MPTP model of dopamine depletion has been helpful in mechanistic studies of the degenerative and regenerative potential of the nigrostriatal DA system. MPTP is metabolized to 1-methyl-4-phenylpyridinium (MPP⁺) by monoamine oxidase B. MPP⁺ is then taken up into DA terminals, where it blocks complex I of the mitochondrial respiratory chain. This blockage may lead to adenosine triphosphate depletion with secondary cellular demise due to energy crisis. The possibility that abnormalities in the respiratory chain could also lead to cytotoxic oxygen-based free radicals has also been put forward.¹¹⁰

MPTP has also caused parkinsonism in laboratory workers who were accidentally contaminated through inhalation or skin contact. Bradykinesia and rigidity can be very severe, with muteness and inability to swallow. As in idiopathic PD, levodopa/carbidopa and bromocriptine can provide dramatic relief in these patients. Patients develop typical side effects of these drugs, including dyskinesia, on-off phenomenon, and psychiatric symptoms.

Phencyclidine

Phencyclidine (PCP) was developed initially as an anesthetic. However, a large number of patients developed postoperative psychosis after its administration. As a result of these occurrences, its use for this purpose in humans was stopped. Significantly, PCP affects all neurotransmitter systems. During the 1970s, PCP was sold as “angel dust,” and its use was rampant. Currently, PCP is mainly used by lower middle-class white men in a very few localities. It can be injected, snorted, smoked, or eaten, and it has been found in samples of LSD, amphetamines, and marijuana. PCP has been sold as mescaline or as one of the hallucinogens.

PCP can cause a mixed euphoric-dysphoric syndrome with increasing doses of the drug. Users have reported

sensations of time slowing, relaxation, and numbness. High doses of PCP can cause a psychotic picture similar to that of schizophrenia, with increasing agitation, hallucinations, and bizarre and violent behaviors. Catatonia has also been reported. Patients with PCP-induced psychosis may show increased body temperature, hypertension, and increased sweating. Neurological abnormalities include miosis, horizontal and vertical nystagmus, and ataxia. Increased muscle tone, hyper-reflexia, and tremors have also been reported. Very high doses of the drug have been reported to cause seizures and even coma. Delirium lasting for several days is common in patients recovering from PCP-induced coma.

Treatment of an intoxicated PCP user involves putting the subject in a very calm environment. Neuroleptic drugs are relatively contraindicated because they have the potential to cause development of the neuroleptic malignant syndrome or to precipitate seizures. Benzodiazepines are the drugs of choice in treatment of PCP-induced intoxication. Enhancement of PCP clearance by acidification of the urine is recommended in comatose patients.

Cannabinol (Marijuana)

Marijuana is one of the most commonly abused drugs. Statistics from a 2003 survey revealed that marijuana continues to be the most commonly used illicit drug, with 14.6 million current users.⁸⁵ It was used as early as 3000 BC in cultures as diverse as those found in the Middle East and Asia. The drug is known by a number of names, including hashish, ganja, and bhang. Low to moderate doses of the drug cause very few psychological and physiological symptoms. The pharmacological actions and the long-term effects of chronic use are still unclear.

Delta-tetrahydrocannabinol (THC) is derived from the marijuana plant, *Cannabis sativa*. The drug can be smoked, eaten, or taken intravenously. Its potency varies greatly. When smoked, the peak plasma level of the drug is reached within 10 minutes, although psychological effects do not develop until 20 to 30 minutes. The effects can last up to 3 hours. However, THC is absorbed and accumulates in tissues such as the testes and the brain. In very heavy users of marijuana, urinary clearance can take as long as 30 days.

THC causes euphoria, feelings of relaxation, and heightened sexual arousal. Some individuals experience increased hunger; others report increased suspiciousness, paranoia, and aggressiveness; and still others become quite withdrawn socially.

Acute neurological signs and symptoms include confusion, disorientation, and an organic delusional syndrome. Persistent effects of heavy marijuana use after 1 month of abstinence include cognitive deficits in memory, decision-making, and executive functions.^{111,112} Neuroimaging studies have shown alterations in regional activation in the orbitofrontal cortex, dorsolateral prefrontal cortex, cerebellum, and hippocampus (Fig. 39-4).^{112,113} Transcranial Doppler sonography shows that cerebrovascular resistance and systolic velocity are increased in marijuana abusers compared to controls.¹¹⁴ In fact, cerebral perfusion in 18- to 30-year-old marijuana abusers is comparable to that of normal 60-year-olds. This finding suggests that marijuana abusers may be at increased risk for vascular disease

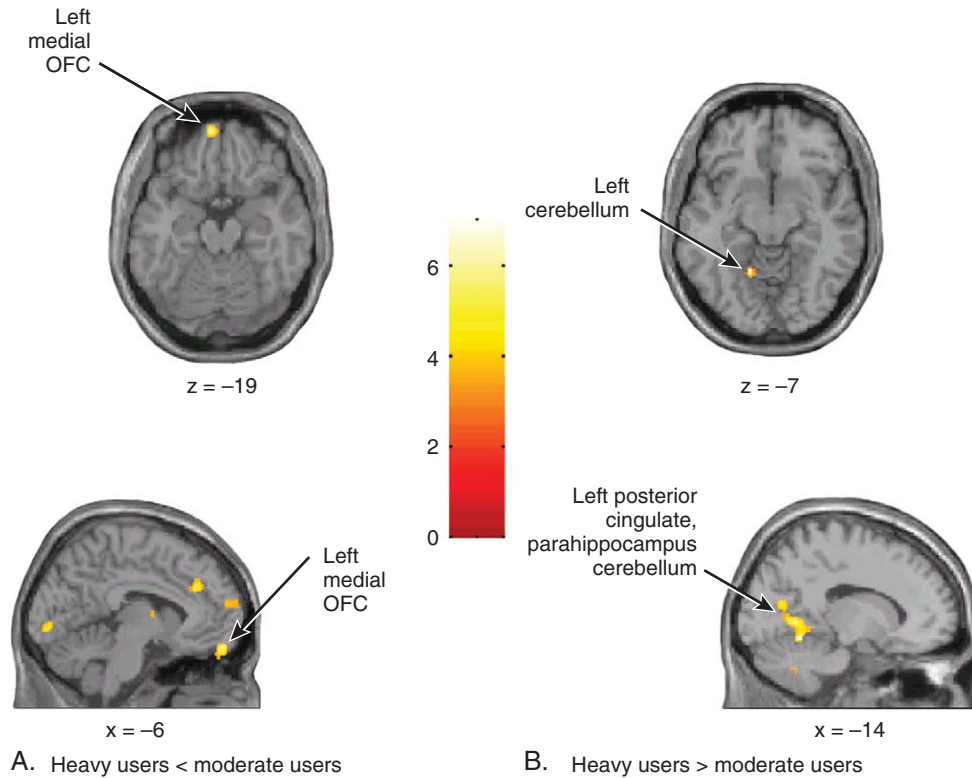

Figure 39-4. Oxygen positron emission tomography (PET) scans comparing group differences between heavy marijuana (MJ) users (53 to 84 joints/week) and moderate marijuana users (8 to 35 joints/week) in brain activation during performance on the Iowa Gambling Decision-making Task (IGT). Axial and sagittal views, neurological convention. **A,** Moderate MJ users showed greater activation than heavy MJ users in the left medial orbitofrontal cortex (OFC) during performance on the IGT. **B,** Heavy users showed greater activation than moderate users in the left cerebellum, left parahippocampus/lingual gyrus, and the left posterior cingulate. (From Bolla KI, Eldreth DA, Matochik JA, Cadet JL: Neural substrates of faulty decision-making in abstinent marijuana users. *NeuroImage* 2005;26(2):480–492.)

and stroke.¹¹⁴ Nystagmus, ataxia, and tremors have also been reported. The drug can precipitate seizures in patients with known seizure disorders. Life-threatening neurological abnormalities are very rare.

Treatment of patients with acute toxic reactions involves reassurance that the problems will clear up within a few hours. Because of the possible high concentration of the drug in various tissues, the neurological effects of the drug may take up to 8 hours to clear. No specific drug is necessary, although a benzodiazepine may be useful. In patients in acute psychotic states, haloperidol 5 to 20 mg/day in divided doses is recommended.

Nutritional Deficiencies and Syndromes Associated with Alcoholism

Laurence J. Kinsella and David E. Riley

HISTORY AND DEFINITIONS

VITAMIN DEFICIENCIES

Thiamin
Niacin and Nicotinic Acid
Cobalamin (Vitamin B₁₂)
Folate (B₉)
Pyridoxine (Vitamin B₆)
Vitamin E
Pantothenic Acid, Vitamin A, and
Vitamin D

PROTEIN-ENERGY

MALNUTRITION

OTHER NUTRITIONAL SYNDROMES

Copper Deficiency Myeloneuropathy
Pyridoxine Toxicity Neuropathy
Strachan's Syndrome
Postgastroplasty Polyneuropathy

ALCOHOL AND THE NERVOUS SYSTEM

Overview and Pharmacology
Acute Intoxication
Withdrawal Syndromes

Alcoholic Dementia and Cerebral

Atrophy
Deficiency Amblyopia
Cerebellar Degeneration
Marchiafava-Bignami Disease
Alcoholic Myopathy
Alcoholic Neuropathy
Alcoholism and Movement Disorders
Fetal Alcohol Syndrome

HISTORY AND DEFINITIONS

A *vitamin* refers to a substance that serves as a cofactor for a biochemical reaction, without which some derangement of function may occur (Fig. 40-1). Thiamin is a classic example, required by three enzyme systems essential for glucose metabolism. However, the term *vitamin deficiency* is too restrictive to account for all disorders of nutrition that may have neurologic consequences. Neurologic injury may be associated with megadose vitamins (pyridoxine and zinc) and dietary supplements (Chinese herbal remedies, St. John's wort, and ephedra). With the recent recognition of mineral deficiencies such as copper myeloneuropathy, mineral excess disorders such as zinc-induced copper deficiency, and polynutritional disturbances such as post-gastroplasty neuropathy, it has become increasingly important for the neurologist to consider a possible nutritional cause for a patient's neurologic complaints.

The study of nutritional disorders of the nervous system is complex for several reasons. First, multiple deficiencies may coexist in the same patient in certain settings, such as malnutrition and malabsorption states. Second, nutritional disorders can occur with the ingestion of potentially toxic agents as in alcohol, making it difficult to separate the neurotoxic effects from a specific dietary deficiency. Third, in several disorders a single so-called biochemical lesion has not been identified, such as in Marchiafava-Bignami disease, central pontine myelinolysis, Strachan's syndrome, and deficiency amblyopia. Fourth, the rapidity of onset of some syndromes may not be interpreted as nutritional. Instead of evolving in a slowly progressive fashion, some deficiency states may become acutely symptomatic when triggered by an environmental stressor or sudden increase in metabolic demands for the deficient nutrient. The administration of intravenous glucose to a

thiamin-depleted alcoholic patient may precipitate acute Wernicke-Korsakoff syndrome (WKS) owing to the sudden increase in thiamin-dependent carbohydrate catabolism. Intractable vomiting due to hyperemesis gravidarum may also cause WKS. Similarly, nitrous oxide administration to patients with asymptomatic cobalamin deficiency may cause an acute myeloneuropathy. Additionally, sudden changes in tissue osmolarity, such as the rapid correction of hyponatremia, may lead to central pontine myelinolysis (Table 40-1).

Fifth, occasionally, the same deficient nutrient may not affect patients uniformly. Thiamin deficiency leads to capillary proliferation, petechiae, and microglial degeneration of midline central nervous system (CNS) nuclei in some patients; in others, it leads to peripheral nerve axonal degeneration. Neurological symptoms and signs of individual deficiency states often overlap, making clinical distinction difficult. For example, encephalopathy may be seen in deficiencies of thiamin, cobalamin, and niacin; myeloneuropathy may be present in deficiencies of cobalamin and vitamin E; neuropathy can result from deficiency of B complex vitamins (thiamin, pyridoxine, and cobalamin) and pyridoxine excess; and optic neuropathy may be seen in cobalamin deficiency, vitamin A excess, or a combined deficiency of B complex vitamins, such as in deficiency amblyopia.

Sixth, the under-recognition of nutritional disorders in industrialized countries has led to difficulties in diagnosis, and these deficiencies may be more common than has been clinically appreciated. Although the incidence of WKS has traditionally ranged from 1% to 3%, autopsy data suggest a higher incidence,^{1,2} and others report thiamin deficiency in up to 17% of elderly patients hospitalized for non-neurological reasons.³ One study of thiamin-deficient alcoholics showed that more than 50% of patients were also

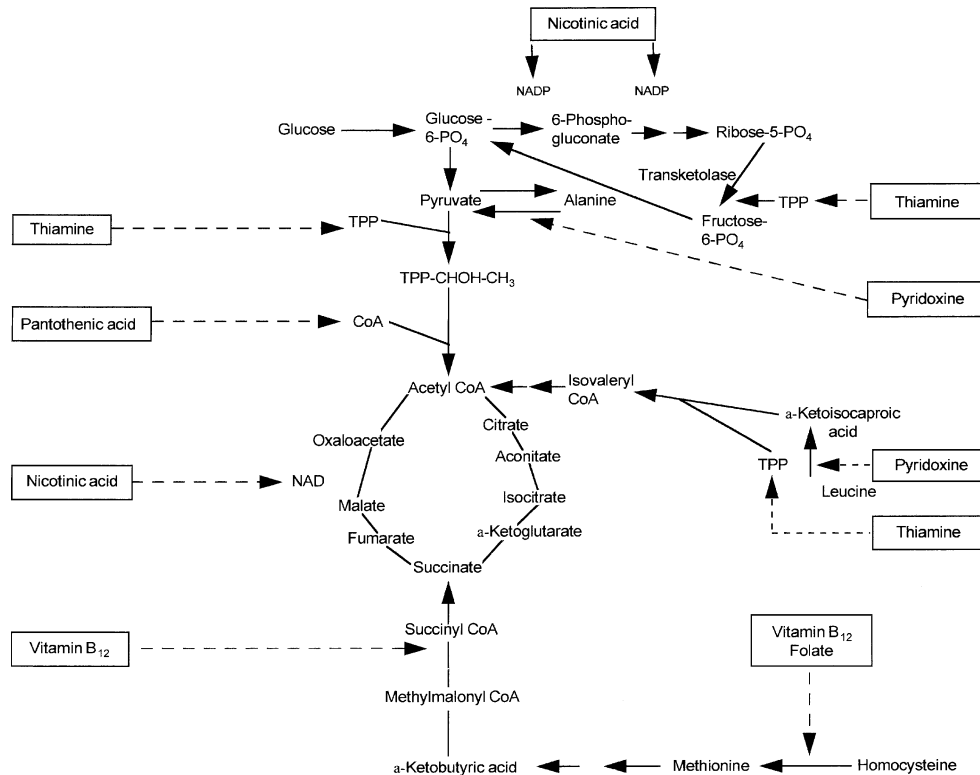

Figure 40-1. Major metabolic pathways involving coenzymes formed from water-soluble vitamins. (Modified from Marcus R, Coulston AM: Water soluble vitamins. In Goodman LS, Gilman A, Gilman AG [eds]: The Pharmacologic Basis of Therapeutics, 7th ed. New York, McGraw-Hill, 1985, p 1556.)

TABLE 40-1

Acute and Subacute Presentation of Nutritional Deficiency Syndromes

| SYNDROME | CLINICAL SETTING |
|---|--|
| Wernicke-Korsakoff syndrome | Administration of intravenous glucose to a thiamine-deficient alcoholic patient |
| Wernicke-Korsakoff syndrome | Intractable vomiting due to hyperemesis gravidarum or gastroplasty |
| Postgastroplasty neuropathy | Intractable vomiting and severe weight loss in patients following weight reduction surgical procedures |
| Vitamin B ₁₂ myeloneuropathy | Nitrous oxide administration in cobalamin-deficient patients |
| Central pontine myelinolysis | Sudden change in tissue osmolarity in critically ill patients or alcoholics |

riboflavin deficient, and 2% had a concomitant deficiency of pyridoxine.⁴ Cobalamin deficiency occurs in 5% to 14% of ambulatory elderly,^{5,6} and up to 27% of hospitalized elderly develop protein-energy malnutrition (PEM) during their hospital stay.⁷

Finally, several inherited enzyme deficiency disorders, although not accompanied by a vitamin deficiency, may nonetheless be vitamin responsive (Table 40-2). Homocystinemia responds to pharmacological doses of folate, cobalamin, and pyridoxine, whereas methylmalonic acidemia responds to cobalamin. Maple syrup urine disease, a branched-chain aminoaciduria, may be responsive to

high-dose thiamin by inducing the enzyme α -ketoacid decarboxylase, promoting metabolism of branched-chain amino acids. β -Methylcrotonylglycinuria and propionic acidemia may be responsive to biotin replacement; Hartnup's disease, a disorder of tryptophan metabolism, is also responsive to niacin.

VITAMIN DEFICIENCIES

Thiamin

The discovery and isolation of vitamins began with the study of beriberi in the 19th century. Although beriberi has been recognized for centuries, it was not until the industrial revolution that the disease reached epidemic proportions. Grain mills began producing polished rice, which was mechanically stripped of the nutrient-rich husk. Epidemics of painful polyneuropathy and heart failure rapidly developed in regions where rice was the major source of carbohydrate, particularly in Asia. In 1897, Eijkman demonstrated the disease in pigeons after feeding the birds polished rice; he then cured the disease by feeding the same birds crude, unpolished rice. A search then began for the antineuritic factor within the rice husks. Funk thought he had identified the anti-beriberi factor in 1911 as an amine within rice bran extracts and coined the term *vitamine*. Elvehjem later identified Funk's substance as the antipellagra factor nicotinic acid amide (niacin). The anti-beriberi factor was synthesized in 1936, and the name was changed to thiamin to reflect the molecule's sulfur content.⁸

TABLE 40-2

Characteristics of Disorders Responding to Large Doses of Vitamins and Cofactors

| VITAMIN | DISORDER | AFFECTED ENZYME | THERAPEUTIC DOSE |
|---|--|---|------------------|
| Thiamine (vitamin B ₁) | Branched-chain ketoaciduria (maple syrup urine disease) | Branched-chain ketoacid decarboxylase | 5–20 mg |
| | Lactic acidosis | Pyruvate carboxylase | 5–20 mg |
| | Pyruvicacidemia | Pyruvate dehydrogenase | 5–20 mg |
| Cobalamin (vitamin B ₁₂) | Methylmalonicaciduria | Methylmalonyl-CoA mutase apoenzyme | 2000 µg |
| | Homocystinuria | Defects in adenosyl-cobalamin and methyl-cobalamin synthesis | 500–1000 µg |
| Pyridoxine (B ₆) | Homocystinuria | Cystathionine synthase | 200–1200 µg |
| | Pyridoxine-responsive infantile seizures | Glutamic acid decarboxylase | 10–50 mg |
| Niacin | Hartnup's disease | Intestinal malabsorption of tryptophan | >400 mg |
| Folic acid | Homocystinuria | Methylenetetrahydrofolate reductase | >10 mg |
| Biotin | β-Methylcrotonylglycinuria | β-Methylcrotonyl-CoA carboxylase | 5–10 mg |
| | Propionicacidemia | Propionyl-CoA carboxylase | 5–10 mg |

Adapted from Moser H: Genetic and metabolic diseases. In Asbury AK, McKhann GM, McDonald WI (eds): Diseases of the Nervous System: Clinical Neurobiology, 2nd ed. Philadelphia, Saunders, 1992, p 676.

PATHOGENESIS AND PATHOPHYSIOLOGY. The metabolically active form of thiamin, called thiamin pyrophosphate (TPP), is critical in the intermediary metabolism of carbohydrate. TPP is involved in three enzyme systems: (1) pyruvate dehydrogenase, which converts pyruvate to acetyl coenzyme A (CoA); (2) α -ketoglutarate dehydrogenase, which catalyzes the conversion of α -ketoglutarate to succinate in the Krebs cycle; and (3) transketolase, which catalyzes the pentose monophosphate shunt (see Fig. 40-1). A deficiency of TPP leads to elevated levels of serum pyruvate and occasionally lactate, reduced red blood cell (RBC) transketolase activity, and a corresponding increase in transketolase activity in response to added TPP (TPP effect). It is not understood how TPP deficiency leads to the hallmark pathology.

Pathologically, patients with WKS show capillary proliferation and petechiae; spongy degeneration of astrocytes with neuronal preservation occurs in midline structures of the brain, such as the medial thalamic nuclei, mammillary bodies, periaqueductal gray area of the mesencephalon, and pontine tegmentum (Fig. 40-2). Degeneration of the superior cerebellar vermis is usually present. The lesions in the thalami and mammillary bodies probably account for the confusion, memory loss, and confabulation. The pontine tegmental lesions may cause the oculomotor palsies, and the truncal ataxia may result from the midline cerebellar degeneration. Cellular injury in these regions may be due to the inhibition of adenosine triphosphate (ATP) synthesis and the induction of abnormal carbohydrate metabolism. With thiamin deficiency polyneuropathy, the nerve shows axonal degeneration with secondary demyelination. Because of the frequency of this neuropathy in alcoholics, there is debate as to whether the cause is alcohol toxicity or thiamin deficiency. It has been theorized that the neuropathy of dry beriberi may be related to TPP deficiency-induced impairment of nerve excitability and conduction.⁹

EPIDEMIOLOGY AND RISK FACTORS. Thiamin is most abundant in yeast, pork, legumes, cereal grains, and rice, and the recommended daily allowance (RDA) of this

vitamin is 0.5 mg/1000 kcal.¹⁰ The total body store is 30 to 100 mg, and it is present in heart, skeletal muscle, liver, kidneys, and brain. Because there is a limited quantity stored, the supply must be constantly replenished. The half-life of thiamin is approximately 2 weeks, and patients may suffer severe neurological complications and even death after 6 weeks of total thiamin depletion. Patients at high risk for deficiency include adults who derive most of their carbohydrate from milled rice, alcoholics, and infants breast fed by malnourished mothers. Other potentially thiamin-deficient states include prolonged total parenteral nutrition,¹¹ hyperemesis gravidarum,¹² anorexia nervosa, gastric or jejunoileal bypass,¹³ intractable vomiting following gastric stapling for morbid obesity,¹⁴ and severe malabsorption. Thiamin deficiency is also found in those who are prisoners of war¹² or those who engage in a hunger strike. Thiamin deficiency has also been reported after long-standing peritoneal dialysis and hemodialysis.^{15,16}

CLINICAL FEATURES AND ASSOCIATED DISORDERS. WKS and polyneuropathy (dry beriberi) are the two neurological disorders resulting from thiamin deficiency. Wernicke's disease and Korsakoff's psychosis often overlap, with Wernicke's disease having acute features of confusion, ataxia, and oculomotor palsies and nystagmus and Korsakoff's psychosis having delayed and often irreversible anterograde and retrograde memory impairment (Video 229, Wernicke's Encephalopathy). Korsakoff's dementia may follow one or more episodes of Wernicke's encephalopathy. Although prospective clinical studies, including those of Victor and colleagues,⁸ suggest a high incidence of the classic triad in WKS, other autopsy series have found pathological evidence for the disorder in many patients with only one or two symptoms during life.²

The frequency of WKS from autopsy series ranges from 0.8% to 2.8%. The disorder is probably underdiagnosed during life. WKS is most common in alcoholics because patients are particularly susceptible to thiamin deficiency due to a combination of poor diet, inadequate intake and impaired absorption of vitamins, and overdependence on alcohol as a source of calories. Certain individuals

Figure 40-2. Wernicke's encephalopathy. Gross appearance characterized by petechial hemorrhages in the typical locations. (Reprinted with permission from Okazaki H: *Fundamentals of Neuropathology*, 2nd ed. New York, Igaku Shoin, 1989, p 192.)

may also have a genetic predisposition toward the development of WKS owing to an abnormality of thiamin-dependent enzymes.^{17,18}

Patients with thiamin deficiency may become acutely symptomatic when challenged with large doses of carbohydrate. An example is the alcoholic patient receiving intravenous glucose who then becomes agitated, confused, and ataxic. Acute attacks may also be produced by excessive vomiting, such as that associated with hyperemesis gravidarum, presumably due to markedly increased metabolic demands in the setting of decreased consumption.⁸

Mental status changes may include a global confusional state, memory loss, and agitation. Rarely, patients develop stupor and coma. Ocular abnormalities include nystagmus, lateral rectus palsies, conjugate gaze palsy, ptosis, retinal hemorrhages, pupillary abnormalities, and scotomas. Ataxia may be severe, preventing an affected patient from standing without assistance. Finger-to-nose and heel-to-shin tests are often normal when the patient is tested in the bed. Truncal ataxia often becomes obvious only on standing or sitting, reflecting the midline degeneration of the superior division of the vermis.

Figure 40-3. Bilateral wrist drop and foot drop in a 40-year-old woman with Wernicke-Korsakoff syndrome and polyneuropathy. (From Victor M, Adams RD, Collins GH: *The Wernicke-Korsakoff Syndrome*. Philadelphia, Davis, 1971.)

Polyneuropathy is present in more than 80% of patients with WKS.¹⁹ Koike and coworkers¹⁹ demonstrated that thiamin and alcohol-induced neuropathy are distinct entities. Thiamin deficiency may present acutely with prominent motor weakness and large fiber sensory loss. Bilateral foot drop and even wrist drop may be present (Fig. 40-3). In contrast, the neuropathy of alcohol presents with slowly progressive muscular weakness and sensory and reflex loss, accompanied by burning feet and lancinating pains. Calf tenderness is a prominent feature. Half of Koike and colleagues' series had evidence of an autonomic neuropathy with orthostatic hypotension.

DIFFERENTIAL DIAGNOSIS. The presence of mild peripheral edema with a peripheral neuropathy may be a helpful physical sign to suggest thiamin deficiency with coexisting cardiac failure (wet beriberi). Thiamin deficiency should be considered in the differential diagnosis of an

Figure 40-4. T2-weighted magnetic resonance imaging of a patient with Wernicke-Korsakoff syndrome, demonstrating symmetrically increased signal intensity in the periaqueductal gray and midline structures. (From Yamashita M, Yamamoto T: Wernicke encephalopathy with symmetric pericentral involvement: MR findings. *J Comput Assist Tomogr* 1995;19:307.)

axonal polyneuropathy and be distinguished from diabetes, uremia, autoimmune and inflammatory conditions, and hereditary neuropathies. Other considerations in patients presenting with confusion, ataxia, and oculomotor disturbances should include hypoxic-ischemic encephalopathy, Leigh's encephalomyelopathy, adrenoleukodystrophy, metachromatic leukodystrophy, brain stem encephalitis, and certain infectious disorders (syphilis and human immunodeficiency virus [HIV]) (Video 252, Neonatal Adrenoleukodystrophy). Other nutrients deficient among alcoholics may include folic acid, pyridoxine, and niacin.²⁰

EVALUATION. The evaluation of patients with thiamin deficiency begins with a high index of suspicion, and the clinician must recognize that the disorder is not restricted to alcoholics. Several tests, including RBC transketolase activity assay, TPP stimulation of RBC transketolase (the TPP effect), and 24-hour urinary excretion of thiamin, are used to assess thiamin status. Serum thiamin levels lack sufficient sensitivity and specificity to be used alone. RBC transketolase activity, with or without TPP challenge, is the most accurate assessment tool.²¹ This test, however, is increasingly difficult to find commercially. Magnetic resonance imaging (MRI) may show abnormal signal in the midline nuclei corresponding to the pathological lesions described (Fig. 40-4).^{11,22}

MANAGEMENT. Treatment of suspected WKS begins with the immediate administration of at least 100 mg intravenous thiamin, followed by 100 mg intramuscular (IM) daily for 3 to 5 days. Patients should then be maintained on 50 mg oral thiamin and daily multivitamins.

PROGNOSIS AND FUTURE PERSPECTIVES. Whereas early recognition and treatment may reverse all symptoms, in practice, WKS often goes unrecognized until late in the disease, and therapy rarely reverses all of its manifestations. The oculomotor disturbances respond best to treatment and may show improvement within hours. Confusion and ataxia are more resistant. The peripheral neuropathy is often resistant to therapy unless it is treated early. Despite treatment, the mental changes of WKS may progress to permanent and disabling dementia.²³ Gold and colleagues²⁴ found abnormalities of thiamin metabolism in patients with Alzheimer's disease. Molecular genetics may help identify patients and families with a hereditary predisposition toward the

development of WKS. Further characterization of the role of thiamin in the sodium-potassium ATPase pump may further our understanding of its role in nerve excitability and conduction, increasing our understanding of the pathogenesis of the neuropathy.⁹ Some countries such as Australia have experimented with fortification of food substances with thiamin to reduce the incidence of WKS, and fortification of alcoholic beverages has been advocated.

Niacin and Nicotinic Acid

Nicotinic acid deficiency was found to be the causative agent of pellagra in 1937, yet the name was changed to niacin in order to prevent confusion with the tobacco derivative, nicotine. Niacin includes both nicotinic acid and nicotinamide, which form the metabolically active nicotinamide adenine dinucleotide (NAD) and NAD phosphate (NADP), an end product of tryptophan metabolism. More than 200 enzymes are dependent on NAD and NADP to carry out oxidation and reduction reactions, and these enzymes are involved in the synthesis and breakdown of all carbohydrates, lipids, and amino acids. Although niacin is endogenously produced in humans, exogenous intake is required in order to prevent deficiency. Niacin is found in meats, liver, fish, legumes, peanuts, enriched bread, coffee, and tea.

Pellagra continues to occur in areas of Africa and Asia, especially in populations dependent on corn as the principal source of carbohydrate. When corn is first soaked in lime water, as is done in Mexico when tortillas are prepared, niacin is liberated and deficiency occurs less commonly. In the United States, niacin deficiency is seen in alcoholics and in those taking isoniazid. There is a single case report of a patient developing nicotinic acid deficiency after valproic acid therapy.²⁵ Pregnant women are protected from niacin deficiency owing to their enhanced ability to convert tryptophan to niacin endogenously, particularly in the third trimester.

Pellagra, or rough skin, affects the skin, the gastrointestinal system, and the CNS. Hence, the classic triad of the "three Ds"—dermatitis, diarrhea, and dementia. In industrialized countries, particularly among alcoholics, niacin deficiency may present only with encephalopathy.²⁶⁻²⁸ Patients may have altered sensorium, diffuse rigidity of

the limbs, and grasping and sucking reflexes. Dementia and confusion are the most constant findings, followed by diarrhea (50%) and dermatitis (30%).²⁸ Spinal cord and peripheral nerve defects have also been reported, particularly in prisoners of war.¹² Coexisting deficiencies of thiamin and pyridoxine are common, especially in alcoholics. Hartnup's disease, an autosomal recessive defect in tryptophan absorption by the gut and kidney, can give a clinical picture identical to pellagra that is responsive to niacin administration. Carcinoid syndrome can also produce niacin deficiency. Because all tryptophan in this disorder, none is available for the production of nicotinic acid, thereby predisposing to deficiency in the absence of supplementation.

Superphysiological doses of niacin (1.5 to 3 g daily) have been used successfully in the treatment of hypercholesterolemia, and this practice diminishes mortality by reducing a coronary artery disease risk factor. Side effects of high-dose niacin include flushing, hyperuricemia, hyperglycemia, and elevations in liver enzymes.

In the evaluation of potential niacin deficiency, nicotinic acid metabolites can be detected in the urine; however, clinical suspicion and ease of treatment make this measurement impractical and unnecessary. The administration of 40 to 250 mg of niacin daily is adequate to reverse most of the signs and symptoms of niacin deficiency. With proper therapy, the prognosis for the resolution of neurological symptoms is good.

Cobalamin (Vitamin B₁₂)

PATHOGENESIS AND PATHOPHYSIOLOGY. Vitamin B₁₂ deficiency produces neurological and hematological effects by impairing the function of two enzyme systems (Fig. 40-5).^{6,29} Methylcobalamin is a cofactor of methionine synthase, a cytosolic enzyme that catalyzes the conversion of homocysteine and methyltetrahydrofolate to produce methionine and tetrahydrofolate. Methionine is further metabolized to S-adenosylmethionine, which is necessary for methylation of myelin sheath phospholipids and proteins. Tetrahydrofolate is the required precursor for purine and

pyrimidine synthesis. In the mitochondria, adenosylcobalamin catalyzes the conversion of L-methylmalonyl-CoA to succinyl-CoA.

In deficiency states, serum levels of homocysteine and methylmalonic acid rise. Although the mechanism of megaloblastic changes in both folate and cobalamin deficiency is reasonably well understood, the biochemical basis of the neurological damage that occurs in cobalamin deficiency remains uncertain. Of the two reactions that require cobalamin, the methionine synthase reaction is considered more likely to play a critical role in nervous system function. Rarely, neurological complications have also been reported in folate deficiency because methionine synthase also requires this cosubstrate.³⁰ It has been proposed that the accumulation of methylmalonate and propionate provide abnormal substrates for fatty acid synthesis, resulting in abnormal odd-carbon and branched-chain fatty acids, so-called "funny fatty acids," which may be incorporated into the myelin sheath and interfere with impulse conduction.

Vitamin B₁₂ deficiency results in demyelination of the posterior columns, corticospinal tracts, and white matter of the cerebral hemispheres (Fig. 40-6).³¹ Less commonly, a sensorimotor and autonomic neuropathy that is axonal and demyelinating in nature may also be present.³² These lesions lead to a constellation of symptoms, including cognitive and affective disorders, ataxia, spasticity, and paresthesias.

EPIDEMIOLOGY AND RISK FACTORS. The total body store of cobalamin is 2000 to 5000 µg, half of which is stored in the liver. The recommended daily allowance is 6 µg/day, and the average diet provides 20 µg/day. Because the vitamin is tightly conserved through enterohepatic circulation, 2 to 5 years elapse before a subject develops cobalamin deficiency from malabsorption, and as many as 10 to 20 years are needed to induce a dietary deficiency from a strict vegetarian diet.

The most common cause of vitamin B₁₂ deficiency is pernicious anemia or autoimmune parietal cell dysfunction (Table 40-3).³¹ The mean age of diagnosis is 60 years, and the female-to-male ratio is approximately 1.5:1. In white populations, the incidence of the disease increases with

increasing age, peaking after age 65 years. In Hispanic and African populations, there is an overall younger age distribution, especially among women. When using radioassay-derived serum cobalamin levels below 200 pg/mL or elevated levels of homocysteine and methylmalonic acid as diagnostic criteria, the prevalence of vitamin B₁₂ deficiency from all causes ranges from 7% to 16%.⁵

The majority of patients, approximately 50% to 78%, have autoimmune parietal cell dysfunction (pernicious anemia).³³ Another 10% to 40% have food-bound cobalamin malabsorption due to achlorhydria.³⁴ The rest have a variety of etiologies, mainly due to malabsorption from medical, surgical, or pharmacological interruptions of gastric acid secretion or intrinsic factor secretion. These include patients following gastric surgery,³⁵ bypass procedures for weight reduction,³⁶ as well as those on long-term histamine-2 (H₂) blocker therapy, due to inhibition of acid secretion.³⁷ Nitrous oxide administration may precipitate acute vitamin B₁₂

deficiency in patients with asymptomatic low cobalamin levels.³⁸ Other causes of vitamin B₁₂ deficiency include ileal resection, parasitic infestations from *Diphyllobothrium latum*, Crohn's disease and other malabsorption states, short gut syndrome, veganism, chronic alcoholism with poor diet, and rare congenital enzyme deficiencies.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Subacute combined degeneration of the spinal cord, peripheral nerve dysfunction, and cerebral dysfunction are classic features of the disorder. Many patients present without accompanying anemia or macrocytosis. Heaton and associates³⁹ reviewed 143 patients who had 153 episodes of cobalamin deficiency. Seventy-four percent of the episodes presented with neurological symptoms, including paresthesias, numbness, gait ataxia (Video 5, Sensory Ataxia), fecal incontinence, leg weakness, impaired manual dexterity, impaired memory, and impotence. Rarely, patients had orthostatic lightheadedness, anosmia, diminished taste, paranoid psychosis, and diminished visual acuity. The remaining 26% presented with non-neurological symptoms classically associated with pernicious anemia, including tiredness, syncope, palpitations, sore tongue, diarrhea, and other bowel disturbances.

On examination, patients demonstrate a neuropathy in 25%, isolated myelopathy in 12%, and a combined neuropathy and myelopathy in 41%. Peripheral neuropathic symptoms and signs were combined with other manifestations, such as myelopathy, cortical dysfunction, and autonomic dysfunction, in 65%. Only 3% had a neuropathy as the only abnormality. Memory dysfunction and affective and behavioral changes were seen in 8%. Cognitive deficits included psychosis, affective disturbances, and memory disturbances, as well as changes in personality. Orthostatic hypotension has been reported and is thought to be due to a disordered release of norepinephrine.^{40,41} Fourteen percent had normal examinations.

There have been several reports of patients developing a myeloneuropathy after exposure to nitrous oxide.^{29,38,42} This occurs in two populations: those with normal cobalamin levels but who chronically abuse the anesthetic gas for recreational purposes and those with a subclinical vitamin B₁₂ deficiency who, after a short exposure to nitrous oxide for a dental or surgical procedure, develop paresthesias, burning feet, and ataxia. Nitrous oxide is a potent oxidizing agent, which irreversibly oxidizes the cobalt core of cobalamin from a 1+ valence state to 3+ valence state, rendering methylcobalamin inactive. This effectively inhibits the conversion of homocysteine to methionine, thus interdicting the supply of S-adenosylmethionine.

Low cobalamin levels have also been found in occasional patients with multiple sclerosis⁴³ and HIV infection⁴⁴; however, no pathogenic relationship or treatment response has been established in either disorder.

DIFFERENTIAL DIAGNOSIS. The diagnostic criteria for vitamin B₁₂ deficiency include a consistent clinical syndrome of ataxia, paresthesias, cognitive dysfunction, and evidence of neuropathic or myelopathic dysfunction. A megaloblastic anemia is often missing in patients with neurological symptoms.³³ In fact, one fourth of patients have no anemia or macrocytosis.³⁹ The most characteristic presentation is gait dysfunction and paresthesias in an elderly individual. The hallmark finding of a myeloneuropathy,

absent ankle reflexes and extensor plantar responses, is present in only 41%.³⁹ Vitamin B₁₂ deficiency must be differentiated from other causes of myelopathy and neuropathy. Myelopathy and mental decline may also be seen in multiple sclerosis, but the other neuropathic signs of vitamin B₁₂ deficiency should clarify the likely diagnosis. Other disorders that may have both central and peripheral manifestations include syphilis, amyotrophic lateral sclerosis, Friedreich's ataxia, vitamin E deficiency, metachromatic leukodystrophy, adrenomyeloneuropathy, mitochondrial cytopathy, and ceroid lipofuscinosis. These diagnoses should be considered in patients with the paradoxical findings of absent ankle reflexes and extensor plantar responses. Cervical spondylitic myelopathy with lumbar osteoarthropathy and cauda equina compression may also give a similar clinical pattern.

EVALUATION. An algorithm for the diagnosis and treatment of cobalamin deficiency (Fig. 40-7) is based on two assumptions: (1) A normal cobalamin assay does not fully exclude cobalamin deficiency, and (2) the normal range may vary depending on the assay type. Many laboratories have switched from radioassay to chemiluminescence assay, which may have a higher normal reference range (250 to 1100 pg/ml).

When cobalamin deficiency is suspected, it is practical to order methylmalonic acid (MMA) at the same time as a cobalamin level. MMA has the advantage of greater specificity for B₁₂ deficiency than homocysteine. If the B₁₂ is low and MMA is elevated, the patient is likely to have true B₁₂ deficiency. False-positive elevations of MMA occur most commonly from renal insufficiency.⁴⁵ A diagnosis of pernicious anemia (autoimmune parietal cell destruction) can be made by finding intrinsic factor antibodies. Unfortunately, this test has low sensitivity (40% to 60%). An elevated serum gastrin may indicate achlorhydria, pernicious anemia or food-bound cobalamin malabsorption. A Schilling test will help distinguish pernicious anemia, food-bound cobalamin malabsorption, or an ileal malabsorption problem.⁴⁶

If metabolites or the serum gastrin levels are elevated, a Schilling test may be performed to evaluate for the presence of cobalamin malabsorption. Technically, patients with classic pernicious anemia have an abnormal test result when radioactive cobalamin alone is given by mouth (Part I of the Schilling test). This abnormality is corrected when the test is repeated with intrinsic factor (Part II of the Schilling test). Abnormally low secretion of cobalamin in Part II of the Schilling test indicates an intestinal cause for the cobalamin malabsorption, such as inflammatory bowel disease. Part II of the Schilling test may be repeated after giving antibiotics or vermicides to exclude bacterial overgrowth (so-called blind loop syndrome) or fish tapeworm infestation due to *Diphyllobothrium latum*. Normal results on Part I of the test in a patient with cobalamin deficiency may be observed in total vegetarians. They may also occur in patients with food-cobalamin malabsorption who show normal absorption of crystalline cobalamin but are unable to digest and absorb cobalamin present in food due to achlorhydria. This defect can be identified using a modified Schilling test in which radioactive cobalamin is administered with food.

MANAGEMENT. Treatment may begin with IM injections of 1000 µg of cobalamin per day for 5 days, then

500 to 1000 µg IM every month. Oral replacement is an alternative for patients who cannot tolerate IM injections or for whom they are impractical. Kuzminski and colleagues⁴⁷ demonstrated that 2000 µg vitamin B₁₂ is as effective or more effective than IM injections given monthly for maintaining normal serum vitamin B₁₂ levels and correcting elevation in serum methylmalonic acid, with a comparable onset of action. This effect occurred regardless of etiology and included patients with pernicious anemia, food-cobalamin malabsorption, and a history of gastric surgery. A loading dose was not necessary for oral replacement because serum metabolite elevations normalized as rapidly as did those in patients receiving IM loading doses.

Because 1% of all ingested cobalamin may be absorbed by passive diffusion, cobalamin requirements can be satisfied with oral therapy, even in patients with pernicious anemia, as long as the dose is sufficient. A dose of 1000 µg/day will yield 10 µg of absorbed cobalamin, which exceeds the recommended daily allowance. It may be practical to replenish cobalamin stores first using injections of cyanocobalamin for 1 week and then to maintain patients using a 1000 µg daily oral supplement.

PROGNOSIS AND FUTURE PERSPECTIVES. The earlier intervention begins, the more likely the patient is to have a complete recovery.^{39,48} Paresthesias often improve within several weeks, whereas spinal cord dysfunction may require several months. Approximately 2% of patients experience an acute worsening of paresthesias immediately following vitamin B₁₂ supplementation, but this addition does not impair the long-term response to therapy. Folate supplementation may reverse the hematological abnormalities but will not prevent neurological deterioration. With early recognition, patients may resume a normal lifestyle with limited impairment of gait or cognition. Spasticity due to spinal cord dysfunction, when it is established, is often difficult to reverse but may continue to improve over many months to years. There are a variety of reports of neuroimaging in vitamin B₁₂ deficiency, showing classic white matter changes in the posterior and lateral columns of the spinal cord. Resolution of the abnormalities on MRI may occur following replacement therapy.^{49,50}

Ten to twenty percent of patients may relapse owing to noncompliance with long-term supplementation. These patients often develop identical symptoms that respond equally well to repeat treatment.⁴⁸

Hyperhomocysteinemia has been directly linked to an increasing incidence of coronary and cerebrovascular disease. It is present in cobalamin, pyridoxine, and folate deficiencies; renal failure; and heterozygous homocysteinemia. Therefore, vitamin B₁₂ deficiency, as well as folate and pyridoxine deficiencies, may be independent risk factors for the development of carotid and coronary disease. This association awaits further study. Approximately 40% of patients with biochemical cobalamin deficiency may be asymptomatic. A high index of suspicion for vitamin B₁₂ deficiency is warranted in view of its high prevalence in the elderly.

Folate (B₉)

Although folic acid has long been recognized as an important contributor to neural tube defects, less well appreciated is its role in cognition and depression. Although both folate

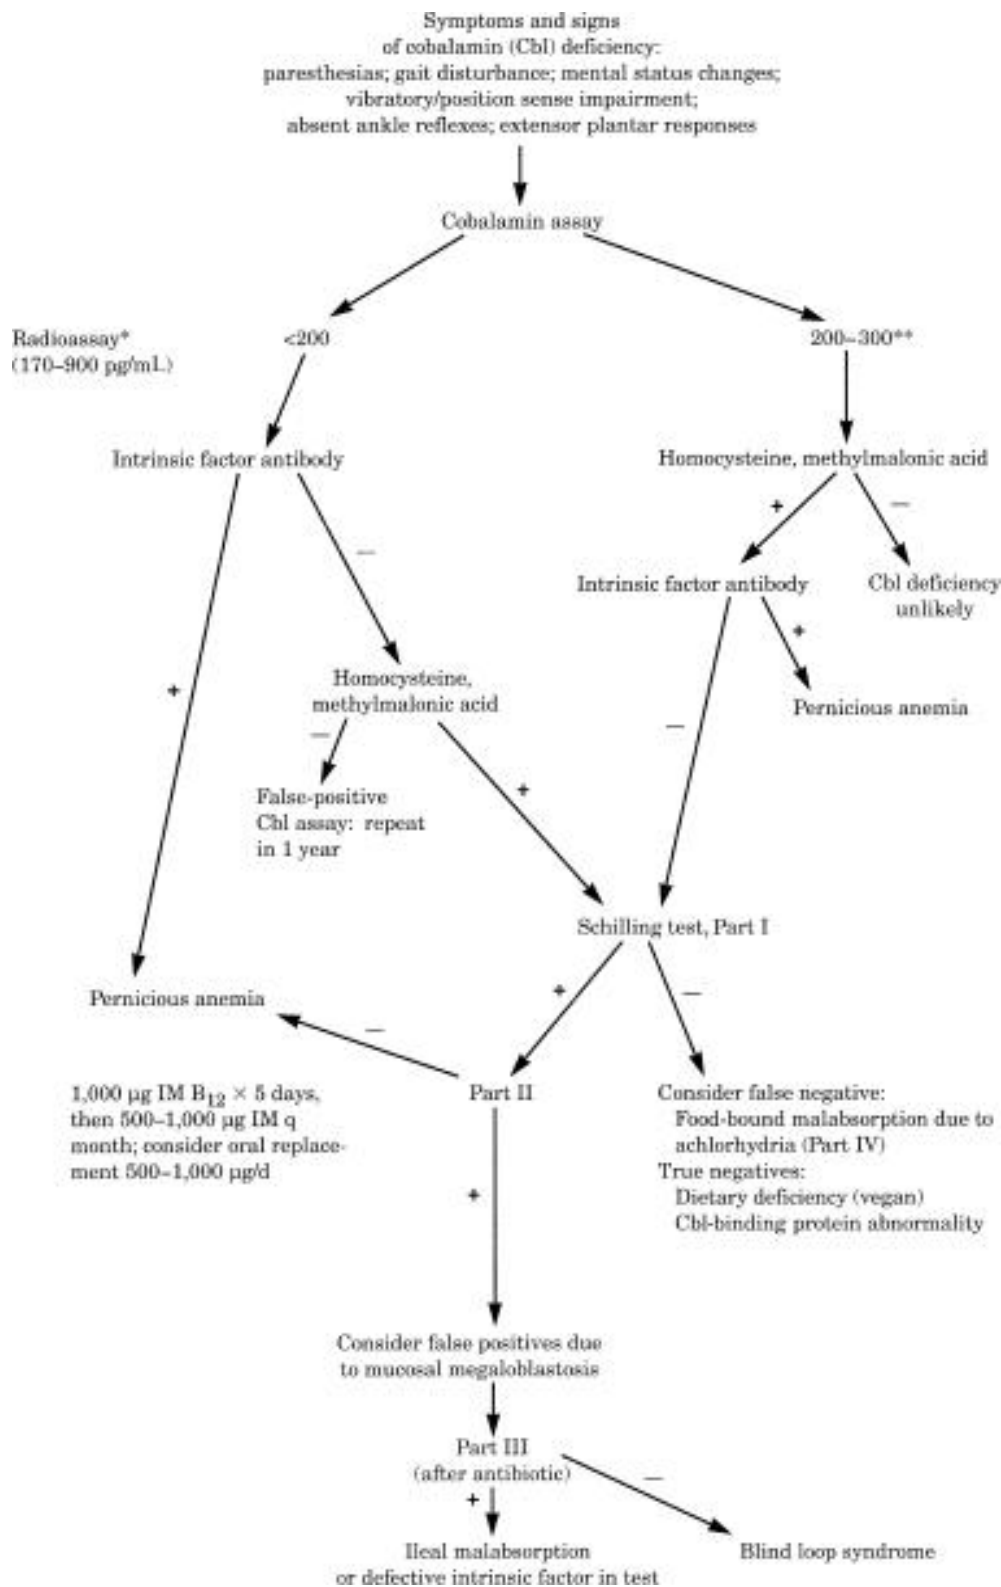

Figure 40-7. Algorithm for cobalamin deficiency diagnosis and treatment. A higher normal reference range should be applied if chemiluminescence or other nonradioisotopic ligand-binding assays are used. If the clinical picture is suggestive of possible cobalamin deficiency, patients with serum B₁₂ greater than 300 pg/mL should be investigated similarly. IM, intramuscular. (From Green R, Kinsella LJ: Current concepts in the diagnosis of cobalamin deficiency. *Neurology* 1995;45:1435-1440.)

and B₁₂ deficiency may cause megaloblastic anemia, the neuropsychiatric disturbances may differ. Whereas B₁₂ deficiency is more likely to result in subacute combined degeneration and neuropathy, folate deficiency is more likely to cause a depression and dementia.

Folate deficiency may occur more frequently in the elderly due to a combination of factors, including poor diet, malabsorption, medications, and increased demand. Sixteen percent of admissions to a geriatric unit showed evidence of folate deficiency and correlated with both depression and cognitive decline.⁵¹

In 1998, folate supplementation of the food supply became mandatory in order to prevent neural tube defects. An unexpected benefit has been a 50% decline in the prevalence of homocysteine elevations in the United States.⁵² What effect this may have on the incidence of atherosclerosis, cerebrovascular events, and dementia remains to be seen. The link between folate deficiency and elevated homocysteine levels and vascular disease is well established. Less clear is whether aggressive suppression of homocysteine levels by folate supplementation reduces cardiovascular and cerebrovascular events. The Vitamin Intervention in Stroke Prevention trial (VISP 2004) demonstrated that moderate reduction of total homocysteine using folate, cobalamin, and pyridoxine supplements in patients with non-disabling cerebral infarction had no effect on vascular outcomes after 2 years.⁵³

Pyridoxine (Vitamin B₆)

Pyridoxal phosphate is the active biochemical form of pyridoxine. It is a coenzyme of amino acid metabolism, particularly tryptophan and methionine. By inhibiting methionine metabolism, excessive S-adenosylmethionine accumulates, which inhibits nerve lipid and myelin synthesis.¹⁰ Because tryptophan is required in the production of niacin, pyridoxine deficiency can produce a secondary niacin deficiency indistinguishable from primary pellagra. Pyridoxine is also involved in lipid and neurotransmitter synthesis. Dopamine, serotonin, epinephrine, norepinephrine, and γ -aminobutyric acid (GABA) all require pyridoxine for their production. Lott and associates⁵⁴ documented reduced pyridoxal phosphate and GABA concentrations in the brain of a child dying with pyridoxine-responsive seizures.

The RDA of pyridoxine is 2 mg. It is found most abundantly in enriched breads, cereals and grains, chicken, orange and tomato juice, bananas, and avocados. Patients at risk for pyridoxine deficiency include those with general malnutrition, prisoners of war, refugees, alcoholics, infants of vitamin B₆-deficient mothers, and patients using isoniazid and hydralazine. Surveys of hospitalized elderly patients have shown that up to 5% may have a vitamin B₆ deficiency.⁴ A rare autosomal recessive disorder of pyridoxine-responsive or pyridoxine-dependent neonatal seizures also exists.

Pyridoxine is unique in that both the deficiency and the toxic states result in a peripheral neuropathy. Deficiency affects the blood, skin, and nervous system. The skin changes are indistinguishable from pellagra, probably due to the close interaction of niacin and pyridoxine. Pyridoxine improves the microcytic anemia of alcoholics as well as the

anemia associated with pyridoxine-responsive seizures in infants. Pyridoxine-deficient peripheral neuropathy is seen primarily in patients on isoniazid or hydralazine, and it is characterized by sensory loss in distal limbs, weakness, and reflex changes. Patients describe burning feet and painful paresthesias. CNS manifestations include depression, irritability, and confusion.⁵⁵ Infants born to pyridoxine-deficient mothers may develop neonatal seizures as part of their vitamin deficiency state, a condition distinct from hereditary pyridoxine-responsive seizures. Up to 10% of patients who are on isoniazid may develop a peripheral sensory neuropathy. Isoniazid promotes increased pyridoxine excretion in the urine, resulting in a deficiency state. Similar changes are seen in patients on hydralazine.

Urinary assays for xanthurenic acid and other pyridoxine metabolites may be performed following tryptophan loading in patients suspected of having pyridoxine deficiency. In the serum, cystathionine levels may also be elevated in this condition.

Daily intake of vitamin B₆ (150 to 450 mg) prevents the neuropathy of isoniazid and should be used by patients on this drug. Once it is established, the neuropathy does not entirely resolve but may improve with replacement vitamin B₆.

Vitamin E

α -Tocopherol is the most active form of vitamin E present in humans. Tocopherol is absorbed and incorporated into chylomicrons in the small intestine. It is carried in portal blood to the liver and α -tocopherol transfer protein (α -TTP) binds and recycles vitamin E in the liver for incorporation into low-density lipoproteins and very low-density lipoproteins.⁵⁶ Once it is delivered to the cells, α -tocopherol serves as an antioxidant, preventing free radical peroxidation and injury to cell membranes. It is stored in adipose tissue, liver, and muscle. Deficiency can occur at any stage of tocopherol metabolism: reduced intake, fat malabsorption, inhibition of enterohepatic circulation, mutation of α -TTP, and abetalipoproteinemia. Vitamin E deficiency leads to axonal membrane injury, with resultant axonal degeneration of peripheral nerve, dorsal root ganglia, and posterior columns (Figs. 40-8 and 40-9).⁵⁷ Superficially, the spinal cord abnormalities bear a striking resemblance to those found with subacute combined degeneration of vitamin B₁₂ deficiency. However, the lesions of vitamin E deficiency are due to spongy demyelination of the posterior columns and lateral tracts, whereas those of vitamin E deficiency are the result of swollen and dystrophic axons, or spheroids, and astrocytosis in the posterior columns, dorsal root ganglia, and Clarke's column.

Vitamin E is fat soluble and found in abundance in vegetable oils and wheat germ. The RDA is 10 mg (10 IU) for men and 8 mg (10 IU) for women. Patients at risk for the development of vitamin E deficiency include those who have the following clinical conditions: hypobetalipoproteinemia or abetalipoproteinemia (Bassen-Kornzweig syndrome); other disorders of the pancreas and liver, such as cystic fibrosis and primary biliary atresia; PEM; familial vitamin E deficiency due to a defect in α -TTP; and other malabsorptive states that result in cholestasis (Crohn's disease, ulcerative colitis, and celiac disease) (Table 40-4). Pregnancy increases vitamin E serum concentrations, but

Figure 40-8. Vitamin E deficiency myelopathy. Cross section of cervical spinal cord. The *triple arrowheads* denote light-staining symmetrical areas of degeneration involving the posterior columns. The two *single arrowheads* indicate involvement of the dorsal and ventral spinocerebellar tracts. In the posterior columns, the fasciculus cuneatus is affected to a greater extent than the gracilis. Microscopically, numerous swollen and dystrophic axons (spheroids) and astrocytosis are present in the posterior columns, and nerve cell loss is seen in the dorsal root ganglia (luxol-fast blue-periodic acid-Schiff). | Generalized weakness |
| Extensor plantar responses |

premature infants often have low levels of vitamin E due to a lack of adipose tissue as well as difficulty in transplacental migration of the vitamin. The majority of patients who have vitamin E deficiency are those with severe malabsorptive states present since birth or rare familial vitamin E deficiency due to transfer protein abnormalities.

Patients develop areflexia, cerebellar ataxia, cutaneous sensory impairment, position and vibratory sense abnormalities, and, less commonly, ophthalmoplegia, muscle weakness, nystagmus, extensor plantar responses, ptosis, and dysarthria (Table 40-5).⁵⁸ Acanthocytosis and pigmentary retinopathy is seen primarily in patients with abetalipoproteinemia. Patients with abetalipoproteinemia and congenital malabsorption develop symptoms in childhood and adolescence. Occasionally, adults with acquired malabsorption present with progressive ataxia. The familial vitamin E deficiency phenotype is indistinguishable from Friedreich's ataxia (Fig. 40-10). Autosomal recessive familial vitamin E deficiency has been studied extensively and found to be due to a frameshift mutation within the α -TTP gene on chromosome 8. Defective α -TTP prevents incorporation of vitamin E into very low-density lipoproteins.^{59,60}

Friedreich's ataxia, Machado-Joseph disease, and other familial spinocerebellar ataxias⁶¹ should be considered in the differential diagnosis of patients presenting with this constellation of signs and symptoms.

Serum α -tocopherol is a reliable indicator of body vitamin E content. Tocopherol isomers can also be assessed using thin layer chromatography. Approximately 90% or more of vitamin E is α -tocopherol, which can be directly measured in the serum. Occasional patients with hyperlipidemia may have a falsely low α -tocopherol level. Vitamin E deficiency may result in electrophysiological abnormalities, including low-amplitude sensory nerve action potentials, slowed conductions, and abnormal somatosensory evoked potentials.⁶²

Administration of α -tocopherol (400 mg bid) may reverse or prevent the progression of the effects of a deficiency state. Doses of up to 100 mg/kg/day may be required in those with abetalipoproteinemia and the familial vitamin E deficiency syndrome. Whereas oral doses of α -tocopherol correlate well with plasma levels, comparable increases in the ventricular cerebrospinal fluid do not occur, suggesting that CNS penetration may be exceedingly low.⁶³ An injectable vitamin E preparation is available for those who cannot absorb oral medication. The prognosis for recovery depends on the duration of symptoms before the initiation of treatment. Vitamin E supplementation has been found to be

Figure 40-10. Patient with isolated vitamin E deficiency demonstrating gait characterized by pseudodystonic extension of the knees, as well as prominent lordosis, and genu recurvatum. (From Jackson CE, Amato AA, Barohn RJ: Isolated vitamin E deficiency. *Muscle Nerve* 1996;19:1163. Reprinted by John Wiley & Sons, Inc.)

protective from chemotherapy-induced neuropathy when administered prior to receiving cisplatin or paclitaxel.⁶⁴

Pantothenic Acid, Vitamin A, and Vitamin D

Pantothenic acid is part of CoA, an essential element of carbohydrate and fatty acid synthesis and degradation. Because of its ubiquity, no single neurological syndrome is known to be caused by pantothenate deficiency, with the exception of generalized malaise.⁶⁵

Vitamin A, derived from β -carotene, is necessary for normal vision and reproduction. Deficiency leads to night blindness and corneal ulceration.⁶⁶ Hypervitaminosis of 25,000 IU daily for 1 or 2 years may cause symptoms of pseudotumor cerebri, including raised intracranial pressure and visual disturbances.^{67,68} Hypervitaminosis in pregnant mothers may lead to birth defects and learning disabilities.

Vitamin D is necessary for calcium absorption in the gut. Deficiency leads to osteomalacia, hypocalcemia, and hypophosphatemia.⁶⁹ The reason why muscle weakness occurs in such patients is unclear, and the phenomenon is explained only in part by low serum calcium.^{70,71}

PROTEIN-ENERGY MALNUTRITION

In acute starvation, the nervous system sustains itself first on glucose derived from alanine and then on ketone bodies from the breakdown of fats. This process continues until fat is depleted, and then catabolism returns to visceral proteins. Death results from cardiac muscle resorption and eventual cardiac failure. In chronic PEM, the nervous system adapts poorly, and a retarded rate of brain growth, hypomyelination, and slowed conduction velocities of peripheral nerves results.

Chronic PEM has traditionally been a disease of the Third World, particularly Africa and Asia. In industrialized countries, it is seen in young children in poverty, the elderly, alcoholics, or children born to malnourished mothers. By a strict definition of acute loss of 10% body weight, PEM also occurs in hospitalized elderly, particularly those suffering from sepsis, burns, or other serious illnesses that preclude a normal diet. Up to 27% of hospitalized elderly develop PEM during their hospital stay, with an associated increased risk of mental status changes, depression, and prolonged length of stay.⁷ In patients with third-degree burns, up to 500 g of muscle may be lost in a day, and death from malnutrition may occur in 2 or 3 weeks.

Traditionally, PEM has been viewed as either a primary protein deficiency (kwashiorkor) or an energy deficiency (marasmus). Kwashiorkor occurs in children older than 18 months and is often associated with diarrheal illnesses or other infectious diseases. Owing to the severe protein deficiency, circulating serum proteins are inadequate to maintain normal oncotic pressure, leading to marked peripheral edema. Marasmus occurs in children younger than 1 year of age and is not accompanied by edema. PEM may cause mental changes, including apathy and irritability, muscle wasting, generalized weakness, hypotonia, hyporeflexia, and gait impairment. Following a return to a normal diet, an acute encephalopathy has been described in some patients with PEM marked by rigidity, tremors, asterixis, and mental confusion.^{72,73} Infectious diseases may precipitate kwashiorkor in a patient with borderline malnutrition. PEM needs to be distinguished from other wasting conditions and edematous states such as thiamin deficiency, HIV infection, and the cachexia of malignancy.

The patient's nutritional status should be assessed by a careful dietary history. Energy malnutrition is defined as a 10% loss of ideal body weight.⁷ Protein malnutrition requires assessment of serum proteins, including albumin, prealbumin, and total lymphocyte count. Because asterixis may be seen in some patients recovering from kwashiorkor and may be mistaken for hepatic encephalopathy, measurement of serum ammonia is often helpful to exclude this diagnosis.

Nutritious food and vitamin supplements generally lead to a complete recovery. Whether PEM results in long-term growth retardation and delayed intellectual development is controversial.⁷⁴ This condition is best prevented by education of affected family members on proper nutrition. In the United States, hospitalized elderly are perhaps at the greatest risk for PEM, and nutritional assessments of all patients at risk should be undertaken at admission to prevent serious malnutrition and to reduce the incidence of morbidity and mortality.

OTHER NUTRITIONAL SYNDROMES

Copper Deficiency Myeloneuropathy

Subacute combined degeneration has been reported in patients with copper deficiency.⁷⁵ In several instances, the cause was excessive zinc consumption in the form of remedies for prevention of colds and upper respiratory infections. Others have acquired the disorder as the result of malabsorption from gastric bypass or gastric reduction surgery. In a series of 25 patients, Kumar and colleagues⁷⁵ found that all had gait dysfunction, likely due to sensory ataxia from posterior column dysfunction. Corticospinal signs and evidence of peripheral neuropathy were present in many. Seventeen of 23 had elevated serum zinc levels. Ten had a prior history of gastric surgery. Copper supplementation did not appear to reverse the clinical findings. Copper may now be added to other nutrient deficiencies, vitamin B₁₂ and vitamin E, that may result in a myeloneuropathy.

Pyridoxine Toxicity Neuropathy

Excess pyridoxine also results in a peripheral neuropathy. Megadoses of pyridoxine produce a large fiber sensory neuropathy, generally in excess of 2 g/day,⁷⁶ but this has been reported with long-standing use of as little as 200 mg/day.^{77,78} Paresthesias, ataxia, and burning feet may occur abruptly after megadoses or from 1 month to 3 years after lower doses. Sural nerve biopsies show reduced myelin fiber density and myelin debris, suggesting axonal degeneration. After stopping pyridoxine, all patients improve, but the condition resolves entirely in only a few. Contrary to common misconceptions, such cases demonstrate that a water-soluble B vitamin may be toxic when taken in megadoses.

Strachan's Syndrome

In 1888, Henry Strachan, a British medical officer stationed in Jamaica, described a syndrome of painful peripheral neuropathy, ataxia, optic neuropathy, and stomatitis among sugarcane workers.⁷⁹ Denny-Brown¹² and others found similar ailments among Allied troops liberated from prisoner-of-war camps after World War II. In these patients, other symptoms included sensorineural deafness, dizziness, confusion, spastic leg weakness, foot drop, Wernicke's encephalopathy, and rare cases of neck extensor weakness and myasthenic bulbar weakness. Poor nutrition, hard physical labor, and concurrent infection were thought to be exacerbating factors. In Fisher's autopsy series of Canadian prisoners of war, the most prominent pathological finding was demyelination of the posterior columns of the thoracic and cervical spinal cord.⁸⁰ This demyelination accounted for the loss of vibratory and position sense and sensory ataxia. Pathologically, the optic and auditory nerves showed moderate to severe demyelination.

An outbreak of optic and peripheral neuropathy closely resembling Strachan's syndrome occurred in Cuba in 1992 and 1993, following the loss of food and fuel exports.⁸¹ Fifty thousand people developed isolated or combinations of optic neuropathy, painful sensory neuropathy, dorsolateral myelopathy, sensorineural deafness, spastic paraparesis, dysphonia, and dysautonomia. Almost half (45%) developed centrocecal scotoma and optic neuropathy only, often fol-

lowing a period of weight loss. Optic neuropathy and myeloneuropathy were seen in 24%, optic neuropathy and sensorineural hearing loss in 14%, and peripheral and optic neuropathies with hearing loss in 7%.⁷² Proposed mechanisms included vitamin B complex and thiamin deficiency, cyanide intoxication, viral infection, and mitochondrial deletion. Infections appeared to precipitate or exacerbate symptoms. Almost all patients responded to early supplementation with B complex vitamins. Evidence for peripheral nerve involvement has been mixed. Clinical evidence of neuropathy is often lacking despite severe symptoms. Fisher⁸⁰ examined the peripheral nerves in 2 of 11 patients at postmortem and found no abnormalities; however, nerve teasing and modern histopathological techniques were not used. Osuntokun⁸² documented peroneal nerve conduction slowing and normal conduction of the median and ulnar nerves, whereas Borrero and coworkers⁸³ found abnormal sural nerve action potentials only in the most severely affected individuals (Video 217, Anterior Interosseous Neuropathy, Pinch Sign; Video 219, Ulnar Neuropathy, Froment Sign). Sural nerve biopsies showed axonal degeneration of large myelinated fibers.

Extensive study of the epidemiology of the Cuban outbreak revealed smoking, weight loss, sugar consumption, and excessive alcohol intake as risk factors. Urban men 25 to 64 years of age were most affected. Pregnant women, children, and the elderly were minimally affected; however, these groups were targeted for supplementation before the outbreak. Women were more likely to develop paresthesias in the feet, whereas men were more likely to develop optic neuropathy.⁸⁴ In Africa, pregnant women are most vulnerable,⁸² and smoking and weight loss are the strongest risk factors for the optic neuropathy variant.

This clinical syndrome should be distinguished from beriberi, vitamin B₁₂ deficiency, pellagra, tropical spastic paraparesis (human T cell lymphotropic virus-1 [HTLV-1]), tropical ataxic neuropathy of Africa, subacute myeloptical neuropathy, clioquinol ingestion in Japan, Leber's optic neuropathy, and nutritional amblyopia. In order to do so, the following should be obtained: dietary and family histories; vitamin B₁₂, folate, and transketolase levels; medication history; and an HTLV-1 assay.

Treatment consists of re-establishing a balanced diet with B complex vitamin and vitamin A supplementation. In the Cuban experience, long-term sequelae were rare because most had early treatment with nutritional supplements, including B complex and vitamin A. In prisoners of war with long-standing symptoms, persistent ataxia, burning feet, and visual defects often persisted despite adequate supplementation.

Postgastroplasty Polyneuropathy

Acute post-gastric restriction surgery (APGARS) neuropathy may affect up to 7% of patients following weight reduction surgery.⁸⁵ Some patients undergoing bariatric, or weight reduction, surgery develop a syndrome of acute or subacute sensory loss, weakness, and areflexia in the limbs, usually following a period of dramatic weight loss and repeated bouts of protracted vomiting.⁸⁶ Some have also developed a type of encephalopathy that is clinically and pathologically identical to WKS, with or without an associated polyneuropathy.¹⁴ Indeed, Wernicke and Korsakoff each described young women with intractable vomiting in

their original reports: One woman had attempted suicide by drinking sulfuric acid, whereas the other had hyperemesis gravidarum.⁸

Thaisetthawatkul and colleagues⁸⁵ compared 435 patients who had bariatric surgery with controls having gallbladder surgery. They found that 16% developed some form of neuropathy compared with 3% in the gallbladder group. Of the 71 included, more than half had entrapment neuropathy, mostly carpal tunnel syndrome. Twenty-seven had a polyneuropathy, and 5 had a radiculoplexus neuropathy. Sural nerve biopsies in 5 patients (4 polyneuropathy and 1 radiculoplexus neuropathy) showed prominent axonal degeneration with variable degrees of perivascular mononuclear cell infiltration. No definite vasculitis was seen. Risk factors identified for neuropathic complications of bariatric surgery were acute weight loss, excessive vomiting, postoperative complications, poor vitamin supplementation, and jejunoileal bypass procedure.

Intractable vomiting is a constant feature. The syndrome may present suddenly several months after surgical procedures that include gastrojejunostomy, gastric stapling, vertical banding gastropasty, and gastrectomy with Roux-en-Y anastomosi.¹³ Following a period of recurrent vomiting and precipitous weight loss, patients develop numbness and tingling in the soles of the feet, calves, and thighs. Distal or proximal weakness may develop, and the patient may have difficulty arising from a chair or climbing stairs. Examination shows symmetrical sensory loss in the legs more than the arms, muscle weakness, and areflexia (Video 259, Sensory Polyneuropathy). Patients may develop quadriparesis and prolonged or permanent disability. Autonomic disturbances and orthostatic hypotension have also been recognized. When the condition is accompanied by encephalopathy, patients may demonstrate confusion, memory loss, and affective disturbances. Many patients have been mistakenly diagnosed early in their course as having a conversion disorder.¹⁴

The polyneuropathy is axonal and demyelinating in type, acute in onset, and slow to resolve. Pathological studies have shown axonal degeneration. One report of lipid-laden neurons and Schwann cells surrounding demyelinating and degenerating axons has not been replicated.⁸⁶

The pathophysiology of this disorder is unknown but is likely polynutritional. The degree of disability appears to depend on the duration and severity of symptoms before diagnosis and treatment. Most patients have some residual weakness and sensory loss.

ALCOHOL AND THE NERVOUS SYSTEM

Overview and Pharmacology

Alcohol is one of the most widely used psychoactive drugs, and alcoholism is characterized by the chronic, repetitive, excessive use of alcohol such that it interferes with the health, personal relationships, and livelihood of the drinker. In pharmacological terms, alcoholism is the addiction to alcohol. Although the cause of alcoholism is unknown, there clearly are genetic, environmental, and cultural factors involved. In the United States, the incidence of alcoholism cannot be determined specifically, but it is estimated that 10% of adult Americans are affected by alcohol abuse and dependence.

The active ingredient in most common alcoholic beverages is ethanol or ethyl alcohol, yet other impurities, including enanthic ethers, amyl alcohol, and acetaldehyde, may be contained in some liquors. Alcohol is absorbed from the stomach as well as the duodenum and jejunum and can be detected in the blood within 5 minutes of ingestion. Absorption rates are faster in patients with gastrectomies and in those individuals who are habituated to alcohol. Once it is in the bloodstream, alcohol enters other organs and can be detected in the cerebrospinal fluid, urine, and alveolar air. Alcohol is metabolized mainly in the liver, where it is oxidized to acetaldehyde via multiple enzymes but most importantly through the actions of alcohol dehydrogenase. Oxidation may also occur through peroxisomal and mitochondrial catalases, as well as by the microsomal ethanol-oxidizing system. Acetaldehyde may have effects independent from those of alcohol in the development of intoxication and addiction, although this remains speculative. As an end product, acetaldehyde is probably converted to acetate through the action of aldehyde dehydrogenase, but the exact degradation product of acetaldehyde is unknown. Once alcohol absorption ceases and equilibration within tissue has occurred, alcohol is metabolized at a constant rate without correlation to its blood concentration. This contrasts with acetaldehyde metabolism, which does depend on the tissue concentration of this metabolite. The rate of metabolism of alcohol can be enhanced by the administration of insulin, amino acids, and fructose, whereas starvation has the opposite effect.

The mechanism of action of alcohol on the nervous system has been debated for decades, and since the beginning of the 20th century, some investigators have speculated that alcohol acts as a nonspecific drug, producing its actions via perturbation of neuronal membrane lipids. More recently, it has been suggested that ethanol acts at the interface between membrane lipids and integral membrane proteins.⁸⁷ Neurotransmitter-gated ion channels have also been the focus of attention regarding the potential sites of alcohol action, including nicotinic acetylcholine, GABA_A, and *N*-methyl-D-aspartate (NMDA) receptor-ion channels. Alcohol affects the function of these receptor-ion channels mostly via direct interactions, yet the molecular structure of the alcohol-binding site has yet to be determined.

Tolerance to alcohol is defined as an acquired resistance to the effects of the drug, which can be related to pharmacokinetic, pharmacodynamic, environmental, and behavioral factors. It has been hypothesized that tolerance represents an adaptive change in the CNS with mechanistic similarities to learning or memory function. Szabo and Hoffman⁸⁸ demonstrated that daily intracerebral injections of human recombinant brain-derived neurotrophic factor, neurotrophin-3, and neurotrophin-4/5, following ethanol withdrawal, maintained ethanol tolerance compared with controls. The authors suggested that some neurotrophins may modulate neuroadaptation to ethanol through their actions as growth factors or the modulation of the function of postmitotic neurons. These actions could ultimately result in alterations in gene expression, producing the observed behavioral consequences. Tolerance to alcohol may also involve adaptive changes in neuronal membrane lipids, neurotransmitter receptors, ion channels, or intracellular secondary messengers that serve to counteract the short-term effects of alcohol.

Acute Intoxication

In the nervous system, alcohol acts as a depressant, and small doses may lead to disinhibition or a slight euphoria. The toxic effects of alcohol become more prominent with rising blood levels, yet through repeated consumption humans can become habituated rapidly. Although blood levels of 100 mg/dL typically cause drunkenness in occasional imbibers, chronic alcohol abusers can tolerate levels up to 500 mg/dL without any apparent effects. The toxic effects of alcohol can be produced in any individual who ingests sufficient quantities of the substance. The state of drunkenness or acute intoxication is recognized by slurred speech, an erratic gait, and disinhibited verbosity and behavior. The phenomenon of acute intoxication depends on the blood alcohol concentration, the rate at which it has been attained, and the time during which it has been maintained.⁸⁹ Pathological intoxication refers to an episode of uncharacteristic behavior during a drinking bout. This behavior may include violence and is mainly attributable to the disinhibiting effect of a heavy consumption of alcohol. This behavior typically abates as the blood alcohol level falls, but occasionally the use of restraints and sedation may be necessary. Parenteral sedatives, including phenobarbital and benzodiazepines, may be used.

An alcoholic blackout refers to a period of time during acute alcoholic intoxication that a person subsequently does not recall. It is a blank space in the continuum of a person's memory and objectivity, and there are no outward signs other than those of typical drunkenness. The blackouts may be complete or partial. These blackout periods correlate poorly with withdrawal symptoms and are not associated with chronic memory disturbances or the alcoholic dementia seen in some individuals. Blackout periods are associated with a high blood alcohol level and may occur in both the social and the dependent drinker. Management includes supportive therapy and education.

The syndrome of drunkenness is so well recognized, even among lay people, that the main challenge for physicians is not to overlook concomitant intoxication with other drugs or other causes for ataxic gait, stupor, and coma. A blood alcohol level is the most important laboratory test to support a diagnosis of alcohol intoxication. However, because habituated alcoholics can tolerate several times the levels of nonhabituated individuals, the test result must be interpreted in light of the person's status in this regard.

The most important therapeutic problem in the setting of acute intoxication is respiratory depression. With higher blood alcohol levels, stupor and coma can occur, yet there are no distinctive clinical characteristics of alcoholic coma. The diagnosis should be suggested by the clinical setting. Respiratory depression is an early feature, so the diagnosis must be made promptly and should be treated in an intensive care unit. Mechanical ventilatory support should be instituted when necessary, and hypovolemia, acid-base balance, electrolyte, and temperature abnormalities must be corrected. Glucose (50 mL of 5% solution) with 100 mg intravenous and 100 mg intramuscular thiamin should be given if hypoglycemia is suspected. Because alcohol is absorbed rapidly, gastric lavage with activated charcoal is not likely to be of value in preventing a deeper intoxication. Death has occurred with blood alcohol levels of

4000 mg/L, and a level of 5000 mg/L is lethal in 50% of patients.⁹⁰ Recovery from alcohol-induced coma with high blood alcohol levels can be hastened with hemodialysis, but this measure is rarely indicated.⁹¹ Unless the patient develops fatal coma or suffers trauma as a result of incoordination, virtually all episodes of acute alcohol intoxication resolve without sequelae.

Withdrawal Syndromes

The manifestations of alcohol withdrawal occur when a person decreases or stops a high level of alcohol intake, either after a binge lasting a matter of days or after the regular ingestion of alcohol sustained over many months. Although the exact mechanisms are not known, most symptoms appear related to overactivity of various portions of the nervous system resembling a "rebound" phenomenon after profound suppression, and its basis may relate to alterations in the function of GABA or NMDA receptor systems. The earliest findings of alcohol withdrawal typically occur within 6 to 8 hours of alcohol cessation.⁹² Tremulousness is the earliest and most common complaint, and many alcoholics view their so-called shakes as an indication that it is time to resume drinking in order to avoid more severe complications of withdrawal. Tremor appears within hours of cessation of alcohol ingestion and gradually increases to a peak within 1 or 2 days.⁹³ The tremor is postural and appears to be irregular due to its variable but large amplitude (Video 60, Marked Postural Tremor). The amplitude may increase at the end points of an action, and the typical frequency varies from 6 to 11 Hz.⁹⁴ This movement abnormality mainly involves the hands but can cause titubation (Video 208, Titubation). The tremor remits during relaxation and sleep but often persists for weeks after discontinuation of alcohol consumption. The pathophysiological mechanisms of the tremor are not known, but it probably represents an exaggerated physiological tremor.⁹⁵ The tremulousness is associated with hyperacuity of all sensory modalities, hyper-reflexia, hypervigilance, anxiety, tachycardia, hypertension, and insomnia. The severity of these signs and symptoms varies with the intensity and duration of the previous alcohol exposure. In mild forms of withdrawal, the signs and symptoms usually resolve after 48 hours.

In severe reactions, patients may experience additional symptoms including auditory hallucinations, which usually take the form of identifiable voices saying critical or threatening things to the patient. When they occur, hallucinations generally appear within 24 hours of withdrawal. At first, patients tend to accept the voices as real and react accordingly, but as the intensity of the hallucinations wanes, they recognize their true origin. The hallucinosis may be accompanied by global confusion, and the autonomic hyperactivity continues and may become more pronounced.

Between 6 and 48 hours following alcohol discontinuation, seizures occur in approximately 3% or 4% of untreated patients.^{96,97} Although the seizures are almost always multiple with short interictal intervals over a few hours, there may be only a single seizure.⁹⁶ The seizures are generalized tonic-clonic, and focal seizures should suggest the presence of a focal lesion in addition to the effects of the alcohol. Alcoholics may also develop seizure disorders

as a result of acute head trauma, the presence of a subdural hematoma, or other causes seen in nonalcoholics. Alcohol withdrawal may also potentially aggravate any preexisting seizure disorder unrelated to the alcohol abuse. Thirty to forty percent of patients with seizures progress to delirium tremens if they are left untreated.^{92,98} One-fourth of these individuals do so without an interceding lucid period. The remaining individuals have a period of improvement ranging between 12 hours and 5 days.^{92,98,99}

Delirium tremens comprises a combination of psychic and autonomic hyperactivity, occurring usually after 3 to 5 days of alcohol abstinence but may be seen as late as 14 days. Only 5% or 6% of untreated patients withdrawing from alcohol develop this syndrome.⁹⁸ Patients with delirium tremens are agitated, hallucinating, and confused. The hallucinations are frequently of a visual nature, but other types occur. In addition, fever, tachycardia, diaphoresis, hypertension, and confusion are typical. Seizures are uncommon during this phase of withdrawal. Once it is present, the delirium typically lasts for 3 days.

Often by the time patients reach the hospital, alcohol is no longer detectable in the blood. Therefore, the diagnosis depends on the history and documentation of other clinical signs that are suggestive of chronic alcoholism (e.g., liver disease). Patients with seizures or delirium tremens require laboratory screening for superimposed metabolic disorders that may contribute to the clinical picture. Additionally, individuals with clinically uncharacteristic seizures should undergo computed tomography scan of the brain to rule out focal trauma, stroke, or hemorrhage. The electroencephalogram (EEG) may also be helpful in this setting because it may demonstrate focal slowing or epileptiform activity. Generally, the EEG shows a sequence of changes induced by alcohol, beginning with a decrease in the frequency during chronic intoxication and followed by a return to normal with alcohol cessation. During the awake EEG, withdrawal seizures may be precipitated by photic stimulation.

Febrile, delirious patients should have close monitoring of their vital signs, preferably in an intensive care unit, while a search is conducted for possible sources of infection that may cause or contribute to the clinical presentation. Volume repletion is often necessary due to excessive perspiration. Owing to possible nutritional deficiencies, 100 mg intravenous and 100 mg of IM thiamin should be provided before the administration of glucose in order to prevent the acute precipitation of WKS. Intravenous fluids should also be supplemented by daily B complex vitamins. Benzodiazepines are helpful in reducing anxiety and tremulousness and may be useful in the prevention of seizure activity during withdrawal.¹⁰⁰ Chlordiazepoxide and diazepam are long-acting drugs with pharmacologically active metabolites, and repeated daily dosages can result in accumulation of these agents. Oxazepam, in contrast, is rapidly converted to an inactive compound and does not accumulate and contribute to excessive CNS depression.

β -Blockers or clonidine can be used to treat the associated tachycardia and hypertension.^{101,102} Because withdrawal seizures are typically self-limited, treatment is generally not required. Furthermore, the value of phenytoin in uncomplicated withdrawal seizures has not been demonstrated, and the long-term administration of anticonvulsants

is usually ineffective in preventing recurrences. Some studies have reported better control of seizures in patients with a previous history of seizures when phenytoin is added to benzodiazepine administration. Evidence from other reports has conflicted with this finding. Status epilepticus is rare in alcohol withdrawal but should be treated in a manner similar to other clinical settings.

As a group, the alcohol withdrawal syndromes represent self-limited episodes that resolve with no residual effects. However, delirium tremens carries a measurable mortality rate (perhaps 10% to 20%) due to autonomic dysfunction. The obvious means of preventing these disorders is drinking alcohol only in moderation. For those who are abusing alcohol already, the only sure way to prevent withdrawal syndromes is to continue the alcohol, which is rarely practical in a hospital setting.

Alcoholic Dementia and Cerebral Atrophy

Some authorities have contended that chronic excess ingestion of alcohol leads to cerebral atrophy and alcoholic dementia. However, the notion that alcohol has a direct toxic effect on cerebral tissue is greatly disputed. Most cases of dementia in alcoholics can be explained on the basis of Korsakoff's disease, other nutritional deficiencies, or medical causes. This syndrome has been described only in long-standing alcohol abusers, and the essential clinical features of this putative syndrome are the combination of cognitive and behavioral deficits, including impaired memory and judgment, loss of social refinements, and paranoid ideation. Symptoms and signs develop gradually and continue to progress as long as alcohol abuse continues. Patients often show other stigmata of long-standing alcohol abuse. The major diagnostic distinction is with a slowly evolving form of Korsakoff's psychosis. Other considerations when encountering an impaired intellect in alcoholics include hepatic encephalopathy, subdural hematoma, hydrocephalus (from prior trauma or meningitis), or anoxic encephalopathy. Other dementing illnesses unrelated to alcoholism, such as Alzheimer's disease, should be considered. Brain imaging may reveal shrinkage of cerebral volume, especially in the frontal lobes. This finding is potentially reversible if patients can cease alcohol intake. Hippocampal volume deficits have been documented in Korsakoff's disease using quantitative MRI scanning.¹⁰³ To the extent that some cases represent a slowly evolving form of Korsakoff's disease, regular ingestion of thiamin supplements should help prevent the development of dementia. Once it is established, the dementia tends to remain static if alcohol consumption decreases, whereas it may progress if there is no change in lifestyle.

Deficiency Amblyopia

This disorder is most likely related to the depletion of one or more B vitamins, although none has been specifically implicated. Deficiency amblyopia occurs only after severe and prolonged nutritional deprivation. The strict dietary deficiencies required to produce amblyopia are known to occur mainly in mistreated prisoners of war and alcoholics. Smoking tobacco was once considered another risk factor (hence the alias tobacco-alcohol amblyopia), but this is no longer believed to be true.

Patients with this disorder experience the subacute onset (over days to weeks) of symmetrical loss of visual acuity, and colors perceived appear to be washed out. On examination, the central portion of vision is especially impaired, and occasionally patients exhibit pallor of the optic discs. Patients often have evidence of other syndromes of nutritional deficiency, including a predominantly sensory polyneuropathy (Video 5, Sensory Ataxia). The possible causes of optic neuropathy are legion, and most are much more common than deficiency amblyopia. The diagnosis should be suggested by the clinical setting.

The most valuable test in the evaluation of these patients is perimetry, which allows for the confirmation of the central or centrocecal distribution of the visual field defect. The diagnosis can be solidified, retrospectively, by a positive response to treatment. Because this disorder results from extreme nutritional deprivation, prevention is relatively easy. Any reasonably balanced diet should provide sufficient vitamin intake for this purpose. Substantial recovery is possible in most cases by eating a nutritious diet supplemented by multivitamins. The majority of patients recover if proper treatment is instituted and the degree of recovery is inversely proportional to the duration of nutritional deprivation.

Cerebellar Degeneration

Although a definite association between cerebellar degeneration and nutritional deficiency is not established in alcoholism, thiamin deficiency is suggested by the clinical and pathological resemblance to the cerebellar involvement in Wernicke's disease. Alcoholism is the chief risk factor for the development of this disorder, and males are affected more often than females. The main clinical manifestation is a disorder of gait characterized by instability and a widened base. Patients are unable to walk with one foot placed in front of the other and occasionally there is frank ataxia of the lower extremities, which is best appreciated on a heel-to-shin test (Video 212, Heel-to-Shin Testing). The gait disorder develops gradually or, occasionally, in a stepwise fashion. The upper limbs are only rarely involved.

Because this disorder is associated with alcoholism, many patients have evidence of other complications of nutritional deficiency, particularly a polyneuropathy. In alcoholics, alternative causes of gait ataxia include Wernicke's disease, acquired hepatocerebral degeneration, and the effects of head trauma. Cerebellar syndromes featuring prominent speech or oculomotor deficits should suggest another cause for the ataxia, even in alcoholics (Video 214, Stance Ataxia).

MRI may demonstrate atrophy of the anterosuperior vermis, which is best seen on a midline sagittal image. With the uncertain pathogenesis, the only known effective preventive measure is the treatment of alcoholism. However, it is likely that avoiding nutritional deficiency would eliminate the risk of alcoholic cerebellar degeneration. The utility of vitamin supplementation after the cerebellar degeneration has occurred is unproven. In most cases, the gait disorder progresses over weeks to months and then persists indefinitely. A small number of patients show only brief manifestations with spontaneous resolution.

Marchiafava-Bignami Disease

The majority of the pathological changes in this disease occur in the middle lamina of the corpus callosum. The mechanism responsible for the white matter damage and the reason for the particular vulnerability of the corpus callosum are unknown. Long-standing alcohol abuse is clearly a risk factor, but Marchiafava-Bignami disease has also been described in nonalcoholics. The rarity of this disorder when measured against the prevalence of alcoholism also suggests that other factors are involved. Originally thought to selectively affect Italians, Marchiafava-Bignami has been found in other populations as well.

There is no consistent or typical clinical presentation, but manifestations usually encompass both cognitive and behavioral aspects. Many patients appear to become progressively demented, disinhibited, or aggressive. Transient neurological deficits, often focal in nature, may form part of the clinical picture. Seizures and impaired consciousness may be terminal events. Because chronic alcoholism is present in most cases, other typical findings in this population include polyneuropathy or ataxia. Hospital admissions, however, are usually precipitated by complications of alcohol withdrawal. Korsakoff's psychosis, alcoholic dementia, hepatic encephalopathy, and subdural hematoma form a partial list of conditions causing dementia or behavioral disorders in alcoholics and should be considered in the differential diagnosis. Brain MRI scans may show lesions in the corpus callosum. In most cases, the disorder progresses slowly, sometimes taking years to lead to stupor, coma, and death.

Alcoholic Myopathy

There are two forms of alcoholic muscle disease: (1) an acute, painful myopathy associated with weakness, cramps, swollen and tender muscles, high creatine kinase (CK), and rhabdomyolysis with or without myoglobinuria; and (2) a chronic myopathy that is painless and often unnoticed by the patient, causing proximal weakness and type II fiber atrophy on nerve biopsy. In addition to skeletal muscle involvement, patients may have an associated cardiomyopathy.¹⁰⁴

Proposed mechanisms of alcoholic injury have included mitochondrial dysfunction, phosphorus and potassium depletion, and rhabdomyolysis induced by either alcohol-related seizures or limb compression from alcoholic stupor. Alcohol may also act synergistically with nutritional deficiencies to disrupt energy metabolism, although a mitochondrial defect has not been demonstrated.¹⁰⁵ The acute myopathy may require an additional insult, such as hypokalemia, fasting, seizures, delirium tremens, or prolonged limb compression. In chronic myopathy, type IIB fiber atrophy and fiber size variability are present.¹⁰⁶ In acute myopathy, necrosis with or without inflammation, regenerating fibers, and type I atrophy are seen pathologically. Women are more susceptible than men to develop this complication due to a 40% lower dose of alcohol required to produce cardiac and skeletal myopathy.¹⁰⁴ Women may metabolize alcohol more slowly, leading to higher blood levels, possibly due to decreased gastric alcohol dehydrogenase and liver metabolism.

Acute necrotizing myopathy and rhabdomyolysis cause severe painful swelling of one or more muscles with

induration of the skin and soft tissues. CK levels may be elevated, and myoglobinuria may result in acute renal failure. Acute attacks resolve in days to weeks after abstaining, and long-term disability is uncommon unless the patient has repeated attacks.¹⁰⁷ Chronic myopathy is painless weakness of proximal muscles. Cardiomyopathy, peripheral and autonomic neuropathies, and other complications of alcohol abuse may be concomitantly present in these patients. Other myopathic processes, including inflammatory (polymyositis/dermatomyositis), endocrine (thyroid, cortisol), electrolyte disorders (low potassium, phosphorus, calcium, and magnesium), toxins (colchicine), and infectious agents (legionella, mycoplasma, viral), should be considered in this clinical setting.

Martin and colleagues¹⁰⁶ performed muscle biopsies in 151 consecutive inpatient alcoholics. Only half had weakness, and 15% had an elevated CK level. Chronic myopathy was observed in 60%, and 5% had necrosis, suggesting an acute myopathy on muscle biopsy. Clinical evidence of peripheral neuropathy was suggested in 65%, yet half were asymptomatic.

In the evaluation of these patients, laboratory studies should include CK, aldolase, electrocardiograph, and echocardiogram. In one series of patients, the aldolase level was more commonly elevated than CK and may be more helpful in the diagnosis.¹⁰⁵ Rarely, when the diagnosis is in question, a muscle biopsy is warranted. Management includes strict abstinence from alcohol, intravenous saline diuresis to prevent renal failure from myoglobinuria, and thiamin and multivitamin supplementation.

Alcoholic Neuropathy

Alcoholic neuropathy is difficult to separate from nutritional, specifically thiamin-deficient, neuropathy.¹⁰⁸ The clinical pattern and pathology of axonal degeneration is virtually identical to beriberi. The incidence ranges from 9% to 30% among hospitalized alcoholics,^{109,110} and up to 93% of ambulatory alcoholics may have electrophysiological evidence of neuropathy.¹¹¹ Victor and associates⁸ found signs of polyneuropathy in 82% of 230 patients with WKS, and 84% of patients who were able to give a dietary history reported at least a 20-pound weight loss in the previous year. Alcoholic neuropathy occurs in those patients consuming at least 100 g of alcohol daily for several years. It is potentiated by nutritional deficiency. Men outnumber women, but women may be more susceptible at lower doses than men.¹¹² Although it is not known how alcohol injures peripheral nerves, theories include altered membrane lipid permeability¹¹³ and oxidation injury from free radical formation.¹¹⁴ Pathologically, the peripheral nerve undergoes axonal degeneration with loss of large and small myelinated fibers in autonomic,¹¹⁵ sensory, and motor nerves.¹¹²

New evidence has emerged that indicates a primary neurotoxic effect of ethanol in humans. In an attempt to separate thiamine from alcoholic neuropathy, Koike and associates¹⁹ examined 18 patients with alcoholic neuropathy and normal thiamin status. The patients demonstrated slowly progressive sensory-predominant neuropathy of the feet, axonal neurophysiology, and loss of small myelinated and unmyelinated fibers on sural nerve biopsy

(Video 98, Romberg Sign). Half the patients demonstrate autonomic dysfunction, such as orthostatic hypotension. In a further study, Koike and associates examined 64 patients with alcoholic neuropathy and measured both thiamin (normal range, 20 to 50 ng/ml) and erythrocyte transketolase activity (123.8 to 206.2 U/L). These were compared with 32 patients with nonalcoholic thiamin deficiency and neuropathy. Patients with normal thiamin levels were found to have a slowly progressive sensory neuropathy affecting small fiber-mediated functions, especially nociception. Pain and burning paresthesias were common in this group. Patients with thiamin-deficient neuropathy, in contrast, had predominant motor involvement of acute onset with large fiber sensory loss.

These individuals are best managed by recommending abstinence from alcohol intake and enhancing their diet with vitamin supplements. Supplemental thiamin and pain control may be warranted in selected individuals. The prognosis depends on the severity and duration of symptoms. Behse and Buchtal¹¹² found no evidence of clinical improvement or regeneration on nerve biopsy in 17 patients studied 2 years later. The earlier patients abstain and establish regular diets, the more likely they are to recover from the neuropathy. Alcoholics with autonomic neuropathy have a reduced life expectancy.¹¹⁶

Alcoholism and Movement Disorders

In addition to the classic postural tremor associated with alcohol withdrawal, other movement disorders can occur in the setting of alcohol abuse and withdrawal.¹¹⁷ A rare, slow tremor of the lower extremities can also occur in alcoholics and is produced by the synchronous flexion-extension of the muscles of the hip girdle.¹¹⁸ This 3-Hz tremor is associated with alcoholic cerebellar degeneration affecting the anterior superior vermis and cerebellar hemispheres.¹¹⁹ When they are supine, patients with this form of tremor may reveal a kicking movement when the legs are elevated and the knee and hip joints are flexed 90 degrees. It can be best observed when the patient stands with the feet together and the knees partially bent. This results in a slow up and down movement of the body.

Transient parkinsonism may rarely appear in the setting of alcohol abuse or withdrawal in patients with no liver dysfunction.^{120,121} This typically occurs a few days after alcohol cessation and is characterized by bradykinesia, stooped posture, and a coarse resting tremor in the hands. Cogwheel rigidity of the limbs can also be appreciated. These episodes may occur during alcohol withdrawal. These signs may last for a few weeks or months, yet they do not persist. Transient dyskinesias with lingual-oral, neck, or limb movements have been reported in some alcoholics.^{122,123}

With chronic abuse of alcohol, hepatic inflammation and fibrosis can occur and may be associated with encephalopathy. In this setting, patients have an altered level of consciousness with diffuse slowing and, occasionally, triphasic waves on an EEG. Asterixis, or so-called negative myoclonus, is a classic finding in these patients and is characterized by clusters of brief irregular lapses of sustained posture.^{124,125} On examination, this may be best demonstrated by asking the patient to hold out his or her upper extremities and extend the hands at the wrist. The

involuntary lapses in posture are associated with 50- to 200-msec periods of electrical silence in muscles that are tonically active. The mechanisms of this movement are unknown. Chronic or persistent choreiform movements may also occur with alcoholic liver disease (Video 15, Facial Chorea).⁴⁸

Fetal Alcohol Syndrome

The mechanism by which the abnormalities of the fetal alcohol syndrome are produced is unknown, but it is thought to be due to a direct teratogenic effect. There is no general agreement regarding the limits of vulnerability of the fetus in terms of gestational age. To date, this syndrome has been described only in children of mothers who drank alcohol frequently during their pregnancy. Fetal alcohol syndrome results in low birth weight and small head circumference. Cranial and joint deformities are common, and the children feed poorly and are “colicky” and tremulous. The infant mortality rate associated with this condition is high, and survivors suffer an increased risk of mental retardation. Many, but not all, of the mothers of affected babies suffered from withdrawal seizures, delirium tremens, or hepatic encephalopathy during the pregnancy. Infants with fetal alcohol syndrome have a higher incidence of various congenital brain malformations.

Because addicts often abuse several drugs, it is important to consider that an irritable, tremulous, small baby may also result from use of crack cocaine or other agents during pregnancy. There are no laboratory tests of value to support or refute the diagnosis of fetal alcohol syndrome. Maternal education regarding the toxic effects of alcohol is of paramount importance in preventing the fetal alcohol syndrome. There is no safe minimum amount of alcohol consumption that can be guaranteed not to be toxic to a fetus, so mothers-to-be are urged to abstain entirely from alcohol throughout their pregnancy. There is no direct treatment for the effects of the fetal alcohol syndrome, although proper postnatal nutrition and care will help affected infants, as they do unaffected ones. Approximately one in six infants born with this syndrome die. Of the remainder, approximately half suffer permanent physical or mental handicaps.

ACKNOWLEDGMENT

We thank Monroe Cole, MD, for his thoughtful review of the manuscript.

The diagnosis and therapy of central nervous system (CNS) viral infections is one of the most rapidly evolving and exciting areas in neurology. Viruses gain access to the CNS either through the bloodstream or through an intraneuronal route from the peripheral nerves. Viruses may cause acute CNS disease such as meningitis or encephalitis, a delayed complication of an acute infection such as post-infectious polyneuritis or autoimmune encephalomyelitis, latent infections with recurrence of disease from time to time, or slowly progressive neurological disorders. The important human nervous system viruses are listed in [Table 41-1](#). The most common acute CNS viral infections are meningitis and encephalitis. The classic clinical presentation of viral meningitis includes fever, headache, photophobia, myalgias, and nausea and vomiting. There is no alteration in the level of consciousness. The viral etiological agents of meningitis are listed in [Table 41-2](#), and [Table 41-3](#) lists a differential diagnosis of aseptic meningitis. Viral encephalitis is characterized by fever, an altered level of consciousness, headache, and seizure activity. The etiological agents of viral encephalitis are listed in [Table 41-4](#). In addition, viral encephalitis may present as a focal encephalitis with focal neurological deficits and focal seizure activity. The etiological agents of focal encephalitis are listed in [Table 41-4](#).

In addition to meningitis and encephalitis, CNS enteroviral infections may present as an acute transverse myelitis (characterized by abrupt onset of weakness of the limbs progressing to flaccid paralysis in association with a sensory level), single or multiple limb paralysis, cerebellar ataxia (a common presentation of enteroviral CNS infection in children), a chronic meningoencephalitis ([Table 41-5](#)), or a postinfectious polyneuritis. Measles and rubella viruses can cause a slowly progressive neurological disease that presents several years after the acute viral illness has occurred. Other viruses, such as the human T cell lymphotropic virus type 1 (HTLV-1), can cause a slowly progressive neuro-myelopathy in adulthood with no prior history of apparent infection. Human herpesviruses, herpes simplex virus and varicella-zoster virus, are the prototypical viruses that

establish lifelong latent infections in human peripheral and CNS sensory ganglia that may episodically reactivate, resulting in acute infection. This chapter reviews the epidemiology, pathogenesis, clinical features, diagnosis, and management of the human nervous system viruses listed in [Table 41-1](#).

RNA VIRUSES

Enteroviruses (Echoviruses and Coxsackieviruses)

EPIDEMIOLOGY AND RISK FACTORS. Enteroviral infections occur primarily in the summer and autumn months in temperate climates; infants, young children, and immunocompromised patients are at greatest risk of infection. The enteroviruses comprise a total of 68 distinct serotypes of human pathogens, but the most common enteroviruses that cause aseptic meningitis are the coxsackieviruses B5, B3, B4, and A9; the echoviruses 30, 11, 7, 9, 6, 4, and 18; and enteroviruses 70 and 71.^{1,2} The clinical signs and symptoms observed during enterovirus CNS infection depend to some extent not only on the patient's age but also on the state of the individual's immune system. Neonates are at greatest risk for severe infection, either meningitis or meningoencephalitis. Enteroviral infection in agammaglobulinemic individuals may cause a chronic meningitis or meningoencephalitis. Enteroviral CNS infection in infants older than 2 weeks of age and in children and adults is rarely associated with severe disease and is most often an aseptic meningitis.

PATHOGENESIS AND PATHOPHYSIOLOGY. Enteroviruses may enter the host through the mucosal surfaces of the gastrointestinal or respiratory tract. Enteroviruses are acquired most commonly by fecal-oral contamination and, less commonly, via aerosolized respiratory droplets. Enteroviruses may also enter through the conjunctiva of the eye, initially producing conjunctivitis before they spread to the CNS. When enteroviruses enter the host through the nasopharynx, the initial spread and replication

tract, causing symptoms of gastroenteritis and diarrhea, or it may traverse the intestinal lining cells, replicate in Peyer's patches in the mucosa of the lamina propria, and then disseminate to other organs, including the CNS.^{2,3} Most enteroviruses spread to the CNS via the bloodstream, but a small percentage may reach the CNS by direct neural spread from nerves terminating in the intestinal tissue. Virus traverses the blood-brain barrier either at the choroid plexus, where it may infect endothelial cells and spread into the cerebrospinal fluid (CSF), causing a meningitis, or at the endothelium of the cerebral capillary cells in the brain parenchyma, causing an encephalitis.²

| Rubella virus (progressive rubella panencephalitis) |

Although viremia typically occurs 2 or 3 days after the enterovirus has infected the alimentary tract, signs and symptoms of CNS disease typically develop 5 to 16 days after the initial infection and may be biphasic, with minor illness preceding the onset of neurological disease.³ Unlike most viral infections, in which cell-mediated immunity is the primary host defense against infection, clearance of enteroviral infection by the host is antibody mediated. For this reason, infants and young children and individuals with antibody deficiencies, particularly patients with X-linked agammaglobulinemia, are prone to severe or chronic enteroviral meningitis or meningoencephalitis.⁴

CLINICAL FEATURES AND ASSOCIATED FINDINGS. Enteroviral CNS infection may be an aseptic meningitis,

an encephalitis, a focal encephalitis (group A coxsackieviruses), an acute transverse myelitis, single or multiple limb paralysis (poliomyelitis syndrome), Guillain-Barré syndrome, cerebellar ataxia, or a chronic meningoencephalitis (Video 7, Abnormal Tandem Gait; Video 221, Miller Fisher Syndrome).^{2,4-7}

Aseptic Meningitis. Enteroviruses are the most common cause of aseptic meningitis, accounting for 80% to 92% of all cases of aseptic meningitis for which an etiologic agent is identified.² Certain serotypes (group B coxsackieviruses and the echoviruses) are associated with a greater frequency of meningitis than other serotypes.^{8,9} In a review of aseptic meningitis in 274 children younger than 2 years of age, the group B coxsackieviruses and the echoviruses were the etiologic agents in 156 (92%) of the 169 laboratory-diagnosed cases.¹⁰ The clinical presentation of aseptic meningitis includes fever (100°F to 104°F [38°C to 40°C]), severe headache, nausea and vomiting, photophobia, and nuchal rigidity. Neurological abnormalities are rare, and enteroviral meningitis in otherwise healthy children and adults is rarely associated with severe disease or poor outcome.²

Encephalitis. Enteroviral CNS infection may be severe, fatal, or protracted in infants and in individuals with agammaglobulinemia. In neonates, the illness begins with fever and nonspecific signs such as vomiting, anorexia, rash, or upper respiratory findings. Signs of meningeal inflammation may or may not be present at this stage. As the disease progresses, hepatic necrosis, myocarditis, necrotizing enterocolitis, disseminated intravascular coagulation, and other signs of “sepsis” may develop. The onset of encephalitis is characterized by an altered level of consciousness, seizures, and focal neurological deficits.² Unlike enteroviral aseptic meningitis, neonatal enteroviral meningoencephalitis may be fatal or associated with long-term sequelae. The infected neonate appears to be at greatest risk for severe morbidity and death when signs and symptoms develop in the first days of life, an onset suggestive of intrauterine or parturient exposure caused by maternal infection.² Chronic enteroviral meningoencephalitis has been reported in patients with agammaglobulinemia. The disease is most frequently caused by echoviruses, and the typical clinical presentation is that of a slowly progressive neurological disease with ataxia, headache, seizures, paresthesias, and loss of cognitive skills. This change in cognitive skills may be marked by loss of developmental milestones, episodic confusional states, and personality changes. Some patients also have non-neurological manifestations of chronic enteroviral infection, including fever, dermatomyositis-like syndrome, rashes, and hepatitis.⁴ An enterovirus may also cause a focal encephalitis, but unlike patients with herpes simplex virus encephalitis, patients with enteroviral focal encephalitis typically improve spontaneously within 1 or 2 days of admission. The association of a macular or maculopapular rash with the clinical signs and symptoms as described previously warrants the inclusion of enterovirus in the differential diagnosis of a focal encephalitis.

Paralysis. Coxsackieviruses and echoviruses have been implicated as the etiological agents of acute transverse myelitis, which is characterized by the abrupt onset of weakness of the limbs that progresses to flaccid paralysis,

and diminished and then absent deep tendon reflexes, in association with a sensory level.^{6,11} Nonpolio enteroviruses may also cause paralysis of a single limb or multiple limbs that may resemble poliomyelitis (Video 100, Poliomyelitis).⁷ The clinical disease and pathology associated with coxsackievirus and echovirus paralytic disease are generally much less severe than those seen with poliovirus. Echovirus type 70, the cause of epidemics of acute hemorrhagic conjunctivitis, has been associated with acute paralytic disease in Asia, Africa, and Latin America. Echovirus type 71, the usual etiological agent of hand-foot-mouth disease, has been responsible for epidemics of paralytic disease in Bulgaria, Hungary, and the United States.^{12,13} Infection of the anterior horn cells by a nonpolio enterovirus may contribute to disease in patients with postpolio syndrome, causing slowly progressive motor neuron damage.

DIFFERENTIAL DIAGNOSIS. The diagnosis of enteroviral aseptic meningitis is based on examination of the CSF. The opening pressure should be normal or slightly increased, and there is a mild lymphocytic pleocytosis, a normal or slightly increased protein concentration, and a normal glucose concentration. The white blood cell (WBC) count typically is less than 1000 cells/mm.³

Because enteroviral meningitis is quite common in neonates, it is important to emphasize the normal values for the CSF total WBC count and protein concentration in neonates (0 to 4 weeks), older neonates (4 to 8 weeks), and children and adults. The upper limit of normal for the CSF total WBC count is 22/mm³ in infants 0 to 4 weeks old, 15/mm³ in infants 4 to 8 weeks old, and 5/mm³ in those older than 8 weeks of age.^{15,16} In normal uninfected CSF in newborns, approximately 60% of the cells are polymorphonuclear leukocytes and 40% are mononucleated cells.¹⁶ In uninfected CSF in children and adults, the normal WBC count ranges from 0 to 5 mononuclear cells (lymphocytes and monocytes) per microliter. In normal uninfected CSF in children and adults, there should be no polymorphonuclear leukocytes; however, with use of the cytocentrifuge, an occasional polymorphonuclear leukocyte may be seen. If the total WBC count is less than 5/mm³, the presence of a single polymorphonuclear leukocyte may be considered normal.¹⁶ The normal protein concentration in neonates and older neonates is greater than that in children and adults. A CSF protein concentration as high as 150 mg/dL is considered normal in the neonate. By 1 year of age, the normal value for the lumbar CSF protein concentration is 45 mg/dL.¹⁶ The upper range of normal for the lumbar CSF protein concentration in the adult is 50 mg/dL. The CSF WBC count is often higher in those with coxsackievirus aseptic meningitis than in patients with echovirus aseptic meningitis, and counts as high as 2000/mm³ have been reported. A predominance of polymorphonuclear leukocytes may be seen early in the disease course, with a transition to a lymphocytic pleocytosis as the disease progresses. In addition, hypoglycorrhachia has been reported in some patients with enteroviral aseptic meningitis.¹⁷

Isolation of an enterovirus by CSF viral culture is the gold standard for diagnosis of an enteroviral CNS infection. When an enterovirus is isolated from a non-CSF site (throat, stool, serum, or urine) in conjunction with a CSF pleocytosis and an absence of bacteria by Gram's stain or culture, enteroviral meningitis is the presumptive diagnosis.

However, an enterovirus isolated from a non-CSF site may be unrelated to the CNS infection.¹⁸ CSF can be examined by the reverse-transcriptase polymerase chain reaction (RT-PCR) for enteroviral RNA. As a general rule, CSF viral culture is negative in approximately 25% to 33% of CSF specimens from patients with enteroviral meningitis. In these patients, approximately two-thirds of CSF specimens are found to be positive for enterovirus by RT-PCR.^{1,2}

An enterovirus is the likely etiological agent in the patient with a clinical presentation of aseptic meningitis, CSF findings of a lymphocytic pleocytosis with a normal glucose concentration, and a fourfold or greater increase in antiviral IgG antibody between acute and convalescent sera or the first-time appearance of virus-specific IgM antibodies.

MANAGEMENT. Because the majority of enteroviral infections are spread by the fecal-oral route, enteroviral infections are best prevented by proper handwashing techniques. Infants and children are at particular risk for these infections, and good hygiene, including parental handwashing after urine and stool diaper changes and washing the hands of the infant or child before eating, can reduce the transmission of these infections. Children and adolescents should be discouraged from sharing water bottles and drinking cups during athletic events.

Pleconaril is an antipicornavirus agent that inhibits viral replication by blocking the viral uncoating process and viral attachment to host cell receptors. In a double-blind placebo-controlled trial, 130 patients with enteroviral meningitis between the ages of 14 and 65 years were treated with either 200 mg of Pleconaril three times per day or a placebo. Those receiving Pleconaril had a shorter duration of headache and returned to work and school earlier than untreated patients.¹⁹ Intravenous immune globulin has been used to treat enterovirus infections in newborns and in patients with agammaglobulinemia and other immunodeficiency states with good success, but it is not recommended in children and adults with uncomplicated enteroviral aseptic meningitis.^{4,20,21}

PROGNOSIS AND FUTURE PERSPECTIVES. With the exception of neonates and patients with agammaglobulinemia, the majority of patients with enteroviral aseptic meningitis have a benign self-limited course of disease. As discussed previously, neonates and patients with agammaglobulinemia may have a severe, fatal, or protracted course of enteroviral meningoencephalitis. The prognosis of patients with acute transverse myelitis due to an enteroviral infection is generally good.^{6,12} The prognosis of limb paralysis due to a coxsackievirus or echovirus infection is generally much better than that due to poliovirus.⁷

Poliovirus

EPIDEMIOLOGY AND RISK FACTORS. Poliomyelitis was the most frightening infectious disease during the first half of the 20th century. Large epidemics led to extensive research in the epidemiology and pathogenesis of the disease. The poliovirus was first isolated in 1908 by inoculation of monkeys with a cell-free extract made from the spinal cord of a patient with fatal poliomyelitis.^{22,23} It was not until 1937, however, that the virus was isolated from intestinal washings, and by 1941 it was clear that the gastrointestinal tract played a major role in the

pathogenesis of this infection.²⁴ Soon thereafter, it was recognized that the majority of poliovirus infections are a form of acute gastroenteritis. Paralysis develops in less than 1 in 100 individuals infected with the poliovirus.²⁵ In 1949, Enders, Weller, and Robbins made the major discovery that the poliovirus could be grown in tissue cultures of human embryonic skin, muscle cells, and intestinal tissue. Prior to that the only source of the poliovirus was nervous tissue from infected monkeys, an unacceptable inoculum in humans.²² The work of Enders and colleagues, combined with the efforts of the National Foundation for Infantile Paralysis, led to the recognition that there were only three serotypes of poliovirus and laid the groundwork for the development of the killed virus vaccine by Jonas Salk in 1955 and the oral live attenuated virus vaccine by Albert Sabin in 1961.^{22–26} Poliomyelitis has been nearly eradicated from North America and Europe, but outbreaks of the disease continue to occur in the Indian subcontinent, the eastern Mediterranean, and Africa.²⁷

PATHOGENESIS AND PATHOPHYSIOLOGY. Poliovirus is a member of the Picornaviridae. There are three immunologically defined serotypes of poliovirus, all of which are capable of causing paralytic disease. The poliovirus is a single-stranded RNA enterovirus.²³ Natural polio infection occurs through ingestion of the virus, which initially multiplies in the oropharyngeal and intestinal mucosa. Poliovirus either enters the CNS via the bloodstream or, alternatively, may be transmitted to the CNS through vagal autonomic nerve fibers in the intestinal lumen.²³ A temporal association corresponding to the incubation period of the disease was observed between tonsillectomy and the development of bulbar poliomyelitis, suggesting that the exposure of nerve endings via tonsillectomy could transmit poliovirus to the CNS.²⁸ A third hypothesis is that ingested poliovirus initially replicates in the gastrointestinal tract; then a viremia ensues, and disseminated virus replicates at an extraneural site (i.e., skeletal muscle cells). Virus is then transported from the muscle cells via the peripheral nerves to the CNS. The hypothesis that poliovirus replicates in muscle cells and then enters the CNS through the peripheral nerves has been supported by the clinical observations that vigorous exertion or injury of a limb was temporally associated with limb paralysis.²³ In the Cutter incident, children inoculated intramuscularly with incompletely inactivated polio vaccine developed focal limb paralysis.^{29,30} Poliovirus replicates in the muscles of monkeys after intramuscular injection and causes limb paralysis of the injected limb.²⁹ The poliovirus receptor (PVR), a member of the immunoglobulin superfamily of proteins, is present at the motor endplate. During acute infection, the poliovirus may bind to the PVR-expressing motor endplate and travel by way of endocytosis and retrograde transport to the anterior horn cells in the spinal cord and brain stem.²⁹ Acute paralytic poliomyelitis is then characterized pathologically by severe anterior horn inflammation with loss of spinal and bulbar motor neurons.³¹

In his classic work on acute polio infection, Bodian noted evidence of a marked scarcity of normal-appearing neurons, even in cases of very mild paralysis, suggesting that acute paralytic polio was a generalized neuronal disease. The earliest cellular change in the motor neurons was dissolution of the cytoplasmic Nissl substance (chromatolysis).

Infected neurons that exhibited only a mild degree of diffuse chromatolysis survived and continued to support motor units; in contrast, neurons that had severe chromatolysis followed by nuclear invagination and perinuclear chromatin aggregation could not support motor units, and subsequently permanent loss of function occurred in these muscle groups.^{31,32}

Postpolio syndrome, defined as “the development of new muscle weakness and fatigue in skeletal or bulbar muscles, unrelated to any known cause, that begins 25 to 30 years after an acute attack of paralytic poliomyelitis,” is most likely explained by the status of the motor neurons that survived the initial infection. The surviving motor neurons, in an attempt to reinnervate the muscle fibers orphaned by the death of their parent motor neurons, adopt in their motor unit territory additional muscle fibers so that the number of muscle fibers innervated by a single motor neuron may be four or five times the normal number. This puts metabolic stress on the neuronal cell bodies that, after a number of years, leads to a slow deterioration of nerve terminals. As each terminal dies, muscle fibers drop out, and weakness slowly progresses.³²

CLINICAL FEATURES AND ASSOCIATED FINDINGS

Nonparalytic or Preparalytic. As stated previously, the majority of poliovirus infections were asymptomatic or characterized by a nonspecific viral syndrome of malaise, myalgias, and low-grade fever.

Paralytic. Patients who developed paralytic poliomyelitis may initially have had clinical symptoms of fever, malaise, headache, and gastrointestinal or upper respiratory tract symptoms. These symptoms subsided, only to recur after several days in association with increasing signs of meningeal irritation, headache, and stiff neck. When the illness progressed to the paralytic form, muscle soreness was prominent, particularly in the back and neck. Patients who developed paralysis usually did so on the second to fifth day after meningeal signs and fever became evident. Once weakness began, it typically progressed for only the first few days after its onset. The fever persisted for several days but often subsided before the paralysis was complete. Patients complained of severe muscle pain and spasms with asymmetrical flaccid muscle weakness that usually affected a lower extremity (Video 100, Poliomyelitis). Severe bulbar weakness occurred in 10% to 15% of patients with paralysis. The disease was most common in infants and children between the ages of 6 months and 10 years, and it was more common in the late summer and autumn months. Acute mortality usually resulted from respiratory or bulbar involvement.²⁵

Postpolio Syndrome. The following criteria are necessary for a diagnosis of postpolio syndrome as the cause of progressive weakness: (1) a history of documented acute paralytic poliomyelitis in childhood or adolescence as evidenced by a well-documented acute febrile paralytic attack during a polio epidemic that resulted in residual lower motor neuron weakness; (2) partial recovery of motor function and functional stability or recovery for at least 15 years; (3) residual asymmetrical muscle atrophy with weakness, areflexia, and normal sensation in at least one limb; and (4) normal sphincteric function.³³

DIFFERENTIAL DIAGNOSIS. Although the poliovirus now can be recovered from stool, throat washings, CSF,

and blood, during the polio epidemic in the past century, virological confirmation was not available. The diagnosis was based on the clinical syndrome of fever with paralysis and residual lower motor neuron weakness. Examination of the CSF in the preparalytic stage showed an increase in the opening pressure and an increase in the WBC count that initially might be a predominance of polymorphonuclear leukocytes, but within a few days' time was characterized by a predominance of lymphocytes. WBC counts of 10 to 1000/mm³ were typically seen. The protein concentration in the CSF at the onset of illness might be normal or slightly increased. Patients who developed paralysis had a higher number of WBCs in the CSF and a higher protein concentration than patients who did not develop paralysis.²⁵

Needle examination shows a reduced number of voluntary motor unit potentials in the initial phase of paralysis, but in subsequent months, as the patient improves, the motor units become markedly enlarged, reflecting the reinnervation of the denervated muscle fibers.

MANAGEMENT. The management of patients with poliomyelitis and the postpolio syndrome is largely supportive. The treatment of bulbar poliomyelitis was significantly improved by the development of the "iron lung" in the 1930s. Patients with lower extremity weakness were initially treated with splints and plaster casts. Prolonged casting, often for months at a time, was typically employed. Eventually, the use of splinting and casting was replaced by physical therapy, braces, and other assistive ambulatory devices.²⁵ Anticholinesterase therapy has been beneficial in the treatment of symptoms of weakness and fatigue in patients with postpolio syndrome.³⁴

In 1995, the Advisory Committee on Immunization Practices (ACIP) of the U.S. Public Health Service recommended that the United States adopt a sequential poliomyelitis immunization schedule—two doses of inactivated polio vaccine (IPV) followed by two doses of live oral polio vaccine (OPV) in order to reduce the occurrence of vaccine-associated polio from the live oral poliovirus vaccine.^{35,36} Although OPV is among the safest of vaccines, one case of vaccine-associated polio occurs for every 2.5 million doses of OPV administered. The proposed sequential schedule recommended by ACIP was a compromise that sought to retain the advantages of OPV while preventing half of the 8 to 10 vaccine-related cases that occurred every year in the United States.³⁶ In order to totally eliminate the risk of vaccine-associated poliomyelitis, in July 1999 ACIP recommended that IPV be used exclusively in the United States beginning in 2000. An all-IPV schedule is currently the recommended schedule for polio vaccination of infants and children in the United States. OPV continues to be used for routine immunization and to achieve polio eradication in countries throughout the world.³⁷

Mumps

EPIDEMIOLOGY AND RISK FACTORS. Mumps is a member of the Paramyxoviridae group and is an enveloped virus containing a single-stranded RNA genome.³⁸ Prior to the widespread use of the trivalent measles-mumps-rubella (MMR) vaccine, mumps was an epidemic disease that occurred in the winter and spring months. Mumps was

the most common cause of viral meningitis and encephalitis in many countries; the frequency of aseptic meningitis was estimated at 1 per 1000 cases of clinical mumps, with much higher figures observed during epidemics.³⁹ In some countries, mumps was the most common cause of meningoencephalitis in children younger than 15 years of age.⁴⁰

The live mumps vaccine has a 95% protection rate, and the MMR vaccine containing the Jeryl Lynn strain of mumps virus has nearly eliminated meningitis and meningoencephalitis due to mumps. In 1989, ACIP estimated that the incidence of postvaccination encephalitis within 30 days of vaccination was 0.4 cases per 1 million doses administered.^{41,42}

The use of the Urabe Am 9 mumps vaccine was associated with a number of cases of aseptic meningitis in Canada and Japan, with an estimated rate of one case per several thousand vaccinations. The vaccine-associated cases of aseptic meningitis were mild and were rarely associated with sequelae, but the occurrence of aseptic meningitis with the vaccine containing the Urabe strain led to replacement of this strain of mumps virus with the Jeryl Lynn strain in many mass vaccination programs.³⁸

PATHOGENESIS AND PATHOPHYSIOLOGY. Mumps virus spreads by respiratory droplets. After local replication occurs in the respiratory mucosa, viremia ensues. Parotitis occurs because the virus has an affinity for parotid ductal epithelial cells.⁴³ The mumps virus is neurotropic and meningotropic, and the CNS is infected in the course of the viremia.⁴² Virus infects the endothelial cells of the choroid plexus.

CLINICAL FEATURES AND ASSOCIATED FINDINGS. The mean incubation period for mumps is 16 to 18 days, and symptoms develop in 60% to 70% of those infected. Thirty percent to 40% of natural mumps infections are asymptomatic.⁴² When symptomatic, an initial febrile illness with parotitis occurs in 95% of patients, and orchitis occurs in 25% of males.⁴³ Although many children with wild mumps meningitis have parotitis, clinical evidence of parotitis is not absolute.⁴⁴ CNS infection occurs in the absence of parotitis in 36% to 50% of cases.⁴³

Mumps meningitis is characterized by fever, headache, vomiting, and signs of meningeal irritation. The clinical presentation of mumps encephalitis includes seizures, altered consciousness, behavioral abnormalities, sensory abnormalities, and difficulty with balance.⁴³ Mumps is a well-recognized cause of acquired deafness due to sensorineural hearing loss, which is typically unilateral and has been attributed to a cochlear neuritis with or without labyrinthine inflammation.⁴⁵ Mumps can cause an epididymo-orchitis, with subsequent infertility, pancreatitis, juvenile diabetes mellitus, fatal myocarditis, and abortions.³⁹

DIFFERENTIAL DIAGNOSIS. The diagnosis of mumps aseptic meningitis is suggested by the clinical appearance of parotitis and meningitis and is established by examination of the CSF. The classic CSF abnormalities are a lymphocytic pleocytosis (300 to 600 cells/mm³) and either a normal or decreased glucose concentration.⁴⁶ A positive CSF viral culture establishes the diagnosis. A fourfold rise in mumps antiviral antibody in convalescent sera compared to acute sera is also diagnostic, except in patients who have recently been immunized, in which case a fourfold rise in mumps-specific IgG may simply represent successful

immunization. The diagnosis of mumps meningoencephalitis is made similarly by isolating the virus from the CSF and/or by noting a fourfold rise in mumps antiviral antibody between the acute and convalescent sera. The electroencephalogram (EEG) is reported to be abnormal in 100% of patients with mumps meningoencephalitis.^{43,47}

MANAGEMENT. No antiviral therapy is available for mumps meningitis or meningoencephalitis. Fortunately, these neurological complications have largely been eradicated through the widespread use of the MMR vaccine. As described previously, there have been no cases of post-vaccine meningitis with use of the Jeryl Lynn strain of mumps virus vaccine. The propensity of the vaccine to cause meningitis appears to have been associated with the Urabe strain, and a reported reduction in vaccine-associated aseptic meningitis in Canada following the change from the Urabe to the Jeryl Lynn mumps virus-containing MMR vaccine supports this observation.⁴⁴

Arthropod-borne Viruses

EPIDEMIOLOGY AND RISK FACTORS. The arthropod-borne viruses (arboviruses) are transmitted to humans by the bite of a mosquito or tick. The epidemiology of arthropod-borne viral encephalitis is influenced by the season; the geographic location; the regional climatic conditions, such as the amount of spring rainfall; and the patient's age. LaCrosse virus is the most important arboviral cause of pediatric encephalitis in the United States.⁴⁸ The midwestern states report the highest incidence of LaCrosse virus infections. The LaCrosse virus belongs to the California group of encephalitis viruses. It is responsible for nearly all infections due to California group viruses in the United States. Most cases occur in late summer to early fall. The vector, *Aedes triseriatus*, is a forest-dwelling mosquito, and the risk of infection is associated with outdoor activities in woodland areas.⁴⁹ West Nile virus, St. Louis encephalitis virus, and Japanese encephalitis virus are all members of the serologic complex of flaviviruses. West Nile virus was first seen in New York City in late summer 1999 and has since spread across North America. West Nile virus infection has been transmitted by the bite of a *Culex* sp. mosquito, blood transfusion, vertical intrauterine transmission, and organ transplantation. St. Louis encephalitis (SLE) occurs as periodic focal outbreaks of encephalitis in the midwestern, western, and southeastern United States, followed by years of sporadic cases. SLE virus has caused large urban epidemics of encephalitis.^{49,50} Western equine encephalitis virus is an alphavirus that infects horses and humans in western North America, with most cases occurring between April and September. Eastern equine encephalitis (EEE) virus is also an alphavirus that infects horses and humans, primarily along the eastern seaboard and the gulf coast; its peak activity occurs in August and September. EEE virus has been isolated from species other than horses, including pheasants, piglets, and litters of puppies.⁵⁰ It causes a much more severe encephalitis than western equine encephalitis virus. Venezuelan equine encephalitis virus is endemic in South America and has caused rare cases of encephalitis in Central America and the southwestern United States, particularly Texas.

Japanese encephalitis virus is a member of the St. Louis complex of flaviviruses and is the most common cause of

arthropod-borne human encephalitis worldwide. Epidemic disease occurs in China and the northern areas of Southeast Asia, as well as in areas of India and Sri Lanka.⁵¹ The principal vector is a rice field-breeding culicine mosquito. There is no seasonal pattern to Japanese encephalitis except in some instances when outbreaks are associated with rainfall, irrigation, or floods.⁵² Dengue, a mosquito-borne flavivirus infection that is hyperendemic in Thailand, is a leading cause of hospitalization of children in Southeast Asia.⁵³ The principal vector is the mosquito *Aedes aegypti*, which breeds indoors in clean water, mainly in artificial water containers.⁵²

The most important tick-borne causes of viral encephalitis in North America are Powassan (POW) virus and Colorado tick fever (CTF) virus. POW virus is a flavivirus most closely related to Russian spring-summer and central European encephalitis viruses. POW virus is widely distributed in the United States, but human infections with POW virus occur infrequently. In the years 1958 to 1994, a total of 24 confirmed POW cases among humans were reported in North America. The risk of infection is highest in wooded areas, where the potential for contact with infected ticks is highest.⁵⁰ CTF virus is a member of the family Reoviridae. This virus has caused human infections in Colorado, Utah, Montana, California, Wyoming, Idaho, Oregon, South Dakota, Washington, New Mexico, Nevada, and southern Alberta and British Columbia, Canada. The primary risk of acquiring CTF is through exposure to infected *Dermacentor andersoni* ticks during outdoor recreational activities in mountain areas where the CTF virus is endemic in the months of April through June.⁴⁸

PATHOGENESIS AND PATHOPHYSIOLOGY. Arboviral infections are transmitted to humans by a mosquito or tick bite. After local replication of the organism at a skin site, a viremia occurs with seeding of the reticuloendothelial system, including the liver, spleen, and lymph nodes. With continued viral replication at these sites, a secondary viremia occurs, seeding the CNS.⁵⁴ The probability of CNS infection depends on the efficiency of viral replication at the extraneural sites and the degree of the ensuing viremia. The arboviruses can invade the CNS through the cerebral capillary endothelial cells of the cerebral blood vessels or through the choroid plexus.⁴⁹

CLINICAL FEATURES AND ASSOCIATED FINDINGS

California Group Virus Encephalitis. Virtually all cases of California group virus encephalitis in the United States are caused by the LaCrosse strain. This virus typically produces clinically recognizable disease only in children and adolescents (aged 4 to 11 years). The LaCrosse virus may produce aseptic meningitis or a mild encephalitic illness. A distinct prodromal phase characterized by fever, chills, headache, nausea, vomiting, and abdominal pain lasting 1 to 4 days commonly precedes the onset of symptoms of encephalitis.⁵⁵ Encephalitis is characterized by fever, somnolence, and obtundation; seizures occur in approximately 50% of children and focal neurological signs in 20%, raising consideration of encephalitis due to herpes simplex virus type 1.⁴⁹ In adults, infection either is asymptomatic or causes a benign febrile illness or aseptic meningitis.⁵⁶

St. Louis Encephalitis. SLE virus may cause a mild febrile illness with headache, an aseptic meningitis, or an encephalitis. The onset of encephalitis may be abrupt or preceded by an influenza-like prodrome of malaise,

myalgias, and fever. The onset of encephalitis is characterized by symptoms of headache, nausea, vomiting, confusion, disorientation, irritability, stupor, tremors, and, occasionally, convulsions. The severity of illness increases with increasing age, and almost 90% of elderly individuals develop encephalitis.⁴⁹ A unique clinical feature of this form of encephalitis is the syndrome of inappropriate antidiuretic hormone secretion with hyponatremia, which can complicate this infection.⁵⁶

West Nile Virus. West Nile virus infection begins as a febrile, influenza-like illness with headache, sore throat, malaise, myalgias, fatigue, and conjunctivitis. There may be a maculopapular or roseolar rash on the trunk and extremities. This is followed by nausea, abdominal pain and diarrhea, and symptoms of encephalitis. Patients may have a coarse tremor and features of parkinsonism. There may also be a mild carditis, hepatitis, or pancreatitis. Some cases of encephalitis are associated with an acute asymmetric flaccid paralysis that has been called a “poliomyelitis-like syndrome.”

Western Equine Encephalitis. Western equine encephalitis tends to occur in children younger than age 1 year and in adults older than age 50.⁵⁴ Inapparent infections with western equine encephalitis virus are more common than symptomatic cases. Like the other arthropod-borne encephalitides, western equine encephalitis begins with an influenza-like syndrome of fever, malaise, myalgias, pharyngitis, and vomiting. As the disease progresses, irritability, convulsions, or coma develops.⁴⁹

Eastern Equine Encephalitis. EEE virus causes a much more severe form of encephalitis than western equine encephalitis virus. Encephalitis is more common in infants and children. There may be an influenza-like prodrome with fever, headache, vomiting, malaise, and lethargy, but more typically patients with EEE have an abrupt onset of high fever and convulsions and a rapid progression from stupor to coma.^{49,57} EEE may present with focal signs or focal seizure activity, thus mimicking herpes simplex virus encephalitis.⁴⁹

In the series by Deresiewicz and colleagues, the mortality rate was 36%, and 35% of survivors had moderate or severe residual disability. Distinctive radiographic features by computed tomography (CT) or magnetic resonance imaging (MRI) of early basal ganglion and thalamic involvement help distinguish this type of encephalitis from herpes simplex encephalitis.

Venezuelan Encephalitis. Infection with Venezuelan encephalitis virus is typically mild, and encephalitis occurs only rarely. Children and the elderly are at greatest risk for encephalitis. Pharyngitis is a unique clinical feature of this form of arthropod-borne encephalitis.⁵⁴

Japanese Encephalitis. The incubation period of Japanese encephalitis after a mosquito bite varies from 5 to 15 days. The onset of disease is characterized by a high fever with malaise, headache, nausea, and vomiting. These symptoms last from 1 to 6 days and may resolve or progress to a severe fulminant encephalitis with fever, vomiting, convulsions, and coma. Children most frequently have an encephalitis syndrome.⁵²

Dengue Encephalitis. The neurological features of encephalitis due to the dengue viruses include headache, seizures, nuchal rigidity, altered level of consciousness, behavioral disorders, delirium, paralysis, and cranial nerve

palsies. The neurological manifestations of CNS dengue virus infection were previously thought to be secondary to vasculitis with cerebral edema, hypoperfusion, hyponatremia, and multiorgan failure, but recently this theory has been challenged by evaluation of a number of cases in which encephalitis occurred early in the illness coinciding with the viremic phase, suggesting that encephalitis is due to direct involvement of the brain by the virus.⁵⁸

Tick-borne Encephalitis. The onset of encephalitis due to POW virus is abrupt, with headache and fever to 104°F (40°C) and convulsions. There may be a prodromal phase of sore throat, lethargy, and headache. The encephalitis may be associated with focal neurological signs and may thus mimic herpes simplex virus encephalitis.⁴⁸ Infection with the CTF virus is typically a biphasic illness. The onset of illness is characterized by fever, chills, arthralgias, myalgias, severe headache, ocular pain, conjunctival injection, nausea, and, occasionally, vomiting. A petechial or maculopapular rash may be seen. Defervescence may then occur, only to be followed by the recurrence of fever in 2 or 3 days. Aseptic meningitis and encephalitis occur primarily in children and may be associated with a petechial or maculopapular rash or a more severe rash with purpura and petechiae. Disseminated intravascular coagulation and gastrointestinal bleeding may complicate the course of the illness.⁴⁸

DIFFERENTIAL DIAGNOSIS. Based on criteria established by the Centers for Disease Control and Prevention (CDC), a confirmed case of arboviral disease is defined as a febrile illness with mild neurological symptoms, aseptic meningitis, or encephalitis with onset during a period when arbovirus transmission is likely to occur, plus at least one of the following: (1) fourfold or greater rise in viral antibody titer between acute and convalescent sera; (2) viral isolation from tissue, blood, or CSF; or (3) specific immunoglobulin M (IgM) antibody in CSF. A presumptive case is defined as a compatible illness plus either a stable elevated antibody titer to an arbovirus (≥ 320 by hemagglutination inhibition, ≥ 128 by complement fixation, ≥ 256 by immunofluorescent assay, or ≥ 160 by plaque-reduction neutralization test) or specific IgM antibody in serum by enzyme immunoassay.⁵⁰ The differential diagnosis of arboviral encephalitis includes herpes simplex virus encephalitis; bacterial, tuberculous, and fungal meningoencephalitis; brain abscess; rickettsial infections; infective endocarditis; CNS vasculitis; and carcinomatous meningitis.

The characteristic abnormalities found on examination of the CSF in patients with arboviral meningitis or encephalitis are (1) a normal or mildly elevated opening pressure, (2) an initial polymorphonuclear leukocytic pleocytosis early in infection with a shift to a lymphocytic or mononuclear pleocytosis later in the illness, (3) a normal glucose concentration, and (4) a normal or mildly elevated protein concentration. LaCrosse virus has not been isolated from CSF. SLE virus, EEE virus, and western equine encephalitis virus are rarely isolated from CSF.⁴⁸ A few distinguishing features of the laboratory diagnosis of arboviral meningitis or encephalitis deserve comment. EEE virus is the arboviral infection with the highest CSF WBC count. The CSF in patients with EEE virus has 200 to 2000 cells/mm³, 60% to 90% of which are polymorphonuclear leukocytes. The typical cell count in the CSF of SLE infection is

fewer than 200 cells/mm³; however, infection with this virus may be suggested by laboratory evidence of hyponatremia due to the inappropriate secretion of antidiuretic hormone.

Although the CDC criteria for arboviral infection were described previously, for general clinical purposes the diagnosis is made by detecting a fourfold or greater increase in virus-specific IgG between the acute and convalescent sera and/or by identifying virus-specific IgM in the serum or CSF.⁴⁹ West Nile virus can be identified in CSF by the detection of antibodies or by PCR. The CSF in Japanese encephalitis usually has a pleocytosis with WBC counts of 10 to 1000/mm³, and viral-specific IgM antibodies can be demonstrated in CSF in 80% of patients at the time of admission.⁵² Dengue viruses can be isolated from the CSF and detected by PCR.⁵⁸ Neutralizing antibody is usually detectable at the time of onset of illness with POW virus. Virus has been isolated from the basal ganglia, cortex, and cerebellum of brain tissue in fatal cases. CTF is characterized by leukopenia and, in some instances, thrombocytopenia. Early in the disease, CTF virus can be isolated from serum, but later it is more easily isolated from blood clots and from erythrocytes. Viremia may last for several months.⁴⁸

MANAGEMENT AND PROGNOSIS. There is no specific antiviral therapy for the arboviral encephalitides, with the exception of La Crosse virus encephalitis. Ribavirin inhibits the replication of LaCrosse virus by inhibiting viral polymerase activity and has been reported to be efficacious in isolated cases of pediatric LaCrosse virus encephalitis.⁵⁹ Small numbers of patients with West Nile virus encephalitis have been treated with an intravenous immunoglobulin preparation containing high titer anti-West Nile virus antibody. There are ongoing clinical trials. The treatment of the other arboviral encephalitides consists primarily of supportive care with management of the neurological complications of seizures and increased intracranial pressure.

The majority of patients with California encephalitis recover completely, but 15% experience sequelae of behavioral abnormalities or recurrent seizures.⁵⁶ Mortality is low—less than 1%.⁵⁴ Sequelae occur in 20% of survivors of SLE, consisting of irritability, memory loss, and, occasionally, seizures or motor deficits.^{49,54} The mortality rate is 2% to 20%, with the higher percentage occurring in the elderly.⁵⁶ Western equine encephalitis has a mortality rate of 5% to 15%. Neurological sequelae are rare except in children who develop the disease when they are younger than 6 months of age. In young children, long-term sequelae consist of seizure disorders, paralysis, and developmental delay. Postencephalitic parkinsonism has been reported in some adult survivors of western equine encephalitis.^{49,54,56} The mortality rate from EEE is 60% to 75%, and neurological sequelae, consisting of mental retardation, seizures, spastic paralysis, and behavioral abnormalities, are common in those who survive.^{54,57} Mortality is less than 1% from Venezuelan equine encephalitis, and neurological sequelae are rare.⁵⁴ Vaccines for pre-exposure prophylaxis are available for western equine encephalitis, EEE, and Venezuelan equine encephalitis viruses but not for SLE or LaCrosse virus.⁴⁸

High-dose dexamethasone therapy has been utilized in the treatment of acute encephalitis due to Japanese encephalitis

virus, but it appears to have little effect on outcome. A clinical trial of interferon- α in Japanese encephalitis patients in Thailand has produced promising results.⁵² The intrathecal synthesis of IgM antibody appears to be an important determinant of survival. The majority of patients who have antibodies in their spinal fluid on the day of admission survive; a large proportion of those who do not, die.⁵¹ Japanese encephalitis is preventable through vaccination. For primary immunization, two doses of inactivated Japanese encephalitis virus vaccine are administered at intervals of 7 and 14 days. A third injection is given a few months after primary vaccination to ensure full protection. This vaccination protocol may be all that is necessary for people who live in endemic areas; however, those in nonendemic areas may need further periodic booster injections.⁵²

The management of dengue encephalitis is nearly always complicated by the systemic effects of this virus, including vasculopathy, thrombocytopenia, and coagulopathy. The majority of patients require transfusion of whole blood, fresh frozen plasma, and platelets. When disseminated intravascular coagulopathy complicates this infection, the mortality rate is high. Full recovery is possible.^{52,58} Of the 24 total cases of POW virus encephalitis that occurred in North America from 1958 to 1994, 4 of the acute infections were fatal, and 2 patients died 1 and 3 years after onset because of sequelae that were reported to be directly related to the disease.⁵⁰ Sequelae are common in patients who survive this infection, the most common of which is hemiplegia. Paralysis and atrophy of the shoulder muscles has also been reported.⁴⁸ Few fatalities and minimal sequelae have been reported in cases of CTF encephalitis.⁴⁸

Influenza Virus

EPIDEMIOLOGY AND RISK FACTORS. The term *influenza* derives from a flu epidemic in the 15th century that was attributed to an influence of the stars. Influenza viruses are single-stranded RNA viruses that are members of the orthomyxovirus family.⁶⁰ Influenza A virus is a major cause of respiratory disease in children and adults.⁶¹ Influenza B and varicella-zoster virus are the most common antecedent infections in patients with Reye's syndrome. Influenza-type illnesses have been reported to precede the development of acute ascending paralysis, the Guillain-Barré syndrome. In utero exposure to the influenza virus has been suggested as a contributing factor to the development of schizophrenia.⁶²⁻⁶⁴ The occurrence of influenza in mothers in the first trimester of pregnancy has been associated with an increased risk of neural tube defects.⁶⁵ A reversible paralytic syndrome and the Guillain-Barré syndrome have been associated with influenza immunizations.^{66,67}

PATHOGENESIS AND PATHOPHYSIOLOGY. The influenza virus is transmitted from person to person by aerosolized or respiratory droplets. The virus attaches to and replicates in ciliated columnar epithelium of the upper and lower respiratory tracts, following which a viremia ensues.⁶⁰ The major neurological complications of influenza are Reye's syndrome, postinfectious polyneuritis, and acute viral myositis.

CLINICAL FEATURES AND ASSOCIATED FINDINGS
Influenza. The symptoms of influenza begin rapidly with fever, usually 101°F to 102°F (38°C to 39°C),

associated with myalgias, headache, lethargy, and respiratory tract symptoms of dry cough, rhinorrhea, and sore throat. Eye pain and photophobia may occur. Influenza rarely causes gastrointestinal symptoms in adults; however, up to 50% of children have nausea, vomiting, and abdominal pain. Systemic symptoms and fever usually last 2 or 3 days and rarely more than 5 days.⁶⁰

Reye's Syndrome. Reye's syndrome occurs primarily in children, most often in association with influenza B and varicella-zoster infections. Reye's syndrome is an acute, noninflammatory encephalopathy associated with hepatic dysfunction due to microvesicular fatty infiltration of the liver.⁶⁸ Reye's syndrome usually begins with severe vomiting, and this is one of the cardinal features of this syndrome. Vomiting is followed by or associated with lethargy progressing to stupor and coma.⁶⁰ The CDC's criteria for Reye's syndrome include (1) an alteration in the level of consciousness with the CSF containing less than 8 cells/mm³; or (2) an alteration in the level of consciousness and cerebral edema without perivascular or meningeal irritation; and (3) either microvesicular fatty infiltration of the liver or a greater than threefold rise in serum aspartate aminotransferase level or ammonia.⁶⁹

Postinfectious Polyneuritis. The clinical picture of Guillain-Barré syndrome following an influenza virus infection is indistinguishable from Guillain-Barré syndrome of other causes (Video 221, Miller Fisher Syndrome).

Acute Viral Myositis. Influenza A and B have been associated with myositis. Benign acute myositis is characterized by transient severe pain and weakness affecting the calves; it primarily affects children and occurs during epidemics of influenza.⁷⁰

DIFFERENTIAL DIAGNOSIS. The influenza virus can be cultured from throat and nasopharyngeal swabs obtained within 3 days of onset of illness. Acute and convalescent sera should be sent to the laboratory to detect seroconversion or a fourfold or greater increase in virus-specific IgG between the serum samples. A fourfold rise in antibody titer indicates that the patient was recently infected with the influenza virus but is not definitive proof that the influenza virus is the etiological agent of the neurological syndrome.

MANAGEMENT AND PROGNOSIS. The majority of acute influenza infections are self-limited. The use of salicylates (e.g., aspirin) should be avoided in children with flulike symptoms to decrease the risk of Reye's syndrome.

Inactivated and live attenuated influenza vaccines are available. Vaccination is recommended for individuals who are at risk for influenza-related complications (e.g., pneumonia, myocarditis, and exacerbation of chronic medical conditions), including individuals older than age 65 years, people with chronic cardiopulmonary disease including children with asthma, and residents of chronic care facilities. In addition, people with chronic illnesses, such as diabetes or renal disease, and those compromised by immunosuppression should be vaccinated. Individuals who can transmit influenza to high-risk people, such as health care workers, nursing home and chronic care facility employees, and household members of high-risk people, should also be vaccinated.⁶⁰

Measles

EPIDEMIOLOGY AND RISK FACTORS. Measles is one of the three major infectious diseases worldwide and causes approximately 1.5 million childhood deaths per year.⁷¹ In the 1960s, prior to routine childhood immunization, more than 400,000 cases of measles were reported annually; in comparison, less than 4000 cases were reported annually in the early 1980s. From 1988 to 1990, the incidence of measles increased eightfold.⁷² Between 1987 and 1990, 52,846 cases of measles were reported to the CDC.⁷³ This marked increase in the number of cases of measles was attributed to outbreaks among unvaccinated preschool-age children and to outbreaks among vaccinated school-age children who had received only a single dose of measles vaccine.⁷³

Encephalitis is a rare complication of measles infection. It occurs in one of three distinct types: (1) postinfectious or autoimmune encephalomyelitis, which presents as a sudden recurrence of fever with an altered level of consciousness, seizure activity, and multifocal neurological signs during convalescence from measles; (2) subacute sclerosing panencephalitis (SSPE), which presents after a latent period of 6 years or more from an acute measles infection and has an insidious onset of neurological dysfunction associated with myoclonus and seizure activity, and it progresses to coma and death within 1 or 2 years; and (3) subacute measles encephalitis (subacute inclusion body encephalopathy and progressive infectious measles encephalitis), which most commonly occurs in immunosuppressed individuals after a latent period of 1 to 10 months between the measles-like illness and the encephalitis.^{74–76} Encephalomyelitis occurs in 1 per 1000 individuals who develop measles (mostly in older people), and between 5 and 10 children per 1 million who contract measles develop SSPE.⁷⁷

PATHOGENESIS AND PATHOPHYSIOLOGY. Measles virus is spread by respiratory droplets, and only a small amount of virus is required to produce the infection. Virus replicates in the respiratory tract and then spreads to the local lymphatic tissues. Amplification of virus in the lymph nodes produces a primary viremia that results in the spread of virus to multiple lymphoid tissues and the skin, kidney, gastrointestinal tract, and liver. In these organs, the virus replicates in endothelial cells, epithelial cells, and monocytes and macrophages. Measles virus can be detected in peripheral blood leukocytes at the time of onset of prodromal symptoms and for several days after the onset of the rash. The fusion of the measles virus-infected cells leads to the formation of multinucleated giant cells, a pathological hallmark of this infection.⁷⁶

Postmeasles encephalomyelitis (postinfectious encephalomyelitis and autoimmune encephalomyelitis) is a perivenular demyelinating disease rather than an inclusion body encephalitis. Histologically, the lesions resemble those induced experimentally by injection of animals with myelin proteins with adjuvant—that is, experimental, autoimmune encephalomyelitis.⁷¹ There is little evidence of virus in the brain, as assessed either by virus isolation and antigen and RNA detection or by the appearance of measles virus-specific antibody in the CSF.⁷⁶

The pathogenesis of SSPE and of subacute measles encephalitis has, however, been attributed to measles virus persistence in the CNS.^{75,78} The histological features of SSPE include inflammatory infiltrates, glial nodules, degeneration of neurons, hyperplasia of astrocytes and microglia, and intranuclear inclusion bodies of Cowdry type A with abundant measles virus antigen.⁷⁴ The histological diagnostic features of subacute measles encephalitis include intranuclear eosinophilic, and sometimes intracytoplasmic, inclusion bodies in neurons and oligodendrocytes with abundant paramyxovirus nucleocapsids and measles virus antigen.^{74,75}

CLINICAL FEATURES AND ASSOCIATED FINDINGS

Measles. The onset of measles is characterized by fever, cough, coryza, and conjunctivitis associated with Koplik's spots, which are small, white punctate lesions on the buccal mucosa. A maculopapular rash appears 2 or 3 days later, first on the face and behind the ears and then spreading in a centrifugal fashion to the trunk and extremities.⁷⁶ The cephalocaudal spread of the maculopapular rash is quite characteristic of measles.

Postinfectious Encephalomyelitis. Postmeasles encephalomyelitis usually occurs within 2 weeks after the onset of the rash. There is a sudden recurrence of fever associated with a decrease in consciousness, seizures, and multifocal neurological abnormalities. Mortality is approximately 20%, and sequelae are common in survivors.^{71,76}

Subacute Sclerosing Panencephalitis. SSPE is a progressive CNS disorder that begins several years after measles infection in early childhood and is characterized by behavioral abnormalities, intellectual deterioration, motor rigidity, and myoclonic jerks that progress to coma and death (Video 256, Subacute Sclerosing Pan Encephalitis).

Subacute Measles Encephalitis. Neurological signs resulting from subacute measles encephalitis typically develop 1 to 9 months after exposure to measles or from the time of onset of clinical measles. The disease is characterized by seizure activity, an alteration in the level of consciousness, and focal neurological deficits including hemiparesis, ataxia, and disturbances of language and vision. Seizure activity may be focal or generalized, and *epilepsia partialis continua* is a prominent feature.^{75,77} The majority of patients who develop subacute measles encephalitis are immunosuppressed.

DIFFERENTIAL DIAGNOSIS. The differential diagnosis of measles includes illnesses associated with fever and an erythematous maculopapular rash, such as scarlet fever, rubella, meningococemia, Kawasaki's disease, toxic shock syndrome, and erythema multiforme due to a hypersensitivity to medications.^{79,80}

During the viremia of measles infection, measles virus can be isolated from peripheral blood mononuclear cells.⁸¹ The clinical diagnosis, however, is more typically based on the presence or a history of the characteristic findings of fever, an erythematous maculopapular rash demonstrating a cephalocaudal spread, coryza, cough, conjunctivitis, and Koplik's spots. Laboratory results that support a diagnosis of measles are the detection of measles IgM and a fourfold increase in measles IgG between acute and convalescent sera.⁷⁹ The diagnosis of postmeasles encephalomyelitis is based on the occurrence of encephalitis within 2 weeks of the rash of measles associated with a recurrence of fever.

The diagnosis of SSPE is typically based on the characteristic clinical appearance as described previously and the appearance of periodic complexes on the EEG; clinical myoclonic jerks have a one-to-one relationship with the periodic EEG complexes.⁸² Measles antibody titers in CSF are typically elevated in patients with SSPE.

The diagnosis of subacute measles encephalitis can be confirmed only by brain biopsy but is suggested by the following: (1) a history of measles or exposure to measles within 1 to 10 months of presentation, (2) an immunocompromised state, (3) refractory focal seizures (*epilepsia partialis continua*) as part of the neurological symptomatology, and (4) absence of fever.⁷⁵ Examination of the CSF reveals a mild mononuclear pleocytosis and a mild elevation in the protein concentration, but in approximately one-third of patients the CSF is entirely normal. The EEG is slow with nonspecific abnormalities. Detection of measles virus RNA by PCR technology may make the diagnosis of subacute measles encephalitis considerably easier.

MANAGEMENT AND PROGNOSIS. The dramatic increase in measles from 1987 to 1990 led to two principal changes in the recommendations for measles vaccination made by both the ACIP and the American Academy of Pediatrics Committee on Infectious Diseases of the CDC: (1) The age for the initial measles vaccination was changed from 15 months to 12 months, and (2) a second dose of measles vaccine was recommended at either 4 to 6 years or at the time of entry to middle or junior high school.⁷³ The vaccine in use today is a live attenuated measles virus that was developed from the original Edmonston strain of measles virus isolated by Enders in 1954.⁷⁶

Measles during pregnancy has a more severe clinical course and is associated with an increased risk of premature labor or spontaneous abortion.^{72,83} Pregnancy is a significant risk factor for mortality during measles.⁷² Measles infection in pregnancy does not, however, appear to be associated with an increased risk of congenital anomalies, leading to the suggestion that although infection with measles increases the risk of premature termination of pregnancy within the first 2 weeks of onset of the rash, if pregnancy continues, the likelihood of a favorable outcome is high.⁸³ It is recommended that susceptible pregnant women exposed to a person with active measles receive serum immune globulin (gamma globulin 16.5%) within 6 days of exposure to prevent or modify subsequent disease. All infants born to mothers with active measles in the 6 days before delivery should also receive intravenous immunoglobulin prophylaxis (500 mg/kg) immediately after birth and again 1 week later.^{72,83,84} Ribavirin has been shown to be effective against measles virus *in vitro*. It has been suggested that ribavirin might be useful as therapy for immunocompromised patients with measles, although anecdotal case reports in which intravenous ribavirin was used have not demonstrated a therapeutic effect. Ribavirin does cross the placenta and is present in amniotic fluid in potentially therapeutic levels. Teratogenic effects have been reported in rats (but not primates) given high doses of ribavirin during pregnancy; therefore, there is some concern about the possible teratogenicity of this drug.⁷²

Treatment of the encephalitis syndrome described previously that may complicate measles infection is primarily supportive. There are a few favorable case reports of the

use of ribavirin in patients with subacute measles encephalitis; however, firm recommendations cannot be made at this time.^{75,85} There are reports of clinical improvement in patients with SSPE who were treated with inosiplex and intrathecal interferon- α , as well as reports of patients who showed no improvement with this therapy. No firm recommendations can be made at this time.

Arenavirus (Lymphocytic Choriomeningitis Virus)

EPIDEMIOLOGY AND RISK FACTORS. The natural reservoir for the lymphocytic choriomeningitis virus (LCMV) is the common house mouse. Hamsters and laboratory animals can also be infected with this virus. Most human infections result from contact with house mice.^{86,87} Four clinical syndromes due to infection with LCMV have been described: (1) subclinical asymptomatic infection, (2) nonmeningeal influenza-like illness, (3) aseptic meningitis, and (4) meningoencephalomyelitis. LCMV was the first specific etiological agent of the aseptic meningitis syndrome to be identified.⁸⁷

PATHOGENESIS AND PATHOPHYSIOLOGY. LCMV is a member of the arenavirus family and is maintained in nature primarily by vertical intrauterine infection in mice, hamsters, and rodents, producing a chronic asymptomatic infection in the offspring. These animals shed the virus in saliva, nasal secretions, semen, milk, urine, and feces.⁸⁷ The route of transmission to humans remains unknown but is presumed to occur through contamination of open cuts or aerosolized spread of virus. There is no evidence of person-to-person transmission of LCMV infection.⁸⁶ Local replication of LCMV is followed by dissemination to the reticuloendothelial system with a subsequent viremia. The CNS is infected during the course of the viremia.

CLINICAL FEATURES AND ASSOCIATED FINDINGS. Clinical manifestations of acute LCMV infection in children and adults range from asymptomatic seroconversion to an influenza-like illness, an aseptic meningitis, and, rarely, a meningoencephalomyelitis. In patients with aseptic meningitis, there is often a history of a biphasic illness. The first stage resembles an influenza-like illness. This is then followed by a symptom-free period of time varying from a few days to 3 weeks, which is followed in turn by the acute onset of high fever, headache, vomiting, and signs of meningeal irritation.⁸⁶ Although the clinical presentation of CNS infection with LCMV is most frequently an aseptic meningitis, it may also be a meningoencephalitis. Congenital LCMV infection can result in intrauterine or early neonatal death, hydrocephalus, chorioretinitis, and psychomotor retardation.⁸⁸

DIFFERENTIAL DIAGNOSIS. The diagnosis of LCMV infection can be made by the appearance of IgM antibodies in a serum sample or by a fourfold or greater rise in antibody titer between the acute and convalescent serum samples. The classic CSF abnormalities include a lymphocytic pleocytosis of 300 to 3000 cells/mm³ and hypoglycorrhachia.⁸⁶ LCMV is one of the few etiological agents of an aseptic meningitis with hypoglycorrhachia. LCMV can be isolated from the CSF. The diagnosis of congenital LCMV infection is based on the clinical presentation and laboratory evidence of persistently high IgG immunofluorescent antibody titers.⁸⁹

MANAGEMENT. Prevention of LCMV infection is the priority. Laboratory animals acquired from areas where arenaviruses are indigenous should be tested for LCMV infection. Pregnant women should avoid contact with laboratory and household mice and hamsters. LCMV aseptic meningitis in children and adults is self-limited, and complete recovery is the rule.

Rubella

EPIDEMIOLOGY AND RISK FACTORS. Since the rubella vaccine became available in 1969, rubella and the neurological complications of rubella have been due primarily to periodic outbreaks of the disease. The neurological syndromes associated with rubella virus infection include (1) the congenital rubella syndrome, (2) acute encephalitis complicating rubella, (3) postrubella polyradiculoneuritis, and (4) progressive rubella panencephalitis.^{90,91} Acute encephalitis is a rare complication of rubella infection, with a reported incidence of 1 in 5000 to 1 in 24,000 cases.⁹¹ Postrubella polyradiculoneuritis complicates rubella in an estimated 4% of patients. Only five cases of acute postrubella polyradiculoneuritis have been reported in the past 30 years.⁹¹ The most common neurological complication of rubella infection is the congenital rubella syndrome. The gestational age at the time of infection determines the risk of fetal anomaly.⁹² The risk of congenital rubella syndrome is greatest when infection occurs during the first trimester. Progressive rubella panencephalitis is a slow virus disease of the CNS that has many clinical similarities to SSPE caused by measles virus and is an uncommon late-onset manifestation of congenital rubella.⁹³

PATHOGENESIS AND PATHOPHYSIOLOGY. The rubella virus is a single-stranded RNA virus. Infection is acquired by droplet inhalation; viral replication occurs in the nasopharynx with a subsequent viremia. The CNS is infected in the course of the viremia. Maternal viremia during the first trimester of pregnancy can infect the placenta and spread to the fetus.⁹⁴ Disease in the fetus exposed to this virus during the first trimester is severe.⁹⁵

CLINICAL FEATURES AND ASSOCIATED FINDINGS

Rubella. Rubella is a generalized maculopapular exanthem associated with fever. Arthralgias, lymphadenopathy, and conjunctivitis may also be associated with the acute illness.

Acute Encephalitis. Acute encephalitis is a rare complication of rubella infection. Symptoms usually appear within 1 to 6 days after the typical maculopapular rash develops and are characterized by headache, dizziness, lethargy, behavioral abnormalities, coma, and generalized or focal seizures in as many as 50% of cases. The case fatality rate of acute rubella encephalitis is low, and most nonfatal cases recover rapidly with minimal or no sequelae.⁹⁰

Postrubella Polyradiculoneuritis. Postrubella polyradiculoneuritis develops abruptly as the exanthem of rubella fades and has the clinical features of the Guillain-Barré syndrome. The duration of the illness is usually brief.⁹¹

Congenital Rubella Syndrome. Features of the congenital rubella syndrome include intrauterine growth retardation, sensorineural deafness, cataracts, congenital glaucoma, patent ductus arteriosus, pulmonic stenosis, microcephaly,

mental retardation, meningoencephalitis, purpuric rash, hepatosplenomegaly, and radiolucent bone densities.⁹⁶ In addition to these clinical signs, which are present at birth, children with congenital rubella syndrome may develop delayed-onset progressive rubella panencephalitis, a disease of the CNS that has many clinical similarities to SSPE caused by measles virus.⁹³ This syndrome may also follow childhood rubella in rare instances.⁹⁷ Symptoms typically begin between ages 8 and 19 years with deterioration in school performance and behavior sometimes associated with seizures. The neurological deterioration progresses to a global dementia with ataxia, spasticity of gait, dysarthria, and dysphagia. Progressive pallor of the optic discs and a maculopathy occur.⁹⁷

DIFFERENTIAL DIAGNOSIS. Examination of the CSF in patients with rubella encephalitis may be normal or may demonstrate a mild to moderate mononuclear cell pleocytosis and an elevated protein concentration. Virus is rarely isolated from the CSF in patients with rubella encephalitis. Electroencephalography may demonstrate diffuse or focal abnormalities. Diagnosis is made by detection of rubella-specific IgM antibodies in serum or by demonstration of a fourfold rise in rubella-specific IgG in the convalescent sera compared to the acute sera.⁹⁰ Similarly, the diagnosis of post-rubella polyradiculoneuritis is based on the findings of a demyelinating peripheral neuropathy following an exanthematous illness. One of the characteristics of the rash of rubella is that the maculopapular rash almost invariably begins on the face before it becomes generalized, and it is often associated with posterior cervical adenopathy.⁹⁷ A description of this type of rash preceding the clinical syndrome of polyradiculoneuritis is suggestive of rubella. By the time the polyradiculoneuritis develops, serum for IgM antibodies to rubella virus may be negative. A single elevated rubella IgG titer is suggestive but not diagnostic of a recent rubella infection, but when associated with a history of the rubella rash as described previously, it is quite compatible with the diagnosis.

In infants who have clinical evidence of the congenital rubella syndrome at birth, serum IgM antibody to rubella virus and viral cultures should be obtained. Other laboratory abnormalities supporting the diagnosis of congenital rubella syndrome include hyperbilirubinemia, thrombocytopenia, elevated serum transaminase levels, and long-bone radiographs demonstrating metaphyseal lucencies. Neuroimaging studies reveal intracranial calcifications, delayed myelination, or ventriculitis.⁹⁸ Several different methods have been used to make an intrauterine diagnosis of rubella infection, including isolation of the rubella virus in the amniotic fluid obtained by amniocentesis, cordocentesis, use of the PCR method on extracts from chorionic villi and placenta, and ultrastructural examination of amniotic fluid cells using transmission and scanning electron microscopy.⁹⁹ Examination of the CSF in progressive rubella panencephalitis demonstrates a mild lymphocytic pleocytosis (0 to 37 cells/mm³), a moderate increase in the protein concentration (60 to 142 mg/mL), and intrathecal immunoglobulin synthesis.⁹⁷

MANAGEMENT AND PROGNOSIS. The key to management of the neurological complications of rubella is prevention. The rubella vaccine licensed for use in the United States is a live attenuated Wistar RA 27/3 rubella

virus.⁹⁴ The immunogenicity of the vaccine is reduced by whole blood transfusion; therefore, it is recommended that rubella vaccine not be given for 3 months after immunoglobulin or whole blood transfusion.⁹² The incidence of arthritis after vaccination is low when the RA 27/3 strain of rubella vaccine is used. Breast-feeding is not a contraindication to postpartum immunization. Infants infected with the rubella virus through breast milk may experience a mild rash, but the majority remain asymptomatic, and no serious adverse effects have been reported.⁹⁶ Currently, the first dose of rubella vaccine is given to children as part of the MMR vaccine at 12 to 15 months of age. A second dose of the MMR vaccine is recommended when the child first enters school or later when he or she enters middle school.⁹⁴

Human T Cell Lymphotropic Virus Type 1

EPIDEMIOLOGY AND RISK FACTORS. The human T cell lymphotropic virus type 1 (HTLV-1) causes a rapidly progressive adult T cell leukemia or lymphoma and a slowly progressive neuromyelopathy known as HTLV-1-associated myelopathy-tropical spastic paraparesis (HAM-TSP).^{100,101} The distribution of HTLV-1 infection is worldwide, with major foci of endemic infection in southwestern Japan, the Caribbean, Central and South America, sub-Saharan Africa, the Middle East, and Melanesia. It is estimated that between 10 and 20 million people are infected with HTLV-1. In the United States and Europe, HTLV-1 is found primarily in intravenous drug abusers.¹⁰⁰ Transmission of HTLV-1 can occur from mother to child primarily by breast milk, between intravenous drug addicts through the sharing of contaminated needles and syringes, by sexual contact, and by the transfusion of contaminated blood products. Vertical transmission of HTLV-1 from mother to child has been reported to occur in 15% to 20% of children born to HTLV-1-positive mothers. Breast milk appears to be the principal route because seroconversion rates are 14% to 20% for breast-fed infants compared to 3% to 5% for bottle-fed infants.¹⁰² Sexual transmission of HTLV-1 is fairly inefficient compared to transmission of the human immunodeficiency virus (HIV). Blood transfusion, however, is a very efficient means of transmission of HTLV-1, and the greatest risk is incurred by recipients who receive seropositive blood stored for less than 1 week, who require multiple transfusions, or who receive immunosuppressive therapy at the time of the transfusion.¹⁰³

PATHOGENESIS AND PATHOPHYSIOLOGY. There are two major theories of the pathogenesis of HAM-TSP—an autoimmune model and a cytotoxic model. In the autoimmune model, HTLV-1 activates autoreactive T cells, which then migrate to the CNS, penetrate the blood-brain barrier, and stimulate the production of inflammatory cytokines, leading to subsequent tissue destruction.^{101,104} In the cytotoxic model, tissue destruction is caused by a CD8-mediated cytolytic attack against HTLV-1-infected CNS cells or infected CD4 T cells in the CNS. An early event in HAM-TSP appears to be a breakdown of the blood-brain barrier, leading to perivascular influx of mononuclear cells. CD4 T cells are the predominant cell type early in disease, but CD8 T cells are found almost exclusively in the later stages of disease. As the duration of HAM-TSP progresses, an

increasing number of CD8 cells infiltrate the CNS. This infiltration is associated with an upregulation of HLA class 1 and class 2 molecules and an increased expression of cytokines. The end result is demyelination with axonal involvement that is widespread in the spinal cord, and the corticospinal tracts tend to be more affected than the more heavily myelinated posterior columns. The thoracic spinal cord is the area of maximum involvement.^{101,105}

CLINICAL FEATURES AND ASSOCIATED FINDINGS. HAM-TSP is a slowly progressive spastic paraparesis marked by hyper-reflexia, bladder dysfunction, constipation, and impotence in males. Sensory abnormalities due to demyelination of the posterior columns occur less frequently than motor abnormalities and present primarily as paresthesias of the lower extremities.¹⁰³

DIFFERENTIAL DIAGNOSIS. The differential diagnosis includes myelopathy due to a compressive lesion of the cord from a disc, tumor, or infection; subacute combined degeneration resulting from vitamin B₁₂ deficiency; HIV-1 myelopathy; multiple sclerosis; and syphilis (Video 5, Sensory Ataxia).

Serological testing should be performed to detect HTLV-1 antibodies in serum. MRI of the brain may demonstrate hyperintense lesions in the subcortical white matter on T2-weighted scans, resembling the lesions of multiple sclerosis.¹⁰⁶ MRI of the spinal cord may show hyperintense lesions in the thoracic spinal cord. Elevated antibody titers to HTLV-1 can be detected in blood and CSF of patients with HAM-TSP.

MANAGEMENT AND PROGNOSIS. The presence of inflammatory cells, including macrophages and T cells, in HAM-TSP spinal cord material, in addition to the upregulation of HLA and cytokine molecules, suggests that an increase in immunological activity in the CNS is the basis of the pathogenesis of HAM-TSP.¹⁰⁵ Immunosuppressive therapy is the only modality currently available to treat HAM-TSP. There is no specific antiviral therapy. The best means of treatment may be prevention through an HTLV-1 vaccine, and it has been suggested that the development of vaccination against the HTLV-1 retrovirus would serve as a pathfinder for the development of a vaccine against HIV.¹⁰⁰

DNA VIRUSES

Herpes Simplex

EPIDEMIOLOGY AND RISK FACTORS. Herpes simplex virus (HSV) infections of the CNS are of several types: (1) an acute encephalitis, (2) a benign recurrent lymphocytic meningitis, (3) an acute facial nerve paralysis, (4) recurrent ascending myelitis, and (5) a neuritis localized to a single sensory nerve. Neonatal HSV infections occur at a rate of approximately 1 in 3500 to 5000 deliveries per year in North America. Three forms of infection of the newborn are recognized: infection localized to the skin, eye, and mouth; encephalitis; and disseminated disease with involvement of the CNS. Neonatal HSV infections are usually caused by HSV type 2 (HSV-2).¹⁰⁷

In children age 6 months or older and in adults, HSV type 1 (HSV-1) is the most common cause of sporadic fatal

encephalitis. Herpes simplex encephalitis is estimated to occur in 1 in 250,000 to 500,000 people per year.¹⁰⁸ HSV-2 is increasingly recognized as the etiological agent of benign recurrent lymphocytic meningitis and HSV-1 as the etiological agent of acute facial nerve paralysis, Bell's palsy.

PATHOGENESIS AND PATHOPHYSIOLOGY. The human herpesviruses are neurotropic viruses that are able to establish active and latent infections in the CNS and can cause tissue damage through viral replication in nervous tissue and reactivation from the latent state.¹⁰⁹ The pathogenesis of neonatal HSV disease is different from that of HSV disease in older infants, children, and adults. Neonatal HSV infection is acquired most commonly when the fetus comes in contact with infected maternal genital secretions. The type of maternal infection, whether primary or recurrent, has a significant influence on the risk of infection to the fetus. Maternal primary infection at the time of delivery is associated with a fetal risk of infection of approximately 35%. Maternal recurrent infection at the time of delivery is associated with a significantly lower risk to the fetus of approximately 3%.¹⁰⁷

There are two forms of HSV encephalitis during the neonatal period. In infants with encephalitis alone, the illness begins, on average, within 2 weeks of birth. Infection of the CNS by HSV in these neonates is thought to occur by intraneuronal routes. The majority of these infants do not develop skin lesions, and brain disease is often localized to one or both temporal lobes, but it can progress to involve other areas of the brain. In contrast, in newborns with encephalitis resulting from disseminated disease, symptoms of brain involvement begin at the age of 7 to 9 days or earlier. The CNS becomes infected through blood-borne spread of the virus, and neuroimaging procedures reveal multiple areas of hemorrhagic necrosis throughout the cerebral cortex.^{107,108}

In children and adults, HSV-1 encephalitis occurs as either an acute infection or reactivation of latent infection in the trigeminal ganglion. Infection most commonly involves the temporal cortex, the orbital-frontal cortex, and the limbic structures. In most cases, the initial infection begins in the oral cavity, and the virus spreads transneuronally along a division of the trigeminal nerve to the trigeminal ganglion.¹⁰⁹ In experimental animal models of HSV-1 encephalitis, intranasal inoculation leads to viral entry via the olfactory nerve with subsequent infection of the olfactory bulb. Infection then develops in the temporal cortex analogous to human disease; however, the olfactory bulb is rarely affected in humans, and therefore the olfactory nerve is less likely to be the site of viral entry in humans.¹¹⁰ The extent and severity of CNS disease is related to the neurovirulence of the virus, the degree of viral inoculum, the immunocompetence of the individual, and possibly genetic determinants of susceptibility to HSV infection.¹¹¹

The human herpesviruses have the ability to establish lifelong latent infection in the peripheral sensory ganglia (PSG), in the trigeminal ganglion, and in the motor neurons of the hypoglossal nucleus. During acute infection, cells that are infected with HSV-1 ultimately die. The pathogenesis of virus that establishes latency is fundamentally different. Following peripheral inoculation, HSV-1 DNA viral particles are carried by retrograde axonal flow to the

PSG. Since HSV is a lytic virus and replication within a cell results in cell death, latency cannot be established in cells in which the virus has completed a full replication cycle. During attachment of HSV-1 to the axonal membrane of the peripheral nerve, the virus loses its envelope, and the contents of the tegument as well as the capsid are transported to the neuronal nucleus. Vmw65, an HSV-1 transactivating protein that is a component of the viral tegument, has a role in this process. The amount of Vmw65 that is carried with the virus to the cell nucleus eventually determines the fate of the infection. If a sufficient amount reaches the neuronal cell body, a replication cycle ensues, and the cell dies; if, however, the amount of Vmw65 is insufficient, no replication cycle begins, and latent infection is established.¹⁰⁹ No infectious viral particles are present during latent infection. During latent HSV-1 infection, the linear DNA is present as a circular molecule that is not integrated into the host cell DNA.¹¹² External stimuli triggering reactivation of HSV include injury to tissues innervated by the neurons harboring latent infection and the systemic conditions of exposure to sun, fever, malignancy, and immunosuppression. Even after numerous repeated bouts of reactivation, most patients do not have permanent sensory loss or any other neurological deficit in the affected dermatome, presumably because reactivation is not associated with significant destruction of latently infected neurons.^{109–112}

The nature of the latent state of the HSV infection in the trigeminal ganglion is not as well understood as HSV infection in the peripheral nervous system (Video 107, Herpes Ophthalmicus). CNS disease as a result of HSV-1 infection—herpes encephalitis—in immunocompetent individuals is a very rare single event, whereas HSV infection in the peripheral nervous system may recur many times during an individual's lifetime. It is estimated that in approximately one third of patients, HSV-1 encephalitis occurs during the primary viral infection, and that in the other 70% HSV-1 encephalitis is due to reactivation of latent infection in the trigeminal ganglion.¹⁰⁹ The pathogenesis of herpes simplex virus infection as a cause of benign recurrent lymphocytic meningitis is postulated to be due to HSV-2 primary infection or to reactivation in a sacral dorsal root ganglion that seeds the CSF subarachnoid space and produces meningitis.¹¹³ The pathogenesis of herpes simplex viral infection in acute facial nerve paralysis is presumed to be reactivation of latent infection in the geniculate ganglion.¹¹⁴

CLINICAL FEATURES AND ASSOCIATED FINDINGS

Acute Encephalitis. As discussed in the preceding section on pathogenesis, HSV encephalitis typically involves the temporal lobe or lobes, the orbital-frontal cortex, and the limbic structures. The clinical presentation is that of a focal encephalitis characterized by focal neurological deficits (hemiparesis in approximately one third of patients) (Video 11, Hemiplegic Gait), focal seizure activity often involving the temporal lobe, headache, altered behavior, personality changes, fever, and altered levels of consciousness (Video 248, Complex-Partial Seizures with Automatism). The classic paper on diseases that mimic herpes simplex encephalitis appeared in the *Journal of the American Medical Association* in 1989.¹¹⁵ This study, which included a total of 432 patients who underwent brain biopsy for presumptive herpes simplex encephalitis, predated the

routine use of MRI and the availability of CSF PCR. Today, the differential diagnosis of acute focal encephalitis with fever, after neuroimaging and CSF analysis, is that of a focal viral encephalitic process. The causes of a focal viral encephalitic process are listed in Table 41-4.

Recurrent Lymphocytic Meningitis. HSV-2 is an etiological agent of benign recurrent lymphocytic meningitis (Mollaret's meningitis).¹¹³ This meningitis is characterized by recurrent attacks of fever, headache, and meningeal irritation that last from 2 to 5 days. There may also be symptoms of a sacral radiculitis.

Bell's Palsy. HSV is an etiological agent of acute facial nerve paralysis (Video 23, Cranial Nerve VII, Facial Diplegia).¹¹⁴

DIFFERENTIAL DIAGNOSIS. MRI is preferred over the CT scan for demonstration of the early lesions of herpes simplex virus encephalitis. On T2-weighted and fluid-attenuated inversion recovery images, high signal intensity lesions are seen in the medial and inferior temporal lobes, which may extend up into the insula. The CSF is under increased pressure, the protein concentration is mildly to moderately elevated, and a lymphocytic pleocytosis is present, as are red blood cells and/or xanthochromia, which reflect the hemorrhagic necrotic nature of the encephalitis; the glucose concentration is normal or mildly decreased. CSF viral cultures for HSV-1 are almost always negative.

The PCR technique, a highly sensitive and specific test for herpes simplex virus encephalitis, may be negative initially in the first 24 to 48 hours of infection but then becomes positive and remains positive for at least 2 weeks. HSV DNA was detected by PCR in the CSF of 53 of 54 (98%) patients with biopsy-proven HSV encephalitis. Positive results were found in 3 of 47 (6%) patients whose brain tissue was culture negative.¹¹⁶ False-positive PCR analysis for HSV DNA has been reported, and a laboratory with expertise in the PCR technique should be used.¹¹⁷ PCR should not be performed on bloody CSF. Porphyrin compounds derived from the degradation of heme in erythrocytes may inhibit the PCR reaction, giving a false-negative result. CSF and serum should also be sent for HSV antibody assay. The intrathecal synthesis of HSV-specific antibody can be detected, usually within 3 to 10 days or more after the onset of symptoms, and antibodies can be detected for as long as 3 months after the onset of symptoms. A serum-to-CSF ratio of less than 20:1 suggests intrathecal production of antibodies to HSV-1. The EEG may also contribute to the diagnosis by showing periodic focal or unilateral high-amplitude complexes consisting of a single wave or a group of waves that repeat at fairly regular intervals and are expressed maximally over the involved temporal lobe. For the diagnosis of benign recurrent lymphocytic meningitis, CSF should be analyzed by the PCR method for HSV-2.¹¹³

Establishing the etiological agent of a facial nerve paralysis is typically difficult except when the characteristic lesions of the Ramsay Hunt syndrome are present. The PCR technique has been used to detect HSV DNA in facial nerve endoneurial fluid and in patients with Bell's palsy, thus identifying HSV-1 as an etiological agent.¹¹⁸

MANAGEMENT. Acyclovir is the drug of choice for neonates with HSV infections of the CNS and for patients with herpes simplex virus encephalitis. Although the standard

of care has been a dose of 10 mg/kg three times daily (for a total of 30 mg/kg/day) for a minimum of 14 days, higher dosages and longer courses (3 weeks followed by an oral antiviral agent) are being investigated. Approximately 5% to 10% of patients with herpes simplex encephalitis show a relapse clinically.¹⁰⁸ It is recommended that the use of brain biopsy be reserved for patients in whom the diagnosis remains unclear, despite the previously described diagnostic studies, and for those in whom progressive neurological deterioration occurs despite acyclovir therapy.¹⁰⁸ Patients with HSV-related Mollaret's meningitis may benefit from prophylactic acyclovir because this treatment has been demonstrated to be effective in preventing recurrent genital herpes.¹¹⁹ A combination of oral acyclovir and prednisone has also been recommended for the treatment of acute idiopathic facial nerve palsy, but firm recommendations cannot be made at this time.

Varicella-Zoster Virus

EPIDEMIOLOGY AND RISK FACTORS. Varicella-zoster virus (VZV) is the etiological agent of chickenpox. Von Bokay was the first to observe that susceptible children might develop varicella after exposure to the herpes zoster virus. Joseph Garland, a long-term editor of the *New England Journal of Medicine*, was the first to suggest that zoster reflected activation of a latent varicella virus.¹²⁰ In 1954, Thomas Weller confirmed von Bokay's observation that children develop varicella following exposure to patients with herpes zoster by demonstrating, with tissue culture and antibody studies, that the two diseases were caused by the same virus.¹²¹ The likelihood of developing zoster increases with advancing age, a phenomenon attributed to immune senescence and a decline in the VZV-specific T lymphocyte population.¹²² Varicella, or chickenpox, results from the initial exposure to VZV, and approximately 1 in 1000 to 4000 patients with varicella developed neurological complications of encephalitis (which most often presented as an acute cerebellar ataxia) (Video 91, Cerebellar Ataxia), aseptic meningitis, polyneuritis, multiple cranial neuropathies, or Reye's syndrome.¹²¹ The incidence of varicella has decreased significantly since the licensure of a live, attenuated varicella virus vaccine in the United States in March 1995. Postherpetic neuralgia is the most common neurological complication of zoster. VZV is also the etiological agent of the Ramsay Hunt syndrome. J. Ramsay Hunt introduced the term herpes zoster oticus in 1907 to refer to a herpetic inflammation of the geniculate ganglion.¹²³ VZV encephalitis is increasingly recognized in immunosuppressed individuals, particularly those with the acquired immunodeficiency syndrome (AIDS), and is characterized by multifocal ischemic and hemorrhagic infarctions associated with demyelination.¹²⁴

PATHOGENESIS AND PATHOPHYSIOLOGY. VZV is a double-stranded DNA virus. Initial infection occurs in the mucosa of the upper respiratory tract and/or in the conjunctivae. The initial site of replication of the virus is unknown but most likely includes adenoid-tonsillar tissues of the head and neck. A primary viremia occurs 4 to 6 days later. The virus then undergoes a second cycle of replication at multiple sites within the host. Thereafter, a second viremia occurs with infection of the capillaries of the skin and

the appearance of the characteristic vesicular lesions of chickenpox.¹²⁵

The mechanism by which VZV establishes latency in the sensory ganglia is not as well understood as the mechanism by which HSV establishes latency. However, by analogy to HSV, it is presumed that viral multiplication in epithelial cells extends locally to involve the distal ramifications of sensory nerves. The virus then travels by axonal transport along the sensory nerves to the neuronal cell body in the sensory ganglia. VZV may also arrive at the sensory ganglia via a hematogenous route during the viremic stage of chickenpox. Once in the ganglia, VZV establishes a life-long latent infection. Non-neuronal cells are also involved in the pathogenesis of VZV latency. In contrast, in primary HSV infection few non-neuronal cells are infected. Zoster exhibits a predilection for the mid to lower thoracic (T3–T12), upper lumbar (L1–L2), and ophthalmic (V1) dermatomes. The propensity for zoster to occur in these dermatomes is attributed to the fact that chickenpox lesions are concentrated in these regions; thus, there is a greater proportion of cells in the corresponding sensory ganglia that become latently infected via neural transport.¹²² In an autopsy series of 14 adults in which the PCR technique was used to detect VZV DNA in the sensory ganglia, VZV DNA was detected in the trigeminal ganglia in 10 of 11 (91%) adults and in the thoracic ganglia in 12 of 14 (86%) adults.¹²⁶ Reactivation of VZV from the sensory ganglia leads to centrifugal migration of the virus through the nerve to the epithelial surface of the corresponding dermatome, yielding the classic vesicular eruption.¹²² Pathological studies of sensory ganglia during herpes zoster show extensive necrosis and neuronal destruction, and it has been suggested that zoster-associated neuralgia may be a consequence of this extensive cytopathology.^{112,122}

CLINICAL FEATURES AND ASSOCIATED FINDINGS.

As described previously, the neurological complications of varicella include encephalitis, aseptic meningitis, polyneuritis, multiple cranial neuropathies, and Reye's syndrome.

Encephalitis. Approximately 1 in 4000 children with varicella who are younger than 15 years old develop acute cerebellar ataxia days to 1 week after the appearance of the varicella rash. There is a 5% mortality rate and a 17% morbidity rate, including mental retardation, seizures, and ataxia.¹²¹

VZV encephalitis in immunosuppressed patients occurs days to months following zoster or may develop without any history of a vesicular rash. The symptoms of encephalitis include fever, seizures, focal neurological deficits, and an alteration in consciousness. There is radiological evidence of multifocal ischemic and hemorrhagic infarctions that involve white matter more than gray matter and are often concentrated at the gray-white matter junction. Small demyelinating lesions with preservation of axons are also seen and are attributed to small vessel vasculopathy.¹²⁴

Facial Nerve Paralysis. Both HSV and VZV are etiological agents of Bell's palsy. VZV is more likely than HSV to cause a complete cranial nerve VII paralysis with concomitant severe pain and sensorineural hearing loss (Video 23, Cranial Nerve VII, Facial Diplegia). Complete recovery of facial function may not occur.¹²³

Reye's Syndrome. Reye's syndrome is discussed in the previous section on influenza virus.

Neuralgia. Pain is the most common symptom of zoster and may precede the eruption by days to weeks. It may occasionally be the only manifestation—the so-called zoster sine herpette.¹²⁷ The pain of zoster tends to resolve with time, or it may be associated with or followed by postherpetic neuralgia. The latter is defined as the presence of pain for more than 1 month after the onset of the zoster eruption.¹²⁷ Postherpetic neuralgia is the most common neurological complication of VZV (Video 106, Trigeminal Neuralgia; Video 107, Herpes Ophthalmicus).

Thrombotic Cerebrovasculopathy. The neurological syndrome of thrombotic cerebrovasculopathy associated with herpes zoster infection presents as a herpes ophthalmicus eruption followed by headache and the apoplectic onset of hemiplegia. On neuroimaging, there is evidence of infarction in the distribution of the anterior or middle cerebral arteries, which on angiography is seen to be due to multifocal thrombosis. The pathogenesis of this syndrome appears to be direct viral invasion of the arterial walls via viral spread along the intracranial branches of the trigeminal cranial nerve. This syndrome is extremely rare.¹²¹

DIFFERENTIAL DIAGNOSIS. The diagnosis of VZV encephalitis is suggested by the clinical presentation, supported by the preceding neuroimaging abnormalities, and associated with a CSF lymphocytic pleocytosis. Varicella-zoster antibody measured by indirect immunofluorescence is present in a titer of 1:2 or more in the CSF in 94% of patients.¹²¹ Detection of VZV DNA in CSF by PCR can confirm the diagnosis.¹²⁴ The diagnosis of Bell's palsy due to VZV is suggested by the classic vesicular eruption on the pinna, or the ear may be reddish and have a hyperemic concha or helix.¹²³ The diagnosis of postherpetic neuralgia is made on clinical grounds.

MANAGEMENT AND PROGNOSIS. VZV encephalitis is treated with intravenous acyclovir (Table 41-6). Early treatment with prednisone and acyclovir appears to improve the outcome in patients with Bell's palsy due to VZV.¹²³ Prednisone also appears to be beneficial in the treatment of neuritis due to zoster but does not appear to have any effect on the development of postherpetic neuralgia. Similarly, oral acyclovir (800 mg five times daily) appears to reduce the pain associated with a zoster rash

but does not have an effect on the development of postherpetic neuralgia.¹²⁷ Valaciclovir (1.0 g orally three times per day) and acyclovir (800 mg orally five times per day) were approximately equal in their ability to decrease virus shedding and accelerate the time to cutaneous healing of zoster.¹²⁸ Valaciclovir is a prodrug of acyclovir and achieves by oral administration plasma acyclovir concentrations similar to those achieved only with intravenous acyclovir.¹²⁷ Famciclovir is a prodrug of penciclovir, an acyclic guanine derivative that is similar to acyclovir in terms of structure, spectrum of activity, and mechanism of action.¹²⁸ A trial comparing famciclovir (at doses of 250, 500, or 750 mg three times daily) with acyclovir (800 mg five times per day) in 544 immunocompetent adults with herpes zoster demonstrated that famciclovir was equivalent to acyclovir in terms of acceleration of cutaneous healing, loss of acute pain, safety, and tolerance.¹²⁸ If begun within 72 hours after the appearance of the rash, famciclovir, valaciclovir, or acyclovir reduces the acute pain in patients with zoster. At this time, no single drug can be recommended over another except to say that famciclovir and valaciclovir can be given less often than acyclovir. Corticosteroids appear to improve the quality of life after zoster even though they do not alter the course of postherpetic neuralgia; therefore, their administration in combination with an antiviral agent is recommended in individuals in whom they are not contraindicated.¹²⁷ Postherpetic neuralgia can be treated with topical lidocaine-prilocaine cream or 5% lidocaine gel. Topical capsaicin cream is not recommended because of the burning that occurs with its application. A tricyclic antidepressant agent such as amitriptyline or desipramine can be started at a low dose (12.5 to 25 mg) at bedtime. Patients should be advised that it takes several weeks to achieve maximum benefit from an antidepressant drug. Anticonvulsant drugs, specifically gabapentin, reduce the lancinating component of the neuropathic pain.¹²⁷

Cytomegalovirus

EPIDEMIOLOGY AND RISK FACTORS. Cytomegalovirus (CMV) is the most common life- and sight-threatening

TABLE 41-6

Antiviral Agents

| ANTIVIRAL AGENT | DOSAGE | INDICATIONS | ADVERSE EFFECTS |
|-----------------|---|---|---|
| Acyclovir | 1) 10 mg/kg intravenously every 8 hours 2) 800 mg orally 5 times/day | 1) Herpes simplex virus encephalitis 2) Zoster | Renal toxicity, nausea, confusion Headache, nausea, diarrhea |
| Valaciclovir | 1.0 g orally tid | Zoster | |
| Famciclovir | 750 mg orally tid | Zoster | |
| Ganciclovir | Induction therapy: 5 mg/kg bid intravenously Maintenance therapy: 6 mg/kg once daily intravenously | CMV | Neutropenia, thrombocytopenia, confusion, convulsions, dizziness, headaches, nausea |
| Foscarnet | Induction therapy: 60 mg/kg intravenously every 8 hours Maintenance therapy: 100–120 mg/kg intravenously daily | CMV | Renal toxicity, anemia, hypocalcemia, hypophosphatemia, seizures |

opportunistic viral infection in patients with AIDS.¹²⁹ CNS infection by CMV in patients with AIDS may take the form of one or more of five distinct neurological syndromes: retinitis, polyradiculomyelitis, encephalitis with dementia, ventriculoencephalitis, and mononeuritis multiplex.¹³⁰ Organ transplant recipients are also at risk for encephalitis due to CMV. Newborns with congenital CMV infection may have seizures, spasticity, microcephaly, chorioretinitis or optic atrophy, and neuroradiographical evidence of intracerebral calcifications and cerebral atrophy.¹³¹

CMV is a DNA virus and a member of the herpesvirus group, which includes VZV, HSV-1 and -2, and Epstein-Barr virus. All of these viruses have a propensity to assume a latent state in humans and to undergo reactivation.¹³¹ Primary infection with CMV is usually benign; approximately 80% of adults in the United States have complement fixation antibodies to CMV by the age of 40 years, but under conditions of immune suppression, latent virus may be reactivated, producing a variety of systemic and neurological syndromes.

PATHOGENESIS AND PATHOPHYSIOLOGY. CMV is acquired by close personal contact through saliva, cervical secretions, and semen, and also through blood transfusion. In congenital CMV infections, the fetus acquires the infection transplacentally. Symptomatic congenital CMV infection is a complication only of primary maternal infection; infants born to immune mothers may be infected but appear to be asymptomatic in the newborn period. Perinatal infection in infants occurs either through contact with CMV-infected uterine cervical secretions or through transmission of CMV in breast milk. Infection of the CNS results from viremia, and CMV has a predilection to infect the ependymal cells lining the ventricles and the gray matter in the cortex, basal ganglia, brain stem, and cerebellum.^{130,131} The CNS symptoms and neuropathological abnormalities observed in CMV-infected fetuses have been attributed to chronic intrauterine CMV encephalitis.¹³¹

CLINICAL FEATURES AND ASSOCIATED FINDINGS. As stated previously, CMV may cause congenital disease, retinitis, lumbosacral polyradiculopathy and myelitis, encephalitis with dementia, ventriculoencephalitis, mononeuritis multiplex, and infectious polyneuritis—the Guillain-Barré syndrome.

Congenital Cytomegalovirus Infection. The clinical spectrum of congenital CMV infection varies from an asymptomatic infant to one who has the signs and symptoms of disseminated disease. In the most severe form of congenital CMV infection, the virus affects multiple organs, and the infant has hepatitis, splenomegaly, pneumonitis, jaundice, thrombocytopenia, chorioretinitis, hemolytic anemia, petechial or purpuric rash, seizures, spasticity, microcephaly, optic atrophy, and neuroimaging evidence of intracerebral calcifications and cerebral atrophy.¹³¹

Retinitis. The presenting complaint of CMV retinitis is usually unilateral “floaters” or decreased visual acuity. Ophthalmological examination demonstrates large white-colored areas with perivascular exudates and hemorrhages. Initially, these abnormalities are found at the periphery of the fundus, but if left untreated, lesions progress to involve the macula and the optic disc.¹³²

Lumbosacral Polyradiculopathy and Myelitis. The presentation of this syndrome is characterized by a subacute

onset of weakness, areflexia, and sensory loss in the legs in association with bladder- or anal-sphincter dysfunction. The disease evolves as an ascending paraparesis.¹³⁰ Clinical evidence of lower extremity weakness, areflexia, and bilateral Babinski’s signs (if the spinal cord is involved) suggests this syndrome.

Encephalitis. Patients with AIDS and encephalitis due to CMV present with forgetfulness, memory impairment, apathy, and withdrawal, like patients with HIV encephalitis, except that patients with CMV encephalitis have had AIDS longer and have lower mean CD4 lymphocyte counts at presentation. Patients with CMV encephalitis also have rapidly progressive cognitive impairment, and their survival is markedly shorter than that of patients with HIV dementia. CMV encephalitis is characterized by multifocal, diffusely scattered, small microglial nodules and inclusion-bearing cytomegalic cells that are concentrated in the gray matter in the cortex, basal ganglia, brain stem, and cerebellum. There is a strikingly high incidence of hyponatremia, hyperkalemia consistent with an Addisonian state, dilutional hyponatremia with hypo-osmolality, or hypernatremia due to dehydration in patients with CMV encephalitis.¹³⁰

Ventriculoencephalitis. A distinction is made between CMV encephalitis, described previously, and CMV ventriculoencephalitis, which is characterized by necrosis of the cranial nerves and of the periventricular parenchyma.¹³⁰ This syndrome presents as a rapidly fatal delirium with oculomotor palsies and nystagmus, and a linear homogeneous increased signal on T2-weighted MRI scans around the ventricles with ventriculomegaly.

Mononeuritis Multiplex. CMV mononeuritis results from focal necrotizing vasculitis of the epineurial arteries and presents as a multifocal or asymmetrical sensory or motor deficit in the distribution of a peripheral or cranial nerve.¹³⁰

DIFFERENTIAL DIAGNOSIS. The diagnosis of congenital CMV infection is made by recovery of infectious virus from urine, saliva, buffy coat leukocytes, or CSF. Demonstration of seroconversion or a fourfold increase in CMV antibody titers between the acute and convalescent sera strongly supports recent CMV infection. CT scan demonstrates intracerebral calcifications and cerebral atrophy in newborns with CNS symptoms.¹³¹ The diagnosis of CMV retinitis is made clinically because it is impractical to obtain fluid or tissue from the eye for culture or microscopic examination. Blood, urine, or semen can be cultured to document active CMV infection in the patient, but the relevance of these cultures is questionable because patients without retinitis have positive cultures.¹³² In patients with CMV lumbosacral polyradiculopathy, the CSF often demonstrates a pleocytosis with a neutrophilic predominance, the protein concentration is elevated, and the glucose concentration may be low or normal. Culture of CSF for CMV is the gold standard, but this test is insensitive (positive in 60% of patients), and CSF should also be analyzed by the PCR technique.^{133,134} MRI may reveal enlargement of the conus medullaris, clumping of lumbosacral rootlets, or enhancement (with gadolinium) of the leptomeninges of the lower spinal cord.¹³⁰ In patients with CMV encephalitis there may be a mild mononuclear pleocytosis and an elevated protein concentration. CSF should be analyzed for CMV DNA by PCR.

In patients with CMV ventriculoencephalitis, MRI (as described previously) may demonstrate increased periventricular signal intensity on T2-weighted images. In all patients in whom a CMV neurological syndrome is suspected, culture of the CSF and analysis of CSF by PCR to detect CMV DNA should be performed.

MANAGEMENT. Ganciclovir and foscarnet are the two antiviral agents that have been proved effective in the treatment of CMV retinitis. CMV polyradiculopathy, encephalitis, and ventriculoencephalitis have been treated with dosing regimens that are identical to those used for CMV retinitis, although their clinical efficacy has not been established (see Table 41–6). Ganciclovir 5 mg/kg intravenously is given twice daily during “induction” therapy for a minimum of 2 or 3 weeks. This is followed by maintenance therapy at a dose of 6 mg/kg intravenously daily. Foscarnet is given in a dose of 60 mg/kg administered intravenously every 8 hours for induction therapy for a minimum of 2 or 3 weeks, followed by maintenance therapy of 100 to 120 mg/kg given intravenously daily. The doses of ganciclovir and foscarnet must be reduced when renal function is impaired or renal toxicity develops. A reversible leukopenia is an adverse effect of ganciclovir, as is a thrombocytopenia. Adverse effects of foscarnet include renal toxicity, anemia, hypocalcemia, hypophosphatemia, and seizures.¹³² Both CMV encephalitis and ventriculoencephalitis have been reported in patients receiving maintenance therapy for CMV retinitis even when the retinitis remains under control.^{129,130}

Human Herpesvirus-6

EPIDEMIOLOGY AND RISK FACTORS. Human herpesvirus-6 (HHV-6) is the causative agent of the common childhood infection roseola infantum (exanthem subitum).¹³⁵ The virus was first isolated in 1986 from the peripheral blood lymphocytes of patients with AIDS and those with lymphoproliferative disorders. It is a member of the human herpesvirus family and shares some DNA sequence homology with CMV.¹³⁶ Saliva may be the major mode of transmission of HHV-6. Primary infection may be symptomatic or asymptomatic; the virus is then able to become latent in the host and reactivates in the presence of immunosuppression. The majority of the population is exposed to HHV-6 in infancy; by age 2 years, most children are seropositive.¹³⁶

PATHOGENESIS AND PATHOPHYSIOLOGY. HHV-6 DNA has been detected by PCR in 6 of 9 (66%) normal brain tissue specimens in one study and in the CSF of 9 of 10 patients with exanthem subitum and neurological symptoms.^{137,138} Human T lymphocytes are the primary cell type infected by HHV-6, but HHV-6 has also been shown to infect cells of neuronal and glial origin in vitro.¹³⁷ The detection of HHV-6 DNA by PCR in children with exanthem subitum and neurological symptoms suggests that HHV-6 invades the brain during acute infection.¹³⁸ The presence of HHV-6 DNA in normal brain tissue specimens is evidence of the persistence or latency of HHV-6 in the CNS.¹³⁷ Reactivation of latent HHV-6 infection has been demonstrated in children and in immunocompromised adults.^{139,140}

CLINICAL FEATURES AND ASSOCIATED FINDINGS. As previously stated, HHV-6 is the etiological agent of

childhood exanthem subitum. The most common CNS complications of primary HHV-6 infection are seizures, meningoencephalitis, and encephalopathy.¹³⁹ HHV-6 has been reported as the etiological agent of focal encephalitis in bone marrow transplant recipients and in immunocompetent adults with focal encephalitis in whom the clinical presentation suggested herpes simplex virus encephalitis.^{136,140} CNS infection with HHV-6 has also been associated with diffuse or multifocal demyelination and a clinical picture of fulminant multiple sclerosis.¹⁴¹ Disseminated HHV-6 infection has been reported in children and adults with AIDS.^{142,143}

Exanthem Subitum. Roseola infantum or exanthem subitum is a common disease of infancy characterized by high fever for a few days followed by the appearance of a generalized maculopapular rash when the fever subsides. Febrile convulsions in this disease have a reported incidence of 13% to 30%, with children 12 to 15 months of age being at highest risk.^{135,138}

Encephalitis and Focal Encephalitis. HHV-6 DNA has been recovered from the brain of a patient at autopsy who died of encephalitis 5 months after undergoing allogeneic bone marrow transplantation.¹⁴⁰ Three of 37 patients with a clinical presentation suggestive of herpes simplex encephalitis and 6 of 101 patients with clinical and laboratory evidence of herpes simplex encephalitis were found to have HHV-6 DNA in their CSF when samples of CSF were sent to the University of Alabama for the purpose of undergoing diagnostic PCR analysis for possible herpes simplex encephalitis. The spectrum of disease ranged from mild encephalitis with complete resolution to severe neurological dysfunction and death.¹³⁶ A dense and disseminated active HHV-6 infection was found in the brain tissue of a young woman with a fulminant demyelinating disease that was clinically and histopathologically diagnosed as acute multiple sclerosis.¹⁴¹

DIFFERENTIAL DIAGNOSIS. Primary HHV-6 infection is diagnosed by culture of peripheral blood mononuclear cells and a concomitant fourfold or greater rise in IgG titer between the acute and convalescent sera. CSF can be analyzed by PCR to detect HHV-6 DNA. IgM antibody may be present during reactivation, and therefore its presence does not differentiate a primary infection from reactivation.¹³⁹

MANAGEMENT. Limited information is available on the susceptibility of HHV-6 to antiviral agents. The pattern of antiviral inhibition of HHV-6, however, resembles that of the human cytomegalovirus, suggesting that ganciclovir and foscarnet may be effective for the treatment of HHV-6 infections.¹⁴⁴

Epstein-Barr Virus

EPIDEMIOLOGY AND RISK FACTORS. Epstein-Barr virus (EBV) is a human B lymphotropic virus, the causative agent of infectious mononucleosis. The major route of transmission of EBV is through saliva, and EBV infects the epithelial cells of the oropharynx and adjacent structures as well as those of the uterine cervix. Epithelial cells may play a major role in the persistence of EBV by allowing chronic viral replication and release of infectious particles throughout the lifetime of a virus-infected host. Eighty percent to 90% of children in developing countries are

seropositive for EBV between 2 and 3 years of age. By the third decade, nearly 100% of adults have EBV serum antibodies.¹⁴⁵

PATHOGENESIS AND PATHOPHYSIOLOGY. EBV is a lymphotropic virus that selectively infects B lymphocytes. B lymphocytes are infected by EBV during their passage through the chronically EBV-infected oropharyngeal epithelium. EBV has the unique biological property of being able to induce dysregulated activation and growth of a subpopulation of the infected B cells that then grow continuously as lymphoblastoid cell lines that secrete immunoglobulins.^{145,146} CNS invasion by infected B lymphocytes appears to be important in the pathogenesis of CNS disease.¹⁴⁷

CLINICAL FEATURES AND ASSOCIATED FINDINGS. Infectious mononucleosis is the only known disease caused by acute EBV infection. The neurological complications of infectious mononucleosis include meningoencephalitis, Guillain-Barré syndrome, cerebellitis, transverse myelitis, cranial nerve palsies (of which the most common is cranial nerve VII palsy), and a variety of optic nerve abnormalities (papilledema, optic neuritis, and retrobulbar neuritis).¹⁴⁸ EBV infection is almost universally associated with primary CNS lymphomas in patients with AIDS.¹⁴⁹ Persistent viral activity or reactivation of EBV has been studied in the etiology of chronic fatigue syndrome.

Infectious Mononucleosis. The term *infectious mononucleosis* was first used in 1920 to describe the clinical findings of medical students attending Johns Hopkins University who had the typical clinical picture of this disease associated with atypical mononuclear cells.¹⁴⁸ The clinical course of infectious mononucleosis is characterized by a 7-day prodromal illness followed by a 4-day to 3-week acute illness characterized by fever, headache, malaise, pharyngitis, cervical lymphadenopathy, and mononuclear leukocytosis with atypical lymphocytes. Splenic and hepatomegaly may be present with transient hepatic dysfunction.^{145,148} The neurological complications of infectious mononucleosis include Guillain-Barré syndrome, an aseptic meningitis or encephalitis of which nonfebrile seizures are a common presenting manifestation, and cranial nerve palsies, the most common of which is an isolated or bilateral facial nerve palsy (Video 23, Cranial Nerve VII, Facial Diplegia).¹⁴⁸ Overall, meningoencephalitis is the most common neurological complication, whereas transverse myelitis is the least common.

Central Nervous System Lymphoma. EBV is detectable from a majority of primary CNS lymphomas in AIDS patients and to a lesser degree from primary CNS lymphomas in immunocompetent individuals.¹⁴⁹ The clinical presentation is that of progressive personality changes, seizures, and signs of increased intracranial pressure.¹⁵⁰

Chronic Fatigue Syndrome. Chronic fatigue syndrome is characterized by debilitating fatigue accompanied by a variety of symptoms, including cognitive difficulty, myalgias, and arthralgias.¹⁵¹

DIFFERENTIAL DIAGNOSIS. The diagnosis of infectious mononucleosis is based on a positive heterophil antibody test, the appearance of atypical lymphocytes in the blood at 1 to 4 weeks after onset of disease, and/or changes in EBV-specific antibodies. An acute infection is documented by detection of antiviral capsid antigen (VCA) titers of 1:320 or higher, the presence of anti-D (i.e., diffuse

component of EBV-induced early antigen complex), or EBV VCA IgM antibodies and the absence of antibodies to virus-associated nuclear antigen (anti-EBNA IgG). In acute and convalescent paired sera, fourfold or greater increments in anti-VCA or anti-D titers, or a late decrease in anti-VCA titers or loss of anti-D titers, and the appearance of anti-EBNA IgG denote a recent infection. Anti-VCA titers peak early and then decline to persistent lower levels. Anti-D responses and virus-specific IgM antibodies are present for only a few weeks. Anti-EBNA antibodies appear late in convalescence and persist for life.¹⁴⁸ In patients in whom neurological complications of infectious mononucleosis are suspected, the combination of serological tests and PCR performed on CSF for the EBV DNA genome is recommended. If PCR for EBV DNA on CSF is negative, an acute EBV infection can be documented by evidence of positive IgM antibody titers to the viral capsid antigen early in the disease course, with a fourfold decrease in IgG antibody titers to the viral capsid antigen corresponding to a fourfold or greater increase in antibody to Epstein-Barr nuclear antigen between the acute and convalescent sera. A distinction between latent and symptomatic EBV infection cannot be made based strictly on positive results of PCR on CSF for EBV DNA.¹⁵²

The diagnosis of primary CNS lymphoma is based on CT or MRI evidence of a focal enhancing mass lesion or lesions, and typically an unsuccessful response to antitoxoplasma therapy, because the neuroimaging appearance of *Toxoplasma gondii* encephalitis and primary CNS lymphoma is similar. The gold standard for the diagnosis has been brain biopsy; however, the PCR technique is both sensitive and specific in making the diagnosis. EBV DNA was detected by PCR in the CSF from 7 of 8 patients with primary CNS lymphoma diagnosed by brain biopsy (87.5% sensitivity) but in none of the 11 controls with brain mass lesions (100% specificity).¹⁴⁹

Although there are reports of patients with chronic fatigue syndrome and high antibody titers to viral capsid antigen and early antigen of EBV, to date there is no scientific evidence that the reactivation of EBV is involved in the chronic fatigue syndrome.¹⁵³

MANAGEMENT. Although there are no EBV antiviral agents, ganciclovir is known to inhibit EBV replication in vitro, and there are a few reports of successful treatment of EBV meningoencephalitis with ganciclovir in transplant recipients.¹⁵⁴ Primary CNS lymphoma is treated with radiation therapy.

Variola Virus (Smallpox)

EPIDEMIOLOGY AND RISK FACTORS. No infectious disease in history has been more lethal than smallpox. In the 20th century, smallpox killed 300 million people worldwide. Through an effective immunization program, the World Health Organization was able to eliminate smallpox. One of the last outbreaks occurred in Iran and then spread to northern Iraq and to Syria in the mid-1970s. In 1980, the World Health Assembly recommended that all countries cease vaccination. Several vials of virus were to be retained in two designated laboratories, the Institute of Virus Preparations in Moscow and the CDC in Atlanta, Georgia. The 52nd World Health Assembly established a deadline

of December 31, 2002, to destroy all remaining stocks of variola virus.^{155,156} Terrorist groups are believed to have obtained smallpox. Specimens were taken from patients in Iran, Iraq, and Syria, and smallpox was isolated. The whereabouts of these specimens of smallpox are not known.

PATHOGENESIS AND PATHOPHYSIOLOGY. Smallpox spreads from person to person by droplet nuclei from oropharyngeal secretions and can be spread by contaminated clothing and beds.¹⁵⁷ The infectious dose is very small; for this reason, disease can spread quickly.

CLINICAL FEATURES AND ASSOCIATED FINDINGS

Smallpox. The incubation period is 7 to 17 days between the time the virus attaches to the oropharyngeal or respiratory mucosa and the onset of high fever, sore throat, headache, and backache. A maculopapular rash appears on the mucosa of the mouth and oropharynx, face, and forearms and spreads to the trunk and legs. The lesions become vesicular and then pustular (small boils). The lesions are denser on the face and extremities than on the trunk. The lesions are all in the same stage at the same time and thus appear similar to each other. Patients are most infective when they have lesions in their mouth because virus titers in saliva are highly infectious at this time.¹⁵⁷ Smallpox can be complicated by encephalitis and postinfectious encephalomyelitis.

Hemorrhagic Smallpox. This form of smallpox presents with high fever, headache, backache, and abdominal pain, followed by petechial and hemorrhagic lesions in the skin and mucous membranes. The skin rash initially has the appearance of meningococcemia. Pregnant women are particularly susceptible, and this is uniformly fatal.¹⁵⁷

Postvaccinal Encephalomyelitis. Postvaccinal encephalomyelitis, also called postinfectious encephalomyelitis, acute disseminated encephalomyelitis, and acute demyelinating encephalomyelitis, is an acute inflammatory, demyelinating disease of the brain, optic nerves, and spinal cord that historically was a major complication of smallpox vaccination. The illness is characterized by the abrupt onset of fever, altered level of consciousness, and multifocal neurological deficits.

DIAGNOSIS. Smallpox is a DNA virus that is a member of the orthopoxviruses. Smallpox infection can be rapidly diagnosed in the laboratory by the electron microscopic appearance of brick-shaped virions from vesicular or pustular fluid that is collected from an open lesion or by an examination of a specimen from scabs. The characteristic abnormalities on MR scan in postvaccinal encephalomyelitis are multifocal areas of hyperintensity on T2-weighted images consistent with a multifocal demyelinating disease.

MANAGEMENT. The care of patients with smallpox is primarily supportive. Patients should be isolated; those caring for them should wear gowns, gloves, and masks; and bed linens should be autoclaved. All close contacts of any person with smallpox should be promptly vaccinated. Vaccination that is administered within 4 days of exposure has been shown to offer some protection against acquiring infection.¹⁵⁷

JC Virus

EPIDEMIOLOGY AND RISK FACTORS. The JC virus is ubiquitous; antibodies to the virus are present in up to 85% of individuals by the age of 9 years.¹⁵⁸ The JC virus is the

etiological agent of progressive multifocal leukoencephalopathy (PML).

PATHOGENESIS AND PATHOPHYSIOLOGY. The kidneys are thought to be the site of latent JC viral persistence. Reactivation of the virus associated with immunosuppression results in hematogenous dissemination of the virus to the brain. Foci of PML are frequently located in proximity to blood vessels.¹⁵⁹ Progressive multifocal leukoencephalopathy occurs in patients with impaired cell-mediated immunity such as those with AIDS, chronic lymphocytic leukemia, Hodgkin's disease, other lymphomas, systemic lupus erythematosus, organ transplantation, and sarcoidosis.^{158,159} The virus preferentially infects the myelin-producing oligodendrocytes, resulting in cell lysis and demyelination.¹⁵⁹

CLINICAL FEATURES AND ASSOCIATED FINDINGS. Focal neurological deficits (hemiparesis, dysarthria, and cerebellar limb and gait ataxia), seizure activity (Video 74, Secondary Generalized Seizure), and cognitive impairment characterized by memory impairment, psychomotor retardation, and inattentiveness characterize the clinical presentation of PML.¹⁵⁹

DIFFERENTIAL DIAGNOSIS. On CT scan, PML appears as single or multiple nonenhancing, hypodense lesions in the white matter, most commonly in the parietal-occipital regions. On T2-weighted MRI scans, the lesions have increased signal intensity and do not enhance after contrast administration. Examination of the CSF is usually normal.¹⁵⁹ The PCR technique can detect JC virus DNA in CSF with a reported sensitivity of 75% and a specificity of 96%.¹⁶⁰ Serum and CSF antibody titers for JC virus are not useful in establishing the diagnosis of PML because 80% of the population show antibodies to JC virus by adulthood.¹⁵⁹ Brain biopsy should be used for diagnosis in patients who have suspicious white matter lesions on MRI and in whom JC virus is not detected by PCR on CSF.¹⁶⁰

MANAGEMENT. There is no proven therapy for PML, but clinical trials are ongoing. There is a correlation between the CD4 T cell count and survival, in that patients with higher CD4 T cell counts survive longer. Notable improvement in PML has been observed in AIDS patients treated with high-dose 3-azido-3-deoxythymidine (AZT), and it is hypothesized that the AZT-induced elevation of CD4 T cell counts improves cell-mediated immunity sufficiently to resist the JC virus infection.¹⁵⁹ The average length of survival from the onset of symptoms to death is 1 to 4 months, but a small percentage of patients reportedly have improved spontaneously and survived for several years.¹⁵⁹

ACKNOWLEDGMENT

The assistance of Mrs. Linda Hagan in the preparation of the manuscript is greatly appreciated.

Acute Bacterial Meningitis

EPIDEMIOLOGY AND RISK FACTORS. There are approximately 25,000 cases of bacterial meningitis in the United States each year, but this disease is much more prevalent in developing countries. Group B streptococci and gram-negative enteric bacilli are the etiological organisms of the majority of cases of bacterial meningitis during the neonatal period in developed countries. In underdeveloped countries, gram-negative bacilli, predominantly *Escherichia coli*, are the most common pathogens.¹ Risk factors that predispose the newborn to bacterial meningitis include maternal infections, particularly of the urinary tract and uterus; obstetrical risk factors, including prolonged rupture of membranes and birth trauma; prematurity; low birth weight (<2500 g); congenital anomalies; perinatal hypoxia/asphyxia; cardiopulmonary resuscitation and monitoring; prolonged ventilatory support; and intravenous lines.¹ After the neonatal period, *Streptococcus pneumoniae* and *Neisseria meningitidis* are the most common etiological agents of bacterial meningitis. *Haemophilus influenzae* type b (Hib) was the leading cause of bacterial meningitis in young children before the widespread use of the Hib conjugate vaccine. The latter has resulted in a marked reduction in the incidence of invasive infections caused by Hib in the United States. *Neisseria meningitidis* causes meningitis primarily in children and young adults, with the majority of cases occurring in individuals younger than age 30 years. Major epidemics are heralded by disease occurring in older age groups. The “meningitis belt” of sub-Saharan Africa refers to areas of Africa where there are repeated epidemics of serogroup A meningococcal meningitis.² Annual outbreaks of meningitis occur in the meningitis belt in late April and early May when the dry desert winds have ceased and temperatures are high throughout the day. The epidemic tends to end with the

onset of the rainy season. Transmission of meningococci is facilitated by airborne droplets, and the nasopharynx is the natural reservoir for this organism. During periods of low humidity, an alteration in the nasopharyngeal mucosal barrier predisposes the individual to infection. In addition, crowding, the presence of other respiratory pathogens, poor hygiene, and other poorly defined environmental factors contribute to the development of an epidemic of meningococcal meningitis.² Colonization of the nasopharynx in an individual may result in an asymptomatic carrier state or invasive infection.

Streptococcus pneumoniae is the most common causative organism of community-acquired bacterial meningitis in the adult. Pneumonia and acute and chronic otitis media are important antecedent events. Chronic disease, specifically alcoholism, sickle cell anemia, diabetes, renal failure, cirrhosis, splenectomy, and hypogammaglobulinemia, and organ transplantation are predisposing conditions for pneumococcal bacteremia and meningitis. The pneumococci are a common cause of recurrent meningitis in patients with head trauma and cerebrospinal fluid (CSF) rhinorrhea. In the older adult (age 50 years or older), *S. pneumoniae* is likely to cause meningitis in association with pneumonia or otitis media, and gram-negative bacilli are the likely organisms to cause meningitis in association with chronic lung disease, sinusitis, a neurosurgical procedure, or a chronic urinary tract infection.^{3,4} The most common gram-negative bacilli causing meningitis in the older adult are *E. coli*, *Klebsiella pneumoniae*, *H. influenzae*, *Pseudomonas* organisms, *Enterobacter* species, and *Serratia* species.^{3,5,6} *Listeria monocytogenes* is an important causative organism of neonatal meningitis and of meningitis in patients who are diabetic, alcoholic, elderly, or immunosuppressed, especially transplant recipients.² Infection with *L. monocytogenes* may be acquired through the consumption of soft cheeses, raw vegetables, seafood, cole slaw, and undercooked chicken and delicatessen meats. The staphylococci are the etiological organisms of meningitis

primarily in the neurosurgical patient. *Staphylococcus aureus* and coagulase-negative staphylococci are the predominant organisms causing infections in patients with CSF shunts or subcutaneous Ommaya reservoirs.

PATHOGENESIS AND PATHOPHYSIOLOGY. The most common bacteria that cause meningitis, *N. meningitidis* and *S. pneumoniae*, initially colonize the nasopharynx by attaching to the nasopharyngeal epithelial cells. The organisms are able to attach to the nasopharyngeal epithelial cells via an interaction between bacterial surface structures, such as the fimbriae of *N. meningitidis* and host cell surface receptors. The bacteria are then either carried across the cell in membrane-bound vacuoles to the intravascular space or invade the intravascular space by creating separations in the apical tight junctions of columnar epithelial cells.^{7,8} *Streptococcus pneumoniae* and *N. meningitidis* are both encapsulated bacteria, and once they gain access to the bloodstream, they are successful in avoiding phagocytosis by neutrophils and classic complement-mediated bactericidal activity because of the presence of the polysaccharide capsule. Bacteria that are able to survive in the circulation enter the CSF from the bloodstream through the choroid plexus of the lateral ventricles and other areas of altered blood-brain barrier permeability. The CSF is an area of impaired host defense because of a lack of sufficient numbers of complement components and immunoglobulins for the opsonization of bacteria.⁷ Normal uninfected CSF contains no phagocytic cells, has a low protein concentration, contains no IgM, and has low concentrations of C₃ and C₄.⁹ In addition, the fluid medium of the CSF impairs the phagocytosis of bacteria by neutrophils.^{9,10} Bacteria multiply rapidly in the subarachnoid space. Both the multiplication of bacteria and the lysis of bacteria by bactericidal antibiotics result in the release of bacterial cell wall components. These induce the formation of the inflammatory cytokines, interleukin-1 (IL-1) and tumor necrosis factor (TNF), by monocytes, macrophages, brain astrocytes, and microglial cells, which leads to altered blood-brain barrier permeability and the recruitment of polymorphonuclear leukocytes. This process results in the formation of a purulent exudate in the subarachnoid space, which is the basis for the neurological complications of bacterial meningitis. The inflammatory cytokines IL-1 and TNF, which are produced in response to the release of bacterial cell wall components, induce the formation of leukocyte adhesion molecules on vascular endothelial cells. The adherence of neutrophils to vascular endothelial cells is a necessary prerequisite for neutrophils to traverse the blood-brain barrier. It is not clear what role, if any, neutrophils play in eradicating the infection in the subarachnoid space. Large numbers of leukocytes in the subarachnoid space contribute to the purulent exudate and obstruct the flow of CSF. Adherence of leukocytes to the cerebral capillary endothelial cells increases the permeability of blood vessels, allowing for the leakage of plasma proteins through open intercellular junctions that lead to vasogenic brain edema. The leukocytes that successfully migrate into the CSF can subsequently be stimulated by the inflammatory cytokines to degranulate and release toxic oxygen metabolites, producing cytotoxic cerebral edema. IL-1 is a chemoattractant for neutrophils.^{7,11} IL-1 may also have a role in the altered level of consciousness and the production of fever in

bacterial meningitis. It has been demonstrated that IL-1 facilitates slow-wave sleep and produces fever by its effect on the hypothalamus.^{12,13} Other inflammatory cytokines, including IL-6 and IL-8, also have a role in the induction of meningeal inflammation, but the role of these cytokines has not been studied as extensively as that of IL-1 and TNF. Platelet-activating factor also has a prominent role in increasing blood-brain barrier permeability.¹⁴

The alteration in blood-brain barrier permeability during bacterial meningitis results in vasogenic cerebral edema, which contributes to increased intracranial pressure. It also allows for the leakage of plasma proteins into the CSF that contribute to the inflammatory exudate in the subarachnoid space.⁸ The purulent exudate in the subarachnoid space interferes with the resorptive function of the arachnoid granulations. As resorption is obstructed, CSF dynamics are altered, and there is transependymal movement of fluid from the ventricular system into the brain parenchyma, which contributes to interstitial edema. The purulent exudate in the basal cisterns obstructs CSF outflow through the ventricles, also contributing to interstitial edema.

An increase in intracranial pressure (ICP) affects cerebral perfusion pressure (CPP), which is defined as the difference between the mean arterial pressure (MAP) and the ICP ($CPP = MAP - ICP$). CPP is also adversely affected by a loss of cerebral autoregulation. Cerebral blood flow is initially increased in bacterial meningitis; however, soon thereafter, cerebral blood flow begins to decrease. Cerebral blood flow is normally protected through cerebrovascular autoregulation. There is dilatation or constriction of cerebral resistance vessels in response to alterations in CPP, as a result of either changes in the MAP or changes in ICP.¹⁵ The loss of cerebral autoregulation means that cerebral blood flow decreases when systemic blood pressure decreases and increases when systemic blood pressure increases. Because patients with bacteremia and bacterial meningitis are at risk for hypotension, the loss of cerebral autoregulation also puts them at risk for decreased cerebral blood flow. Cerebral blood flow is also affected by narrowing of large arteries at the base of the brain due to encroachment by the purulent exudate in the subarachnoid space. Furthermore, infiltration of the arterial walls by inflammatory cells with secondary intimal thickening and thrombosis of the major sinuses and thrombophlebitis of the cerebral cortical veins contribute to diminished cerebral blood flow.

CLINICAL FEATURES AND DIFFERENTIAL DIAGNOSIS. The classic presentation of bacterial meningitis is headache, fever, stiff neck, and an altered level of consciousness, but the clinical symptoms and signs may vary depending on the age of the patient and the duration of illness before presentation. The symptoms and signs of bacterial meningitis in the neonate are often subtle and typically nonspecific, and they include fever or hypothermia, lethargy, seizures, irritability, bulging fontanel, poor feeding, vomiting, and respiratory distress. Meningitis should always be considered when sepsis is suspected in the neonate.^{1,16} In children and adults, the symptoms and signs of bacterial meningitis are fever, headache, vomiting, photophobia, nuchal rigidity, lethargy, confusion, or coma. Meningitis in children typically presents as either a subacute infection that gets progressively worse over several days, following

an upper respiratory tract or ear infection, or an acute fulminant illness that develops rapidly in a few hours. The typical rash of meningococemia is a petechial-purpuric rash that develops on the trunk, lower extremities, mucous membranes, conjunctiva, and occasionally on the palms and soles. A petechial, purpuric, or erythematous maculopapular rash is also seen in enteroviral meningitis, *N. gonorrhoeae* sepsis, Hib and pneumococcal meningitis, Rocky Mountain spotted fever, and *Staphylococcus aureus* endocarditis. Children with bacterial meningitis may also be ataxic as a result of labyrinthine dysfunction or vestibular neuronitis. In adults, an upper respiratory tract infection frequently precedes the development of meningeal symptoms, and its presence should be sought in the history.^{7,16} Adults typically complain of headache, photophobia, and stiff neck, and they may have a rapid progression from lethargy to stupor and coma. The clinical presentation of meningitis in an older adult consists of fever and confusion, stupor, or coma.

Cranial nerve palsies, and most notably sensorineural hearing loss, are a common complication of bacterial meningitis and may be present early in the course of the illness. A stiff neck is the pathognomonic sign of meningeal irritation, resulting from a purulent exudate or hemorrhage in the subarachnoid space. Nuchal rigidity or meningismus is present when the neck resists passive flexion. Kernig's sign is also a classic sign of meningeal irritation, and as originally described by Kernig, it requires the patient to be in the seated position. Kernig noted that attempts to passively extend the knee while the patient was seated were met with resistance in the presence of meningitis so that a contraction of the extremities was maintained.^{17,18} Jozef Brudzinski described at least five different meningeal signs. His best known sign, the nape of the neck sign, is elicited with the patient in the supine position and is positive when passive flexion of the neck results in spontaneous flexion of the hips and knees.^{18,19}

Seizures occur in 40% of patients with bacterial meningitis, typically during the first week of illness. The etiology of seizure activity can be attributed to either one or a combination of the following: (1) fever; (2) cerebrovascular disease consisting of focal arterial ischemia, infarction, or cortical venous thrombosis with hemorrhage; (3) hyponatremia; (4) subdural effusion or empyema producing a mass effect; and (5) antimicrobial agents (e.g., imipenem and penicillin).¹⁶ Raised ICP is an expected complication of bacterial meningitis and presents as one or a combination of the following clinical signs: (1) an altered level of consciousness; (2) the Cushing reflex—bradycardia, hypertension, and irregular respirations²⁰; (3) dilated, nonreactive pupil or pupils; (4) unilateral or bilateral cranial nerve VI palsies; (5) papilledema; (6) neck stiffness; (7) hiccups; (8) projectile vomiting; and (9) decerebrate posturing.¹⁶ Acute ischemic stroke may occur in the course of bacterial meningitis as a result of narrowing of the large arteries at the base of the brain. This may occur from encroachment by a purulent exudate in the subarachnoid space or infiltration of the arterial wall by inflammatory cells (vasculitis). Vasospasm, thrombotic or stenotic occlusion of branches of the middle cerebral artery, and septic venous sinus thrombosis with thrombophlebitis of cortical veins may also occur.⁷

The differential diagnosis of this clinical presentation includes viral meningoencephalitis, fungal meningitis, tuberculous meningitis, focal intracranial mass lesions, subarachnoid hemorrhage, Rocky Mountain spotted fever, and neuroleptic malignant syndrome.

EVALUATION. The gold standard for the diagnosis of bacterial meningitis is the examination of the CSF (Video 111, Lumbar Puncture). The classic CSF abnormalities in bacterial meningitis are (1) an increased opening pressure, (2) a polymorphonuclear leukocytic pleocytosis, (3) a decreased glucose concentration, and (4) an increased protein concentration. Raised ICP is an expected complication of bacterial meningitis and can theoretically contribute to brain herniation following lumbar puncture. When there are clinical signs of raised ICP and urgent lumbar puncture is indicated, a bolus of mannitol 1 g/kg of body weight can be given intravenously and the lumbar puncture can be performed 20 minutes later. In addition, the patient can be intubated and hyperventilated. Alternatively, lumbar puncture can be deferred and blood cultures obtained until the raised ICP can be treated. Regardless, the lumbar puncture should be performed with a 22-gauge needle.²¹ When obtaining CSF for analysis, it is important to remember that adults have approximately 150 mL of CSF, but infants and children have smaller amounts, in the range of 30 to 60 mL in the neonate and 100 mL in the adolescent.²² The volume of CSF in a child 4 to 13 years of age is in the range of 65 to 140 mL, with an average volume of 90 mL.²³ Approximately 10 to 12 mL of CSF should be withdrawn from an adult, and the withdrawal of 3 to 5 mL is recommended in the neonate and child.²² The CSF glucose concentration is low when the value is less than 40 mg/dL or when the CSF: blood glucose ratio is less than 0.6. When an ampule of 50 mL of 50% glucose (D50) has been given en route to the emergency room, 30 minutes is required for the ampule of D50 to influence the CSF glucose concentration. The CSF white blood cell (WBC) count is usually more than 100 cells/mm³ and is often more than 1000 WBCs/mm³ in bacterial meningitis. Although there is typically a predominance of polymorphonuclear leukocytes in the CSF in bacterial meningitis, a predominance of lymphocytes has been reported in cases of acute bacterial meningitis when the CSF WBC concentration was less than 1000/mm³ and in bacterial meningitis due to *L. monocytogenes*.^{24,25} The initial CSF examination in neonatal bacterial meningitis may have an absence of pleocytosis and normal glucose and protein concentrations. A Gram's stain of the CSF should be examined carefully, and a high index of suspicion for meningitis should be maintained for the neonate with fever, seizure activity, irritability, lethargy, and/or respiratory distress.^{26,27} Oral antimicrobial therapy administered before lumbar puncture will not significantly alter the CSF WBC count or glucose concentration but will decrease the likelihood of identifying the organism on Gram's stain or isolating it in culture.²¹ The latex particle agglutination test for the detection of bacterial antigens of Hib, *S. pneumoniae*, *N. meningitidis*, group B streptococcus, and *E. coli* K1 strains in the CSF has been replaced by a broad-range polymerase chain reaction (PCR) that can detect small numbers of viable and nonviable organisms in CSF. When the broad-range PCR is positive, a PCR that uses specific bacterial primers to detect the

nucleic acid of *S. pneumoniae*, *N. meningitidis*, *E. coli*, *L. monocytogenes*, *H. influenzae*, and *Streptococcus agalactiae* should be done. The PCR is also helpful in making the diagnosis of bacterial meningitis in patients who were pretreated with antibiotics and in the patient whose Gram's stain and CSF culture are negative. The Limulus amebocyte lysate test is very sensitive in detecting gram-negative bacterial meningitis. It has a 77% to 99% sensitivity for the detection of gram-negative endotoxin in the CSF.²¹ A good rule is that the Gram's stain and bacterial culture should be negative in the CSF obtained 24 hours after the initiation of intravenous antimicrobial therapy, if the organism is sensitive to that antibiotic.

MANAGEMENT. Empirical therapy of bacterial meningitis in the neonate should include the combination of ampicillin (50 mg/kg every 6 to 8 hours) and either cefotaxime (50 mg/kg every 8 to 12 hours) or an aminoglycoside, such as gentamicin (2.5 mg/kg every 8 to 12 hours) or amikacin (10 mg/kg every 8 to 12 hours).¹ Empirical therapy of bacterial meningitis in infants 4 to 12 weeks of age requires antimicrobial agents that are active against the likely pathogens of the neonatal age group as well as those that cause infection in infants and children. An appropriate regimen in this age group is ampicillin and either cefotaxime or ceftriaxone (100 mg/kg/day intravenously in divided doses every 12 hours). A third-generation cephalosporin, either cefotaxime (225 mg/kg/day intravenously in

divided doses every 6 hours) or ceftriaxone (100 mg/kg/day intravenously in divided doses every 12 hours) plus vancomycin (40 mg/kg/day intravenously in divided doses every 6 hours) is recommended for empirical therapy of bacterial meningitis in the older infant and child. Empirical therapy of bacterial meningitis in adults should include a combination of ceftriaxone (2 g intravenously twice a day) or cefotaxime (8 to 12 g/day intravenously in divided doses every 4 hours) or cefepime (2 g intravenously twice a day) plus vancomycin (500–750 mg intravenously every 6 hours). In the older adult and in the immunocompromised adult in whom *L. monocytogenes* may be the etiological organism, ampicillin (12 g/day in divided doses every 4 hours) should be added to this regimen. In patients who have recently undergone a neurosurgical procedure or who are immunocompromised, *Pseudomonas aeruginosa* may be the etiological agent, and meropenem (6 g/day in divided doses every 8 hours) should be substituted for cefotaxime or ceftriaxone. Once the causative organism has been identified, antimicrobial therapy can be modified based on the recommendations for that specific organism. Recommendations for antimicrobial therapy based on the infecting organism are listed in Table 42-1.

The American Academy of Pediatrics recommends the consideration of dexamethasone for bacterial meningitis in infants and children 2 months of age or older. The recommended dose is 0.6 mg/kg/day in four divided doses

TABLE 42-1

Antimicrobial Therapy Based on Etiological Organism

| ORGANISM | ANTIBIOTIC AND DOSE (INTRAVENOUS UNLESS INDICATED) | | |
|---|--|--|--|
| | Infants (>2000 g) | Children | Adults |
| Group B streptococcus | Ampicillin 50 mg/kg q 6 hr plus amikacin 10 mg/kg q 12 hr or gentamicin 2.5 mg/kg q 8 hr | | |
| <i>Neisseria meningitidis</i> | | Penicillin G 250,000-400,000 U/kg/day (divided q 4 hr) plus (at end of therapy) oral rifampin, older than 1 yr: 10 mg/kg q 12 hr for 2 days Younger than 1 yr: 5 mg/kg q 12 hr for 2 days | Penicillin G 20-24 million U/day (divided q 4 hr) plus (at end of therapy) oral rifampin 600 mg q 12 hr for 2 days |
| <i>Streptococcus pneumoniae</i> | | Cefotaxime 225 mg/kg/day (divided q 6 hr) or ceftriaxone 100 mg/kg/day (in a once or twice daily dosing interval) plus vancomycin 40 mg/kg/day (q 6 hr dosing interval) | Cefepime 4 g/day (2 q 12 hr) or cefotaxime 8-12 g/day divided q 4 hr or ceftriaxone 4 g/day (2 q 12 hr) plus vancomycin 2 g/day (in a 6- or 12-hr dosing interval) |
| Enteric gram-negative bacilli (except <i>Pseudomonas aeruginosa</i>) | Cefotaxime 50 mg/kg q 8 hr plus amikacin or gentamicin | Cefotaxime or ceftriaxone (as above) | Cefotaxime or ceftriaxone or cefepime (as above) |
| <i>Pseudomonas aeruginosa</i> | Meropenem 120 mg/kg/day (divided q 8 hr) | Meropenem 120 mg/kg/day (divided q 8 hr) | Meropenem 6 g/day (divided q 8 hr) |
| <i>Listeria monocytogenes</i> | Ampicillin 50 mg/kg q 6 hr plus amikacin or gentamicin for 3-5 days | Ampicillin 150-200 mg/kg/day (q 4-hr dosing interval) | Ampicillin 12 g/day (divided q 4 hr) ± gentamycin 6 mg/kg/day divided q 8 hr in critically ill patients |
| <i>Haemophilus influenzae</i> type b | Cefotaxime | Cefotaxime or ceftriaxone | Cefotaxime or ceftriaxone or cefepime |
| <i>Staphylococcus aureus</i> | | | |
| Methicillin-sensitive | Methicillin 50 mg/kg q 6 hr | Oxacillin 200-300 mg/kg/day (divided q 4 hr) | Oxacillin 12 g/day (divided q 4 hr) |
| Methicillin-resistant | Vancomycin 15 mg/kg q 8 hr | Vancomycin 40 mg/kg/day (divided q 6 hr) | Vancomycin 2 or 3 g/day (divided q 6 hr) |

(0.15 mg/kg/dose) given intravenously for the first 4 days of antimicrobial therapy.²⁸ The first dose of dexamethasone should be administered several minutes before the first dose of antimicrobial therapy. The results of a prospective, randomized, multicenter, double-blind trial of adjunctive dexamethasone therapy for bacterial meningitis in 301 adults in five European countries demonstrated that dexamethasone improves the outcome in adults with acute bacterial meningitis and reduces mortality.²⁹ Dexamethasone was administered in a dose of 10 mg 15 to 20 minutes before or with the first dose of antibiotic and given every 6 hours for 4 days. Dexamethasone is beneficial in preventing the neurological complications of bacterial meningitis by decreasing meningeal inflammation. Dexamethasone inhibits the synthesis of the inflammatory cytokines IL-1 and TNF, which are produced by brain astrocytes and microglial cells in response to bacterial cell wall components in the subarachnoid space. As discussed previously, the inflammatory cytokines increase the permeability of the blood-brain barrier and recruit polymorphonuclear leukocytes from the bloodstream to the CSF. The result is the production of a purulent exudate in the subarachnoid space. Dexamethasone appears to be reasonably safe. The third- and fourth-generation cephalosporins penetrate the CSF extremely well even in the presence of dexamethasone.^{30,31} The penetration of vancomycin, however, may be adversely affected by dexamethasone therapy because meningeal inflammation improves the penetration of vancomycin into the CSF. The clinical significance of this is unclear. Consideration should therefore be given to the use of higher doses of vancomycin (60 mg/kg/day in divided doses every 6 hours) or intrathecal vancomycin in cases of highly penicillin-resistant and cephalosporin-resistant pneumococcal meningitis when dexamethasone is used concomitantly with antimicrobial therapy. The use of a histamine-2 antagonist with dexamethasone is recommended to avoid gastrointestinal bleeding.

The majority of children with bacterial meningitis are hyponatremic with serum sodium concentrations less than 135 mEq/L at the time of admission owing to the syndrome of inappropriate antidiuretic hormone secretion (SIADH). The time-honored treatment of SIADH was fluid restriction. This practice, however, has received renewed attention because of the knowledge that autoregulation of cerebral blood flow is lost in the course of bacterial meningitis. A decrease in the mean systemic arterial pressure is therefore associated with a decrease in the cerebral blood flow. In experimental pneumococcal meningitis, fluid-restricted rabbits had a greater decrease in MAP and cerebral blood flow than did euvoletic rabbits.³² The current recommendations are to limit the initial rate of intravenous fluid administration to approximately three fourths of the normal maintenance requirements (or 1000 to 1200 mL/m²/24 hr). The intravenous fluid should be a multielectrolyte solution containing between one fourth and one half normal saline and potassium at 20 to 40 mEq/L in 5% dextrose. Once the serum sodium concentration increases above 135 mEq/L, the volume of the fluids administered can be gradually increased.^{33,34}

The development of seizure activity should be anticipated in the patient with bacterial meningitis. Seizure activity occurs in approximately 30% to 40% of children

with acute bacterial meningitis and in more than 30% of adults with pneumococcal meningitis, typically occurring in the first few days of the illness. There is an increased risk of epilepsy following bacterial meningitis, especially in those individuals who have seizures in the first few days of infection.³⁵ Raised ICP is an expected complication of bacterial meningitis and should be anticipated at the time of the initial lumbar puncture. The ICP should be measured by an ICP monitoring device. The treatment of raised ICP in bacterial meningitis includes one or more of the following: (1) elevation of the head of the bed 30 degrees; (2) hyperventilation to maintain the Paco₂ between 32 and 35 mmHg; (3) mannitol 1.0 g/kg bolus intravenous injection, then 0.25 to 0.5 g/kg intravenous every 3 to 5 hours to achieve a serum osmolarity of 295 to 320 mOsm/L; (4) dexamethasone 0.15 mg/kg every 6 hours; and (5) pentobarbital coma with a loading dose of 5 to 10 mg/kg administered intravenously at a rate of 1 mg/kg/min and a maintenance dose of 1 to 3 mg/kg/hour.^{36,37} Subdural effusions commonly develop in the course of bacterial meningitis in children when the infection in the adjacent subarachnoid space leads to an increase in the permeability of the thin-walled capillaries and veins in the inner layer of the dura. The result is leakage of albumin-rich fluid into the subdural space. This is usually a self-limited process, and as the inflammatory process subsides, fluid formation ceases and the fluid in the subdural space is reabsorbed.^{34,38,39} The indications for aspiration of a subdural fluid collection include the clinical suspicion of infected fluid (prolonged fever), a rapidly enlarging head circumference in a child without hydrocephalus, focal neurological findings, or clinical signs of increased ICP.³⁴

Brain Abscess

EPIDEMIOLOGY AND RISK FACTORS. Brain abscess is a rare disease in immunocompetent individuals. In adults, otitis media and paranasal sinusitis (frontal, ethmoidal, or sphenoidal sinuses) are the most common predisposing conditions for brain abscess formation. In children, otitis media and cyanotic congenital heart disease are the most common predisposing conditions for brain abscess formation. Individuals with the acquired immunodeficiency syndrome (AIDS) are at increased risk for focal intracranial infections caused by *Toxoplasma gondii* (see Chapter 44). Organ transplant recipients are at risk for brain abscesses caused by *Aspergillus fumigatus*. Patients receiving chronic corticosteroid therapy and those who are immunosuppressed from bone marrow transplantation are at a particular risk for central nervous system (CNS) candidiasis manifested as multiple intraparenchymal microabscesses, mainly in the territory of the middle cerebral artery. Brain abscesses may develop as a result of cranial trauma, either penetrating brain injuries or neurosurgical procedures, of which the most common is craniotomy. The reported incidence of brain abscess following clean neurosurgical procedures is 6 or 7 per 10,000 cases.⁴⁰ A brain abscess may develop as the result of hematogenous spread of infection from a remote site such as in chronic pyogenic lung diseases, wound and skin infections, osteomyelitis, intra-abdominal and pelvic infections, and endocarditis. Finally, pulmonary arteriovenous

malformation is a predisposing condition for brain abscess formation.

PATHOGENESIS AND PATHOPHYSIOLOGY. A brain abscess may develop in association with any of the following: (1) direct spread from a contiguous cranial site of infection such as otitis media, odontogenic infections, sinusitis or mastoiditis, or retrograde septic thrombophlebitis from these sites as well as facial and scalp infections; (2) following cranial trauma; (3) hematogenous spread from a remote infection site; and (4) immunosuppression from neutropenia, organ or bone marrow transplantation, lymphoma, leukemia, or AIDS. Approximately 20% of brain abscesses are said to be cryptogenic, with no predisposing factor. The results of animal experiments suggest that in order for brain abscesses to form, there must be a preexisting area of ischemia, necrosis, or hypoxia in brain tissue.⁴¹ Intact brain parenchyma is relatively resistant to infection.⁴² Once bacteria have established an infection, brain abscess formation evolves through four stages regardless of the infecting organism. These stages were described in animal models of brain abscesses and have been shown to correlate with human brain abscess evolution observed by computed tomography (CT) imaging. These stages are early cerebritis, late cerebritis, early capsule formation, and late capsule formation. The early cerebritis stage (days 1 to 3 following intracerebral inoculation with α -hemolytic streptococci in dogs) is characterized by perivascular infiltration of inflammatory cells composed of polymorphonuclear leukocytes, plasma cells, and mononuclear cells that surround a central core of coagulative necrosis. Marked cerebral edema surrounds the lesion at this stage.^{43,44} The CT scan reveals a low-density lesion with faint contrast enhancement at its edge. The late cerebritis stage (days 4 to 9) is characterized by a lesion with a necrotic center surrounded by an inflammatory infiltrate of macrophages and fibroblasts. Rapid new vessel formation occurs around the developing abscess. A thin capsule of fibroblasts and reticular fibers gradually develops, and the area is surrounded by cerebral edema. The CT scan image demonstrates a low-density lesion surrounded by a prominent ring of enhancement following contrast administration. In the stage of early capsule formation (days 10 to 13), the necrotic center decreases in size, and the inflammatory infiltrate changes in character and contains an increasing number of fibroblasts and macrophages. Mature collagen evolves from reticulin precursors, forming a capsule that is better developed on the cortical than the ventricular side of the lesion. The CT scan image shows an area of low density, and the diameter of ring-contrast enhancement has decreased in size. The stage of late capsule formation (day 14 and later) is characterized by a well-formed necrotic center surrounded by a dense collagenous capsule. On the CT scan image, the low-density lesion is surrounded by a sharply demarcated, dense ring of contrast enhancement. The preceding description of brain abscess formation may be modified slightly by different microorganisms and altered in the immunocompromised host. Depending on the etiological organism and the predisposing condition leading to infection, there may be delayed or incomplete encapsulation of the abscess cavity or the abscess may enlarge more quickly than described previously.⁴⁰

CLINICAL FEATURES AND DIFFERENTIAL DIAGNOSIS. A brain abscess presents as an expanding focal infectious mass lesion. The most common clinical presentation is headache, either hemispheric or generalized; fever; vomiting; a focal neurological deficit; or focal or generalized seizure activity. The findings on neurological examination are related both to the site of the abscess and to the degree of raised ICP. Patients with increased ICP will have alterations in consciousness ranging from lethargy to irritability, confusion, or coma. There may be papilledema and deficits of cranial nerves III or VI or both (Video 1, Cranial Nerve VI Palsy; Video 32, Cranial Nerve III Palsy). If the abscess has ruptured into the ventricular system or if there has been spread of infection to the subarachnoid space, there may be signs of meningitis. The differential diagnosis of this clinical presentation includes herpes simplex virus encephalitis, subdural empyema, cranial epidural abscess, a focal cerebral infarction with edema, a cerebral hemorrhage, a primary neurological tumor, or a metastatic tumor.

EVALUATION. The diagnosis of a brain abscess is made through neuroimaging using either a cranial CT or magnetic resonance imaging (MRI) scan that demonstrates a ring-enhancing lesion. Typically, the cranial CT scan demonstrates the abscess as a low-density lesion with a sharply demarcated, dense ring of contrast enhancement surrounded by a variable hypodense region of edema. In the early and late stages of cerebritis, there is often diffusion of contrast medium into the low-density center of the abscess on delayed scans obtained 30 minutes after the administration of intravenous contrast. As the abscess matures, its margin becomes more defined and the enhancement around the abscess becomes more homogeneous. In the early and late stages of capsule formation, there is no significant inward diffusion of contrast on delayed scans. Cranial MRI scanning is superior to cranial CT scanning in detecting a lesion in the early cerebritis stage. On this type of image, the abscess appears as an area of hypointensity on T1-weighted images and hyperintensity on T2-weighted images with indistinct margins. When the abscess becomes encapsulated, it appears as a lesion of low intensity surrounded by an area of isointensity or hyperintensity on T1-weighted images. The T2-weighted MRI images reveal a hyperintense lesion surrounded by a rim of hypointensity with surrounding area of hyperintensity that represents edema. The T1-weighted MRI images obtained after intravenous gadolinium administration demonstrate ring enhancement of the abscess capsule.⁴⁰ Patients with a brain abscess may have a peripheral leukocytosis or an elevated erythrocyte sedimentation rate; however, in a significant number of patients, the laboratory criteria for infection will be lacking. The serum C-reactive protein (CRP) concentration has been reported to be useful in distinguishing brain abscess from brain tumor. Patients with brain abscesses have an elevated CRP level, whereas those with a brain tumor will have low levels.^{40,45} Indium-111-labeled leukocyte scintigraphy may also be useful in distinguishing between a brain abscess and tumor. This scan uses radiolabeled leukocytes to detect areas of active inflammation. False-positive results may occur when there has been leukocytic infiltration into a brain tumor, especially those with severe necrosis. A lumbar puncture is contraindicated

in a patient with a brain abscess because of the risk of herniation. The etiological organism is rarely identified from CSF cultures obtained by lumbar puncture, but it can be identified by CT- or MRI-guided stereotactic aspiration of the abscess. This approach is the procedure of choice for the identification of the infectious organism. All patients should also have a chest x-ray. Additionally, a CT scan of the head with bony windows for the evaluation of the paranasal sinuses, middle ear, and mastoids should be done when a contiguous site of infection is suspected as the source of the brain abscess. Blood cultures should be obtained when hematogenous dissemination from a remote site of infection is the likely etiology.

MANAGEMENT. The management of a brain abscess is directed at decreasing the mass effect associated with the abscess, draining the pus, and using antimicrobial therapy to treat the abscess and the primary source of infection.⁴⁰ Surgical management of a brain abscess involves either complete extirpation of the abscess or aspiration of the abscess cavity through a burr hole with or without placement of a drainage catheter into the abscess cavity. The purulent material obtained at the time of aspiration allows for the identification of the infecting organism. Aspiration of the contents of an abscess cavity has a lower morbidity and a lower risk of seizures compared with complete excision. Complete excision removes the lesion from the parenchyma of the brain and allows for a rapid decompression but may cause damage to brain parenchyma. Complete excision is recommended when gas is present within the abscess cavity and for an abscess due to *Nocardia* species.

In the majority of patients with a brain abscess, stereotactic aspiration of the abscess should be performed for Gram's stain and bacterial culture, as well as fungal smear and culture. In patients with AIDS, however, the majority of focal infectious CNS lesions are caused by *T. gondii*, and in such cases, serum should be sent for antitoxoplasma IgG. The lesions of *T. gondii* are typically located at the gray-white junction in the cerebral hemispheres, in the deep white matter, and in the thalamus and basal ganglia. With contrast administration, most lesions enhance in a ringed, nodular, or homogeneous pattern and are surrounded by edema. Cranial MRI scanning is superior to CT scanning in detecting the multiple lesions of toxoplasma abscesses. Thallium single-photon emission computed tomography (SPECT) imaging may be helpful in distinguishing cerebral toxoplasmosis from primary CNS lymphoma. Focal areas of increased uptake are seen in patients with lymphoma. In patients with a detectable toxoplasma serology and more than one enhancing lesion on neuroimaging, a presumptive diagnosis of toxoplasma encephalitis can be made and a treatment trial with pyrimethamine and sulfadiazine or pyrimethamine and clindamycin can be initiated. The other group of patients who provide an exceptional diagnostic and therapeutic challenge are those not infected with human immunodeficiency virus (HIV) but who have multiple brain abscesses. In these patients, stereotactic aspiration of the largest lesion for purulent material for culture is recommended.

The etiological organism of a brain abscess can be predicted to some degree based on the location of the abscess and the predisposing condition. Streptococci, specifically *Streptococcus milleri*, are the most frequent organisms

isolated from frontal lobe abscesses associated with chronic sinusitis. Temporal lobe abscesses are most frequently secondary to chronic infections of the ear, and streptococci (anaerobic or aerobic), Enterobacteriaceae, and Bacteroides species are the most commonly isolated bacteria. A brain abscess owing to chronic otitis media frequently yields multiple organisms in culture. The majority of brain abscesses secondary to trauma or craniotomy are caused by *Staphylococcus aureus*.⁴⁰ Viridans, anaerobic, and microaerophilic streptococci are the usual organisms isolated from brain abscesses caused by cyanotic congenital heart disease. A brain abscess in an immunocompromised individual may be from *Candida* species, *Nocardia asteroides*, *Aspergillus*, Zygomycetes, Enterobacteriaceae or *P. aeruginosa*.

A combination of vancomycin (2 or 3 g/day intravenously in an adult and 40 to 60 mg/kg/day in a child), a third- or fourth-generation cephalosporin (cefotaxime, ceftriaxone, or cefepime), and metronidazole (500 mg every 6 hours intravenously for an adult and 7.5 mg/kg every 8 hours for a child) is the recommended empirical therapy for immunocompetent patients with brain abscesses. The final culture results and organism sensitivities are used to make the antibiotic coverage more specific. Aspergillosis should be considered in immunosuppressed patients with unremitting fever and multiple brain abscesses. A chest x-ray study may demonstrate pulmonary infiltrates and bronchoscopy may identify the infecting organism in some cases. Fungal brain abscesses are treated with amphotericin B; liposomal amphotericin B should be used for brain abscesses due to *Aspergillus* species. Corticosteroid therapy is recommended for the treatment of vasogenic cerebral edema that surrounds a brain abscess and to treat any mass effect. Because steroid therapy may decrease the penetration of antibiotics into brain tissue, it should be discontinued when the edema and mass effect improve or resolve. Abscesses that enlarge or do not become smaller during antimicrobial therapy may need repeat aspiration or excision.

Cranial and Spinal Subdural Empyema

EPIDEMIOLOGY AND RISK FACTORS. Subdural empyema is a pyogenic infection in the space between the dura mater and the arachnoid and represents 13% to 20% of localized intracranial infections. The arachnoid is not a very strong barrier, and subdural empyema may breach the arachnoid and cause subpial infection.⁴⁶ The most common predisposing condition that leads to the development of a subdural empyema is paranasal sinusitis, especially frontal sinusitis. Paranasal sinusitis is the primary cause of a subdural empyema in 50% to 80% of patients, and otitis media is the primary cause in 10% to 20%.^{47,48} Superficial infections of the scalp and skull, craniotomy, or septic thrombophlebitis from sinusitis, otitis, or mastoiditis may extend to the subdural space, causing empyema.⁴⁶ Subdural empyema in infants usually represents an infected subdural effusion complicating a bacterial meningitis.^{49,50} An empyema may rarely develop in the subdural area of the spinal cord.

PATHOGENESIS AND PATHOPHYSIOLOGY. The most important pathophysiological antecedent of a subdural empyema is septic thrombophlebitis of the mucosal veins of the sinuses that results in retrograde extension of infection

with drainage of bacteria into the regional dural veins, and then into the superior sagittal sinus.^{48,51} Subdural empyema may also result from the direct infection of the subdural space during a neurosurgical procedure. Once the infection is established in the subdural space, evolution of an empyema tends to be remarkably rapid because the subdural space has no barriers. The infection can spread medially over the tentorium toward the falx and posteriorly to the infratentorial area.^{46,51} Septic thrombophlebitis extends in a retrograde fashion from the dural sinuses to the cortical veins. Cortical venous infarction may follow and is largely responsible for the severe symptoms, particularly the focal signs, that develop during the course of the illness.^{51,52} Cortical venous thrombosis and infarction cause hemorrhagic and ischemic necrosis of brain parenchyma that subsequently permits brain abscess formation. A coexistent cerebral abscess has been reported in up to 24% of cases of subdural empyema.^{48,53} Spinal subdural empyema may be the result of hematogenous spread of infection from a distant site, trauma, spine surgery, or a dermal sinus tract that connects the skin and the dura.

CLINICAL FEATURES. A patient with a cranial subdural empyema appears acutely ill with headache that is often localized initially to the side of infection and has fever, chills, and nuchal rigidity. In children and adults, the triad of sinusitis, fever, and an acute neurological deficit should be treated with a high index of suspicion for a subdural empyema.⁴⁶ A progressive disturbance of consciousness occurs as the subdural empyema produces a mass effect that results in increased ICP. Focal neurological deficits are present in 80% to 90% of patients and are caused by mass effect from the subdural collection of fluid and cortical vein thrombophlebitis. Periorbital edema and erythema may be present in patients with a subdural empyema originating from the frontal sinus.^{48,52} Seizures, which are typically focal, occur in 30% to 60% of patients.⁴⁶ Infants with subdural empyemas usually have an increase in their head size, a bulging fontanel, irritability, poor feeding followed by hemiparesis, convulsions, stupor, and coma.⁴⁷ A spinal subdural empyema presents as fever with signs of rapidly progressive spinal cord compression. Backache may be present, but it is not as characteristic of the presentation of a spinal subdural empyema as it is of the presentation of spinal epidural abscess.

DIFFERENTIAL DIAGNOSIS AND EVALUATION. The differential diagnosis of the signs and symptoms of a cranial subdural empyema includes bacterial meningitis, superior sagittal sinus thrombosis, epidural abscess, and cerebral abscess.⁵¹ A lumbar puncture should not be performed in patients with the clinical signs of raised ICP or focal neurological deficits. In most series, bacteria are not demonstrated by microscopic examination or culture of CSF obtained by lumbar puncture in patients with a subdural empyema.^{51–53} Cranial MRI is the diagnostic procedure of choice to demonstrate the presence of a subdural empyema. The subdural empyema will have a mildly increased signal intensity on MRI T1-weighted images and a markedly increased signal intensity on T2-weighted images when compared with ventricular CSF.⁴⁶ A benign subdural effusion can also be differentiated from an infected subdural empyema using a cranial MRI scan. A subdural effusion is isointense compared with CSF on MRI T1- and

T2-weighted images, and a subdural empyema is hyperintense when compared with CSF on T2-weighted images.⁴⁶ On a CT scan, a subdural empyema has the appearance of a crescent or lentiform-shaped area of low density adjacent to the inner border of the skull.⁵⁴ The empyema consists of an inflammatory exudate and appears denser than CSF. MRI is the best neuroimaging procedure to demonstrate the presence of a spinal subdural empyema.

MANAGEMENT. The treatment of subdural empyema consists of intravenous antibiotic therapy, surgical drainage of the empyema and infected sinuses, and management of increased ICP when present. The majority of cranial subdural empyemas are caused by those organisms typically isolated from patients with chronic sinusitis or otitis. Aerobic streptococci are the causative organisms in 30% to 50% of patients with subdural empyema. Anaerobic organisms, particularly anaerobic and microaerophilic streptococci, are isolated from 15% to 25% of cases; staphylococci are isolated from 15% to 25% of cases; and aerobic gram-negative bacilli are isolated from 5% to 10% of cases.^{47,48} Empirical therapy must cover aerobic and anaerobic streptococci, staphylococci, and gram-negative bacilli. A combination of penicillin G (20 to 24 mIU/day for adults and 400,000 U/kg/day for children and infants) or a third- or fourth-generation cephalosporin (ceftriaxone, cefotaxime, or cefepime), metronidazole (600 mg/day for adults and 22.5 mg/kg/day for infants and children), and nafcillin (9 to 12 g/day for adults and 200 mg/kg/day for infants and children) or vancomycin is recommended (Table 42-2). Surgical drainage can be accomplished by either craniotomy or multiple burr holes.⁴⁶ Intravenous antibiotics should be continued for at least 3 weeks after surgical drainage, and then oral antibiotic therapy can be substituted to complete a 6-week course of therapy. Reoperation for further irrigation and drainage of loculated pockets of pus is typically necessary. It is therefore recommended that the patient undergo frequent CT or MRI scans to evaluate whether resolution of the infection has occurred.⁴⁶

Staphylococcus aureus is the causative organism in the majority of cases of spinal subdural empyema, and such cases should undergo a laminectomy and dural incision with drainage. Extensive irrigation of the subdural space with bacitracin and either vancomycin or gentamicin is recommended. Intravenous antimicrobial therapy for 4 to 8 weeks, and often longer, is also recommended.⁵⁵

Cranial and Spinal Epidural Abscess

EPIDEMIOLOGY AND RISK FACTORS. Cranial epidural abscesses develop in the space between the dura and inner table of the skull and are usually caused by the spread of infection from the frontal sinuses, middle ear, mastoid, or orbit.⁴⁸ Epidural abscesses may also develop as a complication of a craniotomy or compound skull fracture. The most common cause of a cranial epidural abscess is craniotomy that has been complicated by an infection of the wound, bone flap, or epidural space.⁴⁶ Epidural abscesses may result from or be associated with an area of osteomyelitis.

A spinal epidural abscess develops in the space outside the dura mater but within the spinal canal. The spinal epidural space is only a true space posterior to the spinal cord

TABLE 42-2

Antimicrobial Therapy for Subdural Empyema

| ORGANISM | ADULT | DOSING INTERVAL | CHILD | DOSING INTERVAL |
|------------------------------|---------------------------|-----------------|---------------------------------------|-----------------|
| <i>Staphylococcus aureus</i> | | | | |
| Methicillin-sensitive | Nafcillin 9-12 g/day | Every 4 hr | Nafcillin 200 mg/kg/day | Every 4 hr |
| Methicillin-resistant | Vancomycin 2-3 g/day | Every 12 hr | Vancomycin 40-60 mg/kg/day | Every 12 hr |
| Streptococci | Penicillin G 20-24 MU/day | Every 4 hr | Penicillin G 250,000-400,000 U/kg/day | Every 4-6 hr |
| Gram-negative bacilli | Ceftriaxone 4-6 g/day | Every 12 hr | Ceftriaxone 80-100 mg/kg/day | Every 12 hr |
| | <i>or</i> | | <i>or</i> | |
| | Cefotaxime 8-12 g/day | Every 4 hr | Cefotaxime 200 mg/kg/day | Every 6 hr |
| | <i>or</i> | | <i>or</i> | |
| | Cefepime 4 g/day | Every 12 hr | Ceftazidime 125-150 mg/kg/day | Every 8 hr |
| Anaerobes | Metronidazole 600 mg/day | Every 8 hr | Metronidazole 22.5 mg/kg/day | Every 8 hr |
| | <i>or</i> | | <i>or</i> | |
| | Chloramphenicol 4 g/day | Every 6 hr | Chloramphenicol 100 mg/kg/day | Every 6 hr |

and the spinal nerve roots. The anteroposterior width of the epidural space is greatest in the area where the spinal cord is smallest (i.e., from approximately T4-T8 and from L3-S2).^{56,57} The most common location for an epidural abscess is the posterior midthoracic region between the fourth and eighth thoracic vertebrae.⁵⁸ The anterior epidural space is only a potential space because the dura is virtually adherent to the posterior surface of the vertebral bodies along the ventral aspect of the spinal canal from the first cervical to the second sacral vertebrae. Anterior abscesses usually occur at cervical levels.⁵⁹ The most common etiology of a spinal epidural abscess is hematogenous spread of bacteria from a remote site of infection to the epidural space. This includes such sites as the skin, urinary tract, lungs, pelvis, cardiac valves, and pharynx. An epidural abscess may also develop by direct extension from a contiguous infection such as vertebral osteomyelitis. The latter disorder is a particularly common etiology for spinal epidural abscess formation in intravenous drug abusers. Immunosuppression from any cause, but most commonly from AIDS or diabetes mellitus, is a predisposing condition in approximately 50% of cases of spinal epidural abscesses.⁵⁵ The formation of a small hematoma owing to mild blunt trauma may also provide a *locus minoris resistentiae* that may allow for hematogenous seeding of infection resulting in the formation of a spinal epidural abscess.

PATHOGENESIS AND PATHOPHYSIOLOGY. Infection in the frontal sinuses, middle ear, mastoid, or orbit is able to reach the epidural space through the retrograde spread of thrombophlebitis in the emissary veins that drain these areas, by way of direct spread of the infection through bone (osteomyelitis), or through direct infection of the epidural space during craniotomy.⁶⁰ As stated previously, hematogenous spread to the epidural space from a remote site of infection is an extremely rare cause of cranial epidural abscess but an extremely common cause of spinal epidural abscess.

A spinal epidural abscess may develop as a result of the hematogenous spread of infection from a distant focus of infection to the epidural space. There may also be hematogenous spread of infection to a vertebral body or disc that results in discitis and/or osteomyelitis that subsequently extends into the spinal epidural space. Infection of the

epidural space may also occur from direct extension of infection from decubitus ulcers, infected abdominal wounds, or psoas abscesses.⁵⁵ The pathophysiology of spinal cord dysfunction from spinal epidural abscess has been investigated in a rabbit model.^{61,62} The gross appearance of the spinal cord at the level of the epidural abscess is usually normal. Microscopically, scattered areas of softening, vacuolization of the cord, areas of necrosis with the disappearance of cells, loss of myelin, and axonal swelling are frequently seen. Myelomalacia occurring in the spinal cord beneath an epidural abscess results from the direct compression of neural tissue and inflammatory thrombosis in the intraspinal vessels with subsequent infarction.

CLINICAL FEATURES. The clinical presentation of an intracranial epidural abscess is an unrelenting hemicranial headache or persistent fever that develops during or after treatment for frontal sinusitis, mastoiditis, or otitis media. Focal neurological deficits, seizures, and signs of increased ICP do not develop until the infection extends into the subdural space.⁵¹ Approximately 10% of epidural abscesses are associated with a subdural empyema.⁴⁶ An epidural abscess that develops near the petrous bone and involves cranial nerves V and VI presents with ipsilateral facial pain and lateral rectus weakness (Gradenigo's syndrome) (Video 106, Trigeminal Neuralgia). A spinal epidural abscess presents as fever and pain at the affected spinal level. Heuser⁶³ described a characteristic clinical pattern of symptom progression. Back pain is the initial symptom, which is followed by radicular pain in the extremities or pain in an intercostal thoracic dermatomal pattern within 2 or 3 days. As the disease progresses, paresis of appendicular muscles is associated with loss of sensation below the level of the lesion and the loss of bowel and bladder control. Finally, there is complete paralysis of appendicular muscles and a loss of all sensory modalities below the level of the lesion.

EVALUATION. The MRI is the diagnostic procedure of choice to demonstrate a cranial epidural abscess because it is free from bony artifacts adjacent to the inner table of the skull and is easily able to demonstrate extracerebral fluid collections. The epidural fluid will be of higher signal intensity on both MRI T1- and T2-weighted images than the ventricular CSF. Following the administration of

gadolinium, a significant enhancement of the dura on MRI T1-weighted images is seen.⁴⁶ On the noncontrasted CT scan, an epidural abscess has the appearance of a poorly defined lentiform area of low density adjacent to the inner table of the skull. After the administration of contrast, the convex inner side of the low-density lesion enhances. This represents the inflamed dural membrane.⁵¹

MRI is also the procedure of choice to demonstrate a spinal epidural abscess. A spinal epidural abscess extends 3 spinal segments on average and may extend for as long as 13 segments.⁵⁵ MRI is able to visualize the entire extent of the epidural abscess in all directions and the degree of spinal cord compression. An epidural abscess is isointense to CSF on MRI T1-weighted images and hyperintense compared with CSF on MRI T2-weighted images. Following the administration of gadolinium, enhancement of the lesion occurs. Because spinal epidural abscess is usually a result of the hematogenous seeding of the epidural space, there may be evidence of systemic illness with a peripheral leukocytosis or an elevation in the erythrocyte sedimentation rate. The examination of the CSF may be useful to determine the infecting organism. A lumbar puncture should not be performed when the possibility of a lumbar abscess exists, however, because of the risk for spread of the infection from the epidural space to the subarachnoid space.

MANAGEMENT. The primary treatment of a cranial epidural abscess is surgical debridement, Gram's stain and culture of the purulent material, and intravenous antibiotic therapy. Recommendations for the choice of empirical antibiotic therapy are the same as those described for empirical therapy of subdural empyema and should cover aerobic and anaerobic streptococci, staphylococci, gram-negative bacilli, and anaerobes.

An acute spinal epidural abscess must be managed with an immediate laminectomy and decompression and drainage of the epidural space, followed by 4 to 6 weeks of intravenous antibiotic therapy and then 2 or 3 months of oral antibiotic therapy.⁵⁵ Empirical antibiotic therapy should include coverage for *Staphylococcus aureus* because this organism is the etiological agent in the majority of spinal epidural abscesses. However, there is an increasing incidence of spinal epidural abscess due to gram-negative aerobic bacilli, aerobic streptococci, anaerobes, and *Mycobacterium tuberculosis*. Empirical therapy should also include antituberculous chemotherapy, including isoniazid, rifampin, ethambutol, pyrazinamide, and streptomycin, rifabutin, or clofazime. A tuberculous spinal epidural abscess is usually associated with vertebral osteomyelitis.

Cat-scratch Disease

Cat-scratch disease is caused by the bacterium *Bartonella henselae* and begins with a cutaneous papule or pustule at the site of inoculation, usually a kitten scratch or bite, within 1 week of the injury. A regional adenopathy involving the head, neck, and upper extremity follows in 1 to 7 weeks. Fever and malaise occur in approximately one-third of patients. The diagnosis is made by demonstrating pleomorphic bacilli by Warthin-Starry silver stain of a lymph node biopsy or by PCR amplification techniques on lymph node tissue. The neurological and ophthalmological manifestations associated with cat-scratch disease include

(1) encephalopathy (in 2% to 4% of patients with cat-scratch disease), characterized by headache, restlessness, irritability, focal or generalized seizure activity, confusion, disorientation, and coma; (2) possible focal neurological deficits, including disturbances of language, cranial nerve palsies, hemiplegia, and ataxia; and (3) neuroretinitis, characterized by a painless, unilateral, sudden loss of visual acuity. On examination, papilledema is associated with macular exudates in a star formation. *Bartonella henselae* infection has been associated with HIV dementia and HIV-associated focal brain lesions, aseptic meningitis, and neuropsychiatric disease. The serological test for anti-*Bartonella* antibodies cannot discriminate between anti-*Bartonella henselae* and anti-*Bartonella quintana* (the etiological agent of trench fever) antibodies. Examination of the CSF in cases of cat-scratch disease encephalopathy demonstrates an elevated protein concentration, a lymphocytic and rarely a leukocytic pleocytosis, and a normal glucose concentration. CSF cultures for *B. henselae* are negative. In patients with lymphadenopathy, biopsy of a lymph node may reveal the typical features of cat-scratch disease. Skin tests with the Hanger-Rose cat-scratch disease antigen are positive in the majority of patients. In a few patients with neuroretinitis associated with cat-scratch disease, *B. henselae* has been isolated from blood. Gram's stain reveals small, gram-negative, slightly curved rods. The physician should question the patient about the history of a scratch by a kitten or a cat and the appearance of any skin lesion. No clear guidelines exist regarding which patients should be treated and what antibiotic should be used. The majority of patients with cat-scratch disease without an associated neurological manifestation have a self-limited illness. The demonstration of *B. henselae* bacteremia associated with neuroretinitis has led to the recommendation that antimicrobial therapy with erythromycin, doxycycline, azithromycin, clarithromycin, or ofloxacin be considered in these patients. As stated previously, an increasing amount of evidence exists for *B. henselae* as an etiological agent in a small proportion of cases of HIV-associated dementia, neuropsychiatric illness, focal brain lesions, and aseptic meningitis. Antimicrobial therapy may benefit these patients, but firm recommendations cannot be made at this time.⁶⁴

Whipple's Disease

Whipple's disease is caused by the rod-shaped bacillus *Tropheryma whippelii* and presents with arthralgias, abdominal pain, fever, diarrhea, malabsorption, and weight loss.^{65,66} Whipple's disease occurs predominantly in middle-aged men and most often in farmers. Approximately 6% or 7% of patients with Whipple's disease have neurological manifestations, but many cases of CNS involvement in Whipple's disease go unrecognized.⁶⁶ The characteristic triad of Whipple's disease is dementia, ophthalmoplegia, and myoclonus (Video 57, Myoclonus).⁶⁶ Nearly all cases of ophthalmoplegia involve a conjugate vertical gaze palsy. A peculiar mixture of smooth convergent-divergent pendular oscillations of the eyes with synchronous rhythmic contractions of the jaw, oculomasticatory myorhythmia, is thought to be unique to Whipple's disease. The diagnosis of CNS Whipple's disease

is difficult. Examination of the CSF may be normal or may demonstrate a mild pleocytosis. Para-aminosalicylic acid-positive cells are rarely identified in CSF, but if they are, CNS Whipple's disease is a strong possibility. Para-aminosalicylic acid staining of a CSF cytocentrifuged pellet should therefore be performed in all patients in whom CNS Whipple's disease is suspected.⁶⁶ The para-aminosalicylic acid reagents will also stain *Mycobacterium avium* complex, *Histoplasma capsulatum*, and nonmicrobial glycoprotein. The PCR technique has allowed for the identification of *T. whippelii* from small intestinal biopsy tissue, lymph node tissue, and CSF.⁶⁷ Brain biopsy is not routinely recommended for CNS Whipple's disease. *Tropheryma whippelii* infection of the duodenal mucosa can be detected by PCR in patients in whom an isolated extraintestinal disease exists and in patients with isolated CNS disease. It has been suggested, therefore, that a patient with suspected CNS Whipple's disease should undergo a duodenal tissue biopsy by endoscopy, and the material obtained should be examined by PCR for *T. whippelii*. PCR-based Whipple's disease diagnostic tests, however, are not yet standardized.⁶⁶ Trimethoprim-sulfamethoxazole appears to be the most effective therapy for the treatment and prevention of CNS Whipple's disease. Treatment should be initiated with trimethoprim-sulfamethoxazole 160 mg/800 mg by mouth two or three times daily, procaine penicillin G 1.2 million units by intramuscular injection daily, and streptomycin 1 g by intramuscular injection daily. Penicillin and streptomycin are continued for a total of 14 days. Trimethoprim-sulfamethoxazole should be continued for at least 1 year. Some clinicians continue antibiotic therapy for CNS Whipple's disease for at least 2 years, and some continue it indefinitely.⁶⁶

MYCOBACTERIAL INFECTIONS

Mycobacterium tuberculosis

EPIDEMIOLOGY AND RISK FACTORS. Chopin, Keats, Thoreau, Paginini, Modigliani, Elizabeth Browning, and Thomas Wolfe died of tuberculosis.⁶⁸⁻⁷⁰ In the beginning of the 20th century, tuberculous meningitis was common; then, after World War II, a dramatic decrease in the incidence of tuberculosis occurred in the United States and Europe, although tuberculosis and CNS tuberculosis continued to be prevalent in developing countries. Beginning in 1985, however, the incidence rates of tuberculosis began to increase in the United States. This resurgence of disease was concentrated among males, 25 to 44 years of age, and particularly among immigrants from areas with a high prevalence of tuberculosis infection. A marked increase in the incidence of tuberculosis in long-term residents of U.S. nursing homes was also noted. CNS tuberculosis is considerably more frequent in individuals with AIDS and tuberculosis involving other organ systems than in immunocompetent people with tuberculosis. In some areas of the world, the most common AIDS-associated CNS infection is tuberculous meningitis.⁷¹

PATHOGENESIS AND PATHOPHYSIOLOGY. Tuberculous meningitis does not develop acutely from the hematogenous spread of tubercle bacilli to the meninges from a

pulmonary source of acute infection. Isolated miliary tubercles form in the parenchyma of the brain or the meninges during the hematogenous dissemination of tubercle bacilli during the course of the primary infection or episodically from the endogenous reactivation of latent tuberculosis elsewhere in the body. The tubercles tend to enlarge and are usually caseating.⁷² The fate of these tubercles and the subsequent course of infection are at least, in part, a function of the immunological capacity of the host. Minute caseous foci may be completely eliminated by macrophages, leaving no residua of infection. Larger caseous foci may shelter viable mycobacteria that cause reactivated disease only in the presence of impaired host immunity.⁷¹ The propensity for a caseous lesion to produce meningitis is determined by its proximity to the subarachnoid space, the rate at which fibrous encapsulation develops, and the rate at which the lesions enlarge. Organisms proliferate in the caseous centers, eventually leading to the rupture of the tubercle. Subependymal caseous foci may remain quiescent for months or years but then cause meningitis through the discharge of bacilli and tuberculous antigens into the subarachnoid space.^{72,73} The neurological complications of tuberculous meningitis are initiated by a hypersensitivity reaction that occurs in the subarachnoid space when tubercloproteins are released by the rupture of a caseous lesion. The exudate is located predominantly in the basilar cisterns and surrounds the cranial nerves and major blood vessels at the base of the brain. As the basilar cisterns are filled with a purulent exudate, the flow of CSF is blocked and an obstructive hydrocephalus may develop. The inflammatory exudate also obstructs the resorption of CSF by the arachnoid granulations, the result of which is a communicating hydrocephalus. Cerebral ischemia and infarction occur either as the result of vasculitis caused by direct invasion of the arterial walls by mycobacteria and inflammatory cells or by the compression of the blood vessels at the base of the brain from the inflammatory exudate.^{72,74} Cranial nerve abnormalities resulting from tuberculous meningitis are either due to either mechanical compression of the nerve by the purulent exudate or vasculitic infarction of the nerve.⁶⁸ Border zone encephalitis describes an inflammatory reaction in the brain tissue underlying areas of thick, adherent exudate.⁶⁸⁻⁷¹ Tuberculous encephalopathy refers to the development of cerebral edema, occasionally with perivascular demyelination or hemorrhagic leukoencephalopathy deep in the white matter of the brain at a distance from vascular abnormalities and purulent exudate. It is hypothesized that this is a purely allergic phenomenon mediated by tissue hypersensitivity, either to the bacilli or their antigens or possibly to a myelin-related antigen of brain tissue.⁷¹

CLINICAL FEATURES. The clinical presentation of tuberculous meningitis is either an acute meningoencephalitis characterized by coma, raised ICP, seizures, and focal neurological deficits or a slowly progressive illness with persistent and intractable headache followed by confusion, lethargy, and cranial nerve deficits. Fever may or may not be present in the course of this infection. Cranial nerve VI (Video 1, Cranial Nerve VI Palsy) is the most frequently affected by tuberculous meningitis, followed by cranial nerves III, IV, VII, and, less commonly, cranial nerves II, VIII, X, XI, and XII (Video 23, Cranial Nerve VII, Facial

Diplegia; Video 32, Cranial Nerve III Palsy; Video 45, Tongue Atrophy; Video 230, Exotropia).⁷¹ Hemiparesis may develop as a result of ischemic infarction in the medial striate and thalamoperforating arteries. The most commonly reported symptoms in children include nausea, vomiting, and behavioral changes. Seizures are an infrequent presenting sign, although more than 50% of patients develop seizures during the initial hospitalization.⁷¹ In patients with an acute meningoencephalitis syndrome, coma may evolve rapidly because of increased ICP from both cerebral edema and communicating and obstructive hydrocephalus. The clinical syndrome of tuberculous encephalopathy is characterized by convulsions, stupor, coma, involuntary movements, paralysis, and decerebrate spasms or rigidity with or without clinical signs of meningitis or CSF abnormalities of tuberculous meningitis.⁷⁵ The clinical presentation of tuberculous meningitis in HIV-infected individuals is similar to the clinical presentation in immunocompetent patients; however, HIV-infected patients are more likely to have an acellular spinal fluid at presentation and have a higher incidence of intracerebral mass lesions.⁷¹

EVALUATION. The combination of an unrelenting headache (with or without low-grade fever) with malaise and anorexia and a CSF lymphocytic pleocytosis with a mild decrease in the glucose concentration is suggestive of tuberculous meningitis. The initiation of therapy should not await bacteriological proof of tubercle bacilli by smear or culture. The development of hydrocephalus and the clinical scenario just described are additional strong evidence for tuberculous meningitis. The absence of radiographical evidence of pulmonary tuberculosis and/or a negative tuberculin skin test does not exclude the possibility of tuberculous meningitis. The classic “Ghon complex” refers to Anton Ghon’s observation from autopsy specimens that the primary lesion of tuberculosis is in the lung, with secondary infection in the tracheobronchial lymph nodes.⁷⁶ In addition to the primary complex, chest radiographic abnormalities suggestive of pulmonary tuberculosis are hilar adenopathy, a miliary pattern, upper lobe infiltrate, cavitations, and lobar consolidation. CNS disease may develop from caseous foci in organs other than the lung, with subsequent hematogenous dissemination of virulent tubercle bacilli to the CNS. The adrenal gland, bone, genitourinary tract, and the mediastinal and abdominal lymph nodes are all potential sources of caseous foci, which may serve as “seed beds” for the later development of hematogenous dissemination of tubercle bacilli.⁷⁷ The intradermal tuberculin skin test is negative in 50% to 70% of patients with tuberculous meningitis and often becomes positive during the course of therapy.^{73,78} The classic CSF abnormalities in tuberculous meningitis are as follows: (1) an elevated opening lumbar pressure, (2) increased WBC count between 10 and 500 cells/mm³ with a predominance of lymphocytes, (3) an elevated protein concentration in the range of 100 to 500 mg/dL, (4) a decreased glucose concentration (the median glucose concentration is approximately 40 mg/dL), and (5) a positive culture in 75% of patients requiring 3 to 6 weeks for growth. A cobweb-like “skin” may form at the top of the CSF specimen and is the classic pellicle of tuberculous meningitis. Tubercle bacilli may become entangled in the skin of the pellicle and are more easily located by smear or culture of the pellicle than

elsewhere in the CSF.⁷¹ The last tube of CSF collected should be sent for acid-fast bacilli smear. Positive smears are typically reported in only 10% to 40% of patients with tuberculous meningitis. The CSF chloride concentration and the bromide partition test have been disappointing in their ability to differentiate tuberculous meningitis from other etiologies of lymphocytic meningitis. The CSF chloride concentration typically decreases as the CSF protein concentration increases; therefore, this is a rather nonspecific test. The bromide partition test measures the ratio of serum to CSF bromide 24 hours after the oral administration of sodium bromide or the intravenous injection of radioactive bromide.⁷⁹ A low bromide partition ratio is seen in any infectious or inflammatory CNS disease that increases the permeability of the blood-CSF barrier. The concentration of tuberculostearic acid in CSF has been reported to be a sensitive marker for CNS tuberculosis and enjoyed a brief period of popularity, even though it was extremely difficult to find a laboratory that was able to run this assay. The PCR technique and other molecular diagnostic techniques for the detection of *M. tuberculosis* DNA in the CSF hold the greatest promise.⁶⁷ The sensitivity of the PCR technique for the detection of *M. tuberculosis* DNA in CSF is approximately 54%; however, false-positive results occur with rates of 3% to 20%.⁷¹

MANAGEMENT. The American Academy of Pediatrics recommends a combination of isoniazid (INH), rifampin, pyrazinamide, and streptomycin as the initial therapy of tuberculous meningitis in children.⁸⁰ The doses are listed in Table 42-3. When antimicrobial sensitivities are known, the treatment regimen may be altered. Standard therapy uses four drugs for 2 months followed by INH and rifampin alone for 6 to 9 months. Most drug regimens include INH, rifampin, and pyrazinamide and either ethambutol or streptomycin (in children too young to be monitored for visual acuity).⁸¹ When the results of drug susceptibility studies are available, and if the organism is sensitive to INH and rifampin, ethambutol and pyrazinamide are continued for only 2 months, and then INH and rifampin

TABLE 42-3

Empirical Therapy for Tuberculous Meningitis

| DRUG | DOSAGE | |
|-----------------|-------------------------|-------------------|
| | Children | Adults |
| Isoniazid (INH) | 10 mg/kg/day once daily | 300 mg/day |
| Pyridoxine | | 50 mg/day |
| Rifampin | 10 mg/kg/day | 600 mg/day |
| Pyrazinamide | 30 mg/kg/day | 30 mg/kg/day |
| Ethambutol* | 15-25 mg/kg/day | 15-25 mg/kg/day |
| Streptomycin† | 20-40 mg/kg/day | |
| Corticosteroids | | |
| Dexamethasone‡ | 0.15 mg/kg q 6 hr | 0.15 mg/kg q 6 hr |
| Prednisone§ | 1 mg/kg/day | 1 mg/kg/day |

*When antimicrobial resistance is suspected.

†The American Academy of Pediatrics recommends a combination of INH, rifampin, pyrazinamide, and streptomycin for tuberculous meningitis in children.

‡For altered consciousness, papilledema, focal neurological signs, impending herniation, spinal block, and hydrocephalus.

§For intractable headache, and papilledema with otherwise normal neurological examination.

TABLE 42-4

Antituberculous Chemotherapy in HIV-infected Individuals

| DRUG | DOSAGE |
|--------------|-----------------|
| Isoniazid | 10-15 mg/kg/day |
| Rifampin | 10-15 mg/kg/day |
| Pyridoxine | 50 mg/day |
| plus | |
| Ethambutol | 25 mg/kg/day |
| or | |
| Pyrazinamide | 20-30 mg/kg/day |
| plus | |
| Streptomycin | 20-40 mg/kg/day |
| or | |
| Rifabutin | 300 mg/day |
| or | |
| Clofazimine | 300 mg/day |

are continued for a total of 9 to 12 months. Empirical therapy for tuberculous meningitis in HIV-infected individuals should include a combination of INH, pyridoxine, and rifampin plus ethambutol or pyrazinamide and either streptomycin or rifabutin or clofazimine (Table 42-4). Corticosteroid therapy decreases meningeal inflammation. Isoniazid and pyrazinamide penetrate the CSF with or without meningeal inflammation, but the penetration of rifampin, streptomycin, and ethambutol is considerably better in the presence of meningeal inflammation. Dexamethasone therapy is recommended for patients with altered consciousness, papilledema, focal neurological signs, impending herniation, spinal block, and hydrocephalus. In addition, as patients are treated for tuberculous meningitis, the slow resolution of the inflammatory exudate in the basilar cisterns may obstruct the flow and resorption of CSF, with the subsequent development of hydrocephalus. These patients may benefit from a short course of oral prednisone. A basic principle of management for patients with organisms that are resistant to one or more drugs is the administration of at least two agents to which a demonstrated susceptibility exists. For example, for patients with isolated INH resistance, INH should be discontinued and pyrazinamide and rifampin continued for the entire course of therapy.⁸¹

***Mycobacterium avium* Complex**

CNS disease from *M. avium* is a result of the hematogenous dissemination of this organism from a respiratory or gastrointestinal source of infection. *Mycobacterium avium* and *M. intracellulare* are separate species but are grouped together because of their slow growth and referred to as the *M. avium* complex. Infection with these species of mycobacteria occurs primarily in immunosuppressed individuals and patients with advanced HIV disease, generally in patients with fewer than 50 CD4⁺ cells/mm³. Infection of the CNS can present as meningitis, meningoencephalitis, rhombencephalitis, brain abscess, or cranial neuropathies. Neuroimaging may demonstrate meningeal enhancement, hydrocephalus, or single or multiple enhancing lesions. Diagnosis is made by acid-fast smear and culture of the CSF or brain abscess aspirate. There have been few randomized,

comparative controlled treatment trials for *M. avium* and *M. intracellulare* CNS infections. Clarithromycin and azithromycin have excellent activity in the therapy of disseminated *M. avium* disease in HIV-infected individuals, but their therapy in *M. avium* CNS infections has not been studied. Rifabutin is efficacious for the prophylaxis of disseminated *M. avium* infection in HIV patients and has been shown to increase survival in HIV-infected individuals with disseminated disease when used at higher doses (450 to 600 mg). The treatment of a CNS complication of disseminated disease should include at least a four-drug regimen, which currently is clarithromycin (500 mg twice daily), rifampin (600 mg daily), ethambutol (25 mg/kg/day for 2 months and then 15 mg/kg/day), and streptomycin (0.75 to 1.0 g at least three times per week). A combination of azithromycin (250 mg/day), rifabutin (300 mg daily), and ethambutol and streptomycin has been recommended as an alternative treatment regimen. Treatment is continued until cultures are negative for at least 12 months and will likely need to be continued for the life of the patient.⁸²

SPIROCHETE INFECTIONS**Neurosyphilis**

The origin of the name *syphilis* is from a poem titled “Syphilis sive morbus Gallicus” by an Italian physician, Girolamo Fracastoro. The poem is about a shepherd boy named Syphilus who lives in the time of King Alcithous of Haiti. When Syphilus loses his sheep because of a drought, he blames the Sun God and convinces the natives of Haiti to offer sacrifices to King Alcithous rather than to the Sun God. The angered Sun God revenges himself by sending a plague to the island natives. The shepherd boy Syphilus is, of course, the very first victim.⁸³ One of the Pinzon brothers who sailed with Christopher Columbus as captains of the Niña and the Pinta is historically blamed for bringing syphilis to Spain. The first documented case of syphilis in the colonized New World occurred in Connecticut in 1646.⁸³ The term *neurosyphilis* describes any of six neurosyphilitic syndromes: asymptomatic neurosyphilis, acute symptomatic syphilitic meningitis, meningovascularitis, parenchymatous neurosyphilis (dementia paralytica or tabes dorsalis), CNS gummata, and congenital neurosyphilis.⁸⁴

EPIDEMIOLOGY AND RISK FACTORS. In the preantibiotic era, tabes dorsalis was the most common form of neurosyphilis. During the past decade, an increasing number of patients with asymptomatic or symptomatic syphilitic meningitis, meningovascularitis, and syphilitic eye disease have been reported. The increasing number of cases of early neurosyphilis is occurring in individuals infected with HIV.⁸⁵⁻⁸⁸

PATHOGENESIS AND PATHOPHYSIOLOGY. Primary syphilis is defined by the appearance of a painless chancre at the site of inoculation. If untreated, the chancre will heal within 3 to 6 weeks, after which most patients progress to the secondary stage of disease in which systemic spirochetemia becomes manifest by skin rash and flulike symptoms with lethargy, fever, headache, and sore throat. The skin rash is typically nonpruritic and widespread but is most

marked on the palms and soles. There may be generalized lymphadenopathy. Untreated, secondary syphilis also resolves over a period of weeks to months. A period of latency during which there are no clinical manifestations of syphilis occurs, but there is historical and serological evidence of syphilis. Approximately one third of patients with untreated latent syphilis develop tertiary manifestations of the disease after a variable period ranging from months to years. Tertiary syphilis may present as cardiovascular syphilis, gummatous syphilis, or neurosyphilis.^{89,90} Invasion of the CNS by *T. pallidum* occurs early in the course of infection. Clinical neurosyphilis may present at any point in the natural history of infection beyond the primary stage.⁹⁰ During the early stages of *T. pallidum* CNS infection, pathological changes are limited to perivascular infiltration of the meninges with lymphocytes and plasma cells. Focal meningeal inflammation may lead to the formation of hypertrophic meninges or gummata. Inflammatory cells invade blood vessel walls causing arteritis and eventually luminal occlusion by thrombosis, ischemia, and infarction.^{90,91} Parenchymal involvement occurs in late neurosyphilis and is characterized by neuronal degeneration and loss and gliosis. The brain becomes atrophic, and the meninges are thickened and cloudy.⁹¹ In tabes dorsalis, the preganglionic portion of the dorsal roots is infiltrated with lymphocytes and plasma cells, and the posterior columns of the spinal cord become atrophic.⁹¹

CLINICAL FEATURES AND EVALUATION. Asymptomatic neurosyphilis is defined by an abnormal CSF evaluation, including a mild lymphocytic or mononuclear pleocytosis, an elevated protein concentration, and a reactive CSF Venereal Disease Research Laboratory (VDRL) test in a patient without neurological signs or symptoms.^{85,91}

Acute symptomatic syphilitic meningitis was first described by H. Houston Merritt in 1935.⁹² The most common symptoms of syphilitic meningitis are headache, nausea and vomiting, and stiff neck. In Merritt's review, papilledema was frequently present resulting from acute hydrocephalus associated with meningeal inflammation with increased ICP. Papilledema is not a common finding today. Abnormalities of cranial nerves II, VI, VII, and VIII are common. The meningeal symptoms typically develop within 1 or 2 years of the initial infection.⁸⁵ Examination of the CSF in cases of syphilitic meningitis reveals an increased opening pressure, a lymphocytic pleocytosis, a normal or slightly decreased glucose concentration, an elevated protein concentration, and a positive VDRL test. A nonreactive CSF-VDRL test does not rule out neurosyphilis. A reactive CSF-VDRL test virtually confirms the diagnosis of neurosyphilis except when the CSF is blood tinged. Blood in the CSF may give a false-positive CSF-VDRL test.^{84,85,88,92}

Meningovascular syphilis is defined by the appearance of focal neurological signs from an inflammatory, obliterative endarteritis involving small and medium-sized arteries associated with signs of meningeal inflammation. The middle cerebral artery is commonly involved, and its involvement is clinically manifest by the so-called luetic hemiplegia. Examination of the CSF may reveal an isolated elevation of protein concentration or a mild pleocytosis and a reactive VDRL. Cerebral angiography may demonstrate a nonspecific pattern of diffuse narrowing of intracerebral arteries and arterioles. Neuroimaging may demonstrate

multiple areas of infarction. The peak incidence for the development of meningovascular syphilis is 5 to 7 years after the primary infection.⁸⁹ Syphilitic arteritis can also develop in any intraspinal artery, resulting in acute transverse myelitis with paraplegia, sensory level, and loss of sphincter control.⁹¹

Dementia paralytica is manifest as a slow deterioration in cognitive functioning with impaired memory, loss of insight and judgment, language abnormalities, loss of appendicular strength, tremor of the tongue and hands, pupillary abnormalities, and loss of bowel and bladder control. The syndrome of dementia paralytica typically occurs 10 to 20 years after primary infection. Examination of the CSF at this stage demonstrates one or a combination of the following: (1) a positive VDRL test, (2) lymphocytic pleocytosis, or (3) an elevated protein concentration.⁸⁵

Tabes dorsalis is characterized by paresthesias or dysesthesias in a radicular distribution.⁹¹ As the disease progresses, proprioceptive and vibratory sense is lost due to neuronal degeneration and infiltration of inflammatory cells into the dorsal columns and posterior spinal nerve roots of the spinal cord. Loss of the pupillary reaction to light with preservation of pupillary constriction to accommodation—the Argyll-Robertson pupillary abnormality—may be present. The patient has a broad-based, foot-slapping gait. The peak incidence for tabes dorsalis is 15 to 20 years after the primary infection.⁸⁹ It has been suggested that the lancinating pains typically attributed to tabes dorsalis in the past were due to the heavy metal therapy used to treat neurosyphilis in the preantibiotic era and not the primary infection.⁹¹

Gummatous neurosyphilis is characterized by gummata located in the basal cisterns, leptomeninges, or within the parenchyma. They produce focal neurological deficits and cranial nerve palsies by exerting pressure on adjacent structures.⁹¹

DIAGNOSIS. The serological tests for syphilis can be grouped into two categories: treponemal tests, which detect specific antibodies against *T. pallidum* and include the fluorescent treponemal antibody absorption test (FTA-ABS) and the microhemagglutination-*Treponema pallidum* test (MHA-TP), and nontreponemal tests, which detect antibodies to lipids found on the membranes of *T. pallidum* using cardiolipin-lecithin-cholesterol antigens. The nontreponemal tests in routine use today include the VDRL and the rapid plasma reagin test. The FTA-ABS test is the first serological test to become positive after inoculation. The FTA-ABS and the MHA-TP tests are nonquantitative; they are either positive or negative. The VDRL test may be quantitated by serial dilutions of serum, and the titer is reported as the greatest serum dilution that produces a positive result. The VDRL titer reaches low levels in late syphilis and may eventually become nonreactive.⁸⁵ The causes of biological false-positive VDRL and FTA-ABS tests are listed in Table 42-5. Most false-positive VDRL tests have a low titer of 1:8 or less.⁸⁵ In a patient with presumed neurosyphilis, a serological test for syphilis—either the FTA-ABS test or the MHA-TP test—is performed initially. Because the VDRL test may become nonreactive in later stages of syphilis, only approximately 70% of patients with neurosyphilis have a positive VDRL test. A CSF examination should be performed in patients with a reactive

TABLE 42-5

Causes of False-Positive Serological Tests for Syphilis

| |
|---|
| False-Positive Fluorescent Treponemal Antibody Absorption (FTA-ABS) Test |
| Technical error |
| Lyme borreliosis |
| Genital herpes simplex |
| Lupus erythematosus |
| Scleroderma |

MHA-TP or FTA-ABS. The diagnosis of neurosyphilis is made in the presence of a reactive serological test with either neurological manifestations consistent with neurosyphilis or CSF evidence of a lymphocytic pleocytosis and an elevated protein concentration, and/or a positive CSF-VDRL test. Most clinicians treat patients for neurosyphilis when they have a positive serological test and a CSF lymphocytic pleocytosis with an elevated protein concentration, whether the CSF-VDRL is reactive or not. A reactive CSF-VDRL establishes the diagnosis, but a nonreactive test does not exclude the diagnosis. When the CSF-VDRL is negative, a CSF FTA-ABS or CSF MHA-TP should be obtained. The lack of CSF FTA-ABS or CSF MHA-TP reactivity excludes a diagnosis of neurosyphilis. The CSF FTA-ABS and CSF MHA-TP are not routinely recommended for the screening of neurosyphilis in non-HIV-infected individuals because reactivity of these tests on CSF does not establish the diagnosis of neurosyphilis.⁹¹

Screening for the presence of syphilis in HIV-1-infected individuals should be performed by the serum FTA-ABS test because the nontreponemal tests for syphilis may be falsely negative in HIV-infected individuals. A loss of reactivity to the treponemal tests occurs in individuals infected with HIV-1 with advanced immunosuppression.⁸⁸ In HIV-infected individuals with neurosyphilis, the CSF should demonstrate a lymphocytic pleocytosis and an elevated protein concentration

MANAGEMENT. Primary, secondary, and latent syphilis are treated with benzathine penicillin; neurosyphilis is treated with intravenous aqueous crystalline penicillin G, 3 to 4 million units every 4 hours for 10 to 14 days. An

alternative regimen is procaine penicillin, 2.4 million units intramuscularly daily with probenecid and 500 mg orally four times a day, both for 10 to 14 days. Patients with a history of penicillin allergies should be skin tested and desensitized if necessary.^{85,91} The frequency with which intravenous antibiotics are unsuccessful in the therapy of neurosyphilis is extremely low. In instances in which a progression of clinical disease or persistence of a CSF lymphocytic pleocytosis or a reactive CSF-VDRL is present, re-treatment of the patient with an additional 24 million units/day for 10 days is reasonable. The initial CSF pleocytosis will resolve 6 months after penicillin therapy in 80% of patients. Serial CSF-VDRL titers should decrease with treatment. Re-examination of the CSF should occur in HIV-infected patients with neurosyphilis.

Lyme Disease

EPIDEMIOLOGY AND RISK FACTORS. The Swedish dermatologist, Afzelius, first described an expanding ring-like skin lesion following a tick bite in 1910. He called this lesion erythema chronicum migrans.^{93,94} The first case report of erythema migrans in the United States involved a physician in Wisconsin who was bitten by a tick while hunting. This was reported in 1970.⁹⁵ In the mid-1970s, a number of children and adults from Lyme, Old Lyme, and Haddam, Connecticut, presented with recurrent attacks of asymmetrical large joint pain and swelling that was often preceded by an erythematous expanding plaque-like skin lesion with central clearing.⁹⁶ This disease was termed Lyme arthritis. Lyme arthritis was later renamed Lyme disease. In 1979, Andrew Spielman, while searching for the tick vector of human babesiosis, named one tick suspect, *Ixodes dammini*, in honor of the distinguished Harvard pathologist Gustave Dammin.^{96,97} This tick would later be identified as the vector of Lyme disease.⁹⁶ In 1981, Willi Burgdorfer isolated the Lyme spirochete from ticks collected on Shelter Island.⁹⁸ By 1983, two separate groups headed by Steere⁹⁹ and Benach¹⁰⁰ cultured *Borrelia burgdorferi* from patients with Lyme disease, conclusively establishing this organism as the infectious agent.^{94,96}

In Canada, Lyme disease occurs in Ontario and Manitoba; in the United States, the highest incidence of Lyme disease has been reported in Connecticut, Delaware, Maryland, New Jersey, New York, Pennsylvania, Rhode Island, and Wisconsin. The tick vector in the Northeast and Midwest is the black-legged tick, *I. scapularis*, which has a northern (*I. dammini*) and southern form.⁹⁴ The usual vector of Lyme disease on the West Coast is *I. pacificus*; the frequency of Lyme disease is much lower on the West Coast than in the Northeast.

PATHOGENESIS AND PATHOPHYSIOLOGY. Lyme disease is caused by invasion of the CNS by the spirochete *B. burgdorferi*. The pathophysiology of Lyme disease bears several similarities to the pathophysiology of syphilis. The organism initially invades the body through intradermal inoculation. This occurs through a painless tick bite. *Borrelia burgdorferi* is transmitted through the mouth parts of the tick, and transmission of infection occurs only after prolonged attachment and feeding over 24 hours. Humans are most likely to be bitten in the late spring and early summer.⁹⁴ Similar to syphilis, inoculation is followed

by a spirochetemia with wide dissemination, and like syphilis, invasion of the CNS initially presents as a meningitis. The various neurological syndromes are believed to result not only from infection of the CNS by *B. burgdorferi* but also from the reaction of the immune system to the spirochete and the associated inflammatory response. The spirochetes activate T cell subsets and induce cytokine production (including interleukins 1 and 6 and tumor necrosis factor α). In addition, they cause production of autoantibodies to axonal proteins, gangliosides, neurons, myelin components, and cardiolipin.⁹⁴

CLINICAL FEATURES. The neurological manifestations of Lyme disease are classically divided into early syndromes and late syndromes. The early syndromes include meningitis, facial nerve and other cranial nerve palsies, and radiculoneuritis (Video 23, Cranial Nerve VII, Facial Diplegia). Delayed syndromes include sensorimotor polyradiculoneuropathy, encephalopathy, and encephalomyelitis.^{94,101,102}

Meningitis. Signs and symptoms of meningitis may develop while the characteristic skin lesion, erythema migrans, is still present and typically occur within 12 weeks of infection. Most patients complain of headache and fatigue; some may have severe pain between the scapulae, severe fatigue, myalgias, and arthralgias. The diagnosis of Lyme disease is made by examination of the CSF that demonstrates a lymphocytic pleocytosis with a normal glucose concentration and a mildly to moderately elevated protein concentration. Paired samples of serum and CSF should be sent to detect the intrathecal production of *B. burgdorferi* antibody (usually IgG or IgA). Intrathecal anti-*Borrelia burgdorferi* antibody production can be detected in 50% to 90% of cases. CSF PCR can be used to amplify *B. burgdorferi* DNA and is positive in 30% to 40% of patients with Lyme meningitis.^{94,101} Culture of the organism from CSF is rarely positive.

Facial Nerve and Other Cranial Nerve Palsies. The most frequent neurological abnormality in patients with Lyme disease is facial nerve palsy (Video 23, Cranial Nerve VII, Facial Diplegia) that is unilateral or bilateral and most often occurs within 4 weeks of the appearance of erythema migrans. Patients may also complain of headache and fatigue. Other cranial nerves may also be involved in Lyme disease, including cranial nerves II, III, IV, V, VI, VIII, and IX to XII, although such involvement is rare.⁹⁴ The most useful diagnostic tests for patients with a facial nerve palsy are a serum Lyme enzyme-linked immunosorbent assay (ELISA), Western blot, and a CSF examination. The CSF may demonstrate a lymphocytic pleocytosis and intrathecal antibody production of anti-*Borrelia burgdorferi* antibodies. In patients with a facial nerve palsy and a normal CSF examination, oral doxycycline (100 mg twice daily for 2 weeks) can be used; however, patients with facial nerve palsy and CSF pleocytosis should be treated with intravenous ceftriaxone.¹⁰¹

Radiculoneuritis. Early in the course of spirochetemia, patients may complain of severe sharp, jabbing, or deep and boring pain in a radicular nerve distribution. Often, the limb that was the site of the tick bite is the site of the pain.¹⁰² Within days to weeks, there may be sensory loss, weakness, or hyporeflexia in the limb (Video 237, Foot Drop). There may be clinical signs of an associated myelitis

characterized by sphincter dysfunction or Babinski's sign. Patients may also have a facial nerve palsy. The diagnosis is made by the examination of CSF and through electromyography (EMG). The majority of patients have a CSF lymphocytic pleocytosis, an increased CSF protein concentration, and evidence of intrathecal production of anti-*Borrelia burgdorferi* antibody.¹⁰² The majority of patients also have a positive Lyme serology and Western blot.¹⁰¹ The abnormalities on EMG are consistent with a polyradiculopathy with a predominantly axonal process.⁹⁴ Some patients may have a clinical presentation suggestive of the Guillain-Barré syndrome with areflexia and a predominantly motor involvement. EMG findings of a primarily axonal process and CSF evidence of a lymphocytic pleocytosis, however, are not consistent with a diagnosis of Guillain-Barré syndrome. Guillain-Barré syndrome may occur as a postinfectious complication of Lyme disease. In these patients, the EMG does show changes typical of a demyelinating process, and examination of the CSF demonstrates the characteristic cytoalbuminological dissociation.⁹⁴

Encephalopathy. Encephalopathy was initially described in patients with systemic manifestations of Lyme disease and, in particular, arthritis. The patients have a mild confusional state characterized by difficulty with memory and cognitive slowing often accompanied by fatigue and malaise. Neuropsychological testing is abnormal, but CSF abnormalities may or may not be present. Pleocytosis is reported in 5% of patients, and intrathecal anti-*Borrelia burgdorferi* antibody production is present in less than 50% of patients.^{94,102} Active neurological involvement that is suggested by CSF abnormalities, the psychological consequences of chronic illness, and possibly residual neurological deficits of a past infection with Lyme disease may affect a patient's perception of cognitive dysfunction. In addition, evidence from quantitative analysis of SPECT scans suggests that Lyme encephalopathy patients with measurable memory deficits have reduced perfusion affecting primarily subcortical frontotemporal white matter and basal ganglia.¹⁰³

Sensorimotor Polyradiculoneuropathy. Patients with chronic Lyme radiculoneuropathy present with sensory symptoms, particularly distal paresthesias in a stocking and glove or a stocking distribution. A less common presentation is pain in the distribution of the cervical, thoracic, or lumbosacral dermatomes. This syndrome is distinct from the painful symptoms of radiculoneuritis that occurs within a few weeks of infection with *B. burgdorferi*. Although patients with a chronic radiculopathy complain of pain, it is much less severe than in the acute radiculoneuritis form. Electrophysiological studies demonstrate a mild sensorimotor radiculoneuropathy with axonal loss, minor decreases in the distal compound action potential amplitudes (sensory greater than motor), little or no slowing of nerve conduction velocities, and mild to moderate distal and paraspinal muscle denervation.¹⁰¹ In patients who complain of paresthesias, mildly prolonged distal motor or sensory latencies and mild slowing of distal motor conduction velocities are present.⁹⁴ These patients do not typically have a facial nerve palsy, and examination of the CSF is usually normal.⁹⁴

Encephalomyelitis. A very rare, late neurological syndrome in North American Lyme disease affects both the

brain and spinal cord white matter. Examination of the CSF demonstrates a lymphocytic pleocytosis, a mildly elevated protein concentration, and the intrathecal production of anti-*Borrelia burgdorferi* antibodies.¹⁰²

EVALUATION. The diagnosis of CNS Lyme disease begins with asking the patient about a history of a tick bite, whether there was travel to an endemic area, and if the skin lesion was characteristic of erythema migrans. This lesion begins as a painless macule, which continues to expand until it becomes an annular erythematous plaque. It occurs at the site of a tick bite an average of 8 or 9 days after infection. As the lesion expands, the center may become clear, vesicular, or edematous forming a bull's-eye lesion.⁹⁴ Serum should be sent for ELISA and Western blot testing. A positive serology is indicative of exposure to the organism and should not be considered proof of active infection.¹⁰² Interpretation of the serological test is further confounded by the evidence that seronegative Lyme cases exist. CNS infection is most readily confirmed if the paired serum and CSF anti-*Borrelia burgdorferi* antibody titer demonstrates the intrathecal production of these antibodies. This occurs when the antibody titer in the CSF is greater than the antibody titer in serum. Other CSF abnormalities suggestive of Lyme disease are a mononuclear or lymphocytic pleocytosis, an elevated protein concentration, and a normal glucose concentration. As described for the specific clinical features of each neurological syndrome, the CSF is almost always abnormal in Lyme meningitis and early radiculoneuritis. The CSF is occasionally abnormal, with an isolated facial nerve palsy or with encephalomyelitis, and can be normal or abnormal when encephalopathy is present. The CSF is typically normal in chronic Lyme disease sensorimotor polyradiculoneuropathy.⁹⁴

MANAGEMENT. Facial nerve palsy without CSF abnormalities may be treated with oral doxycycline 100 mg twice a day for 2 weeks. Intravenous ceftriaxone is the drug of choice for all other neurological syndromes of Lyme disease. The adult dose is 2 g/day, and the pediatric dose is 75 to 100 mg/kg/day. Treatment with ceftriaxone should be continued for at least 2 weeks, and many physicians prefer 4 weeks of therapy.¹⁰¹ A vaccine made of a lipidated outer surface protein of *B. burgdorferi* is now available.

OTHER TICK-BORNE INFECTIONS

Ehrlichiosis

Ehrlichia are small gram-negative pleomorphic coccobacilli that primarily infect circulating leukocytes and other cells derived from the hematopoietic system.¹⁰⁴ There are two species of ehrlichia that cause human disease. *Ehrlichia chaffeensis* is the causative organism of human monocytic ehrlichiosis. *Anaplasma phagocytophilum* causes human granulocytic ehrlichiosis (anaplasmosis).^{104–106} *Ehrlichia chaffeensis* infects mononuclear phagocytes in the blood and tissues, and *A. phagocytophilum* infects granulocytic phagocytes in blood and tissues.¹⁰⁴ The infectious agents of human ehrlichiosis and Lyme disease are both transmitted by tick bites. Most cases of human granulocytic ehrlichiosis have been identified in Wisconsin, Minnesota,

New York, Connecticut, and Massachusetts, and most cases of human monocytic ehrlichiosis have been identified in the southeastern and south-central United States.¹⁰⁶

The pathogenesis of the diseases caused by ehrlichiae are not well understood. It is clear, however, that the ehrlichiae damage and lyse host phagocytic cells once they have attached to these cells, resulting in leukopenia and thrombocytopenia.¹⁰⁶

Patients with *A. phagocytophilum* infection present with a febrile illness associated with myalgia, headache, malaise, and, occasionally, nausea, vomiting, or a cough. The clinical presentation may be helpful in distinguishing Lyme disease from anaplasmosis. Nausea, vomiting, and cough are very infrequent in Lyme disease. Fatigue is more often a complaint with Lyme disease than with anaplasmosis.¹⁰⁶ The incubation period is approximately 7 days following a tick bite, and approximately 20% of patients with ehrlichiosis have a rash that consists of a maculopapular eruption or petechiae.¹⁰⁷ Despite the different causative agents of monocytic and granulocytic ehrlichiosis, the clinical and laboratory manifestations of the infections are similar. Neurological manifestations of both include severe headache, lethargy, confusion, coma, and seizure activity. The most common CSF abnormalities are lymphocytic pleocytosis with an elevated protein concentration and a borderline low CSF glucose concentration.¹⁰⁸ Laboratory evidence of leukopenia, thrombocytopenia, and anemia and mild to moderate elevations in levels of aspartate and alanine aminotransferases, alkaline phosphatase, and lactate dehydrogenase are present.¹⁰⁴

Monocytic and granulocytic ehrlichiosis are separate diseases caused by different etiological agents; therefore, laboratory diagnosis requires different tests for each. The current Centers for Disease Control and Prevention (CDC) recommendation for the serological diagnosis of monocytic ehrlichiosis is a fourfold increase in *E. chaffeensis* antibody titer (a minimum titer of 64) or a single high-serum antibody titer (≥ 128) in patients with a clinically compatible history. The current CDC recommendation for serological confirmation of human granulocytic ehrlichiosis requires a serological reaction or a fourfold increase in antibody titer to *A. phagocytophilum*. A minimum titer of 80 is required.¹⁰⁴ Diagnosis during the acute phase of the illness can also be made by PCR amplification of the nucleic acid of *Anaplasma* or *Ehrlichia* from blood.¹⁰⁶ Wright's or Giemsa staining of a blood smear may also demonstrate morulae in leukocytes. Co-infections with *B. burgdorferi* and *A. phagocytophilum* can occur.

Ehrlichiosis are treated with doxycycline. *Ehrlichia chaffeensis* is susceptible to doxycycline and rifampin. Doxycycline is the recommended agent for *A. phagocytophilum* infection. The recommended dose is 100 mg twice daily for adults and 3 mg/kg/day in two divided doses for children. Doxycycline can be given by either the oral or the intravenous route.¹⁰⁴

Rocky Mountain Spotted Fever

Rocky Mountain spotted fever is a rickettsial disease caused by *Rickettsia rickettsii*, a small intracellular parasite. Infection is acquired by a tick bite. The majority of infections are acquired in the south Atlantic coastal and

the western and southern central states, with the highest incidence in Virginia, North Carolina, South Carolina, Oklahoma, and Tennessee. The disease typically occurs during spring and summer. Fever, rash, and a history of exposure to ticks are the classic triad of Rocky Mountain spotted fever. The illness usually begins 5 to 7 days after the tick bite. The majority of patients have fever, severe frontal headache, malaise, myalgia, and vomiting. An altered level of consciousness and meningismus may develop during the course of the illness in addition to abdominal pain, hepatosplenomegaly, respiratory failure, renal dysfunction, and myocarditis.

The classic rash of Rocky Mountain spotted fever first appears as macules on the wrists and ankles and subsequently spreads to involve the trunk, face, palms, and soles. The rash appears 1 to 15 days after the onset of the illness.¹⁰⁷ The rash is initially a diffuse erythematous maculopapular rash that blanches with pressure. It progresses to a petechial rash, then to a purpuric rash and, if untreated, to skin necrosis or gangrene. The rash begins on the wrists and ankles and then spreads distally and proximally within a few hours. Ten percent of patients do not have a rash (spotless Rocky Mountain spotted fever). Neurological manifestations of Rocky Mountain spotted fever include severe bifrontal headache that is unresponsive to common analgesics, delirium, confusion, seizures, coma, hyperreflexia, spastic paraparesis or quadraparesis, facial diplegia, nystagmus, and/or ataxia. Stupor and coma occur in approximately 25% of patients and are associated with a poorer prognosis than those cases without signs of encephalitis. Laboratory abnormalities in patients with Rocky Mountain spotted fever include thrombocytopenia, hyponatremia, and elevated liver enzyme abnormalities. CSF abnormalities include a mild (rarely more than 100 cells/mm³) lymphocytic pleocytosis and an elevated protein concentration. In the acute stage, the diagnosis of Rocky Mountain spotted fever can be made by skin biopsy with the demonstration of rickettsiae in the endothelial cells of blood vessels by immunofluorescence. Serological tests are useful for the confirmation of the diagnosis and include an indirect immunofluorescent antibody assay (IFA), an indirect hemagglutination assay (IHA), latex agglutination (LA), and complement fixation (CF). According to the CDC, diagnostic titers for Rocky Mountain spotted fever include a titer of 1:64 for IFA, 1:16 for CF, and a fourfold increase between acute and convalescent sera for LA and IHA. The PCR is also under development for the diagnosis of this disease. The treatment of Rocky Mountain spotted fever is outlined in Table 42-6.¹⁰⁹

Babesiosis

Babesiosis is a malaria-like illness caused by a protozoan parasite and transmitted by a tick bite. Most human cases of babesiosis have occurred during the summer months in the northeastern United States, Maryland, Virginia, Georgia, Wisconsin, Minnesota, California, and Washington. Symptoms of babesiosis typically begin approximately 1 week after a tick bite and include malaise, anorexia, and fatigue followed several days later by fever, drenching sweats, myalgia, and headache. The clinical spectrum ranges from a mild self-limited illness to a serious disease

TABLE 42-6

Recommended Antimicrobial Therapy of Rocky Mountain Spotted Fever

| ANTIBIOTIC | DOSAGE | DURATION OF THERAPY |
|--|--|---------------------|
| Tetracycline-child* | 25-50 mg/kg/day (oral dose) in 4 divided doses | 7-10 days |
| Tetracycline-adult | 500 mg (oral dose) qid | 7-10 days |
| Doxycycline-adult | 100 mg (oral dose) bid | 7-10 days |
| Chloramphenicol (for children younger than 8 years of age) | 50 mg/kg/day IV in 4 divided doses | 7-10 days |

*Not recommended for children younger than age 8 years to avoid staining of the teeth.

Reproduced with permission from Pourmand R, Roos KL: Seasonal (spring-summer) encephalitides. In Roos KL (ed): Central Nervous System Infectious Diseases and Therapy. New York, Dekker, 1997, pp 193–211.

with hemolytic anemia, renal failure, and hypotension, primarily in patients of advanced age or in those with underlying chronic disease. Babesiosis can be diagnosed by examining Wright-stained or Giemsa-stained peripheral blood smears. The parasites invade erythrocytes and appear as small intraerythrocytic ring forms resembling the causative organism of malaria, *Plasmodium falciparum*. An indirect immunofluorescence test titer greater than or equal to 1:64 is considered positive for babesiosis, although most patients with acute illness have titers greater than or equal to 1:1024. The recommended treatment for this illness consists of a 7-day course of oral quinine plus clindamycin (by the intravenous or oral route).¹⁰⁷

FUNGAL INFECTIONS

As a general rule, fungal infections occur in individuals who are immunosuppressed as a result of (1) AIDS, (2) organ transplantation, (3) immunosuppressive chemotherapy or chronic corticosteroid therapy, or (4) chronic disease. The single exception to this generalization is cryptococcal meningitis, which may occur in healthy individuals. The fungus-causing infection can be predicted to some degree based on the predisposing condition. For example, individuals with AIDS are at risk for meningitis due to *Cryptococcus neoformans* and *Histoplasma capsulatum*. Cryptococcal meningitis is the most common life-threatening opportunistic fungal infection in patients with AIDS and occurs in 5% to 10% of patients, typically when their circulating CD4⁺ T lymphocyte count is less than 100 cells/mm³.¹¹⁰ Two fungi are responsible for the majority of CNS fungal infections in patients who have undergone organ transplantation. Fungal meningitis in these patients is typically due to *C. neoformans*, and fungal brain abscesses are often due to *A. fumigatus*. Patients receiving chronic corticosteroid therapy and patients who have received bone marrow transplantation are at risk for cryptococcal meningitis and CNS candidiasis. *Candida* tend to cause intraparenchymal microabscesses, mainly in the territory of the middle cerebral artery. Individuals with granulocytopenia for any reason are at risk for infections due to *Candida*, *A. fumigatus*, and the Zygomycetes organisms

(mucormycosis).¹¹¹ Intravenous drug abusers are at a particular risk for fungal brain abscesses due to *Zygomycetes* and *Candida*. *Coccidioides immitis* is a dimorphic fungus that is endemic to the desert areas of the Southwest, specifically California, Arizona, New Mexico, and Texas. The disease is acquired by inhaling the infectious particles, but less than 1% of individuals who develop a primary infection develop disseminated disease. Coccidioidomycosis should be considered in the differential diagnosis of any febrile illness in a transplant recipient in an endemic area for this fungus.¹¹² The fungus *Blastomyces dermatitidis* is found principally in North America in the Mississippi, Ohio, and St. Lawrence river basins; the Great Lakes area; and the southeastern United States. Infection is most likely to be acquired as a result of occupational exposure to contaminated soil.¹¹³ CNS involvement by this fungus is nearly always the result of hematogenous spread from a pulmonary source or occurs as a result of infection in contiguous structures or with osteomyelitis.¹¹⁴

Cryptococcus neoformans

Cryptococcus neoformans is an encapsulated yeastlike fungus. Infection is acquired through direct exposure to bird droppings. The infection is initially characterized by a localized pneumonitis, but when dissemination occurs the CNS is a preferential site for disease, presumably because the CSF is a good culture media for cryptococci.¹¹⁵ The most common symptoms of cryptococcal meningitis are headache, fever, and malaise, but cryptococcal meningitis may also present with nausea and vomiting, meningeal signs, altered mental status, and cranial nerve palsies. Cryptococcal skin lesions may precede the development of meningitis; when present, they are an indication for lumbar puncture, even in the absence of signs and symptoms of meningitis.¹¹⁶ Diagnosis is made by examination of the CSF, and the following are typical abnormalities: (1) normal or slightly elevated opening pressure, (2) lymphocytic pleocytosis, (3) elevated protein concentration, (4) decreased glucose concentration, and (5) positive cryptococcal antigen. The cryptococcal antigen is a highly sensitive and specific test and should be performed on all CSF specimens. A reactive CSF cryptococcal antigen test establishes the diagnosis. *Cryptococcus neoformans* can also be grown in culture of CSF.

The treatment of cryptococcal meningitis in immunocompetent patients includes either a combination of intravenous amphotericin B (0.5 to 0.7 mg/kg/day) plus oral flucytosine (25 mg/kg twice daily) or Ambisome 5 mg/kg/day. A combination of amphotericin B plus flucytosine or Ambisome monotherapy is used for 2 weeks or until the CSF culture is sterile. This induction therapy is followed by fluconazole 400 to 800 mg/day, which is continued for 8 to 10 weeks. The therapy of cryptococcal meningitis in patients with AIDS includes a combination of intravenous amphotericin B (0.7 to 1.0 mg/kg/day) with flucytosine (100 mg/kg/day in four divided doses) for at least 2 weeks or until the CSF culture is sterile followed by fluconazole (400 mg/day) for 10 to 12 weeks, at which point the CSF should be recultured. When the CSF culture is sterile, the patient is switched to maintenance fluconazole (200 mg/day) therapy.

The management of increased ICP is critical to successful outcome from cryptococcal meningitis. ICP should be measured at the initial lumbar puncture, at the completion of induction therapy, and anytime during the course of the illness when the patient has a change in mental status or a change in the neurological examination (gait abnormalities, pathologically brisk reflexes, cranial nerve abnormalities, and visual changes) (Video 80, Hyper-Reflexia). The increased ICP is due to altered CSF hemodynamics and should be managed with daily lumbar punctures (to decrease CSF pressure by 50% and maintain CSF pressure at less than 300 mm H₂O), a ventriculostomy, or a ventriculoperitoneal shunt. Corticosteroid therapy should not be used in cryptococcal meningitis.

The most common adverse reactions to amphotericin B are fever, chills, and hypotension 1 to 3 hours after initiation of the intravenous infusion. Renal insufficiency and anemia are common adverse reactions during the course of therapy, and renal insufficiency may necessitate interruption of therapy or reduction of dose. The most common adverse reactions to flucytosine are leukopenia and gastrointestinal side effects. The most common adverse reactions to fluconazole are nausea, vomiting, and elevated serum transaminases.

Histoplasma capsulatum

Histoplasma capsulatum is a dimorphic fungus that is endemic to the Ohio and Mississippi River valleys of the central United States. The fungus is acquired by inhalation. Dissemination is rare and occurs primarily in patients with defective cellular immunity, such as patients with AIDS, patients with lymphoreticular malignancies, and organ transplant recipients.¹¹⁵ The most common presentation of CNS histoplasmosis is meningitis. The typical presentation includes fever, sweats, weight loss, headache, mental status abnormalities (including decreased level of consciousness, confusion, personality changes, and/or memory impairment), cranial nerve palsies, stroke, or seizures (Video 74, Secondary Generalized Seizure).¹¹⁵ CNS histoplasmosis may also be a solitary abscess or multiple lesions, but meningitis is the much more common presentation. The majority of patients with CNS histoplasmosis have an abnormal neuroimaging study with meningeal enhancement, hydrocephalus, solitary or disseminated contrast-enhancing lesions, or various combinations of these entities. Chest radiographs should be obtained. The most common x-ray abnormalities in histoplasmosis are diffuse or focal pulmonary infiltrates. *Histoplasma* polysaccharide antigen (HPA) in urine, blood, and CSF may allow for a rapid diagnosis. The presence of HPA in CSF is a reliable indicator of CNS involvement; however, cross-reactions with *C. immitis*, *C. neoformans*, and *Candida* have been reported.¹¹⁵ Serological tests for anti-*Histoplasma capsulatum* antibodies may be helpful. They may also be misleading and can be negative in 10% to 25% of patients with disseminated histoplasmosis or falsely positive in patients with other fungal diseases or tuberculosis. Antibodies remain elevated for several years despite resolution of histoplasmosis and may lead to a misdiagnosis of patients with neurological illnesses caused by other diseases.¹¹⁷ Examination of the CSF typically reveals a lymphocytic pleocytosis

(≤ 100 cells/mm³), although a predominance of polymorphonuclear leukocytes may also occur. The CSF protein concentration is increased, and the CSF glucose concentration is usually decreased. It is rare to identify the fungus on CSF India ink stain. The CSF culture, however, is frequently positive, as are blood, bone marrow, and urine cultures. In general, when fungal meningitis is suspected, multiple cultures of lumbar fluid should be obtained to identify the organism. Consideration should also be given to obtaining CSF by a cisternal puncture. In cases of *H. capsulatum* meningitis, one CSF culture out of several is typically positive, stressing the need for repeated attempts to isolate the fungus using large volumes of centrifuged CSF.¹¹⁵ Intravenous amphotericin B (0.75 to 1.0 mg/kg/day) remains the mainstay of treatment of CNS histoplasmosis. A total dose of 30 mg/kg is recommended. A course of amphotericin B is followed by oral itraconazole 200 mg twice daily for 6 months to 1 year. Itraconazole is the antifungal agent of choice for chronic suppressive therapy in patients with AIDS.¹¹⁵

Coccidioides immitis

Coccidioides immitis is a dimorphic fungus that is endemic to the desert areas of the Southwest, specifically California, Arizona, New Mexico, and Texas. *Coccidioides immitis* grows as a mycelia that releases airborne arthroconidia, which when inhaled and in the alveoli transform into spherules containing endospores. Infection is most often either asymptomatic or a limited pneumonitis with fever and cough. Dissemination occurs in less than 1% of patients, and CNS disease is primarily a meningitis. A predisposition to disseminated disease has been associated with the following: (1) pregnancy—infection that is acquired during the third trimester is associated with an increased risk of severe disease; (2) hemodialysis; (3) immunosuppressive therapy; (4) extremes of age; (5) race—patients of African American, Hispanic, and Filipino descent have a higher risk of dissemination; (6) AIDS; and (7) organ transplantation.¹¹⁵ Meningitis is a common initial presentation of coccidioidomycosis in AIDS patients. The most common symptoms and signs of *C. immitis* meningitis are headache, change in mental status (particularly lethargy and confusion), low-grade fever, and weight loss.¹¹² There may be evidence of skin lesions, and biopsy of these with visualization of typical *C. immitis* spherules makes the diagnosis. The coccidioidal skin test has no role in the diagnostic evaluation of a CNS infection because false-negative results are common, and positive results only indicate prior exposure to the fungus.¹¹⁵ The diagnosis of *C. immitis* meningitis is made by examination of the CSF. The complement fixation antibody test on CSF is reported to have a specificity of 100% and a sensitivity of 75% in the setting of active disease.¹¹³ Coccidioidal meningitis can present as an eosinophilic meningitis.¹¹⁵ Positive cultures may be obtained in up to one-third of patients. *Coccidioides immitis* meningitis is treated with either high-dose fluconazole (1000 mg daily) as monotherapy or a combination of intravenous and intrathecal amphotericin B. High-dose fluconazole therapy as induction therapy can be followed by lower doses of fluconazole (200 to 400 mg daily) indefinitely. For patients with coccidioidal meningitis who do not respond either clinically

or by monthly repeat CSF analysis to fluconazole, either voriconazole (4 mg/kg every 12 hours orally) or intrathecal amphotericin B (0.25 to 0.75 mg/day three times weekly) is recommended. Some experts recommend a combination of intravenous amphotericin B (0.5 to 0.75 mg/kg/day) plus intrathecal amphotericin B instead of high-dose fluconazole. Intravenous amphotericin B is continued for at least 1 year after obtaining a normal CSF. Intrathecal amphotericin B is continued for 3 months, followed by a tapering course. The CSF glucose and protein concentrations can remain abnormal for years, and the CSF cell count is unreliable because it may decrease spontaneously in untreated CNS coccidioidomycosis. A sudden rise in cell count or CSF complement fixation antibody titer, however, is a sign of a relapse, and more intense antifungal therapy should be administered in this instance.¹¹⁵

Blastomyces dermatitidis

As discussed previously, infection with *B. dermatitidis* is primarily associated with outdoor activities including occupational exposure, such as in construction work and mining, and recreational activities. The AIDS epidemic has not affected the epidemiology of blastomycosis.¹¹⁵ Initial infection with this fungus is essentially a pulmonary disease. The chest x-ray demonstrates nonspecific infiltrates, predominantly at the bases.¹¹⁵ Dissemination to the CNS presents as single or multiple intracranial abscesses or granulomas, cranial and spinal extradural abscesses, and acute or chronic meningitis. Meningitis due to *B. dermatitidis* presents as a subacute infection with headache, anorexia, and weight loss. *Blastomyces dermatitidis* brain abscess or abscesses present with focal neurological deficits, seizures, and signs of increased ICP. Neuroimaging demonstrates evidence of a single or multiple homogeneously enhancing lesions. Chronic blastomycotic meningitis predominantly involves the basilar meninges and may be associated with hydrocephalus.¹¹⁵ The one exception to the rule that fungal meningitis presents with a lymphocytic pleocytosis is *B. dermatitidis* meningitis, which may present with a polymorphonuclear leukocytic pleocytosis. A CSF cell count greater than 5000 cells/mm³ is not uncommon. The CSF glucose concentration may be markedly decreased, and the protein concentration is typically elevated. It is rare to identify *B. dermatitidis* from CSF obtained by lumbar puncture. Culture of cisternal or ventricular CSF has a better yield. There is no reliable *B. dermatitidis* antigen detection test available.¹¹⁵ Treatment requires the administration of intravenous amphotericin B (0.5 to 0.8 mg/kg/day). Lifelong suppressive therapy with itraconazole in AIDS patients is recommended.

Aspergillus fumigatus

Aspergillus species are ubiquitous, and infection is acquired by inhaling conidia. CNS aspergillosis is rare in immunocompetent individuals. Isolated aspergilloma are unusual, except in intravenous drug abusers. Individuals who are granulocytopenic and those who have received organ transplantation are at risk for brain abscesses owing to aspergillosis. CNS aspergillosis typically occurs

preferentially in major vascular territories and presents as isolated or multiple ischemic infarctions or subarachnoid hemorrhage from a ruptured mycotic aneurysm.¹¹⁵ The majority of patients with aspergillosis will have an unremitting fever, despite broad-spectrum antibiotics, and pulmonary infiltrates on chest radiographs.¹¹⁸ The diagnosis is made through sputum culture or lung tissue biopsy culture. CSF analysis is usually not helpful because meningitis is unusual.¹¹⁵ *Aspergillus* is rarely, if ever, cultured from blood. Treatment should include intravenous amphotericin B (0.8 to 1.0 mg/kg/day) or preferably a lipid preparation of amphotericin B, either liposomal amphotericin B (Ambisome) 5 mg/kg/day or amphotericin B lipid complex (ABLC) 5 mg/kg/day.

Candida

CNS candidiasis occurs in patients who have undergone organ transplantation, those receiving chronic corticosteroid therapy, those with a prolonged stay in the intensive care unit requiring invasive monitoring devices, and those who are treated with broad-spectrum antibiotics. CNS infections due to *Candida* present as either meningitis or cerebritis from multiple small parenchymal abscesses.¹¹⁵ CNS infection due to *Candida* often occurs in conjunction with fungemia.¹¹⁹ The majority of patients with CNS *Candida* infections have positive fungal blood cultures and are neutropenic.¹¹⁹ Scattered, irregular ring-enhancing lesions surrounded by edema may be present on neuroimaging studies. A definitive diagnosis is made through CSF or tissue biopsy and culture. Standard therapy includes intravenous amphotericin B (0.5 to 0.7 mg/kg/day) plus flucytosine (100 mg/kg/day in four divided doses).

Zygomycetes

The Mucoraceae are in the Zygomycetes class and cause the disease mucormycosis. This disorder is typically an acute fulminant CNS infection that occurs primarily in immunocompetent patients with ketoacidosis and in diabetic transplant recipients receiving immunosuppressive agents. The infection tends to originate in the palate or paranasal sinuses and spreads through the orbits and paranasal sinuses into the brain. The infection is often manifest by a black eschar on the palate or nasal mucosa with a blackish purulent discharge from the involved areas. Examination of the CSF demonstrates an elevated opening pressure, a pleocytosis with a predominance of polymorphonuclear cells, a normal glucose concentration, and an elevated protein concentration. Diagnosis is made by a biopsy of the black eschar.¹²⁰ The treatment of CNS mucormycosis involves debridement of all devitalized tissues and high-dose amphotericin B (1.0 mg/kg/day) or Ambisome (5 mg/kg/day) or ABLC (5 mg/kg/day).¹¹⁵

AMEBIC INFECTIONS

Naegleria and *Acanthamoeba* are free-living amoebae that infect the CNS. *Naegleria fowleri* causes an acute fulminant meningoencephalitis, known as primary amoebic meningoencephalitis, and is acquired by swimming or waterskiing in

small, shallow freshwater lakes as a result of direct contamination through the nasal cavity. Infection with this organism has also been acquired from swimming in chlorinated pools; presumably, the organism gets into the pool through cracks in the pool. In Africa, cases have been reported during the dry and windy season by inhalation of dust containing amoebic cysts.¹⁰⁹

Acanthamoeba CNS infections are generally not water related and occur in immunosuppressed and debilitated individuals. This organism has been isolated from the nasopharynx of asymptomatic individuals. *Acanthamoeba* keratitis has been reported in healthy contact lens wearers.¹⁰⁹

Naegleria fowleri invades the nasal mucosa and ascends to the brain through the cribriform plate via the fila olfactoria, extensions of the olfactory nerves.¹²¹ Amoebae can then spread throughout the meninges. The temporal and frontal lobes are most severely affected. *Acanthamoeba* spp. reach the nervous system through the bloodstream from a distant site of infection or from a corneal infection of the eye and typically cause a subacute or chronic meningoencephalitis or inflammatory lesions in multiple areas of the brain, particularly the white matter, the basal ganglia, the brain stem, and the cerebellum. A necrotizing vasculitis is common owing to invasion of arterial walls by trophozoites.¹²¹

The incubation period for infection by *N. fowleri* is usually 4 to 7 days. The patient presents with severe bifrontal headache, high fever, nausea, vomiting, and meningismus—a clinical presentation resembling bacterial meningitis. Twenty-four to 48 hours later, signs of encephalitis with focal neurological deficits, confusion, delirium, stupor, and, finally, coma occur. Meningoencephalitis due to *Naegleria* is typically a fatal disease, with death occurring within 2 to 4 days. Because of involvement of the olfactory bulbs and tracts, early symptoms of abnormal smell or taste sensation have been reported. The incubation period of *Acanthamoeba* is longer than that of *Naegleria* infections and is typically weeks to months. The insidious onset of symptoms and signs of focal encephalitis or focal mass lesions follows. The presentation may include seizures, hemiparesis, visual disturbances, headache, low-grade fever, and ataxia.

A diagnosis of *N. fowleri* meningoencephalitis is rarely made while the patient is alive. Examination of the CSF demonstrates a leukocytosis with a neutrophilic predominance, an increased protein concentration, and a decreased glucose concentration. The amoeboid movements of the trophozoites can be seen on fresh or wet unstained specimens of CSF. Trophozoites can also be demonstrated in the brain by light or electron microscopy. Serological tests for *Naegleria* are of limited value because patients usually die before the results are available. In contrast, serological tests for *Acanthamoeba* infections are helpful in diagnosis. Neuroimaging scans may demonstrate one or multiple abscesses of *Acanthamoeba*. Examination of the CSF shows a mild lymphocytic pleocytosis with a normal to decreased glucose concentration and a mild increase in protein concentration.¹⁰⁹

The drug of choice for acute *N. fowleri* meningoencephalitis is intravenous amphotericin B (1 mg/kg/day) for at least 2 or 3 weeks. A few survivors of this infection have been documented, but one survivor required treatment with

a combination of intravenous and intrathecal amphotericin B, intravenous and intrathecal miconazole, and rifampin, sulfisoxazole, and dexamethasone. The outcome may be improved by adding intrathecal amphotericin B (0.5 mg on alternate days) to parenteral amphotericin B.^{109,122,123} *Acanthamoeba* abscesses are treated with surgical excision and amphotericin B. Although amphotericin B is amebicidal for *N. fowleri*, it is much less active against *Acanthamoeba*.¹²¹ No effective vaccine for free-living amebae infections exists. Children should be prevented from swimming in contaminated freshwater, and *Acanthamoeba* keratitis can be prevented by using appropriate antimicrobial contact lens cleaning solutions.¹²¹

NEUROCYSTICERCOSIS

EPIDEMIOLOGY AND RISK FACTORS. Neurocysticercosis is considered the most common parasitic disease of the CNS. In countries where this infection is endemic, it is the most common cause of late-onset epilepsy. Humans acquire cysticercosis by the ingestion of food contaminated with *Taenia solium* eggs.

PATHOGENESIS AND PATHOPHYSIOLOGY. After food contaminated with *T. solium* eggs is ingested, the eggs hatch into oncospheres in the stomach of the host. Oncospheres cross the intestinal wall, enter the bloodstream, and are carried to the eye, skeletal muscle, and the CNS. After 2 months, cysticerci develop in the brain parenchyma, subarachnoid space, ventricular space, or spinal cord. When the parasite invades the CNS, it may stimulate either an intense inflammatory response or an inflammatory response that develops so slowly that the cysticerci may live in the CNS for several years. When the parasite lodges in the brain parenchyma, the inflammatory response results in a thin capsule of fibrous tissue surrounding the cyst. With the passage of time, the capsule thickens. The parasite may be destroyed, and the site where the cyst was located is replaced by a granuloma composed of astroglial and fibrous tissue that subsequently becomes mineralized with deposits of calcium salts. The process of calcification of the granuloma takes several years after the disappearance of the parasite.¹²⁴ In any individual, one or several hundred cysticerci may exist. Cysts that develop in the subarachnoid space are associated with an inflammatory response in the subarachnoid space with subsequent fibrosis of the arachnoid membranes. Hydrocephalus is a complication of the inflammation and fibrosis in the subarachnoid space that interferes with the normal CSF resorption in the arachnoid granulations. Cysts in the sylvian fissure and the subarachnoid space at the base of the skull may grow as large as 10 to 15 cm. A single cyst that is lodged inside the fourth ventricle can produce a valve mechanism on the outflow of CSF and can lead to subacute hydrocephalus with episodes of sudden increases in ICP related to movements of the head. This ventricular form of neurocysticercosis is the result of the arrival of the oncospheres at the choroid plexus of the lateral ventricles via the bloodstream with the parasites remaining in the ependyma of the choroid plexus. In meningeal and spinal cord cysticercosis, the oncospheres also enter the CNS at the choroid plexus, but the passage of the parasites along the CSF pathways is rapid, and the oncospheres hatch in

the arachnoid membranes along the neural axis and evolve into cysticerci.¹²⁴

CLINICAL FEATURES. The diagnosis of neurocysticercosis should be considered in any patient who is a resident or immigrant from areas endemic for cysticercosis, or who has traveled to areas endemic for cysticercosis, and has new-onset partial seizures, with or without secondary generalization (Video 74, Secondary Generalized Seizure), cognitive impairment, confusion, stupor, or signs of raised ICP. In the majority of patients, the clinical manifestation of parenchymal granulomas is partial seizures. Patients with meningeal cysticercosis may present with headache, vertigo, vomiting, papilledema, an altered level of consciousness, and gait disturbances due to the intense and widespread immune response in the subarachnoid space and the subsequent development of hydrocephalus. Cysticerci located in the spinal canal may manifest with signs and symptoms similar to an intraspinal tumor.¹²⁴

EVALUATION. The lesions of neurocysticercosis are readily visualized by CT and MRI. Granulomas are the most common finding in patients with neurocysticercosis. A very early sign of cyst death is hypointensity of the vesicular fluid on MRI T2-weighted images compared with CSF. The enzyme-linked immunoelectrodiffusion transfer blot is the preferred serologic test for neurocysticercosis,¹²⁵ but false-positive results occur in healthy individuals from endemic areas who have cysticerci outside the CNS. ELISA and the complement fixation test can be performed on CSF and are highly specific and sensitive for the detection of anticysticercus antibodies. It is recommended that both tests be done on the CSF to increase the probability of diagnosis. These CSF immunodiagnostic tests are also useful to distinguish the inactive sequelae of neurocysticercosis, such as granulomas and calcifications, from the active forms. The test results are negative in the absence of active forms of the parasite. These tests remain positive for a few months in patients who are successfully treated with an anticysticercus drug after the disappearance of cysts. In addition, patients with parenchymal or ventricular neurocysticercosis with positive immunodiagnostic tests on CSF may have negative serology.¹²⁴

MANAGEMENT. Treatment of neurocysticercosis is controversial and must be individualized based on the neuroimaging characteristics of the lesions, which help define the stage of evolution of the cysts, cyst location (intraparenchymal, ventricular, or subarachnoid), associated inflammation, and severity of clinical presentation. Albendazole and praziquantel are cysticidal. Most authors agree that viable intraparenchymal cystic lesions should be treated with anticysticidal therapy, and that calcified lesions do not require anticysticidal therapy. The dose of albendazole is 15 mg/kg/day for at least 7 days. Albendazole is administered with dexamethasone (0.1 mg/kg/day) for at least the first 7 days of therapy. Praziquantel is given in a single-day regimen in three doses of 25 to 30 mg/kg every 2 hours or the standard 15-day regimen of 50 to 100 mg/kg/day. Dexamethasone (0.1 mg/kg/day) is also recommended to decrease the inflammatory reaction due to the destruction of the parasites.¹²⁵ Approximately 85% of parenchymal cysts are destroyed by a single course of albendazole, and approximately 75% are destroyed by a single course of praziquantel. During the first few days of cysticidal therapy,

headache, vomiting, or seizures may develop owing to an intense inflammatory response from the host to the acute death of the parasites. These symptoms are particularly intense in patients with many cysts. In the management of parenchymal cysticercosis, a differentiation must be made between active and inactive forms of the parasite, such as granulomas and calcification, because no response to cysticidal therapy will occur in inactive disease. Seizure activity secondary to parenchymal cysts should be managed with anticonvulsants. Parenchymal cysts that are destroyed by cysticidal therapy, without leaving granulomas, do not result in long-term seizure disorders. In these patients, the early withdrawal of antiepileptic drugs is recommended. A seizure disorder that is secondary to granulomas requires long-term anticonvulsant therapy.¹²⁴

MALARIA

Human malaria is caused by one of four species of *Plasmodium*. The majority of cases of malaria worldwide are caused by *P. falciparum*, and *P. falciparum* is the only species that causes cerebral malaria. Malaria is transmitted to healthy individuals through the bite of an infected mosquito.¹²⁶ The World Health Organization defines cerebral malaria as “unrousable coma not attributed to any other cause in a patient with *P. falciparum* malaria.”¹²⁷ Malaria can be transmitted by the bite of an *Anopheles* mosquito, through blood transfusions, and by intravenous injections with blood-contaminated needles. The incidence of cerebral malaria in a population is determined by the population’s immunity. In holoendemic areas, which are areas of the world where significant transmission of malaria occurs annually with little change from year to year, native adults rarely develop cerebral malaria. People at risk for severe malaria in these areas are children 1 to 4 years of age, new residents from nonendemic areas, returning residents who have lived abroad for years, residents who were maintained on chemoprophylaxis but have stopped, and pregnant women. Travelers to endemic areas are at high risk for infection. Infected mosquitoes can be transported from endemic areas via airplane, and travelers may acquire malaria during brief stopovers without disembarking from the airplane. *Plasmodium falciparum* malaria requires a minimum of 8 days for incubation, and 95% of all infections present within 4 weeks of the last mosquito exposure.¹²⁵

Systemic signs of malaria include jaundice, retinal hemorrhage, hepatosplenomegaly, fatigue, diarrhea, vomiting, abdominal pain, chest pain, cough, myalgia, and arthralgia. The majority of patients are febrile. Cerebral malaria presents with headache followed by an altered level of consciousness and convulsions. On neurological examination, upper motor neuron signs are common, as is decerebrate or decorticate posturing, delirium, hallucinations, delusions, and disorders of dysconjugate gaze. Coma is often associated with shock, acidosis, noncardiogenic pulmonary edema, hemolysis, anemia, renal insufficiency, and hypoglycemia. These are all potentially treatable complications.¹²⁸ Diagnosis is made by examining a blood smear for parasites. Blood smear should be examined every 12

to 24 hours for a period of 2 or 3 days, and the number of intraerythrocytic parasites should be counted.

In the United States, parenteral quinidine is the drug of choice for the treatment of cerebral malaria. Cerebral malaria is treated with a loading dose of 10 mg/kg of intravenous quinidine gluconate over a period of 1 or 2 hours followed by continuous infusion of 0.02 mg/kg/min. Loading doses of quinidine are not recommended for patients who have received mefloquine, quinine, or quinidine in the 24 hours before initiation of therapy. When the patient is able to take oral medication, therapy can be changed to one of the oral antimalarial agents to complete a total of 7 days of treatment from the initiation of intravenous therapy.¹²⁶ Quinidine is cardiotoxic, and patients receiving parenteral forms of this agent should be monitored for arrhythmias, prolongation of the QT interval, and widening of the QRS complex.

Recommendations for malaria chemoprophylaxis depend on the area to which the individual plans to travel. In the few areas where the parasite remains sensitive to chloroquine, this antimalarial agent should be taken in a weekly dose of 300 mg base. Chemoprophylaxis should begin 2 weeks before departure and should continue for 6 weeks after return. In areas where the parasite is resistant to chloroquine, mefloquine is recommended at a once per week oral dose of 250 mg beginning 2 weeks before departure and continued for 4 weeks after return.¹²⁹

ACKNOWLEDGMENT

The technical assistance of Mrs. Linda Hagan in the preparation of this chapter is greatly appreciated.

Transmissible Spongiform Encephalopathy

Paul Brown

SPORADIC DISEASE
FAMILIAL DISEASE

IATROGENIC DISEASE
VARIANT DISEASE

The outbreaks of “mad cow” disease (bovine spongiform encephalopathy [BSE]) and its human analog (variant Creutzfeldt-Jakob disease [vCJD]), which generated such concern during the past two decades, are now receding and have left a legacy not only of death but also of significant advances in our understanding of these diseases and of transmissible spongiform encephalopathies (TSEs) in general.

This evolution stems from the fact that the different TSEs are merely variations on a theme and are more properly considered as a single disease taking different forms in humans and animals. Historically, these forms were given different names only because they were described before their shared properties were appreciated. Because there is now good evidence that they all result from a “proteinaceous infectious particle,” the TSEs are often referred to as *prion diseases*.

The first TSE to be described was scrapie, a disease of sheep that devastated the woolens industry in 18th-century England. Scrapie remained the sole recognized example of TSE until the 20th century, when a number of additional animal and human diseases were identified that subsequently proved to be spontaneous or transmitted forms of TSE (Fig. 43-1). In animals, the disease occurs in mink (transmissible mink encephalopathy [TME]), deer and elk (chronic wasting disease [CWD]), and, most recently, cattle (BSE). In humans, the prototypic disease was kuru, brought to epidemic proportions in an isolated population of New Guinea by the practice of ritual endocannibalism but now extinct because the practice has ceased. The other human varieties—Creutzfeldt-Jakob disease (CJD), Gerstmann-Sträussler-Scheinker disease (GSS), and fatal familial insomnia (FFI)—have a worldwide distribution. They occur in sporadic, inherited, and environmentally acquired forms (CJD), sporadic and inherited forms (FFI), or exclusively as an inherited disease (GSS). The most important, numerically speaking, is the sporadic form of CJD, first described in the 1920s by the German neurologist Alphonse Jakob but not recognized as a transmissible disease until the 1960s.

SPORADIC DISEASE

PATHOGENESIS AND PATHOPHYSIOLOGY. A critical early observation by Alper and colleagues¹ emphasized

that infectivity of scrapie was not decreased by levels of ionizing irradiation sufficient to destroy the biological function of nucleic acid. Subsequent research fostered a number of hypotheses about non-nucleic acid replication by membrane-complexed polysaccharides or proteins. Upon a background of repeated failures to detect any foreign disease-specific nucleic acid, the protein hypothesis was further bolstered in the 1980s by the demonstration that highly purified brain extracts from diseased subjects contained a host-encoded membrane-bound glycoprotein (PrP) that is inseparable from infectivity.²

The controversy about whether this protein is not only necessary but also sufficient to initiate the infectious process has not been resolved; however, two studies, if confirmed, support the prime role of the protein. In the first study, recombinant mouse PrP polymerized into fibrils was reported to have induced a transmissible spongiform encephalopathy when injected into healthy transgenic mice.³ In the second study, an infectious extract of brain tissue was incubated with normal brain tissue and then subjected to repeated cycles of sonication and further incubations with fresh normal tissue, continuing to a point at which (by virtue of dilution) no further residual infectivity from the original extract could have been present, but substantial infectivity was still detectable.⁴ Both studies lead inescapably to the conclusion that the protein was indeed “replicating” but neither study excludes the participation of an additional molecular entity; in fact, amplification by sonication does not proceed in the absence of normal brain tissue.

The primary structure of the protein does not differ from that of the protein in healthy individuals. In consequence, the functional differences between the protein in normal and affected individuals—solubility, proteinase resistance, ease of separation from cell membranes, and, most important, ability to replicate (infectivity)—must reside in post-translational secondary or tertiary alterations in protein folding. The normal form of the protein is rich in α -helical domains, whereas the abnormal isoform has fewer α helices and a greatly increased amount of anti-parallel β sheet structure, the “signature” of amyloid protein (Fig. 43-2). The mechanism by which such protein misfolding leads to replication is presumed to be either a process of polymerization akin to inorganic crystal formation or a molecular constraint imposed by the misfolded protein upon normal molecules to assume its own abnormal configuration.

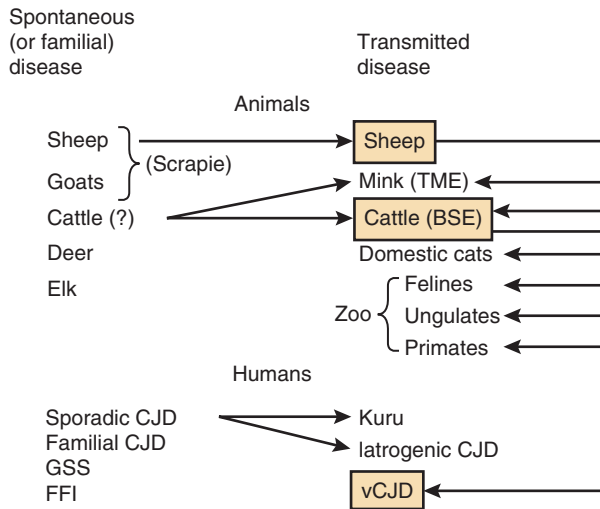

Figure 43-1. Inter-relationships between animal and human transmissible spongiform encephalopathies.

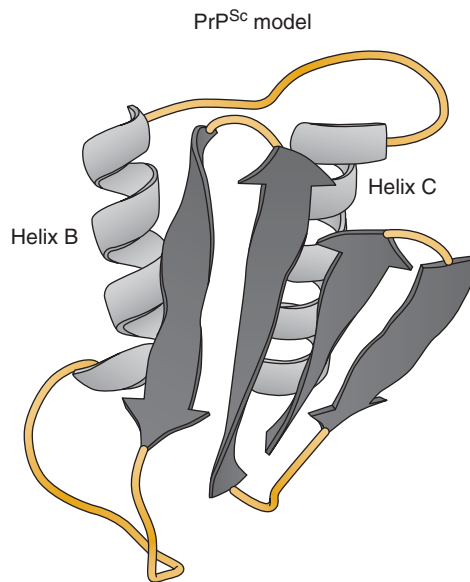

It had been thought until recently that amyloid deposition was the principal cause of neuronal disease and death, but new studies indicate that submicroscopic molecular intermediates formed during the misfolding process are far more harmful than the “mature” amyloid. One study has shown that maximal infectivity is found in particles within a molecular range of 300 to 600 kDa, which would correspond to approximately 14 to 28 PrP molecules;⁵ another study showed that in genetically engineered mice in which neurons are unable to produce PrP, infection does not destroy the neurons, and symptomatic disease is prevented, even when the surrounding non-neuronal brain tissue is full of stainable PrP amyloid deposits.⁶ Characterization of the molecular steps in the misfolding process is thus a subject of intense study.

The spread of infectious molecules is as puzzling as the original conversion event and subsequent misfolding process. Tissue sampling has revealed widespread infectivity not only within the brain (which contains by far the highest concentration of the infectious agent) but also in the spinal cord, cerebrospinal fluid, lymphoreticular tissues, and, occasionally, at much lower concentrations in other peripheral organs.⁷ Infectivity has never been demonstrated in any external secretion or excretion (urine, feces, tears, sputum, or saliva). A comprehensive up-to-date listing of the tissue distribution of infectivity and PrP in most forms of TSE has been published by the World Health Organization.⁸

EPIDEMIOLOGY AND RISK FACTORS. The sporadic form of the disease accounts for approximately 90% of all cases of spongiform encephalopathy, and it occurs in a random distribution in all studied populations of the world at an annual frequency of 1 or 2 cases per 1 million people.⁹ There is no documented instance of the disease being “caught” from normal contact with other humans (whether in the preclinical or clinical stages of illness), nor is there any indication (by seasonality, geographical distribution, or disease clusters) of a nonhuman environmental source of infection. Although some of the many studies evaluating possible risk factors have reported associations with prior surgery, physical injury, occupation, or diet, the large

Figure 43-2. Proposed conversion of normal to pathological isoform of “prion” protein. *Strings* denote unstructured regions; *coils* denote α -helical structure; *ribbons* denote β sheet structure. Note the reduction in α -helical structure and corresponding increase in β sheet structure in the pathological isoform (the normal protein structure was determined by nuclear magnetic resonance analysis; the abnormal structure is hypothetical).

case-control study generated by the EU Collaborative Study Group of CJD failed to confirm any plausibly significant nongenetic risk factors.^{10–12} Therefore, each case must be considered a *de novo* event that has no antecedent cause or subsequent links to any chain of infection.

CLINICAL FEATURES. The disease affects males and females equally and typically becomes manifest in late middle age. Peak incidence occurs in the 55- to 70-year-old age group, and the disease has a bell-shaped distribution curve that is skewed toward the younger age groups, including rare cases in adolescents (Fig. 43-3). Clinical features are to some extent related to the genotype of the “prion” gene, but such correlations have little practical

Figure 43-3. Age at onset of sporadic Creutzfeldt-Jakob disease (based on the NIH series of 232 experimentally transmitted cases).

utility apart from predicting longer or shorter survival times after the onset of illness.¹³ The earliest symptoms usually appear gradually over a period of weeks but can occur suddenly. They are limited to mental deterioration in approximately one third of patients, physical disabilities (especially incoordination) in another third, and mixed mental and physical abnormalities in the remaining third (Table 43-1). The frequencies of various symptoms at the onset of illness, at medical presentation, and at an advanced stage of disease are shown in Table 43-2. Memory loss and either cerebellar (Video 12, Dysdiadochokineses) or visual-oculomotor signs are comparatively frequent at the outset and, as the illness evolves, these are joined by pyramidal and extrapyramidal signs and a variety of involuntary movements, especially myoclonus (Video 50, Myoclonus in Creutzfeldt-Jakob Disease). A small number of patients present with sleep and autonomic disorders that mimic fatal

familial insomnia.¹⁴ Progressive mental deterioration terminates in mutism and global dementia. Death commonly occurs within 6 months of the onset of illness, but a significant proportion of patients have more acute courses of a month or two, and approximately 10% have an extended course of 2 or more years (Fig. 43-4). A number of factors have been shown to be associated with comparatively longer survival times, of which the most important are a younger age at onset of illness, heterozygosity at codon 129 of the prion gene, and a type 2a pattern of the misfolded protein when visualized by Western blots.¹⁵

This description applies to the great majority of patients, but the literature is replete with case reports illustrating unusual variations on the theme. Among these are sudden or stuttering onsets that suggest a cerebrovascular accident or multiple sclerosis and syndromes that span a range of appearances from the Wernicke-Korsakoff syndrome (Video 229, Wernicke's Encephalopathy) or bulbar palsy to parkinsonism or amyotrophic lateral sclerosis. All represent the extremes in a continuum of multisystem disease based on the topographically unpredictable cerebral pathology of spongiform encephalopathy.

LABORATORY EVALUATION. Three laboratory examinations are available as aids to diagnosis. The electroencephalogram (EEG) remains a useful and easily performed examination.¹⁶ Early in the course of illness, the EEG may be normal or may show only some background slowing, and terminally it may simply reflect a dying brain. However, in the fully developed phase of disease, most patients show some form of periodic activity (Fig. 43-5). In its most pathognomonic form, the one- or two-cycle per second slow-wave triphasic spiking activity resembles an electrocardiogram; less specific but still suggestive is a “burst-suppression” pattern in which short runs of high-voltage spikes alternate with periods of near electrical silence.

The second test is an immunological analysis of cerebrospinal fluid (CSF) to detect one or more brain-derived proteins that leak into the CSF as a result of neuronal cell death. Two proteins have proved especially valuable: a protein kinase inhibitor called 14–3–3 and τ protein. Although these proteins are structurally and biologically unrelated to the prion protein, the presence of elevated CSF levels of either 14–3–3 or τ protein has proved to have diagnostic sensitivity and specificity for CJD in the 90% range, when used in an appropriate clinical setting and when routine examination of the CSF is normal.¹⁷

The third test is magnetic resonance imaging (MRI), which has only recently been appreciated as a useful diagnostic procedure.^{18,19} Many patients with sporadic disease at some point in the course of illness show a symmetrical or sometimes unilateral hyperintense signal in the basal ganglia (Fig. 43-6). Nonspecific abnormalities may be seen in other types of radiographic imaging procedures, such as computed tomography scans, which are primarily useful in exploring alternative diagnoses.

None of these tests is 100% sensitive or specific, especially on clinical presentation, but each can provide a highly useful clue either for or against the diagnosis of CJD during the course of illness (Table 43-3). As such, these laboratory procedures have entirely eliminated the need for biopsy, except when there is reason to suspect an alternative treatable disease that cannot otherwise be diagnosed.

TABLE 43-2

Sporadic Creutzfeldt-Jakob Disease: Symptomatology of the NIH Series of 232 Experimentally Transmitted Cases

| Symptoms/Signs | Percentage of Patients With Symptoms or Signs | | |
|--------------------------|---|----------------------|---------------|
| | At Onset | On First Examination | During Course |
| Mental deterioration | 71 | 84 | 100 |

Figure 43-4. Duration of illness of sporadic Creutzfeldt-Jakob disease (based on the NIH series of 232 experimentally transmitted cases).

DIFFERENTIAL DIAGNOSIS. The spectrum of diseases with which spongiform encephalopathies can be mistaken is not surprising in view of the variable distribution of neuropathological changes found at autopsy. As always, the guiding principle in differential diagnosis should be the investigation of all potentially treatable diseases before winnowing through untreatable neurodegenerative alternatives.

From a practical standpoint, differential diagnosis can be separated into two categories: First and most important are diseases that can mimic the onset and early course of spongiform encephalopathy; the second category comprises

diseases that can be confused with later stages of the illness. In the first category are drug intoxications (bismuth, lithium, and cyclical antidepressives), infections (herpes simplex encephalitis, cryptococcal meningoencephalitis, and multiple cerebral abscesses), metabolic-endocrine disorders (hyperparathyroidism, Hashimoto's encephalitis, Wernicke-Korsakoff syndrome, and vitamin B₁₂ deficiency), cerebrovascular accidents, neoplasms, and normal pressure hydrocephalus. In the second category are Parkinson's disease with dementia, diffuse Lewy body disease, amyotrophic lateral sclerosis with dementia, progressive supranuclear

palsy, olivopontocerebellar atrophy, Huntington’s disease, Ramsay Hunt syndrome, Pick’s disease, and that most difficult of all differential diagnostic problems, Alzheimer’s disease. Diagnostic uncertainty sometimes cannot be resolved prior to necropsy.

MANAGEMENT, TREATMENT, AND PREVENTION. During hospitalization, “universal precautions” should be followed in managing the patient, including the handling and disposal of tissues, excretions, and other contaminated material.²⁰ Ordinary surface contact is not hazardous, but if

blood or spinal fluid is involved, the exposed area of the worker’s skin should be swabbed with bleach and then, after a minute or so, thoroughly washed with detergent and water. The golden rule is to avoid penetrating injury with anything that has penetrated the patient (e.g., needles), just as for patients with acquired immunodeficiency syndrome or hepatitis.

Despite early claims of clinical improvement in some patients with CJD who had been treated with the antiviral drugs amantadine or vidarabine, and, more recently, with quinacrine or intrathecal pentosan polysulfate, subsequent published and unpublished experience has failed to validate these successes. At best, only temporary pauses in the progression of disease occur. Thus, management of the patient with CJD is still limited to good nursing care and the suppression of myoclonus or seizures, if they occur, with a benzodiazepine or anticonvulsant. Like all patients who become progressively helpless and bedridden, death is usually the result of sepsis from respiratory, skin, or urinary tract infections or, when swallowing becomes difficult, from aspiration.

This poor prognosis may soon change because new tools for screening potentially useful chemicals and promising new immunotherapeutic strategies have ignited optimism that some form of preventive or at least palliative treatment may be within reach. Various polyanionic compounds, as well as randomly ordered “degenerate” oligonucleotides,

Figure 43-6. FLAIR magnetic resonance image (MRI) in normal individual (A) compared to patients with sporadic (B) or variant (C) forms of Creutzfeldt-Jakob disease. Hyperintense signals are seen in the basal ganglia in sCJD and in the putamen in vCJD. (Courtesy of Dr. Donald Collie, National CJD Surveillance Unit, Edinburgh, UK.)

significantly prolong the incubation period of scrapie-infected mice when given near the time of infection,²¹ and oral immunization with a salmonella vaccine genetically engineered to contain PrP has produced survivors in a group of subsequently infected rodents.²² The key issue is the requirement for any truly useful treatment to be effective in advance of symptomatic disease, which will depend on the availability of one or more of the several preclinical screening tests for infection that are currently under development.²³

FAMILIAL DISEASE

PATHOGENESIS AND PATHOPHYSIOLOGY. The molecular genetic basis for inherited disease resides in mutation-induced alterations in the primary amino acid structure of PrP that evidently facilitate its transition from an α helix to a β -pleated sheet configuration. If the magnitude of this facilitation were 1 millionfold, the 1 per million occurrence of sporadic disease would assume the appearance of a fully penetrant inherited disease linked to the mutation.

EPIDEMIOLOGY AND RISK FACTORS. Approximately 10% of cases of spongiform encephalopathy are familial and are associated with one of nearly 40 different insert and point mutations in the gene that encodes the amyloidogenic prion protein.^{24,25} Many of the mutations have been described in only single families, some have been found in several families, and three account for the majority of familial cases: These occur at codons 102 (GSS), 178 (CJD or FFI), and 200 (CJD). All are inherited in an autosomal dominant genetic pattern, and all are experimentally transmissible.

Like sporadic disease, familial disease affects men and women equally, but its temporospatial distribution is determined by the origins and migrations of affected families. All case clusters of spongiform encephalopathy have a familial basis—for example, those in rural Slovakia and among Sephardic Jews, whose migrations have created high-incidence pockets of disease in Israel, North Africa, and Chile (due to the Spanish Inquisition and subsequent diaspora). More typically, in the highly mobile world of today, familial cases are geographically scattered, and individual patients may have lost all contact with and knowledge of their ancestors, leading to the mistaken appearance of sporadic mutation-positive cases.

CLINICAL FEATURES. Familial disease can present as CJD, GSS, FFI, or atypical Alzheimer-like syndromes, depending on which of the mutations is present in the family^{24,25} (Table 43-4). For example, point mutations at codons 200 or 210 usually produce an illness that begins 5 to 10 years earlier but in other respects is indistinguishable from sporadic CJD, whereas repetitive octapeptide encoding insert mutations cause illnesses that may begin as early as the third or fourth decade of life and produce a very slowly evolving dementia that ends in death after a period of 10 to 15 years with little or no brain pathology. Other mutations can produce a wide spectrum of intermediate disease syndromes.

GSS typically begins in members of affected families between ages 40 and 55 years as a slowly evolving ataxia,

TABLE 43-4

Mutations of the Chromosome 20 “Prion” Gene Associated with Inherited Forms of Transmissible Spongiform Encephalopathy*

| MUTATION | DISEASE PHENOTYPE |
|---|----------------------------------|
| Octa-repeats: 1, 2, 4-9 insertions between codons 51 and 91 | CJD, GSS, or atypical dementia |

CJD, Creutzfeldt-Jakob disease; FFI, fatal familial insomnia. GSS, Gerstmann-Sträussler-Scheinker disease.

*Neuropathological description was not available, or PrP^{TSE} was not demonstrable, in dementia patients with mutations P105T, T188R, E196K, V230I, and Q160Stop, and thus the diagnosis of familial TSE remains unconfirmed.

sometimes with associated mental deterioration, and progresses through a multisystem array of symptoms, including dementia and myoclonus, finally terminating fatally after an average duration of 5 to 10 years. It is characterized neuropathologically by a profusion of multifocal amyloid plaques in the cerebellum, with or without spongiform change. The classic syndrome (including Gerstmann's original case) is associated with a mutation at codon 102, but variants of GSS have been described with mutations at other codons.

FFI is the most recently admitted member of the spongiform encephalopathy group and is unusual in that patients typically show early and pronounced autonomic and endocrine dysfunction, including intractable insomnia (often associated with daytime somnolence), and unexplained disorders of temperature, cardiovascular, and respiratory regulation.²⁶ Later in the course of the illness, more typical features of CJD supervene (pyramidal and extrapyramidal signs, cerebellar ataxia, and myoclonus), and death occurs after an average duration of 1 to 2 years. At autopsy, severe neuronal loss and astrogliosis are seen in the medio-dorsal and anterior ventral thalamic nuclei, with variable pathology in the neocortex. The disease is caused by a mutation at codon 178, but curiously, it occurs only when the mutant allele specifies methionine at polymorphic codon 129; when valine is specified by codon 129, the pathogenic codon 178 mutation produces a CJD-like phenotype.²⁷

From both diagnostic and genetic standpoints, it is important to remember that these clinical stereotypes have many exceptions, that significant phenotypic heterogeneity is the rule even among members of the same family, and that no matter what mutational phenotype is typical, at least one family member will usually have died from an illness that resembles sporadic CJD.

LABORATORY EVALUATION. In addition to the EEG, CSF, and MRI tests described for patients with sporadic disease, familial disease offers the possibility of identifying the causative mutation by molecular genetic analysis of DNA in the blood. Identification of the responsible mutation is not merely an academic exercise but has practical prognostic value for the patient's family. First, it permits a rough prediction of the duration of illness. Second, it can have a crucial impact in counseling about the risk of disease inheritance. For example, mutations at codons 200 and 210 are not fully "penetrant" during a normal life span so that although the mutation will be transmitted as an autosomal dominant trait, not everyone who carries the mutation will die from the disease.

MANAGEMENT, TREATMENT, AND PREVENTION. The care and outlook for patients with familial disease are no different from those for patients with sporadic disease; however, familial disease can be prevented in subsequent generations through the use of molecular genetic testing of amniotic fluid and elective therapeutic abortion of fetuses found to carry a lethal mutation.²⁸ This option should be carefully explained to family members for their ethical and medical consideration.

IATROGENIC DISEASE

PATHOGENESIS AND PATHOPHYSIOLOGY. When the infectious agent is accidentally introduced into the body, whether directly into the nervous system or by peripheral routes, the seed is sown for its replication and spread, and when infectivity and pathology in the brain have reached a sufficiently high level, the disease becomes symptomatic. The length of the incubation period between the infecting event and the onset of symptomatic disease ranges from approximately 2 years in cases in which infection is introduced directly into the brain to an average of nearly 15 years in those who are inoculated subcutaneously.

EPIDEMIOLOGY. The first case of iatrogenic disease was recognized in the early 1970s in a U.S. recipient of a corneal graft from a patient who was later discovered to have died from CJD. Soon afterward, two cases occurred in Swiss patients who had undergone stereotactic EEG with needles that had been previously used in a patient with CJD. A few years later, retrospective analysis of a series of British neurosurgical cases revealed that three of the patients had probably been infected by surgical instruments contaminated during a previous operation on a CJD patient. These few reports constituted the totality of iatrogenic disease until the past decade, when separate outbreaks of disease were traced to contaminated batches of pituitary hormones and dura mater grafts obtained from human cadavers. More than 400 cases of iatrogenic disease approximately equally divided between the two sources have been identified since 1985 (Table 43-5), but new

*Additional possible single cases following corneal transplant or keratoplasty (not listed in the table) occurred in Japan and the United States.

†Additional possible single cases due to hGH (not listed in the table) occurred in The Netherlands, Scandinavia, and New Zealand. Brazil and New Zealand hormone was prepared in the United States; Qatar hormone was prepared in France.

‡Donors with variant CJD.

TABLE 43-6

Clinical Features of Iatrogenic Creutzfeldt-Jakob Disease According to the Mode and Route of Infection

| MODE OF INFECTION | AGENT ENTRY INTO BRAIN | MEDIAN INCUBATION PERIOD (RANGE) | CLINICAL PRESENTATION |
|--------------------|------------------------|----------------------------------|------------------------------|
| Corneal transplant | Optic nerve | 16, 18, 320 mo | Dementia/cerebellar |
| Stereotactic EEG | Intracerebral | 16, 20 mo | Dementia/cerebellar |
| Neurosurgery | Intracerebral | 17 mo (12–28) | Visual/dementia/cerebellar |
| Dura mater graft | Cerebral surface | 11 yr (16 mo–23 yr) | Cerebellar (visual/dementia) |
| Growth hormone* | Hematogenous (?) | 15 yr (4–36) | Cerebellar |
| Gonadotrophin | Hematogenous (?) | 13 yr (12–16) | Cerebellar |
| Blood transfusion† | Hematogenous | 6.5 and 8 yr | Dementia/cerebellar |

*Median and range were 12 years (4–22) in France, 17 years (8–26) in the United Kingdom, and 21 years (10–28) in the United States.

†One of the three transmissions was discovered only by detection of the pathognomonic “prion” protein in spleen and lymph node at autopsy in a patient with neither neurologic symptoms nor brain pathology, who died from an unrelated disease 5 years after having received contaminated blood (i.e., in a preclinical or subclinical stage of CJD).

cases have radically diminished in recent years, and the few that still occur are the result of incubation periods of up to 30 years between exposure in the 1970s and 1980s and symptomatic disease.^{29,30}

CLINICAL FEATURES. Iatrogenic disease syndromes are significantly influenced by different routes of infection.²⁹ Introduction of the infectious agent into the brain parenchyma, directly or via the optic nerve, produces an illness that is in all respects similar to sporadic CJD (Table 43-6). Introduction of the agent into the brain by a peripheral route of infection (hormone therapy) produces a distinctively different illness that begins with ataxia and even in its later stages may not include significant mental deterioration; this syndrome is strongly reminiscent of kuru, which was also acquired through peripheral routes of infection. Application of the agent to the brain surface through dura mater grafts produces an illness with intermediate characteristics, comprising either prominent cerebellar/visual or demential features. The duration of illness is unrelated to the route of infection, and the disease runs a course similar to that of sporadic CJD.

LABORATORY EVALUATION. Periodic EEG activity has been seen in approximately half of all patients, and the CSF 14–3-3 protein is present in most patients in whom it has been examined. MRI studies have not been reported but would likely show the same features as sporadic CJD.

MANAGEMENT, TREATMENT, AND PREVENTION. Good nursing care and attention to symptomatic relief of movement disorders remain the only palliative measures available for these unfortunate victims of our own mistakes. The prevention of future episodes of iatrogenic disease is therefore an object of increasingly close scrutiny by physicians, research scientists, and government regulatory agencies.

In the past, neurosurgical instruments were subjected to not more than 15 to 20 minutes of steam autoclaving at 121°C; EEG needles were disinfected with benzene, ethanol, and formaldehyde vapor; pooled cadaveric pituitary tissue extracts were sequentially passed through glacial acetic acid, acetone, and dilute NaOH; and dura mater grafts were irradiated. We now know that none of these procedures can be fully guaranteed to inactivate the infectious agent. Therefore, the current recommendations are that all surgical instruments, irrespective of type of surgery, should be routinely autoclaved at 134°C for 20

minutes, and instruments used on any patient with CJD should not be re-used. Moreover, instruments used on any patient in whom CJD is suspected must be quarantined until the diagnosis is disproven and discarded if the diagnosis is proven. If an operation is performed on a patient in whom the diagnosis of CJD is not suspected but later shown to be correct, all of the instruments should be traced and either discarded or, if that is impractical by virtue of the sheer magnitude of potential cross-contamination, immersed in either undiluted bleach or 1 N NaOH for 1 hour and then washed thoroughly by hand and steam autoclaved at 134°C for at least 20 minutes.²⁰ The problem posed by expensive instruments that cannot withstand these harsh measures has still not been satisfactorily resolved, but a number of gentler inactivation procedures have been shown to be effective alternatives to bleach, NaOH, and autoclaving.^{31,32} Cadaveric pituitary extracts should be replaced by recombinant human growth hormone, and dura mater grafts should be replaced by synthetic or homologous nondural tissue grafts; if dura mater is considered preferable for surgical reasons, it should never come from an “undiagnosed” cadaver and always be processed with a 1 N NaOH immersion step. Renewed attention is being paid to other potential sources of infection from human-to-human transfers of tissue, tissue extracts, and blood or plasma derivatives; chemical, chromatographic, or filtration processing steps continue to be developed in order to minimize any potential contamination from biological products.

VARIANT DISEASE

EPIDEMIOLOGY. vCJD was first recognized in the United Kingdom in 1996, approximately 10 years after the BSE epidemic had begun,³³ and as of January 1, 2007, the number of cases had grown to 168, with 21 additional cases in France, 2 cases in Ireland, the Netherlands, and Saudi Arabia, and single cases in some other European countries and Japan (all of which have also experienced BSE outbreaks), as shown in Figure 43-7. Humans became infected with the agent that causes BSE through the consumption of beef products containing mechanically recovered meat that was pressure extracted from carcasses and often contained spinal cord and paraspinal ganglia in addition to residual muscle shards.³⁴

Figure 43-7. Chronology of bovine spongiform encephalopathy (BSE) and variant Creutzfeldt-Jakob disease (vCJD) outbreaks in the United Kingdom. *Dark bars*, BSE; *light bars*, UK cases of vCJD; *white bars*, non-UK cases of vCJD; SBO, ban on use of specified bovine offals (tissues with high infectivity); MBM, ban on mechanically recovered meat (containing crushed vertebral column with embedded paraspinous ganglia). *Short arrow* indicates period of maximum human exposure to BSE; *long arrow* indicates the probable mean incubation period.

The period of maximum exposure to BSE in the United Kingdom occurred in the mid-1980s before the ban on high-risk tissues was instituted, and the delay in the peak occurrence of vCJD clearly delineates an average incubation period of approximately 12 to 15 years, although it is likely that (like the iatrogenic CJD outbreaks) additional cases with increasingly longer incubation periods will continue to occur in the years to come. The delay in the appearance of non-UK cases reflects a delay in exposure to BSE in other countries as a result of importation from the United Kingdom of contaminated beef products and cattle. In particular, because of the magnitude of its UK imports, France may see many more cases in the years ahead. Also, because all cases have so far been homozygous at codon 129 of the prion gene, there is concern about the possibility that heterozygous individuals may have a significantly longer incubation period than the already affected homozygotes and may form a second wave of cases that has not yet begun.

In three instances, patients with orally acquired disease have transmitted infection via blood transfusions,³⁵⁻³⁷ causing much concern in the blood donor/recipient communities, as well as in government regulatory circles. Most countries have put into motion programs of blood donor deferrals of individuals with specified lengths of residence in the United Kingdom (and, in some cases, other European countries) or who have received blood or blood products from individuals in the United Kingdom. Plasma products are considered to pose a negligible risk because of experimental evidence indicating large reductions of infectivity by one or more of the processing steps used in their manufacture.

CLINICAL FEATURES. The most distinctive feature of vCJD is the young age at onset of illness (Fig. 43-8), which averages 28 years, with many adolescents but only occasional adults older than 50 years of age. The clinical presentation is also unusual in that the patient often has some form of psychiatric disturbance and complains of sensory symptoms, particularly limb pain (Table 43-7). However, symptoms more typical of early sporadic CJD (mental deterioration, incoordination, and visual complaints) may also be present at the outset, and as the illness progresses, the clinical distinction between the sporadic and variant forms of illness becomes progressively blurred.^{38,39} Nevertheless, the combination of psychiatric and sensory symptoms in an adolescent or young adult is enough to raise a suspicion of vCJD in patients who reside or have resided in countries in which BSE occurred. The average duration of illness is 14 months, or approximately twice as long as that of sporadic CJD (Fig. 43-9).

LABORATORY EVALUATION. Periodic EEG activity has not been seen in any of the UK cases of vCJD, and the CSF 14-3-3 protein test has been positive in only approximately half of the patients. However, the MRI has become an extremely valuable examination⁴⁰ because approximately 90% of cases examined with T2 diffusion-weighted or fluid attenuated inversion recovery (FLAIR) imaging show bilateral hyperintensity in the posterior thalamus (pulvinar), as opposed to the lower frequency of basal ganglia hyperintensity seen in sporadic disease (see Fig. 43-6). One other interesting and so far unexplained feature of vCJD is its restriction to individuals with a homozygous methionine-coding genotype at polymorphic codon 129 of the prion protein gene. However, alternative

Figure 43-9. Comparison of duration of illness of all cases of sporadic (sCJD) and variant Creutzfeldt-Jakob disease (vCJD) in the United Kingdom during the period 1994 to 2004. (Data courtesy of Dr. Robert Will, National CJD Surveillance Unit, Edinburgh, UK.)

TABLE 43-7

Clinical Features of Variant Creutzfeldt-Jakob Disease

| SYMPTOM OR SIGN | PERCENTAGE OF PATIENTS | |
|-----------------------|------------------------|--------|
| | Onset | Course |
| Mental | 17 | 100 |
| Psychiatric | 66 | 98 |
| Incoordination | 9 | 98 |
| Visual/oculomotor | 0 | 34 |
| Sensory | 19 | 70 |
| Pain | 13 | 38 |
| Involuntary movements | 4 | 94 |
| Myoclonus | 0 | 70 |
| Akinetic mutism | 0 | 49 |

genotypes could conceivably have longer incubation periods and only begin to appear in future cases, as suggested by the asymptomatic (pre- or subclinical) infection in a heterozygous recipient of blood from a patient with vCJD. Neuropathological examination (without which a definitive diagnosis cannot be made) reveals diffuse spongiform changes that are especially severe in the basal ganglia, posterior thalamus, cerebellum, and myriad amyloid plaques

surrounded by halos of vacuolation—so-called “florid” or “daisy” plaques.⁴¹

MANAGEMENT, TREATMENT, AND PREVENTION. The management, treatment, and prevention of vCJD are similar to those of other varieties of TSE. Long-term ventricular infusion of pentosan polysulfate is being used in several patients in the United Kingdom, with uncertain results.⁴²⁻⁴⁴

DEFINITIONS AND HISTORY

In 1981, the Centers for Disease Control and Prevention (CDC) reported the occurrence of *Pneumocystis carinii* pneumonia (PCP) in five Los Angeles homosexual men. Within months of this report, clusters of similar cases of young, previously healthy homosexual men, who had developed unusual neoplasms and unexplained opportunistic infections, were reported in New York and California. The disorder, which had the clinical and immunological hallmarks of a cell-mediated immunodeficiency (development of opportunistic infections, depressed numbers of circulating T helper cells, with “reversed T4/T8 ratios”), was termed the gay related immune deficiency (GRID) syndrome. By the following year, the same syndrome complex was recognized in recipients of blood or blood products (mostly hemophiliacs) and in Haitians. Soon thereafter, other high-risk groups were identified, namely men and women intravenous drug users and women whose only risk factor was sexual contact with men who were intravenous drug users, bisexuals, or both. These women's children were also a high-risk group. The disorder was renamed the acquired immunodeficiency syndrome (AIDS). Its epidemic nature was appreciated as increased numbers of cases were identified from specific geographic regions in the United States, Europe, and Africa. It was also appreciated that transmission of the disorder was from sexual contact, via mother to infant, or through blood-borne mechanisms. At that time, the agent was thought to be most likely a virus that could survive the processing of blood factor VIII.

The etiological agent of AIDS, a retrovirus, was isolated in 1983¹⁻³ and named the human immunodeficiency virus (HIV) in 1986.⁴ Once the agent was identified, studies confirmed the presence of HIV in sera that had been collected in central Africa in 1959 and the United States in 1968. However, it was not until the early 1980s that HIV-1 infec-

tion began to reach epidemic proportions. Since then, the epidemic has expanded relentlessly. From its beginning until December 2001, an estimated 66 million people worldwide have been infected with HIV-1.⁵

As a matter of definition, all individuals with AIDS are necessarily infected with HIV. However, patients with HIV infection do not qualify for classification as having AIDS unless certain criteria are fulfilled (Table 44-1). In certain settings (i.e., pediatric cases), the actual demonstration of HIV infection per CDC definition is not required for the diagnosis of AIDS (see Table 44-1).

Nervous system involvement complicating the course of AIDS was recognized in the very early years of the epidemic. In fact, the first reports of neurological complications appeared when the disorder was still termed GRID and thought to be restricted to homosexual males. Initially, in adults, neurological complications were believed to be caused strictly by central nervous system (CNS) opportunistic infections and neoplasms as a consequence of the immunodeficiency.⁶ However, in 1985, distinct primary HIV-1-associated neurological disorders, unrelated to secondary infections or neoplasms, were described. In that same year, HIV-1 was isolated from brain, spinal cord, cerebrospinal fluid (CSF), and peripheral nerves.^{7,8} Between 1985 and 1988, further evidence from clinical, virological, and neuropathological studies indicated that neurological impairment in HIV-1-infected patients, referred to as AIDS-dementia complex in adults⁹ and AIDS encephalopathy/progressive encephalopathy in children,¹⁰ was associated with primary HIV-1 CNS infection. These studies included the following: (1) recovery of ribonucleic acid (RNA) and deoxyribonucleic acid (DNA) from the brain, (2) demonstration of intrathecal synthesis of anti-HIV antibodies, (3) localization of HIV-1 antigen in brain macrophages and monocytes by immunocytochemistry, (4) identification of viral particles within multinucleated giant cells and macrophages by electron microscopy, and

PGL, persistent generalized lymphadenopathy.

(5) demonstration of increased levels of HIV-1 DNA in the brain compared with other organs by Southern blot analysis.^{11–16} HIV-1 was also shown to belong to the lentivirus subfamily of retroviruses. In 1987, HIV/AIDS encephalopathy was recognized by the CDC as a major complication of HIV-1 infection and designated as one of the AIDS-defining conditions (i.e., a condition specific enough to diagnose AIDS in the context of documented HIV infection).¹⁷

It is now well recognized that neurological disease at every anatomical level is a common complication of HIV-1 infection, and neurological symptoms and signs may be the initial manifestation of HIV/AIDS.^{18,19} Primary HIV-1-associated clinical syndromes are diverse and can occur not only at the onset but also at other times during the

course of infection. For example, a self-limited “aseptic meningitis”²⁰ may occur soon after initial infection, as may an acute encephalopathy,²¹ myelopathy,²² or neuropathy. During the next stage of HIV-1 disease (mild immune dysfunction), neurological complications such as “aseptic” meningitis, inflammatory demyelinating polyradiculopathy, myopathy, or zoster radiculitis may occur. With advancing HIV-1 disease (moderate to severe immunodeficiency), signs and symptoms of cognitive dysfunction, dementia, myelopathy, sensory neuropathy, and myopathy become more prevalent, as do nervous system opportunistic infections and neoplasms.²³

In general, neurological involvement becomes increasingly more frequent with progression of HIV-1 disease;

as the immunodeficiency worsens, the prevalence of associated neurological disorders increases. This chapter first presents a review of HIV, an overview of the virus's general role in disease, and the clinical criteria for AIDS. This is followed by a detailed account of HIV-1-related neurological disorders and a brief summary of the neurological malignancies and opportunistic infections that occur in the setting of AIDS.

HUMAN IMMUNODEFICIENCY VIRUS: BIOLOGY AND GENERAL MEDICAL OVERVIEW OF SEROCONVERSION AND EARLY INFECTION

PATHOGENESIS AND PATHOPHYSIOLOGY. HIV-1, the etiological agent of AIDS, is a non-oncovirus RNA retrovirus that belongs to the lentivirinae genus of the Retroviridae family. Lentiviruses are species specific, contain RNA genome and reverse transcriptase, and have long periods of clinical latency and mechanisms to evade immune clearance. They target specific organs and cause persistent infection and multisystem disease in their natural hosts. Lentiviruses characteristically cause neurological disease. There are two distinct types of human AIDS viruses, HIV-1 and HIV-2, which are distinguished on the basis of their genome organizations and phylogenetic (i.e., evolutionary) relationships with other primate lentiviruses. Both have been further subclassified on the basis of phylogenetic criteria. Current data indicate that HIV-1 comprises three distinct virus groups (termed M, N, and O), with the predominant M group consisting of 11 classes, denoted subtypes A through K.²⁴ Similarly, HIV-2 strains infecting humans have been found to comprise six distinct virus groups (termed A through F).²⁴ Reconstruction of the phylogenetic relationships among the many strains of HIV-1 and HIV-2, as well as related viruses from African primates, has elucidated the simian origins of AIDS as well as factors that contributed to the beginning of the AIDS epidemic.

HIV-1, as other human retroviruses, is an enveloped virus containing RNA genomes of positive polarity. Structurally, HIV-1 is similar to other retroviruses (Fig. 44-1). There are two copies of the single-stranded RNA and

reverse transcriptase (RNA-dependent DNA polymerase) in the central cylindrical core, which also contains four nucleocapsid proteins—p24, p17, p9, and p7. The nucleoprotein core is surrounded by a lipid bilayer membrane. The viral genome encodes for two classes of proteins: structural and regulatory. Three major segments code for the structural proteins: GAG (the internal core protein), POL (the polymerase), and ENV (the envelope protein complex) (Fig. 44-2). These are situated in a left-to-right 5'-to-3' order. The GAG gene encodes the internal core proteins of the virion particle (p24). The POL gene encodes the polymerase reverse transcriptase, a ribonuclease that copies the viral RNA into DNA, a ribonuclease (RNase H) that degrades the viral RNA once an initial DNA copy has been synthesized, and an endonuclease (integrase) that is responsible for integration of the DNA copy into the host cell genome. POL also encodes a protease that is required for the processing of the mature GAG and POL products from their polyprotein precursors during virion assembly. The ENV gene codes for the surface envelope glycoprotein gp160, which is cleaved into two major glycoproteins, gp120 and gp41. Gp120 forms surface spikes on the virion, and gp41 is a transmembrane glycoprotein. They mediate binding of the virus to the host target cell. Long terminal repeats are situated at each end of the retroviral genome and are involved in the regulation of viral expression and the initiation and termination of viral RNA transcription.

In general, retroviruses capable of replication contain only three genes (GAG, POL, and ENV). However, the viral genome of HIV-1 is more complex and contains additional genes for regulatory proteins. There are at least six genes (TAT, REV, NEF, VIF, VPU, and VPR) that regulate viral gene expression and are essential for virus replication. TAT, a transcriptional activator, stimulates the synthesis of HIV messenger RNAs early in the viral life cycle. REV modulates the pattern of viral RNAs expressed in infected cells, such as splicing and transport, and allows ordered production of viral proteins during the virus life cycle. The genes termed VIF, VPU, VPR, and NEF encode products that enhance the ability of the virus to productively infect host target cells and maximize the efficiency of viral replication. It is believed that the actions of these

Figure 44-1. A schematic depiction of the HIV-1 virion. Virion protein components of the envelope and nucleocapsid are indicated. (Modified from Greene WC: The molecular biology of human immunodeficiency virus type 1 infection. *N Engl J Med* 1991;324:308–317.)

Figure 44-2. HIV-1 genomic structure. (Modified from Staprans SI, Feinberg MB: Natural history and immunopathogenesis of HIV-1 disease. In Sande MA, Volberding PA [eds]: The Medical Management of AIDS, 5th ed. Philadelphia, Saunders, 1997, pp 29–55.)

“additional” genes contribute to HIV-1’s pathogenicity. Products of the TAT, REV, VPR, and NEF genes are neurotoxic.

The outer envelope of HIV-1 is derived from the host cell lipid bilayer during viral budding, when viral glycoproteins (coded by the ENV gene) are inserted. Electron microscopy has revealed that the HIV virion has an icosahedral structure containing 72 external spikes. These envelope spikes are responsible for binding to the receptor on the host cell and are important for cellular entry. They are composed of two components, gp120 and gp41. Gp120, the external protein, contains the receptor-binding determinants of the virus. The transmembrane protein, gp41, serves to anchor the envelope glycoprotein complex at the surface of the viral lipid bilayer and is responsible for cell entry through fusion with the cell membrane. The HIV-1 lipid bilayer also contains host proteins, including class I and class II histocompatibility antigens acquired during viral budding. Once within the cytoplasm of the host cell, the envelope of the virus is shed, its contents are released, and reverse transcription occurs. Reverse transcriptase enables the transcription of DNA from genomic RNA (contrary to the conventional informational flow from DNA to RNA to protein). The provirus DNA is then integrated into the host cell’s DNA, where it may replicate, remain latent, or replicate at a restricted rate. When activated, the proviral DNA transcribes genomic and messenger RNA (Fig. 44-3). After the viral proteins are synthesized, new virions are assembled. Two DNA microarray studies have illustrated a remarkably broad-based perturbation in host transcriptional responses, which is in part mediated by the HIV-encoded NEF protein. HIV therefore seems to function as a “master regulator” of cellular gene expression.²⁵ The virus matures by budding from the surface of cells or into vacuoles within the cells.²⁶

HIV-1 targets, infects, and damages cells that have critically important functions in the host immune response. CD4 receptor is the principal target site for HIV. This target cell preference results from the high-affinity binding

of HIV-1 gp120 to the receptor molecule, CD4, which is used by HIV-1 during the initial stages of virus infection of host cells. Human CD4⁺ T lymphocytes, monocytes/macrophages, and dendritic cells are the major cellular targets of HIV-1 infection in vivo.²⁷ Macrophages are an important reservoir of infection, including the microglia in the brain.²⁸ Dendritic cells bind HIV through DC-SIGN receptors and carry it from mucosal ports of entry to the lymph nodes, where they activate lymphocyte infection.²⁹ Based on the target cell preference, HIV-1 strains have been divided into T-tropic, which replicate in T lymphocytes, and M-tropic, which replicate in macrophages.

The CD4⁺ T cell molecule is essential in interactions between helper-inducer T lymphocytes and antigen-presenting cells. It facilitates efficient recognition of antigens by CD4⁺ T cells, an obligate step in the generation of host immune responses. CD4⁺ lymphocytes serve as both essential regulators and effectors of the normal immune response. For example, they are involved in activation of macrophages, induction of cytotoxic T lymphocyte function, natural killer and suppressor cell function, induction of B cells (dysfunction of which leads to impairment of the humoral arm of the immune system), growth and differentiation of lymphoid cells, regulation of hematopoietic colony stimulating factors, and other factors inducing nonlymphoid cell function. It is noteworthy that the CD4⁺ molecule is expressed at a very early stage of T cell development, even on immature thymic T cells. Therefore, CD4⁺ T cells appear to be susceptible to HIV-1 infection and consequent destruction at essentially all stages of differentiation. The progressive loss of these critically important cells and basic components of the immune system ultimately leads to development of the profound immunodeficiency characteristic of advanced HIV-1 infection and eventually AIDS. In addition to the CD4 receptors, specific chemokine receptors have been shown to serve as important secondary cellular receptors, which guide the viral envelope glycoproteins into a specific conformation that allows membrane fusion and viral entry into the cell.^{30,31} T-tropic strains use CD4 receptor and

Figure 44-3. RNA interference susceptible targets in the HIV-1 replication cycle. (Reproduced with permission from Stevenson M: Dissecting HIV-1 through RNA interference. *Nature Rev Immunol* 2003;3:851–858.)

chemokine CXR4 or fusin, whereas M-tropic strains use chemokine CCR5 receptor.³² Interestingly, a genetic variant of CCR5, Delta32, has been found to be protective against HIV infection and to delay disease progression.

Even though most researchers agree that HIV induces both quantitative and qualitative defects in the CD4⁺ T cell compartment, it is still not known how, *in vivo*, the virus destroys CD4⁺ T cells. In addition, it is not known whether cell loss is due to direct destruction by the virus or to some other, indirect factors.³³ Most researchers agree that HIV infection results in progressive loss of CD4⁺ T cells from the circulation as well as depletion of CD4⁺ T cells from total body stores. The normal young adult harbors approximately 2×10^{11} mature CD4⁺ T cells.³⁴ In the HIV-infected patient, the total number is halved by the time the peripheral blood CD4⁺ T cell count falls to 200 cells/mL.^{34,35} In more advanced disease, destruction of parenchymal lymphoid spaces is so extensive that counting of CD4⁺ T cells has not even been attempted. With disease progression, there is also a decrease in the proportion of quiescent, naïve T cells and an increase in the proportion of activated, memory/effector T cells.³⁶ Among those cells that persist, many may be dysfunctional.³⁷ Hence, the circulating CD4⁺ T cell count is very imprecise. However, it is still one of the best surrogate markers used to initiate treatment and to determine the prognosis late in infection.

Despite the enormous wealth of information accrued during the past decade concerning molecular properties and actions of the retrovirus, many fundamental questions remain concerning immunopathogenetic events. The following overview traces some of the major events once HIV-1 is transmitted to the host (Fig. 44-4). In-depth reviews that discuss postulated HIV's virological and

immunological mechanisms have been published.^{38–40} The virus, free or within cells, enters the blood or lymphatic vessels and is delivered to lymphoid tissue. It is suggested that macrophages may be the first target cell of HIV-1 early after invasion. Macrophages deliver HIV-1 to lymph nodes and other lymphoid tissue and may serve as a reservoir for HIV-1. A selection of HIV-1 strains may occur during this acute infection stage. Studies of HIV-1 isolates from donor-recipient transmission pairs show that donors have heterogeneous viral populations. In contrast, viral isolates from the newly infected person are predominantly homogeneous in their envelope sequences and these viruses are mainly M-tropic.⁴¹

HIV-1 then enters the lymphoid tissue and an active immune response is mounted. A preferential infection of cells that are responding to or are proliferating in response to antigenic stimulation occurs. This leads to new cycles of HIV-1 replication and target cell infection.⁴² Viral spread occurs to T cells and macrophages, and during the weeks after the initial infection, more cells are infected and more are lost. There is an increase in viral burden and an associated decline in the CD4⁺ lymphocyte counts. At this point, some individuals may develop symptomatic acute primary infection with both systemic and neurological signs (see later discussion). It is believed that a host immune response, cell-mediated and humoral, is mounted and controls the infection to some degree. Clinical symptoms of the acute illness resolve, and the amount of virus in peripheral blood declines. Monocytes, macrophages, and follicular dendritic cells are able to foster viral replication without cell death. These cells may serve as a reservoir for the retrovirus, allowing transport and dissemination (and possibly persistent infection) of the virus to nonlymphoid

Figure 44-4. HIV-1 natural history. (Modified from Staprans SI, Feinberg MB: Natural history and immunopathogenesis of HIV-1 disease. In Sande MA, Volberding PA [eds]: *The Medical Management of AIDS*, 5th ed. Philadelphia, Saunders, 1997, pp 29–55.)

tissues such as the brain and other organ systems with subsequent development of organ-specific HIV-1-related disorders. For example, HIV-1 infection of gut epithelium may contribute to the diarrhea-wasting syndrome seen commonly in patients with more advanced HIV-1 infection, whereas infection of bone marrow progenitor cells may contribute to hematological abnormalities observed clinically in symptomatic HIV-1-infected patients. HIV-1 infection of these diverse organ cells may not be mediated by the CD4⁺ receptor but by others, such as the glycolipid galactosylceramide.

HIV seeds the meninges and CSF early during the course of infection.⁴³ Viral load is distributed unequally in the brain, mostly concentrating in the hippocampus and basal ganglia (caudate and globus pallidus), correlating with the clinical symptoms of HIV-associated dementia.⁴⁴ However, absolute brain viral load does not correlate well with the presence of HIV-associated dementia and the exact mechanisms by which HIV-1 infection leads to dementia are not understood. HIV-1 free viral particles, as well as infected monocytes, penetrate to the brain tissue through the disrupted blood-brain barrier, most likely due to the dysfunction of endothelial cells and changes in the basal lamina proteins, such as laminin, entactin, and collagen.⁴⁵ In addition, some viral proteins may be transported to the brain even through the intact blood-brain barrier, as was shown for TAT.⁴⁶ Both CD4 receptors and chemokine receptors CCR5 and CCR3 have been implicated in viral entry of HIV-1 M-strains into the brain microglial cells,³¹ which then undergo a productive infection, syncytial for-

mation, and cell death. In addition to the infection of microglia, HIV-1 infects astrocytes, mostly by T-tropic strains.⁴⁷ The mechanism is not known because astrocytes lack both CD4 and cytokine receptors. The HIV-1 infection of astrocytes behaves differently than infection of microglial cells. Initially, the virus undergoes a productive infection, but then it enters a latent phase and does not cause cell death.⁴⁷ It practically stays in astrocytes indefinitely, escaping all antiretroviral agents.

After the acute symptomatic or asymptomatic primary infection, there is a period of clinical latency. Patients enter a chronic clinically asymptomatic or minimally symptomatic period. Studies show that even during the clinically “latent” period of disease there is a high rate of viral expression and replication in lymphoid tissue.⁴⁸ In the stage of early and intermediate HIV-1 disease (Table 44-2), the greatest concentration of HIV-1-infected cells is still found in the lymphoid organs (lymph nodes, adenoids, tonsils, and spleen). However, there is involvement of nonlymphoid tissues as well.⁴⁹ A very dynamic pattern of HIV-1 replication and turnover may occur. Ho and colleagues⁴⁸

TABLE 44-2

Stages of HIV-1 Disease as Related to CD4⁺ Count

| | |
|------------------------------|-----------------------------------|
| Early HIV-1 infection | CD4 ⁺ ≥ 500 cells/µL |
| Intermediate HIV-1 infection | CD4 ⁺ 200–500 cells/µL |
| AIDS | CD4 ⁺ ≤ 200 cells/µL |

estimated that approximately 1 billion new virions are produced daily, with replication occurring in lymphoid tissue. At the same time, approximately 1 to 2 billion new CD4⁺ cells are produced. Persistence of virus in lymphoid tissue can cause chronic stimulation of the immune system.⁵⁰ This may lead to dysfunction and destruction of the responding T cells. Even before the occurrence of a marked decline in CD4⁺ cell numbers, specific defects in T cell function can be noted. The effect on the immune system is widespread, affecting multiple aspects of lymphocytic function, the interaction of T cells with antigen-presenting cells, and disruption of lymphoid tissue architecture.

As CD4⁺ lymphocytes are lost as a result of virus-induced damage, the host's immune system attempts to compensate for depleted T cells by producing more cells, which become infected. It is hypothesized that homeostatic mechanisms exist to maintain a "normal" T cell count. This hypothesis implies that the selective loss of CD4⁺ cells will induce production of both CD4⁺ and CD8⁺ cells in order to maintain homeostasis of T cell number (referred to as "blind homeostasis"). CD4⁺ and CD8⁺ cells continue to be produced to maintain the total lymphocyte count as CD4⁺ cells are lost. This results in CD4⁺ cell lymphopenia and CD8⁺ lymphocytosis.⁵¹ CD8⁺ lymphocytosis may in itself cause symptomatic complications. Approximately 18 months before the development of AIDS, this mechanism breaks down, resulting in lymphopenia. An increase in the rate of loss of CD4⁺ lymphocytes and perhaps in the appearance of more virulent viral phenotypes heralds the progression to AIDS.⁵²

Humoral immunity is much less effective than cellular responses in controlling HIV-1 viremia. The remarkable efficiency of the HIV-1 virus to evade host antibody responses has been a major challenge for the development of a protective and effective HIV vaccine.⁵³

Regarding the pathophysiology of HIV-1 infection in children, a bimodal evolution of disease progression is noted (see later discussion). Infants with rapid disease progression (the first form) have high levels of detectable virus at birth and manifest severe clinical symptoms and immunological abnormalities within the first years of life. Some of these infants may lack anti-HIV-1 antibodies. This rapidly progressive course may reflect the effects of HIV-1 on the developing fetal thymus and immune system. In some cases, however, high levels of viral expression are found with normal CD4⁺ cell counts, suggesting that in this subset of children, early HIV-1 thymic infection may be impaired, resulting in immunological tolerance.

In children with slowly progressive disease (the second form), there is the occurrence of more frequent and severe infections with common childhood pathogens followed later by opportunistic infections. Although the principal target of HIV-1 is the human peripheral blood CD4⁺ T lymphocyte, in children one of the first immunological abnormalities is impairment of B cell function. This is manifested by polyclonal hypergammaglobulinemia, spontaneous B cell proliferation, and increased *in vitro* spontaneous production of immunoglobulin. The development of polyclonal hypergammaglobulinemia may also be noted in adults.⁵⁴ Although the quantity of immunoglobulins is elevated, there are diminished *in vivo* vaccine responses to both T cell-dependent and T cell-independent antigens, as

well as decreased responses to B cell mitogens.⁵⁵ *In vitro* studies demonstrate diminished lymphocyte proliferation to B cell mitogens. The decreased antibody responses predispose these infants and children to serious bacterial infections, which at times may be overwhelming. The B cell activation may also result in polyclonal polymorphic B cell lymphoproliferative disorders, such as lymphoid interstitial pneumonitis, parotitis, and unusual B cell-related complications such as B cell lymphomas. Increased production of autoantibodies may also result from B cell dysfunction. Circulating immune complexes, antinuclear antibodies, antibody to double-stranded DNA, red cell antibodies, and antiplatelet antibodies have been reported.

EPIDEMIOLOGY AND RISK FACTORS. HIV-1 predominates throughout the world, whereas HIV-2 accounts for a minority of cases confined to West Africa. Both are transmitted either by sexual contact, parenteral exposure to blood, blood products, or body fluids or from mother to infant. In the United States, western Europe, Australia, and in some Latin American countries, the majority of AIDS cases were initially among men infected through sexual contacts with other men. In the United States, the proportion that this group now represents has declined from approximately 72% in 1986 to 53%.⁵⁶ It is estimated that 75% of HIV-1 infection worldwide is the result of heterosexual transmission. Heterosexual transmission predominates in sub-Saharan Africa, the Caribbean, Southeast Asia (Thailand), and India. In the United States, the number of women with heterosexually acquired infection continues to rise.

In the United States, western Europe, and Latin America, intravenous drug use (sharing of contaminated needles/equipment) was and remains a significant risk factor for transmission.⁵⁷ Approximately 24% of AIDS cases in the United States are related to intravenous drug use. Iatrogenic spread of infection by the reuse of contaminated needles is also reported.⁵⁸ Since HIV-1 donor blood screening has been instituted, transfusion-acquired HIV-1 infection is rare in developed countries, but it still occurs and accounts for a proportion of cases in undeveloped nations. Overall, in the United States, transfusion recipients and hemophiliacs represent less than 2% of cases.⁵⁹

Maternal-to-infant transmission can occur *in utero*, during labor and delivery, or postnatally by breast-feeding.⁶⁰ Both the risk factors of mother-to-infant transmission and its timing are under active investigation. *In utero* transmission before 20 weeks of gestation is well documented. However, evidence suggests that transmission during the third trimester and at parturition may be most common.⁶⁰⁻⁶⁴ The rate of mother-to-infant infection is estimated at approximately 25% (range, 13% to 45%).⁶⁵ Maternal factors reported to be associated with increased risk of transmission include low CD4⁺ counts, high viral titers, advanced primary HIV-1 disease, AIDS, placental membrane inflammation, premature rupture of membranes, premature delivery, increased exposure of the infant to maternal blood, and low vitamin A.^{58,60,61,66,67}

The epidemiology of HIV and AIDS has fluctuated during the past two decades. Currently, an estimated 40 million people worldwide are living with HIV, and at least 20 million people have already died, resulting in a cumulative total number of HIV infections of 66 million.⁵ The worst of the epidemic is in sub-Saharan Africa, where, at

the end of 2000, there were an estimated 25.3 million people living with HIV. Sub-Saharan Africa has accounted for approximately three-fourths of the global death toll. There, HIV-1 transmission continues to be dominated by heterosexual sex, together with a significant level of mother-to-child transmission. Reports from the Joint United Nations Programme on HIV/AIDS (UNAIDS) show HIV spreading rapidly in other areas as well, including areas of China, eastern Europe, and central Asia. By the end of 2001, there were an estimated 2.7 million children younger than 15 years of age living with HIV, more than 90% of whom acquired infection from their mother.⁶⁸ Another tragic consequence of the epidemic is the increasing numbers of “AIDS orphans” (children younger than 15 years of age who have lost one or both parents to AIDS). By 2010, 25 million children are projected to be orphaned as a result of HIV/AIDS (www.UNAIDS.org). Therefore, despite the stabilization of the HIV epidemic in the developed world, the number of affected individuals continues to increase.

In the developed countries, the epidemic changed due to initiation of the highly active antiretroviral therapy (HAART). During 2000, an estimated 30,000 adults and children became infected with HIV in western Europe and 45,000 in North America, bringing the total number of those living with HIV in these regions combined to 1.46 million. In recent years, an estimated 40,000 new cases have been diagnosed in the United States each year, indicating a slight decline in the number of new cases. During 2001, 5 million people were newly infected with HIV-1 worldwide; 1.8 million were women and 800,000 were children; approximately 2000 HIV-1-infected infants were born per day.⁶⁸ Persistent incidence at relatively low levels during the past decade has combined with longer survival.⁵⁹ UNAIDS provided a comprehensive review of the HIV/AIDS epidemic worldwide, with detailed distribution of the disease as well as predominant ways of transmission, which differ in different continents and countries.⁶⁸

Although adolescents comprise only approximately 1% of total AIDS cases in the United States, approximately 20% of total AIDS cases are in the young adult age group (up to 29 years of age). Given that it may take approximately 10 years between infection with HIV-1 and the onset of symptoms, it can be assumed that many of these people were infected as adolescents. In fact, it is estimated that at least 50% of the worldwide HIV-1 population were infected between ages 15 and 24 years.⁶⁹ In the United States and Europe, transfusion-acquired HIV-1 infection had been the most common cause of adolescent HIV-1 infection. However, since HIV donor blood screening has been instituted, the percentage of all cases that this group now represents has declined. Currently, the most common risk factors for adolescents include sexual exposure and intravenous drug use.⁵⁸ It is estimated that approximately 65% of adolescents ages 13 to 19 years and 90% of 20- to 24-year-olds with AIDS were infected through these means.^{69,70} Because of improved medical management and the differential natural history of pediatric AIDS, an increasing number of vertically infected children are living into adolescence and even young adulthood. It is anticipated that the percentage that this group represents will continue to increase as more effective therapies for HIV-1 and its associated disorders lengthen survival.

CLINICAL FEATURES AND ASSOCIATED DISORDERS.

Within 2 to 6 weeks after HIV-1 infection, virus can be detected in the blood (see Fig. 44-4).⁷¹ Primary HIV-1 infection may be associated with constitutional, dermatological, gastrointestinal, as well as neurological signs and symptoms (Table 44-3). A self-limiting acute viral syndrome (fever, myalgia, arthralgia, lymphadenopathy, maculopapular rash, and aseptic meningitis [see later discussion]) is described in a subset of patients a few weeks after primary infection and may last 1 or 2 weeks.⁷² The HIV-1 rash is characterized as an erythematous, nonpruritic, maculopapular rash that is symmetrical, may affect the face or trunk with or without involvement of the palms and soles, or may be generalized. Lesions may be 5 to 10 mm in diameter. Other patients are asymptomatic. Factors determining if a newly infected person will develop symptomatic primary infection are not clearly defined. Inoculum size, immunological state of the individual, transmission of HIV-1 from a person with late-stage disease, possibly viral strain differences, and other host factors may be important variables. It is suggested that those people who are symptomatic with the acute retroviral syndrome (especially those with symptomatic disease lasting more than 2 weeks), those with neurological signs and symptoms, or those who acquired HIV-1 from a person with late-stage disease may be more likely to have more rapid disease progression than those without these early symptoms.⁷³ Clinical and laboratory features at the time of acute primary HIV-1 infection may also portend the subsequent course of disease.⁷³ Thrush, persistent fever, diarrhea, weight loss, oral hairy leukoplakia, cutaneous herpes zoster, and age older than 35 years during this early phase of infection appear to be associated with more rapid disease progression.⁷⁴ Virological markers include infection with the SI strain of virus, persistent p24

antigenemia, and high HIV RNA viremia after seroconversion. Immunological features that may have adverse prognostic significance include low p24 antibody titers, high gp120 antibody titers, the presence of specific anti-HIV-1 IgM and IgA antibodies after infection, persistent low CD4⁺ lymphocyte count, high CD38 expression on CD8⁺ lymphocytes, and an oligoclonal T cell response.

Within 6 months of infection, most infected people have detectable levels of anti-HIV antibodies.⁷⁵ A stage of clinical latency follows. Signs and symptoms of progressive immune dysfunction or of HIV-1 generally develop from 6 months to several years thereafter. Mild to moderate clinical manifestations during the intermediate stage of the disease (see Table 44-2) may include generalized lymphadenopathy, chronic diarrhea, night sweats, weight loss, fatigue, and infections indicative of cell-mediated immunodeficiency (e.g., herpes zoster [see Chapter 41], oral candidiasis, and oral hairy leukoplakia). These diverse clinical manifestations of HIV-1 infection may in part reflect the immunological response to the rapid and extensive dissemination of HIV-1.

The time to occurrence of AIDS is variable. A small percentage of patients may develop an AIDS-defining condition (see Table 44-1) during the first 2 years of infection, whereas some infected people remain healthy for more than 15 years. In the absence of treatment, approximately 50% of adults will develop AIDS within 10 years after infection.⁷⁶ As the CD4⁺ count declines, more serious opportunistic infections develop. The risk of developing an AIDS-defining condition increases as the duration of HIV-1 infection increases and usually occurs in patients with less than 200 CD4⁺ cells/mL. The natural history of vertically acquired HIV-1 infection in infants and children differs from that of adults. The adverse effects of HIV-1 on the developing immune system and nervous system often result in more rapid onset of clinical symptoms and progression to death. A bimodal evolution of symptomatic pediatric HIV-1 disease, with different rates of survival, is recognized from both clinical and data modeling studies. The first “hump” occurs in infancy, and the second (and larger hump) occurs later in childhood.^{66,70,77} There is probably a trimodal evolution with the third hump (albeit smaller) occurring in the pre- and early adolescent years.^{60,70,78} As in adults, latency to onset of symptoms in this group of children may be 10 years or more.

Infants in the first group develop symptomatic disease during the first years of life (“AIDS/HIV encephalopathy,” PCP, cytomegalovirus [CMV] infection, and/or wasting syndrome). The children in the second group have a more “benign” initial course (slower progression). Evidence of lymphoproliferative processes characteristic of pediatric HIV-1 infection is frequent and includes lymphadenopathy, hepatosplenomegaly, and parotid gland enlargement. Multiple or recurrent bacterial infections, ranging from otitis media, pneumonia, and bone and joint infection to sepsis and meningitis, are common in both groups, as is failure to thrive, persistent oral candidiasis, and chronic or recurrent diarrhea.⁵⁵ Although these children have a form of HIV-1 disease that progresses more slowly, the disease may ultimately involve many organ systems, including the CNS, cardiovascular system (cardiomyopathy), and kidneys. A polyclonal, polymorphic B cell lymphoproliferative disorder is commonly described with nodular lymphoid lesions in the lung as well as other organs and with lymphoid infiltrate in both nodal and extranodal sites. With HIV-1 disease progression, T cell abnormalities develop, including lymphopenia, low absolute numbers of CD4⁺ cells, poor in vitro lymphocytic proliferation to T cell mitogens, and cutaneous anergy. Infections indicative of cell-mediated immune dysfunction occur. PCP is the most common opportunistic infection, whereas disseminated candidiasis, *Mycobacterium avium-intracellulare* (MAI), and disseminated invasive CMV are the next most common. As in adults, CMV may produce colitis, pneumonitis, or retinitis. Other infections include disseminated ulcerative herpes simplex infections, cryptosporidiosis, and, rarely, toxoplasmosis.

The 1993 revised CDC classification system for HIV-1 infection incorporates both clinical conditions and immunological parameters determined by CD4⁺ cell counts. There are three clinical categories: (A) asymptomatic infection, persistent generalized lymphadenopathy, acute primary HIV-1 infection; (B) symptomatic conditions occurring in an HIV-1-infected person, excluding those conditions specified in categories A and C; and (C) symptomatic conditions occurring in an HIV-1-infected person (AIDS-indicator diseases). Immunological categories are stratified according to CD4⁺ cell counts: (1) CD4⁺ cells greater than or equal to 500 cells/mL; (2) CD4⁺ cells 200 to 499 cells/mL; and (3) CD4⁺ cells less than 200 cells/mL (AIDS-indicator counts).

For the purpose of epidemiological surveillance, the CDC initially defined AIDS in children younger than age 13 years with the same restrictive clinical case definition as adults (i.e., required documentation of an opportunistic infection or an AIDS-related malignancy). Additionally, primary (congenital) or secondary immunodeficiency disorders and congenital infections had to be excluded. After HIV-1 was identified and with the advent of serological testing for the presence of anti-HIV-1 antibodies in 1985, only a small proportion of children with confirmed HIV-1 infection and HIV-1-related disease manifestations were found to fit the case definition criteria for AIDS. Subsequent revisions by the CDC broadened this definition. In 1985, biopsy-proven lymphoid interstitial pneumonitis was included as a pediatric AIDS indicator condition. In 1987, a major revision substantially expanded the criteria. This classification was based on laboratory evidence of HIV-1 infection, immunological function, and a spectrum of clinical manifestations (Table 44-4). In 1994, revised CDC criteria based the diagnosis of AIDS in children on three indices: (A) infectious status, (B) clinical status, and (C) immunological status (Table 44-5).⁷⁹ The revised classification system reflects the child’s disease and establishes mutually exclusive categories.

DIFFERENTIAL DIAGNOSIS. Serological testing for anti-HIV-1 antibody (enzyme-linked immunosorbent assay [ELISA]), with a confirmatory Western blot, usually provides the diagnosis. However, during the stage of acute HIV-1 infection before seroconversion, there may be a false-positive heterophil, which can confuse the diagnosis.⁸⁰ The clinical syndrome of acute HIV-1 infection in the adult is distinctive (see preceding discussion). It contrasts with the distribution of rubella rash, which is

TABLE 44-4

CDC Classification System for HIV in Children (Revised 1994)**Category N: Not Symptomatic**

Children who have no signs or symptoms considered to be the result of HIV infection or who have only one of the conditions listed in category A

Category A: Mildly Symptomatic

Children with two or more of the conditions listed but none of the conditions listed in categories B and C:

- Lymphadenopathy (≥ 0.5 cm at more than two sites; bilateral equals one site)
- Hepatomegaly
- Splenomegaly
- Dermatitis
- Parotitis
- Recurrent or persistent upper respiratory infection, sinusitis, or otitis media

Category B: Moderately Symptomatic

Children who have symptomatic conditions other than those listed in category A or C that are attributed to HIV infection. Examples of conditions in clinical category B include but are not limited to the following:

- Anemia (< 8 g/dL), neutropenia (< 1000 cells/ μ L), or thrombocytopenia ($< 100,000/\mu$ L) persisting ≥ 30 days
- Bacterial meningitis, pneumonia, or sepsis
- Candidiasis, oropharyngeal thrush
- Cardiomyopathy
- Cytomegalovirus infection
- Diarrhea, recurrent or chronic
- Hepatitis
- Herpes simplex virus (HSV) stomatitis, recurrent
- HSV bronchitis, pneumonitis, or esophagitis
- Herpes zoster (at least two distinct episodes or more than one dermatome)
- Leiomyosarcoma
- Lymphoid interstitial pneumonia (LIP)
- Nephropathy
- Nocardiosis
- Persistent fever (lasting > 1 month)
- Toxoplasmosis, onset before 1 month of age
- Varicella

Category C: Severely Symptomatic

Children who have any condition listed in the 1987 surveillance case definition for acquired immunodeficiency syndrome (with the exception of LIP)

- Serious bacterial infections
- Candidiasis, esophageal or pulmonary
- Coccidioidomycosis
- Cryptococcosis
- Cryptosporidiosis
- Cytomegalovirus disease
- Encephalopathy
- HSV infection
- Histoplasmosis
- Kaposi's sarcoma
- Lymphoma, primary, in brain
- Lymphoma
- Mycobacterium tuberculosis*
- Mycobacterium*, other species or unidentified species
- Mycobacterium avium* complex or *M. kansasii*
- Pneumocystis carinii* pneumonia
- Progressive multifocal leukoencephalopathy
- Salmonella*
- Toxoplasmosis of the brain with onset > 1 month of age
- Wasting syndrome

Adapted from Centers for Disease Control and Prevention: Revised classification system for human immunodeficiency virus infection in children less than 13 years of age. MMWR Morb Mortal Wkly Rep 1994;43:1.

characterized as an erythematous fine and mild maculopapular rash that rapidly spreads in a cephalocaudal fashion from face to extremities, is usually generalized within 1 day, and clears within 72 hours to 4 days. A rash is also unusual in Epstein-Barr virus or CMV infection ($< 5\%$ of patients) unless antibiotics have been given.

The infant or child with vertically acquired HIV-1 infection may present with several clinical manifestations. Differential diagnosis, therefore, is dependent on the presenting signs and symptoms and the age of the child. Later in infancy and in childhood, if the presenting symptoms are chronic or recurrent infections or opportunistic infections, the most important and likely diagnosis is an immunodeficiency disorder. An appropriate history, examination, and immunological analysis, including HIV-1 testing, can usually rule out these conditions.

EVALUATION. The goal of the diagnostic workup is to establish the presence of HIV-1 infection and determine the stage of the disease, extent of immune dysfunction, and the presence or absence of neurological involvement. Accurate staging helps to formulate a prognosis, plan prophylactic therapy for opportunistic infections, and determine antiretroviral therapeutic strategies for primary HIV-1 infection. Once HIV-1 infection is confirmed by anti-HIV-1 antibody testing (i.e., ELISA, with a confirmatory Western blot in adults), a complete history should be obtained, including a review of risk factors for HIV-1 exposure, drug and alcohol history, sexual history, travel history, and medical history. A complete baseline physical examination should be performed. Focused follow-up examinations are then recommended with attention directed to findings that indicate disease progression, such as general appearance and weight loss, dermatological conditions (seborrheic dermatitis, folliculitis, dermatophytosis, Kaposi's sarcoma, and bacillary angiomatosis), oral lesions (candidiasis, hairy leukoplakia, aphthous ulcers, and periodontal disease), localized lymphadenopathy, splenomegaly, and signs or symptoms of neurological/neuropsychiatric involvement (mood or affective disorders, psychomotor slowing, abnormal eye movements, hyper-reflexia, and change of gait).

Initial laboratory studies should include CD4⁺/CD8⁺ counts (absolute cell counts and percentages) and, if possible, HIV-1 RNA levels. Complete blood count (CBC) with differential count, electrolyte and liver function panel, hepatitis screen, reactive protein reagent or Venereal Disease Research Laboratory (VDRL) titer, anti-toxoplasma IgG antibodies, purified protein derivative with anergy panel, and chest x-ray should also be obtained. Ophthalmological, dental, and gynecological examinations (including a Papanicolaou smear and chlamydia and gonorrhea studies) should be pursued. The stage of HIV-1 infection will then determine follow-up, prophylaxis, and therapeutic strategies.

In addition to declining CD4⁺ cell counts and CD4⁺/CD8⁺ lymphocyte ratios, other immunological markers of disease progression include elevated levels of serum β_2 microglobulin, neopterin, serum acid labile interferon, and decreased or absent levels of anti-p24 antibody. Virological indicators of disease progression are p24 antigenemia, HIV culture, quantitative polymerase chain reaction (PCR) of proviral DNA in cells or RNA in serum, and the presence of syncytium-inducing strains of virus.

TABLE 44-5

CDC Pediatric Human Immunodeficiency Virus Classification (1994)

| IMMUNOLOGICAL CATEGORIES | AGE OF CHILD | | |
|----------------------------------|--------------------------|-------------------------|--------------------------|
| | <12 Months, Cells/mL (%) | 1–5 Years, Cells/mL (%) | 6–12 Years, Cells/mL (%) |
| No evidence of suppression | ≥1500 (≥25) | ≥1000 (≥25) | >500 (≥25) |
| Evidence of moderate suppression | 750–1499 (15–24) | 500–999 (15–24) | 200–499 (15–24) |
| Severe suppression | <750 (<15) | <500 (<15) | <200 (<15) |

Elevated erythrocyte sedimentation rate (ESR) and decreased hematocrit values serve as nonspecific markers.

HIV-1 infection in infants can be diagnosed as early as 1 month and by 6 months in the vast majority of children.^{81,82} All children known to be at risk or exposed to HIV in utero need to be tested. HIV DNA PCR is the recommended test for infants. Neonates at risk should be tested before 48 hours of age and subsequently at 1 or 2 months, as well as between 3 and 6 months of age. Positive virological test at 48 hours of age is indicative for in utero HIV infection. Negative virological test at 48 hours of age but positive at the subsequent test times is indicative for the acquired infection during the intrapartum period. Two negative virological tests on separate blood samples, performed at more than 1 month of age and at more than 4 months of age, tentatively exclude the diagnosis of HIV-1 infection in an exposed infant. If an infant is older than 6 months, two or more negative virologic tests or two negative HIV IgG antibody tests, performed at least 1 month apart, again tentatively exclude HIV infection if there is no evidence of clinical HIV symptomatology. Finally, at 18 months of age, if all virological tests are negative, HIV IgG antibody test is negative, there is no hypogammaglobulinemia, and there are no clinical signs of HIV infection, HIV infection can be definitely excluded.^{81,82}

The initial laboratory evaluations of children older than age 18 months suspected of having HIV-1 infection should include HIV-1 serological testing (ELISA/Western blot), a CBC, and lymphocyte subsets (CD3, CD4, CD8 [and CD4:CD8 ratio]) enumeration. Other routine diagnostic tests, such as chest x-ray study, urinalysis, appropriate cultures for pathogens, a chemistry panel, and IgA, IgM, and IgG levels, may also be warranted.

MANAGEMENT. Early recognition and diagnosis of HIV-1 infection is important to institute appropriate counseling, prevent further spread of the virus, limit the number of additional clinical and laboratory evaluations, and exclude possible other disorders. Thereafter, the mainstays of management of HIV-1 infection include antiretroviral therapy for primary HIV-1 infection and prophylaxis and treatment of opportunistic infections.⁸³ Drugs that treat HIV-1 infection attempt to interfere with the replication of HIV. Targeted points in the growth cycle of the virus include (1) blockage of viral entry (soluble CD4⁺ preparations), (2) prevention of transcription of RNA to DNA (reverse transcriptase inhibitors), (3) interference with translation (drugs acting on regulatory genes or their proteins), (4) inhibition of assembly (protease inhibitors), and (5) interruption of the release of virus (interferon) (Fig. 44-5). Guidelines for the evaluation and medical

management of the HIV-infected person and use of antiretroviral agents are available on the HIV/AIDS Treatment Information Service Web site (www.hivatis.org) and should be consulted by the clinician.⁸⁴

The 15 drugs currently approved for the treatment of HIV-1 infection fall into three therapeutic classes: the nucleoside (and nucleotide) analogue reverse transcriptase inhibitors (NRTIs), the non-nucleoside reverse transcriptase inhibitors (NNRTIs), and the protease inhibitors (PIs). Retroviral drugs (NRTIs) include zidovudine (ZDV and AZT), didanosine (ddI), dideoxycytidine (ddC), stavudine (d4T), and lamivudine (3TC). These agents are nucleoside analogues that inhibit reverse transcriptase. NNRTIs inhibitors include delavirdine and nevirapine. PIs include saquinavir, indinavir, ritonavir, and amprenavir. The primary goal of antiretroviral therapy is to maintain viral suppression as long as possible.⁸⁵ Effective treatment reduces plasma HIV RNA levels and increases CD4⁺ cell counts. Treatments offer the potential to delay onset of AIDS, prolong survival, and interrupt transmission.⁸⁵ Unfortunately, limitations have also been observed. Antiretrovirals do not completely inhibit viral replication, and HIV-1 disease progresses despite therapy. Studies show that treatment with antiretroviral drugs favors the fall of HIV RNA titers, the rise of CD4⁺ cell counts, the prolongation of time until HIV-1-related symptoms begin, and prolongation of survival. When to initiate primary HIV-1 therapy to an individual patient, however, remains unclear.

Recommendations for institution of antiretroviral therapy are guided by evaluation of the individual's clinical status and use of surrogate markers, such as CD4⁺ cell counts and plasma HIV-1 RNA levels.⁸⁵ Some investigators suggest treatment before the onset of HIV-related symptoms when the CD4⁺ cell count falls to or below 500/mL, HIV RNA titer is 30,000 to 50,000 copies/mL, or CD4⁺ cell count is rapidly declining. Treatment may also be considered if the HIV RNA titer is greater than 5000 copies/mL in those individuals whose CD4⁺ cell count is less than 500/mL.

It is not certain which initial antiretroviral agent or combination of agents should be used. The specific initial antiretroviral treatment should be based on an assessment of the potency, expected duration of benefit, resistance, toxicity, potential interactions with other medications, ease of use, and cost.⁸⁵ These medications are extraordinarily expensive and have certain common and distinct side effects (Table 44-6; see also Chapter 55). Because this information is rapidly changing, clinicians should review yearly updates on therapy recommendations.

Cellular targets

Viral targets

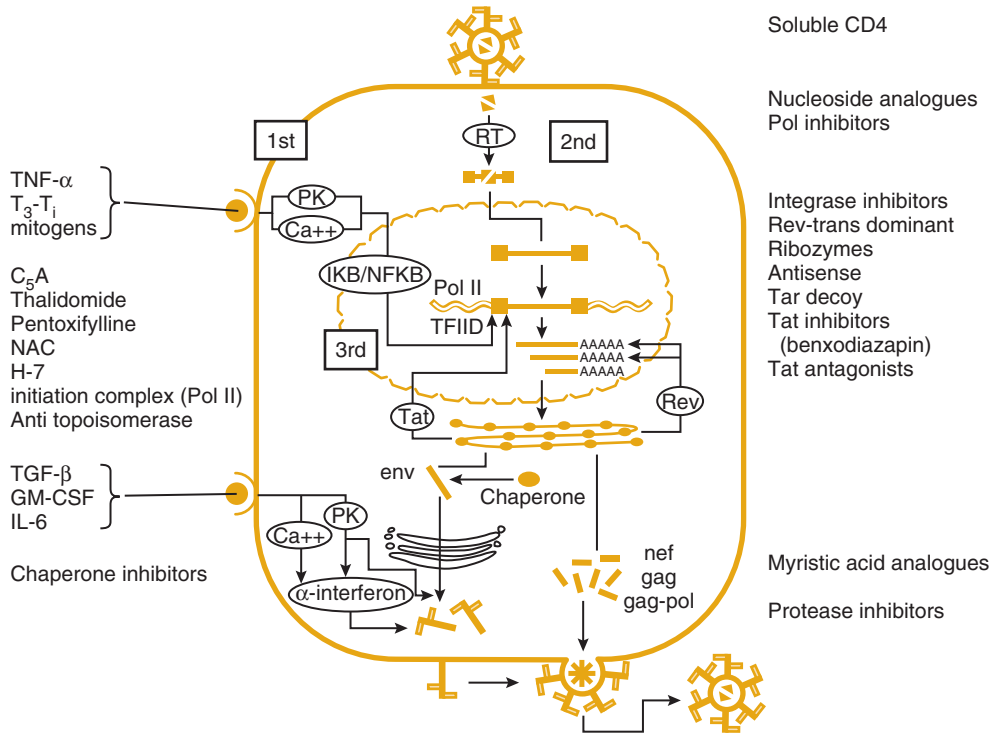

Figure 44-5. Potential locations for treatment intervention in the life cycle of the HIV. The boxes depict the cellular signaling pathways used for replication by HIV. The first box indicates the cellular surface receptors; and the second depicts the intracellular signals that transmit the first signal; the third pathway is assembled in response to second messenger signaling and includes protein-DNA and protein-RNA interactions. In DeVita VT, Hellman S, Rosenberg SA [eds]: AIDS: Biology, Diagnosis, Treatment and Prevention, 4th ed. Philadelphia, Lippincott-Raven, 1997, pp 29–43.)

TABLE 44-6

Complications of Treatment with Specific Agents

| AGENT | COMPLICATIONS |
|--|---|
| Nucleoside (and Nucleotide) Analog Reverse Transcriptase Inhibitors (NRTIs) | |
| Zidovudine | Anemia, neutropenia, nausea, anorexia, fatigue, insomnia, headache, myalgia, myopathy |
| Didanosine | Pancreatitis, peripheral neuropathy, hyperamylasemia, hyperuricemia, transaminase elevations |
| Dideoxycytidine | Peripheral neuropathy (dose-dependent), pancreatitis, rash, stomatitis, gastrointestinal disturbances |
| Stavudine | Peripheral neuropathy, arthralgia, myalgia, anemia, asthenia, gastrointestinal disturbances, headache, insomnia |
| Lamivudine | Pancreatitis, paresthesias, peripheral neuropathy, rash, cough, headache, dizziness, fatigue, hair loss, insomnia |
| Abacavir | Fatal hypersensitivity reactions, gastrointestinal disturbances, weight loss, sleep disorders |
| Zalcitabine | Peripheral neuropathy, pancreatitis, lactic acidosis, hepatic toxicity with steatosis, ulcers, cardiomyopathy |
| Nonnucleoside Reverse Transcriptase Inhibitors (NNRTIs) | |
| Delavirdine | Skin rash, multiple drug interactions, myalgias, gastrointestinal disturbances, encephalopathy |
| Nevirapine | Skin rash, hepatitis/hepatic failure, granulocytopenia, encephalopathy |
| Efavirenz | Psychiatric symptoms including depression and psychosis, dizziness, sleep alterations |
| Protease Inhibitors | |
| Saquinavir | Bleeding disorders, gastrointestinal disturbances, hepatic dysfunction, myalgias, arthralgias, skin rash |
| Indinavir | Nephrolithiasis/uroolithiasis, hyperbilirubinemia, abdominal pains, nausea |
| Ritonavir | Diabetes, bleeding disorders, elevated cholesterol and plasma lipids, multiple drug interactions |
| Amprenavir | Bleeding disorders, fat redistribution, skin rash, multiple drug interactions, gastrointestinal disturbances |
| Nelfinavir | Diabetes, bleeding disorders, gastrointestinal disturbances, multiple drug interactions |

Clinical experience has shown that, over time, antiretroviral therapy has a diminished benefit. The optimum choice of secondary treatment is often a major dilemma. Many factors must be taken into consideration; for exam-

ple, the patient’s previous antiretroviral regimen, length of time the antiretroviral was taken, toxicities encountered, as well as side effects or toxicities of the new agent. Development of resistance to antiretroviral agents

is a major problem, especially when protease inhibitors are administered as monotherapy or when not taken by the patient as directed.

The long-term clinical effectiveness of all available drugs is limited by the ability of patients to adhere to their complex dosing regimens and to tolerate their side effects. Over time, inadequate drug exposures due to limited drug efficacy or inadequate adherence may permit viral replication in the presence of the drug, leading to the emergence of drug-resistant viruses. In addition, because of their similar chemical structures and mechanisms of action, the emergence of viral resistance to one drug frequently results in cross-resistance to other, often all, members of the same therapeutic class. Therefore, there is an urgent need for new and effective drugs that will be convenient, well tolerated, and capable of suppressing viruses that are resistant to existing drugs.

Numerous clinical trials aimed at providing new treatment options for AIDS patients are currently ongoing. Among NRTIs, the tenofovir prodrug, tenofovir disoproxil fumarate, has demonstrated antiviral activity in two phase III clinical trials and is currently under consideration for marketing approval for HIV-1 therapy. Two others, emtricitabine (FTC) and diaminopurine dioxolane/dioxolane guanosine (DAPD/DXG), show somewhat greater potency, the potential for once-daily dosing, good tolerability, and antiviral efficacy in phase I/II studies.^{86,87} In addition, several NNRTIs are in phase I/II trials,⁸⁸ and protease inhibitors tipranavir and BMS-232632 are in phase III clinical trials.^{89,90}

In addition, there are attempts to design new drugs that will have a novel mechanism of action compared to the existing drugs. The major classes of these new drugs are integrase inhibitors, viral entry inhibitors, and viral assembly inhibitors. Integrase is the third of the enzymatic proteins encoded by HIV-1, which catalyzes the insertion of the HIV-1 DNA into the genome of the host cell. Viral entry inhibitors are being designed to block HIV-1 entry by inhibiting gp120-CD4 binding, gp120-coreceptor binding, or gp41 function. In fact, each of these potential targets has been exploited by multiple inhibitors in cell culture systems. There is now at least one inhibitor in each class being tested in clinical trials. Also, antagonists of cytokine receptors CCR5 and CXCR4, used by HIV-1 strains to enter the target cells, are currently being tried as possible therapeutic agents.⁹¹ Assembly and release of HIV-1 are primarily governed by the viral GAG and VPU proteins. It might be possible to discover and develop drugs that block assembly or release by binding to one of these components. Indeed, there is one known example of a small molecule that has antiviral efficacy in vivo and is thought to inhibit assembly by binding to a GAG protein. This compound, a tripeptide with the sequence Gly-Pro-Gly-NH₂ (GPG), is being developed by Tripep AB, which has presented unpublished results from a 2-week clinical trial.⁹² The RNA interference (RNAi) has been considered as a possible approach to treat HIV-1 infection.⁹³ As RNAi operates in the cytoplasm, it can degrade the genomic viral RNAs that enter the cytoplasm upon infection as well as prevent the formation of the integrated provirus.⁹⁴ Some studies are examining how to use the RNAi to affect HIV-1 replication.⁹⁵ All these attempts provide hope for

future management and control of HIV-1 infection and AIDS.

Finally, there is now ongoing research to develop an HIV vaccine. Despite initial optimism and high expectations, there are many obstacles confronting the development of an effective vaccine.⁹⁶ HIV vaccines have been evaluated so far in more than 70 phase I (dose-escalation safety and toxicity), 5 phase II (expanded safety and dose optimization), and 2 phase III (efficacy) clinical trials. These studies have evaluated safety and immunogenicity of preventive vaccines in more than 3500 subjects.⁹⁷ However, no study to date has demonstrated sustained clinical benefits to “therapeutic vaccination.”

During the past decade, it has been recognized that many patients develop resistance to antiretroviral drugs. Therefore, current guidelines in the United States recommend that resistance testing is done in patients who have been infected for 2 or more years, in cases of retroviral failure, and during pregnancy.⁹⁸ Two types of HIV resistance testing are available—genotypic and phenotypic assays. Genotypic assays test the coding regions of the HIV isolated from the patient and require an HIV viral load of greater than 1000 copies/mL.⁹⁹ Phenotypic assays are standard bacteriologic sensitivity assays and provide the minimal inhibitory concentration for a specific patient. However, phenotypic assays can be done only for one drug at a time and cannot predict the effects of combination of drugs.¹⁰⁰

HIV-RELATED CENTRAL NERVOUS SYSTEM DISORDERS

Aseptic Meningitis

Retrospective studies have suggested that up to 10% of patients with HIV-1 infection and AIDS develop clinically apparent aseptic meningitis during the course of their illness. Additionally, HIV has been isolated in blood and CSF of patients with an acute self-limited aseptic meningitis at the time of HIV seroconversion. The clinical features in these cases are similar to those present in patients with aseptic meningitis owing to other viruses, outside the setting of HIV infection. Patients may have fever, meningeal signs, and headache that can be mild or severe with a dull or throbbing quality. These features may be accompanied by other constitutional signs that are characteristic of a viral syndrome, including fatigue, malaise, myalgias, nausea, chills, and minor vomiting. Some individuals may have associated arthralgias, lymphadenopathy, and a maculopapular rash. This rash is erythematous, nonpruritic, and typically involves the face or trunk. Occasionally, cranial neuropathies may be a concomitant finding, most often affecting the trigeminal, facial, or vestibulocochlear nerves (Video 23, Cranial Nerve VII, Facial Diplegia; Video 28, Nystagmus; Video 106, Trigeminal Neuralgia).

The differential diagnosis of this clinical presentation includes other causes of aseptic meningitis (enteroviruses and varicella zoster), bacterial meningitis, intracranial mass (abscess), subarachnoid hemorrhage, and other causes of headache (migraine). In HIV-related aseptic meningitis, the CSF will reveal a mononuclear pleocytosis ranging from 20 to a few hundred cells/mL in the association of

an elevated protein. The diagnosis will be made by the demonstration of HIV-1 infection, which may require repeat testing after the resolution of the acute presentation.

The treatment of aseptic meningitis is supportive in nature and includes symptomatic treatment. In association with fluids and bed rest, acetaminophen, aspirin, and nonsteroidal anti-inflammatory agents may be utilized to reduce fever and lessen headache.

HIV-associated Cognitive Impairment—Adults

During the past two decades, various terms have been used to describe the cognitive features, including mental slowness, diminished concentration, and a decline in memory, in the setting of HIV infection. These cognitive changes are variably associated with changes in behavior (lethargy, apathy, and diminished emotional responses) and motor symptoms (clumsiness, gait abnormalities, tremor, and reduced motor control). The term *HIV-associated dementia* or *HIV dementia* incorporates the cognitive changes seen in HIV-1 infection as well as those occurring in the setting of AIDS. It is synonymous with the previously existing terms *AIDS dementia complex*¹⁰¹ and *HIV encephalopathy*.¹⁰² A separate term, *HIV-associated minor cognitive/motor disorder*, has been used to denote minor degrees of cognitive and motor impairment that are not sufficient for the diagnosis of dementia. According to the American Academy of Neurology AIDS Task Force,⁶⁵ this term is appropriate because it is unclear whether this degree of impairment uniformly progresses to overt dementia. The term *HIV-associated delirium* should be used in the setting of an alteration in consciousness with a rapid worsening of cognitive function in at least two domains (Table 44-7). The terms *HIV encephalitis*, *HIV-associated diffuse gliodystrophy*, and *HIV leukoencephalopathy* are pathological findings that may be seen at autopsy in patients with HIV dementia and should not be used to denote clinical syndromes.

PATHOGENESIS AND PATHOPHYSIOLOGY. Much has been learned about the biology of HIV-1, the cells it

infects, and the mechanisms by which viral entry into cells occurs. However, just how HIV-1 exerts its effects on the CNS remains uncertain and continues to be the focus of ongoing research. Current knowledge indicates that HIV-1-infected macrophages/monocytes in blood are recruited to the brain by upregulation of chemoattractant-chemokines such as MCP-1¹⁰³ and adhesion molecules on endothelial cells. Upregulation enables transendothelial migration of activated macrophages/monocytes¹⁰⁴ and has been correlated with a high frequency of circulating activated monocytes expressing CD14/CD16 and CD14/CD9 in patients with HIV-associated dementia. Endothelial cells, oligodendrocytes, and neurons contain the virus only rarely, although a decrease in neuronal density and dendritic spines has been demonstrated.¹⁰⁵ Takahashi and coworkers,¹⁰⁶ however, have demonstrated a latent HIV DNA provirus in some astrocytes. Furthermore, development of HIV-associated dementia in advanced AIDS may correlate with the existence of neurotropic HIV-1 strains that have an increased propensity to invade the CNS rather than neurovirulent strains, which have an increased propensity to cause CNS damage. In vitro studies of HIV-1 neurotoxicity indicate that changes in the envelope sequence might influence neuronal survival.¹⁰⁷ It has already been shown in in vitro models of simian immunodeficiency virus (SIV) and feline immunodeficiency virus (FIV) that specific sequences of ENV or NEF genes confer neurovirulence.¹⁰⁸ FIV specifically activates proteases that lead to the induction of matrix metalloproteinase-2 (MMP-2) and proteinase-activated receptor (PAR-2), leading to gliosis and NMDA-mediated neuronal death.¹⁰⁹ HIV-affected macrophages secrete MMP-2, indicating similar mechanisms as shown for FIV.¹¹⁰

Pathogenetic mechanisms of HIV-associated dementia are complex and most likely multifactorial. Activated macrophages release multiple proinflammatory cytokines, as well as other factors that might impair the function of virtually all neural cell types and interfere with the release of neurotransmitters and therefore synaptic transmission. This process would then correlate with the neuropsychological findings in HIV-associated dementia. Most recent studies have indicated the role of tumor necrosis factor- α (TNF- α) in HIV-induced neuronal apoptosis, and this finding promoted subsequent clinical trials with TNF- α antagonists.¹¹¹ However, little progress has been made. An initial trial with pentoxifylline was aborted due to the side effect profile of the drug.¹¹² A novel TNF- α antagonist, CPI-1189, is currently undergoing trials in the United States.

Studies of the viral load in HIV-associated dementia have indicated that plasma HIV RNA level is predictive of the development of dementia.¹¹³ Similar data have been reported in SIV encephalitis.¹¹⁴ However, HIV PCR analysis of the CSF viral load of patients with HIV-associated dementia has been controversial because not all studies indicate a correlation between CSF HIV load and severity of dementia.^{115–118} It is not clear how well the CSF viral load reflects brain parenchymal viral loads. It has been shown that CSF and parenchymal levels did not correlate when CSF levels were low ($<10^5$ copies/mL) but did correlate when CSF levels were high ($>10^6$ copies/mL). In addition, CSF HIV RNA levels sometimes correlated well with the treatment efficacy.^{119,120}

TABLE 44-7

Classification of HIV-associated Cognitive Dysfunction

| | |
|--|---|
| Category 1 (HIV-associated, minor) | 0.5 SD below normal on standardized neuropsychological tests Decline in work or other activities of daily living (ADLs) Symptoms for 1 month Criteria for HIV-1-associated dementia or delirium is absent No other etiology |
| Category 2 (HIV-associated dementia) | Marked impairment in at least two ability domains Significant impairment in work and other ADLs Symptoms for 1 month No other etiology Free of delirium for a period sufficient to establish the presence of dementia |
| Category 3 (HIV-associated delirium) | Clouding of consciousness Marked, rapid worsening of cognitive function in ≥ 2 domains |

SD, standard deviation.

Macroscopic brain pathology from HIV-infected individuals with cognitive impairment shows cerebral atrophy of variable degrees. There is ventricular enlargement, particularly in the frontal and temporal lobes, widening of sulci, and attenuation of deep cerebral white matter with, occasionally, softening of the centrum semiovale.^{121,122} A spectrum of characteristic gross and microscopic changes has been described and categorized by an international working group consensus in 1991 as follows (Table 44-8). HIV-1 encephalitis is characterized by foci of inflammatory cells, microglia, and macrophages, called microglial nodules, as well as multinucleated giant cells (Fig. 44-6). Location tends to be perivascular with predominance in the basal ganglia and subcortical white matter, although to a lesser degree the cortical gray matter may also be affected. In adult series, HIV encephalitis is reported in up to 90% (15% to 90%) of AIDS cases studied. The severity of pathological findings in HIV encephalitis is generally greater in adults than in infants and young children.¹²³ HIV-1 leukoencephalopathy is characterized by diffuse myelin pallor and extensive damage to white matter with myelin loss. Associated findings, such as reactive astrogliosis, the presence of macrophages, and multinucleated giant cells, may also be present. Symmetrical white matter pallor can be seen in the hemispheres (Fig. 44-7) and less often in the cerebellum. Leukoencephalitis was reported in one third of patients clinically diagnosed with HIV dementia¹²⁴ and in 38% of autopsy series cases.¹²⁵ A diffuse poliodystrophy has also been described in approximately 50% of cases. Neuronal loss, dendritic changes, and reduced levels of synaptophysin have also been demonstrated by quantitative methods with a frontal and parieto-occipital predominance.^{126,127} In addition, increased levels of ceramide have been reported both in brain tissue and in the CSF in HIV encephalitis.¹²⁸ Ceramide is produced during the sphingomyelin breakdown and may contribute to neuronal apoptosis.

TABLE 44-8**CNS Neuropathological Findings in HIV**

| | |
|---|--|
| Gross Examination | |
| Cerebral atrophy of variable degrees | |

| Diffuse poliodystrophy | |

MGC, multinucleated giant cells.

Modified from Budka H, Wiley CA, Kleihues P, et al: HIV-1 associated disease of the nervous system: Review of nomenclature and proposal for neuropathology-based terminology. *Brain Pathol* 1991;1:143-152.

Microscopic examinations reveal that HIV-1 is most frequently localized in cells of bone marrow lineage (blood-derived macrophages), intrinsic microglia (the resident mononuclear phagocytic system of the brain), and multinucleated giant cells (formed by the fusion of these cell types). It is these cells that support productive infection.^{15,16,129} Their presence correlates both with the degree of dementia and with the detection of HIV-1.¹³⁰ Interestingly, it seems that particular HIV-1 strains have specific affinity for specific cells types. For example, the V3 region of the HIV-1 envelope (ENV) gene sequences was different in astrocytes than in macrophages or multinucleated giant cells, indicating cell-specific compartmentalization.¹³¹ By immunocytochemistry, HIV-1 antigen is localized most often in the basal ganglia, subthalamic nucleus, substantia nigra, dentate nucleus, and white matter.¹³² PCR studies, however, show HIV to be more abundant in subcortical white matter than in basal ganglia, deep white matter, or cortex.¹³³ With more sensitive and specific techniques of viral detection, a greater number of both infected cells and cell types infected have been demonstrated. These include endothelial cells,¹³⁴ astrocytes,^{135,136} and neurons,¹³⁷ although this may be restricted infection.

The clinicopathological correlates of HIV-1-associated CNS disease are not clearly delineated, nor is the exact role of the virus defined. Although studies have confirmed direct HIV-1 CNS infection early in the disease, the development of clinical HIV-1-associated CNS disease does not occur until the late stage of HIV-1 infection when the patient is immunosuppressed. Moreover, the pathological changes seen at autopsy in some cases do not always correlate with the clinical course. Some patients with clinically severe neurological disease may have relatively mild neuropathological findings. Even in cases with more marked pathological findings, there may be a relatively small proportion of infected cells and those actively replicating. Indeed, one prospective study found that 50% of patients with clinically diagnosed dementia had neither the hallmark features of HIV encephalitis nor white matter pallor, and only 25% of dementia cases had multinucleated giant cells.¹²⁴ Brain levels of HIV RNA correlate with the pathological features of encephalitis but do not clearly distinguish demented from nondemented subjects.^{44,118} These discrepancies suggest that other factors besides direct cellular damage by HIV-1 may be important in pathogenesis.¹³⁸ Both virological and neuroimmunological processes have been implicated (Table 44-9). Many questions remain unanswered concerning the role of the virus, CNS viral load, evolution of neurotropic strains, mechanisms underlying viral protein and cytokine-mediated effects and toxicities, undefined host factors, and viral-host interactions.

EPIDEMIOLOGY AND RISK FACTORS. Of the 1 to 1.5 million HIV-1-infected people in North America,¹³⁹ up to 30% will manifest some form of cognitive impairment during the course of their infection. However, estimates vary as to the frequency and degree of neurocognitive deficits. Two major factors account for the differences in estimate. First, people with HIV infection who came to medical attention in the early years of the epidemic were generally in more advanced stages of the disease. Early reports were thus probably biased toward a higher frequency rate of dementia. Second, terminology, study design, and methodology

differed among studies, particularly with regard to the classification schemes used to categorize levels of HIV-1-related neurocognitive impairment. Thus, initial clinical reports described characteristics of a disorder with cognitive, motor, and behavioral manifestations, which was described in unitary terms as a single diagnostic entity, "AIDS dementia complex."⁹ Delineation of clinical stages and precise definitions of clinical characteristics were not uniformly used across different studies. This lack of precise definition led to considerable variation in estimates of dementia in HIV-infected people.¹⁴⁰

Current data suggest that dementia develops in 10% to 20% of patients with AIDS, occurring at an annual incidence of approximately 7% after AIDS onset.¹⁸ HIV dementia occurs as a late complication of HIV-1 infection when patients are immunosuppressed. It develops as the first AIDS-defining illness in only 3% of adults.¹⁰¹ More generally, patients at risk for dementia are those who are farther along in the disease process and who have experienced moderate to severe immunosuppression, constitutional symptoms (e.g., anemia, weight loss, and poor nutrition), and systemic opportunistic processes.^{141,142} Higher plasma HIV RNA levels and lower CD4 counts are predictive of dementia, as well as of sensory neuropathy.¹¹³ One study suggested that the presence of E4 isoform of apolipoprotein E indicates higher risk for development of dementia. Education and premorbid capacities are factors as well: Individuals with lower levels of education and premorbid function show more frequent cognitive deficits; those with higher levels of education appear to benefit from the protective effects of "cognitive reserve" despite the impact of the virus on the CNS.¹⁴³ Concurrent with the widespread use of antiretrovirals, a decline in the frequency of HIV dementia was reported.¹⁴⁴⁻¹⁴⁶

Nonetheless, estimates of HIV dementia suggest its prevalence ranges from approximately 5% to approximately 14%.¹⁴⁷ Unfortunately, there are no clear estimates of the rates of either HIV-associated minor cognitive/motor disorder or HIV-associated delirium. Most investigators believe that symptomatic HIV-1 infection presents at least some risk of neurocognitive impairment, but estimates of the rate of impairment vary. Neurocognitive findings on asymptomatic individuals have varied considerably as well. An early report suggested an increased incidence of impairment among asymptomatic patients.¹⁴⁸ However, subsequent studies indicated no significant differences between asymptomatic HIV-positive patients and controls on selected cognitive measures.^{149,150} Still other concurrent efforts have again indicated mild deficits in asymptomatic individuals relative to control subjects.¹⁵¹⁻¹⁵³ Among studies that have shown impairment in HIV-infected asymptomatic individuals, estimates of rates of impairment range from 9.1% to 30.5%.

Since the introduction of the antiretroviral therapy, the incidence of HIV-associated dementia has declined by 40% to 50%, whereas prevalence has remained unchanged.¹⁵⁴ Patients with HIV-associated dementia live longer, which indirectly leads to a proportional increase in the number of patients diagnosed.¹⁵⁵

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Clinical features of HIV-associated dementia encompass changes in behavior, cognition, and neurological function.

Initial clinical features of HIV-related cognitive impairment vary considerably in terms of time of presentation and severity. Symptoms are often sufficiently subtle that they may be overlooked or mistaken for psychiatric problems. Neuropsychological findings have not been completely consistent across the literature, particularly with regard to asymptomatic individuals and people with a mild disorder. In part, this is due to the varying measures that have been used with subjects, as well as the variety of parameters used to define subject groups. It is also likely due simply to the fact that presentation varies from individual to individual. There are indications that a subgroup of seropositive, asymptomatic individuals may show deficits, particularly in memory and executive functioning.^{151,153} These deficits may be related to declines in CD4⁺ lymphocyte counts and may precede clinical evidence of AIDS.

HIV dementia has been termed subcortical in nature, at least with respect to initial presentation, whereas subsequent deterioration is more global in nature. In early stages, typical symptoms of behavioral changes include apathy, inertia, and mild depressive symptoms. Change of personality and social withdrawal are very common. In some cases, however, behavioral changes are quite opposite, and agitation and mania may be the presenting manifestations.¹⁵⁶ Cognitive symptoms are intermixed and include forgetfulness, difficulty with sustained concentration, and psychomotor slowing. Manifestations of these problems in daily life may include problems in keeping track of appointments, telephone numbers, or medications; misplacement of personal items; and difficulty following the direction of conversations or the plots of films or books. Other neurological features that occur early include primarily motor abnormalities, such as slow and clumsy handwriting, other fine-motor problems, insecure balance, and impaired gait.

On neuropsychological testing, these patients may have memory loss with particular difficulty in retrieval of newly learned information, impaired manipulation of known material, and slowed psychomotor and information processing speed. Simple attention and language skills are not typically affected during the initial stages of HIV-related cognitive impairment,¹⁴⁶ although these functions may also mildly deteriorate as the disease progresses.

HIV dementia in the setting of AIDS occurs along with increasing constitutional symptoms, immunosuppression, and opportunistic processes. With advancing dementia, the patient is likely to develop global behavioral deterioration. Mutism and abulia are typical, but euphoria and denial of deficit, lack of insight/awareness, and hallucinations can be alternative syndromes. The most pronounced neurocognitive deficits remain in the areas of retrieval of new information and psychomotor function, although deficits in executive function, language, attention, and new learning become more pronounced as well. Neurological examination is notable for diffuse signs of CNS dysfunction, for example, slowed and erroneous motor programming, hyper-reflexia, hypertonia, and frontal release signs (Video 80, Hyper-Reflexia; Video 82, Cross-Adductor Reflex). Myelopathy and neuropathy might occur. Motor function and posture testing may be notable for marked psychomotor retardation, spasticity and weakness, ataxia, and, ultimately, decorticate posturing. Although myoclonus is not

consistently a feature of late dementia, generalized seizures may occur.¹⁵⁷

Progression of the dementia varies widely from individual to individual. In some, it may occur rapidly over the course of 3 to 6 months, whereas others may show relatively mild and stable dementia up until death. The reason for this difference between rapid progressors and slow progressors is not known, but those with CD4⁺ cell counts less than 100/mL at the onset of HIV dementia tend to progress more quickly. It is interesting to note that despite the widespread use of antiretrovirals, survival after diagnosis of HIV dementia has not improved significantly in recent years.

Systemically, it has been reported that patients with HIV-1-associated dementia may develop diabetes.¹⁵⁸ Those who are treated with the antiretroviral therapy develop hyperlipidemia and hypertension, increasing their risk factors for cerebrovascular events.

DIFFERENTIAL DIAGNOSIS. The differential diagnosis of HIV dementia is often problematic, particularly in the early period. Initial symptoms overlap with and can be mistaken for adjustment and mood disorders, alcohol and other substance abuse, medication effects, metabolic encephalopathy, and other brain disorders.¹⁵⁹ It is important to pursue information from those close to the patient regarding the individual's history and current behavior in order to rule out psychiatric or substance abuse complications as causes of an apparent dementia. Metabolic derangements (e.g., hypoxia and sepsis) must be considered. Other CNS processes, such as CMV encephalitis, toxoplasmosis, primary lymphoma, progressive multifocal leukoencephalopathy, and cryptococcus, can complicate the diagnostic process and must be excluded as causes of cognitive deterioration. Time course, level of consciousness, the presence of fever and headache, and focal signs and symptoms on neurological examination may help differentiate these conditions. Of these disorders, CMV encephalitis is probably the most frequent and problematic differential diagnosis. In approximately 10% of all patients with AIDS, it presents as a rapidly developing encephalopathy. CMV encephalitis can be distinguished from HIV dementia by the presence of coexisting CMV infection, electrolyte abnormalities, and periventricular abnormalities.

Depression frequently complicates cognitive function in HIV infection. HIV-infected individuals are known to have higher rates of major depression than those seen in the general population, and it is thought that in most cases depression predates HIV infection.¹⁵⁹ It appears that a substantial number of HIV-positive individuals can experience depression in concert with neurocognitive impairment, whereas others may show significant deficits without depressed mood, suggesting that although depression is a frequent concomitant of cognitive impairment in HIV infection, it does not play an etiological role in such impairment.¹⁶⁰ All of the preceding factors necessitate the need to screen individuals at high risk, who have unsuppressed plasma levels of HIV RNA and CD4⁺ cell counts less than 200/mL. In those individuals, a complete cognitive and behavioral evaluation and particularly neuropsychological testing is warranted.

EVALUATION. A thorough neurological examination and history are essential. In the early stage, there may only

be mild abnormalities of rapid eye and limb movements, as well as diffuse hyper-reflexia. Increased tone, especially in the lower extremities, hyper-reflexia, clonus, frontal release signs, and tremor are seen with disease progression. Focal neurological signs are suggestive of another CNS process (opportunistic infections, neoplasm, and vascular events). In addition to mental changes, CNS-based motor complications are also frequently seen in association with HIV dementia, especially myelopathies, myopathies, and neuropathies.

Neuropsychological assessment is particularly useful for characterizing the dementia and for tracking its progress; it can also help in monitoring the patient's response to antiretrovirals and other medications. Critical domains and specific assessment tools are listed in Table 44-10 and are reviewed in Chapter 27. Particularly important are tests of both explicit and implicit learning and memory, complex attention, information processing speed, and psychomotor speed, such as Trailmaking, Grooved Pegboard, and Symbol-Digit tests. These areas are most likely to appear abnormal during early stages of HIV dementia and to demonstrate deterioration as the dementia progresses. On the other hand, calculation and language are usually not affected in initial stages of HIV-associated dementia.¹⁴⁶ Although neuropsychological assessment can be helpful with respect to the objective quantification of the nature and severity of cognitive impairment and the tracking of such impairment over time, it should be noted that neuropsychological testing in the case of HIV infection tends to be sensitive rather than specific. Clearly, numerous disease processes may present with a similar neurocognitive picture. Consideration of this issue is particularly important because HIV-infected individuals often present with histories that include other problems (e.g., alcohol/drug abuse, depression and other psychiatric disorders, learning disabilities, and head injury). In addition, concurrent CNS processes such as metabolic encephalopathy and opportunistic infections can cause similar cognitive deficits, and some of these can be specifically treated.

Cerebrospinal fluid in HIV dementia is abnormal, but similar abnormalities can be found in HIV-seropositive patients who are neurologically normal. CSF is usually acellular or shows mild lymphocytic pleocytosis. Total protein is elevated in approximately 65% of cases, with elevated β_2 microglobulin and increased total IgG fraction. Elevated β_2 microglobulin, an immune activation marker, has the greatest diagnostic value, particularly in cases of mild dementia in the absence of opportunistic infections. A β_2 -microglobulin level greater than 3.8 mg/dL has a positive predictive value of 88%.¹⁶¹ Work by Martin and colleagues¹⁵² has also suggested that elevated CSF quinolinic acid concentrations in HIV-infected individuals are associated with deficits in motor learning and reaction time. Even though the CSF HIV RNA levels are not diagnostic for HIV-associated dementia, they should be measured because they correlate with its severity.¹⁶² Measurement of serum and CSF interleukin-18 levels may indicate the presence of HIV-associated dementia and opportunistic infections, respectively.¹⁶³

Imaging studies are essential for differentiation between HIV-associated dementia and opportunistic infections. Computed tomography (CT) and magnetic resonance imaging

(MRI) may not show abnormalities in people with HIV-associated minor cognitive and motor disorder, despite positive neuropsychological findings. In mild HIV dementia, neuroimaging suggests subcortical and cortical atrophy with MRI abnormalities seen in deep white matter. White matter abnormalities, which may represent disruptions of the blood-brain barrier, progress and are more diffuse with increasing severity of dementia.¹⁶⁴ The degree of atrophy also correlates with cognitive impairment.¹⁶⁵ Volumetric MRI indicates caudate atrophy as well as decreased gray matter.^{166,167} Proton MR spectroscopy is emerging as a tool to

assess brain damage as well as treatment efficacy over time. *N*-acetylaspartate, a marker of neuronal viability, can be changed in cortical areas, whereas myoinositol, a marker for glial turnover, may indicate tissue damage even earlier.^{168,169} MR spectroscopy indicates higher myoinositol-to-creatine ratio and increased choline levels in white matter and basal ganglia, indicating glial activation in AIDS patients.¹⁷⁰ Positron emission tomography (PET) studies have suggested that subcortical hypermetabolism occurs during early HIV dementia, particularly in the basal ganglia and thalamus. This hypermetabolism later appears to progress to subcortical and cortical hypometabolism.^{171,172} PET scanning with ¹¹C-PK11195, used to image brain macrophages and recently applied to SIV-infected macaques, demonstrated an increase of labeling in the presence of encephalitis,¹⁷³ indicating potential usefulness of this marker for predicting encephalitis development in human patients. Single-photon emission computed tomography (SPECT) indicates abnormalities in cerebral blood flow in both neurologically normal HIV carriers and demented patients. However, cocaine ingestion may also produce similar PET and SPECT patterns and should be ruled out. Neither PET nor SPECT scans are useful as diagnostic tools for HIV-associated dementia, and their patterns do not correlate with treatment efficacy.

Electroencephalographic (EEG) abnormalities have been reported in some asymptomatic seropositive patients,¹⁷⁴ but this is not the experience of all investigators.¹⁷⁵ Patients with early dementia may show EEG abnormalities, but up to 50% of subjects have normal recordings. As dementia becomes severe, diffuse slowing is frequently noted, consistent with widespread dysfunction.⁹ Despite the observations, EEG can be used only as an adjunct tool and has no specific diagnostic or predictive value.

MANAGEMENT. During the past several years, major advances have been made in antiretroviral therapy and care for patients with HIV-associated dementia. There are now 15 Food and Drug Administration-approved antiretroviral agents in the United States, and many studies have monitored the response to therapy through regular measurement of CSF-to-plasma drug level ratios, CSF HIV RNA levels, and CD4⁺ counts, all currently part of standard clinical care for AIDS patients.

Initial studies reported a decline in the number of new cases with HIV dementia after the introduction of zidovudine therapy in 1987.¹⁴⁴ The dose was 1000 to 1200 mg/day, and other groups reported a decrease in the number of patients developing new HIV-1 dementia when treated with zidovudine 1200 mg/day compared with patients taking lower doses.¹⁷⁶ However, there were only two placebo-controlled monotherapy antiretroviral trials showing that zidovudine improved neuropsychological performance.^{177,178} The response was dose dependent, with recommended doses of 2000 mg/day.¹⁷⁹ Since 1992, as new antiretroviral drugs emerged, polytherapy has replaced monotherapy in the treatment of HIV-associated dementia. Although only a few systematic studies have been performed, they indicate that the use of combination antiretroviral therapy without protease inhibitors can reduce risk of developing HIV dementia¹⁸⁰ and can improve neuropsychological performance in patients with HIV dementia.¹⁸¹ With the introduction of protease inhibitors in 1996, trials of combination of antiretrovirals and protease

inhibitors showed improvement of neuropsychological performance compared to monotherapy or no treatment.^{182,183} In 1998, a new reverse transcriptase inhibitor, abacavir, was tested in a placebo-controlled, double-blinded fashion and showed that CSF viral load decreased and neuropsychological performance improved when the drug was used in combination with antiretrovirals. Two other drugs, stavudine and nevirapine, have been shown to be useful when combined with antiretrovirals, particularly due to their pharmacokinetic properties, tolerability, and dosing. Patients on antiretroviral therapy have shown improvements in psychomotor speed, verbal fluency, and visuo-construction tasks, but not complex attention and learning efficiency.^{184,185} Despite mixed cognitive improvement, patients on antiretroviral therapy can have dramatic improvements from a state of marked cognitive impairment to independent living.

In addition to the antiretrovirals and protease inhibitors, several adjunctive therapies have been clinically tested in order to block macrophage activation and restricted release of neurotoxic factors. These include Lexipafant, an antagonist of platelet-activating factor¹⁸⁶; memantine, an open-channel NMDA antagonist¹⁸⁷; peptide T¹⁸⁸; selegiline¹⁸⁹; and, most recently, valproic acid.¹⁹⁰ Because patients with HIV-associated dementia are very susceptible to adverse effects of psychoactive drugs, hypnotics and anxiolytics should be avoided. Risperidone in small doses may be useful in agitated and combative patients; stimulants such as methylphenidate may be tried for excessive inertia.

During the past several years, it has been recognized that HIV-1 protease and transcriptase genes can undergo development of drug-resistance mutations. In patients with HIV-associated dementia receiving HAART therapy, this represents a significant problem because mutations seem to develop independently in different brain regions and therefore pose a considerable challenge for treatment.¹⁹¹ HIV-1 genome mutations that particularly affect drug resistance have been found in the POL gene within the HIV-1 localized in the chorioid plexus.¹⁹²

In summary, even though there are no specific guidelines for antiretroviral therapy in HIV-associated dementia, combination of antiretrovirals with or without protease inhibitors and adjunctive medications are generally recommended. These agents have complex side effects and are very expensive, making them inaccessible to the majority of HIV-infected patients worldwide.

Cerebrovascular Disease in AIDS

Cerebrovascular abnormalities in patients with HIV-1 infection have been unrecognized. A recent study, however, indicates an estimated prevalence of 1% or 2% for transient ischemic attacks and strokes.¹⁹³ The likely reason is a combination of hyperlipidemia, hyperglycemia, and hypertension due to the antiretroviral therapy in aging patients with AIDS, associated with a high prevalence of nicotine abuse. Development of aneurysms is well recognized in children and involves direct endothelial invasion, release of cytokines, and fibrotic inflammatory vasculopathy. However, the mechanism of HIV-1-induced cerebral vascular damage is still not clear.

HIV-associated Central Nervous System Disorders—Children

Neurological involvement was reported as a frequent complication of pediatric AIDS in the early years of the epidemic. A devastating progressive encephalopathy (PE) was described,¹⁹⁴ as was more stable neurological impairment.¹⁹⁵ It was observed that by the time HIV-1 infection had advanced to full-blown AIDS, cognitive and motor impairments of varying duration, progression, and severity were extremely common. In the majority of cases, neuropathological studies revealed no evidence of CNS opportunistic infections or neoplasms.^{14,195,196} The clinical syndrome of PE in children (variously termed AIDS encephalopathy, HIV-1 encephalopathy, PE, subacute PE, HIV-1-associated CNS disease, and HIV-1-associated PE of childhood) is now recognized to be similar to the adult counterpart, HIV dementia,¹⁷ and is directly related to HIV-1 brain infection.

PATHOGENESIS AND PATHOPHYSIOLOGY. In adults, the pathophysiological mechanisms underlying HIV-1-associated CNS disease are not clearly defined. In infants and children, the study of neuropathophysiological mechanisms and their clinicopathological correlates is even more complex because developmental-maturational issues must also be considered. Adult, horizontally transmitted HIV-1 CNS infection and disease occur in the mature, fully developed, and completely myelinated nervous system. The immune system and CNS elements of the mononuclear phagocyte system (intrinsic microglia) are also fully developed. Pediatric, vertically transmitted HIV-1 infection and disease occur in an immature, evolving organism. It is believed that HIV-1 invades the CNS early in the course of infection. Maternal-infant transmission may occur during gestation in some patients, whereas in others, the infection may occur during the perinatal period. The time of infection (gestational versus perinatal, and if gestational, in which trimester) is likely to be an important factor. The developmental stages of the nervous and immune system when exposed to the direct and indirect effects of the virus must be considered. Innumerable dynamic interactions occur between these two systems during development, and these undoubtedly interact in complex ways with HIV-1 variables. The maturational stage of CNS development when exposed to the effects of the virus is likely to manifest as different patterns of pediatric HIV-1 CNS disease.¹⁹⁷

The nervous system may also be affected secondarily by complications related to the immunodeficiency, including CNS neoplasms, infections with pathogens other than HIV-1, and strokes. The nervous system may also be affected by systemic AIDS-related conditions (neurological complications of systemic illness), nutritional deficiencies, endocrinological and metabolic derangements, and by toxic/metabolic complications that arise as a consequence of therapy. These conditions are not mutually exclusive, and coexisting conditions are common.^{197,198}

In addition, the developing nervous system in HIV-1-infected infants (as in non-HIV-1-infected infants) may be adversely affected by maternal conditions during pregnancy, such as substance abuse, inadequate nutrition, deficient prenatal care, and AIDS-associated illnesses (e.g., infections with pathogens other than HIV-1).¹⁹⁷ Premature

delivery is associated with some of these high-risk maternal conditions. The prematurely born HIV-1-infected infant, like any premature infant, is, in turn, at risk for developing perinatal CNS complications—intraventricular hemorrhages, periventricular leukomalacia, hypoxic encephalopathy—that carry the risk of neurological sequelae.

EPIDEMIOLOGY AND RISK FACTORS. The true incidence of pediatric HIV-1-associated CNS disease is not known. A review of the published literature is difficult to interpret because of differences in terminology, definitions, study populations, and study designs.^{66,77,198–201} Extrapolating from the experiences of many investigators, it appears that HIV-1-associated CNS disease in children generally parallels the progression and severity of immunodeficiency and systemic disease. One study indicates that increased viral load appears to be the only significant factor associated with the development of PE in children.²⁰²

More than 1 million children are currently infected with HIV-1 worldwide, and more than 1000 new pediatric cases occur daily, as reported by Association Francois-Xavier Bagnoud.²⁰³ Whereas 1% to 3% of reported AIDS cases in Western countries account for HIV-1 infection of children, in sub-Saharan Africa it reaches 20%. This epidemic of pediatric HIV-1 infection and disease represents a major international health crisis.

The pediatric HIV-1-associated CNS disease follows a bimodal distribution, with an “early,” very aggressive form that occurs within the first 2 years of life and a “late” form that occurs years after the perinatal infection. The latter corresponds in its course to the adult HIV-associated dementia. The incidence of the early form is much higher than the incidence of adult CNS infection 1 or 2 years after infection: approximately 10% in the first year and 4% in the second year, compared to 0.5% in adults. In these children, HIV-1-associated CNS disease is frequently the initial clinical manifestation: in up to 56% of infants younger than 1 year old and 32% of older children, compared to 9% of adults.^{66,77,204–207} The incidence of the late form is similar in children and adults: less than 1%.^{206–208} Although the initiation of zidovudine therapy in the second and third trimester in HIV-1-infected mothers significantly decreases the incidence of perinatally infected infants, the lack of resources in many Third World countries limits treatment availability. Pediatric HIV-1 infection and disease remain significant worldwide problems.²⁰⁷ Due to improving therapies throughout the years, there is a growing population of perinatally infected children who survive well into adulthood.²⁰⁹

CLINICAL FEATURES AND ASSOCIATED DISORDERS. HIV-associated CNS disease is a clinical diagnosis, supported by neuroimmunological/virological testing, neuroimaging, and psychometric evaluation.²⁰⁸ HIV-1-infected newborns are usually well at birth, and clinically recognizable neurological features of HIV-1-associated CNS disease are exceedingly rare. However, some HIV-1-infected neonates do have neurological problems owing to comorbid conditions. Observations in both clinical care settings and longitudinal research studies show that the rate and pattern of disease progression have considerable clinical diversity.^{140,197} In some infants and young children, neurological deterioration is rapidly progressive; in others, it occurs over a period of weeks to months, followed by a

relatively stable period and then further deterioration. Clinical deficits may not evolve uniformly, and some children develop progressive and disabling motor problems yet maintain relatively stable cognitive and socially adaptive skills. In contrast, others have more impaired cognitive than motor function. Finally, there is a subset of children who have relatively minor and stable motor and cognitive findings, defined as HIV-1-associated static encephalopathies.^{195,197,201,204,208,210} In an effort to delineate further the clinical characteristics of HIV-1-associated CNS disease syndromes in children, a classification scheme was adopted based on (1) age of onset of clinically apparent disease, (2) rate and pattern of disease progression, and (3) domains of function most affected.²⁰¹

The most severe, devastating, and clearly recognized syndrome is HIV-1-associated PE of childhood.⁶⁵ This entity corresponds to the HIV-associated dementia of adults.^{211,212} Age of onset is usually in the first year of life (3 to 8 months of age) but may begin later. It can develop in perinatally infected infants even though they are immunocompetent.^{206,207} There is evidence that the development of PE during the first year of life correlates with the viral load and not strictly with the CD4⁺ lymphocyte markers.²¹³ Even in severe cases of PE, CSF and brain viral load can be significantly lower compared to plasma levels. Furthermore, there is no evidence that prenatal ZDV treatment prevents early development of PE.²⁰⁷

Neurological signs of PE of childhood consist of a well-defined triad: impaired brain growth, progressive motor dysfunction, and loss, plateau, or inadequate acquisition rates of neurodevelopmental milestones.^{81,208} The clinical diagnosis of PE is made if one of the preceding clinical findings is present in a child who was neurologically normal at baseline or if two of the preceding clinical findings are present in a neurologically abnormal child at baseline.⁸¹ Microcephaly at birth in an HIV-1-exposed neonate is suggestive of in utero HIV-1 infection and indicates high risk for the development of PE in the first year of life.²⁰⁷ Acquired microcephaly is easier to detect in children younger than 3 years of age, due to the rapid head growth. In older children, head circumference velocity decreases, and a much longer interval is required to detect impaired brain growth. In these cases, serial neuroimaging studies are valuable because progressive loss of brain parenchyma can be observed.²¹⁴ Progressive motor dysfunction results in fine and gross motor impairments, gait disturbance, and spasticity. Opisthotonic posturing and rigidity may develop and are usually superimposed on spasticity. Some children display extrapyramidal syndromes, with rigidity, dysarthria or oromotor dyspraxia, dysphagia with drooling, hypomimetic facies, and gait abnormalities.²¹⁵ Feeding difficulties due to pseudobulbar signs are frequent. Although these children appear alert and wide-eyed, they have a paucity of spontaneous facial expressions. Despite these features, there is little facial weakness, and the lingual, buccal, and forehead muscles show full and symmetrical movement when the child cries. Nonetheless, the child is hypophonic and has decreased spontaneous and responsive vocalizations. Play deteriorates and previously acquired language skills or adaptive skills are progressively lost. Psychometric measures document a decline in the composite cognitive score. At end stages, the child is apathetic,

withdrawn, and quadriparetic with markedly impaired higher cortical function.^{10,216} Functions associated with cranial nerves and brain stem nuclei are usually spared, although autopsies often reveal HIV-1 within these structures.²¹⁷

Cognitive decline, loss of interest in school performance, social withdrawal, emotional lability, decreased attention, and psychomotor slowing are reported as signs of HIV-1-associated PE in school-age children.^{10,195,201,218} With advancing disease, psychometric tests show a decline in the composite IQ score. No specific neuropsychometric marker has been developed to predict the appearance of PE in asymptomatic children.

Additional neurological and psychiatric manifestations are common. Among them, seizures are particularly frequent and develop not only because of focal pathology²⁰⁸ but also because there is a higher incidence of unprovoked seizures in PE compared to the general pediatric population.²¹² Although HIV-1 is well-known to affect cerebrovascular tissue, infarcts are not common.²¹⁹ However, the syndrome of “reversible occipital parietal encephalopathy” has been described and relates directly to vascular pathology in HIV-1 infections.²²⁰ In addition, some children may develop cerebral aneurysms, usually fusiform involving the major blood vessels.²²¹ These may either be asymptomatic or cause subarachnoid hemorrhages or infarcts. Vacuolar myelopathies and neuropathies are very rare in children and often result as complications of intercurrent illnesses, such as measles or CMV, or due to drug-related adverse effects.^{81,219,222} ZDV-associated myopathy has been reported and can be ameliorated with carnitine supplementation.^{223,224} In addition, cardiomyopathy is present in approximately 30% of children with PE and cardiac evaluation is important in all children with PE.²⁰⁶

Psychiatric and behavioral manifestations are numerous and include acute psychoses, common at the end stage of disease,²²⁵ depression, anxiety, adjustment disorders,^{208,226} attention deficit hyperactivity disorder,^{227,228} as well as language and communication impairments that lead to learning disabilities.²²⁹

A less severe neurological syndrome also occurs in the first 2 years of life.^{204,216} Most of these infants are hypotonic and have marked delays in attaining motor milestones. Cognitive impairment of a variable degree and expressive language problems are common.^{201,210} Poor brain growth as determined by serial head circumference measurements may be present.^{13,197,204,216} In early childhood, some of the children develop a diparesis-type syndrome,²⁰¹ whereas others remain stable and continue to acquire mental, motor, and adaptive skills. A change in gait is often the first sign of HIV-1 motor involvement in early childhood, as the child begins to toe walk. These individuals become hyper-reflexic and have increased tone in the lower extremities.²⁰¹ The rate of progression and the severity of deficits vary. Some children maintain independent ambulation for years, although they have a mildly spastic gait and are clumsy.^{197,204} Impairment of fine motor ability is frequent. Progression and severity in other children may be more rapid and marked. Some require orthotics for ambulation, whereas others become wheelchair-bound within months.^{195,201} Cognitive impairment is frequent but not invariable. In a subset of children, cognitive function is not affected, and composite IQ scores remain within the normal range. For

most, the degree of impairment ranges from borderline intelligence to mild or moderate retardation.^{10,195}

A subset of the children, who had a prolonged stable course, ultimately developed further neurological deterioration, formerly referred to as “plateau followed by further deterioration.” The course then becomes similar to that of subacute PE.¹⁹⁵ Progressive atrophy and white matter changes are invariably seen. In contrast, other children show improvement and steadily acquire additional developmental skills. Their rate of acquisition of new skills accelerates compared with their previous plateau performance.¹⁹⁵ Children who in infancy and early childhood had marked delays in motor and mental development and were followed from birth in prospective studies continued to acquire milestones and skills, although the rate and quality deviated from the norm.²⁰¹ This suggests that HIV-1 may compromise the normal developmental process and result in a stable or static encephalopathy.

It is unknown whether HIV-1-associated CNS disease manifestations in adolescents differ in early signs and progression from that of adults or children, although it is anticipated that manifestations will be similar to those of adults.

DIFFERENTIAL DIAGNOSIS. The differential diagnosis includes other neurodegenerative disorders, infectious etiologies, and psychiatric conditions. CNS opportunistic infections and primary CNS lymphoma are not common in HIV-infected infants and young children, except in cases of congenital opportunistic infections. They are more prevalent in older children and adolescents.⁸¹ However, opportunistic infections should always be considered in a case of acute behavioral changes, headache, focal findings on neurological exam, or overall deterioration.²³⁰ Fungal opportunistic infections (cryptococcal meningitis), *Toxoplasma gondii* abscess, primary CNS lymphoma (sometimes associated with Epstein-Barr virus [EBV]), and herpes simplex or CMV encephalitis can all have the previously listed presentations.^{81,231,232} Noncongenital CNS opportunistic infections are common in children older than 6 years of age, when CD4⁺ levels are less than 200, and particularly when they are less than 100 cells/mL.²³²

EVALUATION. The evaluation of the HIV-1-infected child with neurological involvement requires the clinical skills and major diagnostic tools of the neurologist.²⁰⁴ The approach to the diagnosis of HIV-1-associated CNS disease, including differential diagnosis (secondary complications and co-morbid complications), involves a careful medical and developmental history, HIV-1 systemic disease history, current immunological status, neurological examination, psychological assessment, and neuroimaging studies.^{197,204} The diagnosis of HIV-1-associated PE is relatively straightforward if the patient has been followed prospectively. Longitudinal assessments of the infant or child reveal progressive involvement. The diagnosis is also fairly straightforward if the child on initial examination is found to have motor deficits (e.g., spasticity, ataxia, weakness, abnormalities of tone, and change in gait), and by a careful history, either the new onset or progression of motor impairment can be documented (again, when other causes for progressive motor dysfunction have been excluded). Confirmation of progression can occasionally be obtained by review of family photographs of the child.

However, diagnostic difficulties arise when an HIV-1-infected youngster who was not followed from birth or infancy by the examiner is found at the initial neurological evaluation to have deficits or delays. Because the frequency of neurological and developmental impairment in this population is high, it is often impossible for the clinician to ascribe these findings to HIV-1-associated CNS disease rather than to possible co-morbid conditions. A careful history is paramount. If there are no other risk factors, the diagnosis is likely. The child should have a formal psychological assessment and be re-evaluated by the neurologist and psychologist in 2 to 4 months.²³³

Head circumference measurements are very helpful, and because these measurements are commonly recorded in primary care settings, a careful review of medical records will usually document at least one or two past head circumference measurements. This comparison allows the examiner to plot serial measurements, and the pattern of downward deviation and "crossing percentiles" makes the diagnosis of HIV-1-associated CNS disease likely. Diagnostic probability is especially high if acquired microcephaly is documented.

Examination of CSF for HIV-1 in cases of suspected HIV-associated PE is not always helpful because CSF quantitative HIV-1 microculture, p24 antigen, or HIV-1 PCR, as well as anti-HIV-1 IgG, are not present in all cases.^{81,234} Perinatally infected infants may even have undetectable levels of CSF HIV RNA despite clinical PE.²⁰⁷

Neuroimaging studies are particularly helpful and in fact critical to proper diagnosis. If calcification of basal ganglia, with or without mineralization of the frontal white matter, is present, it is probable that the child has HIV-1-associated CNS disease. If cerebral atrophy is present in the absence of documented perinatal complications, steroid use, or other known causes of atrophy, the diagnosis likewise becomes extremely likely. Neuroimaging evidence of atrophy accompanied by acquired microcephaly clearly strengthens the diagnostic certainty. In addition, a study by Civitello and collaborators indicated correlation between quantitative cerebral atrophy on CT scans and CSF viral load. In recent years, magnetic resonance spectroscopy (MRS) has emerged as a possible tool for monitoring disease progression and treatment efficacy.^{235,236} Follow-up neuroimaging studies should be requested in addition to the previously mentioned serial neurological and psychological evaluations.

TREATMENT. As in HIV-associated dementia of adults, retroviral therapy revolutionized the treatment of HIV-1-infected children. In addition, the emergence of NRTIs, NNRTIs, and PIs further improved the approach to aggressive treatment of HIV-1 infection in children. Initial monotherapy with ZDV did not have a sustained benefit in all children,²³⁷ and it was replaced with monotherapy with NRTIs such as ddI, 3TC, and d4T.^{238,239} However, it was soon evident that polytherapy with ZDV and ddI was clearly better in preventing and treating HIV-associated PE compared with monotherapy with each agent.^{240,241} In addition, a successful introduction of protease inhibitors in HIV-associated dementia of adults led to pediatric guidelines for treatment of HIV-associated PE. Currently, recommendations include an initial antiretroviral regimen consisting of two compatible NRTI agents and one highly active protease inhibitor.⁸²

Adjunctive therapies of HIV-associated PE correspond to some agents tried in adults, such as methyl group donors (S-adenosylmethionine and glutathione, baclofen for spasticity, NSAIDs for pain, stimulants for psychomotor slowing, and selective serotonin reuptake inhibitors for depression). Hypnotics and anxiolytics should be avoided because HIV-1-infected individuals are highly susceptible to adverse effects. Good nutrition is essential, and some anecdotal reports indicate benefits of omega-3 and omega-6 polyunsaturated fatty acid supplements.

In addition, optimal treatment of HIV-associated PE in children is also directed to assist in neurodevelopment, and a battery of services, including not only physical and occupational therapists but also speech pathologists, for both language delays and feeding difficulties should be provided.

HIV-associated Myelopathies

Spinal cord involvement associated with HIV-1 infection has diverse causes. As with other neurological disorders associated with HIV-1 infection, different conditions occur with increased prevalence during different stages of HIV-1 infection. Some conditions are related to HIV-1, whereas others are associated with other infectious, neoplastic, vascular, or nutritional and metabolic etiologies.^{22,242-244} A self-limiting myelitis at the time of seroconversion and a vacuolar myelopathy (VM) that occurs during more advanced HIV-1 disease stages are related to primary HIV-1 infection.^{22,142} Other infectious agents reported include the herpesviruses (VZV, HSV-2, and CMV); HTLV-1 or -2; *Treponema pallidum*, *Mycobacterium tuberculosis*, and other bacterial pathogens; as well as toxoplasmosis, cryptococcus, and aspergillosis. Epidural and paraspinous abscesses due to bacteria, fungi, or mycobacteria should also be considered. Intramedullary lesions due to infectious agents have also been described. Compressive lesions may be caused by neoplasms, of which lymphoma is most common.⁶ In addition, direct involvement of the spinal cord, although rare, has been caused by lymphoma or multiple myeloma. Vascular causes of noninfectious spinal cord disease in AIDS include ischemic myelopathy due to disseminated intravascular coagulation. Finally, vitamin B₁₂ and folate deficiency should always be investigated in HIV-1-infected patients who present with myelopathy.²⁴⁵

PATHOGENESIS. There is no evidence of the direct HIV-1 infection of the spinal cord in patients with VM. The virus can be identified within macrophages, which are abundant in areas of vacuolization, but not in neurons or microglia. It is possible that macrophage-derived factors, such as interferon, interleukin-1 (IL-1), and TNF- α , are directly toxic to myelin, or that these factors may be responsible for a metabolic abnormality that affects myelin.²⁴⁶ These possibilities are supported by the notion that VM clinically and pathologically resembles myelopathy of vitamin B₁₂ or folate deficiency. Cobalamin deficiency is common in AIDS patients, but there is no correlation between VM and vitamin B₁₂ serum levels nor between vitamin B₁₂ supplementation and VM clinical course. However, the similarity between VM and vitamin B₁₂ myelopathy suggests that the transmethylation pathway using cobalamin as a cofactor may be involved in the white

matter vacuolization. HIV-1 may ultimately lead to impairment of transmethylation and myelin vacuolization through the activation of macrophages or other mechanisms.²⁴⁷ In addition, it has been suggested that NEF prevents proper differentiation of oligodendrocytes by affecting both CNPase and MBP, therefore predisposing the development of VM.²⁴⁸

PATHOLOGY. VM is characterized by the presence of intramyelinic and periaxonal vacuoles in the lateral and posterior columns of the spinal cord. The axons are usually intact in areas of mild or moderate vacuolization, but in advanced cases with severe vacuolization, the axons are disrupted. Initially, the vacuolization is symmetrical, but with the progression of the disease, it often becomes asymmetrical. The myelopathy usually affects the midportion of the thoracic cord, but vacuolization can be present in other portions of the thoracic cord, the cervical cord, and lumbar cord.²⁴⁹

CLINICAL COURSE. VM complicates the clinical course of 5% to 27% of all HIV-1-infected patients. It is reported in up to 55% of autopsy series, and in one clinicopathological series examining adult AIDS patients, VM occurred in 47%.^{58,244,250} VM usually appears late in the course of HIV infection, although there are occasional reports of AIDS initially presenting as VM.²⁵¹ The disease develops insidiously, and frequently it is not diagnosed until 3 to 16 weeks after onset. Initial symptoms include urinary urgency and increased frequency, sexual dysfunction, complaints of stiffness or heaviness of the legs, with initially no weakness or pain. As the disease progresses, walking becomes difficult, with painful spastic paraparesis, mild paresthesias, and urinary incontinence.

Neurological examination typically demonstrates spastic paraparesis with asymmetrical weakness, hyper-reflexia, clonus, extensor plantar responses, and mild or moderate loss of vibration and joint position sense in the lower extremities.¹⁶⁶ Sensory level is usually absent. Sensory ataxia may be present due to the severe proprioceptive loss. If there is an associated sensory neuropathy, ankle reflexes may be hypoactive, and hypesthesia to pain may be present in a stocking distribution.

EVALUATION. The clinical examination confirming the preceding findings is essential for the diagnosis since there are no confirmatory tests for VM. Spine MRI is usually normal but may show atrophy of the affected thoracic or cervical region. In addition, increased signal on T2 images may be observed, whereas enhancement after gadolinium injection is very rare.²⁵² CSF studies may show a mild pleocytosis (<20 cells/mL) and increase in protein content. Somatosensory evoked potentials are an important diagnostic and prognostic tool to detect abnormal central conduction time even before the clinical manifestation of VM. When used sequentially, this test can monitor the progression of the disease or response to therapy.

DIFFERENTIAL DIAGNOSIS. VM is a diagnosis of exclusion that can be made only after other causes of myelopathy have been excluded. The differential diagnosis includes opportunistic infections (HTLV-1 or -2, CMV, herpes simplex 2, toxoplasmosis, tuberculosis, syphilis, cryptococcus, or aspergillosis), metabolic disease (vitamin B₁₂ and folate deficiency), neoplastic lesion (lymphoma and multiple myeloma), and toxic myelopathy induced by nitrous oxide.

TREATMENT. There have been very few clinical trials, and no specific treatment is available. Zidovudine and high doses of vitamin B₁₂ given intramuscularly have failed. No clinical benefit has been shown with corticosteroids, intravenous immunoglobulin (IVIg), or protease inhibitors. A double-blinded, placebo-controlled study with L-methionine indicated no clinical benefit in myelopathy, with some improvements in central conduction time.²⁵³ Currently, therapy is primarily supportive and symptomatic.

HIV-RELATED PERIPHERAL NERVOUS SYSTEM DISORDERS

HIV-associated Neuropathies

Peripheral neuropathies are a frequent complication of HIV-1 infection and AIDS. A wide range of disorders have been described, and their causes are diverse. Some neuropathies are related to HIV-1 or HIV-induced immune-mediated mechanisms. HIV-1, for example, in sensory neurons is dependent on CCR5 receptors present on macrophages, although tropic forms of HIV-1 sensitive to CXCR4 receptors have also been reported in peripheral nerves of AIDS patients.²⁵⁴ These receptors are instrumental to the development of infection in the CNS as well. In other cases, neuropathies may be related to toxic complications of therapy, complications of systemic HIV-1 illness, nutritional deficiencies, metabolic derangements, opportunistic infections, or neoplasms (Table 44-11). Drug-induced injury can also exacerbate HIV-associated neuropathic disease. “D” drugs (didanosine, stavudine, and zalcitabine) are most likely to induce such injury, particularly when used in combination with one another or with hydroxyurea.²⁵⁵ Because these drugs have a primary affinity for mitochondrial γ -DNA polymerase, drug-induced peripheral nerve injury has been added to the enlarging spectrum of antiretroviral-associated mitochondrial toxicity syndromes. Risk factors for neuropathy in HIV-infected patients are male sex, older age, alcohol abuse, and NRTI use.²⁵⁶ In addition, studies indicate that HIV-associated neuropathies are not

associated with the viral load or CD4 count but, rather, with the drug abuse, particularly in the case of distal sensory neuropathy (Video 259, Sensory Polyneuropathy).^{257,258}

The major HIV-1-associated peripheral neuropathy syndromes have well-defined clinical characteristics (Table 44-12). Distinctive clinical features that aid in the diagnosis, management, and, occasionally, prognosis of patients are stage of HIV-1 disease, CD4⁺ lymphocyte count, rate of symptom progression, degree of weakness relative to sensory loss, and characteristic electrophysiological findings.

Different neuropathic syndromes occur with increased prevalence at particular stages of HIV-1 disease. Some syndromes are encountered frequently, whereas others are rare. In general, the overall incidence of peripheral neuropathies increases with advancing systemic disease, progressive immunodeficiency, and declining CD4⁺ counts.²⁵⁹ By the time patients develop AIDS, clinical and electrophysiological evidence of neuropathy is present in up to one-third of patients.²⁵⁹ Even higher rates of nerve pathology are reported in autopsy studies. Acute demyelinating polyneuropathy, brachial plexopathy, and mononeuritis multiplex occur at the time of acute infection or seroconversion. Acute inflammatory demyelinating polyneuropathy (AIDP) and chronic inflammatory demyelinating neuropathy (CIDP), although rare, are the most common form of peripheral neuropathy during the latent, asymptomatic, or mildly symptomatic stage of HIV-1 disease when CD4⁺ cell counts are greater than or equal to 500 cells/mL. As immunodeficiency progresses and as CD4⁺ cell counts decline to the 200 to 500 cells/mL range, the most frequent neuropathies encountered are mononeuritis multiplex and herpes zoster neuropathy (Video 217, Anterior Interosseous Neuropathy, Pinch Sign; Video 219, Ulnar Neuropathy, Froment Sign). With HIV-1 disease progression (CD4⁺ <200 cells/mL), the occurrence of distal symmetrical polyneuropathy increases, as does the prevalence of other types of neuropathies, such as autonomic neuropathy, mononeuritis multiplex, cranial mononeuropathies, mononeuropathies-radiculopathies associated with neoplasms, and toxic neuropathies. Progressive polyradiculopathy occurs in advanced HIV-1 disease when the patient is severely immunosuppressed (CD4⁺ <50 cells/mL).

Inflammatory Demyelinating Polyneuropathies

Although they are relatively uncommon, both AIDP and CIDP are well-recognized complications of HIV-1 infection.²⁶⁰ Unlike other HIV-associated neuropathies, the inflammatory neuropathies occur primarily in patients early in the course of the illness, before AIDS develops, and may be the initial manifestation of the disease. AIDP, in particular, may occur coincidentally with seroconversion.²⁶¹ Clinical and electrophysiological features of inflammatory demyelinating polyneuropathies are similar to those of patients without HIV-1 infection (see Chapter 44). Patients with AIDP present with progressive, ascending symmetrical weakness of the lower and upper extremities. Although sensory symptoms may be present, the examination commonly shows sensory deficits that are mild in comparison to the degree of weakness. Areflexia is a common finding. The CSF protein may be elevated,

and a majority of patients have a mononuclear pleocytosis of up to 50 cells/mL, a helpful differentiating feature from AIDP in non-HIV-1-infected patients. Nerve conduction velocity (NCV) studies and sural nerve biopsy frequently demonstrate demyelination. As in non-HIV-1-infected patients with AIDP, the pathophysiological mechanism is thought to be due to autoimmune dysfunction. AIDP is a monophasic illness that responds well to the treatment, but it can also remit without therapy. IVIg and plasmapheresis are the treatments of choice.

The natural history of HIV-1-associated CIDP is unknown. As in treatment of CIDP in non-HIV-1-infected patients, prednisone, IVIg, or plasmapheresis are reported to be efficacious (see Chapter 49).

Distal Symmetrical Polyneuropathies

PATHOGENESIS AND PATHOPHYSIOLOGY. Pathophysiological mechanisms of this form of HIV-associated polyneuropathy remain unclear. Several hypotheses have been proposed: (1) direct effects of HIV-1,^{8,262-264} (2) HIV-1-mediated effects of activated macrophages and the production of cytokines (TNF- α , IL-1, and IL-6),^{265,266} (3) nutritional deficiencies, and (4) toxins. Further studies are needed to clarify the role of these agents in the pathogenesis of distal symmetrical polyneuropathy (DSPN) in AIDS. Infectious etiologies (mainly CMV) have also been implicated; however, some investigators believe that infection-related DSPN should be considered as a separate and distinct category.⁵⁸

Pathological examination of nerve biopsies shows degeneration of first unmyelinated and then myelinated axons,^{263,267} with mild epineurial and endoneurial perivascular mononuclear inflammation. The inflammatory cells are characterized as T lymphocytes and activated macrophages. In the endoneurium, suppressor/cytotoxic cells (CD8⁺) predominate over helper/inducer (CD4⁺) cells. A more equal ratio is seen in the epineurium and perineurium. Immunoglobulin, complement, or fibrin are not seen. Associated demyelination may be present but does not appear to be macrophage mediated or segmental.²⁶³ Distal axonal degeneration is noted in both central and peripheral projections of dorsal root ganglion cells and is a frequent autopsy finding in AIDS patients. Gracile tract degeneration in the upper thoracic and cervical segments may also be seen.²⁶⁴ Loss of dorsal root ganglion cells and mononuclear infiltration is usually mild in comparison with the degree of axonal degeneration and inflammation of distal nerves.

EPIDEMIOLOGY. DSPN is the most frequent type of HIV-associated neuropathy and an incidence of 2.81% is estimated in HIV-1-infected patients; however, it can be detected clinically in more than 35% of patients with AIDS.^{260,268,269}

CLINICAL FEATURES. Characteristically, sensory symptoms in the form of neuropathic pain far exceed motor dysfunction in DSPN.²⁷⁰ Typical symptoms are burning pain, numbness, or tingling of the toes or over the soles. Some patients develop contact hyperalgesia. Upper extremity involvement occurs somewhat later in the course of the neuropathy. Muscle weakness is not a prominent symptom. The most common signs are those typical of a

TABLE 44-12

HIV-1-associated Peripheral Neuropathies: Clinical Features

| NEUROPATHY | HIV DISEASE STAGE (CD4 ⁺ CELLS/ μ L) | ONSET | SYMPTOMS | SIGNS | DIAGNOSTIC STUDIES | COMMENTS |
|--|--|-------------------|---|--|---|--|
| Inflammatory Demyelinating Polyneuropathy (AIDP or CIDP) | AIDP: early (pre-AIDS) CIDP: early > late (variable) | Subacute | Progressive symmetrical weakness, paresthesias | Moderate to severe weakness \pm mild sensory loss Areflexia | EMG: demyelination CSF: $\uparrow\uparrow$ Protein \uparrow WBC | Indistinguishable clinically from AIDP and CIDP in non-HIV-infected states |
| Distal Symmetrical Polyneuropathy | Late (variable <200-400) | Subacute | Pain is predominantly symmetrical distal dysesthesias/paresthesias, numbness, burning pain | Stocking-glove sensory loss (symmetrical length-dependent) \downarrow ankle DTRs | EMG: distal axonopathy | Most common HIV-1-related form of neuropathy |
| Progressive Polyneuropathy | Late (<200) | Acute | Prominent lower extremity syndrome, back pain, radicular pain, paresthesias, lower extremity weakness, urinary incontinence | Bilateral lower extremity weakness \rightarrow flaccid paraparesis, saddle anesthesia, bowel and bladder dysfunction \downarrow ankle and knee DTRs | EMG polyradiculopathy CSF: $\uparrow\uparrow$ WBC + CMV culture | Prominent lower extremity syndrome resembling spinal cord compression |
| Mononeuritis Multiplex | Early: limited Late: extensive progressive (variable) | Acute or subacute | Facial weakness, wrist drop, foot drop Focal deep aching pain | Asymmetrical multifocal cranial and peripheral neuropathy | EMG: multifocal axonal neuropathy Nerve Bx: inflammation vasculitis \pm CMV inclusions | Laryngeal nerve involvement can occur and lead to hoarseness with vocal cord paralysis |

AIDP, acute inflammatory demyelinating polyneuropathy; CIDP, chronic inflammatory demyelinating polyneuropathy; Bx, biopsy.

Modified from So YT, Holtzman DM, Abrams DI, Olney RK: Peripheral neuropathy associated with acquired immunodeficiency syndrome; Prevalence and clinical features from a population-based survey. Arch Neurol 1988;45:945-948.

predominantly sensory length-dependent neuropathy with depressed or absent ankle tendon reflexes, elevated sensory threshold, increased vibratory thresholds, decreased pinprick and temperature, and stocking-and-glove distribution (Video 259, Sensory Polyneuropathy). Joint position sensation is relatively normal. If present, weakness is minimal and is generally restricted to intrinsic foot muscles.^{244,260}

DIFFERENTIAL DIAGNOSIS. HIV-1-associated DSPN should be differentiated from other neuropathic lesions,²⁷¹ including toxic neuropathies attributable to chemotherapeutic and retroviral (NRTI) agents (e.g., vincristine, isoniazid, ddC, ddI, and d4T)^{272,273} and tarsal tunnel syndrome. Electrodiagnostic studies do not differentiate between toxic neuropathies and other causes of DSPN. The diagnosis of toxic neuropathy is based on the temporal association of the peripheral neuropathy with drug treatment and improvement after the suspected agent is removed. However, patients with severe immunosuppression ($CD4^+ < 100/mL$), anemia, and a prior history of DSPN are at highest risk to develop NRTI-associated DSPN. Co-morbid conditions, such as diabetes, vitamin B₁₂ deficiency, or excessive alcohol intake, may exacerbate, unmask, or predispose HIV-1 patients to develop this neuropathy sooner than expected.

EVALUATION. The electrodiagnostic features of DSPN in AIDS are consistent with distal and symmetrical degeneration of sensory and motor axons, in a pattern similar to other forms of DSPN. NCV studies usually demonstrate absent or low-amplitude sural nerve action potentials (SNAPs).²⁶⁰ Late responses are also delayed in a pattern consistent with axonal neuropathy. Reduction in the amplitudes of the peroneal or tibial compound muscle action potential (CMAP) is less common. Electromyography (EMG) may demonstrate signs of active or chronic partial denervation with reinnervation in distal leg muscles.^{260,270} Serum vitamin B₁₂ levels, folate, ESR, antinuclear antibodies, fasting blood glucose, liver enzymes, creatinine, thyroid function tests, and serum protein electrophoresis are usually normal.²⁶⁰ CSF examination is nonspecific and often shows mild abnormalities in cell count and protein level (as is common in HIV-1-infected patients).²⁷⁴

MANAGEMENT. DSPN is often a disabling condition owing to severe pain. The main treatment is symptomatic and includes those agents used in the treatment of painful non-AIDS peripheral neuropathies, ranging from analgesics and NSAIDs to anticonvulsants (see Chapter 20). Studies indicate beneficial effects of gabapentin^{275,276} and lamotrigine^{277,278} in the treatment of HIV-associated DSPN. A controlled study using recombinant human nerve growth factor in HIV neuropathy failed to show prominent evidence of nerve fiber regeneration, although significant reduction of pain occurred. DSPN caused by the nucleoside analogue reverse transcriptase inhibitor therapy leads to depletion of serum acetyl-L-carnithine levels, but the cause is still not established.²⁷⁹ However, this finding offers the possibility of trying the carnithine supplement as a possible treatment for DSPN. Other treatments, such as antidepressants, mexiletine, and even acupuncture, have been tried in HIV-associated DSPN but have proved ineffective.^{280,281} It has been shown that erythropoietin may prevent sensory axonal degeneration due to both HIV envelope glycoprotein gp120 effect and the effect of ddC,²⁸² underscoring a

combined effect of both the virus and the treatment and the necessity for more detailed research on DSPN.

Mononeuritis Multiplex

Two forms of mononeuritis multiplex (MM), both relatively rare, have been recognized as a complication of HIV-1 infection and AIDS. The first form affects patients in early stages of HIV-1 infection ($CD4^+$ cell counts > 200 cell/mL), and the second affects those individuals with advanced disease.^{267,283} Patients in early HIV-1 stages have a more benign disease, the extent of nerve involvement is more restricted, and the course is self-limited. Motor and sensory deficits develop over the course of a few weeks in the distribution of discrete peripheral nerves. This form of MM is a self-limited disease and does not usually require specific treatment. As in non-AIDS MM, an autoimmune vasculitis is proposed (see Chapter 50).^{284,285} This form of mononeuritis neuropathy should be differentiated from compressive neuropathies of the ulnar or peroneal nerves, seen particularly in patients who are bed-bound with profound weight loss (Video 219, Ulnar Neuropathy, Froment Sign; Video 220, Ulnar Neuropathy, Main en Griffes; Video 237, Foot Drop).

In contrast, more widespread, multifocal weakness is characteristic of the second type of MM, which occurs primarily in patients with low $CD4^+$ counts. The clinical presentation is typically subacute with progression over several weeks or a few months. Asymmetrical, multifocal sensory and motor deficits in the distribution of several major peripheral nerves or spinal roots are characteristic of this neuropathy. Significant motor deficits are present, and deep tendon reflexes mediated by the affected nerves are diminished or absent. Cranial neuropathy is common, and some patients have hypophonia, hoarseness, and vocal cord paresis (Video 44, Dysphonia).²⁶⁷ The asymmetrical weakness in discrete distributions of peripheral nerves and occasional laryngeal nerve involvement help distinguish these patients from those with the more frequently encountered CIDP. Before establishing the diagnosis, other causes of MM should be excluded, such as herpes zoster and lymphomatous nerve root infiltration.

Electrodiagnostic studies show multifocal neuropathy with mixed demyelination and axonal loss, reduced CMAP and SNAP amplitudes, and mild reduction in conduction velocities. Compressive or entrapment neuropathies are excluded by these studies. Pathological specimens from patients with advanced AIDS show polymorphonuclear infiltrates, with mixed axonal and demyelinating lesions, as well as evidence of CMV.^{284,285} The late form of MM requires specific anti-CMV therapy, including ganciclovir, foscarnet, or cidofovir, alone or in combination.

Progressive Polyneuropathy/Radiculitis

This syndrome develops primarily in patients with very low $CD4^+$ counts and advanced HIV-1 disease. With the introduction of HAART, the incidence of progressive polyneuropathy significantly declined. It is generally considered to be due to secondary viral, infectious, or neoplastic processes in the immune-compromised host and not directly related to HIV infection. Presenting features of

progressive lumbar polyneuropathy include an acute cauda equina syndrome with rapid progression of bilateral leg weakness and urinary/fecal incontinence. Back pain is a prominent feature in some patients. Initially, weakness is restricted to the lower extremities, as is areflexia. Paresthesias are common, but sensory deficits are rarely marked. Perineal or perianal sensory changes are characteristic but not always present. Areflexia and sensory disturbance (albeit mild) help differentiate this syndrome from weakness due to myopathy or the wasting syndrome. Sphincteric disturbances and sparing of the upper extremities separate this disorder from AIDP, CIDP, and MM. EMG demonstrates denervation in lower extremity muscles as well as in lumbar paraspinal muscles. NCV abnormalities may be present in up to one third of patients and indicate a coexisting polyneuropathy. CSF examination is the most important confirmatory study. Elevated protein content and hypoglycorrhachia are common. Approximately half of patients have a marked pleocytosis, with cell counts in excess of 500 cells/mL. The other half has a less striking mononuclear cell count.

CMV infection is the most important infectious cause of this syndrome²⁸⁶ and may be detected by CSF culture and the use of CMV PCR testing. This disorder should be treated with ganciclovir and foscarnet (see Chapter 41), and early treatment may partially reverse the neurological deficits. Delayed diagnosis and treatment leads to poor prognosis.

A polyradiculopathy syndrome may also be caused by pathogens other than CMV (e.g., herpes zoster infections, *Treponema pallidum*, *M. tuberculosis*, and toxoplasmosis of the conus medullaris) and by leptomeningeal lymphoma.²⁸⁷ Therefore, CSF studies should include viral cultures, VDRL titer, and cytological studies. A lumbosacral spine MRI excludes a compressive or mass lesion and may show enhancement of nerve roots. When herpes zoster radiculitis is present, lesions are improved and the incidence of neuralgia is reduced by acyclovir. Parenteral acyclovir (30 mg/kg/day) should be used when cervical or lumbar dermatomes are involved, in an attempt to prevent severe myeloradiculitis. Amitriptyline, carbamazepine, and capsaicin can be used in the setting of postherpetic neuralgia.

Autonomic Neuropathy

Autonomic neuropathy has been reported in nearly 50% of HIV-1-infected patients. The severity of autonomic impairment is correlated with the degree of immunosuppression. Patients primarily experience dizziness, diarrhea, bladder and sexual dysfunction, and, sometimes, palpitations. Both sympathetic and parasympathetic systems are involved. Sometimes, autonomic neuropathy is caused by pentamidine, and this drug should be excluded in every patient. Treatment is symptomatic and may require cardiovascular monitoring.

HIV-1-related Myopathies

Muscle disorders related to HIV-1 infection include HIV-1-associated polymyositis, ZDV toxic myopathy, pyomyositis or infectious myopathy, cardiomyopathy, and the

so-called wasting syndrome myopathy. Of these conditions, HIV-1-associated polymyositis and toxic myopathy related to ZDV are the most common. Distinguishing between these two forms of myopathy may occasionally be difficult.

PATHOGENESIS AND PATHOPHYSIOLOGY. The pathophysiological mechanisms underlying HIV-related myopathy are uncertain. A wide spectrum of histopathological findings have been described, including inflammatory infiltrates^{288–290} noninflammatory myofiber degeneration,²⁸⁹ nemaline rod bodies,^{288,299} cytoplasmic bodies, and mitochondrial abnormalities.²⁹¹ Muscle biopsy examination usually shows characteristic myopathic features, such as variation in fiber size or degenerating muscle fibers. Features of polymyositis (necrotic fibers and lymphocytic infiltrates in the perimysium and perivascular space) are also noted in some patients, although the degree of these changes is variable.²⁹² In a subset of patients, Gomori trichrome-stained sections of muscle show prominent abnormalities of mitochondria giving the appearance of ragged-red fibers.^{293–295} In other subsets of patients, electron microscopy examination shows granular material that appears as electron-dense rod bodies.²⁸⁹ Variable amounts of inflammatory infiltrates have been described in both of these types.

Before the widespread use of ZDV, overt myopathy or a polymyositis-like syndrome was reported but not frequently. With increasing use of ZDV, and especially at the initially high 1200 mg/day dosage, reports of myopathy in ZDV-treated patients and those who improved following ZDV withdrawal appeared in the literature.^{295–297} Studies showed ZDV to be an inhibitor of the γ -polymerase of the mitochondrial matrix,²⁹⁸ and ZDV toxicity in skeletal muscle mitochondria was demonstrated in some^{291,294,296,299–301} but not all studies.^{300,301}

Investigators have suggested that muscle changes may be due to the virus, the length of time of the patient's infection, and the length of time taking ZDV. Whether there are pathological features that distinguish between HIV-1- and ZDV-related myopathies remains uncertain.^{293,294,296,302} One clinical study of HIV-related myopathy conducted in unselected patients of all disease stages found that none of the patients taking ZDV had symptomatic myopathy thought to be related to ZDV. However, some patients had characteristic ZDV morphological changes on muscle biopsy.³⁰² The clinical relevance of the structural changes described previously in the chapter, the causal role of ZDV, and, thus, the pathogenesis of HIV-related myopathy remain unclear and the subject of controversy.

HIV-1 has been localized in infiltrating monocyte/macrophage cells by immunocytochemistry.³⁰³ Myofibers do not appear to be directly infected.²⁸⁹ This suggests that it is unlikely that HIV-1 has a direct role in myopathy. As in other forms of polymyositis (see Chapter 50), immune-mediated mechanisms are proposed. It is postulated that activated macrophages secrete toxic factors (cytokine hypothesis) that mediate myofiber damage. TNF, which causes cachexia in laboratory animals and is produced mainly by monocytes, is also implicated, as is IL-1 α (shown to accumulate in muscle fibers of HIV-infected patients).³⁰⁴ HIV-1-infected CD8⁺ cells produce cytokines that expose muscle fiber antigens against which there is no

self-tolerance. It has also been suggested that homology between viral GAG protein and muscle ribonucleoproteins triggers an autoimmune process leading to cellular infiltration and myofiber damage.³⁰⁵

EPIDEMIOLOGY AND RISK FACTORS. Risk factors are not clearly defined. One study of 50 unselected patients in all stages of HIV-1 infection found that 26% of patients had myopathy. An autopsy series reported myopathic changes in 26% of AIDS cases.²⁹⁰ A retrospective analysis of patients enrolled in an antiretroviral clinical trial showed a 0.4% incidence of myopathy in patients not treated with ZDV (placebo group), which increased to 3% in ZDV-treated patients (D. Simpson, personal communication). HIV-associated myopathy may develop in patients in all stages of HIV-1 infection and does not appear to be associated with the degree of immunosuppression.²⁸⁹

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Muscle weakness is the predominant sign and symptom.^{289,293} Patients present with slowly progressive symmetrical and predominantly proximal weakness of the upper and lower limbs. Patients have difficulty arising from a chair or climbing stairs. Myalgia is present in 25% to 50% of affected patients. Neurological examinations reveal symmetrical weakness of proximal muscle groups with prominent involvement of neck and hip flexors. HIV-1-associated polymyositis can occur at any stage of HIV-1 infection. Presentation is similar to sporadic polymyositis, with proximal muscle weakness, myalgias, and elevated creatine kinase (CK).

There are no clinical features that differentiate HIV from ZDV myopathy. ZDV myopathy usually occurs after at least several months of therapy, and there appears to be a dose and duration effect. Although some patients may improve after ZDV withdrawal (resolution of muscle pain and a slower recovery of strength),^{295,296} others do not.²⁹³ To add further confusion, ZDV rechallenge in some patients does not cause a relapse.²⁹⁷

DIFFERENTIAL DIAGNOSIS. Other myopathic complications of HIV-1 infection include wasting syndrome and infectious myopathies. Patients with advanced HIV-1 disease frequently develop a wasting syndrome (Slim's disease) consisting of fatigue, profound involuntary weight loss, and diffuse weakness. Affected individuals are cachectic, weak, and have a general loss of muscle bulk. The frequent finding of the wasting syndrome in people with severe HIV-1 infection makes it difficult to delineate a myopathic component. Although a myopathy can also cause a wasting syndrome characterized by involuntary weight loss and chronic muscle weakness,³⁰⁶ occasionally it is difficult to distinguish between the two. HIV-1-associated myopathy can occur at any stage of HIV-1 infection. Thus, if myopathy develops in early HIV-1 infection before other AIDS-defining illnesses and immunosuppression, the diagnosis of HIV-related myopathy is likely if systemic or nutritional factors have been excluded and criteria for a diagnosis of myopathy are met. The importance of determining a specific diagnosis of myopathy in patients is evidenced by some patients' improvement with prednisone therapy.³⁰⁶

Infectious causes of myopathy in patients with AIDS, although infrequent, should be considered in the differential diagnosis. Pathogens reported in muscles of AIDS patients

include *T. gondii*,³⁰⁷ CMV, *Microsporidia*, *Cryptococcus neoformans*, MAI, and *Staphylococcus aureus*.²⁹⁰

HIV-infected individuals may present with acute rhabdomyolysis characterized by a myopathic syndrome (myalgia and muscle weakness) associated with serum CK levels greater than 1500 IU/L. The cause of acute rhabdomyolysis in HIV-1 disease is unknown, although investigators have suggested several etiologies, including HIV-1, drug toxicity (e.g., ddI, sulfadiazine, and pentamidine), and opportunistic infections.³⁰⁸

EVALUATION. The diagnosis of myopathy is made by the presence of limb weakness with CK elevation, along with supportive electrodiagnostic and muscle biopsy studies. As in the diagnosis of polymyositis (non-HIV-1 related), if three of four features are present, the diagnosis is considered probable; if two of four features are present, the diagnosis is possible (see Chapter 50). Electrophysiological studies show typical myopathic EMG features (small, brief, and polyphasic motor unit potentials that recruit with full interference patterns and fibrillation potentials).²⁹³ Some patients also have NCV abnormalities indicative of coincident DSPN.²⁸⁹

In HIV myopathy, CK levels are usually elevated to a moderate degree, with a median level of approximately 500 IU/L.^{289,294-296} The CK elevation parallels the degree of myonecrosis observed in coincident muscle biopsies but does not seem to correlate with weakness and is not a specific marker of HIV myopathy (patients may have elevated CK without clinical features of myopathy).

Muscle biopsy is useful in the evaluation and management of patients. Some investigators propose that the histological finding of ragged-red fibers supports the diagnosis of ZDV myopathy.^{294,296} However, not all ZDV patients with myopathy have ragged-red fibers on biopsy; thus, the absence of the finding does not exclude a toxic myopathy.

MANAGEMENT. Because it is often difficult to distinguish patients with ZDV-related myopathy from those without, the initial management of patients with significant limb weakness and objective evidence of myopathy includes ZDV withdrawal. An 18% to 100% rate of improvement in muscle strength is reported from different series.^{293,295,302} Some patients show further deterioration or no improvement after cessation of ZDV but do respond to treatment with corticosteroids. Thus, if signs and symptoms persist after ZDV withdrawal (approximately 1 month), a muscle biopsy should be considered. If there are signs of inflammation, a trial of steroids is warranted. Prednisone may be effective in treatment of polymyositis or rod-body myopathy.^{288,293} One study indicates that the prognosis of HIV-associated myositis is good because many cases remit even spontaneously and particularly after therapy with prednisone.³⁰⁹

HIV-ASSOCIATED NEOPLASMS

Primary CNS lymphoma (PCNSL), non-Hodgkin's lymphoma metastatic to the CNS, and Kaposi's sarcoma are the principal brain neoplasms associated with HIV/AIDS. Of these neoplasms, PCNSL is the most common in both adults and children and is designated as an AIDS-defining condition. Neurological involvement associated with Kaposi's sarcoma is rare. Metastatic CNS lesions are found

at the junction between gray and white matter, and on MRI scans they enhance with contrast material. They are often highly vascular tumors and can hemorrhage.

Primary Central Nervous System Lymphoma

PCNSL (see Chapter 46) develops in approximately 5% of patients with AIDS and is found at autopsy in up to 10% of cases. It is the initial AIDS-defining illness in 0.6% of adults. In children, PCNSL is the most common mass lesion, and in adults it is the second most common after toxoplasmosis. PCNSL develops in patients with advanced HIV-1 disease who are severely immunosuppressed. The incidence of PCNSL in the AIDS population may be increasing as longevity is extended by medical management and antiretroviral agents. Lymphomas are usually of the diffuse immunoblastic, diffuse large cell, or small cell non-cleaved B cell type³¹⁰ with a predilection for the deep cerebral gray matter, corpus callosum, periventricular white matter, and cerebellar vermis. Strong evidence links PCNSL to EBV. EBV is frequently detected in the tumor tissue, and detection of EBV DNA by PCR in CSF is a sensitive and specific test for establishing a diagnosis in the appropriate clinical setting.³¹¹ It is suspected that in HIV-1-infected patients, destruction of T cells enables a subpopulation of immortalized and latently infected B cells to persist in the CNS, leading to the development of non-Hodgkin's lymphoma, particularly PCNSL. Clinical presentation includes headache, mental status changes (confusion, lethargy, and memory problems), seizures, cranial nerve palsies, and focal neurological deficits such as hemiparesis or aphasia.^{13,310} In children, neurological deterioration at times may be rapidly progressive and fulminant.¹⁴ Because this clinical presentation is nonspecific, neuroimaging is recommended, with MRI as the procedure of choice.

Neuroimaging characteristics of lymphoma include (1) hyperdense or isodense multiple mass lesions with variable ring enhancement, (2) diffusely infiltrating contrast-enhancing lesions, (3) periventricular contrasting lesions, (4) thallium-avid on SPECT, and (5) hypermetabolic area on PET scan.³¹¹⁻³¹³ Surrounding edema is variable, and a large solitary mass may be seen as well as multiple lesions. Diffusion-weighted MRI and MRS have been used to distinguish abscess, *Toxoplasma encephalitis*, and primary lymphoma, although with limited success.^{314,315} In addition to brain MRI, spinal MRI is indicated on the basis of clinical examination, as well as CSF studies for EBV DNA, ocular slit lamp exam, bone marrow, chest x-ray, and abdominopelvic CT scan.

The differential diagnosis of intracranial lesions in AIDS patients includes a variety of infectious, neoplastic, and cerebrovascular processes. In adults, the most common mass lesion is toxoplasmosis. Unlike *T. encephalitis*, PCNSL lesions may cross the midline in the corpus callosum and be associated with patchy nodular ventricular enhancement.

Recommendations for the management of intracranial mass lesions in AIDS patients have been published. Large lesions with mass effect and threatening impending herniation require open biopsy with decompression. SPECT should be performed when available because it appears to be highly specific for PCNSL. A combination of SPECT, PET scan, and CSF EBV analysis, if all positive,

establishes the diagnosis in virtually 100% of patients, eliminating the necessity for brain biopsy.³¹⁶ Biopsy in AIDS patients is generally avoided, not only because of the possibility for HIV-1 contamination but also because of a high risk for significant hemorrhage after biopsy in AIDS patients.³¹⁷ In adults, empirical treatment for toxoplasmosis should be instituted in all other cases except when a single intracranial mass lesion accompanies negative serology for toxoplasmosis, in which case all the preceding diagnostic approaches should be initiated.

Primary CNS lymphoma are radiosensitive tumors, but prognosis is extremely poor.^{318,319} Reduction in tumor size has been noted in patients following whole brain radiation therapy and steroids (300 cGy in 10 fractions for a total of 3000 cGy).^{319,320} A 2- to 4-month survival after diagnosis is reported. In general, chemotherapy regimens have not significantly altered long-term survival rates. Prognosis for long-term survival is grim, with death resulting from concurrent illness and opportunistic infections rather than lymphoma. The absence of opportunistic infections at the time of diagnosis is associated with a longer median survival. Selected patients may be candidates for combined chemotherapy and radiation therapy.³²¹

Metastatic Non-Hodgkin's Lymphoma

Non-Hodgkin's lymphoma occurs in 5% of AIDS patients. This malignancy develops in patients who are severely immunosuppressed, and, like PCNSL, it is linked etiopathologically to EBV. Non-Hodgkin's lymphoma often presents as an aggressive tumor, and there is a propensity for CNS metastasis. Approximately one third to one half of patients with non-Hodgkin's lymphoma develop metastatic CNS disease. Leptomeningeal involvement is common, with extension along the Virchow-Robins spaces, the cranial and spinal nerve sheaths, and the CSF pathways. Clinical features include mental status changes, seizures, cranial neuropathies and radiculopathies, and paraspinal masses.³²² Neuroimaging studies often reveal hydrocephalus with basilar meningeal enhancement. Diffuse leptomeningeal and cortical enhancement may also occur. CSF studies show depressed glucose levels. Lymphoma cells may be seen on cytological studies. Combination chemotherapy regimens have not been as successful in prolonging life in patients with AIDS-associated non-Hodgkin's lymphoma as they have in non-AIDS/non-Hodgkin's lymphoma patients. The poor response and short survival may be due to severe immunosuppression and the occurrence of opportunistic infections.

OPPORTUNISTIC INFECTIONS IN AIDS

A variety of opportunistic infections occur in the setting of AIDS and may affect the CNS (Table 44-13). The susceptibility of individuals with HIV to opportunistic infections is related to the degree of immunosuppression and correlates to the peripheral blood CD4⁺ lymphocyte count (Table 44-14). A full discussion of the clinical features, evaluation, and management of infection with these organisms is detailed in the chapters on viral (see Chapter 41) and nonviral (see Chapter 42) infections.

STROKES IN THE YOUNG

HISTORICAL BACKGROUND

During the 17th and 18th centuries, physicians and morphologists recognized that the brains of patients who died of apoplexy often contained hemorrhages and softening and that brain damage could result from either bleeding or deprivation of the vital blood supply. During the 19th and early 20th centuries, physicians became interested in correlating the neurological symptoms and signs found in stroke patients during life with the anatomical region of damage in the brain found after death. Anatomical-clinical correlations defined the territories of supply of the various vessels within the anterior and posterior brain circulations and noted the findings in patients with infarcts in the territories of the various arteries.

During the middle years of the 20th century, clinicians focused increasingly on the clinical findings in patients with brain hemorrhages and infarcts. In 1935, Aring and Merritt analyzed the clinical findings in patients who died at the Boston City Hospital from large strokes and tried to separate the signs of embolism, thrombosis, and brain hemorrhage. Kubik and Adams, in 1946, reported the first detailed clinicopathological analysis of a stroke syndrome—occlusion of the basilar artery (BA). In 1951, Miller Fisher described the clinical findings in patients who had internal carotid artery (ICA) occlusions in the neck. Fisher emphasized that warning spells, which he dubbed transient ischemic attacks (TIAs), often preceded strokes in his patients and that the causative vascular disease was located in the neck, where it could theoretically be repaired by surgeons, rather than intracranially in the middle cerebral arteries (MCAs), where most of the prior literature had indicated that the usual vascular lesions were located. Soon thereafter, Hutchinson and Yates showed that patients with posterior circulation infarcts and TIAs also often had occlusive disease in the neck, at the origins of the extracranial vertebral arteries (VAs), rather than in the head. Wallenberg and Kubik and Adams had identified the vascular pathology. In 1961, Miller Fisher

described the clinical findings in patients with large fatal brain hemorrhages located in the putamen, thalamus, pons, and cerebellum.¹ Stimulated by these seminal reports and their own clinical experiences, physicians became more interested in the clinical features of stroke, brain ischemia, and cerebrovascular disease.

During the third quarter of the 20th century, most neurologists had only modest interest in stroke, and most patients were cared for by non-neurologists. Furthermore, few investigations were available that could be performed safely during life to clarify the nature, location, and extent of stroke-related brain damage or the causative cardiac and cerebrovascular lesions. Physicians during this era turned to classifications based solely on the temporal features of symptoms. Thus, the terms TIAs, reversible ischemic neurological deficit, stroke-in-evolution, progressing stroke, and completed stroke became popular and were used as a basis for treatment. These terms, however, proved to be of little clinical usefulness and are now obsolete. TIA is the only term that remains useful, mainly for ease in communication but not as a guide to diagnosis or treatment.²

During the last quarter of the 20th century, explosive advances occurred in brain imaging (computed tomography [CT], magnetic resonance imaging [MRI], single-photon emission computed tomography [SPECT], and positron emission tomography [PET]) and less invasive or noninvasive imaging technologies for the cervicocranial arteries were developed (digital subtraction angiography, MR angiography [MRA], CT angiography [CTA], and extracranial and transcranial ultrasonography). Knowledge of the role of blood cells and coagulation factors in causing or contributing to thromboembolism also advanced. During this time, potential treatments proliferated: agents that modify platelet functions; standard anticoagulants including heparin, heparinoids, low-molecular-weight heparins, and warfarin; thrombolytic treatment using intravenous injection of recombinant tissue plasminogen activator (rtPA); endarterectomy and surgical bypass of stenotic or occluded arteries;

angioplasty and stenting; and neuroprotective drugs aimed at increasing the brain's tolerance of ischemia. Treatment now is based mainly on three considerations: (a) the nature, location, and severity of the causative cardiac, vascular, and hematological disorders; (2) the pathogenesis of the stroke; and (3) the state of the brain (normal, stunned, infarcted, or containing a hematoma). The newer available diagnostic technologies now make it possible to collect these data safely and quickly in most stroke patients.

In the early 21st century, stroke still has a major impact on public health and ranks among the leading causes of death, resulting in enormous costs measured in both health care resources and lost productivity. There are still many unanswered questions regarding the most effective therapies to treat acute stroke and prevent recurrent stroke. Therefore, on the basis of advances in imaging technology and research methodology, stroke is under intensive research to define a variety of stroke phenomena more practically, delineate new risk factors, understand mechanisms of acute stroke, and develop innovative acute therapies. Also, the results of many recent clinical studies and therapeutic trials have made it possible for a variety of academic organizations to propose the best evidence-based diagnostic and therapeutic guidelines and practice parameters in acute stroke patient care and primary and secondary prevention of stroke.

OVERVIEW OF STROKES

Classification of Strokes

Ischemia

Brain ischemia results from the occlusion of cervicocranial vessels or hypoperfusion to the brain caused by various processes: atherothrombosis, embolism, or hemodynamic instabilities. Atherothrombosis occurs in the large cervicocranial arteries in the neck and head and in the small penetrating arteries of the brain. A localized thrombus is formed in situ on an atherosclerotic arterial narrowing; it impedes distal blood flow and causes ischemia and ensuing infarction of the brain tissue supplied by the artery. The neurological symptoms and signs depend on the location of the brain vessel affected.

In brain embolism, a brain artery is suddenly blocked by embolic material that has developed more proximally in the heart (cardiogenic), aorta, proximal arteries (intra-arterial), or venous system (paradoxical). These donor sites give rise to various types of particulate matter (white platelet-fibrin and red erythrocyte-fibrin thrombi, cholesterol crystals, fragments of atherosclerotic plaques, calcific fragments of valves and plaques, air, fat, myxomatous tumor fragments, and bacterial vegetations), which then travel within the cervicocranial arteries to reach a recipient site. If the embolic material lodges at a recipient site, the resulting hypoperfusion causes an infarct that often becomes hemorrhagic when the embolus moves distally or fragments and reperfusion occurs. The clinical findings depend on the location of the recipient brain artery affected.

Watershed infarction develops when cerebral blood flow is critically lowered (too severe to be compensated by cerebral autoregulation mechanisms), as in cardiac pump failure

or severe hypovolemia. During such episodes, most patients are hypotensive and infarction develops in the border zones between the major cerebral arteries. There is also widespread bilateral cerebral dysfunction.

Hemorrhage

Rupture of a brain vessel causes leakage of blood into the brain parenchyma, cerebrospinal fluid (CSF) spaces around the brain, or both. Bleeding injures the neighboring tissues by interrupting and cutting vital brain pathways, by exerting local pressure on the surrounding brain structures, and by causing ischemia of tissues adjacent to the hematoma. Further increase in intracranial pressure (ICP) causes shifts and herniations of brain tissues and may compress the brain stem. There are two large subcategories of spontaneous intracranial hemorrhages. Intracerebral hemorrhage (ICH) is bleeding in the brain parenchyma, and subarachnoid hemorrhage (SAH) refers to bleeding around the brain into the subarachnoid spaces and CSF. These two types of hemorrhages have different etiologies, clinical courses, and outcomes and thus require different management strategies.

The major categories of stroke are depicted in [Figure 45-1](#).

Stroke Incidence and Prevalence

Stroke is a major public health problem, ranking among the top three causes of death in most countries. It affects the brains of almost a half million people every year, causing 150,000 deaths, and there are approximately 3 million stroke survivors in the United States. Overall, age-adjusted incidence rates range between 100 and 300 per 100,000 population per year. Stroke is the major cause of serious disability in adults and is responsible for \$20 billion per year in lost wages in the United States.

Stroke incidence rates declined during the 1950s and 1960s but increased during the 1980s. This increase may be due to increased diagnostic recognition related to advances in neuroimaging technology, increased survival of patients with ischemic heart disease, better detection of milder cases of stroke, and other undefined factors during the past few years.³

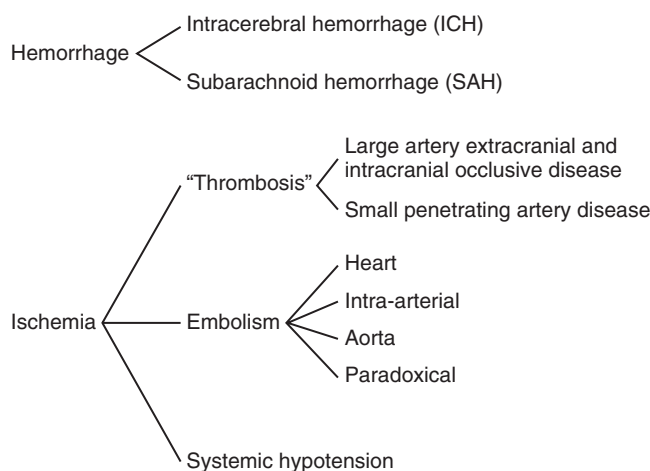

Figure 45-1. Major categories of stroke.

Stroke accounts for approximately 10% of all deaths in most industrialized countries, and the great majority of deaths are among people older than age 65 years. The average age-adjusted mortality rate is 50 to 100 per 100,000 population per year in the United States. Stroke mortality rises exponentially with age, virtually doubling every 5 years. Stroke death rates are higher among African Americans. The stroke mortality rate has steadily declined in the United States since 1915; the decline in black mortality rates has exceeded that of whites and spans all age groups. Improved survival after stroke contributes to this trend most significantly. Ischemic stroke accounts for more than 80% of all strokes. ICH usually accounts for 10% to 30% of cases depending on the ethnicity of the patient, with greater relative frequencies reported in Asians and blacks. Frequency of SAH is usually one third to one half that of ICH.

Among patients with brain ischemia, cardioembolism accounts for 20% to 30% of cases, atherothrombotic infarction accounts for 14% to 40%, and small deep infarcts due to penetrating artery disease (lacunes) account for 15% to 30%.⁴

There are major sex and racial differences in the distribution of occlusive cerebrovascular lesions. Extracranial occlusive diseases usually affect white men; are located at the origins of the internal carotid and VAs in the neck; occur twice as often in men than in women; and are strongly associated with coronary and peripheral vascular occlusive disease, systolic hypertension, and hyperlipidemia. Compared to white men, blacks, persons of Asian origin, and women have more severe diseases of the intracranial arteries and their perforating branches. Intracranial stenosis is usually less frequently associated with coronary and peripheral vascular disease.

Risk Factors for Stroke

Knowledge of stroke risk factors has advanced substantially during the past several decades and exceeds that of many other major neurological diseases. Improved detection and modification of risk factors has reduced the impact of stroke.

Important nonmodifiable stroke risk factors include age, gender, ethnicity, and genetic determinants. Although there is little that can be done to control these factors, they identify people who may be at increased risk for future strokes.

Modifiable risk factors include hypertension, cardiac disease (particularly atrial fibrillation [AF]), diabetes mellitus, cigarette smoking, alcohol consumption, hyperlipidemia, sedentary lifestyle, and carotid artery stenosis. Each of these risk factors carries a different relative risk, and prevalence varies among different groups of people. Although the risk from a specific factor may be only moderate, if its prevalence rate is high, it may be responsible for a significant number of strokes.⁵

Based on epidemiological data from the Framingham study, a risk profile table can be used to estimate a person's 10-year probability of stroke occurrence. Stroke rates increase dramatically with age. Approximately two thirds of all strokes occur after age 65 years. In the Framingham study, the mean age of stroke patients was 65.4 years for men and 66.1 years for women. As the population ages, the burden of stroke becomes greater.⁶ In terms

of gender, the stroke incidence rate is greater in men than in women.

Hypertension is the most significant modifiable risk factor for stroke, and stroke incidence is proportional to the level of the blood pressure. This is particularly true in blacks because of higher prevalence, earlier onset, greater severity, and poorer control of hypertension in this population. Decreasing systolic blood pressure by approximately 10 mmHg reduces the relative risk of stroke by 35% to 40%.⁷ Improved control of hypertension has resulted in a dramatic decline in stroke frequency, most notably in black women. Some large-scale trials have shown that certain antihypertensive regimens may confer benefit beyond the lowering of blood-pressure values. In the Losartan Intervention for Endpoint Reduction in Hypertension (LIFE) study, patients aged 55 to 80 years with hypertension and left ventricular hypertrophy on electrocardiogram (ECG) who took an angiotensin-II receptor blocker had a decreased risk of stroke compared to those who took β -blocker, although both agents lowered blood pressure (BP) equivalently.⁸ In another study, taking an angiotensin-converting enzyme (ACE) inhibitor significantly decreased the risk of stroke, myocardial infarction (MI), and vascular death in patients older than 55 years with stroke, coronary artery disease, peripheral vascular disease, or diabetes mellitus, regardless of initial hypertensive status.⁹ The combination of an ACE inhibitor and diuretic may be particularly effective for secondary stroke prevention. In patients with ischemic stroke or TIA who received an ACE inhibitor plus a diuretic, in addition to any other BP regimen they were taking, the risk of stroke and major vascular events was significantly decreased, regardless of stroke subtype (ischemic or hemorrhagic) and even if they were initially normotensive.¹⁰

Diabetes mellitus is also a significant risk factor and is present in approximately 10% of stroke patients.⁶ It is common among blacks and particularly contributes to the development of intracranial atherosclerosis.

Cigarette smoking is a very important preventable cause of stroke, and approximately 30% of stroke patients smoke. Heavy cigarette smoking (more than one pack per day) carries 11 times the ischemic stroke risk and 4 times the SAH risk of people who do not smoke.¹¹ The combination of hypertension, diabetes, and cigarette smoking is particularly risky and requires aggressive interventions. Smoking has an especially toxic effect on women taking oral contraceptives, in whom it carries 22 times the risk of developing stroke than occurs in nonsmoking women who use other forms of birth control. Migraine also increases the stroke risk remarkably if a subject smokes and/or takes contraceptive pills. With cessation of cigarette smoking, the risk of stroke declines after 2 to 5 years.

A J-shaped relationship exists between alcohol and stroke. Those who drink one or two units per day have a lower ischemic stroke risk than those who do not drink at all. On the whole, the relative risk for ischemic stroke increases significantly with heavy alcohol consumption of five or more units of alcohol per day.¹²

Heart diseases are clearly associated with increased risk of ischemic stroke, particularly AF, valvular heart disease, MI, coronary artery disease, congestive heart failure, left ventricular hypertrophy on ECG, and mitral valve prolapse. AF, which alone carries a fivefold increased risk of stroke,

is particularly important in the elderly and among those with coronary artery disease or heart failure or valvular heart disease. Ischemic stroke associated with AF is nearly twice as likely to be fatal as non-AF stroke. Recurrence is more frequent, and functional deficits are more likely to be severe among survivors. Because stroke is usually the initial manifestation of embolism in AF, prevention is critical to reducing disability and mortality.¹³

Abnormal serum lipid levels are regarded as risk factors. High-density lipoprotein (HDL) is protective against stroke. Higher HDL levels are more protective against atherosclerotic disease (extracranial carotid artery disease and intracranial atherosclerotic disease). Apolipoprotein (a) has both atherogenic and coagulation effects. Apolipoprotein A1 (Apo A1) and apolipoprotein B (Apo B) are major protein components of lipoproteins HDL and low-density lipoprotein (LDL), respectively.

Carotid atheroma is linked to increased LDL (Apo B) and may be inversely related to HDL (Apo A1).⁵ Lipid-lowering agents, particularly 3-hydroxy-3-methylglutaryl-coenzyme A reductase inhibitors or statins, which lower LDL and triglyceride levels and increase HDL, reduced the risk for vascular events such as stroke and MI in at-risk populations with a history of coronary artery disease or MI in recent trials.¹⁴ For patients who have suffered a stroke or MI, LDL less than 70 is considered optimal.^{15,16} In addition, patients taking lipid-lowering agents at the time of an ischemic stroke might have lower poststroke mortality and a lower risk of worsening during hospitalization.¹⁷ Physical activity lowers the risk of stroke even in the elderly.⁵

Factors causing blood vessel endothelial injury, including hyperhomocysteinemia and chronic infections such as *Chlamydia pneumoniae* and periodontal disease, have been found to increase the risk of stroke. Hyperhomocysteinemia is an established risk factor for stroke and myocardial infarction. Homocysteine is both genetically and environmentally controlled. A genetic defect in the enzyme cystathionine β synthetase is associated with hyperhomocysteinemia. An environmental deficiency of vitamin B₁₂, folic acid, or vitamin B₆ affects homocysteine metabolism and increases circulating plasma levels. However, a large randomized clinical trial failed to prove that lowering homocysteine levels (e.g., by prescribing folate, vitamin B₆, or vitamin B₁₂) lowers the risk of a recurrent event.¹⁸ Stroke rates in the United States, however, decreased after government-mandated folate supplementation of grain products in 1996. Dietary supplementation with these vitamins reduces homocysteine levels, thus possibly preventing risk for endothelial injury that can lead to stroke. Excessive alcohol consumption and physical inactivity are also associated with elevated homocysteine levels.¹⁹

Chlamydia pneumoniae is a common cause of community-acquired pneumonia, pharyngitis, and sinusitis. It can infect and injure the endothelium, thus increasing the likelihood of platelet aggregation.²⁰

Transient Ischemic Attacks and Strokes

Miller Fisher first described the phenomenology of TIAs, which nearly always preceded cerebral infarction in patients with occlusion of the ICA.²¹ The classic definition of TIA has been a sudden, focal neurological deficit lasting

as long as 24 hours. However, it is arbitrary and outdated because in reality most TIA symptoms typically last 5 to 20 minutes and rarely more than 1 hour. In addition, with advances in acute stroke imaging such as brain MRI scans, acute lesions are identified very early in the course of stroke in patients whose ischemic symptoms last only hours. Thus, a new definition of TIA based on the presence or absence of a biologic end point was proposed by a group of stroke researchers.^{22,23} The newly proposed definition of a TIA is a brief episode of neurologic dysfunction caused by focal brain or retinal ischemia, with clinical symptoms typically lasting less than 1 hour and without evidence of acute infarction. It indicates that transient ischemic symptoms can cause permanent brain injury, encourages use of neurodiagnostic tests to identify brain injury and its cause, and facilitates rapid interventions for acute brain ischemia. By defining the duration of transient neurological deficits less than 1 hour, the new definition reflects the presence or absence of ischemic brain injury more accurately. If neurological deficits last 4 hours or longer, patients often have infarcts in the locations corresponding to the transient symptoms.

Clinical symptoms of TIA include hemiparesis, hemiparesthesia, dysarthria, dysphasia, diplopia, circumoral numbness, imbalance, and monocular blindness. They are usually similar to those of infarctions located in the arteries affected, except for the transient nature of the clinical episodes. TIA is a strong indicator of a subsequent stroke. Among patients who present to an emergency room with a TIA, 5% will have a stroke within the next 2 days and 25% will have a recurrent event within 3 months. Urgently identifying the cause of a patient's first stroke or TIA is vital in determining the proper therapy to prevent a second, more disabling event. Also, TIAs suggest the underlying cardiological, hematological, and cerebrovascular diseases, and patients should be thoroughly evaluated for the specific vascular lesions and underlying causative diseases to prevent further TIA episodes or subsequent stroke.^{2,21} Detailed clinical information is essential and helps to predict the underlying cause. Laboratory tests are also helpful in defining the causative mechanisms of TIAs, but they should be ordered on the basis of judicious interpretation of clinical data.

Diagnosis

Clinical Diagnosis

To determine the stroke mechanism or mechanisms, the following clinical bedside data should be obtained through careful history taking: (1) ecology—past and present personal and family illnesses; (2) the presence and nature of past strokes and TIAs; (3) the time of onset of the symptoms; (4) activity at stroke onset; (5) the temporal course and progression of the findings; and (6) accompanying symptoms. A general physical examination should then be done to add more data that can be used for diagnosis of the stroke mechanism. Elevated blood pressure, cardiac enlargement or murmurs, bruits in the carotid and supraclavicular region, and symmetry of blood pressure and pulses in the arms are important check points (see Chapter 22).¹

The presence of some findings, such as headache, vomiting, loss of consciousness, and seizures, is helpful in diagnosing

subtypes of strokes. Headache at onset is an invariable feature of SAH and is also common in patients with large ICHs and large cerebral infarcts due to large artery occlusive disease and brain embolism. Headache is rare in patients with lacunar infarction due to penetrating artery disease.

Vomiting is very common in patients with SAH and ICH and in those with brain stem and cerebellar infarcts. Vomiting is very rare in patients with cerebral hemispheric infarction due to large artery occlusive disease or embolism. Seizures at or soon after the onset of the stroke are relatively common in patients with lobar hemorrhages and those with brain embolism but do not occur in patients with lacunar infarcts.

Loss of consciousness at onset is common in patients with large SAHs and in those with embolism to the BA but is rare in strokes due to other mechanisms. Patients with large ICHs often have headache, vomiting, and progressive loss of alertness as the hematoma enlarges and ICP rises.

Neurovascular Imaging

Neuroimaging studies include CT scan, MRI, diffusion and perfusion-weighted MRI, SPECT, and PET. CT scans are best for differentiating ischemic stroke from hemorrhagic stroke. MRI is more sensitive than CT for detecting acute ischemic lesions, and preliminary evidence suggests that certain MRI modalities may be useful for detecting acute hemorrhage.²⁴ Diffusion-weighted and perfusion MRI can often identify acute brain infarcts within minutes of ischemia onset and can delineate the ischemic penumbra.²⁵ A quicker MRI regimen based on diffusion-weighted imaging, fluid attenuated inversion recovery, and MRA images may be used for pre-thrombolysis evaluation of acute ischemic stroke patients. MRI is also the preferred technique for identifying brain stem and cerebellar infarcts. SPECT and PET scans image the perfusion and metabolic state of the brain and can quantify cerebrovascular reserve capacity.

MRA and CT Angiography

Vascular imaging can be divided into noninvasive and invasive studies. Four commonly used noninvasive tests are duplex scans (B-mode and Doppler combined), transcranial Doppler ultrasonography (TCD), MRA, and CTA. Duplex scans show an accurate image of the extracranial carotid and vertebral arteries. TCD is useful for the evaluation of the intracranial cerebral arteries by measuring flow velocities and directions. MRA and CTA are useful for the evaluation of intracranial and extracranial large arteries. Combined use of gadolinium-enhanced MRA and contrast-enhanced CTA may be equivalent to catheter angiography in evaluating extracranial carotid stenosis. Thus, these relatively noninvasive modalities with the ability to evaluate both extracranial and intracranial vasculature may replace carotid duplex, TCD, and catheter angiography in the routine etiologic evaluation of ischemic stroke patients.²⁶

MR venography (MRV) is a very useful diagnostic tool for showing cerebral venous sinus thrombosis and has largely replaced invasive conventional cerebral angiography. When there is any suspicion of significant vascular lesions, such as severe intra- or extracranial stenosis, aneurysm,

arteriovenous malformation (AVM), or vasculitides, standard transfemoral artery catheterization and angiography are usually done to further define and characterize the lesions and, when possible, to intervene to treat vascular lesions at the same time. Important laboratory tests for stroke patients are listed in [Table 45-1](#).

DISEASES THAT CAUSE BRAIN ISCHEMIA

Atherothrombotic Disease

PATHOGENESIS AND PATHOPHYSIOLOGY. Atherothrombosis implies a reduction or occlusion of blood flow caused by a localized thrombotic process in one or more atherosclerotic cervicocranial arteries. Branching points of arteries are the predilection sites of development of atherosclerosis ([Fig. 45-2](#)).

In atherosclerosis, fibrous and muscular tissues of the vessel wall overgrow in the subintima, and fatty materials form plaques that can encroach on the lumen. Platelets adhere to the crevices in the plaques and form clumps that serve as *nidi* for the deposition of fibrin, thrombin, and clot. Plaques and ulcers are associated with denudation of the endothelium and decreased release of endothelium-relaxing factors including nitric oxide. Endothelins can promote platelet activation and thrombus formation. Intraluminal thrombi are of different types: so-called “white clots,” which are mainly composed of platelets and fibrin, and “red thrombi,” which are red blood cells enmeshed in fibrin. White platelet clumps form most often in fast-moving streams, adhering to crevices and irregularities along the intimal surface. Fibrin-dependent red thrombi develop in slow-moving streams, such as in arteries with severe luminal narrowing. Narrowing of arteries decreases

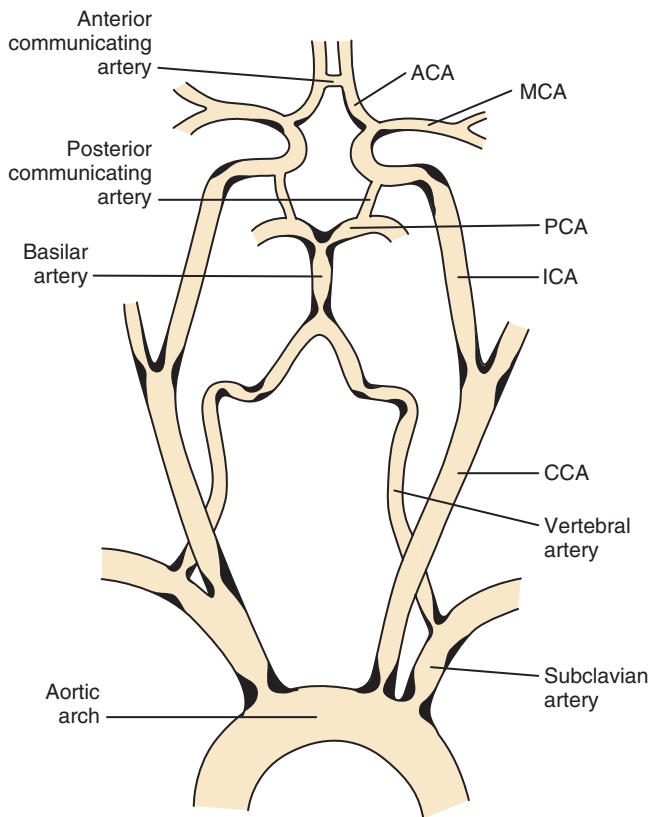

Figure 45-2. Sites of predilection for atherosclerotic narrowing; black areas represent plaques. ACA, anterior cerebral artery; CCA, common carotid artery; ICA, internal carotid artery; MCA, middle cerebral artery; PCA, posterior cerebral artery. (Adapted from Caplan LR: Stroke: Clinical Approach. Boston, Butterworth-Heinemann, 1993.)

blood flow, leading to stagnation of the blood column and activation of clotting factors. Clot and fibrin-platelet clumps form and break off, blocking distal arteries and further impeding flow in the affected parent artery (Fig. 45-3).¹

EPIDEMIOLOGY AND RISK FACTORS. There are important sex and racial differences in the distribution and incidence of lesions. White men have more severe disease of the extracranial arteries, whereas in blacks, persons of Asian origin, and women, there is a predilection for narrowing of the intracranial arteries.⁴

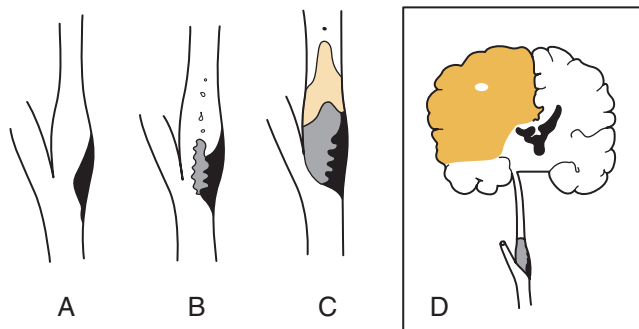

Figure 45-3. Internal carotid artery atherosclerotic lesions: **A**, plaque; **B**, plaque with platelet-fibrin emboli; **C**, plaque with occlusive thrombus; **D**, recent ischemic cerebral infarct due to internal carotid artery occlusion. (Adapted from Caplan LR: Caplan's Stroke: A Clinical Approach, 3rd ed. Boston, Butterworth-Heinemann, 2000.)

Patients with extracranial large artery disease have a high incidence of coronary artery disease (angina pectoris and MI), peripheral vascular occlusive disease (claudication), hypertension, and hypercholesterolemia. Death is more often due to fatal coronary artery disease than stroke.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Development of neurological deficits preceded by brief, frequent shotgun-like TIAs in the same vascular territory usually suggests atherothrombosis as the vascular mechanism. Stroke caused by a thrombotic process often develops during or just after sleep. Atherothrombotic infarctions are usually characterized by postural sensitivity of symptoms; occlusion or severe stenosis of a large artery; the absence of distal embolus by angiography; infarct on CT or MRI near the border zone territory of the affected artery; and the presence of risk factors for atherosclerosis, such as hypertension, diabetes mellitus, and smoking. The neurological symptoms and signs depend on the vessels involved and the regions of brain ischemia.

DIFFERENTIAL DIAGNOSIS AND EVALUATION. The diagnosis of large artery occlusive disease is based on the demographic and epidemiological situation of the patient, analysis of the time course of the brain ischemia, physical examination of the heart and neck vessels, and tests that define the anatomy and function of the cervicocranial arteries.

CT or MRI is used to define the presence, location, and size of infarction and sometimes can show asymptomatic ("silent") infarcts unexpected from the history and neurological examination. MRA, CTA, or both are helpful in imaging the structural status of large extracranial and intracranial arteries (Fig. 45-4).

Ultrasonography is also frequently used for noninvasive vascular imaging. Duplex scans of the origins of the carotid and vertebral arteries combined with color-flow Doppler ultrasound can define and quantify most extracranial ICAs and VA lesions. TCD can detect occlusive or stenotic lesions of the intracranial large arteries, such as the MCAs, anterior cerebral arteries (ACAs), ophthalmic arteries, BA, VAs, and posterior cerebral arteries (PCAs). TCD also yields information on the collateral flows that may develop following the occlusive lesions in extracranial and intracranial arteries. When ultrasound and MRA or CTA are concordant and define the occlusive vascular lesions, conventional angiography is not necessary for diagnostic purposes but is usually performed for therapeutic purposes, such as intra-arterial thrombolysis, angioplasty, stenting, or embolization.

MANAGEMENT. The very basic goal of management of ischemic stroke patients in the acute phase is protection of the so-called penumbra zone. This zone comprises the brain tissues at risk of irreversible ischemic damage. Brain tissues adjacent to the ischemic core are often impaired functionally ("stunned"), but ischemia is potentially reversible if the circulation is restored soon enough. To achieve this goal, the following principles are applied: (1) recanalization of occluded vessels (thrombolytic therapy), (2) maximization of blood volume and cerebral blood flow and reduction of blood viscosity (hemodilution), (3) maintenance of perfusion pressure (by careful control of blood pressure, reduction of cerebral edema, and lowering of ICP), and (4) blocking of progression of occlusive processes using antithrombotic

Figure 45-4. Angiographic features of the proximal internal carotid artery stenosis: **A**, 3D reconstruction image of conventional angiography; **B**, MRA; and **C**, 3D reconstruction image of CT angiography.

agents such as anticoagulants or antiplatelet drugs. All these measures should be guided by the severity and reversibility of the lesion; the nature, location, and severity of the underlying stroke mechanism; and the viscosity and coagulability of the blood.

Recanalization is usually performed by thrombolysis and will be discussed later in this chapter. Hemodilution therapy decreases blood viscosity by lowering the hematocrit level. Blood pressure should not be aggressively lowered during the acute phase because this decreases pressure in the collateral channels and may extend the infarct. Intravenous infusion of autologous bone marrow-derived mesenchymal stem cells has been shown to be a feasible and safe therapy that might improve functional outcome in severe cerebral infarcts.²⁷

For prevention of recurrence of ischemia in the future, prophylactic treatment should be guided by the mechanism of the stroke. Theoretically, red clots would respond more to anticoagulants such as warfarin and heparin, and white clots would be better prevented with platelet antiaggregants such as aspirin.

Surgery (endarterectomy), angioplasty, or warfarin may be indicated for patients with tight stenotic lesions perfusing clinically important tissues at risk for further ischemia. The choice of warfarin versus surgery or angioplasty depends on the accessibility of the lesions to treatment, the risk of surgery and angioplasty, the patient's wishes, the likelihood of the patient's compliance with anticoagulant usage, and any contraindication to the use of anticoagulants. Anticoagulation using intravenous heparin or subcutaneous low-molecular-weight heparin may be used for as long as 2 or 3 weeks to prevent propagation and embolization of clot. Long-term warfarin use is usually not needed after the clot organizes and adheres to the vessel wall in atherothrombotic stroke (usually 3 or 4 weeks). Because platelet adhesion, activation, and aggregation are fundamental components of thrombus formation during vascular

occlusion, antiplatelet agents are effective in the prevention of ischemic stroke. Antiplatelet agents are given regularly to reduce the risk of recurrent stroke and other vascular events following a noncardioembolic (atherothrombotic, lacunar, or cryptogenic) stroke or TIA if there is no contraindication.²⁸

Aspirin, 50 to 325 mg daily, can prevent platelet-fibrin emboli in patients with minor or moderate stenosis. An increase in the dose of aspirin (especially if an *in vitro* aspirin effect is not shown at the lower dose) or use of ticlopidine should be tried if symptoms recur. The combination of aspirin, 25 mg, and extended-release dipyridamole, 200 mg twice a day, is more effective than aspirin alone for the prevention of stroke and has a similarly favorable serious adverse effect profile based on indirect comparisons. The thienopyridine derivatives, ticlopidine hydrochloride and clopidogrel, are also antiplatelet agents. They produce significantly less gastrointestinal hemorrhage and upper gastrointestinal upset than aspirin. Compared to aspirin, the thienopyridines produced a proportional reduction of 9% in the odds of a vascular event, corresponding to an absolute reduction of 11 events prevented per 1000 patients treated for approximately 2 years in a large randomized trial. Ticlopidine hydrochloride, 250 mg twice a day, is effective for prevention. The side effects include diarrhea, skin rash, leukopenia, thrombocytopenia, and thrombotic thrombocytopenic purpura (TTP), which require careful monitoring of clinical findings and blood tests during the first 3 months. Clopidogrel is a newer antiplatelet agent that inhibits ADP-induced platelet aggregation and is at least as effective as aspirin.²⁹ The safety and tolerability seem to be superior to those of ticlopidine, although a few cases of TTP have been reported. For patients who are allergic to aspirin, clopidogrel is preferred to ticlopidine.

The uncertain magnitude of additional benefit and the considerable extra cost of these alternative regimens make their routine use in stroke prevention difficult to justify. It is reasonable to consider the addition of modified-release

dipyridamole to aspirin in patients who continue to have ischemic cerebrovascular events on aspirin and to use clopidogrel in patients for whom aspirin is contraindicated or poorly tolerated. If the patient has a primary coagulopathy, polycythemia, or thrombocytosis, these disorders should be treated more specifically.

PROGNOSIS AND FUTURE PERSPECTIVES. In patients with large artery occlusions, the risk of infarction is maximal in the first few days following occlusion. After the first week, the likelihood of further infarction is much less. Prognosis depends on whether the initial thrombus propagates distally or embolizes to distal arteries and on how sufficiently the collateral circulation develops.

Optimization of blood pressure and blood volume during the time when the collateral circulation is developing helps to augment blood flow to the penumbral zones and thus limits the extent of infarction. Of course, patients with large artery atherosclerosis are at risk of narrowing and occlusion of other arteries during the subsequent months and years, so preventive measures instituted at the time of the initial symptoms may help in preventing or delaying further strokes. The effectiveness of surgery and angioplasty for various occlusive lesions is under study in large trials. Occasionally, thrombolysis and angioplasty may be used together because patients with thrombi superimposed on severe atherosclerotic occlusive disease often experience reocclusion of the artery after thrombolysis unless the atherosclerosis is repaired. The optimal thrombolytic agent, portal of delivery, dose, timing, and target population for thrombolysis are being studied.

Occlusive Disease of Small Penetrating Arteries

PATHOGENESIS AND PATHOPHYSIOLOGY. The so-called cerebral small arteries are the penetrating arteries that have small calibers (<500 μm in diameter) and supply the blood deep into the brain substance. They are comparable to the cortical or leptomeningeal arteries that step down gradually in caliber from the large parent cerebral arteries and thus are protected from abrupt pressure changes. In contrast, the cerebral small arteries arise directly from the large parent arteries and have very thin media of the arterial wall, composed of only one or two layers of smooth muscles. Thus, they are quite sensitive to changes in the

intraluminal pressures of the parent large arteries and are susceptible to hypertensive arteriopathic changes. Because they usually do not have anastomoses with the neighboring arteries and form the “end artery” zone in the deep brain parenchyma, cerebral infarcts can occur relatively easily if they are occluded. They are also the common sites of hypertensive intracerebral hemorrhages.

Lipohyalinosis is the most classical destructive vasculopathy linked to severe hypertension and affects the cerebral small arteries. The arterial lumen is compromised by thickening of the vessel wall but not by an intimal process as in atherothrombosis. Subintimal lipid-laden foam cells and pink-staining fibrinoid material thicken the arterial walls. In places, the arteries are replaced by tangles and wisps of connective tissue that obliterate the usual vascular layers. The small, deep infarcts that result from occlusion of these small arteries are usually called lacunes.³⁰

Small, deep infarcts can also result from microatheromas forming at the origin of penetrating arteries (Fig. 45-5A), as well as by plaques within the parent arteries that obstruct directly or extend into the branches (junctional plaques) (Fig. 45-5B and C). Rarely, they are occluded by microemboli (Fig. 45-5D).

Vascular lesions involving the mouths of penetrating arteries are called intracranial branch atheromatous disease and cause infarcts larger than in lacunar infarcts.³¹ The arteries commonly affected are the lenticulostriate branches of the MCAs, the thalamogeniculate and thalamoperforant branches of the PCAs, and midline and paramedian penetrating branches of the vertebral and basilar arteries (Fig. 45-6; Video 95, Brain Stem Infarction).

Infarcts do not involve the cerebral cortex but usually affect the subcortical structures, such as the basal ganglia, thalamus, internal capsule, white matter, and brain stem.

CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy) is a familial arterial disease of the brain that begins in early adult life. Its gene is mapped to chromosome 19. The CADASIL vasculopathy affects the media of leptomeningeal and perforating arteries of the brain. The media is thickened by an eosinophilic granular material of unknown origin. Clinically, patients present with recurrent subcortical infarcts, progressive or stepwise dementia, migraine with aura, and depression. Usually, there is no hypertension or other vascular

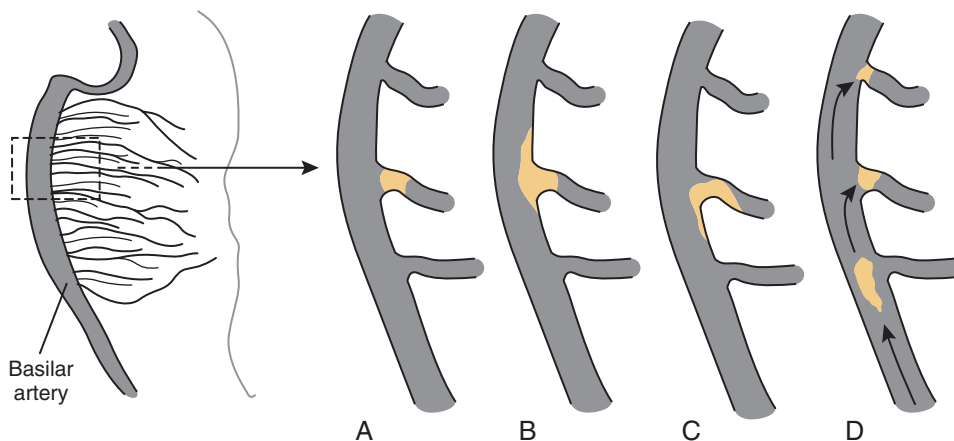

Figure 45-5. Branch atheromatous diseases of the basilar artery: **A**, microatheroma originating in orifice of branch; **B**, plaque within parent artery blocking the branch artery orifice; **C**, plaque extends into the branch from the parent artery (so-called junctional plaque); and **D**, microemboli. risk factors. Prominent subcortical white matter and basal ganglia hyperintensities are noted on T2-weighted MRI. Vascular studies are usually not helpful diagnostically.³²

EPIDEMIOLOGY AND RISK FACTORS. Hypertension is the most significant risk factor for small vessel occlusive diseases and is responsible for approximately 80% to 90% of lacunar infarctions. In addition to hypertension, diabetes mellitus and smoking are also significant risk factors for small vessel occlusive disease, particularly for branch atheromatous disease. Blacks and Asians, races with a predilection for hypertension, also have a higher frequency of penetrating artery disease and lacunar infarction than whites.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Neurological deficits are usually monophasic in pure lacunar infarction but may progress gradually or stepwise over 1 to 7 days in cases of branch atheromatous disease. Clinical findings are characteristically less severe, neurological dysfunctions are restricted within a few systems, and cognitive and behavioral abnormalities are less common (Video 215, CADASIL Stroke). Lacunar infarcts present diverse clinical syndromes.³⁰ Deep infarcts in some strategic areas such as the caudate nucleus, anterior thalamus, and genu of the internal capsule can produce apathy, inertia, and reduced interest in the environment. Bilateral extensive lacunar infarcts are often associated with white matter damage and clinical dementia, causing Binswanger's disease.

DIFFERENTIAL DIAGNOSIS AND EVALUATION. The major differential diagnostic considerations are restricted cortical and brain stem infarcts due to large artery occlusive disease or embolism and small ICHs. The diagnosis of penetrating artery disease is based on (1) the presence of risk factors, especially hypertension and diabetes; (2) clinical neurological symptoms and signs typical for or compatible with occlusion of a single perforating artery; and (3) CT or MRI showing a lacunar cerebral infarct or a brain stem infarct in the territory of a single penetrator, or at least no cortical

infarct. In uncertain cases, vascular and cardiac imaging may be needed to clarify the diagnosis of penetrating versus large artery occlusive disease.¹

MANAGEMENT. There have been no controlled therapeutic trials of patients with acute lacunar infarcts. Antiplatelet agents have not been shown to be effective in classical lacunes but are frequently prescribed. In case of branch atheromatous disease, antiplatelet agents may be effective. Efficacy of heparin and warfarin anticoagulants has not been established. However, if a patient has an embolic source, anticoagulation may be indicated to prevent future recurrence. Preventive treatment consists primarily of controlling the underlying causative process—hypertension. For CADASIL, no specific treatment is available.

PROGNOSIS AND FUTURE PERSPECTIVES. Recovery from lacunar infarctions or branch atheromatous diseases is usually better than that from cortical infarctions. However, many patients develop recurrent lacunar infarcts and white matter ischemia, causing vascular dementia, pseudobulbar dysarthria and dysphagia, gait abnormalities, and parkinsonian-like signs (Video 10, Dysarthria).

Brain Embolism

PATHOGENESIS AND PATHOPHYSIOLOGY. There are three major sources of embolism—cardiogenic, intra-arterial, and paradoxical (Fig. 45-7). Emboli from any source tend to be arrested in a recipient artery, depending on the location of branch points and the size of the embolic material. The most common recipient arteries are the MCAs and ACAs in the anterior circulation and the VAs, distal BA, superior cerebellar arteries, and PCAs in the posterior circulation. Once lodged, infarcts are often wedge shaped, involving the cerebral cortical surface. Embolic materials often migrate distally within 48 hours, allowing reperfusion of the previously ischemic zone. This reperfusion frequently accompanies extravasation of blood through the disintegrated endothelial linings causing hemorrhagic conversion

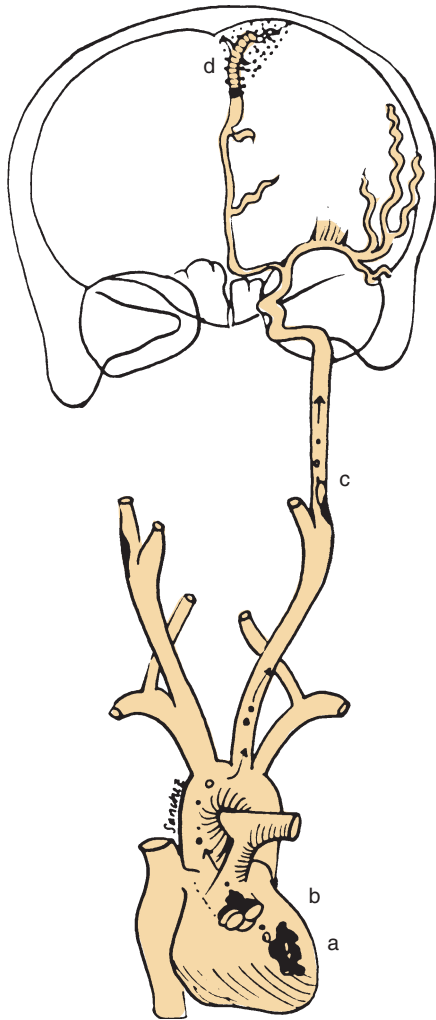

Figure 45-7. Examples of potential sources of embolism: a, cardiac mural thrombus; b, vegetation on heart valve; c, emboli from carotid plaque; and d, infarcted cortex in area supplied by terminal anterior cerebral artery due to embolism. (Adapted from Caplan LR: *Caplan's Stroke: A Clinical Approach*, 3rd ed. Boston, Butterworth-Heinemann, 2000.)

of the ischemic lesions, so-called hemorrhagic infarction. Advances in technology have improved the identification of previously unrecognized potential embolic sources and have demonstrated that a higher proportion of ischemic strokes than previously suspected are embolic in origin. Arrhythmias, especially AF and sick sinus syndrome, are important causes of brain embolism. Thrombi also form within the heart in patients with myocardial infarcts, cardiomyopathies, ventricular aneurysms, and other diseases causing endocardial and myocardial damage. Valvular diseases—rheumatic, congenital, calcific, and bacterial and nonbacterial vegetations—are also very important donor sources for embolism. Cardiac sources of emboli are listed in [Table 45-2](#).

Intra-arterial thromboembolism develops when thrombus is formed on the ulcerative plaque of an atheromatous arterial wall, dislodges, and travels up to a distal intracranial cerebral artery. Usually, emboli are composed of clot, platelet clumps, or fragments of plaques. Embolism is especially likely to occur just after a clot is formed, before it becomes

TABLE 45-2

Common Cardiac Sources of Emboli

Coronary Artery Diseases

- Myocardial infarcts
- Ventricular aneurysms
- Mural thrombi
- Hypokinetic segments (focal and global)

Cardiomyopathies and Endocardiopathies

- Endocardial fibroelastosis
- Alcoholic cardiomyopathy
- Cocaine cardiomyopathy
- Myocarditis
- Sarcoidosis
- Amyloidosis

Valvular Diseases

- Mitral stenosis, rheumatic
- Aortic stenosis, rheumatic
- Bicuspid aortic valve
- Mitral annulus calcification (MAC)
- Calcific aortic stenosis
- Mitral valve prolapse (MVP)
- Bacterial endocarditis
- Nonbacterial thrombotic (marantic) endocarditis—systemic lupus erythematosus (SLE)
- Prosthetic valves

Arrhythmias

- Atrial fibrillation and flutter
- Sick sinus syndrome

Intracardiac Lesions, Defects, and Shunts

- Myxomas
- Fibroelastomas
- Malignant cardiac tumors
- Metastatic tumors
- Ball-valve thrombi

Cardiac Chamber Abnormalities

- Atrial and ventricular thrombi
- Spontaneous contrast on echocardiography

Septal Abnormalities for Paradoxical Embolism

- Atrial septal defects
- Patent foramen ovale
- Atrial septal aneurysms
- Pulmonary arteriovenous fistulas

Modified from Caplan LR: *Stroke: A Clinical Approach*, 2nd ed. Boston, Butterworth-Heinemann, 1993.

organized and adheres to the arterial wall. Cholesterol crystals, fat, tumor, and foreign body material, particularly talc and cornstarch injected by drug abusers, are less frequent intra-arterial embolic materials. Intra-arterial sources of cerebral embolism are usually atheromatous plaques at the carotid bifurcation but may be found at the originating sites of the common carotid arteries or VAs from the subclavian arteries or aorta. Protruding, often mobile and pedunculated, atheromas and clots in the thoracic aorta can cause cerebral embolism. They are often observed during transesophageal echocardiographic studies.³³ Angiographic catheterization and cardiac surgery with clamping of the aorta can promote embolism from atheromatous aortic or arterial lesions.

A less common form of embolism, paradoxical embolism, occurs when the heart serves as a conduit for emboli arising from blood clots in the peripheral veins; these clots pass through septal defects, a patent foramen ovale (PFO),

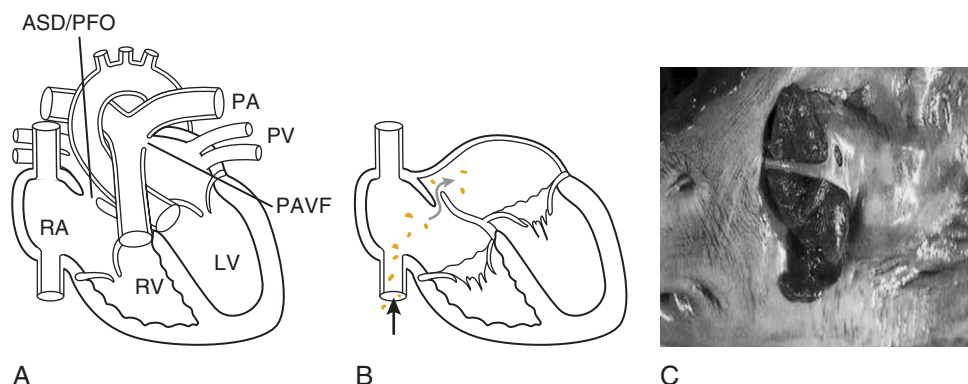

Figure 45-8. Common routes of paradoxical embolism. **A**, Right-to-left shunts. **B**, Emboli passing through the patent foramen ovale (PFO), particularly during Valsalva maneuver. **C**, A large blood clot impinged at the PFO between the right atrium (RA) and left atrium (LA). ASD, atrial septal defect; LV, left ventricle; PA, pulmonary artery; PAVF, pulmonary arteriovenous vein fistula; PV, pulmonary vein; RV, right ventricle. (Adapted and modified from Caplan LR: Caplan's Stroke: A Clinical Approach, 3rd ed. Boston, Butterworth-Heinemann, 2000.)

or pulmonary arteriovenous fistulas to reach the brain and systemic circulation (Fig. 45-8). Because PFO opens with reversed pressure gradient causing a right-to-left shunt, stroke frequently occurs during Valsalva maneuvers as in strenuous exertion or sexual intercourse.

EPIDEMIOLOGY AND RISK FACTORS. At least 30% of ischemic strokes are caused by cardiogenic embolism. The lesions with the highest risk probably involve AF, acute MI with mural thrombosis, ventricular aneurysms, prosthetic heart valves, rheumatic heart disease with atrial enlargement, myocardiopathies, and bacterial and marantic endocarditis. Cardiac surgery and various interventional procedures also pose an important risk of embolism from the heart and aorta.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Embolic events often occur during activity or sudden straining, coughing, or sneezing. Brain embolism usually presents with abrupt neurological dysfunction. During the first 24 to 48 hours, clinical fluctuations are common, probably because of distal migration of emboli. Usually in embolism, infarcts are larger and neurological deficits are more severe than in atherothrombosis. Single or infrequent but longer lasting TIAs may precede embolic infarctions. Infarcts may involve multiple vascular territories and individual infarcts may differ in age.

DIFFERENTIAL DIAGNOSIS AND EVALUATION. Embolic strokes are often difficult to distinguish from in situ thrombosis developing on stenotic lesions and ICH, but embolic strokes often begin instantly and in approximately 80% of patients reach their peak neurological deficits at or near onset. Patients with brain hematomas more often develop signs gradually. Decreased consciousness, headache, and vomiting are less common in embolic infarction than in acute hematomas. Compared to embolic infarct, in patients with an atherothrombotic infarct, stereotypic TIA episodes may occur several times over a period of weeks or months. Because collateral circulation usually develops from the repeated attacks of preceding minor ischemic insults in atherothrombosis, the region of ischemia is smaller than in embolism. Also, the signs tend to accumulate over a longer period of time, producing frequent fluctuations and stepwise changes in neurological signs. CT scanning must be performed to differentiate ischemia from hemorrhage.

Early cerebral angiography performed during the first 12 hours shows distal intra-arterial emboli in a high percentage of cases. However, after 48 hours emboli may no longer be detectable and hemorrhagic conversion of the infarcted areas is commonly noted on CT and MRI scans. In patients in whom brain embolism is suspected, the possible embolic sources should be evaluated to prevent further strokes. Cardiac and aortic sources must be searched using cardiac studies, including transthoracic echocardiography, transesophageal echocardiography, and cardiac rhythm monitoring. Noninvasive vascular tests (ultrasound, MRA, and CTA) are done to evaluate arterial sources.

MANAGEMENT. Treatment of cerebral embolism consists of two major strategies: (1) acute thrombolytic therapy to lyse the embolus and (2) prevention of recurrence of embolic events using long-term prophylactic therapy and removal of the embolic source(s).

Acute thrombolytic therapy to lyse the embolus is usually tried in patients with acute embolic stroke to recanalize the blocked artery, to restore cerebral blood flow, to limit ischemic regions, and thus to reduce neurologic disability. Recanalization may also assist the recovery of reversibly ischemic tissue. Several large-scale trials of intravenous (IV) thrombolysis have been performed for acute stroke.^{28,33} In the National Institute of Neurological Disorders and Stroke (NINDS) studies, IV rtPA given within 3 hours of stroke onset afforded a 30% decrease in risk of disability and no increase in mortality at 1 year, despite a 6.4% rate of symptomatic intracranial hemorrhage. Even within the 3-hour window, the earlier the rtPA administration, the greater the benefit.³⁴ Community studies confirmed a benefit of IV rtPA for up to 1 year after stroke, demonstrated that well-trained non-neurologists can administer IV rtPA with results comparable to those of the NINDS studies, and that IV rtPA administration after 3 hours carries an increased risk of intracranial hemorrhage and poor outcome.³⁵⁻³⁷

The decision for thrombolytic treatment with rtPA must be based on the inclusion and exclusion criteria (Table 45-3). IV rtPA is given in a dose of 0.9 mg/kg (maximum of 90 mg), with 10% of the total dose given as an initial bolus and the remainder infused over 60 minutes for eligible patients. Strict adherence to eligibility criteria and protocol of the NINDS trial is recommended.^{28,38}

TABLE 45-3

Inclusion and Exclusion Criteria for Thrombolytic Treatment with rtPA

| | |
|--------------------|--|
| Inclusion criteria | <p>Ischemic stroke causing measurable neurological deficit (NIH Stroke Scale)</p> <p>Onset of symptoms < 3 hours before beginning treatment</p> <p>Neurological deficit: not clearing spontaneously; not being minor and isolated</p> <p>Hypodensity lesion less than one-third cerebral hemisphere in size</p> <p>Blood pressure – systolic < 185; diastolic < 110 mm Hg</p> <p>aPTT in normal range in patients receiving heparin in previous 48 hours</p> |
| Exclusion criteria | <p>History of head trauma, stroke, or myocardial infarction in previous 3 months</p> <p>Symptoms suggestive of SAH</p> <p>Previous intracranial hemorrhage</p> <p>Gastrointestinal or urinary tract hemorrhage in previous 21 days</p> <p>Major surgery in previous 14 days</p> <p>Arterial puncture at a noncompressible site in previous 7 days</p> <p>Evidence of active bleeding or acute trauma (fracture) on examination</p> <p>Taking oral anticoagulant, INR \leq 1.5</p> <p>Platelet count < 100,000 mm³</p> <p>Blood glucose concentration < 50 mg/dL (2.7 mmol/L)</p> <p>Seizure with postictal residual neurological impairments</p> |

aPTT, activated partial thromboplastin time; INR, international normalized ratio; SAH, subarachnoid hemorrhage.

Because thrombolysis should be performed within 3 hours after stroke onset, rapid assessment of patients with acute ischemic stroke is essential. Thus, an exhaustive neurologic examination is not practical in the emergency setting. Instead, emergency stroke diagnosis requires a syndrome-based knowledge of neuroanatomy. Performance of the National Institutes of Health Stroke Scale (NIHSS) by specially trained personnel allows for rapid (<10 minutes) assessment of stroke severity and prognosis. A low NIHSS score indicates a mild stroke.³⁹ NIHSS scores after IV rtPA administration are an accurate predictor of discharge disposition.⁴⁰

Several prognostic factors must be considered when selecting candidates for IV thrombolysis. Younger age, absence of cardiac disease or diabetes, lower blood pressure on admission, lower neurological score assessed using the NIHSS, absence of early ischemic parenchymal changes and large artery thrombus visible on baseline brain CT, and a developed collateral circulation are all factors associated with a more favorable outcome.⁴¹ Patients who present to the emergency department within 24 hours of stroke onset with NIHSS greater than 15 have a poor prognosis if they receive no acute therapy. Patients with a baseline score greater than 20 who receive rtPA have a higher incidence of intracranial hemorrhage than those with a lower score but still fare better than patients with a score greater than 20 who do not receive rtPA.³⁹

There have been several trials using intra-arterial (IA) rtPA or pro-urokinase directed to thromboemboli lodged in the cerebral artery visualized on angiography between 3 and 6 hours after ischemic stroke onset.⁴² Based on the available evidence,

it is unacceptable to use IA thrombolysis in patients who are eligible for IV rtPA. Also, the Food and Drug Administration has not yet approved IA thrombolysis for stroke patients.³⁹ Use of a combination of IV and IA thrombolysis is under investigation. It has the potential benefit of providing both timely IV and location-specific IA therapy.⁴³ In addition to pharmacological thrombolysis, a wide range of endovascular devices to mechanically fragment thrombi have been designed and are under clinical trial. Repeated passage of a micro-guidewire through a thrombus is a simple form of mechanical disruption frequently performed during IA fibrinolytic procedures.⁴⁴

The most feared complication of thrombolytic therapy is intracranial hemorrhage, mainly into the evolving infarction. Risk factors for developing brain hemorrhage include longer time to treatment, higher dose of thrombolytics, higher systolic blood pressure level, severe neurological deficit (higher NIHSS score), higher serum glucose level, and larger volume of ischemic tissue on MR diffusion-weighted imaging.⁴⁵ Following rtPA administration, BP should be closely monitored and kept less than 180/105 mmHg and antithrombotic agents should be avoided for the initial 24 hours.²⁸ Besides hemorrhage, potential complications of thrombolysis include reperfusion injury, arterial reocclusion, and secondary embolization due to thrombus fragmentation. Thus, adequate hospital facilities and personnel are required for administration of thrombolytic therapy as well as for monitoring and managing potential complications. TCD monitoring for embolic signals can help identify the presence of continuing embolism.

If a patient arrives later than 3 hours after symptom onset, thrombolysis is not recommended but anticoagulation is recommended, particularly for those who are at high risk for early recurrent embolism (i.e., patients with mechanical heart valves, an established intracardiac thrombus, AF associated with significant valvular disease, or severe congestive heart failure). There is no evidence that IV heparin is safe or effective in patients with acute ischemic stroke, although it is still commonly used. Many stroke physicians prescribe IV heparin without a bolus to maintain an activated partial thromboplastin time (aPTT) of 50 to 70 in patients who will likely require chronic warfarin for secondary prevention. Oral warfarin is begun concurrent with IV heparin, and heparin is discontinued when the international normalized ratio (INR) is 2 or 3.

When potential contraindications to anticoagulation are present, such as a large infarction (based on clinical syndrome or brain imaging findings), uncontrolled hypertension, or other bleeding conditions, early aspirin therapy (160 to 325 mg/day) may be administered within 48 hours of ischemic stroke onset to decrease the risk of recurrent stroke and death. For patients with ischemic stroke who are not receiving thrombolysis or anticoagulation, aspirin should be started immediately in combination with low doses of subcutaneous heparin or low-molecular-weight heparins or the heparinoid danaparoid for deep vein thrombosis prophylaxis.²⁸ If a patient receives rtPA, the administration of aspirin should be delayed for at least 24 hours. IV low-molecular-weight heparinoid is not more effective than placebo in stroke patients, and studies of subcutaneous low-molecular-weight heparins in stroke patients have had equivocal results.

For long-term prevention of recurrent embolic stroke in patients with AF or other high-risk cardiac sources, long-term anticoagulation is performed with oral warfarin following IV heparin, particularly in those who experienced a recent stroke or TIA. Patients with a mechanical heart valve require a higher target prothrombin time (PT) level at 3.5 (range, 3.0 to 4.0), whereas the target PT level in most patients is 2.5 INR (range, 2.0 to 3.0).⁴⁶ In older patients, long-term anticoagulation poses important risks and problems. Antiplatelet agents may be useful for prophylaxis in some patients with cardiac lesions of relatively lower embolic risk (e.g., nonvalvular AF in patients younger than 65 years) and in patients with absolute or relative contraindications to warfarin use.²⁸

Cardiac sources of embolism must be searched thoroughly and corrected surgically if indicated. Transthoracic echocardiography is superior for evaluating the left ventricle for cardioembolic sources (e.g., hypokinetic or akinetic wall segment, mural thrombus, and ejection fraction < 35%), whereas transesophageal echocardiography is superior for evaluating the left atrium (e.g., clot in atrium or its appendage, spontaneous echo contrast, valvular disease, PFO, and atrial septal aneurysm [ASA]) and the aortic arch (e.g., atherosclerotic wall thickening > 4 mm and aortic mural thrombus).

Antithrombotic Therapy for Secondary Prevention

In patients with cerebral ischemia due to large artery atherosclerosis or small artery disease, antiplatelet agents are preferred to anticoagulants.⁴⁷ Among antiplatelet agents, aspirin is the first choice in most cases and clopidogrel is a logical second choice. Both of these agents decrease the risk of ischemic stroke and MI. Clopidogrel plus aspirin twice daily resulted in increased bleeding risk without significant reduction in ischemic events compared to clopidogrel alone in patients with previous cerebral ischemia in the MATCH study.⁴⁸ The combination of low-dose aspirin with extended-release dipyridamole significantly decreases the risk of ischemic stroke but does not decrease the risk of MI, and headache is a common side effect of dipyridamole.

In patients with stroke due to high-grade intracranial stenosis, aspirin is superior to warfarin, with less bleeding complications, less coronary ischemia, and no difference in stroke rates (Warfarin Aspirin in Symptomatic Intracranial Disease study). The role of angioplasty in these patients remains unclear, as does the optimal BP management.

If carotid artery stenosis is present, carotid endarterectomy (CEA) can be considered for stroke prophylaxis. Two large randomized trials showed that, among such patients, immediate CEA produced a relative reduction of more than one-half in the risk of major stroke or death during the next 2 or 3 years.^{49,50}

CEA reduces the stroke risk compared to medical therapy alone for patients with 70% to 99% symptomatic stenosis (16% absolute risk reduction at 5 years). Endarterectomy is moderately useful for symptomatic patients with 50% to 69% stenosis (4.6% absolute risk reduction at 5 years) and not indicated for symptomatic patients with greater than 50% stenosis. For asymptomatic patients with 60% to 99% stenosis, the benefit/risk ratio is less compared to that of symptomatic patients, and decisions must be made on a case-by-case basis. Endarterectomy can reduce the future

stroke rate if the perioperative stroke/death rate is kept low (<3%). Low-dose aspirin (81 to 325 mg) is preferred for patients before and after CEA to reduce the rate of stroke, MI, and death.⁵¹

Symptomatic carotid stenosis of 70% or more is a surgical indication. Reduction in stroke risk after CEA is evident within 6 months of surgery and peaks by 2 years.⁵⁰ CEA in patients with symptomatic moderate carotid stenosis of 50% to 69% yields only a moderate reduction in the risk of stroke; patients with less than 50% do not benefit from surgery.⁵² Asymptomatic carotid stenosis of 60% to 99% may be an indication of CEA,⁵³ but one analysis has shown that the risk of stroke among such patients is relatively low and that 45% of strokes are lacunes or cardioembolism rather than carotid artery-related stroke. Thus, absolute benefit of CEA may be low.⁵⁴

In elderly patients, the benefit of CEA has been uncertain, and physicians have been reluctant to recommend CEA for them. Advanced age is associated with an increased risk of stroke in the medically treated group. Therefore, elderly patients benefit more from CEA than younger patients in each category of symptomatic ICA stenosis.⁵⁵

Carotid angioplasty and stenting (CAS) has not been proven superior to CEA but seems to have similar major risks and effectiveness at prevention of stroke compared with carotid surgery. Thus, it is a potential alternative to CEA because the technology for angioplasty and stenting is improving very rapidly, especially in regard to cerebral protection devices.⁵⁶ Endovascular treatment has the advantage of avoiding minor local complications such as damage to the lower cranial nerves or local hematoma formation (Fig. 45-9).⁵⁷ CAS may be used in the following circumstances: (1) when there is high surgical risk due to medical conditions; (2) carotid stenosis following radiotherapy to the head or neck (radiation-induced atherosclerosis); (3) postendarterectomy restenosis; (4) surgically inaccessible stenotic segment; and (5) arterial dissection, fibromuscular hyperplasia, or Takayasu's arteritis.

The roles of PFO and ASA as causes of stroke are controversial, as is the optimal management of stroke patients with these cardiac conditions. PFO alone is not associated with increased risk of subsequent stroke or death among medically treated patients with cryptogenic stroke, but the coexistence of PFO and ASA possibly increases the risk of subsequent stroke (but not death) in medically treated patients younger than 55 years, particularly in patients with hypercoagulable states. Transcatheter closure of PFO is done for patients with paradoxical embolic stroke. However, the role of surgical or transcatheter closure of PFO is still not clear in many patients because there is insufficient data to evaluate the efficacy of surgical or endovascular closure.⁵⁸⁻⁶⁰

PROGNOSIS AND FUTURE PERSPECTIVES. Prognosis depends on the nature of the potential embolic sources and the effectiveness of prophylaxis. The advent of monitoring for emboli with TCD technology has opened new diagnostic possibilities. Further advances in this technology with the use of multiple concurrent channels (e.g., electroencephalography) will allow better recognition of the source and of the nature and frequency of release of embolic material.

Figure 45-9. Carotid angioplasty and stenting (CAS) performed in a 70-year-old woman with a symptomatic carotid stenosis. **A**, Conventional angiography shows a stenotic segment in the right proximal extracranial internal carotid artery (*asterisk*). **B**, Ballooning of the stenotic segment after insertion of a stent. **C**, Dilated stent. **D**, Post-CAS angiographic picture.

Systemic Hypotension (Border Zone Infarction)

PATHOGENESIS AND PATHOPHYSIOLOGY. Inadequate pumping of the heart results in a global lack of blood flow to the brain. This occurs when there is too little blood in the system (shock and hypovolemia), when the pump fails (myocardial failure or severe arrhythmia), or when systemic hypotension is present. Collateral blood flow is affected first by a generalized lowering of blood pressure. In contrast to thromboembolic stroke, hypoperfusion is global and causes so-called border zone or watershed infarcts in the areas between the major regions of vascular supply: between the ACAs and MCAs and between the MCAs and PCAs (Fig. 45-10).

Infarcts are usually bilateral but may also occur unilaterally when there is severe stenosis of the ipsilateral proximal carotid or other large arteries. The most common area of border zone ischemia is in the temporoparietal region between the MCA and PCA supply regions.⁶¹

EPIDEMIOLOGY AND RISK FACTORS. Causes of stroke due to cerebral hypoperfusion include orthostatic hypotension (due to diabetic dysautonomia or antihypertensive therapy), orthostatic brain ischemia (without hypotension), perioperative complications (especially cardiac surgery), myocardial ischemia, cardiac arrhythmias, severe carotid stenosis or occlusion, or combinations of these.

CLINICAL FEATURES AND ASSOCIATED FEATURES. Faintness, pallor, dim vision, dim hearing and lightheadedness, dizziness, and lack of thought clarity are commonly noticed. The patient's symptoms increase with sitting or standing, and the blood pressure is low. Profuse sweating is common. Temporoparietal border zone ischemia most often causes visual abnormalities. Balint's syndrome is common and consists of asimultagnosia (difficulty in seeing multiple objects at one time), optic ataxia (abnormal hand-eye coordination in one or both visual hemifields), and apraxia of gaze (difficulty in directing the eyes where willed). Ischemia in the anterior border zone

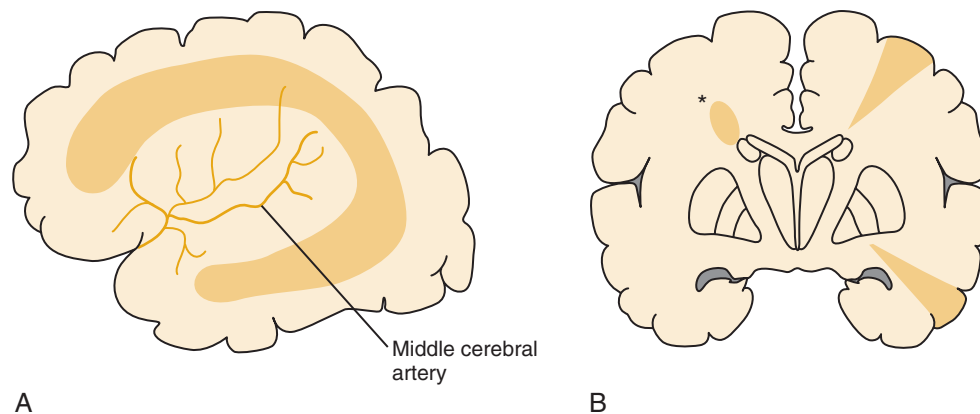

Figure 45-10. Watershed infarction due to low pump pressure secondary to heart failure. **A**, Lateral aspect; **B**, coronal section. Blood flow is deficient in the border zones between the major cerebral arteries (*darker shade*) and in the internal border zone area (*asterisk*).

between the ACA and the MCA affects mostly the convex surface of the precentral and postcentral gyri and causes shoulder and thigh weakness, usually with sparing of the face, feet, and often the hands. Occasionally, patients have ischemia in the cerebellar border zones between the posteroinferior, anterior, and superior cerebellar arteries and have some gait and limb ataxia (Video 14, Tremor with Ataxia).¹

DIFFERENTIAL DIAGNOSIS AND EVALUATION.

Frequently, watershed infarction is diagnosed on the basis of one or more of the following: documented hypotension, a history of syncope or near-syncope preceding the event, and characteristic patterns of infarction on CT or MRI. Orthostatic hypotension is defined as a persistent decline of greater than 20 mmHg in systolic pressure from the supine to the standing position.⁶² Hypotension due to other causes is defined as systolic blood pressure of 90 mmHg or less or at least a 25% drop from preexisting levels. Symptoms of syncope, near-syncope, or cardiac arrhythmia should be sought. Laboratory tests include (1) systemic blood tests including complete blood count (CBC), blood urea nitrogen, and electrolytes; (2) cardiac studies—ECG, echocardiography, and Holter monitoring; and (3) neuroimaging—CT, MRI, and SPECT.

MANAGEMENT. Correction of underlying disorders is essential. Care should be taken when performing interventional procedures such as CEA or cardiac surgery. Excessive use of antihypertensive drugs should be avoided. Recurrences are common, and if they are not treated early, the outlook is poor. The mortality rate is approximately 10%, and there is a high association with MI.

Selected Nonatherosclerotic Occlusive Diseases

Noninflammatory Vascular Diseases

Fibromuscular dysplasia (FMD) is a rare condition that affects any or all of the three layers in the arterial walls of both extracranial and intracranial arteries, particularly those of the bilateral ICAs. FMD causes fibrous dysplastic tissue and proliferating smooth muscle cells in the media, presenting as constricting bands and a string-of-beads appearance on arteriography.¹ FMD is commonly found in middle-aged women and is most often asymptomatic. Because of its frequent association with cerebral aneurysms, FMD is often found during the evaluation of SAH.⁶³ FMD also causes arterial dissections, producing ischemic stroke syndromes, but it may present as a TIA or stroke without any evident compromise of the vascular lumen, possibly due to functional constriction. The stroke recurrence rate is quite low, even with no therapy. If the patient is hypertensive, the renal arteries should be studied.⁶³

Moyamoya disease is defined as progressive occlusion of the intracranial ICAs at their intracranial bifurcations and formation of collateral channels through the basal penetrating branches of the cerebral arteries (Video 216, Moyamoya Stroke). Pathologically, this condition is characterized by endothelial hyperplasia and fibrosis with intimal thickening and abnormalities of the internal elastic laminae and arterial walls of the perforating arteries, probably due to greatly increased flow through these small vessels. Inflammatory changes are absent. Moyamoya vessels are

also found in patients with sickle cell disease, neurofibromatosis, and FMD and also in young women (especially those who smoke cigarettes and take oral contraceptives).¹ Although the disease was first described in young Asians, it has subsequently been found to be widespread and is not limited to Asians. Clinically, children younger than age 15 years usually present with transient episodes of hemiparesis, headache, seizures, or other focal neurological deficits, often precipitated by physical exercise or hyperventilation. In contrast, adults usually present with brain hemorrhages—usually in the thalamus, basal ganglia, or deep white matter. Occasionally, the hemorrhages are SAH. Cerebral angiography, the standard method of diagnosis, shows progressive abnormalities in the intracranial ICAs bilaterally. MCA and ACA branches are also frequently involved. Collateral vessels appear as a cloud of smoke.⁶⁴ MRA has been used as a noninvasive alternative to conventional angiography in typical moyamoya disease. Some patients with moyamoya disease stabilize clinically, often after they have developed disabilities. The best treatment is not known. A variety of surgical revascularization procedures called encephaloduroarteriosynangiosis have been used, but whether they improve the outcome is uncertain.

Cerebrovascular Diseases Especially Related to Pregnancy

There is no increased risk of stroke associated with oral contraceptive use in healthy, nonsmoking, normotensive women. Although there is a three- or fourfold increased risk of venous thromboembolism with current oral contraceptive use, the absolute risk is very small and is half that associated with pregnancy.^{65,66}

Although the incidence of ischemic stroke is not much increased during pregnancy and the early puerperium, pregnancy increases the risk of cerebral hemorrhage. The incidence rates for ischemic stroke associated with pregnancy vary from 5 to 210 per 100,000 deliveries. Ischemic strokes seem to be most common in the puerperal period and third trimester, with few cases occurring in the first trimester. Hypertension contributes independently to the risk of pregnancy-related stroke, especially in older women with chronic hypertension.⁶⁷

Eclampsia is the main cause of both ischemic and hemorrhagic stroke. Eclampsia accounts for approximately half of ischemic strokes, and eclampsia-related ICH carries a poor prognosis. Stroke is responsible for 4.3% of maternal deaths. Up to one third of pregnancy-related brain infarcts may be due to intracranial venous thrombosis, which is most frequent in the third trimester and in the early postpartum period. Dehydration, infection, and sepsis may contribute to venous thrombosis. Patients with eclampsia present with focal neurological deficits of sudden onset in addition to headaches, seizures, or altered consciousness, which usually resolve in several days. The precise pathogenesis is still poorly understood.

Other causes of ischemic stroke during pregnancy include premature atheroma, amniotic embolism, choriocarcinoma, reversible postpartum cerebral angiopathy, arterial dissection, postpartum cardiomyopathy, paradoxical embolism, border zone infarction, use of ergot, pregnancy-related

cardiac diseases, hematological disorders, antiphospholipid antibody syndrome, and homocystinuria. Prognosis is worse than in nonpregnant women or men of the same age.⁶⁸

Arterial dissection, especially spontaneous dissection of the cervicocranial arteries, is an important cause of ischemic strokes, especially in people younger than age 50 years. Congenital changes in the media or elastic layer of the arteries or edema of the arterial wall following mechanical stress promote cervicocranial arterial dissection. They include Marfan's disease, Ehlers-Danlos syndrome, pseudoxanthoma elasticum, or fibromuscular dysplasia, migraine, chiropractic manipulation of the neck, sports and other activities involving sudden neck stretching, or prolonged holding of the neck in an eccentric position. The pharyngeal portion of the extracranial ICA and the first and third segments of the VA are more mobile and thus most vulnerable to dissection.^{69,70}

A tear within the arterial wall leads to bleeding, which dissects along the longitudinal course of the artery. When the dissection develops between the intima and the media, the expanded arterial wall can compromise the lumen and may cause hemodynamic strokes such as TIAs or infarcts (Fig. 45-11A). More frequently, however, the dissection causes thromboembolism. Because clots formed in the lumen of the dissected artery are usually loosely adherent to the intima, they may readily embolize distally, causing embolic infarction. Strokes usually develop within the first few days after the dissection, and late strokes are unusual.⁶⁹ The intraluminal clot is absorbed within several weeks, and the lumen usually returns to its normal size. When dissections extend between the media and the adventitia, tears through the adventitia may lead to SAH (Fig. 45-11B). If the adventitia is not torn, fusiform aneurysmal masses or pouches may develop.

Cervicocranial arterial dissection causes ipsilateral throbbing headache; local sharp pain in the neck, jaw, pharynx, or face; ipsilateral Horner's syndrome; or cranial nerve palsies.⁷¹ Pain in the neck and head is an important symptom that helps to separate the dissection from other

causes of brain ischemia. Occasionally, both carotid arteries and even the VAs are dissected at the same time.

CT and MRI can directly visualize the intramural bleeding and expansion (Fig. 45-12B), confirming the diagnosis. MRA and ultrasound testing are reliable noninvasive tools for diagnosis and follow-up of extracranial ICA dissections, but conventional angiography is more useful for VA dissections.⁷⁰ Angiography may show regions of severe narrowing ("string sign"), or the ICA may be totally occluded, beginning more than 2 cm distal to the ICA origin, sparing the siphon, and having a gradually tapering segment. Localized aneurysmal sacs or outpouchings may be seen.

Duplex scans can show increased arterial diameter, decreased pulsatility, intravascular abnormal echoes, and hemodynamic evidence of decreased flow. TCD can demonstrate diminished intracranial velocities in the ICA siphon and the MCAs or the intracranial VAs and also show the postdissection collateral blood flow.

Although there have been no controlled trials of medical therapy, prevention of embolization of clots at or soon after the dissection is critically important because the risk of thromboembolic strokes is particularly high during the acute period. Unless there are contraindications, anticoagulation with IV administration of heparin followed by oral warfarin with a target INR of 2.0 to 3.0 is generally used for 3 to 6 months. Most extracranial dissections heal spontaneously with time. Arteries retaining some residual lumen invariably heal and become normal, but when complete occlusion has occurred, the arteries often do not recanalize and remain occluded. In patients with SAH, intracranial dissections can be repaired surgically. Recurrence is uncommon, occurring in 3% to 8% of patients with dissection.⁶⁹

Inflammatory Vascular Disorders

This subject is discussed in depth in Chapter 50. Table 45-4 outlines some of the important vasculitides and their key features.

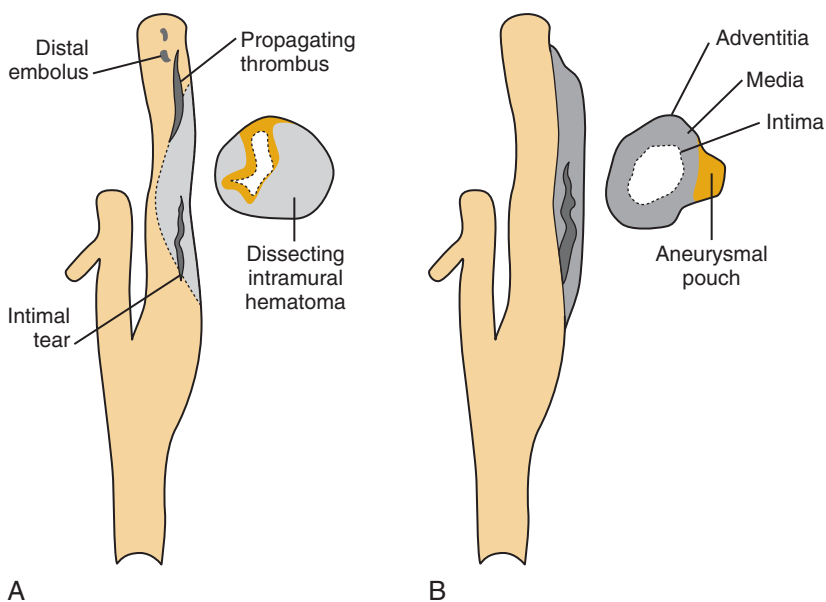

Figure 45-11. Diagrams of two types of arterial dissection: **A**, dissection between intima and media, forming an intramural hematoma compressing and compromising the arterial lumen, causing hemodynamic stroke and/or distal embolism from thrombus developing on the distal portion of the dissecting arterial intima; **B**, dissection between media and adventitia, forming an aneurysmal pouch compressing the neighboring cranial nerves or vessels or rupturing to cause subarachnoid hemorrhage.

Figure 45-12. Radiological findings in a 61-year-old man with a dissection of the internal carotid artery (ICA). **A**, An axial view of brain MRI shows intramural hematoma in the left proximal ICA (*arrow*). **B**, Conventional angiography shows severe narrowing of the left extracranial portion of the ICA, showing so-called “string sign” (*arrow*).

TABLE 45-4

Important Vasculitides

| CONDITION | DEMOGRAPHY | PATHOLOGY VESSEL TYPE | CLINICAL ENVIRONMENT | OTHER FEATURES |
|---|---|---|---|---|
| Polyarteritis nodosa | 1:25 f/m ratio; 30–50 years old | Necrotizing, small-medium muscular arteries | Strokes; kidney, peripheral nerves | Fever, hypertension, circulating immune complexes |
| Churg-Strauss syndrome | 1:1.4 f/m ratio; 10–50 years old | Fibrinoid necrosis with eosinophils; small-medium arteries, veins, capillaries | Asthma; skin, kidney, encephalopathy, peripheral nerves | Eosinophilia, fever, rheumatoid factor |
| Hypersensitivity vasculitis | Any age and sex | Leukocytoclastic vasculitis, postcapillary venules | Peripheral nerves and plexus, encephalopathy, palpable purpura | Drug-induced cryoglobulins, circulating immune complexes |
| Wegener’s granulomatosis | 1:1.2 f/m ratio; any age | Granulomas in organs, necrotizing arteritis | Sinuses, respiratory tract, kidneys, cranial and peripheral nerves | cANCA-positive; upper and lower respiratory tract involvement |
| Sarcoidosis | 20–30 years old; no sex predilection, blacks > whites | Perivenous, granulomas | Peripheral nerves, muscle, eyes, lungs, skin, lymph nodes, brain granulomas | Granulomas in skin, muscle, liver, nodes |
| Temporal arteritis | 1:2 to 1:3 f/m ratio; >50 years | Segmental granulomatous, external carotid, and aortic branches | Eyes, peripheral nerves, occasional strokes | High ESR, jaw claudication, scalp tender |
| Isolated CNS angiitis | 1:2 f/m ratio; any age | Mononuclear perivascular cell, granulomas | Brain only, seizures, confusion | High CSF protein, no systemic symptoms |
| Takayasu’s arteritis | 9:1 f/m ratio; Asians; age range 15–40 years | Acute inflammatory giant cell; large arteries of aortic arch | Syncope, lightheadedness, headache, absent arm pulses (strokes rare) | Systemic symptoms, hypertension |
| Behçet’s disease | 1:9 f/m ratio; Japan and Mediterranean heritage | Perivascular cell loss and demyelination, perivascular plasma cells and lymphocytes | Aphthous oral ulcers, genital ulcers, eye inflammation, meningitis, brain stem lesions | Strokes and meningoencephalitis with focal brain stem lesions |
| Cogan’s disease | Young adults | Arteritis of small and medium-sized arteries | Interstitial keratitis of eye, uveitis, ear involvement | Vertigo, tinnitus, decreased hearing, cornea opacification |
| Eales’ disease | Mostly young men, aged 20–30 years old; Middle East and Indian heritage | Inflammation of retinal arteries and veins | Retinal and vitreous hemorrhages, meningitis, occasional brain and spinal cord infarcts | Characteristic sheathing of retinal arteries and veins and vitreous hemorrhages |
| Microangiopathy of the brain, retina, ear | Almost always women, 15–30 years old | Obliterative, noninflammatory arteries and arterioles | Retina, ear, brain | High CSF protein |

Continued

TABLE 45-4

Important Vasculitides—cont'd

| CONDITION | DEMOGRAPHY | PATHOLOGY VESSEL TYPE | CLINICAL ENVIRONMENT | OTHER FEATURES |
|--------------------------|-------------------------------------|---|--|---------------------------------------|
| Kohlmeier-Degos syndrome | Young adults 15–30 years old | Fibrous vascular proliferation, rare inflammation | Small, yellow, raised skin lesions; GI tract; brain infarcts | Skin, GI, and brain infarcts |
| Sneddon's disease | Females > males; age 30–50 years | Proliferative thrombo- occlusive disease of skin and brain and small arteries and arterioles | Livedo reticularis of skin and brain infarcts | Antiphospholipid antibodies common |

cANCA, classic antineutrophil cytoplasmic antibody; CSF, cerebrospinal fluid; ESR, erythrocyte sedimentation rate; f/m, female-to-male; GI, gastrointestinal.

TABLE 45-5

Drug Abuse and Strokes

| DRUG | ROUTE | ISCHEMIA | HEMORRHAGE | OTHER FEATURES |
|---------------|-----------|-------------------------------|-------------------------------------|----------------------------------|
| Heroin | IV | Strokes—brain and spinal cord | No | Increased gamma globulins |
| Amphetamines | Oral, IV | No ischemic strokes | SAH, ICH; aneurysms and AVMs rare | Hypertension |
| Cocaine HCl | Nasal, IV | Ischemic strokes | SAH, ICH; aneurysms and AVMs common | Hypertension |
| Crack cocaine | Nasal, IV | Ischemic strokes very common | SAH, ICH; aneurysms and AVMs common | Hypertension |
| Mashed pills | IV | Ischemic strokes | No | Talc particles in eyes and lungs |

AVM, arteriovenous malformation; ICH, intracerebral hemorrhage; IV, intravenous; SAH, subarachnoid hemorrhage.

Drug-Related Vasculopathies

Illicit drug use and abuse has become an important cause of stroke, especially in young individuals. This topic is discussed in Chapter 39. Table 45-5 outlines the common drugs implicated and some features of the strokes that they cause.

Migraine-related Stroke

Stroke is a rare but potentially devastating complication of migraine. Ischemic stroke in a migraine sufferer may be categorized as cerebral infarction of other cause coexisting with migraine, cerebral infarction of other cause presenting with symptoms resembling migraine with aura, or cerebral infarction occurring during the course of a typical migraine with aura attack. Increased risk for stroke in migraine patients has been demonstrated in women younger than age 45 years in several studies. Evidence of an association between migraine and stroke in older women and in men is inconsistent. The term *migrainous infarction* is used only when stroke attack occurs in a patient with migraine with aura during a typical attack of migraine with aura and when neuroimaging demonstrates ischemic infarction in a relevant area.⁷² Infarction is thought to be due to prolonged intense vasospasm associated with migraines. Intense vasospasm can impede flow, promoting thrombosis. Platelets are activated during migraine and the vasoconstrictive process may stimulate the endothelium to release factors that promote thrombosis. Severe vasoconstriction and thrombi have been demonstrated in patients with migraine who have PCA and BA territory infarcts.⁷³ To complicate matters, atherosclerotic lesions in the coronary arteries of humans—and in the extracranial and retinal arteries of

experimental animals—seem to predispose them to superimposed vasoconstriction. Thus, vasoconstriction can complicate atherosclerosis. TCD shows promise of identifying vasoconstriction by showing high velocities that change with time and with various pharmacological treatments. Hemorrhage can occasionally complicate a severe migraine attack. Intense vasoconstriction leads to ischemia of a local brain region, accompanied by edema and ischemia of the small vessels perfused by the constricted artery. Then, when vasoconstriction abates, blood flow to the region is augmented, and the reperfusion can cause hemorrhage from the damaged arteries and arterioles. Prophylactic agents (most often calcium channel blockers, cyproheptadine, or methysergide) should be maintained as well as agents that modify platelet function and coagulation. Aspirin may be prescribed, but warfarin can be used in patients with prior infarcts.⁷⁴

Stroke in Coagulation Disorders

Brain ischemia and hemorrhage often result from hematological disorders. Changes in the formed cellular constituents of the blood may be quantitative or qualitative. Polycythemia increases blood viscosity, decreases cerebral blood flow, and increases the risk of thrombosis. Sickle cell disease and sickle cell hemoglobin C disease are examples of qualitative red blood cell abnormalities that affect blood flow. Sickle cell disease causes occlusive changes in large intracranial arteries and small penetrating vessels. Subcortical, cortical, and border zone infarcts are often found on CT and MRI.

Increased platelet counts, especially those more than 1 million, are associated with hypercoagulability. Thrombocytosis can be primary (so-called essential thrombocythemia),

associated with other myeloproliferation, or, less often, secondary to systemic disease. Essential thrombocythemia is associated with strokes and digital arterial occlusions. There are also qualitative abnormalities of platelet function. In some patients, increased coagulability has been attributed to increased adhesion and aggregation of platelets (so-called sticky platelets) in the absence of thrombocytosis.

Leukemia is occasionally complicated by brain hemorrhages and microinfarcts. When the white blood cell count is very high (increased leukocrit), the white blood cells can pack capillaries, leading to microinfarcts and vascular rupture with small hemorrhages in the brain. Larger intraparenchymatous hemorrhages and SAHs are most often related to thrombocytopenia, due to replacement of the bone marrow with leukocyte precursors. Abnormalities of the coagulation cascade can also cause hypercoagulability and lead to venous and arterial occlusions and brain infarction. Table 45-6 lists some of the most common abnormalities.

Stroke in Immunological Abnormalities

Circulating antibodies, such as lupus anticoagulant (LA) and anticardiolipin antibodies, may be related to stroke. The LA is a phospholipid antibody that interferes with the formation of the prothrombin activator. In the laboratory, there is a prolonged activated PTT. Some patients with LA have systemic lupus erythematosus, but most do not. When antiphospholipids of the IgG, IgM, or IgA classes are found in the absence of a known systemic illness, and patients present with an increased incidence of spontaneous abortions, thrombophlebitis, pulmonary embolism, and large and small artery occlusions, the disorder is referred to as primary antiphospholipid lupus anticoagulant (APLA) syndrome. The APLA-associated stroke syndrome is characterized by its younger age at onset, predominance in women, and high risk of recurrent thrombo-occlusive events. Some patients have mitral and aortic valve vegetations and ocular ischemia. In addition to the presence of LA or anticardiolipins or both, laboratory abnormalities include false-positive Venereal Disease Research Laboratory, thrombocytopenia, antinuclear antibodies, and prolonged activated PTT. The risk of recurrent thrombosis in patients with the antiphospholipid antibody syndrome is high. More than one-half of patients have at least one recurrent thrombo-occlusive stroke, with most occurring within the first year. Long-term

anticoagulation therapy is recommended, maintaining the INR at or higher than 3.^{75,76}

Disseminated intravascular coagulation occurs when a primary disorder leads to local or diffuse clotting and the coagulation cascade is activated, with generation of excess intravascular thrombin. The coagulation system is then activated further, fibrin is deposited into the microcirculation, hemostatic elements have a shortened survival, and the fibrinolytic system is activated. The most common disorders inciting disseminated intravascular coagulation are infections, obstetric and vascular emergencies, cancer, nonbacterial thrombotic endocarditis, head trauma, SAH, brain tumors, and vascular malformations. The laboratory findings usually include thrombocytopenia, reduced fibrinogen levels, prolongation of PT and PTT, and increased levels of fibrin split products. Neurological findings are frequent and include an encephalopathy with multifocal signs and frank thrombotic and embolic infarcts. Bleeding can also occur.

Whole blood viscosity is one of the major determinants of cerebral blood flow, especially in the microcirculation. Whole blood viscosity is very dependent on the hematocrit and fibrinogen levels, and these are often elevated in patients with stroke.⁷⁷ Hyperviscosity is also probably pathogenetically related to Binswanger's disease (subcortical arteriosclerotic encephalopathy).⁷⁸ Less often, viscosity is increased by high levels of globulins as in Waldenström's macroglobulinemia or in other disorders with abnormal proteins or cryoglobulins, such as multiple myeloma, or by very high levels of serum lipids, especially chylomicra.

TTP is characterized clinically by fever, renal failure, thrombocytopenia, and microangiopathic hemolytic anemia. Transient focal neurological signs and a more diffuse encephalopathy are common, but occasionally, persistent neurological deficits due to occlusion of medium-sized arteries or brain hemorrhages occur. Plasma exchange can be an effective treatment.

Cerebral Venous Thrombosis

Cerebral venous thrombosis (CVT) is a relatively uncommon disorder. Advances in imaging technologies such as MRI and MRV have resulted in an improved ability to detect CVT early and noninvasively. Thus, treatment and outcome prediction are more feasible. In addition, increased use of anticoagulation has improved the prognosis of patients with even severe neurologic deficits.^{79,80}

CVT is caused by a number of conditions, including endocrine, hematological, immunological, vasculitic, infective, and neoplastic diseases, which cause venous stasis, increased clotting tendency, and traumatic or infective changes in the venous walls. The main causes of CVT differ between age groups. In neonates and children, regional infections (otitis media and mastoiditis), neonatal asphyxia, severe dehydrations, and congenital heart diseases are common associated diseases. In young women, pregnancy, puerperium, oral contraceptive pills, and various connective tissue diseases such as systemic lupus erythematosus are the major causes. Risk of CVT is increased in carriers of prothrombin and factor V gene mutations, which may be enhanced in women receiving oral contraceptives. Other causes include malignancies, antithrombin III protein C and protein S deficiencies, and Behçet's disease.⁸¹

TABLE 45-6

Common Coagulation Disorders Causing Hypercoagulability

| |
|---|
| Deficiencies of natural coagulation inhibitors |
| Antithrombin III |
| Protein C |
| Protein S |
| Resistance to activated protein C |
| Increased levels of serine protein coagulation factors (can occur in patients with inflammatory diseases), factors V, VII, and VIII |
| Cancer, especially mucinous adenocarcinomas |
| Abnormalities of the normal fibrinolytic system |
| Tissue plasminogen activator (t-PA) |
| Plasminogen activator inhibitor (PAI) |
| Dysfibrinogenemias, including increased levels of fibrinogen |

Figure 45-13. MR findings in a 21-year-old man with superior sagittal sinus thrombosis. **A**, MR venography shows poor visualization of the superior sagittal sinus (*arrow*). **B**, Brain MRI shows multifocal infarcts with hemorrhagic transformation.

Occlusion of a dural sinus often results in severe brain edema and venous infarction in the cortex and adjacent white matter, whereas deep cerebral vein thrombosis causes venous infarcts in the basal ganglia, thalamus, or both.⁸² The venous hypertension caused by blockage of blood draining from the skull can also lead to brain hemorrhages. Brain edema, ischemia, and hemorrhages result from extensive thromboses. The sagittal sinus is involved most often, followed by the lateral sinuses and the cavernous sinus. Thrombi in CVT are rich in red blood cells and fibrin but poor in platelets (“red thrombus”) and are replaced by fibrous tissue over time.

CVT has a variable mode of onset, presents with diverse clinical presentations, and usually has a favorable outcome.⁸³ The clinical patterns include (1) isolated intracranial hypertension presenting with headache, vomiting, papilledema, and cranial nerve VI palsy and thus mimicking benign intracranial hypertension (BIH) (Video 1, Cranial Nerve VI Palsy); (2) focal neurological signs or seizure attacks resulting from brain ischemia, edema, or hemorrhage; and (3) a cavernous sinus syndrome.

The key to diagnosis of CVT is clinical suspicion in patients with a condition known to predispose to CVT on the basis of clinical presentations and neuroimaging findings including MRV. Conventional angiography is rarely needed. Venous infarcts appear as unilateral or bilateral, or single or multifocal. Hemorrhagic transformation and small hematoma are common because of the increased pressure in draining veins.⁸⁴ Differential diagnoses include BIH or pseudotumor cerebri, migraine, meningitis, encephalitis, cerebral arterial infarction, ICH, brain abscess, brain tumor, and eclampsia. Diagnosis is based on clinical data, CT or MRI, and MRV findings (Fig. 45-13).

Management of patients with CVT includes administration of full-dose anticoagulant therapy, reduction of ICP, thrombolytic therapy, and antibiotics in case of an infected thrombus. Steroids and osmotic diuretics for brain edema

or increased ICP and anticonvulsants for seizures may also be employed.

Patients show a clear and definite improvement in outcome when treated with anticoagulation using IV heparin followed by warfarin. Unfractionated or low-molecular-weight heparin can be used safely during the acute phase, followed by oral anticoagulation for 3 to 6 months (target INR, 2.5; range, 2.0 to 3.0), even in the presence of hemorrhagic infarction before treatment. In patients who demonstrate progressive neurologic deterioration despite adequate anticoagulation, other options, such as superselective local intra-thrombus infusion of a thrombolytic agent together with IV heparin, are under investigation. Hypercoagulable states must be searched and corrected if present. Patients not responding to anticoagulation may require thrombolysis or rheolytic thrombectomy.^{83,85,86}

CVT usually resolves spontaneously, and the prognosis is generally much better than previously thought but remains largely unpredictable. Among survivors, only a minority develop a permanent deficit, such as focal limb weakness, epilepsy, or optic atrophy. Poor prognostic factors include rapid evolution of thrombosis, coma, infancy or old age, involvement of deep cerebral and cerebellar veins, and septic thrombi.²⁸

HEMORRHAGIC CEREBROVASCULAR DISEASES

Primary Intracerebral Hemorrhage

PATHOGENESIS AND PATHOPHYSIOLOGY. Chronic hypertension causes fibrinoid necrosis in the penetrating and subcortical arteries, weakening of the arterial walls, and formation of small aneurysmal outpouchings, so-called Charcot-Bouchard microaneurysms, that predispose the patient to spontaneous ICH. Bleeding usually arises from the deep penetrating arteries of the circle of Willis, including the lenticulostriate, thalamogeniculate, and thalamoper-

forating arteries and perforators of the BA. Acute increases in blood pressure and blood flow can also precipitate ICH even in the absence of preexisting severe hypertension. A ruptured vascular malformation is the second most common cause of ICH.

Bleeding is limited by the resistance of tissue pressure in the surrounding brain structures. If a hematoma is large, distortion of structures and increased ICP cause headache, vomiting, and decreased alertness. Because the cranial cavity is a closed system, enlargement of a hematoma or development of severe edema may shift brain tissues into another compartment, so-called herniation, and cause deterioration in the clinical condition.

EPIDEMIOLOGY AND RISK FACTORS. ICH is a major cause of morbidity and death and accounts for 10% to 15% of all strokes in whites and approximately 30% in individuals of African or Asian origin. Pregnancy may increase the risk of ICH. Eclampsia accounts for more than 40% of ICHs in pregnancy, and ICH is a common cause of death from eclampsia. Locations of hypertensive ICHs are the putamen (40%), cerebral lobes (22%), thalamus (15%), pons (8%), cerebellum (8%), and caudate (7%) (Fig. 45-14).

Spontaneous ICH can also occur in association with bleeding diatheses, especially the prescription of anticoagulants, primary or metastatic brain tumors or granulomas, and use of sympathomimetic drugs. Aneurysms rarely bleed only into the brain, but when they do, they cause a local hematoma near the brain surface.

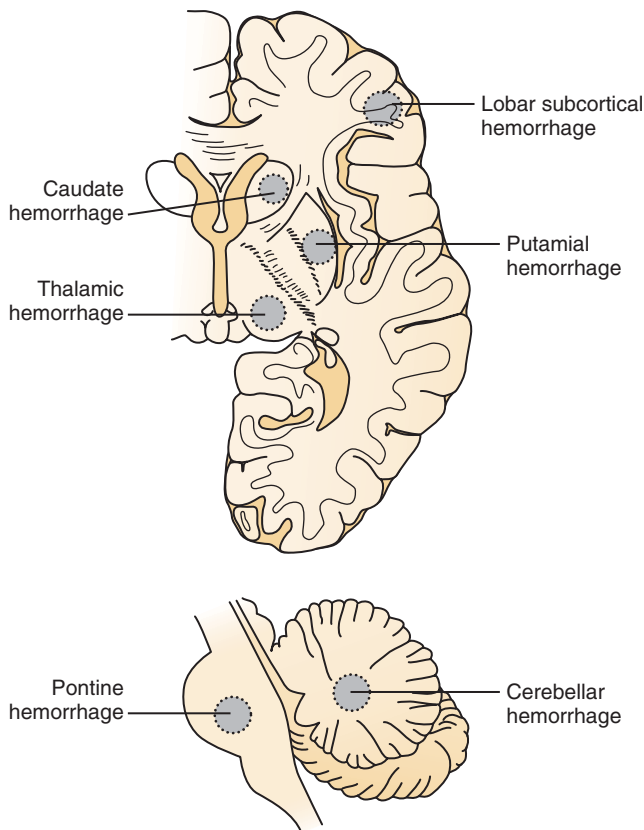

Figure 45-14. Horizontal cerebral section (top) and sagittal brain stem section (bottom) showing most common sites of intracerebral hemorrhage. (Adapted from Caplan LR: Caplan's Stroke: A Clinical Approach, 3rd ed. Boston, Butterworth-Heinemann, 2000.)

CLINICAL FEATURES AND ASSOCIATED DISORDERS. In addition to the symptoms and signs of suddenly increased ICP, ICH presents with specific neurological features according to its location of occurrence. Occasionally, even the hematomas arising in the same anatomical location may present with different clinical features and prognoses because they differ in size, intraregional location, direction of intraparenchymal extensions, and presence of ventricular hemorrhage.^{87,88}

The earliest signs relate to blood issuing into parenchymatous structures. For example, a hematoma in the left putamen and internal capsule would first cause weakness of the right limbs; a cerebellar hematoma would cause gait ataxia. Involuntary movement can develop following basal ganglionic hemorrhage (Fig. 45-15; Video 257, Posthemiplegic Athetosis).

As the hematomas enlarge, the focal symptoms increase. If the hematoma becomes large enough to raise ICP, then headache, vomiting, and decreased alertness develop. Some hematomas remain small and the only symptoms relate to the focal collection of blood. Table 45-7 notes the most important features of hematomas at the most common sites (see Chapter 22).

DIFFERENTIAL DIAGNOSIS AND EVALUATION. Diagnostic considerations include infarcts in similar regions and subdural and epidural hematomas. Rarely, brain tumors and abscesses can have a rapid onset mimicking ICH. It is very important to identify the cause of the hemorrhage. Hypertension, bleeding diatheses (especially as a result of iatrogenic prescription of coumadin), trauma, and amyloid angiopathy are the most frequent causes.

Figure 45-15. A CT scan showing caudate hemorrhage (arrow) with intraventricular hemorrhage in a 68-year-old man who presented with choreoathetoid movement of acute onset in the contralateral side of the body (see Video 257, Post-Hemiplegic Athetosis).

TABLE 45-7

Signs in Patients with Intracerebral Hemorrhages at Various Sites

| LOCATION | MOTOR/SENSORY | EYE MOVEMENTS | PUPILS | OTHER SIGNS |
|-----------------------------|---|---|---------------------|--|
| Putamen or internal capsule | Contralateral hemiparesis and hemisensory loss | Ipsilateral conjugate deviation | Normal | Left: aphasia |
| Thalamus | Contralateral hemisensory loss | Down and in upgaze palsy | Small; react poorly | Right: left-sided neglect Somnolence, decreased alertness; left: aphasia |
| Lobar | | | | |
| Frontal | Contralateral limb weakness | Ipsilateral conjugate gaze | Normal | Abulia |
| Temporal | None | None | | Hemianopia Left: aphasia |
| Occipital | None | None | | Hemianopia |
| Parietal | Slight contralateral hemiparesis and hemisensory loss | | | Hemianopia; left: aphasia; right: left neglect; poor drawing and copying |
| Caudate | None or slight contralateral hemiparesis | None | Normal | Abulia, agitation, poor memory |
| Pons | Quadriparesis | Bilateral horizontal gaze paresis, ocular bobbing | Small; reactive | Coma |
| Cerebellar | Gait ataxia, ipsilateral limb hypotonia | Ipsilateral gaze or cranial nerve VI paresis | Small | Vomiting, inability to walk, tilt when sitting |

In young, normotensive patients, especially those with lobar and intraventricular hemorrhages, vascular malformations are the most likely source of bleeding. Aneurysms can also rarely bleed directly into brain parenchyma. Some primary and metastatic brain tumors, especially renal carcinoma and choriocarcinoma, have a propensity to develop hemorrhages within the tumor, thus causing an abrupt onset or worsening of neurological symptoms. During the initial evaluation, blood samples for basic laboratory studies, including CBC, chemistries, coagulation studies (PT, PTT, bleeding time, and platelet count), arterial blood gas analysis, and toxicology screen, are obtained.

The CT scan is an essential tool for diagnosis, management, and follow-up of ICH. It accurately documents the size and location of the hematoma, the presence and extent of any mass effect, and the presence of hydrocephalus and intraventricular hemorrhage. CT scans should be performed immediately in patients suspected of having an ICH. Follow-up CT scans are requested when there is a change in clinical signs or state of alertness in order to monitor changes in the size of the lesion and ventricular system and to detect important pressure shifts. If the clinical syndrome and CT findings are typical of hypertensive hemorrhage in the basal ganglia, caudate nucleus, thalamus, pons, or cerebellum, angiography is usually not necessary. If the hemorrhage is in an atypical location or the patient is young and not hypertensive, angiography is indicated to exclude an AVM, aneurysm, vasculitis, or tumor. Patients who have ICH after cocaine use have a high likelihood of vascular malformations and aneurysms and need angiography.

MANAGEMENT. Prompt and careful management of patients with ICH may be life saving and is important even in those who will later undergo surgical intervention. Adequate airway and respiratory support should be established. Blood gases should be measured in patients with reduced alertness. Endotracheal intubation is performed for patients presenting in coma, for those who are unable to protect their airway, and for those who have respiratory failure.

Wide swings in blood pressure, especially hypertension, are common in the initial period following hemorrhage. Intravenous labetalol or sodium nitroprusside with concomitant intra-arterial pressure monitoring is an effective method of controlling such elevations. Continuous cardiac monitoring for arrhythmias is important. However, hypotension from cardiac or other etiologies can be devastating due to the impact on cerebral perfusion pressure. Control of local tissue pressure and ICP is also important to guarantee adequate cerebral perfusion pressure. If CT is taken within 3 hours after the onset of ICH, one-third of patients show an increase in the volume of the hematoma related to subsequent bleeding. Recombinant activated factor VII (rFVIIa) has been shown to reduce hematoma growth if used within 4 hours after the onset of ICH, to reduce mortality, and to improve functional outcomes at 90 days. However, it can increase the frequency of thromboembolic adverse events.⁸⁹

The available medical and surgical treatment modalities are outlined in Table 45-8. They are not competitive, but a combined approach utilizing both medical and surgical modalities will often yield satisfactory results.^{90,91}

Seizures may occur at the onset of ICH or within the first 24 hours and require anticonvulsant treatment. The anticonvulsants can usually be discontinued after the first month in patients who have had no further seizures. Patients who have a seizure more than 2 weeks after the onset of ICH are at higher risk for further seizures and may require long-term prophylactic treatment with anticonvulsants.⁹²

Emergency surgical treatments have been tried for several decades, but their efficacy has been disputed. Open surgical hematoma removal, if done early after the onset, seems to be promising in patients with moderate to large hematomas who are still awake. CT-guided stereotactic surgery has made it possible to approach the core of hematoma percutaneously and to evacuate it safely (Fig. 45-16). When the hematoma cannot be drained completely, fibrinolytic agents can be instilled to soften and lyse coagulated hematoma.⁹³

TABLE 45-8

Treatment of Intracerebral Hemorrhage

| Medical |
|--|
| Medical decompression for increased intracranial pressure |
| Intubation and mechanical hyperventilation |
| Dexamethasone (Decadron), 4 mg every 6 hours |
| Mannitol, 0.5–1 g/kg every 4 hours intravenously (IV) |
| Glycerol, 1–1.5 ounces orally every 6 hours |
| Furosemide (Lasix), 40 mg (4 mg/min) IV* |
| Control of hypertension |
| Labetalol, 10 mg IV, followed by 10-mg doses as needed |
| Trimethaphan camsylate (Arfonad), 0.5–1 mg/min IV by drip |
| Nitroprusside sodium, 15–200 µg/min |
| Hydralazine hydrochloride (Apresoline), 50–100 mg twice daily orally |
| Reversal of bleeding diathesis |
| Fresh frozen plasma |
| Antihemophilic factor |
| Phytonadione (vitamin K, AquaMEPHYTON), 20–40 mg IV |
| Platelet transfusion |
| Fresh blood transfusion |
| Surgical |
| Drainage of hematoma—stereotactic drainage or surgical evacuation |
| Ventricular drainage or shunt |
| Removal of bleeding arteriovenous malformation or tumor |
| Repair of aneurysm |

*FDA approved for this indication.

Modified from Chung C-S, Caplan LR: Parenchymatous brain hemorrhage. In Rinkel RE (ed): Conn's Current Therapy. Philadelphia, Saunders, 1995, p 794.

PROGNOSIS AND FUTURE PERSPECTIVES. Survival depends on the location, size, and rapidity of development of the hematoma. ICHs are at first soft and dissect along the fiber tracts. If the patient survives the initial changes in ICP, blood is absorbed over several weeks and a cavity or slit forms that may disconnect brain pathways. Patients with small hematomas located deep and near the midline structures often develop secondary herniation and mass effect, and these patients have a high mortality rate.

Survivors invariably have severe neurological deficits. In patients with medium-sized hematomas, the deficit varies with the location and size of the hematomas. Most patients survive with some residual neurological signs. Recurrence rate of hypertensive ICH is approximately 2% per year. The site of the subsequent ICH usually differs from the first one. Diastolic blood pressure (DBP) is the most critical factor for recurrence, with the average DBP at 90 mmHg (10% if DBP > 90 mmHg; less than 1.5% if DBP < 90 mmHg).⁹²

Subarachnoid Hemorrhage

SAH is a common and often devastating condition. Despite considerable advances in diagnostic, surgical, and anesthetic techniques as well as perioperative management, the outcome for patients with SAH remains poor.⁹⁴

PATHOGENESIS AND PATHOPHYSIOLOGY. The cause of SAH is a ruptured aneurysm in 85% of cases, non-aneurysmal perimesencephalic hemorrhage (with excellent prognosis) in 10%, and a variety of rare conditions such as vascular malformations in 5%. Aneurysms, often referred to as berry or congenital, are outpouchings on arteries, probably caused by a combination of congenital defects in the vascular wall and degenerative changes. Aneurysms usually occur at branching sites on the large arteries of the circle of Willis at the base of the brain (Fig. 45-17).

Approximately one fifth of patients with aneurysms have more than one vascular anomaly or other aneurysms. AVMs are the second most common identifiable cause of nontraumatic SAH, accounting for approximately 10% of SAHs. Rupture of AVMs often causes ICH and SAH. Bleeding of AVMs is usually less vigorous and under less pressure than aneurysmal bleeding. Dissection through the adventitia of arterial walls can cause fusiform aneurysm. Patients with degenerative elongation and tortuosity of arteries (dolichoectasia), fibromuscular dysplasia, polycystic kidney disease, and connective tissue diseases have a higher incidence of aneurysms. Infected materials from

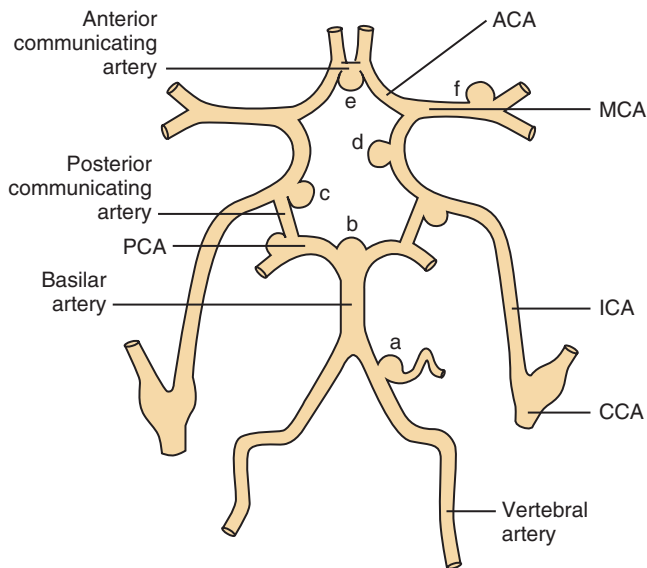

Figure 45-17. Most common sites of intracranial aneurysms: a, posterior inferior cerebellar artery; b, basilar artery; c, posterior communicating artery; d, internal carotid artery (ICA); e, anterior communicating artery (ACA); and f, bifurcation of the middle cerebral artery (MCA). CCA, common carotid artery; PCA, posterior cerebral artery. (Adapted from Caplan LR: *Caplan's Stroke: A Clinical Approach*, 3rd ed. Boston, Butterworth-Heinemann, 2000.)

endocarditis (bacterial or fungal) or cardiac myxoma can embolize to the vasa vasorum of intracranial arteries and can cause mycotic aneurysms. Other less frequent causes of SAH include bleeding diatheses, bleeding into meningeal tumors, and sympathomimetic drugs such as methamphetamine and cocaine. Amyloid angiopathy is an important cause of SAH during the geriatric years.

EPIDEMIOLOGY AND RISK FACTORS. SAH is a significant cause of worldwide morbidity and mortality, predominantly among young adults of both genders. Most patients are younger than 60 years of age. Population-based incidence rates for SAH vary from 6 to 16 per 100,000, with the highest rates reported in Finland and Japan. The annual prevalence of aneurysmal SAH in the United States probably exceeds 30,000 people. Unlike other stroke types, the incidence of

SAH has not declined over time. Any apparent decrease is attributable to a higher rate of CT scanning, by which other hemorrhagic conditions are excluded. The incidence of SAH increases with age (mean age of approximately 50 years) and is higher in women than in men. Blacks are at higher risk than whites. Case fatality is approximately 50% overall (including prehospital deaths) and one-third of survivors remain dependent. Population-based mortality rates for SAH have progressively declined, and the survival rate after SAH has improved since the 1970s.

Risk factors include smoking, hypertension, and heavy alcohol use, and genetic factors operate in only a minority. The risk of SAH is increased during the third trimester of pregnancy. SAH due to aneurysm rupture is a leading cause of maternal mortality, contributing to between 6% and 25% of maternal deaths.^{94,95} During pregnancy, there is also a greater risk of AVM rupture.⁶⁸

CLINICAL FEATURES AND ASSOCIATED DISORDERS. When an aneurysm ruptures, blood is released under arterial pressure into the subarachnoid space and quickly spreads into the cerebrospinal fluid (CSF) spaces around the brain and spinal cord. This causes a sudden increase in ICP and chemical irritation of the meninges, thus causing sudden severe, explosive headache; cessation of physical and intellectual activity; vomiting; and alteration of consciousness. Drowsiness, restlessness, and agitation are especially common. Severe focal neurological signs such as hemiplegia and hemianopia are absent at onset unless the aneurysm also bleeds into the brain. SAH commonly accompanies various complications, including recurrent hemorrhage, acute hydrocephalus, or global brain ischemia associated with vasospasm.

Expanding aneurysms or focal surrounding collections of blood within the cisterns and subarachnoid space can affect the cranial nerves and adjacent brain structures, causing characteristic focal features that depend on the location of the aneurysm. For example, rupture of an aneurysm at the junction of the ICA and posterior communicating artery can compress cranial nerve III, causing oculomotor palsy.

DIAGNOSIS AND EVALUATION. Clinical history and neurological examination form the essential core of SAH diagnosis and grading of clinical status. CT scan performed

Figure 45-18. Brain CT scan and CT angiographic findings of a 49-year-old woman with subarachnoid hemorrhage (SAH). A, High density (blood clot) is noted in the interhemispheric and bilateral sylvian fissures. B, Postcontrast CT scan shows an enhancing aneurysm in the interhemispheric fissure (arrow). C, A saccular aneurysm (8 mm in diameter; arrow) is noted in the anterior communicating artery.

within the first 24 hours detects approximately 95% of all SAH cases (Fig. 45-18A). CT scan is also useful for identifying large AVMs. When the clinical signs strongly suggest the diagnosis of SAH but the CT scan is normal, a lumbar puncture is necessary to detect blood in the CSF. After the diagnosis of SAH is made, a complete diagnostic cerebral angiography should be performed as soon as feasible for precise localization of the source of bleeding (Fig. 45-18B). Once the aneurysm(s) is defined, the surgical or endovascular procedure is routinely carried out within the first 3 days after the bleeding has occurred.⁹⁵ Conventional catheter angiography is gradually being replaced by CT angiography.⁹⁴ Severe migraine and meningitis are the major differential diagnostic considerations.

MANAGEMENT. When patients present to the hospital, they should be stabilized immediately with particular concern for airway management, blood pressure, and pain and agitation control and should be admitted to a neurosciences critical care unit for further monitoring and management. The treatment of patients with SAH involves the prevention and management of the relatively common secondary complications of SAH—rebleeding, vasospasm, hydrocephalus, hyponatremia, and seizures.

Rebleeding may be due to variations or changes in blood pressure rather than to absolute blood pressure. Bed rest, analgesics to relieve headache, and stable maintenance of blood pressure using antihypertensive medications are generally recommended in hypertensive patients. Early surgical clipping of the aneurysm and washing out the cisternal blood clots effectively prevent rebleeding. Because antifibrinolytic therapy to prevent rebleeding has been found to be associated with a higher risk of brain ischemia and no benefits in overall outcome, use of antifibrinolytic agents is usually not recommended.

Endovascular coil embolization techniques are used as an alternative or adjunct to surgery. Endovascular therapy is reported to be associated with fewer complications and lower rates of in-hospital mortality whether the treated aneurysms are ruptured or unruptured. Patients with significant medical co-morbidities, and hence at high risk for surgery, or patients with surgically inaccessible aneurysm or multiple aneurysms are treated with endovascular therapy. Endovascular therapy may be particularly advantageous in patients presenting with vasospasm prior to treatment since angioplasty can be performed simultaneously. However, patients with parenchymal hematomas, mass effect from the aneurysms, or with vessels emanating from the aneurysm dome should be treated surgically rather than with endovascular therapy.

Cerebral vasospasm, which develops in approximately one-half of patients with SAH, is the delayed narrowing of large capacitance arteries at the base of the brain and often leads to diminished brain perfusion in the territory of the constricted arteries. Vasospasm may resolve spontaneously or progress to cerebral infarction. Angiographic vasospasm runs a typical temporal course: onset between 3 and 5 days after hemorrhage, maximal narrowing between 5 and 14 days, and gradual resolution over 2 to 4 weeks. To reduce the risk of delayed cerebral ischemia, patients are treated with supply of fluids, avoidance of antihypertensive drugs, and administration of the calcium antagonist nimodipine. Patients should be closely monitored for hemodynamic changes using TCD in an intensive care

setting. Once ischemia has occurred, so-called “triple H therapy” comprising hypertension, hypervolemia, and hemodilution is recommended. Transluminal angioplasty can be tried in patients for whom conventional therapy has failed.⁹⁴ Fifteen percent to 20% of patients with vasospasm die despite maximal therapy.

Acute obstructive hydrocephalus following SAH complicates approximately 20% of cases. Ventriculostomy is recommended in severe cases, but this intervention may be associated with increased chance of rebleeding and infection. Chronic communicating hydrocephalus also occurs frequently, and temporary or permanent CSF diversion is often required in symptomatic patients. In many patients, hydrocephalus and increased subarachnoid fluid can be relieved by repeated lumbar punctures. Hyponatremia occurs in 10% to 34% of cases after SAH. Hypotonic fluids should be avoided and fluid restriction should not be instituted to treat hyponatremia. Volume should be maintained using isotonic solutions. Seizure-like episodes occur in 25% of patients after SAH. Because seizure increases the potential risk of rebleeding, some recommend the administration of prophylactic anticonvulsants. The long-term use of anticonvulsants is not routinely recommended for patients with no seizure episodes and should be considered only for patients with risk factors such as prior seizure, hematoma, infarcts, or MCA aneurysms.

MANAGEMENT OF UNRUPTURED INTRACRANIAL ANEURYSMS. As a result of improved imaging techniques, intracranial aneurysms are often diagnosed in asymptomatic patients. But because of incomplete and conflicting data about the natural history of these lesions and the risks associated with their repair, management remains controversial. Many factors seem to be involved in management of patients with unruptured intracranial aneurysms. In a large-scale international cooperative study, 4060 patients with asymptomatic unruptured cerebral aneurysms were assessed—1692 did not have aneurysmal repair, 1917 had open surgery, and 451 had endovascular procedures.⁹⁶ Five-year cumulative rupture rates for patients with unruptured aneurysms located in the anterior circulation were 0%, 2.6%, 14.5%, and 40% for aneurysms less than 7 mm, 7 to 12 mm, 13 to 24 mm, and 25 mm or greater, respectively, compared with rates of 2.5%, 14.5%, 18.4%, and 50%, respectively, for the same size categories involving the posterior circulation. In this study, patients' age was a strong predictor of surgical outcome, and the size and location of an aneurysm predicted both surgical and endovascular outcomes.⁹⁶

During pregnancy, the management options after SAH are early clipping or early delivery (spontaneous or by cesarean section), with a possible risk of rebleeding during delivery when aneurysms are unclipped. Cesarean section may be appropriate for patients with an acute hemorrhage who are near term, but management is otherwise similar to that for nonpregnant patients. Craniotomy and clipping have been successfully performed in women at early, mid-, and late stages of pregnancy. There is no difference in prognosis between pregnant and nonpregnant patients with SAH.

Reduction of exposure to the risk factors for SAH might result in a decreased incidence of SAH. Treatment of hypertension with antihypertensive medication, cessation of smoking, and moderation of alcohol use reduce the risk of SAH. Screening of certain high-risk populations for

unruptured aneurysms is of uncertain value. Advances in MRA may facilitate screening in the future. In patients with acceptable surgical risk, clipping of unruptured aneurysms larger than 5 to 7 mm is often recommended.^{94,95}

PROGNOSIS AND FUTURE PERSPECTIVES. Occasionally, the initial bleeding is so severe that death or irreversible brain damage occur. If the bleeding is limited, the patient survives but is at risk for rebleeding in the days and weeks after the initial SAH. For untreated, ruptured aneurysms, there is a 3% or 4% risk of rebleeding in the first 24 hours, 1% or 2% risk per day in the first month, and a long-term risk of 3% per year after 3 months. Urgent evaluation and treatment of patients with suspected SAH is strongly recommended. Many recent advances in endovascular treatment of aneurysms and AVMs may improve the outcome in patients with lesions that are inaccessible to surgery. The major problem is early recognition and referral to neurological centers for early definitive treatment.^{94,95}

Arteriovenous Malformations

PATHOGENESIS AND PATHOPHYSIOLOGY. Vascular malformations are congenital in origin. They are classified into the following subtypes according to the predominant vasculature: (1) AVMs, (2) cavernous angiomas, (3) venous angiomas, (4) dural arteriovenous fistulae (AVF), and (5) capillary telangiectasia. Of these, AVMs and cavernous angiomas are common symptomatic angiomas. Intracranial AVMs, also known as pial AVMs, parenchymal AVMs, or cryptic AVMs, are the most common vascular malformation to cause symptomatic intracranial bleeding. They are composed of clusters of abnormal arteries and veins of varying size, without intervening capillaries. Approximately half of AVMs present with hemorrhage, with ICH being most common, followed by SAH and IVH.⁹⁷ Bleeding is most likely due to fragility of the abnormal vessels. ICH caused by AVM rupture presents as a wedge-shaped lesion from the cortex down to the ventricles as a deep ICH sometimes with extension to intraventricular or subarachnoid spaces (Fig. 45-19). Primary IVH or SAH may also occur. Primary SAH is usually caused by cortically based AVMs and is less severe than aneurysmal SAH. Severe vasospasm can occur rarely in SAH at the base of the brain or in predominately IVH.⁹⁸

Venous angiomas are composed of anomalous veins without any direct feeding artery. Telangiectasia, usually found deep within the brain, particularly in the brain stem, is composed of vessels morphologically resembling capillaries but slightly larger than capillaries and is often found at necropsy. Another less common vascular abnormality, which also rarely causes symptoms, is the venous varix.

EPIDEMIOLOGY AND RISK FACTORS. Vascular malformations are the second most common cause of nontraumatic SAH and ICH. Vascular malformations are one-tenth as common as aneurysms; an estimated 1000 new cases are identified in the United States each year. In the New York Islands AVM study, the average annual AVM detection rate was similar at 1.34 per 100,000 person-years. The incidence of first-ever AVM hemorrhage was 0.51 per 100,000 person-years.⁹⁹ They are often noted prior to the age of 50 years and rupture most commonly during the second and third decades of life. Hemorrhage from malformation is most common during early pregnancy or delivery.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. The presentation, natural history, and management of an AVM are dependent on the type and location of the AVM, its size, overall angioarchitectural characteristics, presenting symptoms, and overall medical status of the patient. The most frequent clinical presentation is hemorrhage, followed by focal or generalized seizures, migraine-like headache, progressive neurologic deficit, and pulsatile tinnitus. They can also be asymptomatic. Symptoms and signs of hemorrhages caused by AVM rupture depend on the location of hemorrhage. There are usually signs of meningeal irritation due to bleeding into the CSF spaces. Not all ruptures are symptomatic, but evidence of previous bleeding is often observed on MRI or at necropsy.

The second most common clinical presentation of AVMs is focal or generalized seizure, occurring in 15% to 35% of cases. Seizures develop most commonly in either frontal or temporal lobe AVMs. Generalized seizures usually occur from frontal AVMs, whereas focal seizures occur from parietal lesions. Chronic migrainous headaches, either ipsilateral or contralateral to the lesion, are another frequent symptom in patients with AVMs (15%). Some present with a typical aura.

Progressive neurologic deficits are uncommon, occurring in 1% or 2% of patients, and seem to be caused by

Figure 45-19. CT, MR, and angiographic images of a 29-year-old man with right temporal lobe hemorrhage and intraventricular hemorrhage on CT scan (A), an enhancing vascular structure on MRI (B), and an arteriovenous malformation (*asterisk*) arising from the right posterior cerebral artery shown on conventional angiography (C).

neuronal injury secondary to chronic ischemia by an intracerebral steal phenomena of blood through the fistula, depriving some surrounding neurons of its required blood supply or secondary to compression of adjacent brain tissue by the pulsating blood vessels.¹⁰⁰ Angiomas in the brain stem may cause serious bleeding or progressive neurological deficits, which may fluctuate in clinical course and may simulate multiple sclerosis. A variety of visual symptoms can occur from occipital AVMs. Pulsatile tinnitus may occur, but it is less common than in dural AVF. Patients with unruptured AVMs may present with increased ICP and papilledema. Rarely, angiomas, particularly aneurysms of the vein of Galen, present with hydrocephalus by disrupting the normal flow of CSF. If there is enough shunting through a large AVM, high-output congestive heart failure may develop, especially in children.

In spinal AVMs, patients may present with back pain, myelopathic symptoms, and root dysfunction. A number of patients with spinal AVMs have intracranial symptoms, including headache, mental status changes, loss of consciousness, papilledema, decreased vision, nystagmus, diplopia, seizures, cranial nerve VI palsy (Video 1, Cranial Nerve VI Palsy), and oculomotor paresis. When a spinal AVM ruptures, severe headache can occur, mimicking aneurysmal SAH.

Some cavernous angiomas are familial. Patients with hereditary hemorrhagic telangiectasias (Osler-Weber-Rendu syndrome) have a higher than normal incidence of vascular malformations.¹

DIFFERENTIAL DIAGNOSIS AND EVALUATION. Diagnostic considerations include aneurysms and brain infarcts and tumors. Diagnosis of AVMs can be suspected clinically when young patients present with ICH, seizures, or frequent unilateral headaches. CT scan, MRI, MRA, and TCD are helpful noninvasive tests. However, a confirmative diagnosis is made using angiography, through which therapeutic embolization can sometimes be performed at the same time. On angiography, a typical AVM shows large feeding arteries; a central tangle of vessels; enlarged, tortuous draining veins; and rapid arterial-to-venous shunting of blood (see Fig. 45-19).

MANAGEMENT. Complete removal of AVM nidus and preservation of normal circulation without complications comprise the ideal management of AVMs. The therapeutic options include surgery, radiation, endovascular embolization, medical therapy for headache and seizure control, or some combination of these. The factors affecting the therapeutic choice are the clinical findings and history; the location of the AVM nidus, arterial feeders, and venous drainage; and the compromise of the normal brain arteries and veins.

Direct surgical excision of AVMs has been improved with the use of the operating microscope and often can be carried out with low rates of morbidity and mortality. The major complications of surgical excision are loss of normal brain tissue, with additional loss of neurological function, and the so-called breakthrough phenomenon. This term describes massive brain swelling and ICH occurring postoperatively, which is caused by redirection of the large volume of blood into small vessels that are unable to handle the large volume that previously flowed into the AVM.

Endovascular treatment of AVMs using embolization techniques can be used alone, before surgery or radiotherapy, or at

the time of surgery. It is particularly useful in treating lesions that are not surgically accessible and as an adjunct to surgical removal. Complications include hemorrhage, ischemic stroke, and angioneurosis due to toxicity of the embolic materials.¹⁰¹

Radiotherapy of AVMs with focused beam irradiation (high-energy x-rays, gamma rays, and protons) is employed to treat small AVMs. It induces subendothelial deposition of collagen and hyaline substances, which narrow the lumen of small vessels and shrink the nidus of the malformations by progressive occlusion of vessels during the months after treatment. The gamma knife, which uses a cobalt source to generate highly collimated gamma rays, focuses the radiation beams on small regions. Modified linear accelerators can deliver radiation to a defined volume of tissue with very good accuracy. Pre-radiotherapy embolization can be done to reduce larger AVMs to a size small enough to permit the lesions to be treated effectively. Complications include radionecrosis of normal brain tissue, bleeding, hydrocephalus, immediate post-therapy seizures, loss of body temperature regulation, and possibly long-term cognitive function deficits.¹⁰² Medical management includes strict control of blood pressure and avoidance of anticoagulants and antiplatelet drugs. Because pregnancy increases risk of bleeding, appropriate contraception may be recommended in fertile women with an AVM.

PROGNOSIS AND FUTURE PERSPECTIVES. In the short term, the prognosis of ruptured AVMs and cavernous angiomas is better than that of aneurysms. The rebleeding rate is low during the first few months. Only 6% of patients rebleed during the first year, and vasospasm occurs only rarely. Mortality from the first hemorrhage is low—only approximately 10%. However, in the long term, the prognosis of AVMs is not as good. With subsequent hemorrhages, the mortality rate is higher—approximately 20%. With each recurrence, the chances of additional bleeding increase. Improved noninvasive diagnosis using MRI and MRA and improved methods of treatment (endovascular and radiotherapy) promise to help reduce the rates of morbidity and mortality of this serious vascular condition.

TRAUMATIC NEUROVASCULAR DISEASES

Carotid-Cavernous Sinus Fistulas

A carotid-cavernous sinus fistula (CCF) is an abnormal communication between the cavernous sinus and the carotid arterial system. CCFs usually develop after head trauma but can occur spontaneously. CCFs are classified as direct and dural types. The most common type is the direct type (70% to 90%), in which there is a direct connection between the intracavernous portion of the ICA and the cavernous sinus. This is a high-flow type often caused by a traumatic tear of the arterial wall. The dural types are communications between the cavernous sinus and meningeal arterial branches of the ICA, the external carotid artery, or both. They develop spontaneously or in the setting of atherosclerosis, systemic hypertension, or collagen vascular disease and during and after childbirth. These fistulas are usually of the low-flow type and almost always produce symptoms and signs spontaneously without antecedent trauma.

Patients with a direct CCF may develop monocular visual loss and abnormalities of the oculomotor nerves (III, IV, and VI) ipsilaterally or bilaterally. Ocular manifestations include diplopia, proptosis, ocular bruit, chemosis, ocular pulsation, dilatation of retinal veins, optic disk swelling, visual loss, and, potentially, glaucoma. There are often signs of intracranial hypertension. Trigeminal nerve dysfunction is the most common cranial nerve abnormality. Dural types usually occur in middle-aged or elderly women. They present similar clinical symptoms and signs but are less severe than those of the direct type. If a CCF is suspected, CT or MRI and ocular ultrasonography are performed and often show enlarged extraocular muscles, dilated superior ophthalmic veins, and an enlarged affected cavernous sinus. The ultimate diagnostic test is cerebral arteriography of both the bilateral internal and external carotid arteries. Recently, CT angiography has been used for diagnosis.¹⁰³

Urgent treatment is indicated in patients who have rapidly deteriorating vision, hemorrhage, and intracranial hypertension. Surgical repair of the damaged portion of the intracavernous ICA is only rarely used. Endovascular occlusion using detachable balloons has a success rate of 90% to 100% with low complication rates (2% to 5%).¹⁰⁴ The recurrence rate is 1% to 3.9%, and recurrence often responds to second balloon treatment. Early complications include migration of balloons and thromboembolism resulting in stroke; delayed complications are pseudoaneurysm formation and persistent ophthalmoplegias. If the condition is left untreated, almost all patients have progressive ocular problems, including increasing proptosis, chemosis, and visual loss. The most feared complications are central retinal vein occlusion and secondary glaucoma. Endovascular techniques have greatly improved the prognosis of CCFs. Most symptoms and signs usually disappear within days after treatment or at least improve with this procedure, but complete resolution may take weeks to months.¹⁰⁵

Subdural Hematomas

A subdural hematoma (SDH) results from venous bleeding after blunt head trauma, which causes brain motion within the skull, shearing off the bridging veins between the surface of the brain and adjacent dural venous sinuses. The most common site of SDHs is the temporal pole, followed by the frontal pole, and then the convexity. The blood leaks and collects slowly in the subdural space. They can be simple or complex. Simple SDHs have no underlying parenchymal injury and the outcome is usually good if evacuated early (within 2 to 4 hours). Complex SDHs are associated with cortical contusions, lacerations, and ICHs.

A chronic SDH usually develops after minor trauma, typically in an elderly person under anticoagulation or in an alcoholic individual with some degree of brain atrophy. Bleeding may continue around the atrophic brain, causing headaches, behavioral changes, altered level of consciousness, or a focal neurological deficit such as hemiparesis. Patients under anticoagulation and those with bleeding disorders may develop spontaneous SDH. Occasionally, subdural collections develop after lumbar puncture, particularly in patients with intracranial CSF hypovolemia. Because a fall frequently causes retrograde amnesia, the patient may not recall the injury.

An SDH may be absorbed spontaneously or may form an encapsulated and liquefied hematoma, a so-called hygroma. After approximately 2 weeks, membranes form around the hematoma. The outer membrane is thicker and more vascular than the inner membrane. The center of the encapsulated SDH liquefies and may enlarge due to repeated bleeding from the vascular outer membrane, assuming a progressively larger biconvex lens shape. Acute SDHs developing after severe head trauma carry a poor prognosis, with a mortality rate of 50% even if treated.

The most common presentations of SDHs are headache, decreased level of alertness, and abnormalities of cortical function. Headache is usually ipsilateral to the hematoma and may be worse at night. Drowsiness and decreased alertness reflect an increase in ICP. Patients may present with contralateral hemiparesis, hyper-reflexia (Video 80, Hyper-Reflexia), positive Babinski sign contralateral to the hematoma, mild aphasia in left-sided hematomas, or neglect in right-sided SDHs. Usually, the neurological deficits are seldom profound as in patients with large hemisphere infarcts or ICHs. Seizures may develop if there is some contusion of the underlying brain tissue. Ipsilateral Babinski sign, signs of ipsilateral cranial nerve III palsy (Video 32, Cranial Nerve III Palsy), or both may indicate midbrain compression.

The diagnosis is usually obvious in patients with head injury. The insidious development of symptoms, especially in patients who provide no history of trauma, can readily mimic brain tumor or abscess. Cerebral infarcts and hematomas usually present with more acute-onset symptoms and signs and more severe focal deficits. On a CT scan, an acute SDH appears as a sickle-shaped, hyperdense lesion over the outer surface of the brain lying against the inner surface of the skull and dura (Fig. 45-20). A chronic SDH appears hypodense on CT scans. MRI clearly demonstrates the extra-axial hematoma and is particularly useful when a subacute hematoma appears isodense on CT. If an SDH is left untreated, it may cause a severe neurological deficit or death. Surgical evacuation is generally indicated for acute SDHs thicker than 3 or 4 mm; however, several studies support conservative medical management if the hematoma thickness is less than 10 mm and the midline shift is not more than 5 mm. A generous craniotomy allows for proper exploration of all potential bleeding sites and serves as a potential treatment option (decompressive craniotomy) for the management of cerebral edema.

The prognosis is primarily related to the degree of associated brain injury. In older patients and in those with brain atrophy, re-expansion of the compressed brain may be delayed. Recovery is usually excellent in patients in whom SDHs are recognized and treated. Small SDHs are common and may heal spontaneously without surgical treatment. Because SDHs represent a very treatable cause of cognitive dysfunctions and neurological signs in the elderly prone to falls, improved screening of these patients would be an important public health advance.¹⁰⁶

Epidural Hematomas

An epidural hematoma (EDH) develops when blood collects between the skull and the dura mater as the result of a severe head injury causing a skull fracture of the squamous portion

Figure 45-20. Precontrast (A) and postcontrast (B) CT scans show subacute subdural hematoma in the right parietal area and mild midline shift. (C) Postoperative CT scan shows disappearance of subdural hematoma.

of the temporal bone (> 90%) and producing a tear in the middle meningeal artery. Thus, the most common location of EDH is along the lateral wall of the middle cranial fossa. Because the blood escapes under arterial pressure, it dissects the dura inward away from the bone and forms a large hematoma rapidly. The underlying brain is displaced inward and brain herniation may follow. Rarely, an EDH may be venous in origin due to laceration of the middle meningeal vein or a dural venous sinus. EDHs are less common compared to SDHs. They may be an important cause of death in patients with severe head injury and are particularly common in those younger than age 40 years because the dura is more adherent to the bone in older adults. SDH, ICH, and SAH often coexist.

Classically, the initial injury causes brain concussion and loss of consciousness from which the patient awakens; the patient may complain of headache but seems to be recovering (so-called lucid interval) and then often progressively deteriorates into coma as the hematoma enlarges rapidly. The acute development of epidural bleeding causes pressure on the ipsilateral cerebral hemisphere and headache, reduction in consciousness, and dysfunction of the ipsilateral hemisphere. Downward transtentorial herniation may develop rapidly, causing dilatation of the ipsilateral pupil due to cranial nerve III compression and an ipsilateral hemiparesis due to compression of the contralateral cerebral peduncle of the midbrain against the contralateral tentorial edge. Altered mental status and hemiparesis develop before signs of brain herniation. Diagnosis is made by CT. The hematoma typically appears as a biconvex lens-shaped hyperdense lesion. There is an underlying skull fracture. EDHs should be surgically evacuated as soon as possible; there is no place for conservative management. Rapid drainage can be life saving, and the outcome is usually excellent when the hematomas are rapidly removed. Death usually results from unrecognized EDH.¹⁰⁷ The overall mortality for epidural hematomas is 10%. However, individual morbidity and mortality depend on patients' Glasgow Coma Scale prior to surgery; therefore, early diagnosis and treatment are critical for good outcome for this highly treatable injury.

Spinal Cord Strokes

PATHOGENESIS AND PATHOPHYSIOLOGY. Spinal cord strokes are very rare in comparison to strokes in the

brain. Spinal cord infarcts are most often caused by interruption of the blood flow in one or more of the arteries that feed into the anterior spinal arterial system, which runs in the ventral midline from the medullospinal junction rostrally to the conus medullaris and the filum terminale caudally. This system is supplied by 5 to 10 single radicular arteries. The cervical region is supplied by the branches of the intracranial VA and inferiorly by branches of the thyrocervical and costocervical branches of the subclavian arteries. The thoracic and lumbar spinal cord segments are fed by radicular arterial branches of the deep cervical and intercostal arteries and branches of the aorta. The lower thoracic cord is supplied by direct branches from the aorta, the largest of which is the artery of Adamkiewicz, which most often enters between T12 and L2. The sacral cord and cauda equina are supplied by branches of the hypogastric and obturator arteries. This system is vulnerable to interruption of flow through any one of the feeding arteries. Resulting infarcts usually affect the anterior horns and the lateral and ventral white matter columns. In contrast to the anterior spinal artery system, there are paired posterior spinal arteries, which are fed by small posterior radicular arteries. The posterior spinal arteries supply the posterior columns and posterior gray horns of the spinal cord. Because of the multiple feeding channels, this system is very resistant to interruption of its blood supply. Interruption of blood flow in anterior spinal branches is probably most often due to diseases within the aorta, including aortic aneurysms, surgery on the aorta, aortic dissections, and emboli from atheromatous aortic plaques. Disk cartilage can also fragment and enter spinal arteries and veins and lead to infarction. Arteriovenous fistulas are an important cause of spinal cord infarction in older men. Direct communications developing between radicular arteries and veins outside the dura mater greatly increase pressure in the venous system, and large drainage veins develop on the surface of the spinal cord. At the same time, shunting of blood decreases flow to the spinal cord from the feeding artery. In order to maintain adequate spinal perfusion, the pressure of blood in the arterial system must exceed venous pressure. The spinal-dural AV fistula often creates a situation in which venous pressure exceeds arterial pressure intermittently, and ischemia develops. At first, ischemia can be intermittent, and spinal cord TIAs can result. Adhesive arachnoiditis following infection of the meninges (syphilis, tuberculosis, and

Lyme borreliosis) and parasitic invasion of the spinal arteries (schistosomiasis) can cause obliteration of spinal arteries and lead to cord ischemia. Hypoxic-ischemic injury to the spinal cord also develops in patients with severe systemic hypotension and shock. Spinal cord hemorrhage most often results from trauma. Bleeding diathesis, especially anticoagulation, is another important cause. Aneurysms of intradural arteries and intradural AVMs and cavernous angiomas are other causes of spinal cord hemorrhages.

CLINICAL FEATURES AND DIAGNOSIS. Spinal cord infarcts usually develop abruptly. Most spinal strokes are thoracic or lumbar so that the lower extremities are selectively involved. The most common signs are motor and include both lower motor neuron and upper motor neuron abnormalities within the lower limbs. Paraplegia is usually symmetrical. There may be a pain and temperature level along the thorax. Sphincter function is most often lost. Posterior column functions (vibration and position sense) are usually spared. The findings are most often roughly symmetrical. When the lesion is asymmetrical or unilateral, sensory dissociation occurs, producing a Brown-Séquard-like pattern. In patients with spinal-dural AV fistulas, TIAs and steplike development of deficits are common. Almost always, the symptoms and signs allow recognition that the lesion is spinal. Occasionally, medullary and pontine infarction can be a consideration. Tumors, abscesses, and syrinxes usually cause symptoms that develop gradually, but hemorrhage into a spinal cord tumor, most often an ependymoma, can be an important consideration. Spinal cord compression caused by cancer, epidural and subdural infections, and hematomas are other considerations. Almost all compressive spinal cord lesions involve the vertebral column. Plain bone x-ray studies and CT, MRI, and bone scans can yield information about osseous lesions that could compress the spinal cord. MRI is the best method to visualize the spinal cord, dura mater, and overlying bony structures. MRI can show spinal hemorrhages and infarcts and can identify the presence of spinal cord compression. MRI is not very sensitive for the detection of spinal-dural AV fistulas. Myelography may be needed to show the characteristic dilated veins that course on the surface of the spinal cord. Lumbar puncture is helpful in identifying spinal hemorrhage and infection. Spinal angiography is often necessary to characterize spinal vascular malformations and fistulas.

MANAGEMENT AND PROGNOSIS. There is little information about treatment of patients with spinal cord infarcts. Definitive treatment depends, as it does in the brain, on identification of the etiology in the individual patient. Hemorrhage, infection, and infarction can be separated by MRI and lumbar puncture. Identification of spinal-dural AV fistulas is very important because obliteration of the abnormalities can prevent further spinal cord damage. Rehabilitation and management of sphincter functions is similar to that pursued in other diseases of the spinal cord. Outcome depends almost entirely on the cause of the spinal cord vascular damage. More accurate ways to study the aortic blood supply to the spinal cord need to be developed. Intravascular ultrasound is promising. Perhaps further development of MRA and venography will be helpful and obviate the need for spinal angiography, which can be hazardous. Basic research on spinal cord protection may help limit damage in patients with vascular spinal cord insults.¹

STROKES IN THE YOUNG

Strokes in children younger than age 15 years are often different from those in adults. Brain infarcts tend to be limited more to the deeper regions of the cerebral hemispheres, especially the striatocapsular areas. Vascular occlusive lesions are more often intracranial and affect mostly the intracranial carotid and the middle cerebral and basilar arteries. Extracranial lesions are less common; when they occur, they usually involve the pharyngeal portions of the carotid and vertebral arteries rather than the arterial origins that are involved more commonly in adults. Vasoconstriction, dissection, fibromuscular dysplasia, trauma, and contiguous infection are the major conditions that affect the extracranial arteries of children. When the vascular occlusive process or embolism involves the MCA, vascular compromise is maximal in the territory of the lenticulostriate branches. Because of the invariable absence of severe occlusive disease, collateral circulation over the convexities is abundant. This explains the striatocapsular localization of infarcts. Because atherosclerosis is very rare in youth, the types of vasculopathies that cause brain ischemia in children are much more diverse than in adults, and the differential diagnosis is very broad. Congenital cardiac disease is an important cause of stroke in children. Table 45-9 lists the most important causes of brain ischemia in children younger than age 15 years. ICH and

TABLE 45-9

Differential Diagnosis of Pediatric Brain Ischemia (1–15 Years)

| |
|---|
| Migraine |
| Trauma: Dissection and other vascular injuries; abuse including whiplash-shake injuries; oral foreign body trauma to the internal carotid artery |
| Cardiac: Congenital heart disease with right-to-left shunts; tetralogy of Fallot; transposition of the great arteries; tricuspid atresia; atrial and ventricular septal defects; cardiomyopathies; endocarditis; pulmonary arteriovenous fistula |
| Drugs, especially cocaine and heroin |
| Infections: Bacterial meningitis, especially <i>Hemophilus influenzae</i> , pneumococci, and streptococci; facial, otitic, and sinus infections; AIDS; dural sinus occlusion and infection; tuberculous meningitis |
| Genetic and metabolic: Neurofibromatosis; hereditary disorders of connective tissue (Marfan's and Ehlers-Danlos syndromes, pseudoxanthoma elasticum); homocystinuria; Menkes' kinky hair syndrome; hypoalphalipoproteinemia; familial hyperlipidemias; methylmalonicaciduria; MELAS syndrome (mitochondrial myopathy, encephalopathy, lactic acidosis, strokes) |
| Hematological and neoplastic: Sickle cell anemia; purpuras; leukemia; L-asparaginase and aminocaproic acid (Amicar) treatment; radiation vasculopathy; hypercoagulable states (e.g., caused by decrease in natural inhibitors such as antithrombin III) |
| Arteritis: Collagen vascular disease; local infections; Takayasu's disease; Behçet's disease |
| Venous sinus thrombosis: Head and neck infections; dehydration; coagulopathy; paroxysmal nocturnal hemoglobinuria; puerperal or pregnancy-related |
| Systemic disease: Rheumatic; gastrointestinal; renal; hepatic; pulmonary |
| Moyamoya disease |

TABLE 45-10

Differential Diagnosis of Ischemia in Young Adults (15–40 Years)

| |
|---|
| Migraine |
| Arterial dissection |
| Drugs, especially cocaine and heroine |
| Premature atherosclerosis, hyperlipidemias, hypertension, diabetes, smoking, homocystinuria |
| Female hormone–related (oral contraceptives, pregnancy, puerperium): eclampsia; dural sinus occlusion; arterial and venous infarcts; peripartum cardiomyopathy |
| Hematological: Deficiency of antithrombin III, protein C, protein S; fibrinolytic system disorders; deficiency of plasminogen activator; antiphospholipid antibody syndrome; increased factor VIII; cancer; thrombocytosis; polycythemia; thrombotic thrombocytopenic purpura; disseminated intravascular coagulation |
| Rheumatic and inflammatory: Systemic lupus erythematosus; rheumatoid arthritis; sarcoidosis; Sjögren's syndrome; scleroderma; polyarteritis nodosa; cryoglobulinemia; Crohn's disease; ulcerative colitis |
| Cardiac: Interatrial septal defect; patent foramen ovale; mitral valve prolapse; mitral annulus calcification; myocardiopathies; arrhythmias; endocarditis |
| Penetrating artery disease (lacunes); hypertension, diabetes |
| Others: Moyamoya disease; Behçet's disease; neurosyphilis; Takayasu's disease; Sneddon's disease; fibromuscular dysplasia; Fabry's disease; Cogan's disease |

From Caplan LR, Estol CE: Strokes in youths. In Adams HP (ed): *Cerebrovascular Disease*. New York, Dekker, 1993, pp 233–254.

SAH, especially from aneurysms and vascular malformations, comprise a much higher percentage of strokes in children than they do in adults.¹⁰⁸

Premature atherosclerosis and stroke risk factors are much more important in young adults than in youths. Cardiac disease and hematological diseases and cancer provide a higher proportion of infarcts in young adults than during the geriatric years. Table 45-10 lists the major differential considerations of brain ischemia in people 15 to 40 years of age.¹ Hypercoagulable states have been found to be an important and underappreciated cause of stroke in young adults. Approximately 25% of patients had thrombophilia and the most common cause was elevation in IgG anticardiolipin antibodies. Therefore, it is best to perform complete hypercoagulability studies on young adults with cerebral ischemia.¹⁰⁹

HISTORY

Primary malignant brain tumors have been a cause of increasing concern in the past several years. There has been a steady rise in the incidence of primary brain tumors, with an almost 25% increase during the past two decades, perhaps due to improved detection with neuroradiological imaging.^{1,2} Although the incidence of some tumors such as lung cancer has declined, and improvements in therapy have increased survival for other tumors such as breast cancer, the incidence of brain tumors continues to increase. Just as important as the rise in incidence is the fact that the need for treatment of these neoplasms is urgent because they afflict the young in disproportionate numbers, significantly affecting their chances of living productive lives.

According to statistics gathered by the American Cancer Society for 2005, the annual incidence of brain and other nervous system cancers is 18,500 (with 12,760 deaths) involving 10,620 men and 7880 women (Table 46-1). More than half of these cases are malignant gliomas. The annual death rate for brain and other nervous system tumors remains high. For comparison, the estimated annual incidence of breast cancer is 212,930 and it is 34,810 for leukemia. In children, brain tumors are the most common solid tumor and are second only to leukemias in overall incidence.

Early studies date back centuries to descriptions or drawings of lethal brain tumors discovered at autopsy. In 1828, John Ambercrombie published the first pathological descriptions of brain tumors in his monograph *Pathological and Practical Research on Disease of the Brain and Spinal Cord*. The first acknowledged resection of a brain tumor was performed in London in 1884 after Hughes Bennett provided sufficient clinical localization to permit Rickham Godlee to perform a craniotomy. Even then, doctors were quick to announce their findings in the lay press, and a report documenting the operation was published in *The London*

Times a mere 21 days following the procedure. Formal reports of the operation were later published in the medical literature. The first monograph on brain tumors was prepared 4 years later by Sir Byron Bramwell.

Pathological criteria for the diagnosis of primary brain tumors remained under study and were controversial for almost a century. Even at the turn of the 20th century, surgeons complained bitterly that a lack of precise pathological criteria hindered diagnosis. Fedor Krause, in his three-volume *Surgery of the Brain and Spinal Cord* (1912), described several successful tumor surgical procedures in which the neuropathologist was either unable or unwilling to venture a diagnosis. Bailey and Cushing published the first modern treatise on brain tumors and pathological description in 1932. Previously, they had histologically defined and coined the term *medulloblastoma*.³ Use of this term to refer to a blue cell tumor of the posterior fossa continues to spark debate.⁴

In the first half of the 20th century, Cushing continued to develop and refine the techniques of neurosurgical removal and localization, including angiography and pneumoencephalography. Greg Walter described the first use of electroencephalography for tumor localization in 1936. Improvements in radiotherapy and chemotherapy⁵ during the second half of the 20th century marked the emergence of neuro-oncology as a multidisciplinary field. In the 21st century, analysis of the biological markers and genetic behavior of these tumors is expected to advance the ability of clinicians to treat effectively this class of cancers.

NEUROECTODERMAL TUMORS

Low-Grade Glioma, Astrocytoma, and Pilocytic Astrocytoma

PATHOGENESIS AND PATHOPHYSIOLOGY. The diagnosis of glioma remains one of the most difficult areas of

neuro-oncology. As advances occur in the understanding of biological behaviors and cellular markers of these tumors, the diagnostic criteria continue to change. The popularity of stereotactic biopsy has resulted in problems of firm diagnosis because small tissue samples may not be representative of the entire tumor. Furthermore, previously determined diagnostic criteria have been found to be inconsistent; therefore, comparisons of results of clinical trials of radiotherapy and chemotherapy have often been unreliable because the patient populations for individual studies were not homogeneous. Finally, and most important, histological interpretation does not necessarily predict biological behavior in the individual patient.

Attempts to devise a grading system that provides ease of interpretation and interobserver consistency have had limited success. For example, the St. Anne-Mayo (Damas-Duport) system proposed a modification of previous grading schemes that relied on histological criteria, including nuclear atypia, mitosis, vascular endothelial proliferation, and necrosis, as differentiating features. A point system was assigned to these histological variables as follows: Grade 1 tumors had none of these features, grade 2 tumors had one feature, grade 3 tumors had two features, and grade 4 tumors had three or more features. In the initial evaluation, these groups led to distinct median survival curves, but a subsequent review of 251 cases at the Massachusetts General Hospital found no statistical difference in survival between patients with grade 2 and 3 tumors.⁶ Even when the histological criteria are consistent, clinical features such as age or extent of resection alter the survival characteristics. For example, a patient with an astrocytoma at age 20 years has a median survival of 5 to 10 years, whereas a patient at age 60 years may have a survival similar to that characteristic of a malignant astrocytoma.

The modified Ringertz system remains the most reasonable grading scheme for astrocytic gliomas. It separates these tumors into three categories (Table 46-2): astrocytoma, anaplastic astrocytoma, and glioblastoma multiforme. This grading system appears to correlate best with survival. The recent World Health Organization classification incorporates the Ringertz system, assigning grades II

TABLE 46-2

Histological Criteria for Cerebral Gliomas

| 2. Foci of coagulative necrosis |

to IV, respectively, to these histological categories and including a fourth category, pilocytic astrocytoma, as grade I (Fig. 46-1). Even with current research, necrosis remains the only significant histological predictor of survival.

Astrocytomas can infiltrate and invade vital neural systems and may prohibit complete surgical removal. They eventually lead to death because of this disruption of neural systems or because of increased intracranial pressure due to volume expansion. Histologically, they appear to be characterized by increased cell number and nuclear pleomorphism without necrosis. Mitotic figures should not be present. Microcystic changes separate these tumors from a glial reaction.

Pilocytic astrocytomas are commonly found in the cerebellum, brain stem, thalamus, and optic nerve tracts of pre-teenage youths, but they can occur in individuals up to 30 or 40 years of age. They have a gelatinous appearance, are often well circumscribed, and, if in a favorable location, can be totally excised. Histologically, they have a highly recognizable pattern marked by fibrillary astrocytes and stellate cells. Rosenthal fibers and microcystic changes are often evident. Pleomorphic xanthoastrocytomas are cerebral tumors with lipid-filled cytoplasm found in teens and young adults. Subependymal giant cell astrocytomas are common in the initial decades of life of patients with tuberous sclerosis and arise from the lateral ventricles. Brain stem gliomas are seen in younger individuals and usually are present in the pons or medulla. They rarely undergo biopsy. Magnetic resonance imaging (MRI) usually demonstrates a “fat” pons without gadolinium enhancement. Cervicomedullary gliomas carry a more favorable prognosis than pontine gliomas because brain stem gliomas in the medulla tend to be lower grade tumors.

EPIDEMIOLOGY AND RISK FACTORS. Gliomas are the most common tumors of the brain and spinal cord.⁷ Astrocytomas occur most commonly in the 20- to 40-year-old age group and represent approximately 15% of all primary central nervous system (CNS) tumors (see Table 46-1). The incidence of low-grade gliomas appears to be on the rise, perhaps because they are often diagnosed incidentally when patients undergo neuroradiological imaging for other reasons such as trauma.^{8,9} Patients with astrocytomas have a more favorable median survival than those with glioblastomas. However, because astrocytomas are usually found in young people, even a survival time

Figure 46-1. Histopathological picture of four types of astrocytomas. **A**, Pilocytic astrocytoma, elongated bipolar tumor cells forming a dense fibrillary matrix with numerous Rosenthal fibers. **B**, Astrocytoma, elongated hyperchromatic nuclei with diffused infiltration of the white matter (note lack of nuclear pleomorphism). **C**, Anaplastic astrocytoma, demonstrating nuclear pleomorphism, frequent mitosis, and vascular proliferation. **D**, Glioblastoma, small, anaplastic tumor cells, vascular proliferation, and areas of necrosis with pseudopalisading of tumor cells.

of 5 to 10 years appears unfavorable to the patient and the family. As a rule, gliomas in children are more often found in the posterior fossa, whereas gliomas in adults are most often located in the cerebral hemispheres. So far, there are no known risk factors associated with the development of astrocytomas.

CLINICAL FEATURES AND ASSOCIATED DISORDERS.

Patients presenting with low-grade gliomas may have a very gradual onset of symptoms, including headache or subtle neurobehavioral changes. Slowly evolving neurological deficits also raise suspicion of a malignant lesion. These tumors can grow very slowly, and diagnosis may be difficult on initial presentation. For example, increased difficulty with schoolwork or other cognitive tasks is easily blamed on social problems but may indicate a neurological malignancy. Patients with brain stem gliomas present with oculomotor problems or symptoms that may be confused with spinal cord involvement.

Seizures can also occur and may be either focal or generalized (Video 74, Secondary Generalized Seizure); if subtle, they may be mistakenly associated with psychological problems, such as anxiety or panic attacks. Among patients with a new onset of seizures, approximately 5% are found to harbor a tumor, although approximately 25% of patients with gliomas have seizures. If patients who have previously had seizures experience an alteration in seizure characteristics or frequency, or if the seizures become refractory to

medication, a re-evaluation with MRI scanning with gadolinium may be warranted. Occasionally, patients with new-onset seizures have normal MRI scans. In these patients, the seizures may be increasingly difficult to control. Repeat neuroradiological imaging after 3 to 6 months may uncover an astrocytoma or other mass lesion that was too small for detection on the earlier imaging. Those patients with seizures as a result of the tumor tend to have a lower grade of tumor, have ore focal seizures, and are more difficult to maintain seizure free.¹⁰

DIFFERENTIAL DIAGNOSIS. The differential diagnosis of astrocytomas includes other malignant gliomas (anaplastic astrocytoma, oligodendroglioma, and glioblastoma multiforme) or primary CNS lymphoma and metastatic lesions. Nonmalignant diagnoses such as abscess and viral infections including herpes encephalitis or demyelinating processes should also be considered. In most patients, the symptoms evolve slowly over a period of weeks. Occasionally, in older patients a stroke may be diagnosed because a low-attenuation lesion vaguely following a vascular pattern is discovered after a sudden onset of new symptoms. Later, with deterioration of the patient's condition, which is occasionally diagnosed as a progressive stroke in evolution, repeat imaging shows an expanding mass, later diagnosed as a tumor and most likely responsible for the initial symptoms. One must always beware of attempts to diagnose lesions histopathologically based on radiological imaging.

EVALUATION. Low-grade gliomas are often seen as diffusely hypodense or isodense lesions with some flattening of the cortical gyral areas on computed tomography (CT) or significant changes on T2-weighted images on MRI (Figs. 46-2 and 46-3). There is correspondingly less edema formation. Often, low-grade tumors do not enhance or there may be very small areas of enhancement that become more evident on triple-dose gadolinium injection. The presence or absence of enhancement does not predict the pathological diagnosis in an individual patient.

Surgical evaluation is usually needed to establish the diagnosis. Although a pilocytic astrocytoma of the cerebellum can often be fully resected, hemispheric astrocytomas are diffuse, and occasionally only a biopsy can be performed. Attempts should be made to perform a biopsy of any small enhancing areas to increase the likelihood of obtaining a representative sample for pathological examination. Surgical intervention for brain stem gliomas was previously thought to be impossible except in some cystic tumors that were amenable to decompression. Recent reports suggest that CT-guided biopsy may be feasible. The morbidity rate was found to be approximately 5%, and, surprisingly, 12% of the patients who underwent biopsy were found to have a benign pathology, usually infectious in nature.¹¹ Nonmalignant causes were seen more often in patients with focal enhancing lesions. Therefore, biopsy may be reasonable in selected patients at centers qualified to perform such procedures.

MANAGEMENT. Although surgery can be curative in patients with pilocytic astrocytomas, it is rarely an option or successful in those with low-grade gliomas. Previous therapeutic interventions were designed to treat symptomatic patients. With an increase in the number of patients diagnosed incidentally and presymptomatically, specific treatment regimens for these patients remain highly controversial. Furthermore, the small number of patients diagnosed with these tumors has led to limited enrollment in clinical trials. The evolution of histological criteria, variable patient clinical status, and prolonged patient accrual periods have all led to more heterogeneous criteria for patient inclusion in treatment studies. However, because histological criteria cannot predict biological behavior, some clinicians advocate the use of serial neuroradiological imaging to establish the growth characteristics of these tumors without intervention that might distort the natural history. One study examined the neurocognitive effects of radiation therapy compared to watchful waiting and found a significant risk of neurocognitive dysfunction with the radiotherapy. The majority of patients in this study, however, were not biopsied, and thus the true number of patients with a low-grade glioma is not known.¹²

Most studies favor maximal surgical removal and radiotherapy, although certain subgroups of patients may benefit more from this combined treatment than others. Questions have been raised about whether purported tumors found on radiological imaging even need to undergo biopsy,

Figure 46-2. MRI of a low-grade astrocytoma demonstrating a hypointense right temporal lesion without contrast enhancement on T1 and hyperintense signal on T2.

Figure 46-3. MRI of a juvenile pilocytic astrocytoma of the thalamus demonstrating contrast enhancement among a hypointense lesion budding into the lateral ventricle.

let alone treatment with radiation.¹² Concern has been raised that because these tumors are so slow growing, standard radiation therapy with 60 to 66 Gy for 6 weeks may not provide treatment when the tumor is less radiation sensitive. A study by the EORTC Radiotherapy and Brain Tumor Groups suggests that radiation therapy immediately after surgery lengthens the time to tumor progression but not overall survival.¹³ Delaying radiotherapy would also delay the neurotoxic effects of radiation that are found many years after treatment, thereby perhaps improving the patient's quality of life. There are incidental reports of successful treatment with chemotherapy following radiotherapy; however, no data are available to support these treatments. Chemotherapy is useful if recurrence is documented and surgical biopsy confirms that the tumor has undergone malignant degeneration.

Pilocytic astrocytomas can be treated with surgical removal alone. Radiotherapy should be reserved for patients in whom resection has been incomplete and evidence of tumor progression is found on clinical evaluation and neuroradiological imaging. Tumors in patients older than age 20 years can behave more aggressively and should be closely monitored.¹⁴ Cranial irradiation and chemotherapy should be considered following surgery in older patients, especially those with poor prognostic factors.¹⁵

Previous studies have not systematically evaluated the neurobehavioral impact of radiotherapy on long-term survivors. A decline in neurocognitive status 3 or 4 years following radiotherapy has been found in children.¹⁶ Patients must be made aware of the risk of late-onset cognitive decline.¹⁷ Astrocytomas in older patients, especially those older than age 45 years, are most likely to represent a poor sampling of heterogeneous tumors. Survival data indicate that these tumors behave like the more malignant gliomas and should be treated aggressively with radiation and chemotherapy as for anaplastic astrocytoma or glioblastoma multiforme.

The primary treatment for brain stem gliomas is radiotherapy to the area of tumor. Recent work has suggested that the brain stem may tolerate higher doses of radiation of up to 72 Gy. Early transient clinical deterioration may result from radiation to the brain stem, but patients thereafter usually improve.¹⁸ Chemotherapy has no consistent benefit, although in anecdotal cases, treatment with nitrosoureas alone has been reported to prolong survival. A trial utilizing temozolamide after radiotherapy demonstrated no benefit of the chemotherapy.¹⁹ Prolonged survival in some patients may be the result of misdiagnosis.

Patients should be followed closely during the first years after diagnosis to establish the biological behavior of the tumor. To facilitate comparison, radiological scanning should be performed in a standardized manner using exclusively MRI or CT. Neuroradiological imaging may demonstrate a change in the original resection area consistent with either tumor regrowth and malignant degeneration or radiation necrosis. Pathological confirmation is required to resolve this diagnostic ambiguity and to exclude other possible explanations. No reliable predictor is available except histological examination. Radiation necrosis is becoming more common as newer radiotherapy techniques and higher dosage radiation therapy protocols are developed. Radiation damage is related to total dose, and there has been a shift toward directing the radiation beam more closely to the tumor areas and less to the surrounding nor-

mal brain. Higher local doses in excess of 66 Gy to the tumor bed may lead to increased risk of necrosis. Studies have shown that the tumor can extend outside radiographically abnormal areas, leading to concern that as radiotherapy protocols attempt to spare the normal areas, the patient may have an increased risk of far-site recurrence. Far-site recurrences are usually present with local-site regrowth of tumor.

People who undergo cranial radiation while taking phenytoin have an increased risk of developing Stevens-Johnson syndrome.²⁰ Complications of the tumor and its treatment include neurobehavioral decline, an increased risk of cerebrovascular events, and seizures. Patients have a higher risk of recurrent seizures with gliomas and a higher incidence of side effects with the use of anticonvulsants, especially if seizures were present at the time of discovery of the tumor.²¹ Seizures should be treated with the appropriate medical therapy. Any sudden change in the frequency of seizures or the occurrence of new neurological findings should prompt re-evaluation with MRI. Occasionally, seizures can become refractory to medication, although the tumor does not progress. In this instance, surgical intervention may be required. Serial examinations should be conducted to determine whether neurobehavioral sequelae of the tumor and its treatment are present. Careful early testing may uncover problems that can be addressed with counseling, training, and an alteration in lifestyle or work environments to enhance the patient's quality of life. Complications resulting from the tumor and the treatment may indicate a need for prolonged rehabilitation or assisted care.

PROGNOSIS AND FUTURE PERSPECTIVES. Patients with low-grade astrocytomas may have prolonged survival with surgery and radiotherapy. Five-year survival occurs in approximately 25% of patients with surgery alone and in 50% when radiation is added.²² Patients with pilocytic astrocytomas can be cured with complete surgical resection; 5-year survival in these patients approaches 90%. A similar length of survival can be expected in patients with xanthoastrocytomas. Those with brain stem gliomas have a poor prognosis, with a survival of only months.

Further examination of these tumors with molecular or genetic markers may provide clinicians with information that will allow them to predict which of these tumors will become more aggressive forms and which treatment strategies can best prevent this progression. Large randomized trials are needed to study the effects of observation versus radiotherapy or even surgery for low-grade gliomas.

Anaplastic Astrocytoma and Glioblastoma Multiforme

PATHOGENESIS AND PATHOPHYSIOLOGY. Malignant tumors are thought to evolve from lower grade tumors, although they can evolve spontaneously, perhaps as the result of abnormalities of certain gene functions. Alteration of one gene may lead to transformation to a low-grade glioma; subsequent cell divisions can lead to the accumulation of multiple genetic alterations that ultimately result in a tumor with the histological characteristics of a glioblastoma multiforme. Alternatively, a putative glioblastoma

multiforme “gene” may be affected immediately, resulting in a high-grade malignancy. A low-grade astrocytoma that is first diagnosed in a young patient may, many years later, recur as an anaplastic astrocytoma and then subsequently as a glioblastoma multiforme. In another situation, a glioblastoma may occur in a patient with only a short history of neurological symptoms and a radiographically small tumor.

In recent years, multiple genetic alterations have been associated with malignant gliomas in different stages of malignant progression. These changes involve chromosomal changes in terms of deletion, addition, duplication, mutation, or amplification of specific genes, as illustrated in Table 46-3. The most frequently observed alterations include deletions in chromosomes 17p, 9p, and 10q as well as multiple copies of chromosome 7. Some changes are specific to certain types of tumor; for example, losses of genetic materials from chromosomes 1p, 9p, 10p, 10q, 11p, 13q, and 17p are often found in astrocytic tumors, whereas deletions in 19q are seen more often in oligodendrogliomas, and those of 22q occur in meningiomas. Interestingly, 1p/19q deletions have been noted in both the astrocytic and the oligodendroglial areas of an oligoastrocytoma, suggesting that this tumor arises from a common cell. Mutations of the p53 gene are found in low-grade as well as high-grade gliomas, indicating that they may represent early events in the malignant transformation of normal astrocytes to astrocytic tumors. Alterations of the p16 and Rb (retinoblastoma) genes as well as the loss of chromosome 10 and amplification of the epidermal growth factor receptor (EGFR) ERBB gene are found mostly in glioblastomas, suggesting that these changes are associated with late-stage tumor progression. Other, less frequently observed genetic abnormalities in malignant gliomas include overexpression of the platelet-derived growth factor (PDGF), transforming growth factor (TGF)- α and TGF- β , basic fibroblast growth factor (bFGF), vascular endothelial growth factor (VEGF), insulin-like growth factors I and II, and the MYC, GLI, RES, FOS, and ROS oncogenes.²³

The p53 gene encodes a 53-kDa protein that functions as a transcriptional factor and is mapped to the short arm of chromosome 17. The wide-type (WT) p53 protein has been shown to have tumor suppression activity, and mutation of the WT gene has resulted in loss of this tumor suppressive function, thus increasing the transformation risk of the

normal cells. Deletion of the short arm of chromosome 17 (17p13) on which the p53 gene resides has been observed in more than 60% of malignant astrocytomas. Mutations of p53 are rare in low-grade astrocytomas but are equally common in anaplastic astrocytomas and glioblastomas, suggesting that this p53 mutation may represent an early event in the genesis of glioma. However, other studies have demonstrated a higher frequency of p53 mutations in glioblastomas than in anaplastic astrocytomas. The fact that p53 mutations are detectable in small numbers of cells in a group of low-grade astrocytomas and are more frequently seen in the recurrent high-grade astrocytomas may indicate that the histological progression of low-grade astrocytoma to high-grade anaplastic astrocytoma is associated with clonal expansion of the transformed astrocytes carrying the same p53 mutations. The p53 protein is also a nuclear protein involved in the regulation of cell cycle proliferation. It mediates its growth effect through two major mechanisms: induction of apoptosis and transient cell cycle arrest at G1 by induction of the p21 WAF1 (Cip1) protein. Furthermore, p53 gene function is inhibited by the oncogene mdm-2. Thus, amplification of the mdm-2 protein may result in an alternative pathway for apoptosis independent of p53.

Loss of or deletions associated with chromosome 10 have been observed in high-grade malignant astrocytomas examined by cytogenetic and molecular techniques. Loss of an entire copy of chromosome 10 occurs in 80% to 90% of glioblastomas, and approximately 40% of these tumors also show amplification of the EGFR gene. Such a high frequency of loss of genetic material involving an entire copy or a large segment of chromosome 10 strongly suggests the presence of one or more tumor suppressor genes (TSGs) on chromosome 10. This conclusion is partially substantiated by experiments in which a copy of normal chromosome 10 was reinserted into a glioblastoma cell; the resulting hybrid cells showed reversal of the malignant phenotype in vitro and in vivo. The hybrid cells were not able to form colonies in soft agar nor able to form tumors in nude mice.

Epidermal growth factor receptor ERBB, a 170-kDa glycoprotein, is amplified and overexpressed in 40% to 60% of gliomas. Approximately 40% of gliomas show increased autophosphorylation activity of EGFR. However, no apparent relationship between amplification of EGFR and tumor grading can be established except that amplification of EGFR occurs almost exclusively in glioblastomas. Several structurally and functionally altered EGFRs have also been found in approximately 40% of gliomas that show amplification of the EGFR gene. One class of mutant EGFR resembles the ERBB oncoprotein and is unable to bind EGF, but its intrinsic tyrosine kinase activity is not fully activated. A second mutant has an 83-amino acid deletion in domain 4, high-affinity EGF binding, enhanced tyrosine kinase activity, and the ability to transduce EGF-mediated glioma cell proliferation. The third mutant, which is seen in approximately 30% of glioblastoma with amplified EGFR, has an in-frame deletion of 267 amino acids in domains 1 and 2 and exhibits low-affinity binding for EGF, which then activates the intrinsic kinase activity. This mutant has been shown to have transformation activity.

TABLE 46-3

Molecular Phenotypes in Gliomas

| ONCOGENES | SUPPRESSOR GENES | GROWTH FACTORS/ GROWTH FACTOR RECEPTORS |
|-----------|------------------------------|---|
| erb-B | p16 (MTS1) | FGF/FGFR |
| mdm-2 | p53 | EGF/EGFR |
| ras | Retinoblastoma (Rb) | PDGF/PDGFR |
| c-fos | Chromosome 10q and 10p | TGF- α |
| ros | Chromosome 1p, 11p, 19q, 22q | TGF- β |
| gli | | IGF-I, IGF-II, VEGF |

EGF, epidermal growth factor; EGFR, epidermal growth factor receptor; FGF, fibroblast growth factor; FGFR, fibroblast growth factor receptor; IGF, insulin-like growth factor; PDGF, platelet-derived growth factor; PDGFR, platelet-derived growth factor receptor; TGF, transforming growth factor; VEGF, vascular endothelial growth factor.

The fourth mutant is a larger (190-kDa) protein that has autoactivated tyrosine kinase activity.

The TGF- α gene, which encodes for the 6-kDa TGF- α peptide, has increased expression in many glioblastomas and anaplastic astrocytomas. TGF- α protein can be detected in all tumor specimens tested, and the higher grade tumors show stronger staining with anti-TGF- α monoclonal antibodies. In several glioma cell lines, TGF- α is cell associated and is not secreted into the medium. Together with EGFR, TGF- α forms an autocrine growth mechanism. Moreover, TGF- α has also been shown to have angiogenesis activity that is capable of stimulating endothelial cell growth, thus forming small capillaries feeding the tumor.

Vascular endothelial growth factor, a 34- to 43-kDa dimeric glycoprotein, induces endothelial cell proliferation, angiogenesis, and capillary permeability. Three mRNA forms are produced by alternative splicing and code for three protein products, VEGF₁₈₉, VEGF₁₆₅, and VEGF₁₂₁. VEGF, as opposed to EGF, is mitogenic specifically for tumor endothelial cells that display increased expression of VEGF receptors, suggesting that VEGF acts as the mediator for tumor angiogenesis. VEGF has also been shown to increase capillary permeability, suggesting that it may play an important role in tumor-induced edema. Because increased tumor vascularity and peritumoral edema are key features of high-grade astrocytomas, and because VEGF plays a unique role in angiogenesis and edema, it is especially important to understand VEGF's role in glioma transformation and progression.

Fibroblast growth factors are a family of heparin-binding proteins that express both mitogenic and angiogenic properties. Elevated levels of aFGF and bFGF are expressed in human glioma cells. More recently, elevated levels of bFGF and bFGF receptor have been described in a human glioma cell line in which the influence of endogenously excreted bFGF on cellular proliferation is downregulated by antisense oligonucleotide primers. Immunostaining experiments have also demonstrated elevated levels of bFGF in glioma cells as well as endothelial cells in all glioma specimens tested.

The p16 gene, also known as the MTS1 gene, is localized to the 9p21 region. It is a potent inhibitor of the cyclin-dependent kinases 4 and 6 (cdk4 and cdk6) and is often mutated and deleted in a variety of human cancers including gliomas. The p16 protein functions by forming a complex with D1 cyclin and prevents D1 cyclin and cdk4 from forming a phosphoprotein complex, thus paralyzing the activation of the Rb gene and resulting in a G1 blockade. A mutation or deletion of the p16 gene allows formation of an active Rb protein, thus allowing cells to proceed through the normal cell cycle and maintain continued proliferation.

Mutations of the Rb gene, a well-characterized tumor suppressor gene, have been reported in 20% to 30% of malignant gliomas. They are usually associated with glioblastomas, suggesting that alteration of the Rb gene represents a late event. Hypophosphorylated Rb protein is essential to allow cells to remain in G1 without entering mitosis and proceeding to the G2 to M phases. Mutation and deletion of the Rb gene renders this critical step inactive and allows cells to continue to go through proliferation.

One problem with the management of these tumors is the evolving realization that malignant gliomas are not localized circumscribed malignant clones. They have a facile ability to migrate along white matter pathways. Current management techniques usually revolve around more localized treatments such as resection and radiotherapy. Although localized tumor areas remain difficult to treat, the clinician must bear in mind that numerous studies have demonstrated tumor outside radiographic areas of abnormality and brainwide therapy must be included in any treatment pathway.

EPIDEMIOLOGY AND RISK FACTORS. Malignant astrocytomas, including anaplastic astrocytoma and glioblastoma multiforme, are seen more often in adults and are characterized by a shorter survival time than low-grade astrocytomas. They constitute more than 50% of all malignant tumors of the brain and are the third most frequent type of cancer in the 15- to 34-year-old age group. They are also the fourth most frequent type of cancer in the 35- to 54-year-old age group. Incidence increases with age, especially after 50 years, and a higher frequency of glioblastoma multiforme than anaplastic astrocytoma is seen in successive decades. Malignant astrocytomas arise primarily in the frontal lobes and cerebral hemispheres. Anaplastic astrocytomas are differentiated from astrocytomas by histological evidence of increasing cellular atypia and nuclear pleomorphism. The addition of necrosis labels the tumor as glioblastoma multiforme (see previous discussion). There are increasing numbers of reports of glioblastoma multiforme found outside the CNS.²⁴

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Symptoms of these high-grade tumors can arise gradually, reflecting the manner of evolution of astrocytomas. More often, immediate symptoms are found, such as seizures (either focal or generalized), speech disturbances, a change in or increasingly severe headache, vomiting, nausea, visual disturbances, and weakness or sensory disturbances (Video 4, Pronator Drift) (Table 46-4). Careful interviews with the patient or family members may lead to the unappreciated discovery of neurobehavioral symptoms. Elderly patients may have memory loss, suggesting dementia. Occasionally, older patients present with a sudden onset of focal neurological findings that are believed to be a vascular event. Neuro-radiographic imaging abnormalities (often CT performed without contrast dye) are consistent with a vascular distribution, leading to a mistaken diagnosis of stroke. However, instead of improving, these patients often continue to deteriorate. Such patients should be re-evaluated with MRI performed with gadolinium. Malignant gliomas are considered to have no definite hereditary association. There are case reports of family members who have had similar tumors in an autosomal dominant fashion, and studies have found a familial association in 7% of cases.²⁵ Turcot's syndrome is a genetic disease in which gastrointestinal adenomatous polyps and primary brain tumors, including gliomas and medulloblastoma, are combined. It is dominantly inherited and has been associated with the gene for familial adenomatous polyposis and should be considered a variant. Gliomas are also associated with neurofibromatosis (see subsequent discussion) and tuberous sclerosis.

DIFFERENTIAL DIAGNOSIS. Patients with malignant astrocytomas have a differential diagnosis similar to that

TABLE 46-4

Presenting Symptoms in Patients with Glioma

| | NUMBER (%) | | | P |
|---|-----------------|---------------------|--------------------|------|
| | Total (n = 565) | Grade III (n = 147) | Grade IV (n = 418) | |
| Changes in consciousness | 91 (16.2) | 16 (10.9) | 75 (18.3) | .04 |
| Headache | 314 (56.0) | 77 (52.7) | 235 (57.3) | .34 |
| Memory loss | 200 (35.5) | 39 (26.5) | 161 (39.2) | .006 |

for astrocytomas. Practitioners must be aware that a definitive diagnosis cannot be made on the basis of the neuro-radiological evaluation alone. It is essential to obtain tissue diagnosis by surgical resection or biopsy when feasible. The main differential is between an abscess and a malignant tumor (a primary brain tumor, lymphoma, or metastasis). Because of the increasing number of multifocal gliomas, the presence of multiple lesions does not always indicate metastatic disease from a systemic cancer.

EVALUATION. Patients often present with a single lesion. Physicians may be tempted to undertake an extensive search for a primary cancer elsewhere that is often unfruitful, ultimately requiring resection of the lesion. Patients with large lesions that are amenable to resection should undergo a complete neurological and physical examination with rectal examination and stool guaiac analysis, a pelvic examination in women and a testicular examination in men, complete blood count, serum chemistries, coagulation profile, chest x-ray, and MRI of the brain with high-dose gadolinium (Fig. 46-4). If no other lesions are seen, biopsy and surgical resection are indicated to determine the pathological diagnosis. Even if the tumor is found to be metastatic, resection of a single metastasis has been shown to prolong survival.²⁶

Comprehensive neurobehavioral studies should be performed prior to surgery to determine pretreatment deficits. After surgery, re-evaluation may be indicated to define areas of improvement and provide a baseline before further therapy is undertaken. These studies can help patients and their families define those areas that may be a problem for the patient and a focus for rehabilitation. Such studies can help as the patient begins to adjust to daily living at home, and they can also increase the ease of patient care. Data documenting the risk of cognitive impairment after surgery have not shown that significant worsening occurs. Indeed, in some patients, surgical debulking may improve cognitive status as well as other neurological symptoms and signs of disease.²⁶

MANAGEMENT. Patients are often treated with steroids, usually dexamethasone, immediately on discovery of a lesion

in the brain. Unless the patient is in danger of herniation or has another serious problem that specifically requires steroids, however, such treatment is not indicated. Cases of primary CNS lymphoma in patients without acquired immunodeficiency syndrome (AIDS) have increased in frequency. Dexamethasone can be oncolytic to some tumors, especially leukemias and lymphomas, leading to resolution of lesions and causing diagnostic confusion. Therefore, the authors favor delaying the use of steroids until after the tumor has been evaluated but before surgery.

Figure 46-4. MRI of a glioblastoma multiforme demonstrating a large contrast-enhancing left temporal lesion with irregular border as well as a central lucency suggesting an area of necrosis.

Dexamethasone is the steroid of choice because it is a glucocorticoid with no mineralocorticoid activity and has better CNS penetration than other steroid preparations. Occasionally, patients with large lesions may require dexamethasone for several days before surgery. After surgical debulking has been performed, steroids can be rapidly tapered. Radiation oncologists often maintain patients on low doses of dexamethasone throughout radiotherapy, usually 2 to 4 mg a day. Medications with H₂ blockade activity are routinely given with steroids to prevent ulcers, although some believe the risk of ulceration is not sufficiently high to warrant its use. After radiotherapy is complete, steroids can usually be stopped by gradually tapering the dose.

All patients in whom the tumor is suspected require surgical intervention for pathological confirmation. Recently, there has been an increase in the use of limited surgery with stereotactic biopsy. In patients in whom mass lesions can be safely removed, however, maximum surgery is indicated. Small biopsies may not provide sufficient tissue to allow accurate neuropathological interpretation, leading to incorrect therapeutic interventions. All patients should be offered treatment in clinical trials whenever possible. The advent of computer listings of available studies on the Internet may facilitate enrollment in these studies (www.clinicaltrials.gov).

The use of anticonvulsant medications prophylactically in patients with newly discovered mass lesions remains controversial. There are no studies that allow a direct answer to the question of whether patients are at increased risk of seizures. This question is complicated by the fact that virtually all patients undergo surgical decompression or biopsy and are given anticonvulsants at that time. The authors do not routinely administer anticonvulsants until a patient has sustained a seizure. Certainly, any patient presenting with seizures should be treated with anticonvulsants. If anticonvulsants are utilized during neurosurgical intervention, they can be tapered rapidly in the weeks following surgery. The American Academy of Neurology has published guidelines regarding the use of anticonvulsants in patients with a newly diagnosed mass lesion.²⁷

Cranial radiation following surgery remains the mainstay of treatment. A maximum radiation dose of 6000 to 6500 cGy is recommended. Recent radiotherapy techniques involve the application of approximately 4600 cGy to a larger field with a 2- or 3-cm margin encompassing the contrast-enhancing tumor and an additional 2000 cGy delivered to a reduced field encompassing only the contrast-enhancing abnormality. Irradiation to the brain during pregnancy has been shown to be feasible with minimal risk to the fetus.²⁸ Brachytherapy, in which radioactive seeds are applied to the tumor area, has been shown to be beneficial in some patients with glioblastoma multiforme. This technique, however, is associated with substantial morbidity; the high risk of radiation necrosis necessitates reoperation in approximately 50% of patients undergoing interstitial brachytherapy. It is therefore useful only in a limited number of patients with polar tumors. Stereotactic radiation may increase survival in those patients with radiosensitive tumors²⁹; however, neither the neurobehavioral effects of this treatment nor randomized studies have been reported. A Radiation Therapy Oncology Group (RTOG) study of stereotactic "radiosurgery" with conven-

tional radiotherapy and chemotherapy demonstrated no benefit.³⁰ Use of stereotactic radiotherapy at recurrence also demonstrated no benefit.³¹ Effects of radiation include hypersomnolence during treatment and cognitive dysfunction. These effects are more commonly seen in patients with prolonged survival after radiotherapy.

Chemotherapy regimens produced modest improvement in the overall time of tumor progression and patient survival. It appears that anticonvulsant use may affect efficacy by altering metabolic clearance of the chemotherapy agent, again arguing against their use in patients without seizures.³² The efficacy of chemotherapy declines with patient age.³³

Previously, the standard treatment included the use of nitrosourea-based regimens such as carmustine (BCNU) alone or the triple drug regimen of lomustine (CCNU), procarbazine, and vincristine (PCV).³⁴ Although some advocate use of wafers impregnated with BCNU (at either low or high concentration), studies in which the discs were placed at primary resection or on a second resection have failed to demonstrate any realistic benefit. Furthermore, the placement of the wafers can interfere with interpretation of neuroradiologic imaging, requiring additional surgery to differentiate further tumor growth from side effects of disc placement.

Temozolomide, an oral alkylating agent similar to dacarbazine (DTIC), was approved as monotherapy for the treatment of recurrent anaplastic astrocytoma (and for glioblastoma multiforme in Europe). The use of this agent with radiotherapy was demonstrated to have significant benefit in those patients with glioblastoma multiforme.³⁵ Most of the 573 patients in the study received maximal cytoreductive surgery and were randomized to receive either temozolomide with radiotherapy or radiotherapy alone. Whereas median survival demonstrated a modest 2-month improvement, a 2-year survival rate of 26.5% for patients receiving the combination was found to be statistically significant compared the 10.4% 2-year survival of patients receiving radiotherapy alone (Fig. 46-5). Further work suggests a molecular marker (methylated MGMT promoter) may predict response to temozolomide.³⁶ This is important because for the first time in the treatment of malignant gliomas we may be able to predict treatment response and better direct therapy to those patients for whom we have a better chance of assisting. This will also provide an economic benefit because we can better tailor therapy to the patient's tumor characteristics. Those for whom the marker suggests no benefit could then be immediately placed on alternative therapies, which may have a better chance for success. The role of this agent in combination with other chemotherapeutic and biologic agents and in different schedules is under study.

Salvage chemotherapy regimens with agents such as carboplatin, etoposide, procarbazine, interferons, and diaziquone (AZQ) produce mixed results, but some responses occur. Newer agents under study alone and in combination regimens include thalidomide, radiation sensitization agents, and metalloproteinase inhibitors. The efficacy of chemotherapy declines with patient age.³³ Blood-brain barrier disruption agents, carotid artery infusion, gene therapy, and combination therapy with multiple agents have not demonstrated overall survival benefit. An analysis of the changes in normal biological function or chromosomal aberrations occurring in

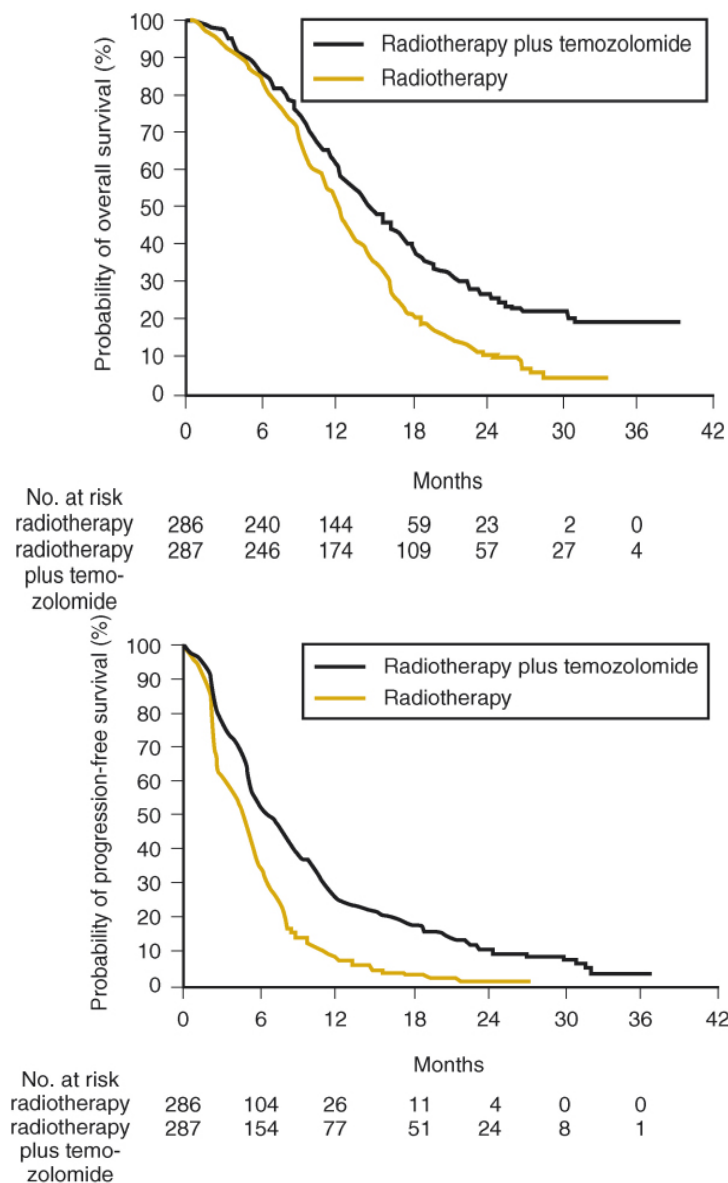

Figure 46-5. A, Kaplan-Meier estimates of overall survival according to treatment group. The hazard ratio for death among patients treated with radiotherapy plus temozolomide, compared to those who received radiotherapy alone, was 0.63 (95% confidence interval, 0.52 to 0.75; $P < .001$). B, Kaplan-Meier estimates of progression-free survival according to treatment group. The hazard ratio for death or disease progression among patients treated with radiotherapy plus temozolomide, compared to those treated with radiotherapy alone, was 0.54 (95% confidence interval, 0.45 to 0.64; $P < .001$). (From Stupp R, Mason WP, van den Bent, et al: Radiotherapy plus concomitant and adjuvant temozolomine for glioblastoma multiforme. *J Clin Oncol* 2005;352(10):987-996.)

tumor cells and their response to chemotherapy is under way.^{37,38}

Although the majority of these patients will be treated by multiple physicians, the neurologist has an important role to play in the general management of these patient's care, including quality of life. The neurologist has an acute understanding of the cognitive dysfunction resulting from the tumor and its treatment and management of seizures, stroke, etc. All neurologists should familiarize themselves with the newest management guidelines for these patients. An ongoing study of care for these patients (Glioma Outcome Project) reveals that patients do not receive aggressive treatment of their tumor nor its complications. For example, patients require extreme vigilance for thromboembolic complications inherent in the natural history of these tumors. All patients are at risk of depression and should be monitored closely. Anticonvulsants should be administered only when indicated. Finally, there is a poten-

tial for drug interactions between chemotherapy agents and so-called "herbal remedies."³⁹

PROGNOSIS AND FUTURE PERSPECTIVES. Overall, prognosis is related to histological diagnosis, age, performance status, and treatment. Patients who receive more complete surgical resection tend to survive longer. Follow-up resection after tumor regrowth also prolongs survival and increases overall well-being in many patients. Median survival for patients with a glioblastoma multiforme, without accounting for age, is approximately 1 year. Patients with anaplastic astrocytoma have a life expectancy of 3 to 5 years. Prolonged survival with diagnosis of a malignant glioma can occur but may suggest incorrect pathological diagnosis of tissue type. In a review of patients entered in RTOG studies, histology was the most important determinant of survival for patients younger than 50 years of age, whereas performance status was the most important variable for patients older than age 50 years.⁴⁰

Clinical trials have to be conducted to better define the effects of treatment, including surgery, radiotherapy, and chemotherapy. Accrual of all brain tumor patients into clinical studies stands at 10%. Careful analysis and evaluation of all patients with these tumors is needed. Recent concerns have been raised about possible enrollment bias.⁴¹ Newer imaging techniques may enhance the ability to evaluate both the disease and the treatment response. Positron emission tomography has not been demonstrated to separate reliably the tumor from the treatment effects. Recent studies of gene therapy for these tumors have demonstrated infrequent short-term responses. Overall utility of this approach using newer viral vectors remains under investigation and is highly experimental. The combination of gene therapy with other modalities, including concomitant chemotherapy, remains to be studied.

Oligodendroglioma and Oligoastrocytoma

PATHOGENESIS AND PATHOPHYSIOLOGY. Because these tumors arise from oligodendrocytes, they usually occur in the white matter of the cerebrum, and because there are relatively more oligodendrocytes in the frontotemporal area, oligodendrogliomas have a predilection for these areas. Usually, surgical specimens contain areas that are identifiable as astrocytoma. Increasing difficulty in the diagnosis of these tumors centers on the percentage of oligodendroglioma cells needed to categorize these tumors as pure oligodendrogliomas rather than mixed oligodendroglioma-astrocytoma (oligoastrocytoma). The grading system of Smith and colleagues⁴² has been used by most neuropathologists for the histological categorization of oligodendroglioma. Only necrosis has been found to be a predictor of biological behavior: Mitotic activity apparently becomes more important with advancing age.⁴³ On microscopic examination, most tumors show tumor cell infiltration into the cortex, and many tumor cells show an artifactual halo around the nucleus (the so-called fried-egg appearance). A delicate vascular pattern is also a prominent feature (Fig. 46-6).

EPIDEMIOLOGY AND RISK FACTORS. Oligodendrogliomas occur most commonly in young adults. The peak incidence occurs in the third to fifth decade, and the tumor occurs predominantly among men. There are no known established risk factors. Recent epidemiological work has suggested that gliomas may be associated with repeated exposure to high-voltage electrical lines. These tumors have a poorer prognosis with age. Although typically considered to represent approximately 2% of intracranial primary tumors, recently the incidence has been increasing owing to changes in neuropathological diagnostic criteria. For example, at the University of Iowa, 25 patients were diagnosed with oligodendroglioma from 1961 to 1991, whereas from 1992 to 1995, 48 such diagnoses were made.

Research on the genetic mutations that may lead to development of a malignancy has determined that most oligodendrogliomas have a characteristic deletion of chromosome 1P (short arm) or 19Q (long arm) or both. This deletion appears to have a greater prognostic significance when combined with typical histologic features of oligodendrogliomas.⁴⁴ More interesting, these deletions, if seen

Figure 46-6. Histopathological picture of an oligodendroglioma. Nuclei are surrounded by swollen, clear cytoplasm, demonstrating a "fried-egg" appearance, and fine vascular channels.

in tandem, appear to define a subset of patients that appear to have a better response to chemotherapy and radiation therapy.⁴⁵ Furthermore, there may be an association of tumors with certain deletions and the tumor location in the brain.⁴⁶ This is important because for the first time we may be able to more reliably predict response to therapy and therefore tailor therapy for an individual patient.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Because of their infiltrative nature, oligodendrogliomas commonly cause seizures. Occasionally, patients with medically refractory seizures who undergo surgical abolition of the seizure focus are found to have an oligodendroglioma. These tumors can infiltrate and surround the neuronal networks without causing loss of function until they achieve a rather large volume. Retrospectively, subtle neurobehavioral changes can be detected long before the tumor is discovered. As with other gliomas, patients may also present with symptoms of hydrocephalus, headache, and sudden focal neurological findings consistent with acute hemorrhage into the tumor. There is also a higher risk of dissemination through the cerebrospinal pathways, resulting in spinal cord or patchy symptoms within the neuroaxis, which are sometimes confused with metastatic disease.⁴⁷ Rarely, oligodendrogliomas can metastasize outside the CNS.

DIFFERENTIAL DIAGNOSIS AND EVALUATION. Evaluation of oligodendrogliomas is the same as that discussed previously for astrocytomas and glioblastoma multiforme. The differential diagnosis for oligodendroglioma and oligoastrocytoma is similar to that for astrocytomas. Because oligodendrogliomas are more often non-contrast enhancing on MRI scans, they may be confused with low-grade gliomas. With CT imaging, hypodense areas may also cause confusion with stroke or gliosis. Oligodendrogliomas are commonly found to have calcium deposits, and in many cases, contrast-enhancing areas are also found in the lesions on CT imaging. However, patients should undergo MRI to better define the areas of tumor involvement. There may be a correlation of genetic abnormalities with magnetic imaging characteristics.⁴⁸ Surgical diagnosis and attempts to achieve maximum cytoreduction are mandatory. Small

stereotactic or open biopsies may lead to a misdiagnosis of astrocytomas, thereby affecting subsequent radiotherapy and chemotherapy treatment of these tumors.

MANAGEMENT. Neurological problems such as seizures should be treated with appropriate medications as discussed previously for astrocytomas. Patients should be monitored closely for tumor regrowth or dissemination within the neuroaxis. The treatment of these tumors has become increasingly controversial. Some believe that these tumors are biologically less aggressive and can be observed with serial imaging until tumor growth is apparent either clinically or radiographically. Others believe that all oligodendrogliomas should be treated with radiation after histological confirmation. A large study at Duke University suggested that radiotherapy may not benefit patients with oligodendrogliomas.⁴⁹ Studies have also suggested that anaplastic oligodendrogliomas are more responsive to chemotherapy and should be treated with PCV in addition to radiation, especially for Smith grade B, C, and D lesions.^{50–53} Others have suggested that although chemotherapy for these oligodendrogliomas before radiotherapy may be harmful, this combination of chemotherapeutic agents is beneficial for patients with oligoastrocytomas.⁵⁴ Finally, there are reports of treatment with chemotherapy alone for patients who have a more benign-appearing histological diagnosis.⁵⁵ A RTOG study suggested that neoadjuvant chemotherapy with PCV had no survival benefit but some extension of progression-free survival.⁵⁶ However, a subset analysis suggested that those patients with 1p/19q deletion may have had a survival benefit. This needs to be confirmed in a prospective study, possibly with temozolamide.

PROGNOSIS AND FUTURE PERSPECTIVES. Patients with oligodendrogliomas presenting with seizures seem to survive longer, possibly due to earlier discovery of the tumor. Reported overall median survival ranges from 5 to 10 years depending on the study, the reporting period, and the treatment regimen. Survival statistics will probably change as the diagnostic criteria continue to evolve and more is learned about the genetic alterations of these tumors. Survival for patients with oligoastrocytomas is similar to that for patients with anaplastic astrocytomas. Better neuropathological criteria for diagnosis of these tumors and higher enrollment of patients into clinical trials will provide better and timelier data on the optimal treatment for these tumors.

Ependymoma

PATHOGENESIS AND PATHOPHYSIOLOGY. There are no known risk factors for these tumors. Ependymomas arise from ependymal cells lining the ventricles and the spinal cord central canal. Histologically, ependymomas are well demarcated from the surrounding structures and are marked by pseudorosettes, often located in the perivascular region. Blepharoplasts, intracellular structures associated with cilia formation, are also present. Anaplastic ependymomas have increasing features of nuclear atypia, necrosis, and mitotic figures. Myxopapillary ependymomas are usually confined to the filum terminale and have a distinctive fibrillary pattern with mucin secretion.⁵⁷ Newer analysis with chromogenic *in situ* hybridization suggests

differentiation of tumor morphological variants by analysis of chromosome 7 polysomy.⁵⁸

EPIDEMIOLOGY AND RISK FACTORS. Ependymomas represent less than 5% of all intracranial tumors. They occur in younger patients, usually children, with a slight predominance among young men, although they can present in adults up to 30 years of age. An infratentorial location is more common in children, whereas supratentorial ependymomas are more common in adults. Cerebrospinal fluid (CSF) dissemination and systemic metastasis can occur.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Patients with ependymomas have symptoms corresponding to the part of the neuroaxis affected by the tumor. For example, tumors arising in the spinal cord can lead to localized back pain, sensory disturbances with a demonstrated dermatomal line, weakness of both legs, or disturbances of bowel or bladder control. Ependymomas arising in the fourth ventricle, brain stem, or lateral ventricles can present with evidence of headaches or other symptoms of hydrocephalus (especially nausea and vomiting), ataxia (Video 211, Gait Ataxia), and increasing head circumference. Neck pain and behavioral changes are also common presenting complaints in children. Because ependymomas may be present for as long as 3 to 6 months before they come to clinical attention, symptoms may sometimes be labeled chronic.

DIFFERENTIAL DIAGNOSIS AND EVALUATION. The differential diagnosis of these tumors includes other CNS tumors such as medulloblastoma and low-grade glioma. Other more benign lesions such as meningioma do not have similar characteristics on MRI. Patients require surgical intervention to obtain pathological diagnosis and for gross total resection. Prior to surgery, the entire neuroaxis should be imaged with gadolinium MRI to determine involvement of other sites such as “dropped” metastasis. The resection attempt should be as extensive as possible, but occasionally this is not feasible. At least 2 weeks following surgery and before radiotherapy, the CSF should be evaluated for seeding of the cerebrospinal pathways with tumor cells. However, if evidence of tumor is present on MRI, some suggest CSF evaluation is of little benefit.⁵⁹

MANAGEMENT. After surgery, radiotherapy is the mainstay of treatment for patients with residual tumor.⁶⁰ Some advocate watchful waiting after surgery and administering radiotherapy only when there is evidence of tumor recurrence or growth, especially if a gross total resection of tumor has been achieved and confirmed with MRI,⁶¹ whereas others advocate localized gamma knife therapy after surgical resection.⁶² Craniospinal irradiation is often given to treat clinically undetected seeding of cerebrospinal spaces. In patients with negative CSF examination after surgery, this is not indicated because it may hamper future treatment of localized recurrence. Myxopapillary ependymomas can often be cured with complete surgical resection. Chemotherapy has been shown to be of minimal benefit in patients with anaplastic ependymoma, although chemotherapy regimens including carboplatin and etoposide have been shown to prolong survival in several small series.^{63,64} The use of craniospinal irradiation results in extensive treatment of the vertebral bone marrow, leaving little reserve for the cytotoxic chemotherapy. With newer cytokines such as the colony-stimulating factors that stimulate bone marrow func-

tion, patients may be able to tolerate more chemotherapy, allowing better appraisal of its use in these patients. Recurrence is usually local, although patients can develop distant metastasis. An increased risk of recurrence is associated with incomplete resection. Surgical resection, if feasible, should be strongly considered when the tumor recurs, followed by conventional radiotherapy to previously nonirradiated areas. Salvage chemotherapy also remains an option at recurrence.

PROGNOSIS AND FUTURE PERSPECTIVES. Survival may be increased in patients who undergo resection of tumor and radiotherapy. Overall survival is similar to that for low-grade gliomas or oligodendrogliomas. Patient age younger than 5 years and a posterior fossa location of the tumor can have a worse outcome. No histological predictors of survival are available. Future improvements in therapy can be expected with better understanding of the histological variants, application of radiotherapy and chemotherapy to more malignant subtypes of these tumors, and a better understanding of the molecular basis of tumor pathogenicity.

Medulloblastoma

PATHOGENESIS AND PATHOPHYSIOLOGY. Almost two thirds of these tumors are located in the midline of the cerebellum, and more than 90% are located in the vermis with encroachment on the cisterna magna. Laterally placed tumors are more common in adults. The macroscopic appearance is that of a soft friable tumor with central necrosis. In adults, these tumors are highly demarcated, but in children, they are less so. Microscopically, neuropathological analysis has attempted to define these tumors as a subset in a larger category termed primitive neuroectodermal tumors.⁶⁵ This classification stems from the belief that these tumors result from the germinal neuroepithelium during embryogenesis and thus can differentiate into tumor cells with neuronal, glial, or ependymal characteristics. Medulloblastomas are often classified as small blue cell tumors with little cytoplasm and pseudorosettes, which may signify neuronal differentiation (Fig. 46-7). A desmoplastic variant has been proposed for tumors in adults and may signify a different cell of origin.

Figure 46-7. Histopathological picture of a medulloblastoma showing primitive, undifferentiated tumor cells with numerous neuroblastic (Homer-Wright) rosettes.

Recent work has attempted to combine histologic features with cytogenetic characteristics in an attempt to identify patients most in need of treatment.⁶⁶ For example, in a group of patients with metastatic disease at diagnosis, a large cell/anaplastic phenotype with associated MYC amplification or 17p13.3 loss defined a set of children with a statistically significant poorer outcome. This has been confirmed by others who also demonstrated that CDK6 may be a prognostic factor.⁶⁷ This is important because the CK6 marker is involved in both the p53 and retinoblastoma (RB1) pathways. Not surprisingly, desmoplastic medulloblastomas had a different genetic profile.

EPIDEMIOLOGY AND RISK FACTORS. Medulloblastomas are usually located infratentorially, accounting for approximately 2% of all CNS tumors in adults and 25% of intracranial tumors in children, second only to cerebellar astrocytomas. Although 50% of medulloblastomas are seen in children in the first decade of life, approximately 25% occur in patients older than the age of 18 years. Tumors diagnosed in the seventh decade of life have been reported. There is a small second peak in incidence in patients 20 to 25 years of age. Interestingly, there seems to be a seasonal variation, with higher incidences in children born during the winter months and in those with congenital cerebral defects, possibly suggesting that these tumors are a remnant of embryonic dysfunction. Familial cases are known, including four cases in monozygotic twins, although there is no proven familial association. An association with leukemias and other CNS tumors, such as glioblastoma multiforme in first-degree relatives, has been noted.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Patients often present with subtle problems that evolve over extended periods of time. In some patients, symptoms can exist for more than 3 months before the tumor is diagnosed. The most common complaints include symptoms of increased intracranial pressure such as headache (especially in the morning) and vomiting. In younger children, behavioral changes such as decreases in activity or appetite may exist. Examination may demonstrate papilledema, truncal or limb ataxia (Video 212, Heel-to-Shin Testing), or nystagmus (Video 8, Gaze-Evoked Nystagmus). A few patients have an increased head circumference or symptoms of leptomeningeal seeding similar to that seen in metastatic meningitis. There is a higher incidence of medulloblastoma in patients with nevoid basal cell syndrome, Turcot's syndrome, ataxia telangiectasia, and xeroderma pigmentosa.

DIFFERENTIAL DIAGNOSIS AND EVALUATION. The differential diagnosis for these tumors includes other primary CNS tumors such as ependymomas or gliomas, as discussed previously, or metastatic tumors. Although CT scans are more readily available and may reveal evidence of hydrocephalus, all patients should undergo MRI with gadolinium. Occasionally, subarachnoid seeding is evident on initial imaging. CT or MRI scans usually demonstrate a hypodense mass with variable heterogeneous enhancement. Patients often present with evidence of obstructive hydrocephalus that requires immediate neurosurgical intervention such as shunting. Often, conservative management with corticosteroids allows surgical planning, and some reports suggest that shunting should not be performed if at all possible. Some believe that midline lesions are more commonly

medulloblastomas, whereas hemispheric lesions are more often astrocytomas, but histological confirmation is mandatory. Gross total resection of tumor should always be the goal.

MANAGEMENT. Once the diagnosis has been established, patients should receive craniospinal MRI with gadolinium enhancement to study the entire neuroaxis for tumor dissemination. This also allows examination of the resection bed without worry about postoperative enhancement caused by the surgery. MRI evaluation may be superior to CSF evaluation to detect dissemination.⁶⁸ If MRI of the spine is contraindicated, myelography can be performed with cytological evaluation of CSF at least 2 weeks after surgery. Although medulloblastomas have been known to spread outside the nervous system, especially to the bone and lungs, staging with bone marrow biopsy and imaging of the chest or radioactive bone scan should be performed only when such spread is clinically suggested. Reoperation should be considered at the time of tumor regrowth.

Patients have an increased risk of recurrence if gross total resection was not possible; if they are younger than 4 years old; or if the tumor has a lateral location, evidence of CSF dissemination, or a differentiated cellular histological appearance. Patients younger than 18 months should undergo chemotherapy alone, whereas older patients should receive both radiotherapy and chemotherapy. Patients without the features just mentioned are considered to have a decreased risk of recurrence and can receive craniospinal irradiation and observation, with chemotherapy given only with evidence of recurrence.

Radiotherapy remains the mainstay of postsurgical treatment. Typically, craniospinal irradiation with increased doses to the tumor bed is performed because undetected tumor may be disseminated in the spinal cord. Newer radiotherapy techniques utilizing conformal hyperfractionated radiotherapy may improve survival with less neurocognitive side effects.⁶⁹ Recent advances in chemotherapy include the use of CCNU, carboplatin, and vincristine.⁷⁰ Newer treatment regimens with postoperative chemotherapy alone (both systemic and intrathecal) show promise but with significant side effects, including cognitive dysfunction and leukoencephalopathy.⁷¹ Use of stem cell rescue after intensive chemotherapy has demonstrated effectiveness in a small study of pre-teen children with poor prognostic factors.⁷² Treatment failure is usually evident at the original site alone; cerebrospinal dissemination may occur, or systemic involvement may be seen in a later stage. Almost half of patients show evidence of cerebral hemispheric involvement at recurrence. Refinements in radiotherapy may increase the incidence of systemic dissemination at relapse.⁷³

Neurobehavioral abnormalities, such as mutism, pseudo-bulbar affect (Video 10, Dysarthria), or derangements of eyelid opening, have been documented in children undergoing posterior fossa tumor resection.⁷⁴ These usually resolve within months of surgery. Patients may have problems with CSF drainage, requiring shunting. Children are at risk of decline in intellectual performance related to radiotherapy and possibly chemotherapy, especially if they are younger than age 7 years.⁷⁵ Treated patients with radiotherapy had substantial declines in reading and math skills with a lower overall IQ.⁷⁶ Post-therapy MRI surveil-

lance for recurrence with the appearance of white matter lesions may be associated with more cognitive problems.⁷⁷ Endocrinological problems resulting from pituitary failure, including delay of puberty, may be seen. Children who survive for a long time display decreases in perceptual motor tasks, manual dexterity, learning, and physical growth and development.⁷⁸

PROGNOSIS AND FUTURE PERSPECTIVES. Medulloblastoma seems to follow Collin's law that the risk of recurrence of tumor is highest during the period equal to the patient's age at diagnosis plus 9 months.^{79,80} Survival is correlated with the extent of surgical resection for those older than the age of 3 years in whom dissemination is absent.⁸¹ Five-year survival can occur in nearly 75% of patients who undergo high-dose craniospinal irradiation after gross total resection. Survival is poorer in patients younger than 5 years of age. Adults seem to have the same survival duration as children.⁸²

Primary Central Nervous System Lymphoma

PATHOGENESIS AND PATHOPHYSIOLOGY. The reason for the increase in primary CNS lymphoma (PCNSL) in the immunocompetent and immunocompromised population is unclear. Because there are no lymphatics in the CNS, the mechanism for neoplastic transformation remains unknown. Viral causes have been suggested. In studies of AIDS-related PCNSL, the Epstein-Barr virus was found in a majority of cases,⁸³ but this was not found in samples analyzed from immunocompetent patients. Herpes virus type 6 has also been proposed as a causative agent. PCNSL is considered a non-Hodgkin's lymphoma, usually of B cell origin, with a high-grade diffuse large cell, immunoblastic, or lymphoblastic type. T cell PCNSL has been reported but is rare.⁸⁴ This is interesting because B cells are not usually present within the CNS. Moreover, there appears to be an association of PCNSL with germinal center, not present in the CNS. For example, BCL-6 protein is required for germinal center development and has been proposed as a possible prognostic survival marker for PCNSL.⁸⁵ Microscopically, the tumors aggregate near blood vessels and may provoke a normal reactive immune response. The tumor cells stain positive for appropriate immunohistological B cell or T cell markers. In the older literature, PCNSL was described as a microglioma or a reticulum cell sarcoma because the tumor stroma stained positive for reticulum.

EPIDEMIOLOGY AND RISK FACTORS. The incidence of PCNSL has shown a three- to fivefold increase during the past 20 years.⁸⁶ Because the treatment for PCNSL is vastly different from that for malignant gliomas, clinicians should always keep the diagnosis of PCNSL in mind during the evaluation of a patient with a new cerebral lesion. The peak incidence, in immunocompetent patients, occurs in the fifth and sixth decades, and there is a slight predominance in men. The tumor is commonly associated with immunodeficiency states including AIDS, drug-induced causes such as immunosuppressive therapy for organ transplants, and other genetic immune deficiency states.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. While patients with PCNSL commonly present with cognitive dysfunction, focal findings or evidence of elevated intracranial pressure can also be present (Video 11, Hemiplegic

Gait). Patients with frontal lesions or the elderly may have neurocognitive changes that are sometimes confused with a dementing process. Seizures are common in immunocompromised patients and less so in others compared with glial tumors. While ocular involvement can be frequent, only occasionally do patients have ocular complaints such as blurred vision.

DIFFERENTIAL DIAGNOSIS. The differential diagnosis for PCNSL includes primary gliomas, metastatic lesions (if multifocal), demyelinating processes such as multiple sclerosis, and acute disseminated encephalomyelitis. In the immunocompromised population, toxoplasmosis, progressive multifocal leukoencephalopathy, and other infectious causes should also be considered.

EVALUATION. Neuroradiologically, PCNSL may be missed on CT; hence, MRI is the imaging modality of choice. Because PCNSL is often densely cellular and highly vascular, lesions usually enhance brightly on MRI with gadolinium, although exceptions have been reported in the literature. In the non-AIDS population, lesions are usually multifocal and periventricular in location. Administration of gadolinium reveals intense enhancement. Immunocompromised patients are more likely to have single lesions, which are often confused with those of toxoplasmosis, and radiographically they have a higher incidence of necrosis with the appearance of ring enhancement. Edema is usually minimal. Leptomeningeal spread of PCNSL is present in more than one fourth of patients. Cytological examination of CSF in patients in whom lumbar puncture can be performed is mandatory. CSF should be evaluated for the concentration of β_2 microglobulin and compared to serum levels as a marker of disease. Slit-lamp evaluation should be done and can sometimes provide diagnosis of vitreous or choroid involvement.

Because steroids can be oncolytic and can change the appearance of PCNSL on CT or MRI scans, whenever possible patients should not be given steroids before diagnostic studies have been completed. A marked reduction in tumor size and contrast-enhancing pattern occurs soon after steroid therapy is initiated. All immunocompetent patients should undergo biopsy for pathological confirmation of disease. Although neurosurgical intervention with maximum cytoreduction is favored in patients with malignant gliomas, in those with PCNSL, which is very sensitive to radiotherapy and chemotherapy, stereotactic biopsy for tissue confirmation is a reasonable option. However, because of concern about the disease and the lack of identifying markers to separate PCNSL from malignant gliomas, open biopsy and tumor resection is usually performed. Once the diagnosis of PCNSL has been established, further resection is not warranted.

In the AIDS population, stereotactic biopsy is the rule. In AIDS patients in whom a single lesion is seen on MRI, treatment is often first performed with antitoxoplasmosis agents. Patients who are unresponsive to treatment, as evidenced by clinical or radiographic deterioration, then receive biopsy. Patients with multifocal disease and negative toxoplasmosis antibody titers should undergo biopsy. Occasionally, some patients may harbor both toxoplasmosis and lymphoma. Development of newer imaging techniques such as positron emission tomography may help in differentiating PCNSL from toxoplasmosis.

MANAGEMENT. After the diagnosis has been confirmed, patients should have a complete neuroradiological evaluation of the spinal cord with gadolinium-enhanced MRI. If not performed previously, a full ophthalmological evaluation and cytological examination of CSF are also required. Because systemic lymphomas spread into the CNS in approximately 10% of patients, the initial evaluation should include a complete physical examination, chest x-ray, abdominal CT, routine serum chemistries, and CBC to rule out systemic lymphoma. Further evaluation, such as bone marrow biopsy or lymphangiograms, is usually not necessary because the diagnostic yield is low.

Treatment of PCNSL includes the use of steroids, which may produce a significant decrease in tumor burden.⁸⁷ Radiotherapy alone has produced little overall increased survival beyond 12 months⁸⁸ and is no longer appropriate except in patients with AIDS or other immunocompromised states who cannot receive steroids or chemotherapy. Occasionally, ocular recurrence requires directed radiotherapy to the orbit. Immunocompromised patients with AIDS should receive whole brain radiotherapy. Craniospinal radiotherapy should be avoided in patients with localized disease.

Because of different response criteria among various clinical trials, attempts have been made to standardize baseline evaluation and definitions of treatment response.⁸⁹ Routine treatment now includes chemotherapy, both intrathecally and systemically, followed by radiotherapy. Chemotherapy has been shown to markedly improve survival, especially when methotrexate is included (Fig. 46-8). In 1992, DeAngelis and colleagues⁹⁰ reported that a regimen that included intrathecal and systemic methotrexate, procarbazine, vincristine, and dexamethasone followed by radiation therapy and subsequent treatment with systemic ara-C yielded an increase in median survival of 41 months compared with 10 months for patients receiving radiotherapy alone. Other reports of preradiation treatment with high-dose methotrexate have provided similar results.⁹¹ It appears that use of higher dosing of systemic methotrexate either alone or with intrathecal administration is primarily responsible for prolonged treatment response. Methotrexate following radiotherapy should be avoided because it is associated with an increased risk of treatment-related encephalopathy. There have been reports that radiotherapy followed by the PCV chemotherapy typically used for malignant gliomas may also induce remission.⁹²

As therapies for PCNSL continue to increase survival times, effects of treatments on neurocognitive function and, therefore, quality of life become exceedingly important. One must bear in mind that radiotherapy administered after methotrexate increases the risk of leukoencephalopathy compared to administration of methotrexates simultaneously or after radiotherapy. Many patients will develop white matter changes as a consequence of treatment, although this does not necessarily correlate with cognitive dysfunction.⁹³ An interesting dilemma with treatment decisions is the balance between treatment of disease and the development of cognitive dysfunction based on treatment modalities (chemotherapy and/or radiotherapy) and age. For example, a study suggested that in the elderly (age > 60 years) there was a higher risk of death due to neurotoxicity if radiation therapy is used with chemotherapy,

Figure 46-8. MRI of a patient with primary CNS lymphoma (HIV negative). *Left*, Before therapy; *right*, after 6 months of therapy with preradiotherapy methotrexate, procarbazine, vincristine, and dexamethasone, followed by radiotherapy and postradiation Ara-C.

but patients experienced a longer disease-free period. Conversely, if radiation therapy was withheld, patients more often died of disease. Younger patients fared better, with less neurotoxicity even after radiotherapy, and improved overall survival.⁹⁴

PROGNOSIS AND FUTURE PERSPECTIVES. Survival of patients with PCNSL who receive no treatment except surgery is poor, usually only several months. Radiotherapy alone can extend survival to approximately 1 year. Chemotherapy combined with radiation therapy can extend survival to approximately 3 or 4 years. Future work should examine the response of this tumor to various combinations of chemotherapy utilizing a standardized selection of response criteria. As survival times increase, more effort should be placed on the effects of treatment on cognition and physical functioning. An interesting issue is whether radiotherapy should be performed only at relapse or at the failure of chemotherapy. There is evidence that radiotherapy may be afforded to patients of a younger age (<60 years) because radiotherapy in older patients may increase the risk of post-radiation dementia.⁹⁵ Further examination of the origins of this tumor and a study of the pathological and genetic markers related to treatment response may offer more information that can be used to direct specific treatment strategies.

NERVE SHEATH TUMORS

Acoustic Schwannoma and Trigeminal Neurilemmoma

PATHOGENESIS AND PATHOPHYSIOLOGY. Acoustic neuromas, found incidentally on imaging performed for other reasons or due to new symptoms as described following, have a variable course. Less than 10% have a familial association. There appears to be no association with unilateral acoustic neuromas or with either form of neurofibromatosis. Some investigators have tried to examine the growth rates of these tumors by performing serial neuroimaging of the tumors to gauge their growth.⁹⁶ Some suggest that the female predominance of these tumors indicates a sex hormonal influence. There is little and conflicting evidence to support an association of cell phone use with the risk of schwannoma. There may be a small increased risk after 10 years.⁹⁷⁻⁹⁹

EPIDEMIOLOGY AND RISK FACTORS. Neuromas (schwannoma and neurilemmoma) are benign tumors that usually involve the sensory and motor cranial nerves, most commonly cranial nerves VIII, V, and VII. Neuromas represent approximately 10% of all intracranial tumors, the majority being acoustic neuromas. They present most frequently in the fourth and fifth decades of life, predominantly among women. Except for bilateral acoustic neuromas, which occur in neurofibromatosis II (see the subsequent discussion), they are unilateral.

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Acoustic neuromas are considered slow growing, but they grow in a physiologically important area, the cerebello-pontine angle, thus leading to multiple subtle complaints that may evolve slowly over many years. Symptoms may progress slowly, although sudden presentations can be seen. Patients usually present with hearing loss (especially sound discrimination), tinnitus, loss of balance, nystagmus, loss of facial sensation, or loss of function of the facial muscles or the muscles of mastication. Pain is uncommon but may sometimes mimic trigeminal neuralgia. Cerebellar findings such as ipsilateral limb can occur; ataxia and gait abnormalities may be noted when extremely large tumors have extended into the cerebellum (Video 7, Abnormal Tandem Gait). In patients with trigeminal pain (Video 106, Trigeminal Neuralgia), multiple sclerosis may be diagnosed initially; only with further hearing loss and a lack of involvement of intracranial areas of the nervous system will re-evaluation be conducted. Meningiomas are occasionally confused with neuromas, and, rarely, cholesteatomas or choroid plexus papillomas are identified at surgery.

EVALUATION. Sometimes, early neuroradiological examination may fail to detect these tumors. Patients with increasing symptoms that are not amenable to medical treatment may require repeat studies. MRI with gadolinium enhancement remains the imaging modality of choice because it permits better definition of soft tissue involvement and identification of alternative diagnoses. Neuromas most often demonstrate bright enhancement with contrast agents. CT is performed to evaluate bony erosion of the skull. All patients should undergo audiometry and brain stem auditory evoked potentials at presentation to define pretreatment abnormalities.

MANAGEMENT. Surgical removal remains the mainstay of treatment for larger tumors. Improvements in stereotactic radiotherapy make this treatment a viable alternative to surgery.^{100,101} No large series are available to compare their efficacy with that of surgery alone. After treatment, patients are at risk of hearing loss and facial nerve paralysis. In patients with smaller tumors, hearing can sometimes be preserved. Radiotherapy has been shown to delay tumor regrowth after subtotal resection but carries a risk of radiation damage to other cranial nerves and brain stem vascular events. Chemotherapy has not been sufficiently explored.

Neurofibroma

PATHOGENESIS AND PATHOPHYSIOLOGY. Both types of neurofibroma are associated with a gene localized to chromosome 17q11.2 for neurofibromatosis type I (NFI)¹⁰² and to chromosome 22 for neurofibromatosis type II (NFII). The NFI gene encodes a protein termed neurofibromin that is involved in regulation of the RAS protein.

EPIDEMIOLOGY AND RISK FACTORS. NFI, also known as von Recklinghausen's disease, comprises a constellation of tumors of the CNS. NFII is defined by bilateral acoustic neuromas. Patients with NFI have an increased risk of astrocytic tumors, including optic pathway glioma and brain stem gliomas.¹⁰³ Patients with NFII are at risk of ocular abnormalities, other cranial nerve schwannomas, and meningiomas. Spinal cord gliomas are seen more commonly in patients with NFII. NFI has a frequency of approximately 1 in 4000, and the frequency of NFII is 1 in 40,000. Both are inherited as autosomal dominant traits, with NFI having incomplete penetrance (see Chapter 32).

CLINICAL FEATURES AND ASSOCIATED DISORDERS. In NFII, the bilateral acoustic neuromas usually become evident at the same time. Presenting complaints include tinnitus or hearing loss. Most patients have a first-degree relative who is similarly afflicted. Patients with NFII are also at risk of meningioma, gliomas, ependymoma, and schwannoma. Symptoms are the same as those discussed for the respective tumors.

DIFFERENTIAL DIAGNOSIS AND EVALUATION. Patients with NFI must be closely examined for any history consistent with visual disturbances or other visual abnormalities or signs of nerve root impingement, including bowel and bladder dysfunction or constipation. Patients may show evidence of peripheral nerve dysfunction caused by impingement by a neurofibroma. Patients may also have a plethora of other complications.¹⁰⁴ Only when the clinical findings suggest changes requiring intervention should tests be performed. Yearly MRI scans of the brain and spinal cord searching for tumor are not indicated. Some clinicians advocate yearly screening of children with visual evoked potentials for early detection of optic gliomas.¹⁰³ Patients and their spouses need genetic counseling for family planning purposes¹⁰⁵ and extensive social work intervention to help with issues related to the disease and the possibility of tumor generation.

Patients with NFII should be closely observed for any changes in auditory function, including hearing loss and tinnitus. During the neurological examination, particular

attention should be focused on other cranial nerve abnormalities. Physicians should monitor the patient for any evidence of vertigo or difficulty with balance, possibly with yearly brain stem auditory evoked potentials. Formal audiometry on a yearly basis is a reasonable alternative as well; yearly MRI scanning is not generally indicated but may be repeated serially to allow a gauge of tumor enlargement.

MANAGEMENT. Patients with NFI should be monitored closely for development of treatable abnormalities, as previously described. Optic gliomas can be treated with surgical removal when feasible or with radiotherapy.¹⁰⁶ Malignant degeneration of a schwannoma or a neurofibroma (neurofibrosarcoma) occurs in 5% of patients. Patients with NFII require intervention to remove the acoustic neuromas, as described previously. In these patients, referral to a center that has facilities to perform a cochlear implant should be considered because these patients are at great risk of bilateral hearing loss. Patients receiving radiotherapy, especially children, are at risk for further neurobehavioral deterioration and endocrine abnormalities.

PROGNOSIS AND FUTURE PERSPECTIVES. Further investigation into the genotype and how it relates to the variable phenotypic expression and manifestation of tumors remains to be conducted. A better understanding of the mechanism of action of the genes responsible for these diseases and the way in which malignant degeneration occurs may advance treatment of patients not only with NF but also with gliomas. In utero diagnosis remains a possibility. Genetic analysis of families and in family planning should be thoroughly explored.

Other Peripheral Nerve Tumors

Benign tumors of the peripheral nerves are often localized to single sites and are related to pressure or trauma. For example, Morton's neuroma is commonly associated with increased pressure or tight-fitting shoes and represents fibrotic swelling of the nerve in response to repeated insult. Located on the plantar surface of the foot, it is treated with excision or observation. Symptoms include localized pain, tenderness, and weakness of the distally affected muscles innervated by the nerve. Ganglion cysts may result from repeated trauma, leading to undue inflammation and cystic degeneration. In other cases, transected stump nerves undergo unorganized sprouting, leading to a large clump of disorganized cells and their processes.

SPINAL CORD TUMORS

Although rare, spinal cord tumors continue to carry a grave prognosis for patients. They are difficult to resect and treat. Both the tumor and the treatment often lead to profound physical and neurological disability due to spinal cord damage. Spinal cord tumors represent approximately 7% of all primary tumors of the CNS and are seen more commonly in children, in whom they represent up to one fourth of all intra-axial tumors by location. The most common histological type is that of the glioma histology, especially astrocytomas and ependymomas. Their frequency is undoubtedly related to the percentage of total tissue of the spinal cord involved.

Often, patients are brought to medical attention because of weakness of the legs, loss of bowel or bladder control, back pain, or, rarely, loss of sensation. In children, these symptoms may be confused with “regression” of the child’s development, “growth pains,” or muscle disease. Often, a child’s lesion is discovered incidentally during evaluation for a minor injury such as a sledding accident, when studies are performed to calm the fears of worried parents. Cervical or foramen magnum lesions may present with torticollis or nuchal rigidity.

Most patients are evaluated by MRI, which demonstrates an enlarged or thickened cord. Frequently, the spinal canal may be enlarged around the area of the slowly expanding tumor. Once the tumor has been identified, the entire neuroaxis should be studied for any other areas of involvement. Although a tissue diagnosis may be suggested by the tumor’s location and radiographic pattern, pathological confirmation is essential prior to treatment. All patients should be evaluated by a neurosurgeon for consideration of biopsy or evacuation of the lesion. Preoperative and postoperative testing with evoked potentials can be performed to monitor disease evolution. Because of the location, patients are at a significant risk of morbidity from the tumor and any treatment for it.

Treatment of these tumors includes surgical evacuation when possible, followed by radiotherapy to a malignant lesion and the surrounding cord. Low-grade tumors may be monitored closely for evidence of recurrence or malignant degeneration. In children, consideration of a delay in radiotherapy will allow the treating physician to weigh risk-benefit options and consider the possibility of unwanted side effects due to the treatment. Although chemotherapy has not been systematically studied in these patients, one would intuitively expect that agents with known effects on supratentorial tumors would also be effective on spinal tumors with a similar histology. Patients with spinal column defects, such as scoliosis, that are related to the tumor or treatment can be treated appropriately with surgery (if necessary) and physical therapy.

PITUITARY TUMORS

Adenomas

PATHOGENESIS AND PATHOPHYSIOLOGY. Pituitary adenomas are neuroepithelial tumors of the adenohypophysis. They are generated in a stepwise fashion from initiation to growth evolution, probably in a manner similar to that characteristic of other CNS tumors. This growth may be caused by derangements in the metabolic processing of cells of the adenohypophysis due to mutations of undetermined gene alterations. Several putative gene alterations have been proposed, including the retinoblastoma gene and, because of its association with pituitary adenomas, the multiple endocrine neoplasia type I (MEN-I) tumor suppressor gene. Approximately 3% or 4% of adenomas of the pituitary are associated with MEN-I. Certainly other gene elements will also be found to play a role as laboratory investigations continue. An alternative hypothesis suggests that overstimulation or deranged signaling from the hypothalamus leads to pituitary cell dysfunction and inappropriate growth.

Pituitary adenomas can be classified by size, hormonal secretion, or histological appearance. Tumors less than 1 cm in diameter are considered microadenomas, and those larger than 1 cm are considered macroadenomas. Alternatively, pituitary adenomas can be classified as hormone secretors or nonsecretors. Approximately 15% to 20% of these tumors do not secrete hormones under current detection techniques. Of those that do, the majority secrete prolactin, followed by growth hormone (GH), adrenocorticotrophic hormone (ACTH), gonadotropins, and thyrotrophic hormone. Some tumors secrete multiple hormones and are termed *null tumors*. Null tumors that contain a buildup of mitochondria are termed *oncocytomas*, but this fact has no clinical relevance. Histologically, cells can appear acidophilic, basophilic, or chromophobic on routine staining techniques. By histological analysis, the tumor can be difficult to differentiate from normal tissue or metastatic disease. Immunohistochemical staining and evaluation by a neuropathologist is essential.

EPIDEMIOLOGY AND RISK FACTORS. Aside from craniopharyngiomas in childhood, pituitary adenomas are the most common tumor in the region of the sella, comprising approximately 6% of all CNS tumors. Although pituitary adenomas are clinically evident more often in young women, autopsy series suggest that they appear equally in men and women. In a survey of clinically normal asymptomatic men and women, a 10% incidence of focally abnormal areas within the pituitary was found on MRI scans with contrast agent.¹⁰⁷

CLINICAL FEATURES AND ASSOCIATED DISORDERS. Most pituitary adenomas can be detected while they are relatively small because they are located in a clinically sensitive area that controls hormonal function, just below the hypothalamus, and in close proximity to the optic chiasm (Table 46-5). If hormonal derangements do not bring the patient to medical attention, the tumor may be discovered during ophthalmological examination for a visual disturbance. Early pressure on the optic chiasm may result in a superior bitemporal quadrantanopia and can lead to a full bitemporal hemianopia. Alternatively, pressure symptoms such as headache may lead the patient to seek medical advice. The headaches can be diffuse and nonpulsatile and may be mistaken for daily headaches. As the adenoma enlarges, the patient may note hypothalamic dysfunction, basal forebrain abnormalities, anosmia, and seizures.

Symptoms of pituitary dysregulation are common. Prolactin-secreting tumors may lead to clinical presentation in women because of menstrual irregularities (usually amenorrhea), galactorrhea, and an inability to conceive. Men have a decrease in potency and libido. Abnormal prolactin function may also result from other pituitary tumors due to obstruction of the dopaminergic pathways between the hypothalamus and the pituitary. GH-secreting pituitary adenomas usually present at a younger age with evidence of acromegaly. Gonadotropin-secreting tumors cause precocious puberty, infertility, or impotence. ACTH alterations cause the typical features of Cushing’s syndrome, including hypertension, diabetes mellitus, fat deposition around the neck and shoulders (buffalo hump), acne, myopathy, and purple striae. Occasionally, patients present with psychiatric disturbances such as psychosis, mood alterations, or sleep

TABLE 46-5

Clinical Features of Derangement of Pituitary Hormone Function

| HORMONE | CLINICAL FEATURES | |
|--|-------------------|--|
| Prolactin Growth hormone | Excess | Hypogonadism, galactorrhea, amenorrhea, infertility, sexual activity dysfunction, impotence |
| | Deficiency | Infertility, ? impotence |
| | Excess | Acromegaly—hypertension, diabetes mellitus, coarse facial features, increased height, gigantism, nerve entrapment, visceromegaly, headaches, visual impairment, myopathy |
| Thyroid-stimulating hormone | Deficiency | Growth failure, dwarfism |
| | Excess | Weight loss, personality changes, psychosis, cardiac dysfunction, myopathy |
| Follicle-stimulating hormone, luteinizing hormone | Deficiency | Cold intolerance, headache, constipation, paresthesias, infertility |
| | Excess | Precocious puberty, amenorrhea, infertility |
| Adrenocorticotropic hormone | Deficiency | Delayed puberty, impotence, amenorrhea |
| | Excess | Cushing's syndrome—easy bruising, amenorrhea, hirsutism, hypertension, diabetes mellitus, acne, moon facies, truncal obesity, purple striae, psychiatric disturbance |
| | Deficiency | Nausea, malaise, weakness, hypotension |

disturbances, especially when the regulation of cortisol or prolactin is altered.

DIFFERENTIAL DIAGNOSIS. The differential diagnosis of a pituitary adenoma includes other space-occupying lesions in this area such as meningioma, metastatic tumors, craniopharyngioma, glioma, or, rarely, pituitary carcinoma. These alternatives can in most cases be resolved by surgical intervention performed with histological diagnosis. Confusion about compression of the sella area due to hemorrhage, a carotid aneurysm, or an empty sella caused by herniation of the meninges into the sella can often be resolved by appropriate neuroradiological imaging. An appropriate history will resolve questions about possible trauma to the area from a skull base fracture, previous surgery in an area near the sella, or a history of irradiation. Autoimmune or infectious causes of problems, including sarcoidosis, histiocytosis X, bacterial meningitis, tuberculosis, or abscess, are typically resolved by the presence of other findings of these diseases. Lymphocytic hypophysitis and Sheehan's syndrome often occur in the peripartum. Finally, one must always be vigilant to detect prescription or recreational drugs that interfere with normal pituitary function.

EVALUATION. X-ray examination of the skull is of limited use in the evaluation of the patient with a suspected pituitary adenoma. CT scanning with bone windows is usually selected first, but this may miss a very small adenoma. MRI with contrast enhancement defines the soft tissue characteristics and is more sensitive to tumor identification in patients with large tumors. Angiography may be necessary to define the arterial supply for surgical planning and to exclude the presence of aneurysm. Neuro-ophthalmological evaluation for accurate mapping of visual disturbances is important prior to surgery. Evaluation of pituitary function is needed in all patients (Table 46-6). All patients require evaluation for cortisol insufficiency, especially to guard against cortisol insufficiency postoperatively.

MANAGEMENT. Prolactin-secreting tumors can be managed with the use of dopamine agonists such as bromocriptine (0.5 to 2.5 mg/day). These drugs interfere with the dopaminergic pathways between the hypothalamus and the pituitary. Ketoconazole has been proposed to stop the effects of ACTH hypersecretion. Use of somatostatin for GH-secreting tumors is still under investigation. Surgery remains the best way to produce a definitive diagnosis. The

†Tests should be performed and related to normal values for timing of menstrual cycle.

typical surgical pathway is a trans-sphenoidal approach and is usually curative. Use of radiotherapy (including stereotactic radiation) remains effective for patients with evidence of recurrence and for those who are not surgical candidates or who have not benefited from postsurgical medical intervention. After surgery, patients remain at risk for visual field defects or pituitary insufficiency, including panhypopituitarism requiring hormonal supplementation.

PROGNOSIS AND FUTURE PERSPECTIVES. Because of the success of surgical intervention, these tumors have a very favorable prognosis. Recurrence is usually confined to patients in whom resection is incomplete. Further refinements in the medical treatment for microadenomas may allow nonsurgical treatment throughout life in some patients.

Craniopharyngioma

PATHOGENESIS AND PATHOPHYSIOLOGY. Craniopharyngiomas are thought to be congenitally derived and to arise from remnants of Rathke's pouch. Embryonic collections of epithelial cells remain after absorption of the hypophyseal-pharyngeal duct, from which the infundibulum/tuber cinereum is derived (Fig. 46-9). The squamous cells are found to be metaplastic and may be present for a significant period before transformation occurs. Alternative

Figure 46-9. MRI of a craniopharyngioma demonstrating a cystic contrast-enhancing mass in the suprasellar area extending upward, compressing the hypothalamus.

proposals suggest that these tumors are derived from a malformation of the embryonic cells that can linger in the area and are not absorbed during fetal life for a significant period of time, leading to abnormal growth. There are two main histological types, one seen in children and the other in adults, suggesting the possibility of two different explanations for their origin.

These tumors range in size from very small round nodules to large loculated cysts. Two main histological types are found. In the majority of children, an adamantinomatous form that appears to resemble tooth-forming material is composed of interspersed fibrous and necrotic tissue as well as many multiloculated cysts. Cholesterol and an oily, thick cystic fluid may also be present, and this fluid can spill from the sack into the subarachnoid space, causing a chemical meningitis. These types of craniopharyngiomas are more often found to have calcium deposits that can be visualized on plain skull radiographs. In adults, a squamous papillary form occurs; although it has no adamantinomatous features, a less cystic stratified squamous epithelium is found histologically. Keratin deposition may also occur. In many cases, it may be difficult to differentiate these two main forms, leading some to propose the presence of a third mixed form.

EPIDEMIOLOGY AND RISK FACTORS. Craniopharyngioma is an epithelial tumor arising from the region of the sella and represents 3% of all primary intracranial neoplasms. It is the most common childhood tumor involving the sella area. Although it is the third most common tumor in childhood, approximately 50% of all cases occur in adults. There are no known risk factors.

CLINICAL FEATURES AND ASSOCIATED FINDINGS. Because this tumor is located near the pituitary, the result-

ing syndromes resemble those characteristics of pituitary adenomas. Symptoms can arise slowly over many months. The most common presenting complaints are compression of the chiasm, causing visual disturbances in the form of bitemporal visual field loss or obstruction of the CSF pathways, yielding papilledema, headache, or nausea and vomiting. Involvement of the hypothalamus or pituitary may lead to endocrinological disorders. With enlargement, pressure on the third ventricle in children can lead to a failure to attain developmental milestones or, in adults, a dementing process. In 90% of cases, endocrinological abnormalities are present, usually involving the anterior pituitary, yet most patients do not seek initial evaluation for problems related to endocrinological dysfunction. Notwithstanding, almost half of affected children are of short stature, and one fourth are obese at presentation. The primary endocrinological disturbance found is related to GH production; next in frequency are disturbances in luteinizing hormone/follicle-stimulating hormone, ACTH, and thyroid-stimulating hormone. In contrast to pituitary adenomas, abnormalities of prolactin are seen in only approximately one fifth of cases.

DIFFERENTIAL DIAGNOSIS. Craniopharyngiomas usually have a characteristic radiographic appearance that generally excludes other pathological processes. The differential diagnosis of these tumors includes pituitary adenomas, which have no calcifications, and separation of these two possibilities without surgery may be difficult in adults. Rathke's pouch cysts are usually single cysts and lack a solid component. Meningiomas often possess a "dural tag," and a cleavage plane can be visualized on imaging studies. In adults, metastatic tumors such as melanoma should also be considered.

EVALUATION. Neuroradiographic studies should be designed to aid in surgical planning. Plain skull radiographs may show enlargement of the sella or calcium deposits, thereby giving a hint of potential diagnoses, especially in children. CT scans with and without contrast agent and paying attention to the sella in the coronal section may show bony alterations, whereas MRI with and without gadolinium can define the soft tissue extension of the tumor and the presence of cysts. Craniopharyngiomas tend to extend downward into the sella, whereas pituitary adenomas extend upward from the sella. Occasionally, angiography is required to define lateral displacement that can interfere with arterial blood supply, especially the internal carotid artery. Full endocrinological evaluation is mandatory before and after surgery (see [Table 46-6](#)).

MANAGEMENT. Surgical resection remains the mainstay of treatment to establish diagnosis and to relieve pressure from the surrounding structures.¹⁰⁸ Patients need corticosteroids at the time of surgery regardless of their preoperative status. All patients require assessment of fluid and electrolyte balance, which should be monitored closely in the operative period. Derangements in water and electrolyte balance caused by diabetes insipidus, the syndrome of inappropriate antidiuretic hormone secretion, or cerebral salt wasting¹⁰⁹ are common in the postoperative period. Following total removal of the tumor, further treatment is usually not required. With subtotal removal, patients can be evaluated with serial neuroradiological imaging, and reoperation at regrowth of the tumor can be considered.

Alternatively, depending on the amount of residual tumor, radiotherapy is also an option. There is increasing controversy about the role of stereotactic radiation or gamma knife as the sole treatment modality. Follow-up periods for patients treated with radiosurgery have been relatively short, and further research in this area is required. Instillation of radioactive phosphorus may be considered in some patients with cystic lesions.¹¹⁰ Endocrinological evaluation and postoperative treatment are similar to the regimen followed for patients with pituitary adenomas. Children require close observation with careful monitoring of neurocognitive and hormonal status and are at risk of obesity.¹¹¹

PROGNOSIS AND FUTURE PERSPECTIVES. Even when these tumors are detected before any neurological deficits become apparent, the prognosis remains guarded. Recurrence approaches 30% within 5 years and is higher in children and in those who have undergone incomplete resection. Recurrence is usually observed within 1 year of surgery. A significant number of patients continue to require hormonal supplementation. Further work is needed to determine ways to identify more aggressive tumors for which the use of radiotherapy and chemotherapy at initial tumor diagnosis may prevent recurrence.

MENINGIOMAS

PATHOGENESIS AND PATHOPHYSIOLOGY. Many classification schemes are used for meningiomas, usually based on the histological appearance (Table 46-7). Meningiomas have a firm off-white appearance, and because they are extra-axial, they are usually well demarcated from the surrounding brain. Microscopically, they display a characteristic whorled pattern with calcifications (psammoma bodies). Discussion abounds about the classifications and subtypes and the histological characteristics of these tumors and their clinical course. For example, proposed papillary and clear cell forms appear to be found more commonly in younger people and children and seem to behave more aggressively. Various cell-labeling tests, such as MIB-1 or p53, and analysis of estrogen and progesterone receptor concentrations have been proposed to predict biological growth.¹¹² However, the pathological features of brain invasion and mitotic activity are the most important pathological determinants of aggressive behavior. Hemangiopericytomas are highly vascular tumors that are seen equally often in usually younger men and women.

TABLE 46-7

Classifications of Meningiomas

| HISTOLOGICAL LABEL | FEATURES |
|--------------------|---|
| Fibroblastic | Narrow, long cells in sheets; less commonly, whorls, psammoma bodies |
| Syncytial | Meningothelial cells, whorls, psammoma bodies |
| Transitional | Features of both syncytial and fibroblastic |
| Angioblastic | Intertwined, complex, thickened blood vessels, reticulin background, seldom contain whorls, psammoma bodies |

Histologically similar tumors can be found in non-CNS regions. They are more prone to malignant behavior.

EPIDEMIOLOGY AND RISK FACTORS. Meningiomas are extra-axial tumors that arise from dural elements within the cranial and spinal spaces. Although considered benign, they can enlarge and cause compression of neural elements and can behave aggressively, invading the bone or brain and threatening life. They comprise approximately 15% of all intracranial tumors and increase in incidence with age. Meningiomas have estrogen and progesterone receptors, possibly explaining why they occur in women almost one-third more often than in men. Because of these receptors, meningiomas show increased growth during pregnancy. Furthermore, meningiomas in the spine are almost always found in women. However, in blacks, men are more often affected. Several risk factors have been proposed for their occurrence, including trauma, infections, electrical exposure, and exposure to radiotherapy. Meningiomas are common in patients with NF1, in whom multiple tumors are commonly found.

CLINICAL FEATURES AND ASSOCIATED FINDINGS. Meningiomas can arise in virtually any extra-axial location in the CNS, although certain locations predominate (Table 46-8). Patients can present with epilepsy or subtle symptoms such as progressive headache, memory loss, or cognitive changes, which occur over an extended period of time. Slow progressive dementia and chronic depression in an older patient are also common presentations. Location of the tumor along the motor strip may present, possibly suddenly, with hemiparesis (Video 4, Pronator Drift). Sagittal tumors along the falx may cause the development of bilateral leg weakness. Sphenoid area tumors may cause ophthalmological or cavernous sinus symptoms, and olfactory groove meningiomas may lead to anosmia. Because these tumors grow slowly, they may be identified incidentally in asymptomatic patients. Although hydrocephalus is extremely rare, children are more likely to present with symptoms of this entity.

DIFFERENTIAL DIAGNOSIS. Meningiomas are often “diagnosed” from neuroradiological scans. The typical features and location do offer a reasonable amount of certainty in this diagnosis, yet clinicians must always be vigilant for unexpected possibilities. The ability to characterize these tumors radiographically still does not allow differentiation of a benign from a malignant meningioma. Malignant forms are more commonly seen in men, and unexpected metastatic

TABLE 46-8

Locations and Presentations of Meningiomas

| LOCATION | PRESENTING MANIFESTATION |
|-------------------|---|
| Parasagittal | Urinary incontinence, dementia, gradual paraparesis, seizures |
| Lateral convexity | Variable depending on structures compressed, including slow hemiparesis, speech abnormalities |
| Olfactory groove | Anosmia, visual disturbance, dementia, Foster-Kennedy syndrome |
| Suprasellar | Hormonal failure, bitemporal hemianopia, optic atrophy |
| Sphenoid ridge | Extraocular nerve paresis, exostoses, proptosis, seizures |

Figure 46-10. MRI of a posterior fossa meningioma demonstrating an extra-axial, homogeneously contrast-enhancing mass arising from the tentorium and compressing the cerebellar hemisphere.

deposits may be discovered. Suprasellar lesions may be confused with pituitary adenoma or craniopharyngioma. Extremely vascular lesions may be hemangiopericytomas.

EVALUATION. MRI with gadolinium remains the diagnostic method of choice. Contrast agents demonstrate significant homogeneous enhancement (Fig. 46-10) and may highlight a dural “tail.” CT may complement MRI findings and should include bone windows to show evidence of hyperostosis, calcifications within the tumor, and bone invasion. MRI angiography or routine angiography may reveal a tumor blush and can help with presurgical planning. In elderly patients, preoperative and postoperative neuropsychological testing can be performed to evaluate patient response to and recovery from surgical resection.

MANAGEMENT. Meningiomas can be cured surgically. The location and size of the tumor and its involvement with close vital structures partially determine the extent of resection that is feasible. For example, sphenoid ridge meningiomas are rarely fully removed. The main decision is whether surgery is required. In patients in whom the tumor is an incidental finding or who are poor surgical risks, observation with serial scanning may be appropriate.¹¹³ In those with large meningiomas, angiography and embolization are frequently used to aid in surgical removal. Extremely vascular lesions may be hemangiopericytomas. Following surgery, whether complete or near-complete, patients should be observed with serial MRI or CT scans for evidence of regrowth. Recurrence is related to extent of resection and location because the site of resection may preclude complete removal. Radiotherapy can be given for relapse following a second surgery or for anaplastic meningiomas.¹¹⁴ Stereotactic radiotherapy and

brachytherapy are under evaluation, with early results promising, although observation times have been short. Patients must be watched closely for evidence of cognitive decline from these intensive radiation doses. Chemotherapy with cytotoxic agents has met with limited success. Because meningiomas do possess estrogen and progesterone receptors, endocrine manipulation of the tumor residua with hormonal or biological agents such as tamoxifen or β -interferon is under study and remains investigational. Study of RU-486 has shown no benefit.

PROGNOSIS AND FUTURE PERSPECTIVES. As the population continues to age, the frequency of meningiomas will only increase. Techniques for neurosurgical removal in the elderly must be further refined.¹¹⁵ Histological variations and groups must be standardized to allow more timely and thorough evaluation of therapeutic treatments designed for a homogeneous population of tumors. Because meningiomas are amenable to resection but can remain to invade and disrupt vital neurological structures, future work must include detailed studies of their nonsurgical management, in relation to both timing and type of therapy. Attempts to predict biological behavior through histological and cell kinetic studies can help in management by identifying which patients are at increased risk of tumor regrowth and which have the potential to respond to medical management.

CONGENITAL TUMORS

Dermoid, Epidermoid, and Teratoma

These rare embryonic remnant tumors may present anywhere in the CNS but most commonly occur in the posterior fossa and the cauda equina. They are congenital tumors and may be seen at any age; however, they are more likely to occur in children or young adults of either sex. They are slow growing and present with symptomatology specific for compressive syndromes at their location within the CNS. These symptoms can be insidious, and blockage of CSF flow occurs rarely. Seizures or headaches are not common. Skin lesions are commonly associated with these tumors, and any infant with a dermal sinus tract should undergo neuroradiological evaluation to exclude these growths. Communication with a dermal tract may lead to recurrent meningitis, and any patient with repeated meningitis, whether associated with a bacterial cause or not, should undergo evaluation for an unnoticed dermal sinus. Prenatal diagnosis with ultrasound and resection soon after birth are now possible.¹¹⁶

Epidermoid tumors, or cholesteatomas, are composed of ectodermal remnants and present as cystic structures in lateral positions within the CNS, especially around the brain stem or thoracic cord. Neuroradiological imaging usually demonstrates a hyperdense structure with poor enhancement characteristics. MRI scans demonstrate low but variable signals on T1-weighted images and high but variable signals on T2-weighted images. CT scans may demonstrate bone destruction and calcium within the lesion. These tumors have a thick ring that may be calcified and can appear “pearl-like.” Epidermoids can interdigitate around vital neuronal structures, complicating surgical removal. Care should be taken during removal to prevent spilling

the contents to avoid a chemical meningitis. Complete surgical removal is curative.

Dermoid tumors, composed of ectoderm and mesoderm, are more likely to be found in the midline, especially in the lumbar area and in the brain stem. Neuroradiological imaging usually shows an appearance similar to that of epidermoids with poor enhancement characteristics. These tumors are round multilobulated lesions containing fluid that also leads to a risk of chemical meningitis if the cysts are ruptured. Dermoids should be considered whenever lumbar puncture yields fat in the CSF.¹¹⁷ Surgical removal is usually curative.

Teratomas are composed of ectoderm, mesoderm, and endoderm and are most often seen in infants and children, especially in the pineal region or the spinal canal. Because these tumors are composed of cells of all embryonic layers, they can generate hair, teeth, or other elements. Surgical removal, often not complete, is curative. Observation and an attempt at more complete re-resection may be feasible.

Pineal and Germ Cell Tumors

Pineal region tumors account for approximately 1% of all brain tumors. They can be extremely difficult to diagnose and treat because of their location. Tissue confirmation is important because of the varied histologies found in this region as well as the implications of these differences in influencing treatment options. Occasionally, small samples of benign lesions may be confused with more malignant processes.

Patients with pineal region tumors often present with symptoms of hydrocephalus caused by compression of the cerebral aqueduct that result in elevated intracranial pressure (Table 46-9). Patients may present acutely with nausea, vomiting, lethargy, headaches, or changes in sensorium and mentation. Enlargement and infiltration of the nearby structures, including the midbrain, may lead to a kinetic mutism. Further expansion to involve the superior colliculus can lead to Parinaud’s syndrome, characterized by paralysis of up-

gaze, near-light dissociation, and convergence-retraction nystagmus. Further compression may result in paralysis of downgaze. In patients with germ cell tumors, precocious puberty, especially in boys, may be observed.

The primary differentiation of lesions in this location can be separated into tumors and cysts or, in infants, a vein of Galen aneurysm. Tumors can be divided into germ cell tumors (germinomas, teratomas, or choriocarcinomas), intrinsic pineal tumors (pinealcytomas or pinealblastomas), metastatic lesions, or other tumors including ependymomas, astrocytomas, or meningiomas. Patients should undergo MRI with gadolinium or, if this is unavailable, CT with a suitable contrast agent. This will help to localize the tumor and define the involvement of local structures. Occasionally, angiography is required for surgical planning or to exclude an aneurysm of the vein of Galen.

MRI can help in differentiating possible pathological causes. For example, teratomas usually contain fat and calcium, whereas meningiomas may reveal a dural tag. All patients should undergo CSF analysis, including cytological examination when feasible. α -Fetoprotein and β -human chorionic gonadotropin (hCG) measurements in the CSF should be compared with serum levels. Any clinical evidence of pituitary dysfunction should prompt thorough endocrinological studies.

Pineal region tumors require histological confirmation. Total resection is curative for benign lesions, whereas maximum resection may improve the overall survival of patients with malignant lesions. Hydrocephalus requiring shunting is common. Pineal or germ cell tumors require post-operative MRI for evaluation of seeding of the cerebrospinal pathway. Patients with germ cell tumors should undergo CSF evaluation when feasible. Testing should include a comparison of serum with CSF β -hCG and α -fetoprotein, which can be used as markers for disease. Radiotherapy can be curative for localized lesions. Patients with evidence of cerebrospinal dissemination require craniospinal radiation. Because these tumors are so radiation sensitive, the use of

TABLE 46-9

Presentation and Evaluation of Pineal Region Lesions

| TYPE | CLINICAL PRESENTATION | EVALUATION | TREATMENT |
|---|--|--|---|
| Germ cell tumor | Headache, Parinaud’s syndrome, endocrine dysfunction, nausea, vomiting, diabetes insipidus | MRI with gadolinium, hormone evaluation; when feasible, CSF evaluation including β -hCG | Biopsy radiotherapy |
| Pineoblastoma | Headache, Parinaud’s syndrome, endocrine dysfunction, nausea, vomiting | MRI with gadolinium | Resection radiotherapy |
| Glial neoplasms (astrocytomas, ependymomas, etc.) | Slowly progressive, headache, nausea, vomiting | MRI with gadolinium | Resection, chemotherapy, radiotherapy |
| Meningioma | Slowly progressive, headache, late nausea, vomiting | MRI with gadolinium | Resection, radiotherapy with incomplete resection |
| Lymphoma | Headache, Parinaud’s syndrome, endocrine dysfunction, nausea, vomiting, diabetes insipidus | MRI of craniospinal contents: when feasible, CSF evaluation including β_2 -microglobulin | Biopsy, chemotherapy, (?) radiotherapy |
| Metastatic tumors | Often history of cancer | MRI with gadolinium, evaluation for other metastatic deposits | Resection, radiotherapy, (?) chemotherapy |
| Pineal cysts | Slowly progressive, headache, late nausea, vomiting, or incidental finding | MRI with gadolinium | Observation, reduction |
| Vein of Galen | Most commonly male, high cardiac output, cranial bruit, enlarging head | CT with contrast | Surgery, (?) embolization |

CSF, cerebrospinal fluid; CT, computed tomography; hCG, human chorionic gonadotropin; MRI, magnetic resonance imaging.

chemotherapy with cisplatin and etoposide has often been reserved for patients with recurrent disease or those with more malignant tumors such as yoke-sac tumors or malignant choriocarcinoma. Although systemic germ cell tumors are very sensitive to chemotherapy, CNS germ cell tumors appear to be less responsive. Use of chemotherapy before or after primary treatment with radiotherapy remains to be fully explored. Use of thiotepa with stem cell rescue was shown to be of some benefit in patients with germinoma.¹¹⁸ Relapse most commonly occurs locally or with CSF dissemination. Overall, survival approaches 75% at 5 years, and survival of patients with germinomatous germ cell tumors is more than 90%.

OTHER TUMORS

Hemangioblastoma

Hemangioblastoma, a benign vascular tumor, is seen primarily in middle-aged adults but often presents at a younger age in patients with von Hippel-Lindau disease. These tumors are primarily located in the posterior fossa, although they can occur anywhere within the neuroaxis. They are usually cystic and are sometimes classified as a variant of meningiomas (angioblastic variant). Histologically, they are characterized by distinctive vascular channels with fat-laden cells. Occasionally, they can be mistaken for xanthochromic astrocytomas.¹¹⁹

The clinical presentation is similar to that of other posterior fossa lesions. The neuroradiological appearance is that of a well-demarcated, cystic lesion with a distinctly enhanced tumor nodule on administration of contrast material. Identification should prompt a search for other lesions, including lesions of the cervical spine, especially in those with von Hippel-Lindau disease; retinal examination and evaluation for intra-abdominal neoplasms such as renal cell carcinoma or pheochromocytoma should also be done. Angiography is performed to help in the search for radiographically silent lesions and to aid in preoperative planning. Surgery is usually curative, although the use of stereotactic radiation is being explored. Because these tumors are known to express an erythropoietin-like factor, the accompanying erythrocytosis may be a marker for the extent of resection or for occult lesions in patients with known hemangioblastoma or von Hippel-Lindau disease.

Chordoma

Chordomas are often considered “benign” tumors that are amenable to surgical resection alone. However, they can be invasive and can metastasize, and without complete resection, they can produce local regrowth. They are considered embryonal tumors and are remnants of the notochord. The primary histological feature is the presence of large mucin-containing physaliferous cells. Areas of hemorrhage and calcification may also be seen. Chordomas may degenerate to a more malignant histological appearance, the chondrosarcoma. Chordomas originate in essentially two locations, the clivus or sphenoid region and the sacrococcygeal region, although they can arise in other areas as well, including infiltration into the facial structures. They are relatively rare

and account for less than 1% of primary CNS tumors. They usually occur at midlife and predominate in men. Men who have smaller non-necrotic tumors seem to have a better overall outcome.¹²⁰

Clinical presentations of patients with clivus or cervical region tumors include headache, oculomotor nerve abnormalities, or other cranial nerve dysfunction, especially in the lower motor nerves. Tumors in the sacrococcygeal region present with symptoms similar to those typical of cauda equina or conus medullaris disruption. Radiological evaluation should include both CT to examine bone abnormalities and MRI to evaluate soft tissue destruction. These tumors are extra-axial, and displacement of brain stem or other structures may be seen. Nerves exiting from the nervous system may become entrapped in the tumor. Chordomas can be confused with craniopharyngiomas, meningiomas, metastatic carcinoma, or possibly adenoma. They show variable enhancement with contrast dye. Angiography may be necessary to define the arterial structures prior to surgery. The differential diagnosis for these tumors includes the malignant variant, chondrosarcoma, and other lesions known to occur in this region such as meningiomas or schwannomas, metastatic tumors such as carcinomas, or, remotely, craniopharyngiomas.

Definitive surgery for diagnosis and maximum tumor removal is imperative. Patients should be referred to large centers staffed by neurosurgeons who are adept at skull-base surgery. Tumors usually exhibit regrowth at the site of the previous resection. Radiotherapy, including directed stereotactic radiotherapy, is improving overall survival; however, radiotherapy should be reserved for patients who show evidence of tumor after surgery.

In a study of 60 patients with chordoma or chondrosarcoma, overall regrowth-free survival at 5 years was found in 84% of patients with near-total resection and in 64% of patients with partial resection.¹²¹ Extent of surgical resection was the greatest predictor of overall survival. Importantly, extent of surgical resection did lead to some decrease in patient performance postoperatively, but with rehabilitation, most patients regained their level of preoperative performance in approximately 6 months.

Glomus Jugulare (Carotid Body) Tumors

Glomus jugulare tumors arise from the paraganglionic tissue surrounding the jugular vein in the area of the middle ear. These tumors most often present late in life, in the sixth or seventh decade, and may have a genetic predisposition. They are locally invasive and highly vascular. Although presenting symptoms include complaints similar to those typical of acoustic neuromas, with tinnitus or hearing loss, the key differentiating features of these tumors are pain and the presence of loud pulsations in the ear. Occasionally, blood may drain from the ear. On examination, the patient may have tumor visible in the ear canal and, with larger lesions, evidence of cranial nerve or cerebellar dysfunction. The differential diagnosis includes neuromas, cholesteatomas, meningiomas, vascular malformations, or metastatic disease.

MRI with gadolinium enhancement demonstrates a brightly enhancing lesion and defines the spread and involvement of the local structures. Angiography is important to define the presence of vascular involvement before any attempts

are made to remove the tumor surgically. Often, preoperative embolization of the involved vascular territories and intraoperative electrophysiological monitoring will help in surgical removal, which can be curative. Radiotherapy, including the use of stereotactic radiation or gamma knife, is an option for patients who are poor risks for surgery or who have residual disease that appears to be growing on serial MRI examinations. Prognosis is excellent.

Colloid Cysts

Colloid cysts are benign tumors that are amenable to curative neurosurgical resection. They must be diagnosed promptly before symptoms develop that can lead to acute conditions and sudden death. They are rare tumors but, with the advent of neuroradiological imaging, can be identified incidentally when imaging is performed for other reasons. They typically present in midlife, although pediatric diagnoses are known. They are located most frequently in the third ventricle and can cause variable symptoms due to intermittent obstruction of CSF pathways.

Patients may have weakness in the legs not associated with loss of consciousness, headache that is progressive, or paradoxical lightning headache that is relieved by positional changes of the head. Papilledema may be present on examination. Occasionally, patients with colloid cysts present with symptoms consistent with normal pressure hydrocephalus (Video 54, Normal Pressure Hydrocephalus). Imaging with noncontrast CT demonstrates ventricular obstruction and dilatation with a hyperdense mass in the third ventricle. Coronal MRI usually demonstrates the mass in the anterior third ventricle. These tumors can be confused with basilar aneurysms or choroid plexus papilloma, although these lesions are not as hyperdense on noncontrast neuroradiological studies. Management includes immediate attention to hydrocephalus, often with ventricular drainage. Early surgical intervention is recommended to prevent neurological deterioration.¹²²

Choroid Plexus Papilloma

Choroid plexus papillomas are extremely rare vascular tumors that are often located in the ventricular areas of infants and children of both sexes. Although the lateral ventricles are the most common location, these tumors can present in the third or fourth ventricles, especially in adults. Although some believe the childhood predilection suggests that these tumors are congenitally derived, no risk factors are known.

Patients commonly present with symptoms of increased intracranial pressure. In infants and small children, these manifestations can include changes in behavior and decreased feeding. Seizures are not uncommon, and hemorrhages are known to occur. The main differential factor is that of malignant degeneration to a choroid carcinoma or an ependymoma. Choroid plexus carcinomas are more common in children, whereas in adults the differentiation of a choroid plexus carcinoma from a metastatic carcinoma may be difficult.¹²³ Occasionally, these tumors can be confused with colloid cysts, although the latter lesions have much different imaging characteristics, as discussed previously in the chapter.

Evaluation usually begins with CT or MRI. CT scan reveals hydrocephalus with a brightly enhancing rounded mass located within or near the ventricular system. MRI usually establishes the intraventricular location and may identify leptomeningeal seeding of malignant forms. Calcifications may be present. These tumors can be extremely vascular, necessitating angiography prior to surgery.

Shunting may be required prior to surgery to allow time for thorough surgical preparation. Because papillomas are usually well-demarcated lobules that shell out easily, these tumors can be cured with surgical resection. Those that are more adherent suggest a more malignant type. Choroid plexus papillomas require no further treatment beyond serial neuroradiographical studies to survey for early asymptomatic regrowth. A single institution study suggested that only half of those patients with subtotal resection require reoperation.¹²⁴ In patients with choroid plexus carcinomas, further treatment is important. Patients require evaluation of the neuroaxis of any evidence of seeding by craniospinal MRI and CSF evaluation. Because radiotherapy is not favored in young children, chemotherapy is the mainstay of treatment for choroid plexus carcinomas that are not completely resected, those that show evidence of regrowth, and those that have malignant potential. No large series exist in regard to the choice of optimal chemotherapeutic agents, although carboplatin and etoposide are commonly used. Some advocate presurgical chemotherapy in patients who require reoperation.

METASTATIC NEOPLASMS

Intraparenchymal Metastases
Meningeal and Ventricular Metastases

Skull-Base Metastases

Spinal Metastases
Peripheral Nerve Metastases

PARANEOPLASTIC SYNDROMES

Neurological complications occur in as many as 40% of patients with systemic cancer as a direct result of the underlying malignancy, paraneoplastic conditions, or complications of therapy. These conditions are feared and devastating, with significant morbidity. An estimated 170,000 patients annually experience brain or spinal cord difficulties from either direct or remote effects of a systemic neoplasm. One fifth of the yearly cost of cancer in the United States is relegated to therapy for patients with systemic malignancies metastatic to the nervous system or those with primary tumors commencing in the brain. From the first symptoms, patients experience an uninterrupted cycle of repetitive hospitalizations; neurological morbidity; complicated surgical, radiation, or medical therapies; and extended periods of rehabilitation care. Both the prevalence and the associated costs of these disorders will invariably rise as cancer patients live longer and have the benefit of sophisticated blood and imaging diagnostic procedures. The neurological complications of cancer are outlined in [Table 47-1](#). This chapter provides both the primary caregiver and the neurological specialist with the bases for the recognition of these disorders and focuses on neurological issues in day-to-day management as well as those problems best handled at specialized neuro-oncological centers.

METASTATIC NEOPLASMS

Intraparenchymal Metastases

PATHOGENESIS AND PATHOPHYSIOLOGY. A major determinant of distribution of metastases is blood flow with respect to both end organ selection and affected compartment within the end organ.¹ However, receptor-mediated interaction between cancer cells and end organ is required before a metastasis can grow—a mechanism proposed by Paget more than 100 years ago (“seed and soil hypothesis”).² Tumors of the pelvis and mediastinum can spread through the valveless venous paravertebral low-flow system, known as Batson’s plexus. Rarely, metastases develop in another tumor, such as breast cancer metastasizing to meningioma or to a vascular malformation.³

To establish a metastasis in brain, cancers enter a cascade of events. First, tumor cells dislodge from the primary tumor, invade the extracellular matrix using proteolytic

enzymes (metalloproteinases and cathepsins), and enter draining blood vessels. Following intravasation, they embolize to the first capillary bed where, depending on cancer type, they recognize surface molecules on endothelial cells in certain end organs.⁴ The tumor cells extravasate and grow within the parenchyma stimulated by trophic factors. These factors are produced by the tumor cells as well as by the target organs.⁵ As the cells circulate and grow, they survive by avoiding the killing effects of macrophages, natural killer cells, and cells of the reticuloendothelial system. Within the end organ, a metastasis cannot grow larger than 1 or 2 mm unless it develops its own vascular supply.⁶ Once grown to a critical mass, the metastatic cancer cells again enter the circulation. Hematogenous metastasis to the central nervous system (CNS) requires passage of cancer cells to the arterial circulation in the lung. Cancer cells arrest in the CNS at the gray-white junction in the same location as cardiogenic or atherosclerotic emboli.⁷ Gene expression profiling of brain metastases has identified candidate genes of possible importance for brain seeding.⁸ Cancer cells may enter a stage of “dormancy” for months to years after seeding to an end organ.⁹ This is especially common in melanoma and breast cancer and gives rise to tumor relapse years to decades after presumed “cure.”

EPIDEMIOLOGY AND RISK FACTORS. The exact incidence of cerebral parenchymal metastases remains unknown and population-based data are largely unavailable. It is estimated that metastases are between twice and 10 times more common than primary brain tumors. Clinical series underestimate the incidence of brain metastases due to incomplete ascertainment, whereas a frequency of up to 15% reported in autopsy series is likely an overestimation.¹⁰ In a Dutch population-based study, the frequency of brain metastases in patients with five common cancers was 8.5% over a 5-year period ([Fig. 47-1](#)).¹¹ Brain metastases may become more frequent with increasing survival of cancer patients as a result of more effective systemic therapies insufficiently penetrating into the CNS.¹² Virtually all systemic cancers have the capacity to disseminate to the brain or spinal cord. In adults, lung and breast cancer are the most common causes of cerebral metastases, although melanoma has the highest disease-specific incidence.¹¹ Hematological malignancies such as non-Hodgkin lymphoma (NHL) or the acute

TABLE 47-1

Classification of Neurological Complications of Cancer

- I. Metastasis of Cancer to the Nervous System (Direct/Metastatic)
- Intracranial (intraparenchymal and dural)
 - Leptomeningeal and ventricular
 - Bony (calvarium and skull base)
 - Spinal (vertebral, epidural, and intramedullary)
 - Nerves (cranial nerves, peripheral nerves, nerve plexus, or nerve roots)
- II. Nonmetastatic Neurological Complications of Cancer
- Vascular disorders
 - Cerebral hemorrhage in cancer patients
 - Intracerebral hematoma (intratumoral, coagulopathy, hypertension)
 - Subdural hematoma
 - Subarachnoid hemorrhage
 - Cerebral infarction
 - Atherosclerosis
 - Intravascular coagulation
 - Nonbacterial thrombotic endocarditis
 - Septic occlusion
 - Tumor embolus
 - Venous occlusion
 - Infections
 - Bacteria (*Listeria*, *Nocardia*)
 - Fungi (*Cryptococcus*, *Coccidioides*, *Histoplasma*)
 - Parasites (*Toxoplasma*, *Strongyloides*)
 - Viruses (varicella zoster, papovavirus, cytomegalovirus, herpes simplex)
 - Metabolic and nutritional encephalopathy
 - Drugs
 - Sepsis
 - Oxygen deprivation (hypoxia, ischemia)
 - Hypercapnia
 - Fluid and electrolyte imbalance
 - Hepatic failure
 - Vitamin deficiencies
 - Endocrine disorders
 - Side effects of chemotherapy, radiation therapy, surgery, or other diagnostic procedures
 - Paraneoplastic syndromes

Data from Posner JB: Neurologic Complications of Cancer. Philadelphia, Davis, 1995.

Figure 47-1. Primary tumors in patients with intracranial metastases: distribution versus frequency. Tumor type: 1, lung; 2, breast; 3, melanoma; 4, urogenital tract; 5, prostate.

leukemias tend to seed the leptomeninges but are rare causes of parenchymal metastases. In the pediatric population, osteogenic sarcoma, rhabdomyosarcoma, and testicular germ cell tumors are the most frequent solid brain metastases. With the exception of lung cancer, metastases tend to occur late in the course of a systemic malignancy. Up to 10% of patients with non-small cell lung cancer are found to have brain metastases at initial staging,¹³ a number that is surpassed by patients with small cell lung cancer (15%).¹⁴ In contrast, the average interval between the diagnosis of breast cancer and the development of brain metastasis is 3 years.

Delay reflects the speed of tumor growth and the time required to pass through intermediate organs such as the lung. The pulmonary circulation accounts for the usual passage of tumor cells to the cranial vault.

Two thirds of intracranial metastases are to the parenchyma of the brain. The remaining one third involve leptomeninges, subdural or extradural spaces. Brain involvement is in proportion to both tissue volume and blood flow. The cerebral hemispheres receive the majority of blood flow and are the site of nearly 75% of metastases, whereas the smaller and less vascular cerebellum, thalamus, and brain stem account for 15%, 5%, and 3%, respectively.⁷ Highly vascularized areas, including the leptomeninges, ventricles, and pituitary gland, receive a disproportionately large number of cancers. Hemispheric metastases lodge in regions where arterioles rapidly diminish in size to small capillaries, which occurs at the junction of cortical gray and white matter.⁷ Tumors of the pelvis or retroperitoneal space have proclivity for the posterior fossa.

CLINICAL FEATURES. Signs and symptoms of increased intracranial pressure (headache, nausea, and vomiting), seizures, and focal neurological symptoms typically herald the diagnosis of cerebral metastases (Table 47-2). Symptoms are often caused by excessive vasogenic edema surrounding a comparatively small metastasis and thus readily respond to corticosteroids. Headache, the presenting complaint in one half of patients, is mild, not particularly disabling, and seldom migrainous. When visual or auditory features suggest migraine, these symptoms should raise concern for seizure activity (Video 74, Secondary Generalized Seizure). Headache may be worse in the morning as a result of increased edema from carbon dioxide retention and venous pooling within the tumor during sleep. Headache is ominous when associated with emesis, hiccups, yawning, transient visual loss, or altered awareness. Seizures are the presenting complaint in up to one third of patients. Seizure frequency among cancer patients, however, is not sufficiently high to support the use of prophylactic anticonvulsants. Careful examination discloses weakness in two thirds of patients, but less than half complain of focal weakness (Video 4, Pronator Drift). Similarly, although only one third of patients note behavioral or mental status changes, when careful mental status testing is done, impaired cognitive function is apparent in three fourths of patients.¹⁵ The apathy, inattention, and abulia that accompany frontal lobe lesions are commonly attributed to exogenous depression. Psychotic thought disorders, unusually querulous and “viscous” personality changes, food intolerance, or hallucinations of smell and tingling may accompany lesions of the temporal lobe. Right parietal lobe lesions alter the ability to attend to one side of space and may produce apraxia of dressing (Video 40, Apraxia). Multiple metastases, often of breast or lung origin, can produce a confusional state. Cerebellar metastases, likely the most symptom-inducing lesions of all intracranial tumors, are heralded by imbalance, headache, or signs of spinal fluid flow obstruction (Video 214, Stance Ataxia).¹⁶

Hemorrhage within a metastatic brain tumor occurs in one tenth of patients and gives rise to acute symptoms. Metastases of choriocarcinoma, melanoma, papillary thyroid, and renal cell carcinomas are most prone to bleeding, although bronchogenic carcinoma, due to its overall incidence,

TABLE 47-2

Presenting Symptoms and Signs of Brain Metastasis

| SYMPTOM | COMMON SIGNS |
|--|-------------------------------------|
| Headache | Focal weakness or unexplained falls |
| Mental status change | Focal sensory deficits |
| Altered level of consciousness | Speech difficulty |
| Seizures occurring when older than 35 years of age | Aphasia, focal weakness |
| Papilledema or visual obscurations | Ataxia |
| Visual complaints or unexplained motor vehicle accidents | Visual field defect |

remains the most common cause of hemorrhagic brain metastasis.^{17,18}

DIFFERENTIAL DIAGNOSIS. One out of 10 presumed metastases are of other origin, including primary CNS tumors, abscess, granuloma, acute demyelinating disease, resolving cerebral hematoma, stroke, and radiation necrosis. Many nontumor masses have characteristic magnetic resonance diffusion signals and spectroscopy patterns. Brain abscesses occur with frequencies of less than 2% of those for intracranial tumors but are on the rise in immunodeficient populations. Granulomas in the brain result from infection with *Mycobacterium*, *Candida*, *Aspergillus*, *Cryptococcus*, and *Histoplasma* species. Demyelinating lesions of acute disseminated encephalomyelitis present as focal neurological dysfunction with seizures and edematous mass(es).

EVALUATION. Magnetic resonance imaging (MRI) with contrast medium is the most sensitive and specific noninvasive test to exclude or confirm brain metastasis. Unenhanced computed tomography (CT) may serve as an emergency imaging modality in a patient presenting with strokelike symptoms or cerebrospinal fluid (CSF) flow obstruction (Fig. 47-2). Administration of iodinated contrast dye with

CT only exposes the patient to the risks of allergy and renal failure and does not obviate the need for gadolinium-enhanced MR. The characteristic features of metastases include iso- to hyperintense signal on T1-weighted images. Edema appears as “finger-like” T2-weighted hyperintensity surrounding the hypointense tumor and sparing the cortex. The tumors are avidly enhancing after contrast administration but may exhibit irregular rim enhancement when central necrosis is present. Several newer techniques, including proton MR spectroscopy (with elevated ratios of choline to creatine) and diffusion-weighted MRI (DWI), can further delineate brain tumors from infections, abscesses, and strokes. However, these modalities lack sufficient specificity. Metastases from squamous cell or adenocarcinoma may contain cystic components filled with highly viscous proteinaceous material that can mimic the appearance of an abscess on DWI (Fig. 47-3).

In the absence of a known malignancy, the physician should obtain a history; complete physical and neurological examination including palpation of breast and prostate; CT of the chest, abdomen, and pelvis; serum chemistry and differential cell counts; liver enzyme studies; mammography; and cytological evaluation of urine sediment where appropriate. The indiscriminate search for serological “tumor markers” including prostate-specific antigen, carcinoembryonic antigen (CEA), CA-125, and CA19-9, is of little use. Without a known systemic cancer, as occurs in 5% to 10% of patients, the surgeon is obligated to provide surgical material from the brain for diagnosis of the primary tumor. If a primary site cannot be identified, the staining profile using immunohistochemistry may reveal the origin of the tumor (Table 47-3).

MANAGEMENT. The optimal treatment of patients with brain metastasis continues to evolve. Conventionally fractionated photon radiotherapy is successfully given to “radiosensitive” tumors (lung, breast, or germ cell origin), whereas “radioresistant” lesions (melanoma, renal cell

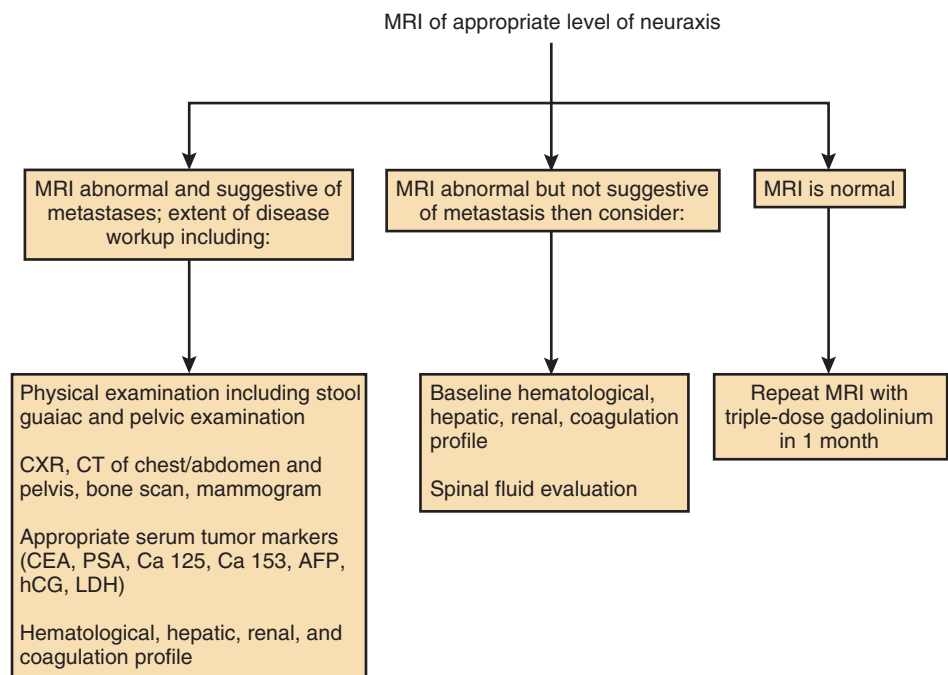

Figure 47-2. Evaluation of patients with suspected metastatic cancer to the central nervous system. AFP, α -fetoprotein; CEA, carcinoembryonic antigen; CT, computed tomography; CXR, chest x-ray; hCG, human chorionic gonadotropin; LDH, lactate dehydrogenase; MRI, magnetic resonance imaging; PSA, prostate-specific antigen.

Figure 47-3. Metastases to the central neuraxis. **A**, Isolated brain metastasis from liver cancer. A rim-enhancing mass lesion surrounded by vasogenic edema is seen at the gray-white matter junction of the left frontal lobe (T1-weighted MRI with gadolinium). **B**, Multiple metastases from non-small cell lung cancer (T1-weighted MRI with gadolinium). **C**, Hypothalamic metastasis in a patient with testicular non-Hodgkin lymphoma (arrowheads; T1-weighted MRI with gadolinium). **D**, Hemorrhagic metastasis in the right occipital lobe from papillary thyroid carcinoma (unenhanced CT). Vasogenic edema in the frontal lobes reflects multifocal metastatic disease. **E**, Left frontal metastasis from squamous cell carcinoma of the lung displays restricted proton diffusion (diffusion-weighted MRI). **F**, This axial T1-weighted MRI with gadolinium of the lower thoracic spine demonstrates an intramedullary metastasis from papillary thyroid cancer.

TABLE 47-3

Histological Stains with Tumor Specificity*

| HISTOLOGICAL STAIN | TUMOR SPECIFICITY |
|---|--|
| Keratin | Carcinomas |
| Mucicarmine (chromogranin) | Neuroendocrine tumors |
| HMB-45 | Melanoma |
| S-100 | Melanoma, sarcoma |
| CEA | Adenocarcinomas of colon, stomach, lung, breast, pancreas, uterus, ovary; medullary carcinoma of thyroid, squamous carcinoma |
| Estrogen and progesterone receptors | Breast and uterus |
| Muscle-specific actin | Rhabdomyosarcomas |
| α -Fetoprotein, human chorionic gonadotropin | Genitourinary tumor |
| Placental alkaline phosphatase | Germ cell tumors |
| Prostatic acid phosphatase or prostate-specific antigen | Prostate carcinomas |
| Leukocytic common antigen, immunoglobulin light chains, L26, UCHL 1, Leu-M1, and CD30 | Lymphoma |

*The approach suggested in the evaluation of patients with suspected brain metastases is identified in Figure 47-1.

carcinoma, colon cancer, or sarcoma origin) are best treated with single or multiple radiosurgical fractions. Prophylactic cranial irradiation provided in the setting of small cell lung cancer reduces the likelihood of CNS relapse by 20%, although it fails to provide long-term survival benefit.^{19,20} In general, these studies do not take into account the quality of life of radiation recipients, a subject of great concern to older individuals likely at risk of memory and intellectual alterations. Radiosurgery utilizes single fractions provided by “gamma knife” or linear accelerators, proton beams, or interstitial x-ray generators. These treatments are optimized for symptomatic lesions less than 3 cm in size (volume < 12 cm³), which are spherical and located in noneloquent brain areas. In general, technologies with rapid “fall-off” of radiation penumbra are best offered to sites close to the optic chiasm or the brain stem. Adjunctive whole-brain irradiation is often added after radiosurgery to prevent recurrence in local or distant sites.

Surgical excision is indicated in sizable solitary lesions, cases of impending morbidity or death from edema, herniation or hydrocephalus, or in patients with an unknown malignancy for whom operation will provide the diagnosis.²¹ Resection of multiple metastases should only be considered in patients with controlled systemic disease and reasonable

performance status. Finally, new chemotherapeutic agents as single or combination treatments (temozolomide,²² topotecan,²³ and capecitabine²⁴) have shown some promise and may play a greater role in the management of brain metastasis in the future. The importance of the blood-brain barrier in the treatment of metastatic brain cancer remains unclear; in fact, the major determinant of response to chemotherapy of brain metastases may be the responsiveness of the systemic cancer as the barrier function of the tumor vasculature is impaired.

PROGNOSIS AND FUTURE PERSPECTIVES. Untreated, brain metastases are fatal within 1.5 months of diagnosis. These patients succumb from neurological, not systemic, causes. Corticosteroids produce a clinical response in 70% of these patients but extend the median survival to only 2 months. For most patients, poor prognosis is associated with extensive systemic disease, multiple lesions, Karnofsky performance score below 70, recurrence within 4 months, and age older than 40 years.²⁵ Patients with breast metastasis younger than 40 years, however, carry a poorer prognosis than older subjects.²⁶ The palliative addition of whole-brain radiotherapy (WBRT), 30 Gy in 10 fractions, has extended median survival to 3 to 6 months. With palliative radiotherapy, the rates of neurological deaths are reduced to the level of those seen from systemic disease. Brain metastases from breast cancer carry a better prognosis than spread from lung cancer, melanoma, or colorectal cancer. Therapy is often based on the prognosis of the systemic cancer. With surgical resection and WBRT, patients with solitary brain metastases remain functionally independent for an extended period of time in comparison to recipients of radiation alone but do not live longer.²⁷ An individualized approach tailored to tumor type, stage, and patients' performance status is required. In a retrospective study, women with breast cancer and brain metastasis had a median survival of 1 month, 6.5 months, and 21 months when rendered corticosteroids only, WBRT, and surgery alone, respectively.²⁶

Future trends are likely to focus on the role of improved chemotherapy and "targeted" cancer treatments, such as small molecule inhibitors of growth promoting pathways, expanded use of radiosurgery to include larger and more numerous lesions, and the concomitant use of oxygen-enhancing or hypoxic radiosensitizers.

Meningeal and Ventricular Metastases

PATHOGENESIS AND PATHOPHYSIOLOGY. Leptomeningeal metastasis (meningeal carcinomatosis, lymphomatosis, and "neoplastic meningitis") denotes seeding of malignant cells to pia, arachnoid, and ventricular spaces. Tumor cells may enter the arachnoid space hematogenously through leptomeningeal veins, the choroid plexus, veins draining the diploe of the skull or marrow of the spinal column, through perineural spread along cranial or spinal segmental nerves, or as a result of inadvertent shedding during neurosurgical procedures. Rarely, primary or secondary parenchymal tumors of brain or spinal cord seed into the CSF, usually when there is involvement of the cerebellum in proximity to the subarachnoid space or fourth ventricle.²⁸ Meningeal seeding of cancer is frequently associated with disturbances of CSF circulation. Meningeal or parenchymal

tumor deposits at "bottlenecks" of spinal fluid flow result in obstructive hydrocephalus. CSF reabsorption at the arachnoid granulations may be impaired by cancer cells or proteinaceous debris. As with meningeal infections, chronic inflammation, or hemorrhage, hypoglycorrachia is observed

EPIDEMIOLOGY AND RISK FACTORS. Between 5% and 15% of patients with systemic cancer develop leptomeningeal metastases.^{29,30} Adenocarcinomas predominate (usually of breast, lung, or gastrointestinal origin), although melanoma, small cell lung cancer, the acute leukemias and high-grade NHLs have the highest disease-specific incidence (up to 50% in Burkitt's and lymphoblastic lymphoma) (Table 47-4). Risk factors for neuraxis seeding in lymphoid neoplasms include involvement of testis, orbit, paranasal sinuses, skull base or bone marrow, nodal invasion, and elevated lactate dehydrogenase at presentation.^{31,32} Although CNS involvement is rare at initial presentation in patients with acute myeloid leukemia, a 30% incidence is seen in patients with translocations involving MLL (11q23)—mostly included within the myelomonocytic (M4) and monocytic (M5) types as defined by the French-American-British Cooperative Group.³³ Although days to years may pass before the meninges are invaded, the diagnosis of leptomeningeal involvement is most commonly made 6 months to 3 years after the primary tumor is discovered. The meningeal compartment serves as a sanctuary for cancer cells where systemic chemotherapy does not achieve sustained therapeutic levels, a problem that has become more relevant with the implementation of more successful treatment protocols for various types of systemic cancer with limited penetration into CSF (taxane- or trastuzumab-based therapy for breast cancer, imatinib mesylate therapy for chronic myelogenous leukemia, and tretinoinic acid therapy for promyelocytic leukemia).

CLINICAL FEATURES. A progressive multifocal asymmetric polyradiculopathy combined with cranial neuropathies in a patient with systemic cancer is an almost pathognomonic manifestation of neoplastic meningitis (Video 43, Tongue Fasciculations). However, the clinical syndrome is commonly elusive and 5% to 10% of patients lack a history of cancer. Classical signs of meningeal irritation are frequently absent. In patients with acute leukemia, meningeal involvement is encountered at the time of staging procedures in the absence of neurological symptoms. Nonlocalizing signs and symptoms predominate. Headache, gait disturbance (apraxia, ataxia, or paresis) (Video 7, Abnormal Tandem Gait), psychomotor decline

TABLE 47-5

Cerebral Symptoms and Signs in Patients with Leptomeningeal Metastases from Solid Tumors

| SYMPTOMS | COMMON SIGNS |
|-------------------------|----------------------|
| Headache | Papilledema |
| Mental status changes | Dysarthria/dysphasia |
| Nausea/vomiting | Extensor plantar |
| Vertigo/lightheadedness | Hemiparesis |
| Seizures | Diabetes insipidus |

reminiscent of a subcortical dementia, and micturition abnormalities reflect direct effects of cancer or hydrocephalus (Video 211, Gait Ataxia). A more fulminant presentation with headache, nausea, vomiting, and hiccups is seen with aggressive neoplasms or CSF flow obstruction. The cranial nerves are either compressed by infiltrates of tumor cells or rendered ischemic when tumor invades the feeding vessels (Table 47-5). This results in impaired visual acuity, diplopia from oculomotor or abducens nerve involvement (Video 1, Cranial Nerve VI Palsy), facial numbness or atypical facial pain, Bell's palsy, sensorineural hearing loss, dysphagia, or hoarseness (Video 44, Dysphonia). The compromised spinal nerve roots induce radicular pain and paresthesias. Involvement of the cauda equina produces pain, foot drop, perineal dysesthesias, and incontinence (Video 237, Foot Drop). Acute focal neurological deficits resembling thrombotic small vessel occlusion arise from tumor progression in Virchow-Robin spaces and obstruction of blood flow in encased penetrating vessels.

DIFFERENTIAL DIAGNOSIS. Meningeal carcinomatosis has to be distinguished from opportunistic meningeal infections such as bacterial, varicella zoster, or cryptococcal meningitis and herpes simplex meningoencephalitis. In the absence of systemic cancer, chronic meningitis of infectious (*Borrelia*) or noninfectious etiology has to be considered. Cranial neuropathies in cancer patients can result from dural tumor growth, leukemic obstruction of vasa nervorum, or hyperviscosity. Communicating hydrocephalus is observed in recipients of whole- or partial brain radiotherapy.

EVALUATION. The diagnosis of meningeal cancer is generally difficult. A single CSF examination reveals tumor cells in 50% of patients, increasing to 80% after two procedures.³⁰ It is recommended that at least 10 mL of fluid from both ventricular and lumbar areas be sampled if possible, especially when assessing response to treatment. Sensitivity may be further increased if the sample is taken in proximity to a site involved clinically or radiographically (i.e., cisternal puncture in a patient with involvement of cranial nerves and lumbar puncture in a patient with cauda equina syndrome).^{34,35} CSF cytology remains persistently negative on repeated fluid examinations in 20% of patients with leptomeningeal disease.³⁰ Certain tumors, such as sarcomas or malignant gliomas, are seldom detected in CSF because their cells strongly adhere to the leptomeninges or occur as focal nodules rather than widespread leptomeningeal disease.³⁶ Lymphatic neoplasms are even more challenging because, in a cell suspension, they are frequently indistinguishable from reactive infiltrates on morphological grounds. Cell numbers are commonly insufficient for flow cytometry

characterization. Polymerase chain reaction (PCR)-based clonality assessment is available, but sensitivity and specificity of this test in CSF remain unknown. MRI is a valuable tool in the investigation of leptomeningeal metastasis. Often, gadolinium-enhanced MRI is definitive in the absence of CSF cytological abnormalities or provides equal sensitivity to CSF cytology. Typically, MRI delineates leptomeningeal or subependymal enhancement, superficial cerebral lesions, enhancement of cranial nerves, or communicating hydrocephalus, with the latter occurring most often in patients with solid, rather than hematological, tumors (Fig. 47-4).^{37,38} The single most characteristic finding is the appearance of thickened, often nodular enhancing lumbar nerve roots within the subarachnoid space. In the absence of contrast-enhancing lesions, increased sulcal signal on fluid attenuated inversion recovery sequences may be of diagnostic value in the correct clinical setting. The notion that intracranial hypotension after a lumbar puncture may mimic the findings of neoplastic meningitis is a myth. Intracranial hypotension results in diffuse pachymeningeal enhancement that is easily distinguished from the typically multifocal, leptomeningeal abnormalities of carcinomatosis. Nonetheless, an imaging study is preferably obtained prior to lumbar puncture, especially if obstruction of CSF flow is suspected.

Biochemical markers such as vascular endothelial growth factor or carcinoembryonic antigen have not improved the diagnosis of leptomeningeal cancer. Exceptions are α -fetoprotein and β -human chorionic gonadotropin, which, given an adequate clinical setting and imaging findings, may be diagnostic for nongerminomatous germ cell tumors of the CNS and obviate the need for tissue-based confirmation of diagnosis.³⁹

In patients without the diagnosis of systemic cancer or in the absence of imaging or CSF findings, a meningeal biopsy may be indicated. As with parenchymal CNS lymphoma, it is advisable to withhold the use of corticosteroids until appropriate diagnostic material has been retrieved if leptomeningeal lymphomatosis or leukemia is suspected.

To plan therapy, many clinicians perform CSF flow studies using ¹¹¹indium- or ⁹⁹Tc-diethylenetriamine pentaacetic acid or ⁹⁹Tc-macroaggregated albumin, which is injected into the lumbar CSF. Sequential scans may reveal obstruction at the level of the basal cisterns, the spinal canal, within the ventricular system, or over the cerebral convexities; localized hypoperfused regions of CSF circulation; or CSF reabsorption abnormalities.⁴⁰

MANAGEMENT. Therapy is based on irradiation and chemotherapy. As a general rule, symptomatic or nodular foci of tumor require irradiation, whereas chemotherapy is provided to patients without these findings. Radiation therapy of tumor nodules larger than 5 mm and sites of obstruction of CSF flow or reabsorption is provided as local boosts. Radiation to the entire neuraxis is generally avoided, with the exception of patients with isolated meningeal disease, excellent performance status, and bone marrow reserve.

Chemotherapy can be administered either systemically or intrathecally, but in most instances intrathecal chemotherapy via an Ommaya device is the preferable route of administration. The device, a titanium-based reservoir covered by a Silastic membrane implanted beneath the galea

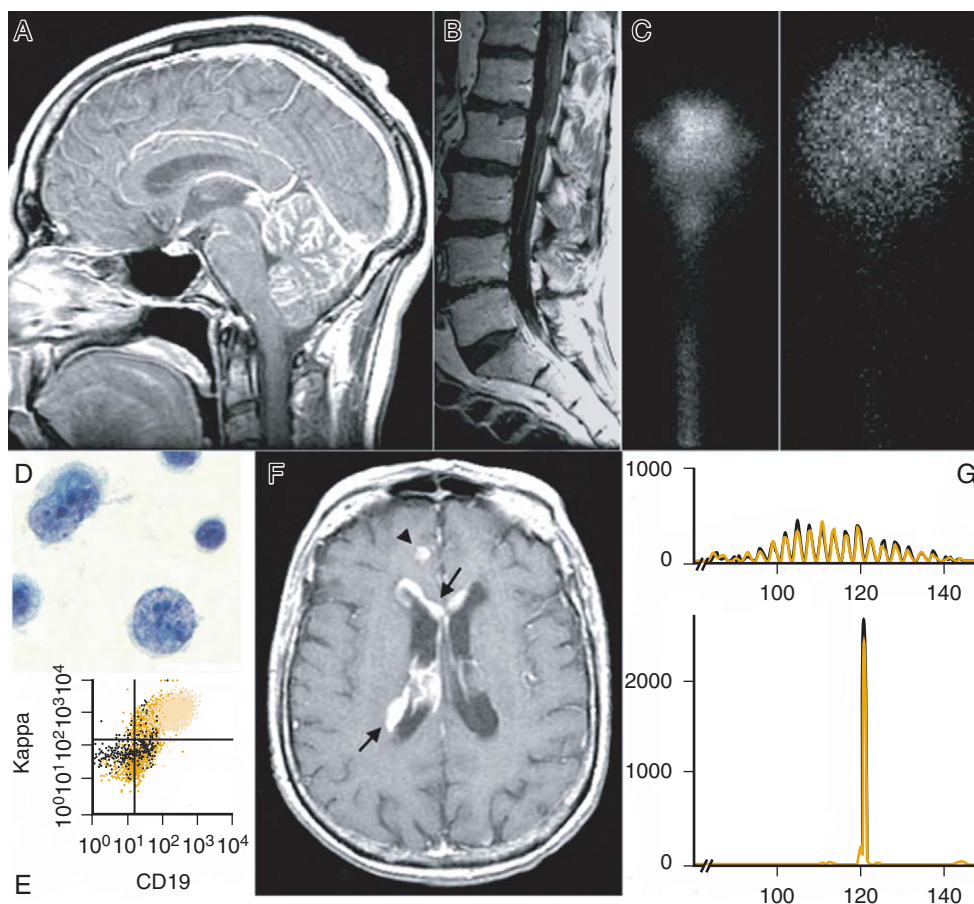

Figure 47-4. Leptomeningeal metastases. **A**, Extensive leptomeningeal seeding to the posterior fossa (cerebellar foliae and surface of pons and midbrain) is demonstrated on this T1-weighted MRI with gadolinium of a patient with esophageal cancer. **B**, This patient presented with cauda equina syndrome after removal of a pituitary metastasis from poorly differentiated adenocarcinoma of unknown origin. T1-weighted MRI with gadolinium shows linear and nodular enhancement of lumbosacral nerve roots. CSF analysis confirmed carcinomatosis. **C**, ^{99m}Tc -DTPA-cisternography of a patient with systemic diffuse large B cell lymphoma shows early ventricular filling 4 hours after radiotracer injection into the lumbar cistern (*left*). The subarachnoid space overlying the cerebral hemispheres is only outlined on late images (48 hours; *right*). Cytopathological evaluation of CSF revealed meningeal lymphomatosis. **D**, Microscopic view of CSF sediment of a patient with meningeal involvement by diffuse large B cell lymphoma. The large atypical neoplastic cells are easily distinguished from small reactive lymphocytes (scale bar = 20 μm). **E**, Automated fluorescent cell sorting using kappa light chain and CD19 antibodies identifies a clonal B cell population (right upper quadrant of this scatter plot; same patient as in part D). **F**, Subependymal (*arrows*) and leptomeningeal (*arrowhead*) tumor deposits in a patient with meningeal metastases from systemic non-Hodgkin lymphoma (T1 with gadolinium). **G**, Immunoglobulin heavy-chain gene rearrangement analysis of DNA isolated from CSF of a patient with lymphomatous seeding of leptomeninges. Polymerase chain reaction using DNA isolated from CSF and degenerate primers for the complementarity determining region III of the immunoglobulin heavy-chain gene yielded a single product of 122 base pairs in length reproducible in duplicate assays (*bottom*, two superimposed curves—x-axis is the length of PCR product in base pairs, and y-axis is the relative concentration of PCR product; *top*, “polyclonal control” using DNA isolated from a human tonsil as a template).

aponeurotica in communication with the ventricle, serves as a painless delivery port.⁴¹ Complications from its use occur in 5% to 20% of patients and include infection, failure, bleeding, or drug toxicities to white matter.⁴² When resorptive hydrocephalus complicates neoplastic meningitis, placement of a ventriculoperitoneal shunt with an in-line on/off valve and reservoir should be used.

Commonly used chemotherapeutic agents include methotrexate (MTX; 12 mg twice a week), cytarabine (50 mg twice a week or liposomal cytarabine every 2 weeks), and thiopeta (10 mg twice a week); these should be used until CSF is cleared of malignant cells. Remission induction is followed by variable consolidation and maintenance schedules. Combination of these drugs or the addition of corticosteroids does not appear to improve outcome compared to single agents.^{43,44} Myelosuppression can occur after intrathecal chemotherapy. If MTX is chosen, this complication can be

prevented by using folinic acid (10 mg every 6 hours for 24 hours after administration of MTX). Use of the extended-release preparation of cytarabine results in extended time to neurological progression and an increased complete response rate but does not prolong survival.⁴⁵⁻⁴⁷ Intrathecal rituximab is an alternative for patients with meningeal seeding from B cell lymphoma.^{48,49} Intensive treatment regimens are required in adults with CSF seeding by leukemia. Early whole brain radiation therapy (WBRT) is provided with intrathecal MTX or triple therapy.⁵⁰ However, the appearance of neurocognitive sequelae without improved survivorship has prompted investigators to delay or defer WBRT in favor of high-dose MTX or cytarabine.⁵¹ The most common adverse reaction to intrathecal administration of chemotherapy is chemical meningitis. This is most common after liposomal cytarabine but can effectively be treated with corticosteroids. A strokelike syndrome is a rare

complication of intrathecal MTX injection occurring 7 to 10 days after treatment. Symptoms are transient and re-exposure without recurrence of the syndrome has been described.^{52,53} A calcific leukoencephalopathy with devastating cognitive sequelae follows the combination of whole brain radiotherapy with high daily fractions and subsequent intrathecal MTX. It must be stressed again that intrathecal chemotherapy is contraindicated if spinal fluid flow is obstructed by a meningeal or parenchymal deposit at a bottleneck such as the foramen of Monro or the aqueduct. Only after successful treatment with irradiation can such treatment be reconsidered.

Systemic chemotherapy options for leptomeningeal cancer exist. High-dose MTX (exceeding 3 g/m²) or cytarabine (3 g/m²) given intravenously penetrate into the CSF at therapeutic concentrations and the pharmacokinetic profile appears even better than with direct intrathecal administration. However, incorporation in chemotherapy regimens targeting the systemic component of the disease is difficult; thus, these regimens are usually reserved for patients with isolated meningeal disease.⁵⁴ Responses of leptomeningeal carcinomatosis from breast cancer to systemic hormonal therapy (antiestrogens and aromatase inhibitors) have been reported.

Patients with NHL at high risk of nervous system involvement commonly receive prophylactic intrathecal chemotherapy or cranial irradiation. Prophylactic treatment of brain or meninges is provided for lymphoma of testicular, eye, or cranial sinus origin as well as lymphoblastic histologies or Burkitt's lymphoma of any location.³¹ Intrathecal MTX (12 mg weekly for five doses) may be combined with cytarabine or hydrocortisone.

MTX-based regimens are provided as prophylaxis of and treatment for CNS involvement in children with acute lymphocytic leukemia. These therapies include intrathecal MTX or MTX in combination with cytarabine and corticosteroids (triple intrathecal therapy: MTX 15 mg/m² to a maximum of 15 mg, cytarabine 30 mg/m² to a maximum of 60 mg, and hydrocortisone 60 mg/m²). In addition, systemic MTX is often included in the consolidation phase of treatment, after which is provided whole brain radiation therapy.⁵⁵ Intrathecal chemotherapy is sufficient for patients with standard risk. High-dose systemic MTX is provided in patients at intermediate risk who are not radiated. Adults are prophylaxed with whole-brain XRT (with inclusion of the posterior retina and orbital apex [optic nerve sheath; 24 Gy at 2 Gy/day in 12 fractions]). High-risk children receive 18 Gy at 1.8 Gy/day in 10 fractions. Lower radiation doses may be possible with intensification of systemic chemotherapy. Because CNS involvement is rare at initial presentation in patients with acute myeloid leukemia, CNS prophylaxis is not generally provided.

PROGNOSIS AND FUTURE PERSPECTIVES. Although a percentage of patients with leukemia, lymphoma, and breast cancer respond to treatment, the prognosis for patients with non-small cell lung cancer, other adenocarcinomas, and melanoma is extremely poor both quoad vitam and in regard to functional recovery. Patients with leptomeningeal spread from breast cancer survive a median period of 7 months. The survival is reduced for other solid tumors. Without treatment, patients succumb within 6 weeks.

Survival extends to 3 to 6 months with radiation therapy to symptomatic sites and intrathecal chemotherapy.³⁸

Future trends are likely to concentrate on treatments utilizing slow-release chemotherapy agents or those with high penetrance of the CSF after parenchymal administration. Drugs being evaluated for neoplastic meningitis include topotecan,⁵⁶ gemcitabine,⁵⁷ mafosfamide,⁵⁸ diaziquone,⁵⁹ cytokines, a microcrystalline formulation of temozolomide,⁶⁰ and radioactively labeled monoclonal antibodies.

Skull-Base Metastases

Less common than parenchymal brain metastases are those tumors compressing dura from sites in bone of the calvarium (plasmacytoma or myeloma), those surrounding paranasal sinuses (carcinomas of the sinus epithelium or parotid, submandibular, or maxillary glands), and the cranial lymphoid tumors (lymphoma or plasmacytoma of the sinuses, lacrimal glands, and orbit) that spread directly through the bone and periosteum to the dura. In addition, cancers of breast and prostate origin also produce these dural masses (Table 47-6).

PATHOGENESIS AND PATHOPHYSIOLOGY. The skull base and the dura are involved by cancer by hematogenous spread, direct extension from tumors of paranasal sinuses, or perineural spread from tumors of the skin and skin appendages of the face and neck. Pelvic and mediastinal tumors may reach these structures through Batson's plexus. Skull-base metastases most commonly involve the middle cranial fossa, in the area of the Gasserian ganglion. Other sites include the jugular foramen, occipital condyle, and orbit. Often, the cancer appears as a thin skin of tumor cells, termed *en plaque*.

EPIDEMIOLOGY AND RISK FACTORS. Metastases to the skull base usually fall within the territory of the otolaryngological surgeon or oncologist. Cancers of the breast, lung, and prostate have a propensity to produce skull-base and dural metastases, which can entrap the cranial nerves and vessels at their exit foramina. Skull-base involvement also occurs in giant cell tumors, tumors of the orbit and nasopharynx, eosinophilic granuloma, chordomas, and sarcomas of the skull base. Dural and skull-base metastases appear to be a late complication of cancer; most patients

TABLE 47-6

Syndromes of Base of Skull Metastases and Their Associated Symptoms

| SYNDROME | SIGNS AND SYMPTOMS |
|------------------------|--|
| Orbital and parasellar | Progressive, dull, continuous pain in the supraorbital area over the affected eye, diplopia, proptosis of the involved eye, external ophthalmoplegia, first-division trigeminal sensory loss |
| Parasellar | Ipsilateral frontal headache, oculomotor or abducens palsies without associated proptosis or visual loss |
| Middle fossa | Facial pain or numbness referable to the second or third divisions of trigeminal nerve |
| Jugular foramen | Paralysis of cranial nerves IX through XI |
| Occipital condyle | Unilateral occipital pain and unilateral tongue paralysis |

Data from Greenberg HS, Deck MDF, Vikram B, et al: Metastasis to the base of the skull: Clinical findings in 43 patients. *Neurology* 1981;31:530-537.

have widely metastatic disease at the time this complication is identified.

CLINICAL FEATURES. Midline lesions in the anterior cranial fossa (tumors arising from the frontal sinus or the nasal cavity, ethmoid bone, or the olfactory groove) give rise to anosmia. Diverse neurological syndromes arise from dural metastases of the middle cranial fossa. Lesions compromising the superior orbital fissure give rise to external ophthalmoplegia, neuropathic pain or dysesthesias of the forehead, and exophthalmos. When the orbital apex is involved, visual disturbances, papilledema or optic atrophy, chemosis, and exophthalmos are encountered (Video 106, Trigeminal Neuralgia). The cavernous sinus syndrome is characterized by ophthalmoplegia and facial sensory disturbances. Destruction of the pituitary fossa or compression of its content leads to diabetes insipidus, heat/cold intolerance, fatigue, menstrual irregularities, and decreased libido. Heteronymous visual field disturbances ensue when the optic chiasm is compromised. Dural neoplasms of the posterior fossa reveal themselves as occipital pain combined with hypoglossal nerve palsy (syndrome of the anterior occipital condyle). Tumors of the jugular foramen cause hoarseness; weakness of the sternocleidomastoideus muscle; sensory disturbance of the soft palate, pharynx, and larynx; and deviation of the soft palate. The presence of Horner's syndrome indicates infiltration of the retropharyngeal space (Video 17, Horner's Syndrome). Hearing loss, vertigo, nystagmus, and cerebellar dysfunction (Video 91, Cerebellar Ataxia) are seen with cerebellopontine angle tumors (Video 210, Bradydiadochokinesia).

In general, facial numbness or atypical facial pain in a cancer patient should elicit a search for a skull-base metastasis. The "numb chin syndrome" is characterized by oral and facial numbness in the distribution of the mental nerve (chin and lower lip) as a result of perineural spread, metastatic involvement of the mandible, infiltration of the Gasserian ganglion, occlusion of vasa nervorum by leukemic cells, or leptomeningeal disease.

EVALUATION. Owing to their insidious subacute onset, skull-based metastases are difficult to identify on MRI or CT where masses may coalesce with changes of prior irradiation or surgical extirpation. Often, the T2-weighted changes in contiguous bone after radiotherapy may be confused with tumor. Radionuclide bone scans with careful evaluation of the skull may improve diagnosis. Positron emission tomography is superior in purely osteolytic lesions. The clinician has to distinguish metastatic lesions from dermoid cysts and infections (*Mucor mycosis*).

MANAGEMENT. Treatment depends on the nature of the underlying tumor and is typically confined to irradiation. Prognosis is dependent on type and extent of systemic malignancy. Radiation to the base of the skull may restore function or at least prevent further progression. Surgical removal is indicated in localized lesions and good performance status. Depending on tumor type, a response to systemic chemotherapy is possible.

Spinal Metastases

PATHOGENESIS AND PATHOPHYSIOLOGY. Malignant spinal cord compression (MSCC) results from the direct extension of a hematogenous metastasis to a vertebral

body into the epidural space or the pathologic fracture of a vertebral body infiltrated by a metastatic deposit resulting in cord injury by a bone fragment or spine instability. Involvement of posterior spine elements with nerve root impingement is less common. Transforaminal progression of paravertebral tumor is encountered in lymphoma and neuroblastoma. Other paravertebral tumors, such as the Pancoast tumor of the lung apex, infiltrate the epidural space after destruction of a vertebral body. Primary hematogenous seeding to the epidural space is a rare cause of MSCC. Spinal cord compression can also result from intradural mass lesions (large leptomeningeal metastases) (Fig. 47-5).

The mechanism of cord injury is not entirely understood. The early myelopathy associated with MSCC may be due to impairment of venous drainage leading to intramedullary vasogenic edema. Irreversible cord necrosis results from ischemia. Pathological fracture of a vertebral body and posterior displacement of bone fragments leads to mechanical cord destruction. Demyelination or necrosis of white matter is the predominant autopsy finding at the level of cord compression, whereas gray matter is relatively well preserved.

EPIDEMIOLOGY AND RISK FACTORS. Compression of the spinal cord is one of the most devastating neurological complications, affecting 5% to 10% of patients with cancer.⁶¹ The majority of patients with MSCC are older than 50 years of age. The lifetime incidence in cancer patients is 1% to 6%, although autopsy series have revealed higher percentages (5% to 10%).⁶² The most common types of cancer accounting for spinal cord compression are breast, prostate, and lung cancer and lymphoma (Table 47-7).⁶¹⁻⁶⁴ The cumulative incidence of MSCC is disease specific and is highest in multiple myeloma (8%),

prostate cancer (7%), nasopharyngeal cancer (6.5%), and breast cancer (5.5%).⁶² The median interval between cancer diagnosis and manifestation of MSCC ranges from 6 to 12.5 months. Late axial bone metastases causing cord compression are more common in breast cancer (43 months). Although spinal cord compression as part of the presenting oncological syndrome is rare, 20% of MSCC cases lack a history of cancer.⁶⁵ MSCC as the primary manifestation of a malignancy is more common in NHL, myeloma, and lung cancer, especially the small cell variant; it is almost unheard of in breast cancer. Two thirds of MSCC cases affect the thoracic spine and most of the remainder occurs in the lumbar region. Colon and prostate cancer seem to have a predilection for the lumbosacral spine. Multiple epidural metastases are detected upon initial presentation in up to one third of patients in whom the whole axial skeleton is investigated.⁶⁶ One in 10 patients develops a second metastatic deposit causing cord compression at a different spine level within 5 months of the first event.

The tumor spectrum causing cord compression is quite different in the pediatric population. Neuroblastoma and Ewing's sarcoma predominate, followed by primary vertebral osteosarcoma and lymphoma. Cord compression at initial manifestation of the tumor occurs more frequently than in the adult population.⁶⁷

CLINICAL FEATURES. Pain is the most common presenting symptom in patients with metastases involving the axial skeleton (Table 47-8). Any back pain in a patient with cancer known to seed to spine or epidural space should be considered of metastatic origin until proven otherwise. In its early stage, the pain may be localized to the affected spine segment. Pain likely ensues when the richly innervated periosteum is involved. The vertebral body affected by metastatic spread is tender to percussion. The pain resulting from epidural mass effect is typically exacerbated by sneezing, coughing, or the Valsalva maneuver. Because the recumbent position aggravates the pain, many patients experience maximum intensity upon awakening in the morning or even have to sleep in a sitting position. Compression of a nerve root is associated with excruciating

TABLE 47-8**Signs and Symptoms of Spinal Cord Compression**

| |
|-----------------------|

| Autonomic dysfunction |
| Sensory loss |
| Ataxia |

pain in the corresponding radicular distribution. It has a lancing character and is likewise aggravated by Valsalva maneuver. Radicular pain in the thoracic region is usually bilateral, whereas cervical and lumbar radiculopathies are unilateral. Paravertebral muscle spasm caused by nerve root irritation from a metastasis results in straightening of the physiologic cervical or lumbar lordosis. Straight leg raising (Lasegue maneuver) or, more specifically, crossed straight leg raising (passive elevation of the contralateral, pain-free leg) exacerbate a radiculopathy. Referred pain may mimic a radiculopathy. Especially with intraneural tumor spread, neuropathic features (allodynia, hyperpathia, and hyperalgesia) may predominate. Neurological symptoms typically evolve within weeks to months of the onset of back pain. Hyperacute presentation with the evolution of paraplegia within hours to days of onset of neurological symptoms is not uncommon in bronchogenic carcinoma. A much slower course is typical for metastases from breast cancer. Motor dysfunction (paraparesis or quadriparesis and spasticity) is the earliest sign and occurs before sensory disturbance. Typical early complaints are leg "heaviness" and difficulty climbing stairs or getting up from a chair. Epidural progression of metastases to the upper lumbar spine results in a conus medullaris syndrome with distal lower extremity weakness, saddle paraesthesias, and overflow leakage from bladder and bowel. Ataxia in a patient with MSCC reflects compression of spinocerebellar pathways (Video 7, Abnormal Tandem Gait; Video 91, Cerebellar Ataxia). Only few patients report diminished sensation to all sensory qualities below the level of compression at initial presentation. The level of hypesthesia is usually two or three segments below the metastatic lesion. Discrepancy of up to 10 levels above or below the lesion has been described. Tingling paresthesias radiating down the spine into the extremities upon brisk flexion of the neck (Lhermitte's sign) indicate an intrinsic or extrinsic spinal cord process. Symptoms of neurogenic bladder dysfunction are less common at symptom onset but are frequently overlooked or "rationalized" by the patient. At diagnosis, almost half of patients with MSCC are incontinent or require catheterization.⁶⁸ The presence of Horner's syndrome indicates transforaminal progression of tumors located at the level of the cervicothoracic junction and infiltration of the stellate ganglion (Video 17, Horner's Syndrome).

DIFFERENTIAL DIAGNOSIS. Infiltration of the lumbosacral plexus or peripheral nerves originating from it (femoral and sciatic nerves) has to be distinguished from malignant epidural compression of a root or the cauda equina. With unilateral involvement, bladder and bowel symptoms are absent; however, bilateral infiltration of plexus or nerve has been seen in neurolymphomatosis and perineural spread from pelvic malignancies. Herpes zoster is encountered at spinal levels previously or concurrently affected by cancer. The presence of the cauda equine syndrome is suspicious for leptomeningeal carcinomatosis. Signs and symptoms referable to intracranial disease (headache and asymmetric cranial neuropathies) facilitate the diagnosis. Intraparenchymal spinal cord metastases and primary cord tumors are rare but may resemble epidural disease. Metastatic cord tumors predominantly arise from small cell lung and breast cancer.⁶⁹ Infectious (herpes simplex and human T lymphotropic virus) or autoimmune

myelitis are examples of myelopathies not directly cancer related that have to be distinguished from MSCC. Predominance of transverse myelopathic features in the absence of pain is indicative of an intraparenchymal process. Spinal cord hemisyndromes indicate intrinsic spinal cord disease. Leptomeningeal spread of highly aggressive tumors can lead to spinal cord infiltration, causing an overlap syndrome of extrinsic and intrinsic cord disease. Metastases have to be distinguished from other pathologic processes involving the axial skeleton, epi- and intradural space, and spinal cord. Bacterial abscesses typically cause end plate destruction and invasion of the disc space, whereas metastatic deposits leave the latter intact.

EVALUATION. With the availability of MRI, the diagnosis of MSCC has been simplified. The decision to use this tool is dependent on the clinical evaluation. New onset or change in character of preexisting back pain in a cancer patient or atypical back pain in the absence of a cancer history warrant measures beyond plain x-ray films and symptomatic therapy. MRI of the whole spine is the most sensitive diagnostic test when MSCC is suspected in a cancer patient (Fig. 47-6). The study can accurately identify the level of the metastatic lesion and guide the radiation oncologist in planning the treatment. Multiple levels of involvement are present in up to one-third of patients. Vertebral metastases without protrusion into the epidural space are detected before a potentially irreversible cord syndrome ensues. Plain films of the spine lack sufficient sensitivity and multiple levels of involvement are easily missed. Myelography after intrathecal injection of water-soluble

contrast dye with or without CT (myelography and CT myelography) remains an option for patients in whom MRI is contraindicated. Scintigraphic examination of the skeletal system is most useful as a screening procedure for bone metastases. The osteolytic lesions of myeloma may completely evade scintigraphic detection. Positron emission tomography is likewise most useful as a staging procedure and cannot substitute for more detailed anatomic imaging procedures. Accurate treatment planning requires a tissue diagnosis. If cancer initially presents with MSCC, a biopsy is mandatory prior to initiation of therapy. This can be done by excisional biopsy of the mass or by CT-guided needle biopsy

A lumbar puncture is of no diagnostic value in epidural cancer. However, the procedure might be considered in a patient presenting with transverse myelopathy or cauda equina syndrome before the results of imaging studies are known. Complete obliteration of the subarachnoid space by an epidural metastasis results in compartmentation of the spinal canal with the possibility of herniation (“coning”) after pressure reduction in the compartment below the level of obstruction by a lumbar puncture. Although cord herniation is a rare event, an MRI scan of the spine is advisable whenever MSCC is suspected before a lumbar puncture is performed. Thrombocytopenic cancer patients or those anticoagulated with fractionated heparinoids are at risk of developing a spinal epidural hematoma at the site of a lumbar puncture. A platelet transfusion or interruption of anticoagulation may be required before the procedure can be safely performed.

Figure 47-6. **A**, Ewing sarcoma (*arrowheads*) infiltrating the left lung apex and brachial plexus (*asterisk*: subclavian vein; artery and surrounding nerve fascicles are seen lateral and superior to the vein; T1-weighted MRI). **B**, Pathologic fracture of T12 (*arrow*) from renal cell carcinoma with posterior dislocation of a bone fragment causing epidural cord compression (T2-weighted MRI). **C**, Neurolymphomatosis in a patient with advanced diffuse large B cell lymphoma. I, iliac; MAX, gluteus maximus; MED, gluteus medius; P, piriformis muscle (T1-weighted MRI with gadolinium, fat suppression).

MANAGEMENT. Treatment with corticosteroids should be initiated immediately when MSCC is suspected. Corticosteroids reduce vasogenic cord edema and may prevent additional damage to the spinal cord from decreased perfusion. At the same time, pain management is facilitated. After an initial intravenous bolus, doses of up to 10 mg every 6 hours are most commonly used. Oral bioavailability is excellent, and intravenous application is only required in patients who cannot swallow. One fourth of patients with MSCC are provided comfort care only due to widespread disease and poor quality of life. Two thirds of patients are treated with conventional external beam radiation therapy.⁶² Various treatment schedules have been applied with comparable results. Protocols consist of 5 to 10 applications of 3 or 4 Gy or higher daily doses (5 Gy) during a 3-day induction phase, followed by daily fractions of 3 Gy for 5 days for consolidation.⁷⁰ In the palliative situation, single fractions of 8 Gy may be preferable. Response to treatment depends on tumor histology. As one would anticipate, patients with radiosensitive tumors (breast cancer and lymphoma) have a higher chance of regaining or preserving motor function than patients with less radiosensitive tumors (non-small cell lung cancer, melanoma, and renal cell carcinoma). Stereotactic radiosurgery of spinal metastases is feasible, but it remains to be shown if patients benefit from this approach.⁷¹

A benefit from surgical intervention has not been convincingly shown for the majority of patients. However, for carefully selected patients surgical intervention may preserve or even restore function. Commonly accepted indications are involvement of a previously irradiated segment, progressive painful radiculopathy despite irradiation, cord compression resulting from pathological fracture, spinal instability, and metastatic deposits from relatively radioresistant tumors. Selection criteria have been confirmed in a randomized prospective study.⁷² Posterior exposure with laminectomy at the level of cord compression has been a common approach.^{73,74} However, the metastatic focus, usually located within the vertebral body, can only be removed partially and laminectomy may increase the degree of instability when there is kyphotic deformity as a result of pathologic fracture. Thus, an anterior approach for surgical decompression is favored in selected patients. This procedure includes resection of the affected vertebral body and implantation of stabilizing instrumentation. Surgical morbidity is considerable, and frequently two surgical sessions are required. Systemic chemotherapy is an appropriate treatment only for patients with MSCC caused by highly chemosensitive tumors such as NHL. Radiation or surgical intervention may not be necessary.⁷⁵

It is unclear if asymptomatic patients benefit from treatment of incidentally detected epidural metastases. The therapeutic decision is dependent on tumor type and the patient's condition. Observation and serial MRI scans may be appropriate until pain ensues. Bisphosphonates are now widely used, particularly in the treatment of breast cancer and multiple myeloma. Monthly provision of intravenous pamidronate at a dose of 90 mg in combination with other treatment modalities for the underlying cancer reduces skeletal morbidity.

PROGNOSIS AND FUTURE PERSPECTIVES. The prognosis for the patient with epidural metastasis and cord compression is dependent on type and extent of the underlying

malignancy. Untreated, patients with MSCC succumb within 1 month of diagnosis. The median overall survival of patients with MSCC ranges from 3 to 16 months. Patients with therapy-sensitive tumors, such as lymphoma or myeloma, live longer (lymphoma, 6 to 14 months) than patients with solid tumors. Most patients die of systemic tumor progression. The most important determinant of functional outcome is the severity of neurological damage at the time treatment is initiated. Eighty percent of patients who are treated when a significant neurological deficit is absent and 50% of those with mild transverse myelopathy, but only 5% of patients who are paraplegic when definitive treatment is initiated, remain ambulatory or regain the ability to walk after treatment. Late return of function within 6 to 20 months of treatment has been observed in long-term survivors of MSCC in NHL. The faster the neurological deficit evolves, the lower the chance for recovery of motor function after treatment.

Peripheral Nerve Metastases

PATHOGENESIS AND PATHOPHYSIOLOGY. Cancer can affect peripheral nerves either by compression or by direct invasion (see Fig. 47-6). Direct invasion occurs from hematogenous spread of tumor to cranial or peripheral nerves or dorsal root ganglia or by direct extension from surrounding structures. Tumor cells spread along a plane of least resistance in the epineurium and perineurium. In the early stages of perineural spread, axial extension exceeds concentric growth. When concentric growth increases, symptoms ensue as a result of pressure degeneration and vascular compromise.⁷⁶

EPIDEMIOLOGY AND RISK FACTORS. Perineural tumor spread is encountered in head and neck malignancies such as squamous cell carcinoma, basal cell carcinoma, adenoid cystic carcinoma, or microcystic adnexal carcinoma; melanoma; lung and breast cancer; and lymphoma and abdominal and pelvic tumors (adenocarcinoma of the prostate). In general, this involvement is late in the disease, with the possible exception of head and neck cancer, neurotropic skin cancers, and lymphoma.^{77,78}

CLINICAL FEATURES. Frequently, pain, sensory symptoms, or weakness reflect involvement of single or multiple cranial nerves, spinal roots, nerve plexus, or peripheral nerves (Video 219, Ulnar Neuropathy, Froment Sign). More complex syndromes arise when tumor cells reach the skull base or the leptomeninges (Video 106, Trigeminal Neuralgia).

DIFFERENTIAL DIAGNOSIS. Distinction between metastatic and radiation-induced plexopathy is challenging. In metastatic plexopathy, pain predominates. Myokymia exists on the electromyogram in approximately two-thirds of patients with radiation fibrosis but rarely in tumor involvement (Video 110, Facial Myokymia).⁷⁹ Acute ischemic or inflammatory neuropathies and complications of paraneoplastic neurological syndromes and peripheral neurotoxicity of therapeutic agents should also be considered.

EVALUATION. Definitive diagnosis often requires neuroimaging studies of the appropriate area. Cranial neuropathies mandate both CT and MRI studies of the foramina of the skull base, whereas lesions of the brachial and lumbar

plexus obligate fat-suppressed MRI studies performed in three planes. Fat-suppressed studies are frequently performed to detect perineural tumor spread. Although this technique, in ideal circumstances, may reveal the cancer as linear contrast enhancement surrounding the nerve, it is prone to artifact, and loss of the perineural fat pad—a sensitive sign of cancerous involvement of cranial nerve exit portals at the skull base—may be obscured.⁸⁰ If imaging studies fail to reveal the presence of tumor, exploration of the affected area is recommended depending on the extent of the underlying malignancy, degree of patient's disability, and surgical accessibility and morbidity.

MANAGEMENT. Control of pain, frequently severe and unrelenting, is a priority. This control may be achieved with systemic chemotherapy or focal radiation. Additionally, pain control with analgesics or anesthetic blocks may be successful. Prognosis is often good for both pain control and functional improvement after treatment of lymphoma, breast cancer, and some head and neck malignancies.

PARANEOPLASTIC SYNDROMES

Paraneoplastic syndromes affect all levels of the central and peripheral neuraxis. In the majority of patients, the neurological syndrome precedes the diagnosis of the underlying neoplasm by months to years and, not uncommonly, the cancer is only identified at autopsy or not at all. Occasionally, a paraneoplastic syndrome develops in the setting of prior cancer that can no longer be identified. Spontaneous resolutions of paraneoplastic neurological syndromes and the causative cancer have been reported (Table 47-9).

PATHOGENESIS AND PATHOPHYSIOLOGY. Paraneoplastic syndromes result when an appropriate immune response against a tumor antigen cross-reacts with similar antigens expressed by the nervous system ("onconeural" antigen). Tumor cells must invade regional lymph nodes in order to trigger such an immune response. Onconeural antigens can be categorized into those expressed on the cell surface (voltage-gated calcium channels [VGCC], voltage-gated potassium channels, EFA6A, and associated dual-pore potassium channels) and intracellular antigens (cytoplasmic [CDR34, CDR62, amphiphysin, and Tr] versus nuclear [Hu and neuro-oncologic ventral antigen {NOVA}]). Other mechanisms of nervous system injury (e.g., possibly antibody-mediated injury to peripheral nerves in plasma cell dyscrasias, paraproteinemic neuropathies in NHL, and Waldenstrom's macroglobulinemia) are not considered in this chapter.

LOCATION OF UNCONEURAL ANTIGENS. Onconeural antigens are classified based on their subcellular expression pattern (Table 47-10). Intracellular antigens are found within the cytoplasm or the nucleus. Antibodies designated as anti-Hu or ANNA-1 (antineuronal nuclear antibody type 1) target 35- to 40-kDa proteins constituting a family of RNA binding proteins characterized by an RNA recognition motif of 80 amino acids. Three of these nuclear proteins (HuD, HuC, and Hel-N1) are neuron specific; the fourth is expressed ubiquitously (HuR). All of them share homology with the *Drosophila* embryonic lethal abnormal visual protein (ELAV). Hu proteins bind to AU-rich elements in the 3'-untranslated region of mRNA. The autoimmune

response targets all homologues, but antibody titers for the neuron-specific Hu proteins are higher than for HuR.⁸¹ The target antigens of anti-Ri antibodies (ANNA-2) are 55- and 80-kDa proteins encoded by NOVA-1 and NOVA-2 and seem to be predominantly expressed in subcortical structures (ventral brain stem and spinal cord).⁸²⁻⁸⁴ NOVA proteins regulate neuronal premessenger RNA splicing by directly binding to RNAs encoding multiple components of the inhibitory synapse (*c-Jun N-terminal kinase 2*, neogenin, and gephyrin).^{85,86} The CRMP-5-antigen (collapsing mediator response protein) is identified by Western blot as a 62-kDa protein that is encoded by a gene on chromosome 2.⁸⁷ The staining pattern for anti-CRMP-5 antibodies resembles that of anti-amphiphysin antibodies (synaptic regions of rat cerebellum, small nociceptive neurons in dorsal root ganglion, and neuronal elements in the rat gut wall). Sera from patients with cancer-associated retinopathy (CAR) contain antibodies against a photoreceptor cell-specific protein.⁸⁸ This calcium-binding protein, named recoverin, regulates rhodopsin kinase in a calcium-dependent fashion. Patients with melanoma-associated retinopathy (MAR) produce a diverse immunologic response targeting bipolar cells and other retinal elements.⁸⁹ There are three different proteins recognized by the anti-Yo antibody named according to their molecular weight: CDR34 (34 kDa),⁹⁰ CDR62-1,⁹¹ and CDR62-2. The 62-kDa protein contains a leucine zipper motif and binds to *c-myc*. These proteins are expressed in

CAR, cancer-associated retinopathy; CRMP-5, collapsin response-mediator protein 5 (likely the same protein as CV2); Glu, glutamate; LEMS, Lambert-Eaton myasthenic syndrome; MAR, melanoma-associated retinopathy; PCD, paraneoplastic cerebellar degeneration; PEM/SSN, paraneoplastic encephalomyelopathy/subacute sensory neuropathy; POM, paraneoplastic opsoclonus-myoclonus; SCLC, small-cell lung cancer; VGCC, voltage-gated calcium channel; VGKC, voltage-gated potassium channel.

the cytoplasm of cerebellar Purkinje cells. Antibodies targeting the metabotropic glutamate receptor mGluR1 have been identified in patients in remission from Hodgkin's disease.⁹² mGluR1 is abundantly present in dendrites of Purkinje cells. As opposed to other central onconeural antigen-directed antibodies, anti-GluR1 antibodies induce a neurological syndrome upon transfer into animals.⁹³ Anti-Tr antibodies are anti-Purkinje cell antibodies that can be recognized by their characteristic strong staining of Purkinje cells and proximal dendrites as well as punctate immunoreactivity in the molecular layer of rat cerebellum. These antibodies likely recognize conformational epitopes because characterization of the antigen has been unsuccessful. Thus, diagnosis can only be established by recognition of the characteristic pattern of immunoreactivity; confirmatory Western blot is unavailable. Anti-Ma antibodies stain all neurons of the central and peripheral nervous system, predominantly nuclei and nucleoli (speckled pattern), and testicular germ cells. In tumors associated with anti-Ma, cytoplasmic staining is observed. On Western blot, two distinct bands are recognized: 37 kDa (Ma1) and 40 kDa (Ma2). Ma2 is a 40-kDa protein exclusively expressed in brain and testicular tumors. Immunohistochemistry of brain slices with an anti-Ma2 antibody ("anti-Ta") stains the nucleus (especially the nucleolus) and cytoplasm of neurons.⁹⁴ Amphiphysin is a 128-kDa protein expressed at nerve terminals and has a putative role in endocytosis of synaptic vesicles. Amphiphysin and glutamic acid decarboxylase are associated with the cytoplasmic surface of synaptic vesicles.⁹⁵

Other onconeural antigens are expressed on the cell surface. In Lambert-Eaton myasthenic syndrome (LEMS), autoantibodies develop to the neuronal voltage-gated

calcium channels, especially the P/Q type, synaptotagmin, a synaptic vesicle protein acting as a calcium sensor, and the β subunit of the neuronal calcium channel. The former occurs far more frequently than the latter (85% to 90% versus 10% to 30%). Calcium channel function is disrupted by the antibody, leading to reduced acetylcholine release at the neuromuscular junction and at synapses of autonomic nerves.⁹⁶ Changes in membrane voltage and depolarization of the neuronal membrane by influx of potassium ions leads to the opening of calcium channels. Calcium ions flow into the nerve terminal, and neurotransmitter vesicles fuse with the neuronal membrane. When muscle biopsy specimens from LEMS patients receive a single supramaximal stimulus, miniature end plate potentials are normal in amplitude but reduced in number, suggesting a reduction in the number of quanta of acetylcholine being released into the neuromuscular junction. An antibody has been described in patients with ovarian teratomas that stains the inner aspect of the molecular layer adjacent to the granular neurons of the dentate gyrus of the hippocampus. Contrary to the intracellular onconeural antigens of central paraneoplastic syndromes, immunolabeling is restricted to neuronal cell membranes and processes, whereas cell bodies are spared. EFA6A, a protein involved in the regulation of dendritic development of hippocampal neurons, has been identified as a putative antigen of this process.⁹⁷ EFA6A interacts with KCNK1 (TWIK-1) and probably also KCNK3 (TASK-1) and KCNK9 (TASK-3), all members of a family of potassium channels containing four transmembrane and two pore-forming domains. TASK-1 and TASK-3 have been implicated in the control of breathing and arousal. Antibodies targeting the nicotinic acetylcholine receptor (nAChR) are found in the few cases of paraneoplastic myasthenia gravis. Antibodies directed against voltage-gated potassium channels (Shaker family) are identified in paraneoplastic neuromyotonia.⁹⁸

MECHANISMS OF PARANEOPLASTIC SYNDROMES. It appears that the serological immune response targeting intracellular antigens is not neuropathogenic but, rather, a surrogate marker for activation of cytotoxic T cells directed at peptide sequences derived from the intracellular antigen.⁸⁷ Thus far, immunoglobulin G (IgG) accounts for the only class of antibody associated with paraneoplastic syndromes, with IgG1 and IgG3 being the major subclasses.⁹⁹ IgG1 and IgG3 synthesis probably reflects a Th1-type response of CD4⁺ helper cells to the antigen. In the anti-Yo syndrome, paraneoplastic immunoglobulin production is entirely restricted to IgG1. In this disease, cytotoxic T cell lymphocytes may play a role in the autoimmune destruction of Purkinje neurons. Expanded populations of major histocompatibility complex class I-restricted cdr2-specific cytotoxic T lymphocytes (CD8⁺) have been identified in the blood of patients with paraneoplastic cerebellar degeneration.¹⁰⁰ For at least some of the onconeural antigens expressed on the cell surface (VGCC in LEMS),⁹⁶ a pathogenetic role has been proven or at least suggested.

CLINICAL IMPLICATIONS OF ONCONEURAL ANTIBODIES. Finding a tumor-specific anti-onconeural autoantibody in a patient with a neurological syndrome predicts the identification of an underlying carcinoma of a specific histological type. All small cell lung cancers (SCLCs) with or without paraneoplastic symptoms express the Hu antigen. Sixteen percent of patients with SCLC without neurological

dysfunction develop low titers of anti-Hu antibody. There is no overlap between the titers of anti-Hu antibodies in SCLC with paraneoplastic encephalomyelitis and sensory neuropathy and those without neurological symptoms. The presence of anti-Hu antibodies at low titers is correlated with confined tumor stage, complete treatment response, and improved outcome.¹⁰¹ Anti-CRMP-5 antibodies are also most commonly associated with SCLC. Immunoreactivity is seen in the underlying tumor. Cerebellar degeneration is most commonly associated with SCLC (anti-Hu and anti-PCA-2), adenocarcinoma of the breast and ovary (anti-Yo), and Hodgkin's disease (anti-mGluR1 and anti-Tr).^{102,103} One third of patients with ovarian cancer without neurological symptoms have circulating anti-Yo antibodies.¹⁰⁴ Antibodies targeting the metabotropic glutamate receptor mGluR1 have been identified in patients in remission from Hodgkin's disease.⁹² Tumor cells are rarely recognized by the anti-Tr antibody, raising the possibility that antibody production may be the result of the polyclonal B cell activation that frequently accompanies Hodgkin's disease.¹⁰⁵ Testicular tumors are discovered in 20% of patients who elaborate anti-Ta (anti-Ma2) antibodies. Anti-recoverin-mediated retinopathy is usually associated with SCLC and breast cancer, but it has also been described in gynecological cancers (ovarian, cervical, endometrial carcinoma, uterine sarcoma, and breast cancer) and Hodgkin's disease. Anti-recoverin antibodies are also found in patients with retinitis pigmentosa. Another type of retinopathy has been observed in melanoma (MAR). Voltage-gated potassium channel antibodies and acquired neuromyotonia have been found in patients with thymoma, SCLC, lymphoma, and plasmocytoma.⁹⁶ Myasthenia gravis is associated with thymic tumors in 10% of patients, especially older males.

PATHOLOGIC CHANGES IN PARANEOPLASTIC SYNDROMES. ANNA-1-related paraneoplastic encephalomyelitis is characterized by extensive, rapid, and irreversible neuronal loss; reactive gliosis; marked perivascular cuffing by lymphocytes; and meningeal infiltrates (CD4⁺ and CD8⁺ lymphocytes) predominantly affecting the limbic lobes, brain stem, cerebellum, and the gray matter of the spinal cord. Loss of neurons in the dorsal root ganglia along with an inflammatory infiltrate as well as secondary degeneration of the dorsal root and posterior column of the spinal cord are found in sensory neuropathy. Neuropathies are predominantly axonal, although segmental demyelination may also be found. Paraneoplastic opsoclonus-myoclonus occurs in the context of Purkinje cell loss, changes in the dentate nucleus, or demyelination of cerebellar white matter. Paraneoplastic cerebellar degeneration (PCD) is accompanied by diffuse degenerative changes of cerebellar cortex, especially loss of Purkinje cells, and deep cerebellar nuclei, thinning of the molecular layer, as well as a decrease in the number of granule cells. Meningeal and perivascular clusters of inflammatory cells are found. Autopsy data are scarce for mGluR1-associated PCD. Loss of Purkinje cells to a lesser degree than with other types of PCA and the absence of an inflammatory infiltrate have been noted. Autopsy findings in a patient with anti-Ma paraneoplastic encephalitis showed loss of cerebellar Purkinje cells, neurons in the dentate and inferior olivary nucleus, as well as perivascular and interstitial lymphocytes in the mesencephalic tectum and the tegmentum of medulla, pons, and midbrain.¹⁰⁶ Paraneoplastic retino-

pathy is characterized by diffuse degeneration of photoreceptor cells with relative sparing of cones, loss of cells of the outer molecular layer, and melanin-laden macrophages in the outer retinal layer and retinal pigment epithelium.¹⁰⁷

EPIDEMIOLOGY AND RISK FACTORS. Population-based incidence data are unavailable. In a large referral center for serologic testing of patients with suspected paraneoplastic syndromes, antibodies targeting ANNA-1 (Hu) are the most commonly detected autoantibodies (0.36% of submitted specimens), followed by CRMP-5 (0.35%), Yo (0.17%), PCA-2 (0.06%), amphiphysin (0.04%), ANNA-2 (0.02%), and ANNA-3 (0.01%).¹⁰⁸ Most patients with ANNA-1-positive paraneoplastic syndrome present in their seventh decade.¹⁰⁹ The majority are smokers, whereas data on gender distribution vary. In up to 20% of patients, a neoplasm is never identified.

CLINICAL FEATURES. Paraneoplastic syndromes afflict multiple sites of the nervous system to produce encephalopathy, rhombencephalopathy and cerebellar syndromes, myelopathy, sensory and motor neuropathy, peripheral neuropathy, disturbances of the neuromuscular junction, and myopathy. In general, the syndromes are never purely confined to one anatomical location.

Encephalopathy. Limbic encephalitis is characterized by dementia, retentive memory deficit indistinguishable from Korsakoff psychosis (Video 229, Wernicke's Encephalopathy), hypersomnia, anxiety, a delirious state, or psychiatric abnormalities (mood changes [depression], panic, delusions, and disinhibition) (Video 21, Disinhibition). Seizures can occur and are typically of the complex-partial type (Video 78, Frontal Lobe Complex-Partial Seizure). The syndrome is of subacute onset and evolves within 6 months.^{109,110} Movement disorders, including chorea, athetosis, parkinsonism, and dystonia (limbs, truncal musculature, and blepharospasm), are indicative of basal ganglionic involvement (Video 51, Parkinsonism in Alzheimer's Disease). Myoclonus can be of various neuroanatomical origin; typically, it is generalized and arises from cortical or brain stem structures (Video 57, Myoclonus).

Brain Stem Encephalitis. Brain stem encephalitis involves the medulla to produce vomiting, vertigo, nystagmus, ataxia, and bulbar palsy with dysarthria and dysphagia (Video 12, Dysdiadochokinesis). With more rostral disease, eye movements become restricted (internuclear or supranuclear gaze abnormalities) and pseudobulbar emotional lability is encountered (Video 10, Dysarthria; Video 202, Internuclear Ophthalmoplegia). Central hypoventilation requiring prolonged ventilatory support probably reflects impaired function of respiratory neurons (Fig. 47-7)

Photosensitivity and painless visual loss (ring scotomata) in combination with attenuation of retinal arterioles represent the classical clinical triad associated with paraneoplastic retinopathy. Patients complain of photosensitivity and light-induced glare, transient visual symptoms, and progressive visual loss. Visual acuity is decreased and color vision is impaired.¹¹¹ Anti-CRMP-5-associated retinitis/optic neuritis is likewise characterized by painless subacute vision loss. Visual hallucinations (spots and flashes) or illusions (tunnel vision) have been described

Cerebellar Syndromes. Paraneoplastic cerebellar degeneration (PCD) presents with appendicular and gait ataxia (Video 208, Titubation), dysarthria, and nystagmus progressing

Figure 47-7. Paraneoplastic syndromes. **A**, Fluid attenuated inversion recovery MRI (FLAIR) of a patient with anti-CRMP-5-associated encephalopathy clinically characterized by a choreiform movement disorder. Increased signal is seen in the right lenticular nucleus and the head of the caudate nucleus bilaterally. **B**, Encephalitis involving the mesial temporal lobes (FLAIR; same patient as in part A). **C**, Brain stem encephalitis (no antibody identified). **D**, Cerebellar degeneration (anti-Yo positive). This T1-weighted MRI demonstrates atrophy of the cerebellar vermis. **E**, Sensory ganglionitis (arrowhead; same patient as in parts A and B; T1 with gadolinium, fat suppressed). **F**, A thorough tumor search in the patient shown in parts A, B, and E only revealed an enlarged mediastinal lymph node (top, CT; bottom, PET; standardized uptake value: 4.7 [mildly increased metabolic activity]). Transesophageal biopsy confirmed small cell cancer. AA, ascending aorta; DA, descending aorta; S, superior vena cava; T, trachea.

over weeks to a few months (Video 8, Gaze-Evoked Nystagmus; Video 211, Gait Ataxia). In addition, patients may complain of diplopia and vertigo. PCD has to be distinguished from the severe sensory ataxia accompanying sensory neuropathy (Video 5, Sensory Ataxia). Continuous rapid, conjugate oscillations of the eyes in yaw, pitch, and roll aggravated by voluntary fixation or movement (opsoclonus) and myoclonus characterize a reversible syndrome observed in children with neuroblastoma (Video 209, Paraneoplastic Opsoclonus); in adults with SCLC, this syndrome is irreversible. Anti-Hu-positive PCD presents as axial ataxia, but signs of pancerebellar dysfunction evolve during the course of the illness.

Myelopathy. Various types of myelopathy have been described in the context of cancer. There are several reports of a rapidly developing necrotizing myelopathy that mimics an acute transverse myelitis in patients with lung cancer. This involves the spinal cord at the thoracic level, which produces CSF protein elevation. MRI can show patchy gadolinium enhancement and T2-weighted signal abnormality. Pathologically, widespread spinal cord necrosis is seen with little inflammatory response or evidence of vasculitis. However, in the absence of specific diagnostic markers, the pathogenesis of these syndromes often remains unclear.

Motor Neuron Disease. Rarely, cancer patients experience a disorder of the spinal cord that is similar to motor neuron disease (amyotrophic lateral sclerosis). One in five

patients with ANNA-1 antibodies develops signs and symptoms of motor neuron dysfunction. Patients complain of proximal muscle weakness at presentation, which can be asymmetric. Atrophy can be profound. Fasciculations are seen, but distinction from amyotrophic lateral sclerosis is usually simple on clinical grounds. With Hodgkin's disease, a subacute motor neuropathy with progressive painless, asymmetrical lower motor neuron weakness appears. The tendon reflexes are decreased. Unlike ALS, the bulbar muscles are usually spared, fasciculations are rare, and the course is benign. Lower motor neuron syndromes should raise the suspicion for lymphoma.¹¹²⁻¹¹⁴ Upper motor neuron syndromes are indicated by extensor plantar response and clonus (Video 84, Sustained Clonus; Video 203, Babinski Sign)¹¹⁰; mimicking primary lateral sclerosis, these are observed in SCLC or breast cancer.¹¹²

Central and Peripheral Hyperexcitability Syndromes. Patients with acquired neuromyotonia (Isaacs' syndrome) complain of muscle stiffness and cramps worsening with activity. On examination, fasciculations and myokymia are found. In contrast to movement disorders and stiff-person syndrome, symptoms may persist during rest and sleep (Video 238, Stiff-Person Syndrome).¹¹⁵ Stiff-person syndrome is characterized by fluctuating muscle stiffness and painful spasms. Symptoms are triggered by activity, emotion, or a startle response. The truncal (thoracic, abdominal, and lumbar paraspinal) and lower extremity musculature is predominantly involved. Symptoms resolve during sleep.^{116,117}

Peripheral Neuropathy. Patients with paraneoplastic peripheral neuropathies present with a wide spectrum of signs and symptoms reflecting involvement of sensory, motor, and autonomic fibers. A symmetrical sensory or sensorimotor polyneuropathy is the most common manifestation. The syndrome is slowly progressive in a fiber-length-dependent fashion, but subacute or acute (Guillain-Barre-like) presentations have been described. A severe, entirely sensory variant is characterized by profound sensory ataxia, polyminimyoelonus, total body hypaesthesia, and loss of deep tendon reflexes emerging over weeks (Video 5, Sensory Ataxia). Patients position their extremities poorly in space and adopt athetoid postures. Autonomic failure results in postural hypotension; gastroparesis, constipation, or intestinal pseudo-obstruction¹¹⁸; sweating abnormalities; and neurogenic bladder dysfunction (urinary retention) and erectile dysfunction. Pupils may be asymmetric and respond sluggishly to light. Involvement of C-fibers gives rise to disabling neuropathic pain. Cranial neuropathies are identified in 10% to 20% of patients with paraneoplastic syndromes and present as failure of olfaction, optic neuropathy, external ophthalmoplegia, facial dysesthesias, facial palsy, trismus, sensorineural hearing loss, loss of taste, and tongue fibrillations (Video 23, Cranial Nerve VII, Facial Diplegia; Video 43, Tongue Fasciculations; Video 230, Exotropia).

Disorders of the Neuromuscular Junction. Myasthenia gravis predominantly affects muscles innervated by nuclei of the brain stem, resulting in ocular palsies (intermittent diplopia), ptosis, weakness of eye closure, myopathic facies, as well as mastication and swallowing difficulty (Video 32, Cranial Nerve III Palsy). Furthermore, patients are dyspneic and struggle to hold their head up. Weakness increases as the day passes. Lambert-Eaton myasthenic syndrome involves muscles of trunk, limb girdles, and lower extremities. Patients, most of them men, complain about difficulty arising from a chair, climbing stairs, and walking. When the examiner requests that the patient perform repetitive or sustained muscle contraction, there is obvious improvement in strength of the lower extremity proximal muscles as the patient continues the task. Deep tendon reflexes are diminished. Autonomic symptoms (dryness of mouth, constipation, difficulty urinating, and impotence) are common.¹¹⁹

Myopathies. Paraneoplastic polymyositis is recognized as painless weakness of proximal limb muscles, especially of hips and thighs. Patients have difficulty arising from a deep chair, climbing stairs, or putting an object on a high shelf. Both neck flexion and extension are impaired. Only few patients complain of an aching pain. In dermatomyositis, a similar distribution of muscle weakness is observed. A lilac-colored (heliotrope) skin change around the orbits, on the bridge of the nose, and around fingernails is pathognomonic. An erythematous scaling rash is seen over the extensor surfaces of joints. Fifteen percent of patients with dermatomyositis have underlying cancer; this proportion is higher in patients older than 40 years.

Clinical-Immunologic Correlations. Neurological syndromes of paraneoplastic etiology are highly variable. Identical immunological profiles result in diverse clinical manifestations. In many cases, more than one paraneoplastic antibody is isolated from the patient's serum.¹⁰⁸ Few "pathognomonic" syndromic manifestations exist.

A severe sensory irreversible neuronopathy accompanied by limbic encephalitis is almost always associated with anti-Hu antibodies. CRMP-5-associated autoimmunity gives rise to a relentlessly progressing syndrome involving multiple levels of the nervous system: subacute dementia, a mostly sensory neuropathy, autonomic failure, an extrapyramidal syndrome (chorea and myoclonus), olfactory or gustatory impairment, and optic neuropathy/retinopathy (Video 57, Myoclonus). The typical patient with anti-Yo antibodies has a gynecological malignancy (ovary and breast) and displays signs of severe cerebellar dysfunction. Anti-Ma1 antibodies are found in patients with a cerebellar or brain stem syndrome. The majority of patients with anti-Ma2 antibodies present with limbic encephalitis or brain stem encephalitis.⁹⁴ Psychiatric symptoms, memory deficits, impairment of consciousness, hypersomnia, central hypoventilation, and seizures are observed in patients with ovarian teratomas and EFA6A-related autoimmunity. The anti-Ri-associated syndrome is typically characterized by opsoclonus, myoclonus, and ataxia (Video 209, Paraneoplastic Opsoclonus). Vision loss due to retinopathy or optic neuropathy is found in patients with antibodies targeting recoverin, retinal bipolar cells, and CRMP-5. Although in a few patients vision loss is the presenting symptom, all patients with anti-CRMP-5-associated paraneoplastic disease develop widespread peripheral and central nervous system involvement.¹²⁰

DIFFERENTIAL DIAGNOSIS. A variety of encephalitides resemble paraneoplastic encephalomyelopathy. Infections from herpes simplex and zoster, or other viral agents, Wernicke's encephalopathy, Leigh's disease, leptomeningeal carcinomatosis, and a cancer-unrelated encephalitis in patients displaying antibodies targeting members of the Shaker-related voltage-gated potassium channel family (KCNA1 [Kv1.1], KCNA2 [Kv1.2], and KCNA6 [Kv1.6])^{121,122} can all mimic the syndrome. The peripheral manifestations are difficult to distinguish from the dorsal root ganglion effects of vitamin B₁₂ deficiency, cytomegalovirus ganglionitis, Sjogren's syndrome, excessive ingestion of pyridoxine and autoimmune disorders, tabes dorsalis, diabetes, chemotherapy-related neuropathy, and direct tumor infiltration. When ataxia, dysmetria, or nystagmus is noted, clinicians must exclude direct metastatic invasion of the cerebellum or its meningeal coverings, the effects of medication such as cytarabine, strokes, disseminated encephalomyelitis, multiple sclerosis, and cerebellitis. Opsoclonus-myoclonus may occur sporadically after viral infections, with medication use such as intravenous phenytoin or diazepam, or in cases of amitriptyline overdose. Some chemotherapeutic agents, such as platinum, nitrosoureas, procarbazine, and tamoxifen, radiation fields inclusive of the optic nerves and chiasm, and the infiltrative effects of lymphoma may cause retinopathy with similar clinical features and should be considered as part of the differential diagnosis of paraneoplastic retinopathy. The rare hyperacute forms of paraneoplastic peripheral neuropathy must be distinguished from acute inflammatory demyelinating polyneuropathy. Clearly, "double-crush" syndromes occur by which these neuropathies have superimposed nerve damage of compressive (e.g., carpal tunnel syndrome and tardy ulnar palsy), neurotoxic (vincristine and paclitaxel), metabolic, and atrophic origins.

EVALUATION

MRI. MRI has aided in establishing the diagnosis, but findings are nonspecific or, unless obtained in the early stages of the disease, no abnormalities are detected (Fig. 47-8). Limbic encephalitis is characterized by subtle T2-weighted alterations of the amygdala and hippocampus reflecting inflammation and gliosis. Neuronal loss can be seen in chronic stages with enlargement of the temporal horn of the lateral ventricle. In the acute setting of paraneoplastic cerebellar degeneration, the MRI is normal, but cerebellar atrophy is soon noted and folia become more visible. The cerebellum becomes atrophic and scarred by glia when Purkinje cells are virtually lost. Electroencephalograms may show epileptic discharges in the temporal lobes. Cerebrospinal fluid analysis is abnormal in two-thirds of cases. However, findings are nonspecific and include lymphocytic pleocytosis, an increased protein level, an increased IgG index, and oligoclonal banding indicative of intrathecal immunoglobulin synthesis. Characteristic features of CAR and MAR exist on electroretinographic studies (decreased and delayed cone and rod-mediated responses). Electrophysiologic studies help in the recognition of peripheral paraneoplastic syndromes and stiff-person syndrome. Mixed axonal and demyelinating features are seen in sensorimotor neuropathies. Polymyositis and dermatomyositis are recognized by low-voltage, short or polyphasic motor unit potentials and increased recruitment. In myasthenia gravis, a decrementing compound motor action potential (CMAP) is elicited upon repetitive stimulation of a peripheral nerve (3 Hz). Single-fiber electromyography (EMG) reveals increased “jitter.” The edrophonium test defines the syndrome clinically and acetylcholine receptor antibodies are of confirmatory value. In LEMS, the weakened muscles exhibit resting and volitional reduced-amplitude CMAP and a decrementing response at low frequencies of stimulation. With rapid stimulation at 20 to 50 Hz or after 15 seconds of strong

voluntary contraction, electrical facilitation occurs, characterized by a twofold increase in CMAP. In neuromyotonia, motor nerve conduction studies reveal “after-discharges”; EMG shows spontaneous firing of morphologically normal motor unit potentials (fasciculations; doublets, triplets, and multiplets; myokymic discharges; and irregular bursts reaching a frequency of more than 50 Hz and up to 300 Hz). Stiff-person syndrome is characterized by continuous motor unit activity with morphologically normal potentials and simultaneous activation of agonist and antagonist muscles.

Serologic Studies. Paraneoplastic antibodies targeting onconeural antigens can help in the differential diagnosis of similar central or peripheral neurological syndromes and direct the search for the underlying malignancy. Paraneoplastic antibodies targeting onconeural antigens are detected in serum and CSF. In a small subset of patients with anti-Tr-positive PCD, antibodies may only be detectable in CSF.¹⁰⁵ Specificity of ANNA-1 for small cell cancer is sufficiently high to justify continued search if a different type of cancer is identified. Anti-CRMP-5 antibodies have been described in patients with SCLC, thymoma, and lymphoma.⁸⁷ In contrast to ANNA-1, antibody detection in neurologically asymptomatic patients with SCLC is exceptional.⁸⁷ CRMP-5 antibody titers in CSF can exceed serum titers. Anti-CRMP-5 and anti-CV2 antibodies appear to be identical.^{87,123}

Anti-Tr antibodies predict Hodgkin’s disease.¹⁰⁵ The most heterogeneous tumor spectrum appears to be correlated with anti-Ma antibodies (lung, breast parotid gland, and colon).¹⁰⁶ Anti-Ma2 antibodies (anti-Ta) are markers for seminomas and nonseminomatous or mixed germ cell tumors.⁹⁴

Management. Control of the underlying tumor may halt the progression after several months. Broad therapeutic guidelines are difficult to outline, but the physician is guided by several rules. Expedient procedures are warranted and should include the exclusion of alternative diagnoses, the provision of appropriate scanning, and serological marker

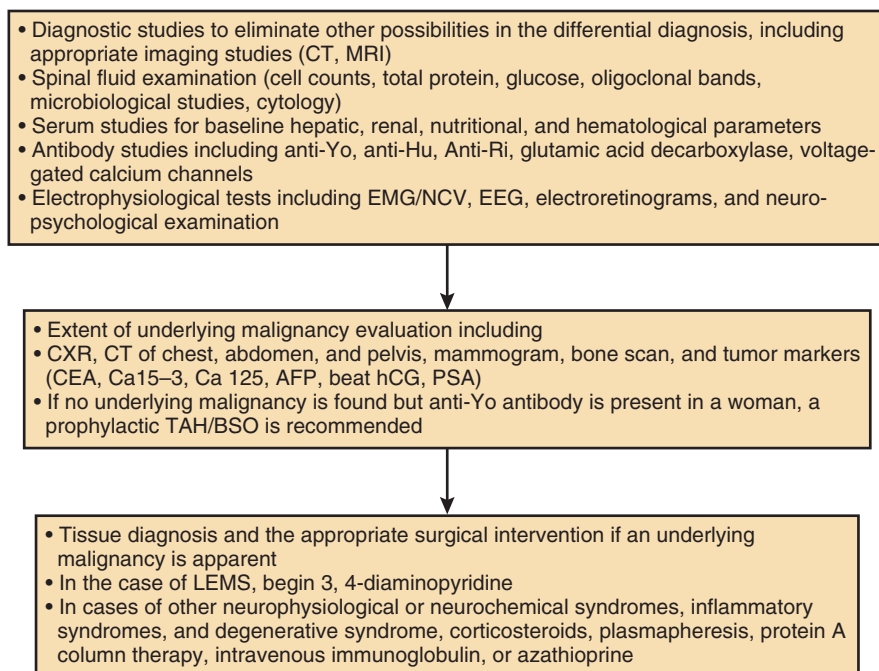

Figure 47-8. Evaluation of paraneoplastic syndromes. AFP, α -fetoprotein; CEA, carcinoembryonic antigen; CT, computed tomography; CXR, chest x-ray study; EEG, electroencephalogram; EMG/NCV, electromyography/nerve conduction velocities; hCG, human chorionic gonadotropin; LEMS, Lambert-Eaton myasthenic syndrome; MRI, magnetic resonance imaging; PSA, prostate-specific antigen; TAH/BSO, total abdominal hysterectomy/bilateral salpingo-oophorectomy.

studies. Certain syndromes justify a thorough search for an underlying cancer and the provision of appropriate treatment with surgery, chemotherapy, or radiation therapy. Concomitant treatment of the paraneoplastic syndrome should be provided rather than awaiting tumor response. Available treatment modalities consist of plasmapheresis, intravenous immunoglobulin infusion (IVIG), or immunosuppression with corticosteroids or cyclophosphamide. Immunosuppressive therapy may be difficult to coordinate with concurrent chemotherapy and reports of its successful use are anecdotal.

The treatment of paraneoplastic myasthenia gravis consists of thymectomy, prednisone, or azathioprine. Plasmapheresis is useful during crisis. Cholinesterase inhibitors are used for symptomatic management. LEMS should be treated with 3,4-diaminopyridine. Because of the renal toxicity of guanidine, use of this drug should probably be avoided in a patient who may be undergoing chemotherapy with agents that require renal clearance. Patients benefit from corticosteroids and tumor-directed therapy. Plasma exchange or IVIG has been successfully used in stiff-person syndrome. For symptomatic relief, benzodiazepines, dantrolene, or antiepileptic agents are indicated.

Prognosis and Future Perspectives. In general, the paraneoplastic syndromes associated with antibodies targeting intracellular antigens are unresponsive to therapeutic intervention, whereas treatment may be successful in those with circulating pathogenetically relevant antibodies targeting surface antigens. However, there are exceptions to this rule because partial recovery has been observed in patients with anti-Tr- and anti-Ma2-associated syndromes.¹⁰⁵ Examples of “treatable” conditions include LEMS, stiff-person syndrome, and opsoclonus-myoclonus in children with neuroblastoma. Refractory to therapy are cell degenerative processes, including Purkinje cell cerebellar degeneration, retinopathy with ganglion cell loss, ANNA-1-mediated sensory neuronopathy and limbic encephalopathy, and motor neuronopathy with reduction of anterior horn cells. Regardless of the poor prognosis of the majority of central paraneoplastic syndromes, patients may live much longer than those with an identical tumor type but lack of an “onconeural” antigen-mediated immune response. For example, the median survival for patients with breast cancer and PCD is approximately 8 years, five times longer than that of patients with gynecologic malignancies.¹²⁴
