Oestrogen specifically maintains verbal memory in women and may prevent or forestall the deterioration in short- and long-term memory that occurs with age (Sherwin, 1999a). There is also evidence that oestrogen may have a role in the prevention and treatment of Alzheimer's disease (AD). Theoretically, oestrogen could be the perfect anti-Alzheimer's treatment (Garcia-Segura *et al.*, 2001). Oestrogen has the properties of an antioxidant, can modify inflammatory response, increases growth of ACh neurons, can affect amyloid precursor protein cleavage, inhibits ApoE levels, stimulates glucocorticoid levels, increases glucose utilization and increase cerebral blood flow. Unfortunately the clinical data to date are somewhat mixed: the estimated risk of AD decreases significantly in women who have been on long-term ERT (Kawas *et al.*, 1997; Paganini-Hill and Henderson, 1994) but others have reported only 50% reduction in incidence (Waring *et al.*, 1999), with some benefit in early-onset AD only and some protection against further deterioration (Costa *et al.*, 1999) whereas others have seen no beneficial effect at all (Mulnard *et al.*, 2000).

The use of ERT continues to be controversial, with the risk of breast and endometrial cancer in long-term users still looming. At the same time, the search for the perfect selective oestrogen receptor modulator (SERM) is ongoing. The 'ideal' SERM would have negative receptor activity on breast and endometrial cells and positive receptor activity on bone, cardiovascular and brain. So far there is evidence that raloxifene is effective in preventing osteoporosis and has protective cardiovascular properties and also seems to reduce the risk for breast cancer (Cauley *et al.*, 2001; Delmas *et al.*, 1997) but its effect on cognitive function in humans has not been established. There is some indication that it may lower the risk of decline in attention and memory (Yaffe *et al.*, 2001) and in animals there is some indication that raloxifene plus oestradiol induces neurite outgrowth to a greater extent than raloxifene or oestradiol alone (Nilsen *et al.*, 1998).

Progesterone, which in the past has been promoted by some as an antidepressant, by itself can not only cause depression but seems also to reverse the oestrogen-induced receptor expression. Progestogens also have potent anaesthetic properties and dampen brain excitability; they also increase the concentration of monoamine oxidase, the enzyme that catabolizes 5-HT in the brain, whereas oestrogen decreases the enzyme, thereby increasing the concentration of 5-HT (Luine *et al.*, 1975; Sherwin, 1999b).

Testosterone is also an extremely important psychoactive compound and its relevance to women's well-being is just beginning to be recognized (Tuiten *et al.*, 2000).

While we are awaiting results of the ongoing long-term prospective studies with ERT and SERM, it is important to recognize that depressive symptoms are a significant risk factor for mortality in older women (Whooley and Browner, 1998). Whether depressive symptoms are a marker for, or a cause of, life-threatening conditions remains to be determined. Nevertheless, treatment for depression may not only enhance the quality of life but may also reduce mortality in this population.

CONCLUSION

The complex integration of the neurotransmitter and steroid hormone systems implies that circulating steroid hormones from peripheral endocrine glands can directly regulate brain function and modulate behaviour. Regulation occurs through a variety of mechanisms, including, for example, direct interaction with or upregulation of specific receptors on neuronal cells. Thus, the hormonal milieu surrounding a neuronal cell will, in part, determine the response of that cell to various stimuli.

Adrenal and gonadal steroids regulate the transcription of most of the major neurotransmitter systems.

Steroid hormones also have direct effects on neuronal cell function by non-genomic mechanisms influencing the sensitivity and responsiveness of the neurons.

Levels of oestrogen and progesterone vary significantly across the female lifespan. At puberty there is an increase in oestrogen and initiation of cyclic and diurnal variation in oestrogen production. The sudden appearance of higher levels of oestrogen in puberty alters the sensitivity of the neurotransmitter systems. Behaviours such as moodiness, irritability and conflicts with parents around this time may in part reflect this increased sensitivity. The constant flux of oestrogen and progesterone levels continues throughout the reproductive years. The neurotransmitter systems are thus constantly being attenuated or amplified. PMS and PMDD may be the result of an altered activity (or sensitivity) of certain neurotransmitter systems. Pregnancy and delivery produce dramatic changes in oestrogen and progesterone levels as well as significant suppression along the HPA axis, possibly increasing vulnerability to depression. Finally, at menopause, oestrogen levels decline while pituitary LH and FSH levels increase. The loss of modulating effects of oestrogen and progesterone may underlie the development of perimenopausal mood disorders in vulnerable women.

Since these hormonal changes occur in all women, it seems safe to speculate that the development of mood disorders requires more than just fluctuating levels of hormones, but also a genetic predisposition. These as yet unidentified genetic 'defects' probably relate to subtle alterations in number and function of various receptors and enzymes and to subtle structural and anatomical differences in the CNS. These differences caused by genetic polymorphism, combined with the flux in the hormonal milieu, determine how the system reacts to multiple environmental stresses and predicts the development of mood disorders. Further research into this complex system is needed to identify specific genetic markers which might help us better understand how the balance between oestrogen, progesterone, testosterone and other steroid hormones affects neurotransmitter function.

Therapeutic Armamentarium

Robert H. Howland and Michael E. Thase

INTRODUCTION

Currently, a wide variety of therapies are available for the treatment of mood disorders. These therapies have been studied mainly in major depressive disorder and bipolar I disorder, although they also are commonly used in clinical practice for the treatment of such related mood disorders as dysthymia, minor depression, cyclothymia and bipolar II disorder (Howland, 1991; Howland and Thase, 1993). The diversity of the many antidepressant and antimanic therapies that are effective likely reflects the underlying pathophysiological heterogeneity that exists among the mood disorders (Howland and Thase, 1999b), although seemingly different therapies also may share common therapeutic mechanisms of action. For a significant proportion of mood disorder patients, the available standard antidepressant and antimanic therapies are not entirely effective, contributing to the development and clinical use of novel treatments. In this chapter we review standard antidepressant and antimanic therapies for mood disorders. We also review novel pharmacological and non-pharmacological therapies that are being studied and sometimes used for the treatment of major depressive and bipolar disorders.

TREATMENT OF DEPRESSION

Antidepressant Drugs

During the 1950s, the clinical effects of tricyclic antidepressant (TCA) and monoamine oxidase inhibiting (MAOI) drugs were first discovered (Crane, 1957; Kuhn, 1958). Since the 1980s, numerous antidepressant drugs unrelated to the TCAs and MAOIs have been developed and studied for the treatment of depression (Kent, 2000; Sampson, 2001).

Tricyclic Antidepressants (TCAs)

After their discovery, the TCAs were the cornerstone of pharmacotherapy for depression for nearly three decades (Nelson, 2000). The most commonly used TCAs, so called because of their cyclic chemical structure, include imipramine, desipramine, amitriptyline and nortriptyline. Doxepin, trimipramine and protriptyline are less commonly used. Clomipramine is approved for use in the United States only for the treatment of obsessive-compulsive disorder, but it is a highly effective antidepressant. The antidepressant effects of the TCAs are believed to be primarily due to their inhibition of the reuptake of the neurotransmitters norepinephrine and serotonin (Richelson, 2001), although they and other antidepressant drugs also directly or indirectly affect second-messenger systems (Popoli *et al.*, 2000; Vaidya and Duman, 2001) that are implicated in the neurobiology of depression (Duman *et al.*, 1997). Aside from clomipramine, the TCAs are more active on noradrenergic reuptake inhibition. They also potently block several important postsynaptic neurochemical receptors, which account for most of their typical side effects. Dry mouth, constipation, blurred vision, sinus tachycardia, urinary retention and memory dysfunction are due to cholinergic receptor blockade. Sedation and weight gain are primarily related to histaminic receptor blockade, although serotonergic and anticholinergic effects may also contribute to the weight gain associated with the TCAs and other types of antidepressant drugs (Fava *et al.*, 2000). Dizziness, hypotension and reflex tachycardia are caused by their blockade of α-1 adrenergic receptors. The TCAs also have quinidine-like effects on cardiac conduction, which can cause serious cardiotoxic effects, including arrhythmias and conduction abnormalities, and can be fatal with an overdose as small as 7–10 times a daily therapeutic dose.

As a group, the TCAs do not differ significantly in their relative antidepressant efficacy (Thase, 1997). Two TCAs, nortriptyline and desipramine, are secondary amine metabolites of amitriptyline and imipramine, respectively, and they are often preferred because of less pronounced anticholinergic side effects. Placebo-controlled studies have found TCAs to be effective in adult and geriatric patients, but not in younger age groups (Brent *et al.*, 1995). Interestingly, compared to men and to postmenopausal women, there is evidence that premenopausal women respond less well to TCAs than to other antidepressant drugs (Kornstein *et al.*, 2000; Thase *et al.*, 2000a). Higher TCA doses are often associated with greater therapeutic benefit, but this is limited by their greater side effect burden. Measuring plasma levels of imipramine, amitriptyline, desipramine and nortriptyline is clinically useful for achieving a therapeutic response (Bernstein, 1995). Because of their side effects and potential lethality, the use of TCAs has been gradually supplanted by newer generation antidepressants. The TCAs, however, can be quite effective in treating patients who do not respond to other drugs, and they remain especially effective treatments for more severe melancholic depressions (Thase and Rush, 1995).

Monoamine Oxidase Inhibitors (MAOIs)

The pharmacology and presumed mechanism of action of the MAOIs is distinctly different from all other antidepressants (Kennedy *et al.*, 2000). The MAOIs phenelzine, tranylcypromine and isocarboxazid irreversibly and non-selectively inhibit the enzyme monoamine oxidase (MAO), which degrades norepinephrine, serotonin and dopamine, thereby increasing the availability of these neurotransmitters and likely contributing to their antidepressant effects (Richelson, 2001), although they may also directly or indirectly affect second-messenger systems (Popoli *et al.*, 2000; Vaidya and Duman, 2001) that are implicated in the neurobiology of depression (Duman *et al.*, 1997). Typical side

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

effects of the MAOIs include hypotension, dizziness, sedation, weight gain, dry mouth and sexual dysfunction. Phenelzine is more often associated with these side effects than is tranylcypromine, whereas tranylcypromine may be more likely to cause insomnia. Because the MAOIs inhibit MAO in the gut, severe hypertension can occur when foods containing the amino acid tyramine (which stimulates the release of norepinephrine) are ingested. As a result, patients treated with MAOIs must follow a tyramine-free diet. In addition, use of the MAOIs is associated with potentially severe and fatal interactions with various other drugs, including antidepressants, narcotics and sympathomimetics.

Because of their side effect profile and dietary restrictions, the MAOIs are not commonly used in clinical practice. However, comparative studies have found the MAOIs to be more effective than the TCAs and other antidepressants in the treatment of atypical depression (Jarrett *et al.*, 1999; McGrath *et al.*, 2000) and bipolar depression (Thase and Sachs, 2000). In addition, the MAOIs have consistently been found to be effective in 40–60% of patients who do not respond to other antidepressants (Thase *et al.*, 1995). Like the TCAs, higher doses (within the therapeutic range) also are associated with a greater antidepressant effect if tolerable.

Some MAOIs are relatively selective for the Type A or Type B subforms of MAO (Lotufo-Neto *et al.*, 1999). Selegiline is a selective inhibitor of MAO-B at low doses, but there is little evidence that it has antidepressant effects at these doses. At higher doses, however, selegiline loses its selectivity and has greater antidepressant effects. A selegiline transdermal application system is currently being developed, which avoids peripheral MAO-A inhibition in the gut and permits greater systemic selegiline levels without the risk of a tyramine reaction, potentially making it a more viable antidepressant therapy (Barrett *et al.*, 1997; Mahmood 1997; Sacktor *et al.*, 2000). By contrast, moclobemide and brofaromine are reversible inhibitors of MAO-A (RIMAs). The RIMAs have demonstrated antidepressant effects, are much better tolerated than the TCAs and older MAOIs, and do not require any dietary restrictions, although there is some evidence that they may be slightly less effective compared to TCAs and older MAOIs (Amrein *et al.*, 1997; Lotufo-Neto *et al.*, 1999; Parker *et al.*, 2001; Philipp *et al.*, 2000).

Heterocyclic Antidepressants

Problems with the tolerability and safety of the TCAs and MAOIs led to interest in developing alternative antidepressant drugs (Bernstein, 1995). These pharmacologically diverse drugs include amoxapine, maprotiline and trazodone (Richelson, 2001). Amoxapine is a TCA-like compound that is related to the antipsychotic drug loxapine, and can have similar extrapyramidal side effects (e.g. dystonia, akathesia, parkinsonian symptoms, and possibly tardive dyskinesia). As a result, it has not been a commonly used antidepressant, although it is sometimes used as a 'monotherapy' for the treatment of psychotic depression (Wheeler Vega *et al.*, 2000). Maprotiline is a tetracyclic drug that primarily blocks the reuptake of norepinephrine, but is rarely used because of a higher risk of seizures and cardiac toxicity compared to other antidepressants. Trazodone is a phenylpiperazine compound that has weak effects on monoamine reuptake, but does block postsynaptic serotonin (5-HT2) receptors. Trazodone has been used almost exclusively in lower doses as a safe and effective non-habit forming hypnotic, often in combination with other antidepressants. Higher doses are usually needed to treat severe depression and have been associated with severe hypotension and, rarely, the development of priapism.

Serotonin Reuptake Inhibitors (SRIs)

The SRIs have become the most commonly used class of antidepressants for the treatment of depression around much of the world (Gram, 1994). These drugs include fluoxetine, paroxetine, sertraline and citalopram (Sampson, 2001). A fifth SRI, fluvoxamine, is approved in the United States as a treatment for obsessive-compulsive disorder, but also is an effective antidepressant. As a class, the SRIs are chemically dissimilar, which accounts for various pharmacologic differences (e.g. different half-lives, active metabolites and hepatic enzyme inhibitory effects). Despite the pharmacologic differences, these drugs have a similar mechanism of action, which is their potent and specific inhibition of serotonin reuptake (Richelson, 2001), although they also directly or indirectly affect second-messenger systems (Popoli *et al.*, 2000; Vaidya and Duman, 2001) that are implicated in the neurobiology of depression (Duman *et al.*, 1997). Typical side effects of the SRIs include nausea, diarrhoea, insomnia, nervousness, headache and sexual dysfunction. Additional clinical experience with the SRIs also suggests that some patients may complain of sweating, fatigue and weight gain (Fava *et al.*, 2000). They do not have significant cardiac effects, and are much safer than the TCAs and MAOIs in overdose. Several of the SRIs also can inhibit various hepatic enzymes, which are important for drug metabolism and can lead to clinically significant drug interactions, but this limitation has not lessened the utility of the SRIs (Thase, 1997).

As a group, the SRIs do not differ significantly in their relative efficacy or typical side effect profiles, although there may be subtle differences in the degree of certain side effects (Kelsey and Nemeroff, 2000). There is some evidence that patients who do not respond to or cannot tolerate one SRI may do better after switching to an alternative SRI (Howland and Thase, 1999a). Comparative studies with the TCAs have generally found similar efficacy rates, although indices of tolerability usually favour the SRIs. There continues to be debate about whether the TCAs are more effective among patients with more severe melancholic depressions (Perry, 1996; Thase and Rush, 1995). Unlike the TCAs, placebo-controlled studies have found the SRIs to be effective in treating depression in adolescents (Emslie *et al.*, 1997). Moreover, compared to men and to postmenopausal women, premenopausal women may respond relatively better to SRIs than to other antidepressant drugs (Kornstein *et al.*, 2000; Thase *et al.*, 2000a). The SRIs are generally considered to be safe for use during pregnancy (Ericson *et al.*, 1999).

Atypical Antidepressants

The term 'atypical antidepressants' is used to group the remaining antidepressant drugs (bupropion, venlafaxine, nefazodone, mirtazapine and reboxetine), which are chemically unrelated to each other and to the TCAs, MAOIs or SRIs (Preskorn, 1995; Kent, 2000).

Bupropion

Bupropion is a novel antidepressant that belongs to the aminoketone class of drugs (Golden and Nicholas, 2000). Its mechanism of action is uncertain, although bupropion appears to facilitate or modulate the effects of norepinephrine and dopamine. Bupropion has virtually no effect on serotonergic, cholinergic, histaminic or other adrenergic systems (Richelson, 2001). As a result, it lacks the usual side effects seen with the TCAs, MAOIs or SRIs. Typical side effects include restlessness, insomnia, nausea, headache, constipation and tremors. Bupropion is not associated with sexual dysfunction or weight gain and does not have significant cardiac effects. Bupropion is a modest inhibitor of the hepatic isoenzyme CYP450 2D6, but is not notorious for clinically significant drug interactions. High doses (greater than 450 mg per day) are associated with an increased risk of seizures, but within the manufacturer's recommended dose range the rate of seizures does not differ from other antidepressant drugs.

Comparative studies of bupropion and other antidepressants in depression have not found any significant differences in efficacy,

but it has a different tolerability profile (especially with regard to sexual and weight effects) (Spier, 1998). It is sometimes combined with SRIs to lessen sexual dysfunction or augment antidepressant effects (Howland and Thase, 1999a). Bupropion may not be as effective in the treatment of severe anxiety states associated with depression (e.g. obsessive-compulsive or panic anxiety), but might be especially useful in anergic, atypical, seasonal or bipolar depressions (Sachs *et al.*, 1994; Thase, 1997).

Venlafaxine

Venlafaxine is a novel antidepressant belonging to the phenylethylamine class of drugs (Beauclair *et al.*, 2000). The primary mechanism of action is the inhibition of serotonin and, at higher doses, norepinephrine reuptake (Richelson, 2001). Typical side effects include nausea, headache, dizziness, dry mouth, constipation, loss of appetite, nervousness and insomnia (Kent, 2000). Some patients may complain of fatigue, sweating and sexual dysfunction. A small proportion of patients may develop increased blood pressure at high doses, but it does not have any other significant cardiac effects. It also does not have any clinically significant effect on hepatic metabolic enzymes and appears to be relatively safe in an overdose.

Some studies directly comparing venlafaxine to several different SRIs have found it to be more effective and more likely to lead to a full remission, especially at higher doses (Thase *et al.*, 2001a). There also is some evidence that venlafaxine may have a more rapid onset of action compared to other antidepressants, but this has not been well studied (Thase *et al.*, 2001c). In addition, other studies have found it effective in the treatment of refractory depression, including patients who had not responded to various antidepressants from different classes (Thase *et al.*, 2000b).

Nefazodone

Nefazodone is a novel antidepressant that, like trazodone, belongs to the phenylpiperazine class of drugs (Garlow *et al.*, 2000). Its primary mechanism of action may be blockade of postsynaptic serotonin-2 receptors. It has very weak inhibitory effects on reuptake of norepinephrine and serotonin (Richelson, 2001). Typical side effects include sedation, dry mouth, nausea, headache, constipation and dizziness (Kent, 2000). Compared to SRIs and TCAs, it is not associated with sexual dysfunction or weight gain (Ferguson *et al.*, 2001; Sussman *et al.*, 2001). Although nefazodone is a chemical analogue of the antidepressant trazodone, it is much less sedating initially and has not been found to cause priapism. Hypotension may occur rarely at high doses and rare cases of hypatotoxicity have been reported, but it does not have any other significant cardiac effects and seems to be relatively safe in an overdose. Nefazodone can inhibit the hepatic isoenzyme CYP450 3A4, which has some potential for drug–drug interactions (Thase, 1997).

Comparative studies have not found any significant difference in efficacy between nefazodone and SRIs or TCAs in the treatment of depression (Feighner *et al.*, 1998). Across 6–8 weeks of treatment, nefazodone appears to have more beneficial effects (than SRIs) on insomnia associated with depression. Nefazodone is effective in treating anxiety symptoms in depression, and its side effect profile (especially its sexual and weight effects) may be preferable for some patients compared to the SRIs (Sajatovic *et al.*, 1999).

Mirtazapine

Mirtazapine is a novel tetracyclic antidepressant belonging to the piperazinoazepine class of drugs (Claghorn, 2000). It has a very complicated presumed mechanism of action, involving blockade of several different adrenergic and serotonergic receptors, with the net effect of increasing serotonin and norepinephrine transmission (Richelson, 2001). It also blocks postsynaptic histamine receptors, which contributes to its most common side effects (i.e. sedation and weight gain). Compared to the SRIs, it is less likely to cause nausea, headache and sexual dysfunction (Kent, 2000). In some patients, it can cause dry mouth, constipation and dizziness. It does not have significant cardiac effects, or any clinically significant drug interactions, and it appears to be relatively safe in an overdose.

Comparative studies with other antidepressants generally have not found any significant differences in efficacy (Fawcett and Barkin, 1998; Guelfi *et al.*, 2001), although several recent studies found mirtazapine to have a more rapid onset of action compared to SRIs (Thase *et al.*, 2001c). Its advantage over the SRIs with respect to gastrointestinal and sexual effects must be counterbalanced against its greater degree of sedation and weight gain. However, it may have more rapid and beneficial effects on sleep and anxiety in many patients, compared to the clinical effects of other antidepressants.

Reboxetine

Reboxetine is a novel antidepressant compound, not yet approved for use in the United States, that is unrelated to the TCAs, MAOIs, SRIs or other atypical antidepressant drugs (Healy and Healy, 1998). It is a potent and selective norepinephrine reuptake inhibitor and does not bind to serotonin, dopamine, cholinergic or histamine receptors (Richelson, 2001). As a result, reboxetine is not associated with sedation, weight gain or sexual dysfunction (Kent, 2000). Typical side effects include dry mouth, constipation, insomnia, increased heart rate and urinary hesitancy/retention (in men). It does not have significant cardiac effects, does not have any clinically significant effect on hepatic metabolic enzymes, and appears to be relatively safe in an overdose. Comparative studies with other antidepressants generally have not found any significant differences in efficacy, although the side effect profile differs (Massana, 1998; Versiani *et al.*, 2000).

Antidepressant Psychotherapies

Historically, before the discovery of effective antidepressant compounds, long-term psychodynamic therapy was considered the treatment of choice for non-psychotic depressions. This approach, although helpful to patients in many ways, was never studied to determine if it is effective in treating the core symptoms of depression. During the past 30 years, psychological models of depression have been used to develop short-term highly-structured forms of psychotherapy specifically for treating depression (Wells and Giannetti, 1990). Compared to traditional forms of psychotherapy, several of these depression-focused psychotherapies have been studied in clinical trials and found to be as effective as pharmacotherapy for the treatment of depressed outpatients (Persons *et al.*, 1996; Rush and Thase, 1999). Depression-focused psychotherapies should not be considered for treatment of psychotic or bipolar forms of depression without concomitant pharmacotherapy, although there is developing evidence that the use of specific psychosocial interventions together with pharmacotherapy may lead to a better outcome in bipolar disorder (Frank *et al.*, 2000; Miklowitz *et al.*, 2000).

Interpersonal psychotherapy (IPT) is a time-limited form of psychotherapy that focuses on difficulties in the patient's intimate and vocational relationships (Klerman *et al.*, 1984). IPT has been shown to be an effective and easily used intervention in the treatment of depression (Klerman and Weissman, 1993; Markowitz, 1998). Some studies have found it to be as effective as medication among outpatients with mild to moderate levels of depression (Persons *et al.*, 1996; Weissman and Markowitz, 1994). Interestingly, a recent functional brain imaging study of patients with major depression treated with paroxetine or IPT found that regional brain metabolic abnormalities tended to normalize with either treatment (Brody *et al.*, 2001). There also is developing evidence that IPT may be beneficial for the depressive phase of bipolar disorder (Swartz and Frank, 2001).

Various behavioural therapy (BT) approaches have been developed and studied in the treatment of depression, such as activity scheduling, self-control techniques and social skills training (Becker *et al.*, 1987; Rush and Thase, 1999). A number of controlled studies have found BT to be effective among outpatients with depression. Some evidence suggests that BT may be as effective as antidepressant medications in depression (Hersen *et al.*, 1984; Rush and Thase, 1999).

Cognitive behavioural therapy (CBT) is another time-limited form of psychotherapy that is based on the theory that depression is invariably associated with automatic negative thoughts about oneself, the world and the future (Beck *et al.*, 1979; Clark and Fairburn, 1997). CBT is the best studied form of psychotherapy for major depression and dysthymia (Howland, 1996a; Persons *et al.*, 1996). Many studies have found it to be as effective a treatment for major depression as TCAs (Hollon *et al.*, 1992). Several controlled studies have found that the efficacy of CBT may be limited in more severe depressions, but this finding has not been observed by a number of other studies (Rush and Thase, 1999). Cognitive Behavioural Analysis System of Psychotherapy (CBASP) is a modified form of CBT that incorporates some principles of IPT (McCullough, 2000). CBASP was recently found to be as effective as nefazodone in the treatment of chronic depression (Keller *et al.*, 2000). There also is some evidence that CBT may be helpful for depression in bipolar disorder, but this deserves further study (Patelis-Siotis, 2001).

Other Standard Drug Therapies for Depression

Despite the availability and effectiveness of a large number and variety of antidepressant drugs, some important problems exist in the treatment of depression (Howland and Thase, 1997). First, all antidepressants have a delayed onset of action. Second, a significant minority of patients do not respond to an initial choice of drug, and the majority of patients who do respond show only a partial improvement in their depression. Third, a large proportion of patients who have an initially good response to an antidepressant will suffer a subsequent relapse or recurrence despite adequate ongoing treatment. Finally, many patients who respond to an antidepressant drug will have intolerable side effects. As a result, many different drugs have been studied and/or used in clinical practice to accelerate the antidepressant response, improve partial- or non-responders, treat depressive relapses or recurrences, or alleviate noxious side effects (Howland and Thase, 1999a).

Lithium, buspirone (a 5-HT1A receptor agonist), pindolol (a beta-adrenergic receptor antagonist that also blocks presynaptic 5-HT1A receptors) and stimulant drugs have been used to accelerate the response to antidepressants (Howland and Thase, 1999a). With the exception of pindolol, which has been shown to be effective in some placebo-controlled studies (Bordet *et al.*, 1998), these approaches have not been adequately studied under controlled conditions.

Lithium is the most extensively studied and best established augmentation strategy for treatment-resistant depression (Bauer and Dopfmer, 1999; Baumann *et al.*, 1996). Augmentation with many other drugs is commonly done, but has little empirical support (Thase *et al.*, 1998). These include the use of buspirone, pindolol, anticonvulsants such as valproate, atypical antipsychotics such as risperidone and olanzapine, the analgesic tramadol (which also inhibits the reuptake of serotonin and norepinephrine), the opioid buprenorphine, and psychostimulants such as methylphenidate, pemoline and modafanil (Bodkin *et al.*, 1995; Howland and Thase, 1999a; Menza *et al.*, 2000; Shelton *et al.*, 2001b). Combining different antidepressants (e.g. SRIs with TCAs, bupropion, mirtazapine or nefazodone) also has been a common clinical practice for treatment-resistant depression. Psychotic depression does not respond well to antidepressant monotherapy (with the exception of amoxapine), and combining antidepressants and antipsychotics is considered the treatment of choice (Wheeler Vega *et al.*, 2000). Many of these augmentation strategies or drug combinations have been employed in the management of patients who have depressive relapses or recurrences while taking antidepressants, but none have been sufficiently studied to clearly demonstrate their efficacy (Howland and Thase, 1999a).

Psychostimulant drugs, because they affect dopamine and norepinephrine transmission, may be useful in treating the apathy and sexual dysfunction that sometimes occur during antidepressant treatment, especially with the SRIs, but have not been well studied for this indication (Howland and Thase, 1999a). These drugs include modafanil, methylphenidate, pemoline, amphetamine, amantadine, bromocriptine, pramipexole, ropinirole and pergolide (Zajecka, 2001). Other drugs that have been used for treating antidepressant-associated sexual dysfunction include cyproheptadine, yohimbine, buspirone, bethanechol, bupropion, mirtazapine and nefazodone (Ferguson *et al.*, 2001).

Novel Drug Therapies for Depression

Abnormal regulation of the hypothalamic–pituitary–adrenal (HPA) axis, leading to persistent elevations in cortisol levels, has been implicated in the pathophysiology of depression (Reus *et al.*, 1997). A number of open-label and controlled studies of drugs that suppress or inhibit HPA axis function, such as dexamethasone, aminoglutethimide, metyrapone, ketoconazole and mifepristone, have shown promise in the treatment of major depression, including refractory depression (Belanoff *et al.*, 2001; Brown *et al.*, 2001; Murphy *et al.*, 1993, 1998; Thakore and Dinan 1995; Wolkowitz *et al.*, 1999). Other drugs acting on the HPA axis (e.g. CRH or glucocorticoid receptor antagonists) are currently being developed for study in depression and other psychiatric disorders (McQuade and Young, 2000).

Several lines of evidence have suggested an important role for gonadal and adrenal steroid hormones in mood regulation. Women are especially vulnerable to mood disturbances during premenstrual, post-partum and perimenopausal periods (Epperson *et al.*, 1999). There also is evidence that mood disturbances may be associated with decreased steroid hormone levels in men (Margolese, 2000; Seidman and Walsh, 1999). In addition, steroid hormones act on specific receptors in the brain and affect neuronal function and neurotransmission. Considerable evidence suggests that oestrogen may improve mild mood symptoms in perimenopausal women (Epperson *et al.*, 1999; Joffe and Cohen, 1998), but there is less consistent evidence that oestrogen is an effective monotherapy for major depression (Halbreich, 1997; Morrison and Tweedy, 2000; Saletu *et al.*, 1995). There also is inconsistent evidence of the antidepressant effects of testosterone in men (Grinspoon *et al.*, 2000; Seidman *et al.*, 2001). Several recent placebo-controlled studies, however, found that oestradiol was effective for post-partum and perimenopausal major depression, suggesting important mood differences among oestrogen preparations (Ahokas *et al.*, 2001; De Novaes-Soares *et al.*, 2001). Some, but not all, studies have found that oestrogen or testosterone may augment the effects of antidepressant drugs in major depression (Amsterdam *et al.*, 1999; Schneider *et al.*, 1997; Seidman and Rabkin, 1998; Shapira *et al.*, 1985). Finally, there is developing evidence that adrenal steroid hormones such as dehydroepiandrosterone (DHEA) have significant antidepressant effects in older men and women (Bloch *et al.*, 1999).

Thyroid hormone also has been studied and used in the treatment of depression, especially as an augmentation strategy in refractory depression (usually triiodothyronine; T3) (Thase *et al.*, 1998).

The antidepressant use of thyroid hormone is based on the known association between depression and hypothyroidism as well as evidence that the hypothalamic–pituitary–thyroid axis affects neuronal function and neurotransmission in the brain (Howland, 1993). Thyroid augmentation has been studied almost exclusively in TCA non-responders, and these studies have suggested that it may be more effective in women, perhaps because of their higher risk for thyroid disease (Howland and Thase, 1999a).

Melatonin is a pineal gland hormone that regulates circadian sleep cycles. Although melatonin has not been adequately investigated in controlled trials of major depression, some evidence suggests that it has antidepressant effects (Wetterberg, 1998). Moreover, it also may be a clinically useful adjunct together with antidepressants, because of its potentially beneficial effects on disturbed circadian sleep–wake rhythms found in mood disorders (Wirz-Justice, 1995).

Although most psychotropic drugs have direct effects on neurotransmitter reuptake sites or neurotransmitter receptors, they may also have direct or indirect effects on second-messenger signal transduction systems, which ultimately mediate the synthesis of various protein products that lead to their therapeutic benefit (Chen *et al.*, 1999; Vaidya and Duman, 2001). Inositol, a precursor of the phosphatidyl-inositol second-messenger system, has been found effective in unipolar and bipolar depression in some, but not all, studies (Chengappa *et al.*, 2000; Levine *et al.*, 1995, 1999; Nemets *et al.*, 1999). Omega-3 fatty acids, which have an inhibitory effect on neuronal signal transduction systems, have been studied as a mood stabilizer in bipolar disorder. One recent study found that they had relatively greater antidepressant than antimanic effects (Stoll *et al.*, 1999).

Numerous herbs and plant extracts are known to have psychotropic effects, and historically many have been used therapeutically for the treatment of depression, anxiety and other emotional maladies (Fugh-Berman and Cott, 1999). Indeed, the use of herbs, nutritional supplements and other unorthodox homeopathic therapies has increased tremendously in recent years, but unfortunately many of these products have not been well studied with respect to their safety or efficacy. Two exceptions to this are studies of St John's wort and S-adenosylmethionine (SAMe) in the treatment of major depression. St John's wort (*Hypericum perforatum*), a wild flowering plant, has been used since ancient times to treat a variety of nervous conditions, and has become a very commonly used contemporary treatment for depression and anxiety. The most common adverse effects of St John's wort include photosensitivity, headache, dry mouth, dizziness, constipation and other gastrointestinal problems. St John's wort also is a potent inducer of hepatic metabolic enzyme systems, which may lead to decreased levels of various drugs (especially protease inhibitors, cyclosporine, theophylline, warfarin, digoxin and oral contraceptives). A meta-analysis of randomized trials in outpatients with mild to moderate levels of depression concluded that St John's wort was significantly superior to placebo and comparably effective to standard antidepressant drugs, although many of these trials were considered to have serious methodological flaws (Linde *et al.*, 1996). A recent large multicentre randomized study in patients with more severe and chronic symptoms of major depression did not find any difference between St John's wort and placebo (Shelton *et al.*, 2001a). Results from another large randomized study did not find any significant difference among St John's wort, sertraline, or placebo (Hypericum Depression Trial Study Group, 2002). The dietary supplement SAMe is an amino acid compound that is essential for methylation processes in the nervous system, which are important for neurotransmitter synthesis and second-messenger system function (Reynolds and Stramentinoli, 1983). The most common adverse effects are insomnia, nervousness, headaches and mild gastrointestinal problems, and it is not known to interact adversely with other drugs (Fava *et al.*, 1995). A meta-analysis of randomized trials in depressed outpatients found that SAMe was more effective than placebo and as effective as TCAs (Bressa, 1994), but it has not been compared to newer generation antidepressants and it has not been well studied in more severe forms of depression (Echols *et al.*, 2000).

Other Somatic Therapies for Depression

Electroconvulsive Therapy (ECT)

Historically, ECT has been considered the most effective treatment for major depression, and has also been shown to be highly effective for the treatment of severe melancholia, psychotic depression, bipolar depression, catatonia associated with mood disorders and treatment-resistant depression (Swartz *et al.*, 2001; Thase and Rush, 1995; Thase and Sachs, 2000; Wheeler Vega *et al.*, 2000). Because of its relative effectiveness, tolerability and safety, ECT is considered to be especially appropriate for geriatric patients and pregnant women, who might otherwise be at risk for adverse pharmacological effects (Kelly and Zisselman, 2000). ECT involves the passage of a brief electrical current through the brain to induce a generalized seizure lasting about 30–90 seconds, and is performed under general anaesthesia and muscle relaxation using short-acting drugs. A typical course of ECT consists of 6–12 treatments given three times weekly, although some patients might require a greater number of treatments. One of two electrode placements are used for ECT: unilateral non-dominant hemisphere placement or bilateral placement. Most patients are treated initially with unilateral ECT. Bilateral ECT usually is reserved for patients who have shown a minimal response after six unilateral treatments, or for patients with a history of a poor response to prior courses of unilateral ECT, a history of a positive prior bilateral ECT response, or extremely severe symptoms (Bailine *et al.*, 2000). Aside from the potential adverse effects and risks associated with general anaesthesia, the most common adverse effects of ECT include transient changes in heart rate and blood pressure, postictal and postanaesthetic confusion, memory impairment, muscle soreness, nausea and headaches. There is no convincing evidence that acute or long-term treatment with ECT causes brain damage. Increased efficacy and side effects of ECT are correlated with higher intensities of the electrical current, and efficacy and side effects are also somewhat greater with bilateral ECT (McCall *et al.*, 2000; Sackeim *et al.*, 2000). The acute clinical benefits of ECT are usually time-limited. For this reason, patients at risk for a depressive relapse should receive longer-term continuation treatment with pharmacotherapy or ECT after completing a course of acute ECT (Sackeim *et al.*, 2001a). However, patients who failed to respond to adequate trials of antidepressant medication prior to ECT have a higher risk of relapsing with pharmacotherapy after successful ECT and therefore should preferentially receive continuation treatment with ECT (Sackeim, 1994). Moreover, there is some evidence that continuation ECT is more effective than medications alone in preventing relapse and recurrence in depression (Gagne *et al.*, 2000).

Repetitive Transcranial Magnetic Stimulation (rTMS)

By contrast with ECT, rTMS is a novel non-invasive method for causing focal non-electrical stimulation of the brain (George *et al.*, 1999). In rTMS, a high-intensity electrical current is passed through an electromagnetic coil on the scalp. Rapidly turning the current on and off generates repetitive pulses of a magnetic field that can be focused on particular regions of the brain. Slow frequency stimulation with rTMS tends to inhibit neurons, whereas fast stimulation is excitatory. The most common adverse effect is headache, but seizures have been reported. Adverse cognitive effects of rTMS also are uncommon. Short-term placebo-controlled

(using sham rTMS) studies of fast rTMS focused on the left dorsolateral prefrontal cortex have found it effective in major depression (George *et al.*, 1997, 2000a), although there is evidence that slow rTMS focused on the right prefrontal cortex also is effective (Klein *et al.*, 1999). The results from studies using rTMS in treatment-resistant depression are mixed (Berman *et al.*, 2000; Loo *et al.*, 1999). A recent open study found that ECT may be somewhat more effective than rTMS, especially among patients with psychotic depression (Grunhaus *et al.*, 2000). Unfortunately, the long-term clinical efficacy, tolerability and safety of rTMS in mood disorders is unknown.

Vagus Nerve Stimulation (VNS)

The vagus nerve (cranial nerve X) is a parasympathetic nerve composed of afferent (carrying sensory information from the viscera) and efferent (regulating parasympathetic autonomic function) fibres. Animal studies found that VNS has behavioural and anticonvulsant effects, which led to the study and approved clinical use of VNS as a treatment for refractory partial-onset seizures in epilepsy (George *et al.*, 2000b). VNS involves the surgical implantation of a pacemaker-like programmable pulse generator, which is connected to and intermittently stimulates the left cervical vagus nerve. Studies in epilepsy patients also found that VNS had positive effects on mood symptoms. Brain imaging and neurochemical studies have shown that VNS activates various limbic regions and affects various neurotransmitters. This work led to interest in studying VNS in depression. An open-label pilot study using VNS in a group of very chronic and highly treatment-resistant patients with major depression reported a response rate of approximately 40% (Rush *et al.*, 2000). VNS was very safe and generally well tolerated, similar to its safety and side effect profile in epilepsy (Sackeim *et al.*, 2001b). Longer-term follow-up of these patients has found that the antidepressant response to VNS increases over time and continues to be well tolerated (Marangell *et al.*, 2002). Results of a recently completed large multicentre randomized controlled study of VNS in treatment-resistant major depression have not yet been reported.

Acupuncture

Acupuncture, like other complementary and alternative therapies, is becoming a more popular medical treatment for depression (Ulett *et al.*, 1998). Several controlled studies comparing 'active' acupuncture to 'sham' acupuncture and/or to antidepressant medication have reported some antidepressant benefit (Allen *et al.*, 1998; Luo *et al.*, 1998; Roschke *et al.*, 2000). Although these studies suffer from various methodological problems, the results suggest that acupuncture might be considered a safe and well tolerated alternative treatment for some depressed patients that warrants further study. More research clearly is needed to establish the safety and efficacy of acupuncture in major depression and other mood disorders. Moreover, because different procedures are used in the application of acupuncture, additional work is needed to determine the most effective acupuncture procedure in depression.

Psychosurgery

In the absence of effective pharmacological therapies, psychosurgery was widely accepted and commonly practised during the 1940s and 1950s for the treatment of schizophrenia, mood disorders and anxiety disorders. Although somewhat effective, the early surgical procedures were rather primitive (i.e. the prefrontal lobotomy crudely severed white matter connections between the prefrontal cortex and the rest of the brain) and had significant complications (e.g. bleeding, seizures, frontal lobe syndrome and death). However, the refinement of stereotactic neurosurgical methods, together with a better understanding of the neuroanatomical pathophysiology of psychiatric disorders, has led to more selective interventions with improved clinical outcomes and reduced morbidity and mortality. The most common currently performed neurosurgical procedures are anterior cingulotomy, subcaudate tractotomy, limbic leukotomy and anterior capsulotomy, which involve selective lesioning of particular brain regions using magnetic resonance imaging-guided stereotactic techniques. Psychosurgery is considered a treatment of last resort, for patients with chronic, severe and debilitating illnesses that have not responded to any available treatment. Short-term and long-term studies have found that one-third to two-thirds of patients with intractable depression show clinically significant improvement after psychosurgery, with low rates of surgical and neurological complications and minimal adverse effects on intellectual, personality and behavioural functioning (Binder and Iskandar, 2000; Spangler *et al.*, 1996).

Non-Somatic Therapies for Depression

Mood disorders are commonly characterized by clinical and EEG sleep disturbances. Hence, disturbed sleep is not only a symptom of depression, but may also reflect abnormal underlying biological processes that regulate sleep–wake cycles and are relevant to the pathophysiology of mood disorders (Wirz-Justice, 1995). Approximately 30–50% of depressed patients have a significant but transient antidepressant effect from total sleep deprivation, but this positive benefit is often lost with a full night of sleep (Wu *et al.*, 1999). Serial partial sleep deprivation, whereby patients stay awake daily from 2 a.m. to 10 p.m., has been used to achieve a more sustained antidepressant response, but this has not been especially effective. Sleep deprivation followed by pharmacotherapy may be more effective (Benedetti *et al.*, 1999; Smeraldi *et al.*, 1999). In addition, some evidence suggests that sleep deprivation may accelerate the response to antidepressant drugs and may be a useful augmentation strategy for antidepressant partial responders (Thase and Rush, 1995). Patients with seasonal depression or bipolar depression may be somewhat more sensitive to the antidepressant effects of sleep deprivation. Indeed, sleep deprivation may precipitate mania in patients with bipolar disorder.

Phototherapy (bright light therapy) was studied and introduced as a treatment for seasonal affective disorder, primarily winter depressions (Wirz-Justice, 1995). Phototherapy typically involves the daily morning use of 1–2 hours of bright light (2000 lux or more) (Terman *et al.*, 2001). The most common adverse effects are irritability and headache. Phototherapy also may be beneficial for patients with non-seasonal depression or bipolar depression (sometimes precipitating hypomania or mania), and has been used to accelerate or augment the effects of antidepressant drugs (Kripke, 1998; Thase and Rush, 1995). A positive response to sleep deprivation predicts a positive response to phototherapy, and the combination has been used to obtain a more sustained antidepressant effect (Colombo *et al.*, 2000; Fritzsche *et al.*, 2001). An alternative form of phototherapy is dawn simulation, which uses a low intensity light that gradually increases in illuminance before the subject awakens. This has been found to be as or more effective than bright light therapy in some studies (Avery *et al.*, 2001).

A novel approach in the treatment of winter depression is the use of a negative ion generator as an antidepressant therapy (Terman and Terman, 1995). In this method, an electronic negative ion generator is used to produce negative ions in the ambient air. Patients use the device at home for approximately 30 minutes. A

controlled trial comparing low-density and high-density negative ion generation found a greater antidepressant effect with the high-density treatment. This method is currently being compared to phototherapy and dawn simulation in a randomized trial of winter depression.

Clinical Issues in the Treatment of Depression

Given the availability of a wide variety of effective antidepressant therapies, how does one choose among these treatments? Because of the delay in onset of action of treatment, adherence to treatment is very important. Hence, patient preference is important to consider. Patients who strongly favour medication or psychotherapy should be offered treatment as such. The choice of psychotherapy will depend, of course, on the availability of a therapist trained in the use of a particular therapy model. The choice of medication also will depend on such factors as patient preference, past treatment history, family treatment history, clinical symptoms, health and side effect profile (Thase, 1997).

The goal of antidepressant treatment should be an optimal outcome; that is, the absence of any depressive symptoms along with a complete recovery of psychosocial function. This type of outcome is referred to as remission. About 50% of patients will have a significant response to the first-choice treatment, which is defined as a 50% or greater decrease in their symptoms of depression. Of these responders, however, only about one-half to one-third attain a full remission. Hence, a significant number of depressed patients are left with residual or persistent symptoms despite adequate antidepressant treatment (Rush and Trivedi, 1995). For these patients, switching to an alternative antidepressant drug or therapy, or combining different antidepressant treatments (e.g. pharmacotherapy and psychotherapy) may lead to a full remission.

The treatment of depression, whether with pharmacotherapy or psychotherapy, is now provided in three phases, each having different therapeutic goals (Thase and Kupfer, 1996). The acute phase, which typically lasts 6–12 weeks, refers to the initial treatment period, where the treatment is administered with the goal of full symptom remission. The continuation phase, which typically lasts 4–9 months, follows acute phase treatment and is recommended for all patients. The goal of continuation phase treatment is to prevent early relapse and to allow further symptomatic and psychosocial functional improvement. The goal of maintenance phase treatment is to prevent further recurrences of depression among patients who have a high risk of developing depression again. Such risk factors include three or more previous episodes of major depression, chronic depression, residual or persistent symptoms despite adequate treatment, and severe or disabling episodes of depression. The length of maintenance treatment will depend on the number of risk factors, and may range from a year to even life-long treatment.

For patients who do not have a satisfactory response to their initial antidepressant treatment, various strategies have been advocated (Thase and Rush, 1995). Switching to a different treatment (e.g. an alternative antidepressant drug or psychotherapy) is recommended for patients who have shown no response at all or for those who have intolerable side effects (Howland and Thase, 1999a). Augmentation (the strategy of adding a second medication to an antidepressant drug) may be most useful in patients who have shown a partial response to treatment (Thase *et al.*, 1998). Although combining pharmacotherapy and psychotherapy is commonly recommended, there is no clear evidence that the combination is more effective than either modality alone in the treatment of uncomplicated depressions (Thase *et al.*, 1997). Complicated depressions (e.g. very severe depression, treatment-resistant depression, chronic forms of depression, and partially remitted depression), however, may respond better to the combination of psychotherapy and pharmacotherapy (Fava *et al.*, 1997; Keller *et al.*, 2000; Paykel *et al.*, 1999; Thase *et al.*, 2001b).

TREATMENT OF BIPOLAR DISORDER

Antimanic Drugs

Lithium

Compared to other antimanic therapies (McElroy and Keck, 2000; Sachs and Thase, 2000), lithium is the best studied short-term and long-term treatment for bipolar disorder in adults (Baldessarini and Tondo, 2000; Maj, 2000) and in children and adolescents (Kowatch *et al.*, 2000). There is some evidence that patients with mixed episodes (mania together with depression) or a rapid-cycling pattern of illness may be less responsive to lithium (Montgomery *et al.*, 2000; Post *et al.*, 2000), but this has not been definitively proven (Baldessarini *et al.*, 2000). Although its antimanic effects are relatively greater than its antidepressant effects, it is the best studied and established pharmacological treatment for bipolar depression (Nemeroff *et al.*, 2001; Zornberg and Pope, 1993), and is less likely than antidepressants to be associated with the development of hypomania, mania, mixed states or rapid-cycling (Montgomery *et al.*, 2000; Post *et al.*, 2001; Thase and Sachs, 2000). There also is clear evidence that long-term treatment with lithium is associated with a reduced risk of suicide in bipolar and unipolar disorders (Coppen, 2000; Tondo and Baldessarini, 2000), an effect that has not been demonstrated with other antimanic therapies (Goodwin, 1999).

Although lithium has been used clinically for more than three decades, its precise mechanism of action is uncertain. Developing evidence, however, strongly suggests that lithium has direct and indirect effects on various components of second-messenger signal transduction systems, including G proteins, adenylyl cyclases, protein kinase C and the phosphoinositide cycle, which have been implicated in the neurobiology of bipolar disorder (Manji *et al.*, 1995, 1999). Typical adverse effects of lithium include gastrointestinal irritation, sedation, tremors, polyuria, polydipsia, oedema, acne, psoriasis and weight gain (Watson and Young, 2001). Careful serum level monitoring is required, as lithium toxicity can be serious (affecting cardiac, renal and central nervous system function) and potentially life threatening. Chronic lithium therapy is associated with the development of hypothyroidism, which is easily treated with thyroid hormone replacement. Lithium treatment is associated with teratogenic effects (i.e. cardiac anomalies). With careful clinical monitoring, lithium can be used safely with anticonvulsants, antipsychotics and antidepressants, but adverse interactions can occur with drugs that affect renal functioning (e.g. diuretics, non-steroidal anti-inflammatory drugs, calcium channel antagonists and ACE inhibitors).

Anticonvulsant Drugs

Lithium has been the standard treatment for bipolar disorder for nearly 30 years, but a significant proportion of patients do not respond to or cannot tolerate it (Watson and Young, 2001). As a result, various anticonvulsant drugs have been actively investigated and are increasingly used in clinical practice in the treatment of bipolar disorder (Dunn *et al.*, 1998; Keck *et al.*, 2000; Sachs *et al.*, 2000). There is now abundant evidence of the effectiveness of two anticonvulsants, divalproex and carbamazepine (Dunn *et al.*, 1998; McElroy and Keck, 2000). Divalproex is now considered by many physicians to be the most appropriate first-line treatment. For other patients, these anticonvulsants are useful second-line

or adjunctive treatments for patients who are intolerant of or do not respond to lithium (e.g. those with rapid-cycling or mixed states). Long-term treatment with anticonvulsants has not been as well studied as lithium in adults (Bowden *et al.*, 2000b; Sachs and Thase, 2000) or in children and adolescents (Kowatch *et al.*, 2000). More recently, a variety of newer anticonvulsant drugs have become available for clinical use, including lamotrigine, topiramate, gabapentin, oxcarbazepine, tiagabine, zonisamide and levetiracetam (Tatum *et al.*, 2000). Among these, lamotrigine, topiramate and gabapentin have been of particular clinical and research interest as potentially promising treatments for bipolar disorder (Dunn *et al.*, 1998). Surprisingly, oxcarbazepine, which is a better tolerated pharmacological analogue of carbamazepine, has been studied more extensively than many other anticonvulsants in the treatment of bipolar disorder, but is not yet commonly used in clinical practice (Dunn *et al.*, 1998; Teitelbaum, 2001). Tiagabine, zonisamide and levetiracetam, structurally and pharmacologically novel drugs unrelated to other anticonvulsants, have not been systematically investigated in bipolar disorder (Dunn *et al.*, 1998; McElroy and Keck, 2000; Tatum *et al.*, 2000). Like lithium, the therapeutic mechanism of action of anticonvulsants in bipolar disorder is uncertain. Recent studies, however, have suggested that carbamazepine, divalproex and perhaps other anticonvulsant drugs have direct and indirect effects on various components of second-messenger signal transduction systems (Chang *et al.*, 2001; Manji *et al.*, 1996, 1999).

Divalproex has been intensively studied in the treatment of bipolar disorder. Double-blind placebo-controlled studies have found it to be as effective as lithium in acute mania (Bowden *et al.*, 1994). Divalproex has not been as well studied in the long-term treatment of bipolar disorder, but there is evidence from a number of open studies that it has prophylactic benefits (Bowden *et al.*, 2000b; Sachs and Thase, 2000). The results from a recently completed double-blind placebo-controlled study suggested that it was somewhat more effective than lithium on some clinical measures, especially with regard to depressive symptoms, but there were no overall significant differences in outcome among patients treated with divalproex, lithium or placebo (Bowden *et al.*, 2000a). Open-label studies have shown it to be effective in bipolar depression, although it likely has relatively greater antimanic than antidepressant effects and is less likely than antidepressants to be associated with the development of hypomania, mania, mixed states or rapid-cycling (Montgomery *et al.*, 2000; Thase and Sachs, 2000; Young *et al.*, 2000). Mixed states, rapid-cycling and a poor lithium response tend to predict a positive response to divalproex (Swann *et al.*, 1997). The most common dose-dependent side effects are nausea, sedation and tremor. Transient hair loss can occur, and weight gain is common with long-term use. Blood dyscrasias, typically thrombocytopaenia, are rare. Mild transient hepatic enzyme elevations may occur, but hepatotoxicity is rare. Reports of severe hepatitis have been described primarily among young children with epilepsy taking valproic acid together with other anticonvulsants. There is some concern that women treated with divalproex may be at risk for developing polycystic ovarian syndrome, based on studies in epilepsy, but this has not been clearly demonstrated in mood disorder patients. Divalproex treatment is associated with teratogenic effects (i.e. neural tube defects) (Ferrier, 2001). In general, divalproex appears to be better tolerated than lithium or carbamazepine. Drug interactions are less common with divalproex compared to carbamazepine, because it is a weak inhibitor of hepatic enzymes, but it can increase serum levels of carbamazepine, lamotrigine and TCAs. Aspirin and naproxen can increase levels of divalproex, whereas carbamazepine can decrease its levels. Therefore, use of these drugs together with divalproex may require dose adjustments. Divalproex also can be used safely and effectively in combination with lithium, other anticonvulsants, antipsychotics and antidepressants.

Carbamazepine has been the most extensively studied anticonvulsant in bipolar disorder, although it has not been formally approved for this indication (McElroy and Keck, 2000). Double-blind placebo-controlled studies have found it to be effective in the acute and prophylactic treatment of mania (Keck *et al.*, 2000). Most controlled comparative studies have found that carbamazepine is as effective as lithium, though some have found it slightly less effective (Bowden *et al.*, 2000b). The results from controlled studies also have shown that it is effective in bipolar depression (Thase and Sachs, 2000). Similar to lithium, however, it may be relatively more effective in mania than in depression (Sachs *et al.*, 2000). Patients with mixed mania, rapid-cycling or a poor response to lithium often respond well to carbamazepine (Montgomery *et al.*, 2000). Because carbamazepine induces its own metabolism, periodic dose increases may be needed during treatment. Serum levels may therefore be especially useful to assess compliance, distinguish between poor and rapid drug metabolizers, and maintain patients at a steady-state level during long-term treatment. Sedation, dizziness, ataxia and diplopia are the most common dose-dependent side effects; weight gain frequently occurs during long-term use. Many patients develop benign skin rashes, mild leukopaenia or transient hepatic enzyme elevations, but the Stevens–Johnson syndrome, agranulocytosis, aplastic anaemia and hepatitis are rare complications. Although monitoring blood counts is recommended, this is not needed as frequently as has been suggested in the past. Carbamazepine treatment is associated with teratogenic effects (Ferrier, 2001). Because carbamazepine induces hepatic enzymes, drug interactions are common. It can significantly decrease levels of other anticonvulsants (including divalproex and lamotrigine), antipsychotics, benzodiazepines, TCAs and oral contraceptives. Erythromycin, cimetidine, divalproex, fluoxetine, fluvoxamine and calcium channel antagonists can increase carbamazepine levels. Therefore, concurrent use of these drugs with carbamazepine may require dose adjustments. Carbamazepine has been found to be relatively safe and often effective when combined with lithium or valproate, although the combinations are more likely to cause side effects than monotherapy with any of these drugs alone.

Lamotrigine has pharmacological effects that are very different from those of divalproex and carbamazepine (McElroy and Keck, 2000). The published literature on the use of lamotrigine in bipolar disorder is limited compared to divalproex and carbamazepine, but is very promising. Open-label reports have found that lamotrigine is effective alone or in combination with other antimanic drugs in patients with bipolar disorder, including many who were treatment-resistant or had rapid-cycling (Calabrese *et al.*, 1999a). Double-blind placebo-controlled studies have also found it effective in bipolar disorder (Frye *et al.*, 2000), especially in bipolar depression (Calabrese *et al.*, 1999b) and rapid-cycling (Calabrese *et al.*, 2000). The most common adverse effects are nausea, headache, dizziness, ataxia and diplopia. A benign rash occurs in approximately 10% of patients, and more severe rashes occur in 0.5–1.0%; the Stevens–Johnson syndrome also has been reported. Rashes tend to occur more commonly when higher starting doses are used or the dose is rapidly increased, and when it is used together with divalproex (which inhibits its metabolism). Lamotrigine does not affect hepatic metabolism. Carbamazepine can increase its metabolism, while divalproex decreases it.

Topiramate is a structurally and pharmacologically novel drug unrelated to other anticonvulsants (McElroy and Keck, 2000). The published literature on the use of lamotrigine in bipolar disorder is very limited compared to divalproex, carbamazepine and lamotrigine. Open-label reports have found that lamotrigine may be effective in combination with other antimanic drugs in patients with bipolar disorder, including many who were treatment-resistant (Chengappa *et al.*, 1999; Marcotte, 1998; McElroy, *et al.*, 2000). Unfortunately, the results from one double-blind placebo-controlled study reported only limited benefit with topiramate in mania

(Chengappa *et al.*, 2001). The most common adverse effects are somnolence, dizziness, anxiety, ataxia, speech difficulties, cognitive impairment, anorexia and weight loss.

Gabapentin also has pharmacological effects that differ from all other anticonvulsants. The published literature on the use of gabapentin in bipolar disorder is limited to case reports, uncontrolled open-label studies and two placebo-controlled trials. The open-label reports found that gabapentin was effective alone or in combination with other mood stabilizers in about 60–90% of patients, including those with treatment-resistant or rapid-cycling bipolar disorder (Ghaemi and Goodwin, 2001; McElroy and Keck, 2000). However, the double-blind studies did not find a significant drug–placebo difference (Frye *et al.*, 2000; McElroy and Keck, 2000). Sedation, dizziness and ataxia are the most common adverse effects. Gabapentin is not metabolized, does not affect hepatic metabolism, does not have significant drug interactions, and is not associated with hepatic or haematologic abnormalities. Because it is renally excreted, lower doses may be required in patients with renal disease, but serious toxicity in such patients is unlikely compared to lithium. The combination of gabapentin and other psychotropic drugs is generally well tolerated.

Antipsychotic Drugs

Typical Antipsychotics

For many years, the use of the older typical antipsychotic drugs has been a common clinical practice for the treatment of acute mania and psychotic mania (Keck *et al.*, 2000; Sachs and Thase, 2000). These drugs have a relatively rapid effect on manic and psychotic symptoms, psychomotor agitation and sleep. Most controlled studies have been conducted using chlorpromazine or haloperidol, which had antimanic effects comparable to lithium, divalproex and carbamazepine (McElroy and Keck, 2000). Typical antipsychotics are associated with parkinsonian side effects, akathesia and tardive dyskinesia. They also may be associated with the development of depression in some patients. One advantage of typical antipsychotics is that they are generally considered to be safe for use during pregnancy, and would be an appropriate treatment alternative to lithium or anticonvulsants in pregnant women with bipolar disorder. Another potential advantage is that two of the typical antipsychotics (haloperidol and fluphenazine) have long-acting depot formulations, which may be useful for maintaining compliance during long-term treatment for some patients (Sachs and Thase, 2000).

Atypical Antipsychotics

Because of their clinical effects and side effect profile, atypical antipsychotics have gradually supplanted use of the typical antipsychotics, even in the treatment of bipolar disorder (Sachs *et al.*, 2000). They are less likely to cause extrapyramidal side effects or tardive dyskinesia, and they appear to have more positive effects on mood (Dunayevich and McElroy, 2000; Ghaemi and Goodwin, 1999; Guille *et al.*, 2000). Olanzapine is the best studied and most established atypical antipsychotic for the acute treatment of mania (Bhana and Perry, 2001), and also may be effective for mixed states and rapid-cycling (Meehan *et al.*, 2001; Tohen *et al.*, 1999, 2000). There is evidence from controlled trials that risperidone is effective in the acute treatment of mania when added to ongoing antimanic drugs, but it has not been studied as a monotherapy in placebo-controlled trials (McElroy and Keck, 2000; Sachs *et al.*, 2000). Small open-label reports have suggested some benefit for quetiapine in treatment-resistant bipolar disorder, but there are no controlled studies (Dunayevich and Strakowski, 2000; Ghaemi and Katzow, 1999; Zarate *et al.*, 2000). One randomized double-blind placebo-controlled study of ziprasidone found it effective in bipolar patients with mania or mixed episodes (McElroy and Keck 2000). Clozapine has been reported in open-label studies to be effective in bipolar disorder, especially in treatment-resistant cases, but has not been studied in controlled trials (Dunayevich and McElroy, 2000; Ghaemi and Goodwin, 1999; Guille *et al.*, 2000). The clinical use of clozapine is limited, however, by its side effect profile and the risk of agranulocytosis. Compared to lithium and some anticonvulsants, none of the atypical antipsychotics has been well studied for long-term treatment (Bowden *et al.*, 2000b; Sachs and Thase, 2000; Vieta *et al.*, 2001). Sedation and weight gain are a problem with some of these drugs (e.g. olanzapine, quetiapine and clozapine), although ziprasidone is associated with weight loss. These drugs also are generally well tolerated when combined with other psychotropic drugs.

Novel Drug Therapies for Bipolar Disorder

Considerable evidence suggests that lithium and anticonvulsant drugs have direct and indirect effects on various components of second-messenger signal transduction systems, which may underlie their therapeutic mechanism of action (Chen *et al.*, 1999). As a result, other drugs that affect second-messenger systems have been studied in bipolar disorder. Calcium channel antagonists, which affect intracellular calcium metabolism, have been studied in bipolar disorder (Hollister and Garza Trevino, 1999; Post *et al.*, 2000), with some evidence of efficacy using nimodipine in rapid-cycling (Pazzaglia *et al.*, 1998), but mixed results with verapamil (Dose *et al.*, 1986; Janicak *et al.*, 1998). Omega-3 fatty acid, which has an inhibitory effect on neuronal signal transduction systems, has been studied as a mood stabilizer in bipolar disorder, but may have relatively greater antidepressant than antimanic effects (Stoll *et al.*, 1999). A small open-label study of the protein kinase C inhibitor tamoxifen showed a significant antimanic effect (Bebchuk *et al.*, 2000).

Various cholinomimetic drugs, which stimulate cholinergic pathways (Cummings, 2000), have been found in small open-label studies to have antimanic effects, including physostigmine, RS 86, and donepezil (Burt *et al.*, 1999; Davis *et al.*, 1978; Krieg and Berger, 1986). Other studies using choline or phosphatidylcholine, which are precursors of acetylcholine, also have suggested some antimanic effects (Leiva, 1990; Stoll *et al.*, 1996). These approaches may work in the treatment of mania by readjusting the hypothesized 'adrenergic-cholinergic imbalance'. Alternatively, these drugs may work by inhibiting phosphatidylcholine second-messenger systems (Chen *et al.*, 1999).

A number of reports have suggested that the adjunctive use of high doses of thyroid hormone may be effective in treatment-resistant bipolar disorder, including rapid-cycling, refractory mania and intractable depression (Bauer and Whybrow 1990; Bauer *et al.*, 1998; Baumgartner *et al.*, 1994).

Other Somatic Therapies for Bipolar Disorder

As discussed previously, ECT and rTMS have demonstrated efficacy in the treatment of major depression, including bipolar depression. Surprisingly, there is some evidence that these treatments also are effective in the treatment of mania. A double-blind controlled trial of right versus left prefrontal cortex fast rTMS found greater antimanic effects with right-sided stimulation, which would be consistent with the known antidepressant effects of left-sided stimulation (Grisaru *et al.*, 1998). ECT also has been used in the treatment of refractory mixed states and rapid-cycling, as well as catatonia associated with bipolar disorder (Keck *et al.*, 2000; Mukherjee *et al.*, 1994). Finally, sleep deprivation and phototherapy have been used as adjunctive therapies for rapid-cycling (Sachs *et al.*, 2000).

Clinical Issues in the Treatment of Bipolar Disorder

Bipolar disorder is a chronically recurrent phasic illness. As a result, acute treatments often are phase-specific (Sachs *et al.*, 2000). For acute bipolar mania, lithium, anticonvulsants and antipsychotics are clearly effective. High-potency benzodiazepines (such as lorazepam or clonazepam) or low-potency sedating antipsychotics (such as chlorpromazine or thioridazine) can be used adjunctively to promote sleep, which will have an additional therapeutic antimanic effect. For refractory mania, antimanic drug combinations, atypical antipsychotics, novel anticonvulsants, calcium channel antagonists, cholinomimetics, omega-3 fatty acids, thyroid hormone and ECT can be useful.

For bipolar depression, lithium and anticonvulsants can have antidepressant effects. They are the preferred initial treatment because they are less often associated with the development of hypomania, mania, mixed states or rapid-cycling. Antidepressant drugs can be effective, but may induce hypomania, mania, psychosis, mixed states or rapid-cycling (Altshuler *et al.*, 1995). Although there is some clinical evidence that the risk of antidepressant-induced mania may differ among antidepressant drugs, this has not been clearly established (Boerlin *et al.*, 1998; Howland, 1996b). The dose and/or serum level of antimanic drugs should be optimized if antidepressants are used. For treatment-resistant bipolar depression, atypical antipsychotics, dopamine agonist drugs, sleep deprivation, phototherapy and ECT are potentially effective alternatives. Mixed states and rapid-cycling, which are more common in women than in men, predict a poorer response to most treatments and a poorer long-term prognosis (Montgomery *et al.*, 2000). In these situations, anticonvulsants, atypical antipsychotics, thyroid hormone, calcium channel antagonists, sleep deprivation, phototherapy and ECT may be effective, along with minimizing or avoiding the use of antidepressants.

Virtually all patients with bipolar disorder will require longer-term continuation and maintenance therapy to prevent relapse or recurrence of mood episodes (Sachs and Thase, 2000). For many patients, it is prudent to continue acute treatments indefinitely if their tolerability and efficacy are acceptable. Changes in symptoms (such as depression, hypomania or psychosis) during long-term therapy can usually be effectively managed by careful titration of ongoing antimanic, antipsychotic and/or antidepressant treatments. Significant symptoms unresponsive to titration of current therapies can be treated by adding an appropriate symptom-specific therapy. Because of the inherent mood instability in bipolar disorder, however, medication changes or additions should be done gradually while closely monitoring the patient's clinical condition. For example, adding or discontinuing antidepressant drugs are both associated with the development of mania (Goldstein *et al.*, 1999). Therefore, adjusting the antidepressant dose (rather than abruptly stopping the drug) while maximizing the antimanic drug dose and/or serum level would be an appropriate strategy for managing antidepressant-associated mania.

Animal Models of Anxiety Disorders

Frederico G. Graeff and Hélio Zangrossi Jr

INTRODUCTION

The last decades have witnessed a growing interest in the use and development of animal models in psychiatry. The demand for these models has been motivated by the ethical, methodological and economical constraints that restrain the study of neurobiological processes in human subjects. It is undeniable that animal experimentation has contributed to advances in psychopharmacology and to our understanding of brain mechanisms involved in psychiatric disorders. Suffice to remember that benzodiazepine anxiolytics have been discovered because of the taming effect of chlordiazepoxide observed in *Cynomolgus* monkeys by Randall (Randall *et al.*, 1960). Also, hypotheses on the role of serotonin (5-HT) in anxiety were based on experimental work with conflict tests in rats and pigeons (Robichaud and Sledge, 1969; Graeff and Schoenfeld, 1970; Stein, Wise and Berger, 1973) as well as with aversive electrical stimulation of the rat dorsal periaqueductal grey matter (DPAG) (Kiser and Lebovitz, 1975; Schenberg and Graeff, 1978, Schütz, de Aguiar and Graeff, 1985).

Early animal models of anxiety were developed when behaviourism was the main conceptual framework within experimental psychology, and before classifications of psychiatric disorders split pathological anxiety into distinct nosological entities (see later). These animal models of anxiety rely on either inhibition of ongoing behaviour elicited by conditioned stimuli that predicted unavoidable electric shock or on suppression of rewarded responding by electric-shock punishment. The first type of model is based on principles of associative or Pavlovian conditioning, and the second on instrumental or operant conditioning. Punishment tests also suggest clinically derived constructs that emphasize the role of inner conflict in pathological anxiety, and this may be the reason why these tests became known as conflict models. Early pharmacological analysis showed conflict models to have a higher predictive value than conditioned suppression and, as a result, punishment tests became paradigmatic for assaying anti-anxiety drugs (Kelleher and Morse, 1968).

Surprisingly, classical conflict tests failed to consistently detect the anxiolytic action of drugs that act primarily on the neurotransmission mediated by serotonin (5-HT), such as buspirone and ritanserin (Handley *et al.*, 1993; Griebel, 1995). Such false-negative results undermined the general confidence in conflict models, although many arguments may be summoned to their defence, as for instance the time course of drug action. Unlike benzodiazepine anxiolytics, the newer drugs need several weeks of continuous administration to become clinically effective, initial doses being sometimes anxiogenic (Nutt, 1991). Why, then, should one expect single administration of these agents to be anxiolytic in animal models? In spite of this, it became generally accepted that conflict tests were good only for anxiolytics that acted primarily on the neurotransmission mediated by γ-aminobutyric acid (GABA), which is the case for barbiturates and benzodiazepines.

A theoretical shift from behaviourism to ethology has also contributed to the discredit of conflict models, which have been criticized because of their artificiality and the confounding influence of appetitive drives, such as hunger and thirst, and of pain (Treit, 1985). As a result, a search for ethologically based animal models of anxiety has begun. The most widely used animal model of anxiety resulting from this trend has been the elevated 'X' or 'plus' maze, which is based on the natural fear that rats have for elevated, open spaces, represented by the two open arms of the apparatus (Handley and Mithani, 1984; Pelow and File, 1986). Countless drugs have been assayed in this model, and the results obtained summarized in several comprehensive reviews (e.g., Handley *et al.*, 1993; Rodgers, 1994; Griebel, 1995). Disappointingly, this model also failed to detect non-benzodiazepine anxiolytics. To do this, ethological analysis of behavioural items shown by the animals while exploring the elevated plus-maze has been added to the procedure (Cruz, Frei and Graeff, 1994; Rodgers and Johnson, 1995). However, with this modification one of the main advantages of the test, which is simplicity, is lost.

As these developments were taking place in basic research, the split of anxiety disorders into distinct diagnostic categories, a trend that was initiated by the DSM III classification of psychiatric disorders (American Psychiatric Association, 1980), became accepted worldwide. Even though present-day psychiatric classifications cluster symptoms empirically, they constitute a necessary starting point for systematic research. It is hoped that the evidence thus obtained will either validate or modify the original categories.

The following categories from the DSM IV classification of psychiatric disorders (American Psychiatric Association, 1994) will be considered in the present analysis. (1) Generalized anxiety disorder (GAD), a state of excessive anxiety or apprehension lasting for more than six months. Neurovegetative symptoms are often present, but relatively minor. (2) Panic disorder (PD), characterized by recurrent panic attacks, either unexpected or associated with particular situations. Panic attacks are sudden surges of intense fear or terror, desire of fleeing and feeling of imminent death, going crazy or loosing control. These subjective symptoms are accompanied by major neurovegetative changes, such as palpitation, hypertension, dyspnoea, difficulty in deep breathing, sweating, urge to void the bladder and increased peristalsis. This leads to worry about the next attack or anticipatory anxiety, and avoidance of places where a panic attack would be embarrassing. Ultimately, generalized avoidance or agoraphobia may ensue. Nevertheless, agoraphobia sometimes occurs without panic attacks. (3) Obsessive–compulsive disorder (OCD) characterized by intrusive, distressing thoughts (obsessions) and/or stereotyped or ritualized behaviour (compulsions) that must be performed in order to alleviate intense anxiety. (4) Specific phobias, which are irrational fears of either objects (animals, blood, pointed instruments) or situations (heights, closed environments). (5) Social

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

phobia, or marked anxiety experienced in social situations, such as speaking in public or going to parties or class rooms.

Given this background, it is no longer acceptable to look for animal models of anxiety, in general. Instead, models that represent specific anxiety disorders are due. Animal models of psychopathology have been evaluated according to criteria of predictability of drug response, analogy or face validity, and homology or theoretical construct validity (Treit, 1985; Willner, 1991). As Willner (1991) pointed out, 'Earlier attempts to develop criteria for validating animal models of human behaviour have tended to be concentrated largely on the assessment of face validity. The identification of two further categories reflects two ways in which the literature has developed in recent years. First, there has been a considerable expansion in the literature dealing with the pharmacological exploitation of animal models, much of which contributes to the assessment of predictive validity. Second, there has been significant growth in our understanding of the psychological mechanisms underlying psychopathological states, and examination of construct validity provides a convenient way of bringing animal models into contact with this very relevant literature'.

Indeed, the predictive criterion alone may be insufficient to characterize a test as an animal model of anxiety, since correlation between drug response in the model and in the clinics may happen, despite differences in brain mechanisms of pathophysiology and drug effect (e.g., drug-induced catalepsy and schizophrenia). The analogy criterion in itself may also be misleading, since in different species similar behaviours often serve different adaptive functions and, conversely, distinct behaviours may lead to the same goal. For instance, rat probe-burying behaviour is attenuated by anxiolytics (Treit, 1985), although it does not resemble any symptom of GAD. However, this behaviour is one of the defensive strategies of the rat's repertoire, and thus may be theoretically related to anxiety (see later).

It may be concluded that only homology qualifies animal models as representative of psychopathologies. Yet this conclusion does not look very promising, considering the (purposefully) non-theoretical stance of present-day psychiatric classifications and the scant knowledge available on how psychiatric symptoms are generated and on the neural events that underlie different animal models of anxiety. Nevertheless, we have to face the challenge or, otherwise, are bound to create theoretically shallow animal models, which are likely to generate more noise than information.

In order to assess homology, theories that encompass both pathophysiology and animal behaviour indexes have to be constructed. In this regard, evolutionary psychology and psychiatry provide a sound theoretical framework (see, e.g., McGuire and Troisi, 1998). Charles Darwin himself laid the ground for this line of thought in his book *The Expression of Emotions in Man and Animals* (Darwin, 1872) by advocating that behavioural, no less than physical, characteristics would be acquired as a result of selective pressure exerted by biological evolution. This view justifies the use of animals belonging to the phylogenetic line that resulted in humans to study the neurobiology of psychological phenomena, to the extent that brain properties be conserved along evolution. Since several environmental constraints are similar across species, or even genera and families, many adaptations are species-general, among which stand the basic emotions. Although emotional expression varies from one species to another, functional behavioural classes, such as escape and avoidance from danger or approach sources of food, remain the same and constitute the basis for the classification of basic emotions (Nesse, 1990). No wonder that the neural substrate of such emotions is conserved along biological evolution. On this basis, Panksepp proposed that basic emotions, such as rage, fear, panic and expectancy, are represented by inborn neural networks that co-ordinate behavioural strategies allowing animals to deal with enduring environmental (including social) challenges (Panksepp, 1982).

Fear and anxiety are emotional states with high adaptive value, rooted as they are in defensive reactions displayed in situations of threat to the physical integrity or survival of the organism. The sources of danger are manifold, including predators, environmental stimuli or situations, such as height, illumination, painful stimuli, novel places or objects, and confrontation or competition with animals from the same species. To deal with these challenges, animals generally use one of four basic defensive strategies, namely escape, immobilization, defensive attack and submission (Adams, 1979; Marks, 1987; Blanchard and Blanchard, 1988). The decision to choose one particular strategy takes into account several factors, such as the characteristics of the environment, distance from the threatening stimulus and previous experience with the stimulus and/or environment. Thus, in a highly discernible situation of threat, as in the confrontation with an approaching predator, the animal will preferentially escape, if an exit route is available. In turn, the animal will become tensely immobile (freezing) if the predator is not in close proximity and/or escape is impossible. In this case, being motionless decreases the probability of detection or attack by the predator. On the other hand, in a situation of close proximity or contact with the predator, vigorous flight or defensive threat and attack toward the predator may be more efficient in deflecting predatory action. Alternatively, certain species, including birds, fishes and some mammals, may display a state of tonic immobility, feigning death, by means of which the animals may decrease the predator's interest (Marks, 1987). Finally, submission postures are often observed in confrontation with conspecifics. By acting submissively, the individual may inhibit the attack by a socially dominant animal. However, submissive responses hardly ever inhibit predatory attack (Adams, 1979).

The evolutionary approach views anxiety disorders as pathologies of defence (Panksepp, 1982; Marks, 1987; Marks and Nesse, 1994; Graeff, 1994; Hofer, 1995; Stein and Bouwer, 1997; Gray and McNaughton, 2000; Blanchard *et al.*, 2001). For instance, specific phobias, GAD and PD may be related to predatory aggression. In this regard, the work carried out by Robert and Caroline Blanchard on predatory defence in rats and mice (Blanchard and Blanchard, 1988; Blanchard, Griebel and Blanchard, 1997) classified the behavioural strategies displayed according to the level of threat, namely potential or uncertain, distal and proximal. The first level evokes cautious exploration and hesitant behaviour aimed at risk assessment. The second induces either directed escape or immobility. Finally, when the predator is very close or in contact with the prey, either vigorous flight or defensive aggression occurs. To this ethoexperimental analysis, Gray and McNaughton (2000) have added elements of learning theory, including conditioned stimuli that signal either punishment or loss of an expected reward (frustration) as elicitors of anxiety (first level of defence). The same authors have also highlighted the importance of approach-avoidance conflict and of the direction of response to distinguish anxiety from fear. Thus, anxiety exists only when there is a tendency to approach the source of danger. When only the escape or avoidance component exists there is fear. Indeed, pharmacological data show that active avoidance and escape responses are remarkably resistant to anxiolytic drugs, in contrast to risk-assessment and punished suppressed responding (Gray and McNaughton, 2000).

In a synthesis of experimental evidence from several research fields, the above levels of defence have been related to different emotions and to distinct anxiety disorders (Graeff, 1994; Gray and McNaughton, 2000). Table XIX-1.1 summarizes this view, which provides the theoretical framework presently used to qualify an animal model as representative of GAD, PD and specific phobias, respectively.

Following the same evolutionary approach, social phobia has been related to submissive displays that are expressed by subordinates in social interaction with dominant animals of the same

Table XIX-1.1 Levels of defence, main neural substrate, related emotion and anxiety disorder, and their drug sensitivity

Danger	Defence reaction	Critical brain structures	Emotion	Disorder	Drug sensitivity
Potential (Conflict)	Risk-assessment/behavioural inhibition	Septo-hippocampal system/amygdala	Anxiety	GAD	Anxiolytics Antidepressants
Anticipated (CS)	Freezing	Amygdala VPAG	Anticipatory anxiety		
	Avoidance	Amygdala	Conditioned fear	Specific phobias	None
Distal (US)	Escape	Medial hypothalamus	Unconditioned fear	Specific phobias	None
Proximal (US)	Flight/freezing	DPAG	Panic	PD	Antidepressants

Key: CS, conditioned stimulus; US, unconditioned stimulus; VAPG, ventral periaqueductal grey; DPAG, dorsal periaqueductal grey; GAD, generalized anxiety disorder; PD, panic disorder (Modified from Graeff, 1994 and Gray and McNaughton, 2000).

species (Stein and Bouwer, 1997). Nevertheless, to our knowledge this hypothesis has not been explored to generate animal models of this disorder.

Finally, the most frequent compulsive behaviours found in OCD, washing and checking, have been related to self-grooming and territorial checking routines that many animal species perform to protect themselves against micro-organisms and intruders, respectively (Rapoport, 1991).

The subsequent sections will focus on pharmacological evidence that is relevant to the validation of selected models of each psychiatric disorder. Because the aim of this article is to relate animal models and psychiatric disorders, only drugs that have been evaluated in clinical assays will be considered. Whenever pertinent, there will be mention of evidence from studies using direct intervention on the brain.

MODELS OF GENERALIZED ANXIETY DISORDER

As pointed out earlier, the ethoexperimental analysis of defence strategies against predatory attack made by the Blanchards (Blanchard and Blanchard, 1988; Blanchard *et al.*, 1997) led them to relate GAD to behaviours that occur in response to potential threat, chiefly the so-called risk-assessment behaviour. Gray and McNaughton (2000) also view 'behaviours that occur in the context of potential threat as paradigmatic of anxiety'. But they suggest that 'the critical feature for such behaviours was the approach-avoidance conflict inherent in the "potential threat" situation rather than the potentiality of threat as such'. They also broadened the notion of potentially threatening stimuli to include 'novelty stimuli of certain kinds, signals of punishment, and signals of reward omission, in addition to the paradigmatic innate anxiety stimuli'. Gray and MacNaughton (2000) have further suggested that anxiety has a cognitive component — approach-avoidance conflict — managed by the septo-hippocampal system, and an affective component — aversion — accomplished by the uppermost structure of the brain defence ('fight/flight/freezing') system, the amygdala.

It follows that conflict tests would rank first in homology regarding GAD, since they would engage both the septo-hippocampal system and the amygdala (Gray and MacNaughton, 2000). Because of the shortcomings analysed in the introduction of this paper, classical conflict tests are seldom used for assessing anxiolytic drug action. However, a modification of the latter, inhibitory avoidance in the elevated T-maze (Graeff, Viana and Tomaz, 1993), eliminates most of the objections raised against punishment models, since animals are not deprived, and aversion for an open, elevated arm of the maze replaces electric foot-shock. Also, the light-dark transition model (Crawley and Goodwin, 1980), in which rats or mice are placed inside an experimental chamber divided into two compartments, one bright and another dark, may be viewed as a conflict test: the naïve animal tends to explore both compartments of the box, but the entrance to one of them is punished by exposure to bright light.

Also at the first level of homology are models that involve risk-assessment behaviour determined by potential threat from innate fear stimuli, such as in the anxiety/defence test battery (Blanchard and coworkers, 1993, 2001) and a component of the mouse defence test battery (Griebel, Blanchard and Blanchard, 1996a).

In anxiety models such as conditioned suppression (Estes and Skinner, 1941) and fear-potentiated startle (Davis, 1986) an exteroceptive stimulus predicts unavoidable foot-shock, causing, respectively, suppression of rewarded responding and increased amplitude of the acoustic startle response. Therefore, there is no approach-avoidance conflict and according to Gray and McNaughton (2000) the septo-hippocampal system is not involved. Therefore, the behavioural inhibition seen in these situations would rely entirely on the amygdala. Indeed both the amygdala and the ventral periaqueductal grey (VPAG) have been shown to be critical for the expression of conditioned freezing (Davis, 1992; Fanselow, 1991). Since these tests activate the affective, but not the cognitive component of anxiety (Gray and McNaughton, 2000), they only partially fulfil the theoretical requirements for a model of GAD. It is more likely that these models represent anticipatory anxiety, which like GAD is also sensitive to anxiolytic drugs (Table XIX-1.1). A remark about fear-potentiated startle is in order. Although the anxiety index is the enhancement of the startle response, this is directly proportional to the degree of freezing produced by the conditioned aversive stimulus (Leaton and Borszcz, 1985). Therefore, fear-potentiated startle may be viewed as behavioural inhibition in disguise.

There are also anxiety models that involve defensive aggression — usually threat — provoked by an approaching danger stimulus. A typical example is the primate defensive reaction evoked by the experimenter's gloved hand. Despite the historical importance of this model — in particular the discovery of the anxiolytic action of chlordiazepoxide (Randall *et al.*, 1960) — they are little used today, due to its high cost and low feasibility. Nevertheless, a rodent model that measures defensive behaviour against a conditioned aversive stimulus, the shock-probe-burying test (Pinel and Treit, 1978) deserves attention.

Social interaction in young rats has a pharmacological profile suggestive of GAD (File, 1995). Nevertheless, it seems to involve many variables, and the theoretical construct underlying the test has not been fully clarified. Therefore, this model will not be addressed here.

In the following subsections, the main models of GAD are discussed in detail. The mouse defence test battery and the elevated T-maze will be analysed in a separate section, because these tests are intended to model PD, in addition to GAD.

The Anxiety/Defence Test Battery

The anxiety/defence test battery (A/DTB) was developed in order to measure drug effects on risk-assessment behaviours (Blanchard and coworkers, 1993, 2001). In this model, measures of risk-assessment and inhibition of non-defensive behaviour are evaluated in rats submitted to three situations representing potential threat associated with a predator. In the first situation, the 'proxemics/activity test', the rat's location in the test chamber is measured after non-contact exposure to a cat. It has been shown that after a 5-minute encounter with the predator, rats avoid locations near the cat compartment. In the second condition, the 'eat/drinking test', the frequency and duration of two non-defensive behaviours, feeding and drinking, are measured during and after a 5-minute non-contact exposure to a cat. In the presence of the predator these behaviours are inhibited, being gradually resumed over time. Finally, in the 'cat odour test', the frequency and duration of risk assessment expressed towards an object saturated with cat odour are measured. The indexes used are flat-back approach and stretch-attend posture, as well as the frequency and time spent by rats in direct contact with the cat odour source (for further details on these tests see Blanchard and coworkers, 1990, 1993).

The effects of different classes of anxiolytics in the A/DTB are reviewed elsewhere (Blanchard and coworkers, 1993, 1997, 1998). Overall, benzodiazepines and buspirone-like drugs decrease avoidance from the area close to the cat compartment and counteract inhibition of feeding and/or drinking after cat exposure. These drugs interfere with the expression of risk-assessment behaviours in a bi-directional way. They increase risk assessment when the baseline expression of these behaviours in the control group is low or absent, due to enhanced freezing behaviour. However, they decrease risk assessment in less aversive situations, in which a considerable level of risk assessment is already being expressed by the animals. In both cases the drugs decrease reactivity to the threatening situation, thus moving the animal to a level of defensiveness where approach to the aversive stimulus is more likely to occur. The non-selective 5-HT_2 antagonist ritanserin failed to show the same anxiolytic profile. Chronic administration of the tricyclic antidepressant imipramine caused anxiolytic effects similar to that of diazepam and chlordiazepoxide, but the panicolytic benzodiazepine alprazolam, administered acutely, had no effect. The full pharmacological validation of this test awaits further analysis since neither the effect of anxiogenic drugs nor the selectivity of the model have been explored.

The Light/Dark Transition Model

The light/dark transition model was elaborated by Crawley and Goodwin (Crawley and Goodwin, 1980; Crawley, 1985), based on the exploratory behaviour of mice in a two-compartment box, where one chamber is brightly lit and the other dark. In such conditions, mice and rats have a clear preference for the dark side of the box and the number of transitions made by them between the two compartments and the time spent in the bright side have been used as indices of anxiety. Over the years several procedural modifications have been introduced in order to improve the feasibility of the test or its pharmacological predictability. These modifications include, among others, the introduction of a connecting tunnel between the two compartments (De Angelis, 1992), changes in the dimensions or spatial disposition of the compartments (Imaizumi, Miyazaki and Onodera, 1994; Shimada *et al.*, 1995), use of fully automated data collection (Onaivi and Martin, 1989; Young and Johnson, 1991b; Hascoët and Bourin, 1998) and analyses of additional behavioural indices of anxiety and locomotor activity (Chaouloff, Durand and Mormede, 1997; Smythe *et al.*, 1998; Hascoët and Bourin, 1998).

When interpreting the pharmacological results so far obtained with the light/dark transition model, one should keep in mind that what poses as a simple procedural modification may change the way animals respond to the aversive challenge. As discussed before, the type of defensive response determines the effect of anxiety-modulating drugs in the test. For instance, increasing the illumination of the bright compartment may decrease the amount of risk assessment made by the animal in the transition area between the two compartments of the apparatus. Although this alteration may not necessarily lead to changes in the absolute amount of time spent in the two compartments, it may interfere with the expression of an important set of GAD-related behaviours. Moreover, when comparing results of different studies it is important to notice that in this test, as in other anxiety models, uneven levels of basal anxiety are expressed by different strains of animals (Crawley and Davis, 1982; Hascoët and Bourin, 1998; Griebel *et al.*, 2000). Baseline anxiety also changes along the animal's life span (Hascoët, Colombel and Bourin, 1999). Discrepancies among studies on these and others parameters may be responsible for many of the reported conflicting drug effects found in the literature.

Despite the above caveats, drug results with anti-anxiety agents are remarkably consistent, using either the original protocol or modified versions of the test. Thus, reported results show that acute injection of benzodiazepines (e.g., diazepam, chlordiazepoxide and alprazolam) or buspirone-like drugs have anxiolytic effects in both mice and rats (Crawley, 1985; Pich and Samanin, 1989; Young and Johnson, 1991a; Shimada *et al.*, 1995; Sanchez, 1996; Griebel, Sanger and Perrault, 1996b; Hascoët and Bourin, 1998). Overall, the time spent in the bright compartment seems to be more reliable for assessing anxiety relief than the number of transitions (Hascoët and Bourin, 1998).

However, conflicting results (anxiolytic, anxiogenic or lack of effect) have been obtained with acute injection of the antidepressants imipramine (Pich and Samanin, 1989; Onaivi and Martin, 1989; Young and Johnson, 1991a; De Angelis, 1996), fluoxetine (Kshama *et al.*, 1990; De Angelis, 1996; Sanchez and Maier, 1997; Artaiz, Zazpe and Del Rio, 1998) and citalopram (Griebel *et al.*, 1994; Sanchez and Maier, 1997). Other SSRIs, such as paroxetine, sertraline and fluvoxamine, were ineffective in rats (Sanchez and Maier, 1997), but paroxetine exerted an anxiolytic effect in mice (Hascoët, Bourin and Nic Dhonnchadha, 2000). However, as none of these drugs has been evaluated after chronic administration, the pharmacological profile of the test is incomplete.

Some drugs known to increase anxiety in man and in rodents, such as mCPP and pentylenetetrazol (PTZ), also have an anxiogenic effect in the light/dark transition model (Onaivi and Martin, 1989; Griebel *et al.*, 1991; Bilkei-Gorzo, Gyertyan and Levay, 1998). However, other anxiogenic drugs, such as yohimbine and FG-7142, have shown either an anxiogenic or no effect in the test (Pich and Samanin, 1989; Singh *et al.*, 1991; Shimada *et al.*, 1995; Hascoët and Bourin, 1998; Bilkei-Gorzo, Gyertyan and Levay, 1998).

The selectivity of the light/dark transition model for anxiety-modulating drugs has been supported by findings that the neuroleptics, chlorpromazine, piperone, haloperidol and clozapine (Young and Johnson, 1991a; Costall and Naylor, 1995; Bilkei-Gorzo, Gyertyan and Levay, 1998) as well as the psychostimulant amphetamine (Young and Johnson, 1991a; Bilkei-Gorzo, Gyertyan and Levay, 1998) did not alter the classical anxiety indices. However, in the case of amphetamine and of another psychostimulant drug caffeine, evidences of anxiogenic effects are also reported (Onaivi and Martin, 1989; Imaizumi, Miyazaki and Onodera, 1994; Hascoët and Bourin, 1998).

Fear-Potentiated Startle

The fear-potentiated startle paradigm has been successfully used for studying the neurobiological basis of fear/anxiety conditioning,

mostly by Davis and coworkers (Davis, 1986; Davis *et al.*, 1993; Walker *et al.*, 1997). This model, first described by Brown, Kalish and Faber (1951), is based on principles of Pavlovian classical conditioning and its performance involves two distinctive steps. Initially, the animals are trained to associate a neutral stimulus (the to-be-conditioned stimulus), generally a light, with an aversive stimulus such as an electric foot-shock. After training, the animals are submitted to an intense sound and the amplitude of their startle reflex to this unconditioned aversive stimulus is measured, either in the presence or in the absence of the conditioned stimulus (light). It has been shown that the amplitude of the acoustic startle reflex is higher when the eliciting acoustic stimulus occurs in the presence of the light. This potentiation of the startle response can be found even one month after the training session. Further evidence shows that maximum potentiated startle in the test session is achieved at the time after light onset which was followed by foot-shock presentation in training, that is, when shock is most expected. These results strengthen the view of fear-potentiated startle as a model of anticipatory anxiety (Davis *et al.*, 1993). Considering the above definition of fear, given by Gray and McNaughton (2000), a more appropriate denomination for this test would be 'conditioned anxiety-potentiated startle'. However, for sake of clarity the original name is preserved.

The effects of different classes of psychoactive drugs in rats submitted to the fear-potentiated startle are reviewed by Davis *et al.* (1993) and Hijzen *et al.* (1995).

A selective anxiolytic effect in this test is characterized by attenuation of fear-potentiated startle with no change in the baseline level of startle, that is, the startle response obtained in the absence of the conditioned stimulus. Decreases in both measures may indicate non-specific impairment of motor control. Overall, benzodiazepines, including alprazolam, as well as buspirone-like drugs decrease fear-potentiated startle, often without any change in baseline startle. However, it is interesting to notice that in some cases buspirone and ipsapirone, a similar 5-HT_{1A} agonist, *increase* baseline startle response, in addition to decreasing potentiated startle (Kehne, Cassella and Davis, 1988). These results suggest that these drugs may have differential effects on conditioned and unconditioned responses. In fact, the mechanisms by which 5-HT_{1A} drugs exert their effects seem to be complex, as attested by evidence showing that 5-HT_{1A} antagonists also have anxiolytic effects in this test (Joordens, Hijzen and Olivier, 1998).

As observed with acute injection of the antidepressants amitriptyline (Hijzen *et al.*, 1995) and fluvoxamine (Joordens *et al.*, 1996), administration of imipramine either acutely or chronically (3 weeks) did not affect either fear-potentiated or baseline startle. The lack of imipramine effect has led to the view that this test dissociates anticipatory anxiety from panic (Davis *et al.*, 1993). However, the effects of SSRIs, such as fluoxetine and citalopram, in the test are still unknown.

As expected, the anxiogenic drug yohimbine enhanced potentiated startle, but mCPP had no such effect. The selectivity of the test for anxiety-modulating drugs has been obscured by false positive results obtained with haloperidol (Hijzen *et al.*, 1995) and with the α_2-adrenergic agonist clonidine (Davis *et al.*, 1993). As in the light/dark transition model, amphetamine has been shown to be either anxiogenic (Borowski and Kokkinidis, 1998) or without effect (Hijzen *et al.*, 1995).

Defensive Burying

The conditioned defensive burying test was originally developed by Pinel and Treit (1978, 1979) and explores rodent's species-typical behaviour of burying objects that represent or are associated with aversive stimulation. In the original description of the test, the authors reported that rats shocked once by a probe mounted on the wall of the test box returned to the probe and buried it with bedding material from the floor of the box. They also showed that this behaviour was still observed even when the shock had been delivered 20 days before testing, supporting the role of aversive learning in this paradigm (for further details on the behavioural validation of this test see Treit (1985)). Later on, it was observed that anxiolytic drugs, like diazepam, chlordiazepoxide and pentobarbital, decreased the time spent by animals spraying and pushing bedding material towards the shock source in a way comparable to their relative potencies in clinical settings (Treit, Pinel and Fibiger, 1981). Other psychoactive drugs as picrotoxin, PTZ, d-amphetamine and morphine, injected in a single dose, were ineffective.

However, with the growing use of the test in other laboratories, conflicting results emerged (see Craft, Howard and Pollard, 1988). Soon it became clear that procedural changes, such as intensity and number of shocks delivered (Treit and Fundytus, 1988; Tsuda, Ida and Tanaka, 1988; Treit, 1990), previous habituation to the test box (Treit and Fundytus, 1988) as well as the animal's strain (Pare, 1992) and age (Lopes-Rubalcava, Fernandez-Guasti and Urba-Holmgren, 1996), may influence drug effects. Furthermore, by measuring only the time spent by rats burying the probe it was not possible to clearly separate the anxiolytic effect of the drug from its non-specific effects on general motor activity, due to sedation and/or ataxia. The latter problem still remains as one of the main drawbacks of the model. Nevertheless, the introduction of other indices of anxiety, such as the latency to initiate the defensive burying (Beardsley *et al.*, 1990) and the frequency of contact with a constant electrified probe (Treit and Fundytus, 1988), offered some gains in predictability of drug response. Yet the use of concurrent behavioural tasks for checking animals general activity, such as the rotarod or the arena, has been adopted to discriminate confounding drug effects (Sakamoto *et al.*, 1998; Fernandez-Guasti and Lopez-Rubalcava, 1998).

The conditioned defensive burying test consistently detects acute anxiolytic effects of benzodiazepines and buspirone-like drugs in both rats and mice (Treit, 1990; Fernandez-Guasti, Hong and Lopez-Rubalcava, 1992). Chronic treatment with the antidepressants imipramine, pargyline and desipramine had no effect on rats' burying behaviour (Beardsley *et al.*, 1990).

The pharmacological predictability of the test has been questioned because of failure in consistently detecting anxiogenic drug effects. Neither PTZ nor picrotoxin (Treit and coworkers, 1981, 1987, 1990) enhance burying behaviour and FG-7142, in fact, decreased its expression (Rohmer, Di Scalar and Sandner, 1990). Conflicting results have been obtained with yohimbine, since this drug is reported to be either anxiolytic (Tanaka *et al.*, 2000) or anxiogenic (Tsuda, Ida and Tanaka, 1988; Lopez-Rubalcava and Fernandez-Guasti, 1994) and even to have no effect (Treit, 1990). The selectivity of the test has also been undermined. Whereas the neuroleptic haloperidol had no effect (Sakamoto *et al.*, 1998), as would be expected, other agents ineffective on GAD, such as chlorpromazine (Treit, Pinel and Fibiger, 1981), clonidine and prazosin (Lopez-Rubalcava and Fernandez-Guasti, 1994) behaved as anxiolytics in the animal test (however, in the case of chlorpromazine, lack of effect on anxiety indices was observed with a modified conditioning protocol (Treit, 1990)).

MODELS OF PANIC DISORDER

The available models of panic disorder (PD) are based on two complementary hypotheses. The first considers panic to be related

to the flight response induced by proximal threat (Blanchard and Blanchard, 1988), as discussed in the introduction to this paper. The second hypothesis suggests that panic attacks are due to activation of the medial hypothalamus and/or DPAG (Gentil, 1988; Graeff, 1988, 1991; Deakin and Graeff, 1991), which are brain structures that integrate escape and flight responses, respectively (Table XIX-1.1). The former hypothesis gave origin to the fear/defence test battery (Blanchard, Flannelly and Blanchard, 1986), the mouse defence test battery (Griebel, Blanchard and Blanchard, 1996a) and the one-way escape task in the elevated T-maze (Graeff, Viana and Tomaz, 1993). The second proposal led to animal models that use either electrical (Jenck, Moreau and Martin, 1995; Schenberg *et al.*, 2001) or chemical stimulation (Beckett *et al.*, 1992b) of the DPAG, as well as chemical stimulation of the dorso-medial hypothalamus (DMH) (Shekhar, 1994).

The experimental evidence implicating the DAPG in panic has been extensively discussed elsewhere (Graeff, 1988, 1991; Deakin and Graeff, 1991; Graeff *et al.*, 1996b). One of the main arguments in favour of this view is that electrical or chemical (by excitatory amino acids or anti-GABA agents) stimulation of the DPAG evokes abrupt and clumsy flight responses in experimental animals, reminiscent of a panic attack (Graeff, 1988, 1991). Similar results have been reported with infusion of $GABA_A$ antagonists into the DMH (Shekhar and Di Micco, 1987), although escape induced by $GABA_A$ antagonists or synthesis inhibitors injected into this brain area is more co-ordinated and well oriented toward environmental goals than that obtained in the DPAG (Schmitt *et al.*, 1986). Another argument is that electrical stimulation of the DPAG of patients undergoing neurosurgery produces neurovegetative changes and feelings of terror that are characteristic of clinical panic attacks (Nashold, Wilson and Slaughter, 1974; Amano *et al.*, 1978). Moreover, a PET study carried out by Reiman *et al.* (1989) showed that the midbrain tectum, which includes the DPAG was activated during lactate-induced panic attack.

Blanchard and colleagues (2001) have recently reviewed several of above models of PD. The following description is in large measure based on their account. We have added the version of DPAG electrical stimulation developed by Schenberg's group and the chemical stimulation of the DPAG model introduced by Marsden and coworkers. Because the mouse/defence test battery and the elevated T-maze address both to GAD and PD, they will be analysed separately.

Fear/Defence Test Battery

The fear/defence test battery measures defensive behaviours of wild rats (*Rattus rattus*), more specifically, freezing, flight, defensive sonic vocalization and defensive attack to an approaching/contacting predator, a human subject (Blanchard and coworkers, 1986, 1993). It has been shown that these responses are more evident in wild than in laboratory rats (Blanchard, Flannelly and Blanchard, 1986). Overall, benzodiazepines (diazepam, chlordiazepoxide and midazolam) and buspirone-like drugs did not affect the expression of freezing, avoidance and more importantly, flight responses, during confrontation with the predator. The lack of effect of these GAD-effective drugs on these defensive responses has supported analogies between the test and PD. These compounds do decrease defensive threat/attack reactions towards the predator (Blanchard *et al.*, 1993, 1997, 1998), but the reliability of these behaviours as indices of anxiety has been questioned (Blanchard *et al.*, 1997).

The complexity of this test, derived mainly from the use of wild animals, limits its widespread use in psychopharmacological analysis. This fact can be attested by the lack of studies on the effects in this test of panicolytic drugs such as alprazolam and antidepressants, or panicogens such as yohimbine, in animals submitted to this test.

Electrical Stimulation of the Dorsal Periaqueductal Grey

In the version of this model utilized by Jenck and coworkers, rats are trained to switch off DPAG electrical stimulation by jumping into the opposite compartment of a shuttle-box. Several drugs that affect PD were tested to assess predictive validity. As expected, the anti-panic agents alprazolam and clonazepam impaired switch-off behaviour dose-dependently, while the panicogenic agents caffeine, yohimbine and flesinoxan and CCKb agonists facilitated escape from DPAG electrical stimulation. Nevertheless, several results seem to be inconsistent with the hypothesis that DPAG stimulation models PD, such as the anti-aversive action of the panicogenic mCPP, and of single administration of the SSRIs fluvoxamine and fluoxetine. The latter drugs are known to aggravate PD in the initial phase of drug treatment (Saran and Halaris, 1989; Den Boer and Westenberg, 1990). In addition, there were false positive results, since the antipsychotic agent haloperidol and the CCK_B antagonist L365,260 had anti-aversive effects in the animal test, but do not improve PD (for primary references, see Blanchard, Griebel and Blanchard, 2001).

In the version of DPAG electrical stimulation developed by Schenberg and coworkers (Schenberg *et al.*, 1990; Sudré *et al.*, 1993), the rat is placed inside an arena and the intensity of the electrical current is gradually increased. In this way, a sequence of behavioural and neurovegetative changes is elicited, namely immobility, running, jumping, exophthalmus, micturition and defecation. Pharmacological analysis indicates that running and jumping seem to be correlated with panic. Thus, the threshold current intensity for eliciting these responses was markedly increased by chronic, but not acute, administration of the panicolytic drugs clomipramine and fluoxetine. Long-term administration of the anxiolytics diazepam and buspirone as well as of the selective NA reuptake inhibitor maprotiline was ineffective. Moreover, the panicogenic drug PTZ decreased running threshold (Schenberg *et al.*, 2001; Vargas and Schenberg, 2001). The latter study also showed that plasma levels of ACTH were not affected by DPAG electrical stimulation that induced panic-like behaviour. This finding further supports this test as a model of PD, in relation to claims that the hypothalamus–hypophysis–adrenal axis is not activated during panic attacks (Liebowitz *et al.*, 1985).

Chemical Stimulation of the Dorsal Periaqueductal Grey

In this model microinjection of the excitatory amino acid d,l-homocysteic acid (DLH) is made in both rostral and caudal DPAG, causing explosive motor behaviour characteristic of proximal defence. This behaviour is quantified in terms of response duration, arena revolutions and number of defensive jumps made by the rats inside an arena (Beckett, Marsden and Marshal, 1992a). In the automated version of the test, distance travelled is recorded with a computer-driven automated tracking system (Beckett and Marsden, 1995). As reported with electrical stimulation (Nogueira and Graeff, 1995), pre-treatment with 5-HT_{1A} agonists directly injected into the DPAG markedly attenuated the defence reaction elicited by DLH (Beckett *et al.*, 1992b; Beckett and Marsden, 1997). Conversely, systemic injection of the 5-HT_{1A} agonist 8-OH-DPAT enhanced the DLH effect (Beckett and Marsden, 1997), probably because stimulation of autosomic receptors in the dorsal raphe nucleus decreases inhibitory 5-HT input to the DPAG. Also, intra-DPAG injection of the 5-HT_2-receptor agonist mCPP intensified the defence reaction induced by DLH (Beckett, Marsden and Marshal, 1992a). Chronic (3 weeks), but not short-term (2–3 days) treatment with imipramine enhanced the 5-HT_{1A}-mediated inhibition of flight induced by intra-DPAG injection of DLH (Mongeau and Marsden, 1997a). The latter result supports the suggestion that the therapeutic effect of antidepressants on PD is due to

enhancement of 5-HT inhibition of DPAG neurones commanding flight (Graeff, 1991). Finally, intracerebroventricular injection of the panicogen CCK-4 prolonged the tachycardia induced by intra-DPAG DLH, but failed to affect the flight response. The latter was potentiated by systemically injected butoxycarbonyl-CCK-4, indicating a peripheral site of action (Mongeau and Marsden, 1997b). Although only one panicolytic and one panicogenic drug have been used so far to validate this model, the above results testify to its importance for the study of the neurobiology of PD.

Chemical Stimulation of the Dorso-Medial Hypothalamus

Infusion of the $GABA_A$ receptor blockers bicuculline and picrotoxin into the DMH induces oriented escape response accompanied by hyperventilation and increases in arterial blood pressure and heart rate, reminiscent of a panic attack (Shekhar and Di Micco, 1987). The effects of bicuculline infusion have been abolished following chronic treatment with either imipramine or clonazepam (Shekhar, 1994). The same drug regimen is clinically effective on PD (Nutt, 1991). Also as expected, the panicogenic agents yohimbine and fenfluramine enhanced the behavioural and physiological effects of bicuculline in the DMH (Keim and Sekhar, 1999). However, because a comparative study has shown that escape from the hypothalamus is controlled by environmental stimuli whereas that from the DPAG is undirected (Schmitt *et al.*, 1986), the DMH model is less akin to panic attacks.

COMBINED MODELS OF GENERALIZED ANXIETY AND PANIC DISORDERS

The two animal models analysed below are intended to assess behaviours related to both GAD and PD in the same animal.

The Mouse Defence Test Battery

Based on their ethoexperimental analysis of defence (see the introduction of this paper), Blanchards' group elaborated a test battery to measure both risk assessment, related to GAD and predator-induced flight, related to PD. In the mouse defence test battery (MDTB) a mouse is placed inside an oval runway and a deeply anaesthetized rat, held by the experimenter's hand, is approached at a fixed speed. When the rat–mouse distance reaches about 1 m, the mouse generally flees, running in the alley until the threat is out of sight. This defence reaction is taken as an index related to panic (Griebel, Blanchard and Blanchard, 1996a). During the predator's approach, mice also express risk-assessment behaviour consisting of an abrupt movement arrest often followed by orientation toward the approaching rat. Risk-assessment behaviour (approach to/withdrawal from the rat) is also evidenced when the predator–prey interaction is carried out in a straight alley. These risk-assessment responses are taken as indexes related to GAD. The pharmacological profile of the MDTB evidences its high predictive validity. Thus, flight was reduced by two high-potency benzodiazepines that are clinically effective on PD, namely alprazolam and clonazepam, as well as by chronic administration of several antidepressants, including imipramine, fluoxetine, moclobemide and phenelzine. Whereas either acute or chronic alprazolam had no appreciable effect on risk-assessment responses, chronic administration of imipramine and fluoxetine decreased the expression of these behaviours. The results obtained with these two antidepressants are consonant with their anxiolytic effects on GAD symptoms (Nutt, 1991; Rickels *et al.*, 1993). In addition, panicogenic agents, such as yohimbine, flumazenil and cocaine, as well as therapeutic drugs like imipramine and fluoxetine, that nonetheless aggravate PD in the initial phase of treatment, facilitated flight in the MDTB test when injected acutely. Finally, drugs clinically ineffective on PD, such as the benzodiazepine anxiolytic chlordiazepoxide, the $5\text{-}HT_{1A}$ agonist buspirone and the $5\text{-}HT_2$ antagonist miaserin, did not affect the same flight response, but consistently reduced the GAD-related risk-assessment behaviours (for primary references, see Blanchard, Griebel and Blanchard (2001).

The Elevated T-maze

The elevated T-maze (ETM) is derived from a hypothesis about the role of 5-HT in GAD and PD. In an attempt to conciliate conflicting results on the role of 5-HT in anxiety, Deakin and Graeff (1991) have suggested that conditioned anxiety is related to GAD while unconditioned fear is associated to PD. The former would be facilitated whereas the latter would be inhibited by 5-HT released from fibres originated in the dorsal raphe nucleus (DRN). As a consequence, the ETM was intended to separate conditioned anxiety from unconditioned fear (Graeff, Viana and Tomaz, 1993; Viana, Tomaz and Graeff, 1994). The apparatus is derived from the elevated X- or plus-maze (Handley and Mithani, 1984; Pellow and File, 1986) by sealing the entrance to one of its enclosed arms. As a result, the ETM consists of three arms of equal dimension (50×12 cm) elevated 50 cm from the floor. One of these arms is enclosed by lateral walls (40 cm high) and stands perpendicular to the two opposite open arms. In the experimental session, the rat performs two consecutive tasks, inhibitory avoidance and one-way escape, supposed to represent conditioned anxiety and unconditioned fear, respectively. When placed at the end of the enclosed arm, the rat does not see the open arms until it pokes its head beyond the walls of the closed arm. Being on the open arm seems to be an aversive experience, since rats have an innate fear of height and openness (Treit, Menard and Royan, 1993). This would allow the animal to learn inhibitory avoidance if repeatedly placed inside the enclosed arm to explore the maze. On the other hand, when the rat is placed at the end of one of the open arms it can move towards the closed arm, presumably performing an escape response.

The ETM may also be viewed as a way to circumvent the ambiguities of the elevated plus-maze (see the introduction of this paper). According to Handley *et al.* (1993), the elevated plus-maze is a mixed model, leading to inconsistencies in drug response. To circumvent this shortcoming, systematic recording of behavioural items has been added. Some of these items are selectively affected by non-benzodiazepine anxiolytics, thus improving the predictive value of the test (e.g., Rodgers and Johnson, 1995). However, this strategy is time consuming and strips the elevated plus-maze of its main advantage, which is simplicity. Also, critical behavioural items, such as risk assessment may be more easily observed in contexts different from the elevated plus-maze. An alternative to ethological analysis is the separation of functional categories of behaviour through experimental analysis, which is accomplished by the ETM.

A series of experiments has been performed to validate the ETM behaviourally (Zangrossi and Graeff, 1997). The results obtained showed that restraining the animals at the end of the enclosed arm for 30 s did not change the first (baseline) withdrawal latency, indicating that rats are not escaping from the experimenter's hand. In addition, rats trained in a T-maze with the three arms enclosed did not show the usual increase in withdrawal latency along three consecutive trials. Therefore, open arm experience seems to be critical for inhibitory avoidance learning. The same experiment also showed that the latency to leave the open arm did not undergo habituation over five consecutive trials, evidencing the aversive motivation of this response.

For pharmacological validation, drugs that are known to either decrease or increase clinical anxiety have been used (Graeff *et al.*, 1998). Table XIX-1.2 summarizes the results obtained. As may be seen, the anxiolytics diazepam, buspirone, ipsapirone and ritanserin impaired inhibitory avoidance while leaving one-way escape unchanged. This selective effect on avoidance correlates with the clinical effectiveness of these drugs on GAD, as opposed to their inefficacy on PD (Nutt, 1991). It is worth mentioning that several additional drugs that had anxiolytic-like effects in other animal models of anxiety also selectively impaired avoidance in the ETM (Graeff, Ferreira Netto and Zangrossi, 1998). However, since these drugs have not been assayed in humans, clinical correlation cannot be assessed.

Also as predicted by Deakin and Graeff's hypothesis, the anxiogenic agents yohimbine, TFPP and mCPP facilitated inhibitory avoidance in the ETM. However, the two last drugs attenuated escape, a result that contrasts with clinical reports on aggravation of PD by the same drugs. It may be argued that in these clinical studies anticipatory anxiety rather than panic was enhanced, since mCPP also enhances anxiety in normal subjects (Charney *et al.*, 1987). Moreover, Deakin and Graeff (1991) have further hypothesized that the brain mechanisms that underlie anxiety and panic interact, the former exerting inhibitory influence on the latter. Thus, drugs that facilitate avoidance could indirectly decrease escape. Against this argument, however, stand the results obtained with yohimbine, which facilitated avoidance without impairing escape in the ETM. Another caveat is that in these studies rats had not been pre-exposed to the open arm before the test (see later).

Tricyclic antidepressants usually aggravate anxiety earlier in treatment, the therapeutic effect appearing only following several days of repeated administration (Johnson, Lydiard and Ballenger, 1995). This correlates with the anxiogenic-like effect of clomipramine and imipramine on inhibitory avoidance following single injection (Table XIX-1.2). More important, an anxiolytic effect of imipramine on avoidance developed after chronic administration, and escape from the open arm was simultaneously impaired, which correlates well with the clinical effectiveness of this drug regime on both GAD and PD (Rickels *et al.*, 1993; Johnson, Lydiard and Ballenger, 1995). Nevertheless, the interpretation of the drug effects on escape is not as straightforward as on avoidance. As expected, this behaviour was unaffected by acute clomipramine. Yet, it was impaired by a single injection of imipramine. This inconsistency reminds one of the above-discussed differences between yohimbine, on one hand, and mCPP and TFPP, on the other.

Table XIX-1.2 Effect of clinically assayed drugs on the tasks performed in the elevated T-maze

Drug class	Compound	Avoidance	Escape
Anxiolytic			
	Diazepam	−	0
	Buspirone	−	0
	Ipsapirone	−	0
	Ritanserin	−	0
Anxiogenic			
	Yohimbine	+	0
	MCPP	+	−
	TFMPP	+	−
Antidepressant			
	Clomipramine	+	0
	Imipramine	+	$-^{p,2}$
	Imipramine[c]	−	$-^{p,2}$
5-HT releaser			
	d-Fenfluramine	+	−

Key: + Facilitation; − impairment; 0 no change; [c]chronic administration; [P]pre-exposure to the open arm; [2]two trials.

In addition, there was what appears to be a critical methodological difference, namely the rats used in the imipramine study had been pre-exposed to the open arm for 30 min before the test, and one additional measure of escape latency was taken. This procedure had two consequences: (1) the first escape response became significantly faster and (2) the anti-escape effect of chronic imipramine became statistically significant (Teixeira, Zangrossi and Graeff, 2000). Further comparisons with intracerebral drug injection led to the conclusion that pre-exposure to the open arm renders the escape task more sensitive and reliable to the effect of different brain manipulations. This is probably due to the habituation of behavioural reactions to novelty (exploration, behavioural inhibition), which are likely to interfere with one-way escape.

The 5-HT releaser and uptake inhibitor fenfluramine has been reported to induce attacks in panic patients (Targum and Marshall, 1989). Thus, the impairment of escape that was found with this drug (Table XIX-1.2) was quite unexpected. Nevertheless, Targum and Marshall (1989) themselves point out that, unlike the sudden surge of natural panic attacks, fenfluramine induced a slow wave of anxiety, more like an enhancement of anticipatory anxiety. Accordingly, d-fenfluramine has been shown to facilitate inhibitory avoidance in the ETM (Table XIX-1.2). Results obtained with two human models of anxiety seem to correlate with the opposite effects of d-fenfluramine on the two tasks of the ETM. Thus, the same drug tended to enhance conditioning of skin conductance responses in healthy volunteers, whereas markedly reducing the rise in anxiety induced by simulation of public speaking, a model of anxiety that has been associated with panic (Hetem *et al.*, 1996). Furthermore, a recent study showed that pre-treatment with d-fenfluramine enhanced anticipatory anxiety in PD patients following CO_2 inhalation. In contrast, the intensity of the CO_2-induced panic attack was decreased by the same drug treatment (Mortimore and Anderson, 2000). From these results, d-fenfluramine is expected to have anti-panic properties. Indeed, an open study (Solyom, 1994) as well as a case history (Hetem, 1995) provide suggestive clinical evidence supporting this view. Unfortunately, clinical investigation had to be interrupted because d-fenfluramine was withdrawn from the market due to cardiovascular untoward effects (Curzon and Gibson, 1999). In any case, the results obtained are enough to show that what at first seemed to be a major flaw of the ETM model turned out to strengthen the predictive value of escape in regard to PD.

Taking into account the above discussion on models of GAD, the drug profile of ETM avoidance comes as no surprise. Indeed, inhibitory avoidance of the open arm of the ETM is not unlike classical conflict tests. However, the present version has the advantages of not involving hunger or thirst, which are increased by some anxiolytic drugs (e.g., Berridge and Pecina, 1995). Moreover, the unconditioned aversive stimulus is neither painful nor artificial, like electric foot-shock. Another point that deserves some comment is the similarity of the motor performance in both tasks performed by the rat in the ETM. This serves as a control for non-specific drug effects on motor activity, particularly when the withdrawal latencies for the enclosed arm and the open arm are changed to opposite directions by the treatment. However, whenever the latencies are similarly increased or decreased, there is need for independent assessment of motor effects. Measuring motor activity inside an arena fulfils this requirement (Teixeira, Zangrossi and Graeff, 2000), albeit adding further complexity to the model.

The results of experiments with intracerebral drug injection (Graeff, Viana and Mora 1996a, 1997) and of a recent c-Fos study (Silveira *et al.*, 2001) indicate that the neural substrate of inhibitory avoidance is different from that of one-way escape.

MODELS OF SPECIFIC PHOBIAS

Specific phobias have been attributed to traumatic learning experiences. The classical conditioning of animal phobia in a boy by Watson and Rayner (1920) typifies this approach. Nevertheless, reports of traumatic experiences are lacking in most histories of phobic patients (Barlow, 1988). In addition, despite current dangers in civilized societies including, for example, electricity plugs or approaching cars, practically no exaggerated fears for such objects occur in the clinic. Instead, the most frequent phobic objects belong to certain categories that are constant through history and among different cultures, such as heights (acrophobia), closed environments (claustrophobia), the sight of blood (erythrophobia) or poisonous animals. This led to the alternative view that specific phobias are an exaggeration of ancestral fears, evoked by objects or situations that threatened survival of our hominid ancestors (Marks 1987; Marks and Nesse, 1994). A place for learning is kept in these theories of specific phobia, but learning prepared by evolution, such as in the experiments carried out by Ohman, Erixon and Loftberg (1975) showing that aversive conditioning to images of spiders was far easier and stronger than to pictures of flowers.

From this theoretical perspective, animal models of specific phobia should explore defence reaction against species-specific fears. Examples are the primate fear reaction to snakes (Mineka, 1985) and rats' avoidance response to cat odour (Zangrossi and File, 1992a). Whereas both tests have been used for analysing the behavioural characteristics of fear reactions and aspects of fear habituation/extinction, only the latter has been employed in pharmacological investigations.

The cat odour test developed by Zangrossi and File (1992a, 1992b) is based on the studies of Blanchards' group on the A/DTB discussed above. In this test, rats are exposed to a cloth impregnated with cat odour while in their single home-cage. These rats spend a greater amount of time hiding underneath the shelter formed by the water and food compartment of the home-cage and make fewer contacts with the cloth, compared to animals exposed to a neutral odour cloth. The benzodiazepine chlordiazepoxide has only a weak effect on rats' avoidance reactions; $5\,mg\,kg^{-1}$ of the drug increased the time spent in contact with the cloth, but did not decreased the time spent sheltering. On the other hand, this drug was fully effective in counteracting the anxiogenic effect of cat odour detected by the elevated plus-maze and social interaction tests (Zangrossi and File, 1992b). Acute or chronic (21 days) treatment with other anxiety-modulating drugs, such as buspirone, imipramine and the MAO inhibitor phenelzine, also failed to consistently decrease rats avoidance response to cat odour (File, 1995). Based on evidence showing that human-specific phobias are resistant to treatment with the drugs currently used to alleviate anxiety disorders (Marks, 1987), Zangrossi and File (1992b) have suggested that rats' avoidance to cat odour reflects the development of a phobic-like state. However, the generality of this proposal has been recently questioned by reported results showing that under a different test condition (use of a specific test-cage, different strain of rats and way of presenting the cat odour), benzodiazepine drugs can inhibit the avoidance response to cat odour (Dielenberg, Arnold and McGregor, 1999; McGregor and Dielenberg, 1999). Therefore, more studies are necessary to characterize this test as a model of specific phobia.

Although the homology argument is less strong, the suggestion has also been made that second exposure to the elevated plus-maze generates an emotional state that is akin to phobia (File *et al.*, 1993; File, 1993, 1995). This idea comes from evidence showing that benzodiazepines and barbiturates have either a weak or no anxiolytic effect in rats or mice previously exposed to the elevated plus-maze (File, 1990, 1993). This contrasts with the marked anxiolytic effect of these compounds on the first trial (see Rodgers, 1994). This phenomenon, called one-trial tolerance (OTT), has been observed even when the second trial is performed 2 weeks after the first, and is independent of drug state (either drugged or non-drugged) in the first trial. These results suggest that in the first experience with the plus-maze the animals are acquiring a different anxiety state that is insensitive to benzodiazepines. This idea is supported by findings showing that in a factorial analysis study, plus-maze scores of anxiety taken on the first and the second trials load on different factors. Interestingly, increasing the total time of testing on both trials from the usual 5 to 10 mins, abolishes the phenomenon of OTT. This result has been interpreted in terms of fear extinction after prolonged exposure to the aversive stimuli generated by the elevated plus-maze (File *et al.*, 1993). Based on knowledge that specific phobias respond favourably to exposure to the feared object/situation (Marks, 1987; Barlow, 1988), File *et al.* (1993) proposed that the trial second (trial-two) in the elevated plus-maze represents phobia. This trial-two phobic state would be different from that generated by exposure to cat odour in the sense that, whereas the former is acquired by a learning process, the latter is innate. Recent studies have explored the neural substrate involved in trial-two fear conditioning, revealing the participation of the basolateral amygdala (File, Gonzalez and Gallant, 1998) and dorso-medial hypothalamus (File, Gonzalez and Gallant, 1999) in this process. Further studies have shown that benzodiazepines and buspirone-like drugs exert differential effects on plus-maze trial-one and trial-two anxiety scores after microinjection in brain areas as the DRN (Gonzalez and File, 1997), dorsal hippocampus and lateral septum (Cheeta, Kenny and File, 2000).

MODELS OF OBSESSIVE–COMPULSIVE DISORDER

Clinical observation has shown that hand-washing and checking whether windows or doors are locked are the prevailing compulsive rituals. Rapoport (1991) suggested that these rituals may be related to animal behavioural routines of self-grooming and checking territorial borders, respectively. The adaptive function of grooming is to protect the animal against diseases caused by micro-organisms or parasites, while checking prevents invasion of the territory needed for reproduction and feeding by animals of the same or alien species. Neuroethological research has implicated the striatum in the control of these behavioural routines. Thus, an indirect support to Rapoport's ideas came from functional neuro-imaging studies showing hyperactivation of the nucleus caudatum of symptomatic obsessive–compulsive disorder (OCD) patients, which faded following successful treatment with either fluoxetine or cognitive behavioural therapy (Baxter *et al.*, 1996).

Acral Lick Dermatitis

Based on the preceding argument, Rapoport has looked for repetitive behaviours in animals that resemble compulsive symptoms, and found acral lick dermatitis in dogs the most appealing. Since OCD is responsive to clomipramine (Zohar *et al.*, 1988), similar treatment for the dog's disease was suggested, and indeed was effective (Goldberger and Rapoport, 1991). On this basis, acral lick dermatitis became a candidate for an animal model of OCD (Rapoport, Ryland and Kriete, 1992). The efficacy of clomipramine on canine compulsive disorder was confirmed by a double-blind, placebo-controlled study (Hewson *et al.*, 1998). Like human OCD, acral lick dermatitis is improved by SSRIs, such as fluoxetine (Wynchank and Berk, 1998) and citalopram (Stein *et al.*, 1998). However, acral lick dermatitis is not a true experimental model, in the sense that the conditions cannot be reproduced at will in the laboratory, but rather

an animal analogue of OCD. Also, the use of a large and expensive subject such as dogs, and particularly sick dogs, detracts from its feasibility.

Adjunctive Behaviour Models

Some attempts to model OCD in laboratory animals have been made. Earlier operant behaviour studies have shown that when rats are given food reinforcement under fixed interval schedules, several collateral (adjunctive) behaviours are generated during the post-reinforcement period, among which are compulsive drinking or polydipsia (Falk, 1961). Woods and coworkers (1993) have shown that schedule-induced polydipsia was attenuated by chronic administration of the anti-obsessional drugs clomipramine, fluoxetine and fluvoxamine, and not affected by desipramine, haloperidol and diazepam, all of which are ineffective on OCD. These results qualify schedule-induced polydipsia as a potential animal model of OCD.

Another possible model of OCD is food-restriction-induced hyperactivity. Rats fed for 90 min per day lose some weight and then stabilize. If given access to a running wheel, these animals run excessively, loose weight, and often die. A pharmacological study has shown that chronic administration of fluoxetine decreased running and weight loss. Conversely, depleting 5-HT stores with para-chlorophenylalanine potentiated the effects of food restriction. Imipramine, which is ineffective on OCD, was also devoid of any action in this model (Altemus *et al.*, 1996).

Other Potential Models

Further repetitive behaviours that have been considered as potential models of OCD are the spontaneous alternation of food-deprived rats in a T-maze (Yadin, Friedman and Bridger, 1991) and marble burying in mice (Ichimaru, Egawa and Sawa, 1995). Both were responsive to SSRIs.

Pharmacological models for OCD have also been suggested. One of those is chronic treatment with the dopamine agonist quinpirole, inducing stereotyped behaviour in rats interpreted as compulsive checking. This would provide face validity to the model. This behaviour is attenuated by clomipramine, and its mechanism seems to involve sensitization of dopaminergic neurotransmission in the striatum, implicating this neurotransmitter in OCD (Szechtman, Culver and Eilam, 1999).

There is high comorbidity between OCD and Tourette's syndrome (see, e.g., Frankel *et al.*, 1986). From this background, a transgenic mouse model of comorbid Tourette's syndrome and OCD was created by expressing a neuropotentiating cholera toxin transgene in a subset of dopamine D_1 receptor-expressing neurones thought to enhance cortical and amygdalar output to the striatum. These animals manifest episodes of perseveration and repetitive behaviour, as in OCD, and repeated climbing/leaping and tics, as in Tourette's syndrome (McGrath *et al.*, 2000). Although of interest for the study of the role of glutamate in these conditions, this model lacks pharmacological validation.

CONCLUDING REMARKS

In the preceding sections several potential models of specific anxiety disorder were analysed. These tests have been selected mainly according to the criterion of construct validity or homology. For that, a theoretical stance based on the evolutionary paradigm has been taken.

Since present-day psychiatric classification is based on phenomenology, it may not be a suitable basis for establishing the neurobiological correlates of anxiety disorders. As pointed out by Gray and McNaughton (2000), genetic studies indicate that there is no specific inheritance for diagnostic categories, because what is inheritable is a general vulnerability for anxiety disorders. In this regard, dimensional approaches of personality may qualify as an alternative approach to provide better psychological correlates of biological markers.

Table XIX-1.3 presents an attempt to evaluate comparatively the models of GAD and PD, which have been more systematically explored than the models for other diagnostic categories. From the traditional criteria of model validation, the criterion of analogy was omitted, as it makes little sense within the comparative approach adopted here. In addition, the criterion of feasibility was added, because it often determines the extent to which a given animal model will be used.

Drug response remains the cornerstone for empirical validation, but under the precedence of homology the correlation between drug response in the model and in the clinic is viewed as a test for hypotheses about the model and the disorder rather than a separate criterion. Nevertheless, some critical remarks are due, concerning the interpretation of pharmacological correlation. With regard to models of GAD, non-benzodiazepine agents, such as buspirone and ritanserin, have anxiolytic-like effects after single administration in several models of GAD. However, these drugs improve clinical anxiety only after weeks of continuous administration (Nutt, 1991; Johnson, Lydiard and Ballenger, 1995). Therefore, the question of whether the effects in the animal models reflect reduced anxiety or merely behavioural disinhibition (Thiébot, Bizot and Soubrié, 1991) remains. Against the latter view are the results showing that buspirone-like drugs decrease probe burying as well as attenuate potentiated startle (see earlier). In these tests, the anxiolytic effect is expressed as decreased, rather than increased, motor activity. Yet, the case of potentiated startle is weakened by the demonstrated correlation between the intensity of startle potentiation and the degree of freezing (Leaton and Borszcz, 1985). Thus, it may still be argued that anxiolytic drugs reduce potentiated startle because they decrease behavioural inhibition.

Another instance is the effect of chronically administered antidepressants in models of GAD. In some cases a lack of effect of these treatments is suggested to support the specificity of the model. However, clinical studies have shown that prolonged administration of these drugs improves GAD, in addition to

Table XIX-1.3 Comparison among animal models of GAD and PD

Disorder	Animal model	Homology	Predictability	Feasibility
GAD				
	Light–dark transition	+++	+++	+++
	ETM avoidance	+++	+++	+++
	ADTB	+++	+++	++
	MDTB	+++	+++	++
	Potentiated startle	++	++	+
	Shock-probe burying	++	++	++
PD				
	FDTB	+++	++	+
	MDTB	+++	+++	++
	ETM escape	+++	++	+++
	DPAG electrical stimulation	+++	++	+
	DPAG chemical stimulation	+++	+	+
	DMH chemical stimulation	++	+	+

Key: ETM, elevated T-maze; ADTM, anxiety defence test battery; MDTB, mouse defence test battery; FDTB, fear/anxiety test battery; DPAG, dorsal periaqueductal grey matter; DMH, dorso-medial hypothalamus.

other anxiety disorders (Nutt, 1991; Rickels *et al.*, 1993). In the same way, psychostimulants, such as caffeine, cocaine and amphetamine, are often ineffective in GAD models, and this is taken as evidence for their drug selectivity. Yet, human studies show that these drugs may increase anxiety (Mitchell, Laurent and de Wit, 1996; Nehlig, Daval and Debry, 1992). Such instances undoubtedly blur the pharmacological validation of GAD models.

Similar restrictions can be made with respect to panic models. All the animal models of PD analysed show a reduction of the panic index after treatment with at least one clinically effective antipanic agent. This is indeed a necessary condition for a test to be classified as a model of panic disorder. Yet, it is not sufficient, since the same drug treatments also alleviate GAD (Nutt, 1991; Rickels *et al.*, 1993). Another criterion is the increase of the behavioural index of panic by drugs that induce panic attacks. Once more the interpretation of the results obtained is not straightforward. Some of these agents are specific, in the sense that they induce panic attacks only in panic patients. Among these are sodium lactate and inhalation of CO_2. Others, like cocaine, mCPP, yohimbine, caffeine and d-fenfluramine, induce anxiety in normal subjects as well, although panic patients may be particularly sensitive to these drugs. Therefore, it is difficult to ascertain whether the latter drugs induce a true panic attack or otherwise enhance anticipatory anxiety (Bourin, Baker and Bradwejn, 1998).

The above caveats expose the fragility of the current animal models. Only the capacity for detecting new, clinically useful drugs or behavioural therapies will ultimately validate any animal test, and warrant the approach advocated here of developing animal models theoretically oriented to specific anxiety disorders.

XIX-2

Aminergic Transmitter Systems

Neil McNaughton

INTRODUCTION

A fundamental goal of biological psychiatry should be the separation of symptoms from syndromes. It is clear, for example, that 'headache' is not an appropriate diagnostic category. You cannot use it to define the treatment of the underlying disorder giving rise to the symptom. Nor is the regular decrease in headache symptoms produced by aspirin or paracetamol evidence for common aetiology of the causes of headache or for an 'analgesic insufficiency' as the primary cause of headache.

This problem is particularly acute with mood disorders. In the case of depression, which at first blush seems more coherent as an entity than the spectrum of 'anxiety disorders',

> 'in the DSM-III the "choice principle" was introduced. For the diagnosis of a particular syndrome the presence of X out of a list of Y symptoms suffices, no matter which ones. Hence the various disorders that are distinguished are symptomatologically ill defined. In fact, many different syndromes carry the same designation: major depression and dysthymia.... The utility of the ... discrete diagnostic entities characterized by multiple criteria ... is questionable. Our studies at least have failed to validate them.... Another fundamental shortcoming ... is the lack of an aetiological axis [since] with today's methodologies, one can arrive at an aetiological hypothesis with no less reliability as one can regarding the presence or absence and severity of particular psychopathological symptoms.... Another [problem] is that of [classification in the presence of] comorbidity ... For the diagnosis of major depression, psychotic and organic conditions have to be ruled out. The diagnosis of generalized anxiety disorder cannot be made in the presence of a mood disorder.
>
> This principle is not applicable in biological psychiatry. One can and should not simply discart [*sic*] the possibility that a biological variable observed in a psychotic condition is linked to a concurrent depression, or one found in depression is in fact related to an anxiety disorder....
>
> For [these] reasons I consider these concepts unsuited for [mood disorder] research, particularly biological research, requiring as it does well-defined and assessable diagnostic concepts.'
>
> Van Praag (1995, p. 270)

The problem of comorbidity may be even more acute in the diagnosis of anxiety disorders. For example, panic and obsession, *as disorders*, may well have no necessary connection to anxiety as such. Rather, each may be an indirect cause of, essentially 'normal', anxiety when they occur (as unexpected, uncontrollable and bizarre events) in someone with a pre-existing sensitivity to threatening events. Conversely, both panic and obsession can occur as a simple, non-pathological, consequence of high levels of anxiety. Even this anxiety need not be pathological — consider the obsessive behaviour of a parent with a young and extremely mobile child at an airport.

Syndrome identification faces two additional problems. First, is a lack of connection between cause and treatment. A purely cognitively mediated post-traumatic stress disorder can nonetheless result in brain damage and require pharmacological treatment. Panic attacks resulting from a neural disturbance may be best treated psychologically — resolving the anxiety-related problems engendered by the panic attacks without completely eliminating the latter (Franklin, 1990). Other exclusion criteria, such as the exclusion by 'DSM-III-R [of] persons with socially phobic symptoms secondary to axis III conditions ... [such as] disfiguring or disabling conditions [can lack] empirical basis.... [and cause] a patient group [to be] overlooked with regard to treatment options' (Oberlander, Schneier and Liebowitz, 1994).

A final problem for diagnosis is that the grouping of 'anxiety disorders' as a single class in DSM-III, DSM-IIR and DSM-IV seems inappropriate from the point of view of pharmacology or preclinical analysis of brain systems. These suggest that the different symptomatologies and therapeutic responses of patients presenting with 'anxiety disorders' reflects a confusion of diagnostic categories. Diagnoses should, but currently do not, reflect the primary brain systems that are dysfunctional in any particular case. Symptomatology must often reflect the brain systems, whether functional or dysfunctional, that have extremes of activity. For both these reasons, brains systems will be the focus of the next section.

The most significant aminergic neurotransmitter systems for anxiety and the conventional grouping of anxiety disorders are the monoamines serotonin and noradrenaline. As discussed in the section entitled 'The Neuropsychology of the aminergic systems' basic research implicates them as modulators of the entire defense system with a clear contribution to anxiety — in the sense that this can be distinguished from fear (Blanchard *et al.*, 1988, 1991, 1997). Drugs that manipulate them have therapeutic effects that usually span several of the different types of anxiety disorder (den Boer *et al.*, Chapter XIX-13). Finally, disturbances of their metabolism appear to play a significant role in the generation of anxiety disorders (see below). A weaker case can, also, be made for dopamine. The preclinical review below will also include consideration of acetylcholine because, although not a monoamine, it shares many of the anatomical and functional features of the monoamines.

The primary conclusion is that the success or failure of treatment with a particular drug is likely to reflect the secondary impact of alteration in monoamines on primary brain systems more often than an original disturbance of monoamines was the primary basis of the symptomatology.

THE NEUROPSYCHOLOGY OF ANXIETY

The view of the neuropsychology of anxiety disorders in this chapter is justified at great length in Gray and McNaughton

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

(Gray and McNaughton, 2000) and in its appendices available at http://www.oup.co.uk/academic/medicine/medical_updates/neuropsych_anxiety/ (see also Mohanty and Heller, Chapter XVIII-7).

The most important point to note is that, for each anxiety disorder or symptom recognized by the DSM and ICD classifications, there appears to be a distinct pharmacological specificity (Table XIX-2.1). This specificity is demonstrated by dissociations produced by particular drugs (e.g., buspirone affects anxiety and depression but not panic) and can be obscured in the clinical setting by the fact that a number of drugs can have concurrent but distinct effects on different 'anxiety disorders'. Indeed, clinicians will tend to prefer less specific drugs as a means of protecting against incorrect diagnosis.

Together with much other data (Gray and McNaughton, 2000), this allows us to allocate each symptom and/or syndrome to a specific portion of a hierarchically organized defense system (Figure XIX-2.1). However, this allocation does not allow us to assign a particular symptomatology to pathology in a particular area and so use it to define a particular syndrome. For example, a primary panic disorder (arising, say, from paroxysmal activity in the periaqueductal gray) could result in panic attacks. Given the effects of arousal on panic, full blown attacks are more likely to occur in a public place. Any particular place occasioning the first attack will condition anticipatory anxiety and so an increased probability of panic. The resultant increased general arousal would increase the probability of panic in other locations. Thus conditioning would produce agoraphobia as a symptom not a cause. But this would be likely to be diagnosed as agoraphobia proper. Panic attacks would then be both a primary cause of anxiety *and* a secondary consequence. Conversely, a primary anxiety disorder (conceivably presenting as agoraphobia) could result in panic attacks as a symptom of extreme anxiety (Goisman *et al.*, 1995; Marks, 1987). Indeed, a pure primary 'panic disorder' might not be diagnosed as such unless it was accompanied by additional symptoms resulting from its interaction with a neurotic personality and its resultant production of symptoms of anxiety (Holt, 1990; Gray and McNaughton, 2000).

Table XIX-2.1 Various classes of drugs effective in treating neurotic disorders and their relative effects on different neurotic syndromes and the extent to which they share classical anxiolytic side effects (muscle relaxant; anticonvulsant, sedative, addictive). Exceptional effects of individual members of a class are ignored (e.g., the antidepressant and panicolytic actions of benzodiazepines such as alprazolam). It should be noted that antidepressant monoamine oxidase inhibitors (MAOI), in particular phenelzine, are unlike novel anxiolytics (novel) such as buspirone and tricyclic drugs such as imipramine (IMI) that have separate anxiolytic and antidepressant action. They treat depression but also appear particularly effective in treating atypical depression (in which many symptoms overlap anxiety disorders but are resistant to anxiolytic drugs). They have not been reported to be effective in generalized anxiety

	Class	Novel	IMI	CMI	MAOI	SSRI
Phobia	0	?	?	?	?	?
Generalized Anxiety	–	–	–	–	0?	–
Panic Attacks	0	0	–	—	–	–
Obsessions/Compulsions	0	?	(–)	—	(–)	—
Atypical Depression	0	?	(–)	?	–	?
Unipolar Depression	0	–	–	–	–	–
Classical Anxiolytic Side Effects	=	#	0	0	0	(#)

Class, classical anxiolytics such as benzodiazepines, barbiturates and meprobamate; CMI, Clomipramine; 0, no effect; –, reduction; —, extensive reduction; +, increase; ( ), small or discrepant effects; =, same as classical anxiolytics; #, opposite to classical anxiolytics. Adapted from Gray and McNaughton (2000), see also den Boer *et al.* Chapter XIX-13.

THE NEUROPSYCHOLOGY OF THE AMINERGIC SYSTEMS[1]

The general form of the anatomy of the different aminergic systems is very similar (see also previous chapter). This is shown in cartoon form in Figure XIX-2.2. For example, serotonergic cell bodies are located in the raphe nuclei of the brainstem. From there, they send projections forward making collateral connections with many structures before innervating the cortex fairly diffusely. 'Early studies that used older tracing techniques reported exceedingly few [descending] projections from the dorsal raphe (DR) to the brainstem. . . . [However, there are] moderate to dense projections from the DR [to] pontomesencephalic central gray, mesencephalic reticular nucleus pontis oralis, nucleus pontis caudalis, locus coeruleus, laterodorsal tegmental nucleus, and raphe nuclei, including the central linear nucleus, median raphe nucleus, and raphe pontis' (Vertes and Kocsis, 1994, p. 340). Of particular interest in relation to anxiety disorders, there is serotonergic input to the periaqueductal gray, the hypothalamus, the amygdala, the septo-hippocampal system and the frontal and cingulate cortex (see e.g., Handley, 1995, Fig. 1). As can be seen from Figure XIX-2.1, these structures essentially represent the entirety of the defense system and collectively are involved in the entire spectrum of clinical anxiety disorder.

This anatomy suggests that the aminergic systems are modulatory of other structures in a very general sense. They originate in very small, often caudally placed, nuclei and then innervate huge areas of the forebrain via multiple collaterals. Their fibres, as a group, follow three basic paths (Gaykema *et al.*, 1990; Jacobs and Azmitia, 1992) which 'appear to have remained remarkably stable across phylogeny' (Jacobs and Azmitia, 1992, p. 179). The most ventral innervation of the telencephalon usually involves fibres that send collaterals into the amygdala *en passage* to the temporal portion of the hippocampus. Next there are fibres that pass through the septal area in the medial forebrain bundle and then run in the fornix/fimbria, just under the corpus callosum (the light grey band in Figure XIX-2.2) to innervate the septal portion of the hippocampus. The third path is taken by fibres primarily destined for the cortex. They pass over the corpus callosum peeling off progressively from the cingulum bundle to innervate the neocortex. At its most caudal extent the cingulum bundle provides some fibres that innervate the septal parts of the hippocampus, retrosplenially (Azmitia and Segal, 1978). The dopaminergic system is the most rostral and least diffuse of these systems.

In the case of the noradrenergic system conventional synapses are formed only in the dentate gyrus (Koda, Schulman and Bloom, 1978) and the lack of specialization of the bulk of terminals suggests release of noradrenaline is more neurohormonal than as a neurotransmitter (Descarries, Watkins and Lapierre, 1977; Shimizu *et al.*, 1979).

Nonetheless, there appears to be differentiation of cells even in the locus coeruleus with respect to targets (McNaughton and Mason, 1980). For the other aminergic systems there are discrete components, originating in different nuclei that then have both distinct and overlapping projections compared to other aminergic nuclei.

The amine systems are very similar in anatomy to the ascending cholinergic system. Their similarity to it in function will also be discussed below and, although this does not appear particularly significant for clinical pathology, the amine systems and cholinergic systems have extensive reciprocal interactions with each other. The cholinergic system has a basically similar anatomy to the amine systems but there is better evidence that its connections to the

[1] This section (except for 'Dopaminergic Systems') is a summary of the relevant portions of Appendix 10 of Gray and McNaughton (2000). Many of the ideas are either those of J.A. Gray or arose in discussion with him. Where no reference is given for a statement it can be found at http://www.oup.co.uk/academic/medicine/medical_updates/neuropsych_anxiety/app10/.

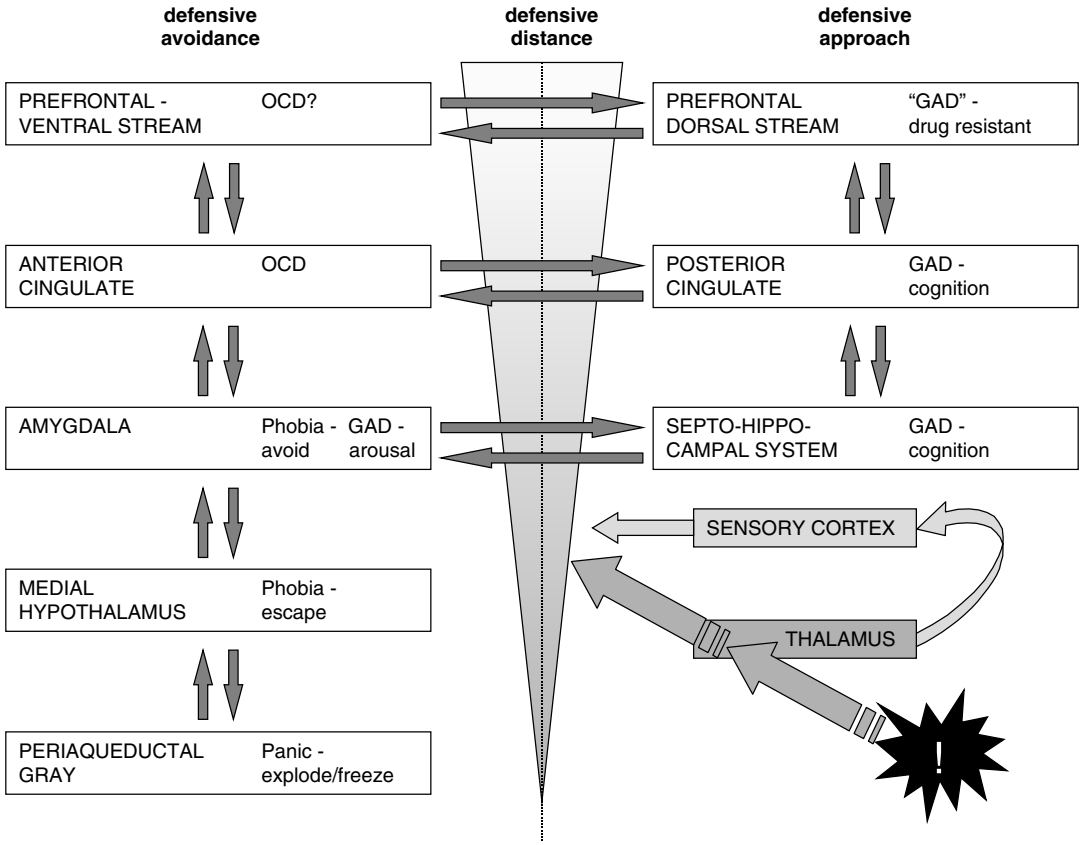

Figure XIX-2.1 A two-dimensional view of the neural systems controlling defense and their relation to neurotic disorders. There is a hierarchy of reciprocally connected neural systems (Graeff, 1994) in which control of behaviour is exerted by the lowest levels when danger is most immediate with control passing to progressively higher levels as the danger becomes less immediate (see also Table XIX-2.3, Figure XIX-2.3). This reflects a dimension of 'defensive distance' (Blanchard and Blanchard, 1989, 1990). In addition there is an essentially orthogonal dimension of defensive direction (Gray and McNaughton, 2000). Avoidance of a dangerous situation and approach into a dangerous situation are controlled by distinct sets of structures. The perception of defensive distance and direction depends on processing by sensory systems that can also be viewed as hierarchical. Signals of danger (!) activate a 'quick and dirty' route through the thalamus that can initiate immediate action if a crude assessment of the situation suggests this is necessary and also activate, in parallel, slower and more sophisticated cortical processing that can confirm or cancel the action or inaction resulting from the crude assessment (LeDoux, 1994, 1998). Figure adapted from Gray and McNaughton (2000), Figures 1.8 and 11.1

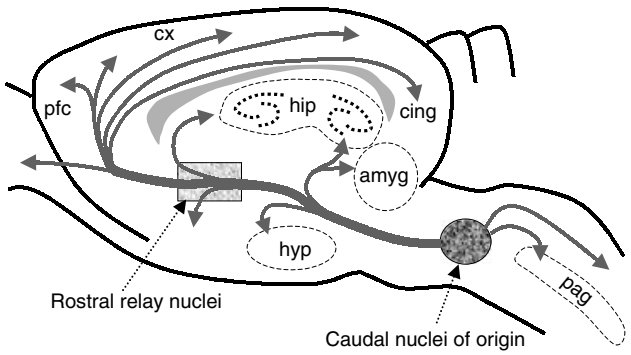

Figure XIX-2.2 A schematic overview of the general anatomy of the aminergic and cholinergic systems. In general, nuclei of origin are relatively caudal and then may relay more rostrally. There tend to be few cells with many collaterals providing diffuse innervation of much of the forebrain. There appears to be some topographic anatomical organization of the systems but relatively little functional differentiation between the parts. The dopamine system is the most rostral, most differentiated, and least diffuse. The cholinergic system originates most caudally, appears functionally least differentiated (see text), and is most diffuse. For the detailed anatomy of each system, see Gray and McNaughton (2000) Figures 6.5, 6.6 and 6.7

forebrain are highly topographically organized (Gaykema *et al.*, 1990, 1992; Zaborszky *et al.*, 1997). The cholinergic system is different from the amine systems in having the most caudally placed nuclei of origin and, possibly as a consequence, having extensive relay nuclei in the basal forebrain. However, functionally, the superficially more differentiated cholinergic nuclei and pathways appear to be part of a coherent, diffuse system originating in the pons (McNaughton *et al.*, 1997, 2001; Swain-Campbell and McNaughton, 2001).

For all the aminergic systems, and the cholinergic system, there is evidence both for a general modulatory role and some capacity of the systems to select subsets of targets of that modulation. The preclinical data on each of these systems is summarized below in alphabetical order followed by an overview of them as contributing to a common general modulation of higher systems. This preclinical summary provides a skeleton for the body of interpretation of the clinically oriented data in the section entitled 'Aminergic involvement in clinical anxiety'.

Cholinergic Systems

Neither anti- nor pro-cholinergic drugs are generally used clinically as anxiolytics. However, systemic or specific intracranial

anticholinergic dysfunctions have not only similar behavioural effects to noradrenergic and serotonergic dysfunction, but also similar neural effects. They all change the signal-to-noise ratio in targets such as the hippocampus and amygdala. Yet, in man, the anticholinergics are amnestic rather than anxiolytic; and some pro-cholinergic drugs may even be anxiolytic (see Brioni *et al.*, 1994; Garvey *et al.*, 1994).

The similar behavioural profiles of nominally 'anxiolytic' and nominally 'amnestic' treatments may reflect a partial overlap in functions. Benzodiazepines block the release of acetylcholine onto cortical targets and this could underlie some but not all of their behavioural effects (Anglade *et al.*, 1994; Sarter and Bruno, 1994). Anticholinergic drugs, by contrast, probably do not produce their amnestic effects via release of endogenous benzodiazepine ligands and there are definite cases where cholinergic dysfunction produces neural effects quite unlike those of anxiolytics (Gray and McNaughton, 2000, Appendix 10).

There are few reports of the effects of specific cholinergic lesions on behaviour. The effects of systemic anticholinergic (usually antimuscarinic) drugs have been well studied (Bignami, 1976; Aigner, 1995) and a superficial resemblance to the behavioural profile of anxiolytic drugs can be seen in the general release of behavioural inhibition they produce (Carlton, 1969). However, they differ from anxiolytics in that they impair some learning tasks in which there is no behavioural inhibition and, consistent with this, acetylcholine is released when simple learning is occurring (Orsetti, Casamenti and Pepeu, 1996).

> 'While there is little doubt that manipulation of cholinergic function can rather specifically alter offensive behaviour in a variety of species, evidence also supports a role for central muscarinic receptors in defensive responding. . . . Antimuscarinics have . . . been reported to inhibit shock-induced defensive fighting in rats and mice . . . Under more naturalistic test conditions . . . scopolamine reduced fear reactions in laboratory rats confronted with a cat . . . reduced fear was indicated by consummatory behaviour in the presence of the cat, more approaches to the cat enclosure and less freezing'.
>
> Rodgers *et al.* (1990, p. 575)

More detailed ethological analysis of the role of anticholinergics in fear and anxiety, respectively suggests they do not alter 'avoidance, freezing, defensive threat or attack in wild *Rattus rattus* confronted by the experimenter and other threat-related stimuli . . . During cat exposure, however, [they] . . . increased the amount of time spent in the vicinity of the cat, increased scanning and rearing, and reduced grooming behaviour. Although reliable, the latter effects were not pronounced' (Rodgers *et al.*, 1990, p. 575). Rather than a genuinely anxiolytic effect this suggests 'a situation- and response-dependent alteration in mechanisms of selective attention' (op. cit. p. 581). However, even in the 'ethological' form of the elevated-plus-maze test of anxiety anticholinergics are anxiogenic (Rodgers and Cole, 1995). Likewise, anticholinergics can reduce fear conditioning to a tone while leaving conditioning to context intact. Hippocampal lesions have the opposite effect, while amygdala lesions affect both (Young, Bohenek and Fanselow, 1995).

Overall then, while the cholinergic system may influence anxiety in a variety of ways these appear to be both anxiolytic and anxiogenic depending on other factors. Like peripheral injections of adrenaline or the partial pressure of carbon dioxide, then, it appears to be able to influence central systems controlling anxiety without being a fundamental component of such systems.

Dopaminergic Systems

There are two main dopaminergic systems innervating the forebrain that only partially conform to the picture of Figure XIX-2.2. 'A dorsal tier of dopamine neurons receive input from the ventral (limbic-related) striatum and from the amygdala and [largely as the mesolimbic system] project widely throughout cortex. A more ventrally located group of dopamine cells receives input from both the limbic and association areas of striatum and projects widely [largely as the nigro-striatal system] throughout the striatum, including the sensorimotor region. Through these projections the limbic system has an enormous influence on dopamine output and can therefore affect the emotional and motivational "colouring" of a wide range of behaviours' (Haber and Fudge, 1997). We will focus here on the more ventrally coursing mesolimbic system and, in particular, its projections to prefrontal cortex (PFC). While strongly implicated in schizophrenia, this input to prefrontal cortex appears also to be involved in anxiety and depression.

The initial component of the ventral system is the dopaminergic input from the ventral tegmental area (VTA) to the nucleus accumbens (or more fully nucleus accumbens septi, NAS). This system is presented in texts as being a 'reward pathway'. However,

> 'Stress consistently has been found to activate peripheral and central catecholamine systems. Dopamine turnover in the prefrontal cortex is especially sensitive to stress produced by relatively mild footshock, conditioned fear or exposure to a novel cage. . . . electrolytic lesions of the central nucleus of the amygdala significantly attenuated the increase in DA turnover in the prefrontal cortex normally seen after mild stress. . . . Dopamine neurons in the ventral tegmental area receive direct input from the central nucleus of the amygdala . . . Stress may activate . . . the central nucleus of the amygdala. In turn this could activate dopamine cells in the ventral tegmental area that project to prefrontal cortex and thereby increase dopamine turnover in this brain area.'
>
> Davis *et al.* (1994)

We will deal later with the peculiarity that stress increases PFC dopamine by double the amount of NAS dopamine (which in turn is about double the amount of striatal dopamine release) in contrast to the fact that 'the noradrenergic projections to forebrain appear to respond to stress in a uniform manner' (Abercrombie *et al.*, 1989). What is needed at this point is

> 'a unifying interpretation that can account for the functions of NAS DA in a variety of behavioural contexts: (1) its role in appetitive behavioural arousal, (2) its role as a facilitator as well as an induced of reward processes, and (3) its presently undefined role in aversive contexts. . . . NAS DA [appears to] facilitate flexible approach responses. . . . Fixed instrumental approach responses (habits) . . . involve the nigro-striatal system more. . . . NAS DA [operates] in two stages: unconditioned behavioural invigoration effects and incentive learning effects. (1) When organisms are presented with salient stimuli (e.g., novel stimuli and incentive stimuli), NAS DA is released and invigorates flexible approach responses. (2) When proximal exteroceptive receptors are stimulated by unconditioned stimuli, NAS DA is released and enables stimulus representations to acquire incentive properties with specific environmental context [*sic*]. . . . Both conditioned and unconditioned aversive stimuli stimulate DA release in the NAS [because] NAS DA invigorates *approach responses* toward 'safety'. Moreover, NAS DA modulates incentive properties of the environment so that organisms emit *approach responses* toward 'safety' (i.e. avoidance responses) when animals later encounter similar environmental contexts.'
>
> Ikemoto and Panksepp (1999) [my italics]

In this view, dopamine release is not a sign of aversion even in aversive paradigms. Indeed 'brief aversive foot shock delivered for the first time does not increase NAS DA, but NAS DA levels increase more and more as, . . . with succeeding trials, animals develop more effective approach to safety strategies' (op. cit.). The increase in dopamine release during avoidance learning to

some extent parallels that of corticosterone — which ceases to be released as avoidance becomes perfect, and so shock is no longer delivered (Coover, Ursin and Levine, 1973). However, with repeated inescapable stress, dopamine is not released during the stress but only after it. In this, 'the activation of the mesolimbic dopaminergic system induced by aversive stimuli adapts to repeated experiences differently from that produced by pleasurable events' (Imperato *et al.*, 1992). It also contrasts with both noradrenaline and corticosterone. Like dopamine, they are not released by shock initially. But unlike dopamine they continue to be released in response to conditioned fear (Brady, 1975a, 1975b).

Thus, in aversive paradigms the release of dopamine appears to equate with 'relieving non-punishment'. It is released by the omission of an expected punisher. Such omission can been equated functionally with reward (Gray, 1975) since stimuli associated with either will elicit approach and are functionally antagonistic to aversive events. In this view the 'anxiolytic' effects of D2 agonists (Bartoszyk, 1998) may reflect the antagonistic relationship between punishers and rewards when these are associated — an antagonism that is not affected by conventional anxiolytic drugs (McNaughton and Gray, 1983). Conversely, desensitization of these receptors by, for example, repeated methamphetamine administration could have the inverse effect (Tsuchiya, Inoue and Koyama, 1996).

The peculiarities of the PFC dopaminergic input remain to be dealt with. As noted above this often shows a greater release of dopamine to aversive stimuli than does the NAS. More surprisingly, unstressed rats can show a DA increase in PFC to both appetitive and aversive stimulation at times when the NAS shows an increase to appetitive but a decrease to aversive stimuli (Di Chiara, Loddo and Tanda, 1999). After chronic mild stress, the responses to appetitive stimuli decreased and to aversive stimuli increased in both areas — with the NAS response to aversive stimuli reversing to the increase commonly observed.

> 'We have proposed that NAS shell DA is involved in associative learning and in the acquisition of motivation, whereas PFC DA is involved in its motor expression. . . . [It is through] phasic DA transmission in the NAS shell . . . [that] stimuli are attributed a motivational value that reflects the biological value of the stimulus . . . [hence] D_1 antagonists . . . impair the acquisition of conditioned place preference and place aversion. . . . This hypothesis interprets the symptoms of anhedonia, lack of interest, and loss of self esteem that are typical of depression as the result of blunting of appetitive motivation; it interprets feelings of worthlessness and guilt . . . as the result of enhancement of aversive motivation. . . . [These] changes in DA responsiveness are [likely to be] secondary to a primary dysfunction of tonic noradrenergic transmission. . . . The relative ineffectiveness of dopamine agonists as antidepressants [is because] increase of tonic DA transmission by a DA agonist would not correct the dysfunction in phasic DA responsiveness that takes place in depression.'
>
> Di Chiara *et al.* (1999)

Thus, at least part of the distinctive dopamine release in PFC would be due to increased noradrenaline release acting on dopaminergic terminals presynaptically. Increased noradrenaline release in PFC increases dopamine levels and decreased noradrenaline release decreases dopamine levels, suggesting a tonic modulation (Gresch *et al.*, 1995). Further, an initial brief experience of stress can release noradrenaline without dopamine or serotonin, with the latter released in addition on a second experience (Jordan *et al.*, 1994). Release of noradrenaline may then produce sensitization of dopaminergic and serotonergic terminals. However, part could also be due to selective activation of a small pool of VTA and NAS cells projecting only to PFC, as occurs with purely cognitively mediated stress in the absence of concurrent release of noradrenaline or serotonin (Kaneyuki *et al.*, 1991). These authors even suggest that inhibition of VTA DA neurons may be 'implicated in the specific anxiolytic action of benzodiazepines'. Certainly, very large doses of benzodiazepines reduce stress-induced dopamine release in PFC (Feenstra, Botterblom and Van Uum, 1995) and, like the anxiolytic effects of benzodiazepines, this does not show tolerance (Hegarty and Vogel, 1995). But chronic stress eliminates the effect (Finlay, Zigmond and Abercrombie, 1995).

There are three main reasons for rejecting this point of view. First, is the fact that prefrontal lesions are effective in treating anxiety that is resistant to conventional anxiolytic drugs. Anxiolytic action on prefrontal dopamine could be a component of their effects — but prefrontal cortex clearly contains additional anxiety-related mechanisms. Second, rapid sampling of extracellular dopamine in the rat prefrontal cortex during food consumption, handling and exposure to novelty found the response was graded to the general intensity rather than valence of stimuli with 'emotional arousal [being] a common denominator'. Interestingly, in this study dopamine release outlasted, e.g., eating by 10–20 min (Feenstra and Botterblom, 1996). Third, data (Espejo, 1997) that suggest that PFC DA 'activation reflects either heightened attention or activation of cognitive processes [that is] a general phenomenon in various adaptive situations'. PFC DA depletion *increased* + maze anxiety while decreasing motility. 'The findings confirm that prefrontocortical dopamine activation is necessary for coping with an anxiogenic challenge, allowing the animal to display adaptive exploratory responses in a fear-inducing environment' (op. cit.).

Thus, for prefrontal dopamine we seem justified in borrowing the conclusion of Ikemoto and Panksepp for NAS dopamine. 'Both conditioned and unconditioned aversive stimuli stimulate DA release [to] invigorate approach responses toward "safety" [and] modulate incentive properties of the environment so that organisms emit approach responses toward "safety" (i.e. avoidance responses) when animals later encounter similar environmental contexts.'

Noradrenergic Systems

The locus coeruleus is the nucleus of origin of ascending noradrenergic fibres that has been most clearly implicated in the control of anxiety. Further, receptors for the benzodiazepine-GABA complex exist in the locus coeruleus and probably mediate some part of the action of classical anxiolytics (Iversen and Schon, 1973). A major output from the locus coeruleus travels in the dorsal noradrenergic bundle (DANB) and follows the general plan of Figure XIX-2.2, reaching frontal cortex, cingulate cortex, pyriform cortex, hippocampal formation, amygdala, thalamus, hypothalamus and basal forebrain. A second output, the ventral noradrenergic bundle travels more ventrally and innervates more ventral structures including an innervation of the hypothalamus and septum that overlaps that of the dorsal bundle (Moore and Bloom, 1979; Owen *et al.*, 1982). The ventral bundle also carries fibres from other noradrenergic nuclei.

The anatomy of the ascending noradrenergic system limits its possible functions. There are only about 1500 cells in the locus coeruleus of the rat and these innervate huge regions of the brain, including the olfactory bulb, much of the neocortex, the hippocampus, septal area and amygdala, some thalamic and hypothalamic nuclei, the geniculate bodies, the cerebellum, and the spinal cord. Although there is some topographic organization, each cell projects to multiple areas (Olson and Fuxe, 1971; Pickel, Krebs and Bloom, 1973). The system cannot, therefore, carry large volumes of data and is likely to be generally modulatory.

Consistent with this, noradrenergic activity increases throughout the brain in response to aversive stimuli (Segal, 1978) and stress, and specifically to increases in corticotropin-releasing hormone (Valentino, Foote and Page, 1993; Smagin, Swiergiel and Dunn, 1995), with a significant part of this being due to outflow from

the locus coeruleus (Corrodi *et al.*, 1971). This increase may be a significant component of stress-induced anxiety since it is blocked by classical anxiolytics. Novel anxiolytics tend to increase locus coeruleus firing (Trulson and Henderson, 1984; Wilkinson *et al.*, 1987) but this appears to be an effect of feedback from presynaptic blockade of noradrenergic terminals by $5HT_{1A}$ agonists. So, all classes of anxiolytic drug appear to block the release of central noradrenaline.

However, novel stimuli and reward can also release noradrenaline. Like dopamine, then, it seems less specifically concerned with aversion than generally related to arousal in the sense of activation of the ascending reticular activating system or the regulation of attention or vigilance (Aston-Jones, Chiang and Alexinsky, 1991).

A role in vigilance would account for changes in noradrenergic output in relation to sleep phases without a role for noradrenaline in the control of sleep itself and for the release of noradrenaline by unconditioned stimuli and 'by stimuli which are not themselves intense or conspicuous, but are salient to the animal by virtue of conditioning' (Aston-Jones *et al.*, 1994, p. 4468). Thus, when the significance of stimuli is changed, noradrenergic cell firing shifts to the new target stimulus (Aston-Jones *et al.*, 1994; see also Rajkowski, Kubiak and Aston-Jones, 1994).

Detailed comparison of the effects of anxiolytic drugs with lesions of the DANB (Table XIX-2.2) shows some interesting parallels and dissociations. Where anxiolytics are without effect so too are DANB lesions. Likewise, where DANB lesions have an effect it is essentially the same as those of anxiolytics drugs, in size as well as nature. However, there are a substantial number of anxiolytic-sensitive tasks where DANB lesions are totally without effect. A review of the electrophysiological evidence suggests that inhibition of release of noradrenaline by anxiolytic drugs (acting at cell bodies in the case of classical anxiolytics and at terminals in the case of novel anxiolytics) accounts for part of the behavioural profile of the anxiolytics. This could include the slight pro-convulsant effect of buspirone and anxiolytic SSRIs (Ferraro *et al.*, 1994; Kokaia *et al.*, 1994).

Table XIX-2.2 Comparison of the common effects of classical and novel anxiolytics (Anx), common effects of lesions of the septum and hippocampus (S = H), lesions of the amygdala (Amyg), lesions of the dorsal ascending noradrenergic bundle (NA), lesions of the ascending serotonergic system (5HT) and systemic blockade of muscarinic cholinergic systems (ACh). A partial involvement of noradrenaline in the effects of anxiolytic drugs and, by implication, the control of anxiety is understandable if it is a quite general arousing system similar in function to the old idea of the reticular activating system (Magoun, 1963). Such arousal, in aversive situations, would normally be termed alarm and even, in some meanings of the word, 'anxiety'. Thus, release of noradrenaline, centrally, is like activation of the sympathetic system peripherally (Aston-Jones, Chiang and Alexinsky, 1991; Van Bockstaele and Aston-Jones, 1995; Haller, Makara and Kruk, 1998).

On the other hand, noradrenergic cells 'decreased tonic discharge . . . during certain high arousal behaviours (grooming and consumption) when attention (vigilance) was low. . . . The most effective and reliable stimuli for eliciting LC responses were those that disrupted behaviour and evoked orienting responses' (Aston-Jones, Chiang and Alexinsky, 1991, pp. 501). So, 'LC cells respond to novelty or change in incoming information, but do not have a sustained response to stimuli, even when these have a high level of biological significance' (Sara, Vankov and Hervé, 1994). Central release of noradrenaline would, then, increase vigilance to external events consistent with the fact that it increases the neural signal-to-noise ratio (Gray & McNaughton, 2000, Appendix 10).

The effect of noradrenaline is not limited to stimulus processing. Its release also increases the vigour of ongoing behaviour (Aston-Jones *et al.*, 1994), another echo of the effects of dopamine. The noradrenergic system, then, appears important for general vigilance and reactivity to stimuli (including, of course, aversive stimuli) but does not equate with arousal in the sense that this can be high when external stimuli are being ignored.

Of particular relevance to clinical anxiety and its relation to depression is the specific case of such effects of noradrenaline on aggressive behaviour.

> 'Hormonal catecholamines (adrenaline and noradrenaline) appear to be involved in metabolic preparations for the prospective fight; the sympathetic system ensures appropriate cardiovascular reaction, while the CNS noradrenergic system prepares the animal for the prospective fight. Indirect CNS effects include: the shift of attention towards socially relevant stimuli; the enhancement of olfaction. . . ; the decrease in pain sensitivity; and the enhancement of memory (an aggressive encounter is very relevant to the future of the animal). . . . [However, while] a slight activation of the central noradrenergic systems stimulates aggression, a strong activation decreases fight readiness. This biphasic effect may allow the animal to engage or to avoid the conflict, depending on the strength of social challenge.'
>
> Haller, Makara and Kruk (1998)

Serotonergic Systems

Central serotonin has previously been postulated to be involved in anxiety (Iversen, 1984) and in specifically anxiolytic action (Moon *et al.*, 1994) but also appears implicated in many other psychiatric disorders (Swerdlow, 1995; Boulenguez *et al.*, 1998; Collier *et al.*, 1996; De Oliveira *et al.*, 1998; Dean *et al.*, 1995; Gobert *et al.*, 2000; Gurevich and Joyce, 1997; Laruelle *et al.*, 1993; Leonard, 1996; Naylor *et al.*, 1996; Sumiyoshi *et al.*, 1996). The serotonergic system conforms to the general plan of Figure XIX-2.2. However, there is noticeable anatomical differentiation within it that is significant for the possible role of different areas in the causes of anxiety. This differentiation cuts across the differentiation of receptor subtypes that is significant for the treatment of anxiety.

> 'The median raphe supplies the dorsal hippocampus and medial septum, the proposed origins of the Behaviour Inhibition System, while the dorsal raphe nucleus innervates the lateral septum and ventral hippocampus, the possible origin of safety signalling. The amygdala, the "head nucleus" of the Defence System, is almost entirely supplied by the dorsal raphe nucleus.'
>
> Handley (1995, p. 108–109)

This differentiation is not complete, as there are minor contributions of, e.g., the dorsal raphe to the septo-hippocampal system. In particular, the dorsal raphe sends projections (which may well be collaterals of the same source cells and hence carry the same information} to the periaqueductal gray (5HT2/1C receptors); ... the amygdala (5HT1A receptors), the ventral striatum (5HT1D receptors), the hippocampus (5HT1A receptors), and the frontal cortex (5HT2 receptors). It can therefore have widespread effects on the defense system.

The dorsal raphe does not appear totally committed to defense, however, since it seems 'to play a role in modulating circadian rhythms ... [and] these modulations may be, in part, mediated by the [direct] retinal projection to the periaqueductal gray and serotonin neurons in the dorsal raphe nucleus' (Shen and Semba, 1994, p. 166; see also review by Morin, 1994). Although there are fewer data on central serotonergic lesions than noradrenergic there are enough to reinforce this conclusion. Inspection of Table XIX-2.2, shows that to a large extent, like noradrenergic lesions, serotonergic lesions have no effect when anxiolytics have an effect and that when serotonergic lesions have an effect so do anxiolytics. Also, as with noradrenergic lesions, there are many cases where anxiolytics have an effect but serotonergic lesions do not. Strikingly, these blanks in the serotonergic and noradrenergic profiles appear to complement each other so that the effects of anxiolytics could, perhaps, be accounted for by concurrent suppression of central noradrenergic and serotonergic function. If this is true then neither system can, by itself, be the basis for anxiety.

Table XIX-2.3 Levels of threat processing and related levels of neural integration. Adapted by Gray and McNaughton (2000) from Graeff (1994)

Level of processing	Behaviour	Neural substrate
Potential danger (to approach)	Risk assessment and Behavioural Inhibition	Posterior Cingulate Septo-Hippocampal System
Potential danger (to avoid)	Avoidance	Anterior Cingulate Amygdala
Distal danger	Escape Inhibition of Aggression	Medial Hypothalamus
Proximal danger	Freezing Flight Fight	Periaqueductal grey

Graeff (1993) (see also Graeff *et al.*, 1996; Graeff and Zangrossi, Chapter XIX-1) provides a detailed analysis of the role of serotonin in the defense system. His starting point is a unidimensional hierarchical view of threat processing which in a slightly modified form (Table XIX-2.3) is the foundation on which the two-dimensional Figure XIX-2.1 was constructed and a further dimension of avoidability could also be added (Figure XIX-2.4). Figure XIX-2.3 shows his picture of how serotonin (5HT) interacts with the lower levels of the defense system.

The key point is that the periaqueductal gray, medial hypothalamus and amygdala will often be activated together by threatening stimuli. But, explosive undirected escape or aggression (periaqueductal gray) is inappropriate if avoidance (amygdala) or directed escape (medial hypothalamus) is possible. As indicated in

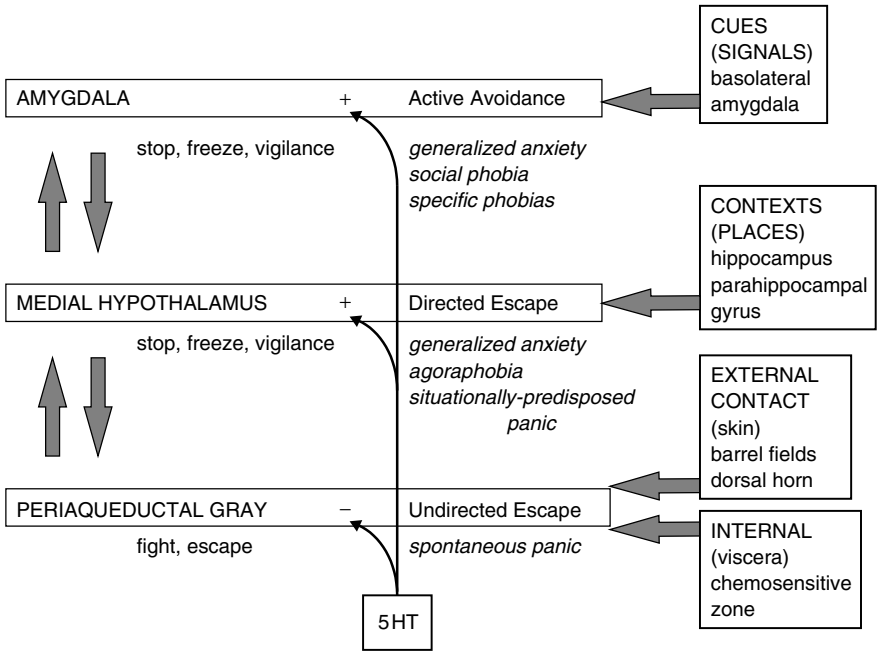

Figure XIX-2.3 The role of serotonin (5HT) in the control of anxiety as proposed by Deakin and Graeff (1991). The opposing effects of input to PAG, compared to structures higher in the defense hierarchy, provides an explanation of the paradoxical effects of some treatments and for phenomena such as panic associated with relaxation or sleep. Note that Deakin and Graeff localize generalized anxiety to the amygdala and hypothalamus and view the hippocampus as a purely sensory structure. This is essentially the same as the view of LeDoux (1994) but differs from Figure XIX-2.1. However, these differences of detail do not have major consequences for the predictions to be derived from the Deakin and Graeff model or for the general principles of operation they attribute to the serotonin system

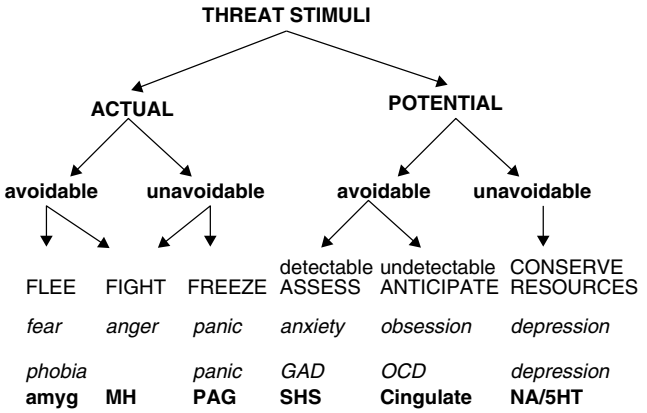

Figure XIX-2.4 The functional differentiation of threat stimuli and its likely relation to neural systems. The stimuli are categorized into different functional classes in the top three rows. The specific functional output required by each class is shown in the fourth row (capitals) and its relation to nominal emotions in the fifth row (small italics). It should be noted that these emotions are presumed to be usually functionally adaptive. The related psychological disorders are given in the sixth row (large italics) and the principle neural system involved in pathology or symptomatology as well as normal function is indicated in the last row. Amyg, amygdala; MH, medial hypothalamus; SHS, septo-hippocampal system; NA/5HT changes in the balance between the monoamine systems. From Gray and McNaughton (2000), Figure 11.2

the figure, (see also Deakin and Graeff, 1991) serotonin shifts the balance between the structures. It 'facilitates defensive behaviour elicited by potential or distal danger signals ... by acting on the amygdala, but, in the periventricular system, inhibits the expression of fight/flight responses that are adaptive only when the threat stimulus is proximal to the animal' (Graeff, 1993). In humans also, 'measures that are believed to represent conditioned anxiety were increased by D-fenfluramine, ... a drug that seems to release 5HT selectively from terminals of the dorsal raphe, ... whereas those thought to reflect unconditioned fear were attenuated' (Graeff, Viana and Mora, 1997). This idea of antagonism between anxiety and panic (at least at low levels of anxiety) also accounts for such paradoxical phenomena as relaxation-related panic attacks (Graeff, 1994).

A similar differential effect, coupled to receptor- or channel-linked polymorphisms may underlie the occasional paradoxical effects of SSRIs. These are usually beneficial in patients with panic. However, fluoxetine can occasionally exacerbate pre-existing panic and Altshuler (Altshuler, 1994) reported two cases where fluoxetine induced panic *de novo* that continued as non-remitting spontaneous panic attacks (see discussion of kindling below) in two patients with no prior history of panic. He noted that 'in the two cases presented, the timing of the onset of the panic attacks (within 10 days of medication) is certainly earlier than the time of onset of the [usual therapeutic] action'. Thus, variation in differential effects across the defense system could result from different rates of receptor adaptation and/or sensitization in different parts of the defense system to serotonin released from collaterals of the same neurons onto different receptor subtypes.

The release of serotonin (and the firing of raphe cells) seems to prime tonic or repetitive motor circuits while suppressing phasic, orienting, startle, and related circuits. This priming also has major effects on circuits (primarily in the septo-hippocampal system) whose business is to *inhibit* ongoing, tonic motor circuits. Thus, the firing of serotonin cells will often be functionally silent; and the effects of serotonin on behavioural inhibition, for example, will become functionally evident only when other conditions are fulfilled. One way to look at this is to view the serotonin signal as increasing 'motor attention', an effect that will have obvious behavioural consequences only when an event occurs to interrupt the motor programme.

Despite their involvement in the processing of threat, then, serotonin systems (like dopamine and noradrenaline) cannot be seen as threat promoting or threat inhibiting as such.

The situation is rendered even more complex by the effects of drugs active at different serotonin receptors. The receptor subtypes cut across the distinct neural systems we have been discussing so far and so select out only part of the action of serotonin with respect to each system while having effects general to all systems. This problem is particularly acute with $5HT_{1A}$ receptors. These are the principal targets of novel anxiolytics such as buspirone and the SSRIs. The drugs act as serotonin agonists in the sense of acting on the $5HT_{1A}$ receptor in the same way as serotonin but, in a number of areas, these receptors are autoreceptors involved in inhibitory feedback and so have an inhibitory effect on overall serotonergic output. Agonists at other serotonin receptors tend to have opposite effects to $5HT_{1A}$ agonists (Aprison and Ferster, 1961; Graeff and Schoenfeld, 1970; Stein, Wise and Berger, 1973). An important point for understanding possible genetic differences in vulnerability to anxiety disorders is that each receptor is a potential target of genetic modulation or deletion and that disorder may result as much from a disruption of normal balance between components of the serotonin system as from loss of a specific receptor-mediated action. A brief summary of the receptors is given in Table XIX-2.4.

Table XIX-2.4 Serotonin (5HT) receptor subtypes. For reviews see Griebel (1995), Saxena (1995), Zifa and Fillion (1992), Wilkinson and Dourish (1991), Uphouse (1997) and Meneses (1999)

5HT-1A	Anxiolytic at low doses. Action both at autoreceptors (dorsal and median raphe) and presynaptically (septum, hippocampus, amygdala). This results in a combination of functional 5HT-agonist-like and functional 5HT-antagonist-like actions.
5HT-1B	Occur in rodents but not humans.
5HT-1C	Now reclassified as part of the 5HT2 family, see 5HT2C.
5HT-1D	Likely to be a homologue of 5HT-1B. High density in the basal ganglia, lower in the hippocampus, neocortex and raphe nuclei. Function unknown. Peripherally involved in vasodilation. Antagonists useful in migraine.
5HT-2A	May be separate receptor or a separate state of the 5HT2B (q.v.).
5HT-2B	(and 5HT-2A) are distinct from 5HT2C. Highest density in the hippocampal formation, frontal cortex, cingulate cortex, nucleus accumbens, hypothalamus and mammillary bodies. Moderate density in the basal ganglia. The mixed 5HT2/1C antagonist, ritanserin, improves generalised anxiety disorder but worsens panic (see Graeff, 1993; see also Figure XIX-2.3 and Griebel, 1995, p. 374). 5HT2 receptors are also involved in the regulation of sleep, temperature and some aspects of motor control.
5HT-2C	(originally 5HT-1C). Highest density in the choroid plexus. Function unknown (but see Zifa and Fillion, 1992, p. 432).
5HT3	Highest density in the area postrema. Low, but detectable levels in septum, hippocampal formation, frontal cortex, cingulate cortex, nucleus accumbens, amygdala, thalamus and hypothalamus. Antagonists initially suggested to be anxiolytic but main current regular use is as anti-emetics (Saxena, 1995).
5HT-4	Agonists have effects on gastric motility.
5HT5+	for 5HT-*n* with $n > 4$ there is virtually no current evidence of function but they may be involved in learning and memory, possibly via modulation of cholinergic function (Meneses, 1999).

Neural sites are not identifiable with specific receptor subtypes. 5-HT_{1A}, 5-HT_2, and 5-HT_3 occur in the septo-hippocampal system, in the amygdala (5-HT_{1A}, 5-HT_3); in the frontal and cingulate cortex and in the nucleus accumbens, and hypothalamus (5-HT_2, 5-HT_3). Except for 5-HT_{1A} and 5-HT_3, most types are found in the basal ganglia. It seems unlikely that specific ligands will have specific, coherent functions (see also Griebel, 1995).

Under normal conditions, indeed, different levels and patterns of activation of relatively diffuse serotonergic projections could have fairly specific effects on particular areas. They could also affect particular functions within areas through the differences among receptor subtypes. The receptors can differ in their affinity (allowing, e.g., opposite effects to different concentrations of transmitter); in their transduction pathways (targeting different second messenger systems or rates of change); in their amount of desensitization/downregulation (allowing differential changes in response to acute as opposed to chronic serotonin release); and in their reaction to the cellular environment, including interaction with other serotonin receptors (Uphouse, 1997).

Like the cholinergic, dopaminergic and noradrenergic system, then, the serotonergic system is in a position to modulate the function of limbic structures and to influence the processing of threatening stimuli and the motor output resulting from them. Of all the systems we have considered so far it has the closest involvement in fear and anxiety. However, also like the noradrenergic system, there is no reason to see the serotonergic system as having a function specifically dedicated to defense as such — although specific receptor ligands could, in principle, have much more selective targets. Conversely, some selective ligands may have more influence on learning and memory than anxiety (Meneses, 1999).

Interactions of the Systems

The neuroanatomy and primary physiological effect (an increase in signal-to-noise ratio) of the systems we have considered is very similar. They may, then, each discharge an essentially similar function, but triggered by different environmental conditions.

In many cases the critical conditions may partially overlap and the systems act synergistically as with spatial learning (Decker and Gallagher, 1987). In some, there is evidence that noradrenaline produces its effects by releasing acetylcholine (Dalmaz, Introini-Collison and McGaugh, 1993) or that acetylcholine acts to increase the release of noradrenaline (Engberg and Hajos, 1994). Likewise, there are synergistic interactions between central serotonergic and cholinergic systems (Riekkinen, Sirvio and Riekkinen, 1990) and many 'histological, electrophysiological, pharmacological and behavioural data suggesting that serotonin is able to modulate central cholinergic function and that this modulation may have, in some respects, cognitive implications' (review by Cassel and Jeltsch, 1995, p. 31). Indeed, one study that recorded from putative cholinergic, noradrenergic and serotonergic neurons concluded 'the rapid cholinergic system controls the general condition of the brain (including sleep and wakefulness), cooperating with the "slow" noradrenergic and serotonergic systems. The three systems, which may interact mutually, may share the function of "the ascending reticular activating system" ' (Koyama, Jodo and Kayama, 1994, p. 1030). We also noted, in the section 'Dopaminergic Systems', interactions between the systems that were often quite local (e.g., presynaptic effects of noradrenaline on dopaminergic cells in PFC).

This is not to say that these systems or their interactions are solely concerned with sudden changes of state of the sort that would characterize normal anxiety in response to ecologically valid threatening stimuli. As is extensively dealt with elsewhere in this book, both serotonin and noradrenaline have important separate involvements in responses to stress, which may underlie the therapeutic effects of their specific re-uptake inhibitors in depression. There may also be important interactions between them in determining the behaviour of depressed people, for example, 'the expression of tyrosine hydroxylase [which controls noradrenaline synthesis] in locus coeruleus may be relevant in the pathophysiology of suicide' (Ordway, Smith and Haycock, 1994, p. 680).

Preclinical Overview of the Aminergic Systems

Combining all of the preclinical data reviewed in this section, we can arrive at a relatively simple picture of the aminergic systems as a whole (and of the similar cholinergic system) — despite the complexities of each of their component parts. Taken together, they appear to function to prime sensory-motor systems for action. At the neural level this represents an increase in signal-to-noise ratio, decreasing the effectiveness of ongoing background processing while increasing the response to any higher level upcoming input. Importantly, their activity, on this view, will only have major functional effects if there is such an upcoming signal to process. Much of the time changes in aminergic or cholinergic activity may be functionally silent.

The systems differ in the circumstances under which they produce such priming. Cholinergic systems act on a short time scale to increase the acuity of the processing of the sensory stimuli (and their associations/'memories') likely to be crucial for upcoming action. Dopaminergic systems act to increase the vigor of current approach responses and increase the probability of future approach responses (including, in both cases, approach to safety). Noradrenergic systems act, like a central 'sympathetic nervous system', to prime systems for upcoming sudden, unexpected action, in particular orienting responses. This priming involves an increase both in acuity of processing and in the vigor of upcoming motor output. Serotonergic systems are most strongly associated with motor output as opposed to sensory processing and prime systems for upcoming actions that cope with common repeated requirements.

To put this another way:

> 'The serotonergic system will be more concerned to prevent the dominant motor programme (e.g., avoidance) from being interrupted by concurrent activation of some other motor programme (e.g., escape); the noradrenergic system will be more concerned to prevent the dominant controlling stimulus from having its control of behaviour interrupted by other concurrent stimuli; and the cholinergic system will be more concerned to prevent the current-to-be-associated stimulus from having its associative connections interrupted by other concurrently activated associations (Vinogradova *et al.*, 1993). These increases in signal-to-noise ratio will have functional effects only if the target structure is processing a signal and if the result of that processing is a functional output.
>
> In achieving these different effects, we can assume that the aminergic systems produce largely similar direct neural effects, but produce their different patterns of response through requiring different adequate stimuli for their activation. We can also assume that the fundamental effect of release of transmitter by the systems is not only similar between them but very simple. The apparent complexities of the effects of drugs and lesions are then attributed to the complexities of the functions of the various target areas.'
>
> Gray and McNaughton (2000, Appendix 10)

AMINERGIC INVOLVEMENT IN CLINICAL ANXIETY

Determining the functional role of aminergic transmitter systems in anxiety disorders is complicated by at least six methodological issues.

First, is the problem of localization of action. This can be exemplified by panic. Related compounds, such as adrenaline

(epinephrine) when present in the blood stream can induce high levels of arousal and hence panic (Veltman *et al.*, 1996, 1998) while the state of platelet adrenergic receptors can influence panic (Gurguis *et al.*, 1999). Likewise, peripheral physiological challenges such as an increased partial pressure of CO_2 can induce panic. Interpretation of the effects of any pharmacological manipulation or state-related biochemical marker on any aspect of any anxiety disorder must therefore allow for the fact that a non-specific peripheral change rather than a specific central change may be the basis of observed effects. Likewise, even if a central action can be demonstrated, it may be as non-specific as a peripheral challenge.

Second, the three monoamine transmitters share a common enzyme that destroys them in the synapse and so renders them ineffective: monoamine oxidase (MAO). Any pharmacological changes (produced by monoamine oxidase inhibitors, MAOI) or effects of genetic differences in MAO-related systems (Deckert *et al.*, 1999) can be due to changes in any or all of the monoamine systems. Of course, MAO itself is a perfectly respectable aetiological candidate — and will be considered separately from the individual monoamines below, as will catechol-0-methyl transferase (COMT) an enzyme that breaks down dopamine and noradrenaline but not serotonin.

Third, dopamine is a precursor to noradrenaline. Treatments that affect dopamine synthesis (e.g., α-methyl-p-tyrosine) will therefore affect noradrenaline synthesis as well. Demonstration of specificity to one or the other transmitter will therefore require additional manipulations (e.g., administration of di-hydroxy-phenylserine that acts as a precursor for noradrenaline but not dopamine).

Fourth, as discussed in the section 'Interactions of the system', there are clear neural interactions between the systems. This is a particular problem in assessing drugs that act presynaptically. Not only may, for example, a $5HT_{1A}$ agonist have the primary effect of releasing noradrenaline but, concurrently, in a different part of the brain it could act to inhibit the release of noradrenaline or one of the other aminergic systems or the cholinergic system.

Fifth, such a presynaptic agonist may, again as exemplified by $5HT_{1A}$, be a functional antagonist of its parent system by acting at autoreceptors. An effect of a nominal agonist (i.e. a compound that has an effect at a receptor like the transmitter) at one receptor may be the equivalent of an antagonist at a different receptor type or of a synthesis blocker. Indeed, where there are high and low affinity receptors, low affinity receptors frequently have an opposite effect to high. The former provide the endogenous ligand with a form of negative feedback that can prevent overdriving of the system.

Sixth, there is a therapeutic lag in the clinical effects of specific serotonergic re-uptake inhibitors (SSRI), specific noradrenergic re-uptake inhibitors, $5HT_{1A}$ binding drugs and even benzodiazepines (e.g., Wheatley, 1990, Figure 14.2). This can lead one to ask whether an abnormality in any system that is involved in these therapeutic approaches to anxiety reflects anxiety disorder itself. They may rather be non-specifically involved as critical components of feedback loops maintaining symptoms.

These problems exist for each symptom or syndrome being studied and are rendered even more problematic by the diagnostic problems of the DSM scheme detailed at the beginning of this chapter. In understanding the role of the aminergic systems in anxiety two simplifying strategies can be used. The first is to base the analysis on the dissection of the anxiety disorders provided by the preclinical data. The second is to focus most attention on acute challenge studies in non-clinical populations (where results are not confounded by pre-existing disorder, but may of course be non-specific) and on genetic analysis of clinical populations (where the detected differences between probands and controls must have existed before the onset of the disorder).

Specific Dopaminergic Involvement

The bulk of attempts to address this question have focussed on changes in plasma or urinary levels of noradrenaline or its metabolites. A review of the data up to 1990 (Norman, Judd and Burrows, 1990) found 'a number of studies are suggestive of a role of catecholamines in the aetiology of anxiety states, particularly panic disorder'. Let us focus on the words 'catecholamines' and 'suggestive'. Why do they not draw specific conclusion about dopamine? Why are their conclusions not definite?

Dopamine presents major problems for attempts to claim specificity. It has, as a major metabolite, noradrenaline and so treatments that alter its synthesis also change noradrenaline. Further, it shares both MAO and COMT with noradrenaline as breakdown enzymes. In essence, this means we must rely on the preclinical data for our assessment of its role in anxiety and anxiety-related disorders. These did not suggest any major involvement. Likewise, genetic polymorphisms of the D4 receptor and dopamine transporter do not appear to be strongly linked to panic (Hamilton *et al.*, 2000).

Even if we ignore specificity to dopamine, why can we not make definite claims about the two catecholamines, lumped together?

> 'Evidence ... has been sought in the measurement of epinephrine, norepinephrine and [its metabolite MHPG] in the periphery.... Interpretation of the findings in relation to changes in brain adrenergic function is, of course, problematic, as indeed is the relationship for other peripheral markers. This question has been addressed for the use of plasma-free MHPG concentrations. In brain "free" or unconjugated MHPG is the major metabolite of norepinephrine and its measurement provides a good estimate of turnover. Evidence from animal studies suggest [*sic*] a direct correlation between MHPG concentrations in noradrenergic-containing brain regions and CSF and plasma in untreated animals or in those treated with drugs that increase or decrease activity. A similar situation pertains in humans where positive correlations between CSF and plasma MHPG concentrations have been observed. Furthermore, the effects of administration of some drugs on plasma MHPG in humans are consistent with their effects on brain MHPG in primates. [However,] the contribution of brain MHPG to plasma concentrations has been estimated as [only] 20–65%. [But], despite [these] significant contributions from outside the brain, is thought to be under central control. [Unfortunately,] numerous other factors such as motor activity, temperature, exercises, sexual arousal, mental tasks requiring concentration and diet may all influence catecholaminergic function.
>
> [Thus, there can be] a highly significant correlation between change in anxiety score and change in urinary MHPG output, but urinary MHPG excretion at baseline and state anxiety score did not covary significantly. Baseline anxiety cannot be used to predict baseline MHPG and vice versa.... Urinary MHPG does not appear to be a useful marker to study comparison with normal control groups. On the other hand within subject designs (i.e. pre- and post-treatment) may be more useful for assessing individual changes of adrenergic function in anxiety disorders.'
>
> Norman, Judd and Burrows (1990, pp. 226–228)

An important negative conclusion, here, is that there is no evidence for a general baseline increase in catecholamines as a cause of excessive anxiety responses. Much more likely, given the preclinical data, is that anxiety-induced arousal results in changes in catecholaminergic output as a non-specific symptom.

Attempts to alter dopamine in normal subjects have been no more conclusive.

> 'Decreased dopaminergic function can be elicited experimentally using low doses of apomorphine, which are thought to act as a presynaptic agonist. However, problems with apomorphine include concern about its specificity for the presynaptic rather than postsynaptic receptor, and side effects.... Repeated administration of α-methyl-p-tyrosine [reduces noradrenaline and dopamine and]

> produces primarily fatigue and sedation [while] administration of the catecholamine ... precursor, tyrosine, attenuates mood lowering and cognitive deficits associated with stressful environmental challenges.... Reducing catecholamine neurotransmission by means of acute phenylalanine/tyrosine depletion ... were similar to those reported to occur in response to other used to decrease catecholamine neurotransmission in humans ... [It] lowered mood, energy, and calmness, but only the mood-lowering effect ... after an aversive psychological challenge (public speaking and mental arithmetic) ... was statistically significant.'
>
> Leyton *et al.* (2000, pp. 52–59)

These effects, then, could have been due to changes in noradrenaline as well as dopamine and appeared to relate more to depression than anxiety. It should also be noted that they are in the opposite direction to the effects that would be predicted if release of catecholamines by stress were producing anxiety but are in the same direction as would be predicted from the therapeutic effects of noradrenergic re-uptake blockers and monoamine oxidase inhibitors.

Specific Noradrenergic Involvement

The evidence of the previous section is as relevant, or irrelevant, to assessment of central noradrenaline function as it was to dopamine. In this section we will consider studies that have attempted to exclude dopamine when assessing the effects of noradrenaline. Noradrenaline has a much longer and closer association with anxiety than dopamine.

> 'In humans electrical stimulation in the region of the locus ceruleus [*sic*] has been reported to produce feelings of fear and imminent death. Coupled with the anxiolytic effects in humans of drugs that decrease locus ceruleus noradrenergic activity and the anxiogenic properties of drugs that increase it, Redmond and Huang suggest[ed] a role for this nucleus in human anxiety states.'
>
> Norman, Judd and Burrows (1990, p. 224)

Our preclinical analysis of the noradrenergic system should make us wary of accepting this suggestion too restrictively, especially in its more specific form that noradrenergic systems are critical for panic disorder. Clearly a pathological increase in 'arousal' could engender anxiety — but only in the non-specific way of other disturbances of the body. However, all anxiolytic drugs so far tested do appear to reduce the outflow of forebrain noradrenaline (although as noted above, buspirone increases rather than decreases locus coeruleus firing as a result of its presynaptic inhibition of outflow). But the same drugs alter other systems, particularly serotonin, in the same way and specific noradrenergic lesions appear to be only partially anxiolytic (Table XIX-2.2). A hard-line equation of noradrenaline release with anxiety does not square with these facts. Equally, as emphasized at the beginning of this chapter a role for a compound in the amelioration of symptoms of a state does not necessarily implicate the systems on which the compound acts in the aetiology of the disorder giving rise to that state.

We are left with the looser question of whether disorders of the noradrenergic system can induce, or increase the likelihood, of anxiety disorders. Certainly, drugs like yohimbine, that increase locus coeruleus firing, can increase panic attacks. But, as emphasised in Section 2 panic and anxiety should be kept distinct and 'the list of "successful" and presumably "biological" challenges has grown quite long over the past few years. It now includes lactate infusion, carbon dioxide inhalation, and hyperventilation as well as oral or intravenous yohimbine, isoproterenol, (nor)epinephrine, caffeine, beta-carboline ligands ... and GABA.... [However,] the effects of [such] panic challenges can be strongly altered by manipulating expectancy experimentally' (Margraf and Ehlers, 1990). This is reminiscent of the older work on the effects of adrenaline challenge in normal subjects. 'The differences in the results of [different] workers are explicable in retrospect by the presence or absence of anxiety-provoking environmental cues. In a neutral setting, the injection of epinephrine (adrenaline) produced no emotional changes, "cold emotion", or "as if" emotion.... In an anxiety-provoking setting, intentionally or accidentally created by the experimenters, subjects showed more evidence of anxiety and in a minority of cases panic attacks were elicited' (Lader and Tyrer, 1975). These data all suggest that increased central or peripheral noradrenaline, like peripheral adrenaline, may increase the effect of existing external or (in the case of panic) internal anxiogenic stimuli but are not anxiety provoking in and of themselves. In this we echo the conclusion of our preclinical analysis that central noradrenaline increase vigilance to and vigor of response to stimuli and the conclusion is nonetheless consistent with the view that these effects need not be limited to aversive stimuli. A final point to note, here, is that apparently selective effects of drugs like yohimbine on patients with panic disorder as compared to controls — which can occur with startle as well as panic (Morgan, III *et al.*, 1995) — may reflect no more than a pre-existing heightened sensitivity to stimuli in such patients. Certainly, carbon dioxide inhalation produces more panic in persons with panic disorder than it does in controls (Gorman *et al.*, 1994).

Surprisingly, there is better evidence for the involvement of noradrenaline in depression, and even in the effects of serotonergic antidepressants, than there is for its involvement in anxiety. For example, in depressed patients treated with tricyclic, SSRI or MAOI antidepressants, plasma MHPG (the metabolite of noradrenaline) was reduced as were both anxiety and depression. But the change in MHPG correlated with the change in depression and not the change in anxiety (Karege *et al.*, 1993). Plasma noradrenaline is also high in depressives, independent of the type of depression, and its level has no relation to the level of anxiety (Kelly and Cooper, 1998). Likewise, in post-traumatic stress disorder there appears to be a general change in the 5HT transporter, which is accompanied by $\alpha 2$ adrenergic receptor changes only in those cases with major depression. Conversely, $\alpha 2$ density prior to treatment of panic disorder predicts the efficacy of that treatment without being changed by it. There is, then, no evidence for $\alpha 2$ involvement in the production of anxiety but 'increased ... density and abnormal coupling may represent an adaptive mechanism ... in Panic Disorder' (Gurguis *et al.*, 1999). Nor is there good evidence that polymorphism of the receptor genes relates to differences in panic (Ohara *et al.*, 2000).

Finally, social phobia (arguably a disorder involving anxiety if not caused by it) in the absence of depression does not appear to be accompanied by peripheral signs of catecholaminergic abnormality (Stein, Asmundson and Chartier, 1994; Stein, Walker and Forde, 1994).

Overall, then, we can be happy with the idea that noradrenergic systems can modulate anxiety. However, it seems clear that increased noradrenergic outflow, as such, need not be linked to anxiety. High levels accompany anxiety states in some cases and can exacerbate panic, but increased outflow is also a common action of all anxiolytic drugs. One way of resolving this apparent paradox (consistent with the fact that anxiolytic drugs, including buspirone, do not alter panic) is to suggest that noradrenaline can increase the probability of panic (as can many other agents) while contributing to decreases in anxiety as such. For noradrenaline, this is speculative. However, we noted earlier Graeff's model of the interaction of serotonin with the defence system where (see Figure XIX-2.3) he postulated an opposite effect on the periaqueductal gray (reducing spontaneous panic) to that on higher levels of the system (increasing avoidance).

Specific Serotonergic Involvement

Serotonergic systems have achieved prominence because of their role in antidepressant action. However, it is clear that they are also involved in specifically anxiolytic action. Disentangling causes and effects is difficult here. But it has been suggested that for some types of depression, the depression is secondary to changes in anxiety and aggression that are in turn secondary to 5HT dysfunction. Specifically, a deficient serotonin system would decrease coping ability and hence increase vulnerability to stress. The stress would activate anxiety and aggression and failure to cope with these would precipitate a depressive episode. Importantly, 'the two subgroups — the one in which anxiety/aggression heralds the depression and the other in which anxiety/aggression are first to respond to antidepressants — coincide to a large extent' (Van Praag, 1996).

'A [single] serotonergic deficit, interacting with different pathophysiological mechanisms, could underlie a component of the vulnerability to [and] recurrence or exacerbation of ... [progressing] panic anxiety disorder, [post-traumatic stress disorder (PTSD)] and OCD.... [In particular, it could underlie the] decreasing well-interval between episodes, and a transition from episodes that were precipitated by losses and related psychosocial stressors to those that occurred more spontaneously' via a kindling-like phenomenon (Post and Weiss, 1998) (Kindling is the gradual development and then increase in severity of seizures to repeated electrical stimulation that does not initially generate seizures). Consistent with this, $5HT_{1A}$ agonists decrease kindling and $5HT_{2A}$ agonists increase it, in line with the relation of these receptors to anxiolytic (and antidepressant) action (Post and Weiss, 1998).

> 'Remarkably, in the restraint stress paradigm, antidepressants with activity at either noradrenergic or serotonergic synapses are sufficient to oppose and block some of the effects of stress on neurotrophic factor gene expression.... Whereas the benefit of not having recurrent depressive episodes based on adequate pharmacoprophylaxis is substantial in itself, it is also possible that antidepressants could impact the course of illness, both by removing the sensitizing effect of episodes on subsequent vulnerability to recurrence and by ameliorating the potential acute and concomitant long-term impact of the stressor.... [Serotonergic vulnerability] could be set either by an inherited genetic mechanism or by an experience-dependent, stressor-mediated impact on gene expression ... or by both mechanisms in combination, providing a "double hit" like that required in the development of some cancers.'
>
> Post and Weiss (1998)

The link with kindling may be even tighter than this. Partial electrical kindling of the limbic system in animals results in increased anxiety-like behaviour that has been explicitly suggested as a model of PTSD and there are many other links between kindling and anxiety in preclinical data (Adamec, 1997).

The idea that serotonin-related changes in depression may be at least in part secondary to changes in anxiety is consistent with results from healthy human subjects subjected to a psychological challenge. Relative to the effects of acute lowering of noradrenaline, acute lowering of serotonin had about twice as big an effect on anxious mood as on depressed mood. Of particular interest relative to van Praag's hypothesis (above) is the fact that, unlike noradrenaline depletion, serotonin depletion increased hostility (Leyton *et al.*, 2000) and that no change was observed in mood in the absence of psychological challenge (making a speech). A similar lack of effect in the absence of challenge has been observed in remitted panic disorder patients (Goddard *et al.*, 1994) and in numerous other studies in healthy subjects (Klaassen *et al.*, 1998). In healthy human subjects submitted to a carbon dioxide challenge serotonin depletion appears to produce a highly variable increase in reported anxiety and produces a significant increase in neurovegetative symptoms of panic (Klaassen *et al.*, 1998). These results are also consistent with van Praag's hypothesis that serotonin deficiency creates a vulnerability to anxiety that is only expressed in response to challenge. However, worsening of symptoms has been observed in remitted OCD patients (Barr *et al.*, 1994 — cited by Goddard *et al.*, 1994).

While a general depletion of 5HT may produce general effects, as with treatment, receptor-specific challenge can produce more specific effects — and even opposite effects. Thus, a $5HT_{2c}$ agonist, while being panicogenic like many other non-specific agents, can increase symptoms in OCD patients in a way that other panicogenic agents do not (Bagdy, 1998). This selectivity mirrors the fact that anti-obsessional agents tend to be panicolytic, but not necessarily vice versa. Likewise 'patients with OCD who also had a family history of OCD had significantly higher whole blood 5-HT levels than either patients with OCD without a family history of OCD or normal control subjects (Hanna *et al.*, 1991)' (Cook, Jr. *et al.*, 1994). The idea that there is a subgroup in which a high (rather than low) level of serotonin (in the blood not necessarily in the brain) is linked to OCD might seem to be supported by the fact that those parents of autistic children who have a high whole blood serotonin have a tendency to higher OCD scores than those with normal whole blood serotonin. However, in their case, hyperserotonemia is much more clearly related to higher depression scores than OCD scores (Cook, Jr. *et al.*, 1994). Unfortunately, Cook *et al.*, did not measure anxiety as opposed to obsession. It is possible, then, that the link with depression was mediated by a change in anxiety.

Support both for this idea, and for a link to central as opposed to peripheral serotonin is provided by studies on blood platelets. These have a serotonin uptake mechanism that appears similar to the central one in that it is blocked by SSRIs. Genetic or environmental changes in this transporter system are likely to occur similarly in platelets and in the brain and are likely to be one of the factors controlling whole blood serotonin levels. Assessment of the serotonin re-uptake mechanism via 'paroxetine binding was negatively correlated with both state and trait anxiety, as well as with depressive and overall PTSD symptoms. However,... [it did not differ] as a function of comorbid psychiatric diagnoses including major depression, other anxiety disorders, and substance abuse' (Fichtner *et al.*, 1995). 'Arora *et al.* (1993) [also] reported ... a negative correlation ... with state-dependent anxiety score. Unlike patients with PTSD, no significant alterations in platelet ... binding ... could be found in major depression. These negative findings in major depression are in agreement with our results that there were no significant differences in ... binding ... between PTSD patients with and without major depression' (Maes *et al.*, 1999).

It might seem peculiar that, on the one hand, a $5HT_{2c}$ agonist or increased blood serotonin levels or decreased serotonin transporter levels should be positively related to neurotic disorder while, on the other hand, challenges that deplete serotonin should increase symptoms related to those same disorders. The difficulty of interpreting such studies (and one of the reasons for this chapter having an extensive preclinical review) is highlighted by the fact that the 'hyperserotonemia' reported in whole blood may be due to 'increased platelet 5-HT uptake.... [such] increased 5-HT uptake may predispose ... to depression' (Cook, Jr. *et al.*, 1994). That is, increased measured whole blood serotonin, if it is inside platelets, would correspond to increased serotonin inside presynaptic terminals and so *decreased* serotonin in the synaptic cleft and so decreased postsynaptic effects. Similarly with the $5HT_{2c}$ agonist, the effects could be the opposite of systemic changes in serotonin if the net effect of the systemic increase on the specific terminals of interest was a decrease of release either through presynaptic or autoreceptors. With the serotonin transporter 'binding correlates highly with tissue 5-HT content' (Fichtner *et al.*,

1995), i.e. the more 5-HT there is around the more transporters there are to transport it. So, while high levels of transporter, all other things being equal, should lead to lower levels of serotonin in the cleft it is likely that high measured levels of transporter indicate that all other things are not equal. It is a higher functionality of the serotonin system that is likely to have produced a feedback increase in number of transporters.

Despite the strong link between the platelet serotonin transporter and anxiety in PTSD, it does not seem to be a basis for anxiety disorder in general. Both social phobics and panic disorder patients have normal binding (Stein *et al.*, 1995). This could be because these are distinct entities from anxiety proper (in which GAD patients would be expected to have low binding) or it may be that transporter changes are related more to aetiology than symptomatology — and are a marker of the means of acquisition of PTSD, or simply of the levels of stress previously experienced.

A causal role for the transporter itself (rather than a role as a marker) is suggested by the linkage of polymorphisms in its genes with anxiety (Evans *et al.*, 1997; Ohara *et al.*, 1998a, 1998b; Katsuragi *et al.*, 1999; Melke *et al.*, 2001). There may be a similar causal role for genetic differences in serotonin synthesis (Du, Bakish and Hrdina, 2001) and these could, of course, combine with transporter differences to produce synergistic (or antagonistic) effects. However, as emphasized earlier, genetic control of the serotonin system is likely to reflect increased vulnerability to stressors rather than a direct and specific promotion of PTSD in general or anxiety in particular.

Given the possible opposite functional effects of different receptor subtypes it is of interest that, as with ' "knock-out" mice lacking the gene that regulates the expression of the 5-HT_{1A} receptor [which] display greater anxiety ... in the open-field and the elevated-plus-maze tests, ... [with] regional 5-HT_{1A} [in] ... healthy volunteers ... there was a significant negative correlation between 5-HT_{1A} binding potential and anxiety in [all of] four regions: the dorsolateral prefrontal cortex, anterior cingulate cortex, parietal cortex, and occipital cortex' (Tauscher *et al.*, 2001).

Aminergic Interactions

There has been much less analysis of the possible interactions of the amine systems at the clinical than preclinical level. Given the difficulty of connecting a particular measure of aminergic activity with functional effect for a single amine (previous sections), we cannot expect too much from studies of more than one amine at a time. The critical feature of such studies will be to partial out the effects of the different systems. For example, we already concluded that anxiety, but not depression, in PTSD is linked to the serotonin transporter. There was also evidence that the serotonin transporter was not linked to depression in cases of depressive disorder as opposed to PTSD. And yet depression itself is a major feature of PTSD and can be treated with specific serotonin agents. Interestingly, in PTSD the presence of major depression is associated with a down regulation of $\alpha 2$ receptors. Decreased serotonergic traffic, then (whether as a result of acute or chronic trauma or genetic polymorphism), could increase the risk of anxiety and/or aggression to stressful events. Combination of this with a decrease in noradrenergic presynaptic autoinhibitory receptors could result in depression, which would also be characterized by increased autonomic activity (Maes *et al.*, 1999). The effectiveness of SSRIs in such cases could then be due to the elimination of one of two necessary or, at least, synergistic changes. If specific noradrenergic re-uptake inhibitors are proved to be effective in PTSD patients with depression, this could result from overcoming decreased autoinhibitory function.

A similar interactive relationship is suggested in generalized anxiety disorder by the pattern of plasma metabolites. Urinary output of serotonergic and noradrenergic metabolites is positively correlated in GAD patients, with 50% common shared variance (Garvey *et al.*, 1995a, 1995b). Apparently the same patient group (Garvey *et al.*, 1995a, 1995b), although there is no cross reference between the papers, showed a weaker[2] relationship (tension being the best with 25% variance accounted for) between a multiple regression function including both these measures and a subset of, mostly somatic, items in the Hamilton Anxiety Scale. The critical point is that the partial correlations of the serotonergic and noradrenergic measures were opposite in sign from each other both within and across items. As with PTSD data, and with the preclinical data, this suggests a complex partially synergistic interaction between the two monoamines in determining anxiety and/or its symptoms and comorbidities.

Conversely, there are 'recent studies of depressed patients where the NE and 5HT neurotransmitter systems have been suggested to produce distinguishable contributions to therapeutic efficacy. ... Dietary depletion of 5-HT pre-cursors leads to clinical relapse in depressed patients who have been successfully treated with SSRIs, but not those treated with NE selective uptake inhibitors, and that blockade of NE synthesis has complementary effects' (Detke, Rickels and Lucki, 1995, p. 71).

Involvement of Monoaminoxidase and COMT

Synergy between the aminergic systems and differences in the balances between different parts of the defense system would account for the wide variations in treatment sensitivity across symptomatologically similar patients. They would also account for the cases where specific noradrenergic agents appear as effective as specific serotonin agents.

The enzyme COMT breaks down both dopamine and noradrenaline and MAO breaks down dopamine, noradrenaline and serotonin. Given synergy between the amines we would expect significant effects on clinical anxiety of disruption of these non-specific amine breakdown systems. It should be noted here that, while tricyclic drugs can be non-specific in their effect on re-uptake systems, genetic polymorphisms are much more likely to be system specific. Polymorphisms affecting the breakdown enzymes will, of course, be more general in their effects. We might, then, expect changes in COMT and MAO to be more significant aetiologically since they would allow synergy. However, for aminergic transmitters, re-uptake is more important for inactivation than breakdown. This said, MAO inhibitors are at least as effective clinically as tricyclic drugs and this appears to remain true for the reversible inhibitors selective for the A form of MAO (MAO-A). These interact much less with tyramine and so are much less toxic (Buller, 1995). Indeed MAO inhibitors can be effective in patients resistant to other antidepressant drugs (Modigh, 1987). They also appear more effective in treating endogenous anxiety than do tricyclic drugs (Sheehan, Ballenger and Jacobson, 1981).

The preclinical data also suggest a potential involvement of MAO-A in anxiety disorders. Mice mutants lacking MAO-A show increased noradrenaline and serotonin in the forebrain (including theoretically important areas such as hippocampus and prefrontal cortex). They show increased fear conditioning to both simple stimuli and environmental context and increased passive avoidance (suggesting effects on both fear and anxiety, see above). However, simple eye blink conditioning is normal suggesting a relatively specific emotional effect (Kim *et al.*, 1997). Interestingly, a polymorphism that would lead to higher levels of MAO activity is found

[2] Some of the weakness in the observed correlations is likely to have been due to compression of the scale scores as a result of the exclusion criteria used rather than reflecting a weak underlying relationship in the normal population.

more in male OCD patients than in either female OCD patients or controls (Camarena *et al.*, 2001).

Polymorphism of genes controlling human COMT can result in as much as a four-fold variation in the activity of the enzyme (Lachman *et al.*, 1996). This might be thought to provide a basis for considerable psychological impact but no marked effects have been reported. It may be significant in OCD but does not appear to be relevant to other anxiety disorders (Ohara *et al.*, 1998a, 1998b).

AMINERGIC INVOLVEMENT IN PERSONALITY

There is a common theme linking the preclinical data, the delayed effects of therapeutic drugs, and the development of disorder later in life linked to polymorphisms present from conception. They all imply that aminergic systems are modulatory of the defense system as a whole. Disorder, then, appears to result from the combination of the presence of long-term general aminergic modulatory risk factors with more specific genetic and environmental factors. 'Modulatory risk factors', in this sense, are best seen as an element of personality.

This is not to imply that personality itself is unmodifiable by events. Even in Australian fire fighters (arguably pre-selected to be relatively insensitive to danger) exposure to a major stressor[3] generated post-traumatic stress disorder in about a third of them and the PTSD appeared to remain chronic (McFarlane, 1989). Thus, rather than being a disorder proper, PTSD may better be thought of as an extreme change in the same personality dimension that controls the risk of anxiety disorder normally (Pitman, Orr and Shalev, 1993). Consistent with this, brief extreme activation of brain defense systems with either anxiogenic chemicals or electrical stimulation can produce increases in reactivity of the defense system that are very long lasting and have been seen as animal models of PTSD (Adamec, 1998a, 1998b, 1998c).

A major contributor to personality, however, is likely to be genes. The tendency to anxiety disorder in current populations has about a 30% contribution from genetic factors and this is true of the tendency to generalised anxiety even when it is comorbid with other conditions, including depression (Kendler *et al.*, 1992a, 1992b, 1992c). This genetic vulnerability appears general to 'neurotic disorders' (including depression) and does not appear selective for individual 'anxiety disorders' (Andrews *et al.*, 1990). With respect to comorbidity, it is interesting that depression and anxiety appear to be the 'result of the same genetic factors. Environmental risk factors that predispose to "pure" GAD episodes may be relatively distinct from those that increase risk for major depression'. By contrast, GAD and panic share only about half of their genetic control, each having a distinct other half (Scherrer *et al.*, 2000). In the case of panic, for example, genetic influences on anxiety, via polymorphisms of aminergic systems, could operate in parallel with panic susceptibility, via polymorphism of CCK systems (Wang *et al.*, 1998a, 1998b). This suggests a tight linking of anxiety with depression but (as argued earlier) a weaker link with panic. The latter is a distinct entity that can be both a cause and a symptom of anxiety, but can occur alone.

The dimensional analysis of personality (Eysenck and Eysenck, 1969; Watson, Clark and Harkness, 1994) suggests that psychiatric patients are simply located near the extreme pole of one or more dimensions of normal personality (Eysenck, 1960). This is analogous to the clustering of disorders such as stroke in those who are at one extreme of the normal distribution of blood pressure. This dimensional approach is becoming increasingly accepted in psychiatry (e.g., Cloninger, Svrakic and Przybecky, 1993). The blood pressure analogy is exact here as personality dimensions reflect liability to disorder not presentation. Prevalence of cases is strongly correlated with mean symptom scores in the normal range, even when diagnosed cases are excluded (Rose and Day, 1990); and there is a high frequency of subthreshold disorders (Goldberg and Huxley, 1992).

In terms of Eysenck's Personality Inventory (Eysenck and Eysenck, 1969; Eysenck and Eysenck, 1976; Costa and McCrae, 1985) those prone to anxiety are neurotic introverts. These people can be viewed as having a 'trait anxiety' that loads about 0.7 on neuroticism and 0.3 on introversion. It should be noted, here, that the risk of specific phobias of items such as snakes (unlike other 'anxiety disorders') is not related to this factor (Marks, 1969) and, consistent with this, such phobias are not relieved by anxiolytic drugs (Fredrikson and Öhman, 1979; Sartory, MacDonald and Gray, 1990). It should also be emphasized that 'trait anxiety' represents a risk for 'state anxiety' and neurotic disorder but is not identical to them. Thus, in the fire fighters mentioned earlier, the traumatic event was required to generate PTSD but, even in this selected population and with this single specific traumatic event, the tendency to neurotic personality predicted the disorder better than the extent of exposure to the event (McFarlane, 1989). Consistent with the heritability of neurotic disorder, the Eysenck dimensions are controlled almost equally by genes and environment (Floderus-Myhred, Pedersen and Rasmuson, 1980).

Factor analysis determines the number of dimensions of personality but not their nature. Although Eysenck's personality inventory is used very extensively it has been argued (Gray, 1970, 1981) that the axes representing the dimensions of neuroticism and extraversion should be rotated resulting in a dimension (0.7 neuroticism, −0.3 extraversion) corresponding to the 'trait anxiety' extracted by others (Cattell, 1965; Taylor, 1953) and an orthogonal dimension of 'impulsivity'. This dimension of 'trait anxiety' is what appears to be changed by the lesions of cingulate and prefrontal cortex used to treat drug-resistant anxiety (Powell, 1979).

There is evidence that 'emotionality' in rats is a homologue of neuroticism or trait anxiety (Broadhurst, 1960; Gray, 1987). It has a major genetic component (Hall, 1951; see review by Gray, 1987) and selective breeding has resulted in the Maudsley Reactive and Maudsley Non-reactive strains of rat.

The two Maudsley strains differ on a huge range of items (for reviews, see Broadhurst, 1975; Blizard, 1981; Gray, 1987). The bulk of these can be interpreted as showing a greater response to fear-provoking stimuli in general rather than to anxiety in particular. Note that this is an increased emotional response rather than an increased sensory response since they do not differ in pain sensitivity (Commissaris *et al.*, 1992) nor in rate of learning as such (Commissaris *et al.*, 1986). They also differ in an animal model of depression (Abel, Altman and Commissaris, 1992; Viglinskaya *et al.*, 1995). and this effect shows a strong linkage between changes in scores on an anxiety test with those on the depression test (Commissaris *et al.*, 1996). Just like 'trait anxiety', then, they appear to influence susceptibility to the full spectrum of neurotic reactions.

I have discussed this issue in such detail because analysis of aminergic systems has been carried out on the Maudsely strains at a depth currently impossible with people with trait anxiety. The Maudsley reactive strain (MR) has an increased response of locus coeruleus neurons to stress (Buda *et al.*, 1994; Blizard and Liang, 1979), need a higher dose of $\alpha 2$ agonist for the same effect and have lower $\alpha 2$ binding in LC, suggesting a less effective autoinhibition[4] (Sara, Devauges and Biegon, 1993). A primary involvement of autoinhibition could well underlie the paradoxical

[3] A bush fire, which comes within the ICD-10 definition of a traumatic situation, i.e. one 'of an exceptionally threatening or catastrophic nature, which is likely to cause pervasive distress in almost anyone (e.g., natural or manmade disaster, combat, serious accident, witnessing the violent death of others, or being a victim of torture, terrorism, rape, or other crime' (World Health Organization, 1992, p. 147).

[4] But note that an opposite pattern appears to be obtained under urethane anaesthesia (Verbanac *et al.*, 1994).

increase in the difference between the two strains on a conflict task after administration of a peripheral noradrenergic neurotoxin (Verbanac *et al.*, 1993). This only reduced central noradrenaline by 30%, whereas over 95% depletion is normally needed for behavioural effects (McNaughton and Mason, 1980) and may have been selectively affecting autoinhibition thus increasing rather than decreasing overall noradrenergic function.

Maudsley reactive rats have also been reported to have higher levels of serotonin in the limbic system (Maas, 1963) and in the brainstem, but the difference in the brainstem does not appear to be a reliable finding (Blizard and Liang, 1979) and, under urethane, neither dorsal raphe discharge rates nor sensitivity of 5HT1A autoreceptors is different (Verbanac *et al.*, 1995). Unfortunately, the sensitivity of presynaptic 5HT1A receptors in the limbic system (on which drugs like buspirone are likely to have their major action) has not been reported. A lack of difference in 5HT levels would be expected if the main difference between the strains, as with healthy humans (Tauscher *et al.*, 2001), is in binding and hence postsynaptic effect of the serotonin released.

Overall, then, we have a picture of polygenetic effects on the efficacy of both the noradrenergic and serotonergic systems that, through synergistic interactions (both within and between the amine systems) contributes to a normal personality factor that can be viewed clinically also as a risk factor for high levels of anxiety and hence anxiety disorder. Additional genetic and particularly specific environmental factors would then increase the risk of, or precipitate, particular disorders. These would then be specific instantiations within a 'trait diathesis common to all anxiety disorders' (Zinbarg and Barlow, 1996; Brown, Chorpita and Barlow, 1998).

CONCLUSIONS

There appears little question that the aminergic systems play a role in adaptive responses to stressors and that their general state of reactivity, set by genes and (often early) experience, contributes to a personality factor of 'trait anxiety' that can be largely equated with neuroticism. However, specific neurotic disorders do not appear to equate with disorder of the aminergic systems as such. They reflect distortions of activity in particular brain centres. The selectivity of therapeutic agents (and receptor-linked genes) then reflects postsynaptic differences in particular terminal areas. The lack of selectivity of trait anxiety for specific disorders reflects changes in synthesis and breakdown that are not only general to many terminal areas but also can be general to several aminergic systems (monoamine oxidase being particularly indiscriminate). The complex effects of kindling, opposite effects of normal and autoinhibitory receptors and direct interactions between terminals of the different amine systems render analysis of the clinical situation difficult. However, there is no reason to suppose that anxiety disorders cannot be viewed as extremes of normal psychological variation or that the component parts of the systems of interest (including their genetic control) cannot be studied, one at a time, in animal models. Highly efficient future treatments are likely if we can understand the different roles of different aspects of monoamine function in anxiety and obtain reliable markers that can reliably indicate specific treatment modalities for specific patients.

Amino Acid Transmitter Systems

Catherine Belzung, Guy Griebel, Florence Dubois-Carmagnat and Jean Michel Darves-Bornoz

INTRODUCTION

Amino acids correspond to a wide range of compounds, including precursors of catecholamine and serotonin synthesis (tyrosin and tryptophan respectively) as well as neurotransmitter systems such as the excitatory amino acids glutamate and aspartate and the inhibitory amino acids γ-aminobutyric acid (GABA) and glycine. As few studies revealed anxiolytics acting on excitatory amino acids via the N-methyl−D-aspartate (NMDA) complex and/or the metabotropic glutamate (mGlu) receptors, only a short paragraph will be devoted to such agents. Furthermore, data suggesting abnormalities in excitatory amino acid systems in some anxiety disorders will be mentioned. On the other hand, we will focus on anxiolytic drugs acting on GABAergic neurotransmission, as most anxiolytics act via GABA-related mechanisms, first focusing on the mechanisms underlying the anxiolytic action of some anti-anxiety agents such as benzodiazepines (BZs) and second describing the use of such compounds in the clinic, in an attempt to link the pharmacology with neurochemical changes that have been observed in these disorders.

ANXIOLYTIC AGENTS ACTING ON EXCITATORY AMINO ACID NEUROTRANSMISSION

The anti-anxiety-like action of compounds acting on excitatory amino acid neurotransmission has mainly been investigated in pre-clinical studies, using animal models of anxiety. Indeed, because of multiple side effects of such compounds (ataxia, myorelaxation, impairment of learning and memory), such agents cannot be proposed as potential anxiolytic drugs in the clinic.

Glutamate and aspartate bind to two types of receptors: the ionotropic receptors (AMPA, kainite and NMDA receptors) and the metabotropic glutamate receptor. Among the ionotropic receptors, solely the NMDA receptor has been proposed as a potential target for anxiolytic agents in pre-clinical studies.

Ligands of the NMDA Receptor

The NMDA complex consists of various binding sites, including a glutamate recognition site, a polyamine site, a glycine site, a phencyclidine site (channel site) and a Zn^{2+} site. Low doses of the non-competitive NMDA antagonist MK-801 or of the competitive NMDA antagonists AP5, AP7 and CPP elicited anxiolytic behaviour in several animal tests (see Chojnacka-Wójcik and Klodzinska (2001) for a recent review). Similar effects were observed with antagonists (7-CIKYN and 5,7-CIKYN) and partial agonists (HA-966, ACPC and D-cycloserine) of the $Glycine_B$ receptors; however, none of these agents crosses the blood−brain barrier. Finally, discrepant results were obtained with antagonists of the polyamine site (ifenprodil and eliprodil) as these compounds are endowed with anxiolytic properties in some, but not all animal models of anxiety.

Ligands of the Metabotropic Glutamate Receptor

The mGlu receptors are a family of eight receptors designated mGlu1 through mGlu8, which can be divided in three groups based on the similarity of the amino acid sequence, pharmacology and second messenger coupling. The first group, which consists of mGlu1 and mGlu5, is positively coupled with phospholipase C and is sensitive to *trans*-ACPD as well as quisqualate. The second group, which includes mGlu2 and mGlu3, is negatively coupled to adenylate cyclase and is sensitive to *trans*-ACPD but not quisqualate. The third group, consisting of mGlu4, mGlu6, mGlu7 and mGlu8, is negatively coupled to adenylate cyclase and does not respond to *trans*-ACPD and quisqualate but rather binds specific compounds. Antagonists of Group I mGlu receptors such as S-4C3HPG or (S)-4CPG, as well as an antagonist of the mGlu1 (CPCCOEt) or of the mGlu5 (MPEP) elicited anxiolytic effects in pre-clinical models. Furthermore, LY-354740, an agonist of Group II mGlu receptors, displayed anxiolytic activity in several models of anxiety. In fact, as Group II mGlu receptors are localized presynaptically, their receptor agonists may inhibit glutamate release, so that they are parallel to the effects of Group I mGlu receptors antagonists. Finally, regarding Group II mGlu receptors ligands, the issue remains to be clarified as discrepant results have been obtained.

ANXIOLYTIC AGENTS ACTING ON GABAERGIC NEUROTRANSMISSION

Early Anxiolytics Acting via a GABAergic Mechanism

Ethanol

There is evidence suggesting that ethanol, a compound usually termed as alcohol, has been used in prehistoric times. It can therefore be considered as the first anxiolytic compound. Mead, a fermentation product of honey, is considered as the oldest alcoholic beverage; it seems that it existed in the paleolithic age, about 8000 B.C. Alcoholic beverages are known to produce relaxation, elevation of mood, anxiolysis and disinhibition in response to social constraints. At higher doses it induces sedation. Most alcohol users drink occasionally (75% of the population of the USA). However, 15% of users are considered alcoholics. This highlights the great abuse potential of this compound.

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

Barbiturates

In 1864, Adolph von Baeyer synthesized barbituric acid (malonylurea). The name of this drug is said to be linked to the presence, on the day of the experiment, of Baeyer in a tavern in which officers were celebrating the Day of St. Barbara, their patron saint. Barbituric acid was devoid of clinical potency but it led to the development of barbiturates after 1903, the date of the synthesis of barbital that became rapidly popular. These compounds rapidly took a dominant place because they facilitated sleep and produced relaxation. However, the bioavailability of barbital was rather low because of the poor solubility in lipids of that drug. Furthermore, it was metabolized slowly so that the effects on drowsiness extended over 36 hours. Consequently, new drugs with short duration of action (amobarbital, pentobarbital, secobarbital) and later, in the 1930s, ultra-short duration of action (hexobarbital, thiopental, methohexital) were introduced into therapeutics. These drugs, termed barbiturates, are widely used as anaesthetics but they also have an excellent efficacy in alleviating anxiety. For example, pentobarbital (Figure XIX-3.1) is effective in most rodent models of anxiety. However, their development in the treatment of anxiety has been spurred by their high abuse potential. This has been shown in animal as well as human studies. Furthermore, it also elicited lethal effects (1500 deaths per year), principally due to accidental poisoning in drug abusers and to suicide.

Carbamates

As in many other cases, the starting point of the use of carbamates in the treatment of anxiety had nothing to do with their action in the central nervous system. In the 1940s, the Wallace Laboratories were developing new antibacterial agents and therefore chemists attempted to improve the potency of phenoxetol, a compound used as disinfectant, by lengthening the carbon chain. When testing the toxicity of that newly synthesized compound, termed mephenesin, they observed that it produced muscle relaxation and a sleeping-like condition in animals. They described this action as 'quieting influence on the demeanor of the animal', an effect that was named in 1946 'tranquillization'. The drug was marketed in 1947 as a short-action muscle relaxant but in 1949 several authors proposed that it may alleviate anxiety. However, mephenesin had several drawbacks, including a very short duration of action. Therefore, researchers attempted to alter the chemical structure of mephenesin to overcome these shortcomings: the result was meprobamate (Figure XIX-3.2), a compound whose duration of action was eight times that of mephenesin. In the early 1950s, Berger demonstrated that meprobamate possessed anxiolytic properties. This was shown in monkeys whose fear was reduced in threatening environmental situations, and in rats, in which meprobamate was effective in disinhibiting behaviour that was suppressed by punishment (Geller–Seifter test). Berger claimed that unlike alcohol or barbiturates, the anxiolytic effects of meprobamate were not associated with impairment of intellectual or physical performance. He explained these effects by an action on 'those specific areas in the brain as the thalamus and the limbic system, that represent the biological substrate of anxiety'. Consequently, between 1950 and 1960, meprobamate was one of the most commonly used drugs for the treatment of anxiety worldwide. Later, however, the image of meprobamate was tarnished by numerous reports of lethal overdoses. Moreover, the anxiolytic effect was accompanied by drowsiness and ataxia.

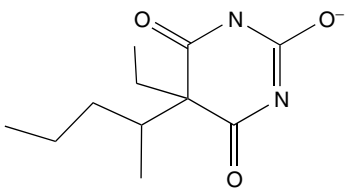

Figure XIX-3.1 The structure of pentobarbital

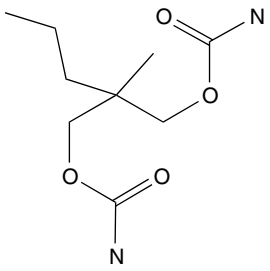

Figure XIX-3.2 The structure of meprobamate

As will be discussed later, these three categories of compounds interfere with GABAergic neurotransmission, which is the principal inhibitory neurotransmitter within the central nervous system.

The Discovery of Benzodiazepines

The Discovery of Chlordiazepoxide

At the end of the 1950s, pharmaceutical companies started to become interested in the field of psychopharmacology. This was related to the commercial success of meprobamate and other psychoactive agents such as chlorpromazine. In this context, a team at Hoffman–La Roche, led by Leo Sternbach, started to study some heptoxdiazines that Sternbach synthesized in the early 1920s when he was a postdoctoral student at the university of Cracow, looking for dyestuffs. In fact, these compounds had no interesting properties as dyes, and no evidence existed in favour of an action of these compounds on the central nervous system. Sternbach decided to study them only because they were unexplored and convenient to test because of their chemical versatility that allowed many transformations. First Sternbach discovered that these compounds were not heptoxdiazines but quinazolone 3-oxides. He then synthesized 40 derivatives and found that all of them, except one that was not tested, were biologically inactive. The last one, labelled RO 5-0690, was disregarded, mainly because of other research priorities. In May 1957, during a cleanup of the laboratory, one of the collaborators of Sternbach found this drug and suggested that it may be tested. Therefore RO 5-0690 was given to the team led by Randall for animal testing. Six tests were used for the screening: a test for sedation and muscle relaxation, a foot-shock test to measure 'taming' effects, another test for muscle relaxation and three tests for anticonvulsant activity. The drug was compared to phenobarbital, chlorpromazine and meprobamate. It was superior to the latter compounds in all tests and therefore Randall announced in 1960 that chlordiazepoxide (the new name of RO 5-0690) may have potent sedative, muscle relaxant, taming and anticonvulsant activity. It was introduced into pharmacotherapy under the tradename 'Librium' (from 'Equilibrium') in 1960, only two-and-a-half years after the first pre-clinical tests. It was then shown that this compound also elicited anti-anxiety effects.

Synthesis of other BZs

A more potent analogue, diazepam, was synthesized in 1961 and, later, 50 other BZs were marketed throughout the world.

Table XIX-3.1 Half-life of major BZs

BZ	Duration of action (h)*
Chlordiazepoxide	55 +/− 35
Diazepam	55 +/− 35
Oxazepam	17 +/− 11
Lorazepam	16 +/− 8
Alprazolam	11 +/− 5

*Including active metabolite

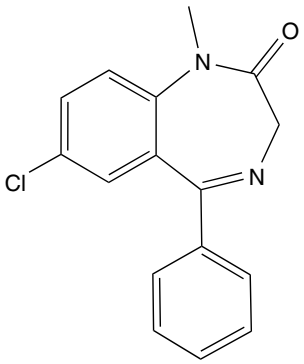

Figure XIX-3.3 Chemical structure of diazepam. The figure shows the core structure made up of the benzene ring (left ring) fused to a diazepine ring (right part, top). The third ring is an aryl substituent ring (bottom, right part)

These new compounds include oxazepam (1965), nitrazepam (1965), clorazepate (marketed in 1968), lorazepam (marketed in 1973), bromazepam (1974), clobazam (1975) and flunitrazepam (1978). The need for new compounds was mainly related to the necessity to develop compounds with a shorter half-life than chlordiazepoxide and diazepam (see Table XIX-3.1 for more details).

BZs are metabolized extensively, generating active metabolites. Some of these metabolites are biotransformed more slowly than the parent compound so that there is no clear relationship between the half-life of a BZ and its duration of action. It should also be noted that BZs display metabolic inter-relationship with common active metabolites. For example, chlordiazepoxide, clorazepate, prazepam, diazepam as well as demozepam are all metabolized in desmethyldiazepam. Some BZs (prazepam, flurazepam) reach the systemic circulation only in the form of active metabolites. All these compounds have a rather close chemical structure. In fact, the name BZ is derived from the benzene ring fused to the diazepine ring (Figure XIX-3.3). They all share common pharmacological properties as they are all sedative–hypnotic, muscle relaxant, anxiolytic and anticonvulsant. Unfortunately, they also display unwanted side effects: they induce anterograde amnesia, tolerance and dependence. However, when compared to the early anxiolytic agents (barbiturates and meprobamate), they displayed a high therapeutic index so that they became rapidly and widely prescribed and very popular, in particular in the treatment of anxiety. In 1972, chlordiazepoxide and diazepam accounted for half of all psychoactive prescriptions in the USA. This led to increasing concerns about their over-use, so that some countries such as the UK introduced a limited prescription list of these compounds in the mid 1980s. However, the prevalence of BZ use is still very high.

Mechanisms of Action

Mechanisms of Action: First Discoveries

The mechanism of action of BZs remained a mystery until a key observation was made in the unravelling of this knot. Indeed, in 1967, electrophysiological studies on the cat spinal cord revealed that diazepam could potentiate the dorsal root potential. The significance of this observation was, however, not realized until the discovery that the dorsal root potential was associated with the activation of local inhibitory neurotransmission using GABA. In fact, the effects of BZs on the dorsal root potential requires an intact GABA system within the spinal cord. It was later observed that the ability of BZs to potentiate GABAergic neurotransmission was a ubiquitous phenomenon, present in many brain areas. This evidence originates not only from electrophysiological studies but also from a biochemical study. The major type of GABA receptor in the brain, termed $GABA_A$ receptor, is associated with an ionophoric postsynaptic Cl^- channel that mediates inhibitory neurotransmission in the brain regulating Cl^- permeability. BZs do not bind to the $GABA_A$ receptor but they potentiate the action of GABA on the $GABA_A$ receptors. Therefore, they require the presence of GABA to express their pharmacological actions.

BZ Receptors

The next milestone in the understanding of the mechanism of action of BZs was the discovery in membrane preparation of high affinity binding sites for [^{3}H]-diazepam that were saturable and stereospecific. This was first reported in 1977 by two independent teams (Braestrup and Squires in Copenhagen, and Möhler and Okada in Basle). One year later, similar binding sites were identified in the human brain, using another ligand, [^{3}H]-flunitrazepam. BZ receptors are located on dendrites, nerve cell bodies and nerve terminals. Autoradiographic studies showed that BZ binding sites are widely distributed within the central nervous system, with the highest concentrations in the cerebral cortex, intermediate concentrations in the limbic system and the cerebellum, and lowest in the pons-medulla and spinal cord (Figure XIX-3.4).

The clinical efficacy of BZs has been attributed to their ability to bind BZ receptors. Indeed, there is a positive correlation between the Ki values for the inhibition of [^{3}H]-diazepam binding by various BZs and their average therapeutic recommended doses (Figure XIX-3.5).

It is important to emphasize that BZs not only bind to BZ receptors. For example, they have also nanomolar affinity for adenosine receptors. However, this is often forgotten so that their psychoactive effects are always attributed to their binding to BZ receptors.

Binding sites are also found in certain peripheral tissues, and represent the so-called mitochondrial BZ binding site. They were first discovered in the kidney, and later they were found in other peripheral tissues such as the adrenal glands and the testes. Such sites also exist in the central nervous system, where they are mainly found on glial cells. These sites are not associated with the $GABA_A$ receptor. The binding site is different from the brain BZ receptor, since it does not recognize all psychoactive BZs (for example clonazepam) and binds some compounds such as the isoquinoline, PK 11195, with nanomolar affinity. They are located subcellularly on the outer membrane of the mitochondria, rather than on the cell membrane. Their function is not well known in all cell types, but it has been suggested that in steroid hormone-producing organs (adrenal glands, testes), they are involved in the transport of cholesterol from the outer to the inner mitochondrial membrane. In the brain, it has been proposed that these receptors may be involved in neurosteroidogenesis.

Ligands of BZ Receptors

Up until the early 1980s, it was widely admitted that the chemical structure of BZs was a prerequisite for the binding to the BZ receptor. However, this view was challenged by the discovery that some chemically unrelated drugs (Figure XIX-3.6) such as cyclopyrrolones (zopiclone, suriclone), triazolopyridazines (CL 218,872), phenyl-imidazo-pyridine acetamides (alpidem, zolpidem), quinolines (PK 8165) and pyrazoloquinolines (CGS 8216, CGS 9896) bind to the same site as BZs, sometimes with dissociation constants in the low picomolar range, thus equalling the affinities of the most potent BZs. They act on the BZ receptor in a similar way to BZs.

However, not all compounds that bind with high affinity to the BZ receptor exhibit the same pharmacological profile as BZs. Indeed, compounds have been described that do not have any intrinsic activity when injected alone, but they block the pharmacological action of BZs. These compounds have therefore been termed antagonists of which the first to be identified was flumazenil, also called RO 15-1788 (Figure XIX-3.7). Indeed, this drug has antagonistic properties both *in vitro* and *in vivo*; it is able to block the anxiolytic, anticonvulsant, amnesic, myorelaxant and sedative effects of BZs. Flumazenil is used therapeutically to control BZ anesthesia. Furthermore, other pharmacological agents that bind to the BZ receptor, such as ethyl-β-carboline-3-carboxylate (β-CCE), have been described, but they induce a pharmacological profile opposite to the one induced by BZs. Indeed, they produce anxiogenic, proconvulsant and promnesic effects. They have therefore been termed inverse agonists. Not all inverse agonists have the same potency. For example, compounds such as DMCM and β-CCM (Figure XIX-3.7) are convulsant, while others such as β-CCE or FG 7142 cannot trigger seizures *per se*, but will sensitize animals to the convulsant effects of other pharmacological agents (proconvulsant effects): the first category has been termed full inverse agonists while the second is called partial inverse agonists.

In fact, subsequent studies have revealed compounds that span the complete efficacy spectrum from full agonists to full inverse agonists, including partial agonists such as bretazenil. Antagonists are able to block the effects of agonists and also the effects of inverse agonists or of partial agonists. See Table XIX-3.2

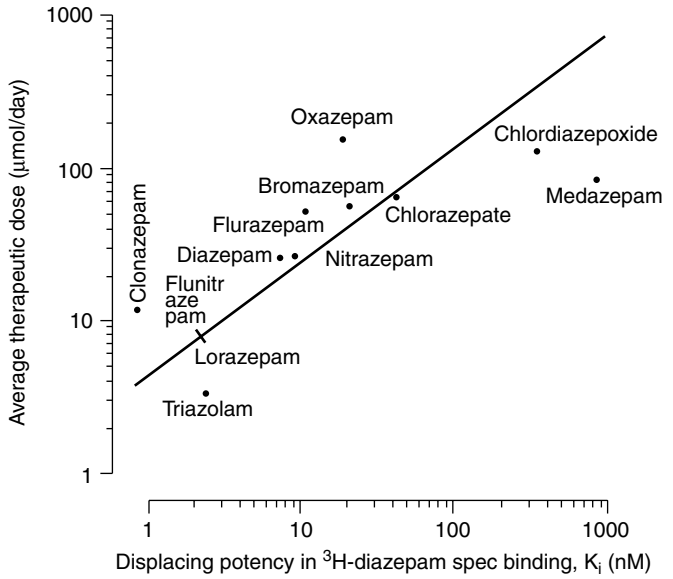

Figure XIX-3.5 Correlation between BZ K_i and mean therapeutical dose recommended. Reproduced by permission from Möhler, H. and Okada, T., 1978. The benzodiazepine receptor in normal and pathological human brain. *British Journal of Psychiatry*, **133**, 261–268

Table XIX-3.2 Properties of the various types of BZ receptor ligands

Different types of ligands	Example of compounds	Pharmacological action
Full agonist	Classical BZ (chlordiazepoxide, diazepam, oxazepam, flunitrazepam, etc.)	Sedative Anxiolytic Anticonvulsant Amnesic Myorelaxant
Partial agonist	Bretazenil	Anxiolytic
Antagonist	Flumazenil	No effect
Partial inverse agonist	β-CCE, FG 7142, RO 15-4513	Anxiogenic Proconvulsant
Inverse agonist	DMCM, β-CCM	Anxiogenic Convulsant Promnesic

A great amount of data exists showing that higher doses of a full agonist are required to produce sedative/myorelaxant effects than to produce anticonvulsant/anxiolytic effects. For example in mice, the dose to induce sedation is twice the minimal effective dose for anxiolytic activity. By combining this approach with *in vivo* binding studies, it is possible to assign a level of receptor occupancy to a given pharmacological effect. This type of analysis demonstrates that for full agonists such as diazepam, between 20 and 40 percent of receptor occupancy is required to produce anxiolytic or anticonvulsant effects. For the same compound, the receptor occupancy must be higher than 60% to elicit sedation or myorelaxant effects (Figure XIX-3.8). This idea has led to the development of partial agonists as anxiolytic agents devoid of sedative side effects. Indeed, partial agonists are not able to activate all the receptors they occupy, so that the dose eliciting sedation may be considerably larger than that inducing anxiolysis (Doble and Martin, 1996).

Endogenous Ligand of BZ Receptors

The presence of BZ receptors has provided some support for the notion that some natural BZ receptor ligands may exist in the central nervous system. Therefore, some research began in the early 1980s that aimed at finding an endogenous ligand for BZ receptors. Such a compound must be present in the organism, bind to the BZ receptors with high affinity and elicit behavioural effects. Diazepam Binding Inhibitor (DBI) is an 86 amino acid peptide that was initially isolated from rat brain on the basis of its ability to displace diazepam from BZ receptors. Splicing of DBI generates several biologically active fragments including the triakontatetraneuropeptide DBI_{17-50} (TTN) and the octadecaneuropeptide DBI_{33-50} (ODN) which are designated by the generic term endozepines. Intracerebroventricular injections of endozepines in rodents elicit anxiogenic effects (Garcia de Mateos-Verchere *et al.*, 1998) and block the anxiolytic action of diazepam. Evidence from *in vitro* and *in vivo* studies indicates that these compounds may act as inverse agonists at the BZ receptor, thus negatively modulating the $GABA_A$ receptor function. Subsequently, it was also observed that endozepines interact with peripheral BZ receptors and stimulate cholesterol transport in the mitochondria, thus participating in the biosynthesis of neurosteroids by brain tissues. It is to be noted here that neurosteroids also modulate the $GABA_A$ receptor function. *In situ* hybridization experiments showed strong DBI mRNA expression in the vicinity of the third ventricle, the hypothalamus and the cerebellum. Long-term isolation in mice, which is a rather stressful procedure in this species, has been shown to induce a decrease in mRNA expression for DBI in the hypothalamus, further suggesting that these peptides may have a biological function related to anxiety and/or stress (Dong *et al.*, 1999).

Interaction with GABA

As mentioned above, BZs potentiate the action of GABA on the $GABA_A$ receptors. Interestingly, the ability of anxiolytic compounds to act on GABAergic neurotransmission is shared by other anti-anxiety agents, such as barbiturates, meprobamate and ethanol. For example, barbiturates such as pentobarbital increase the affinity of $GABA_A$ receptors to GABA and increase the duration of the opening of GABA-activated Cl^- ionophoric channels. Moreover, at high doses, this compound is able to directly open Cl^- channels, even in the absence of GABA. This action is exerted via a specific binding site, termed the barbiturate binding site. As to the mechanism of action of carbamates, recent data suggest that meprobamate may also act at the barbiturate binding site of the $GABA_A$ receptor (Rho, Donevan and Rogawski, 1997). However, the enigma of the mechanism of action of meprobamate is not completely resolved, because meprobamate does not always have the same effects as barbiturates (Haefely *et al.*, 1981). Finally, ethanol is also able to interact with the GABAergic neurotransmission. Indeed, ethanol activates the $GABA_A$ receptor-coupled Cl^- channel, thereby increasing Cl^- conductance and mimicking the action of GABA. Although some effects of ethanol are also mediated via other molecular targets such as the NMDA and the 5-HT_3 receptors, one may suggest that its anxiolytic effects are mediated via $GABA_A$ receptors. Indeed, BZ antagonists such as flumazenil or BZ inverse agonists such as RO 15-4513 are able to block the anxiolytic effects of ethanol in rodents at doses where they do not have any intrinsic activity.

Present knowledge proposes a model in which the $GABA_A$ receptor may in fact be allosterically modulated by compounds binding to at least six different sites (for a review, see Hevers and Lüddens (1998)): the BZ receptors; a binding site for barbiturates; a site for neurosteroids; a site for the convulsant drugs picrotoxine and TBPS; one for flurosemide and one for loreclezole. Binding

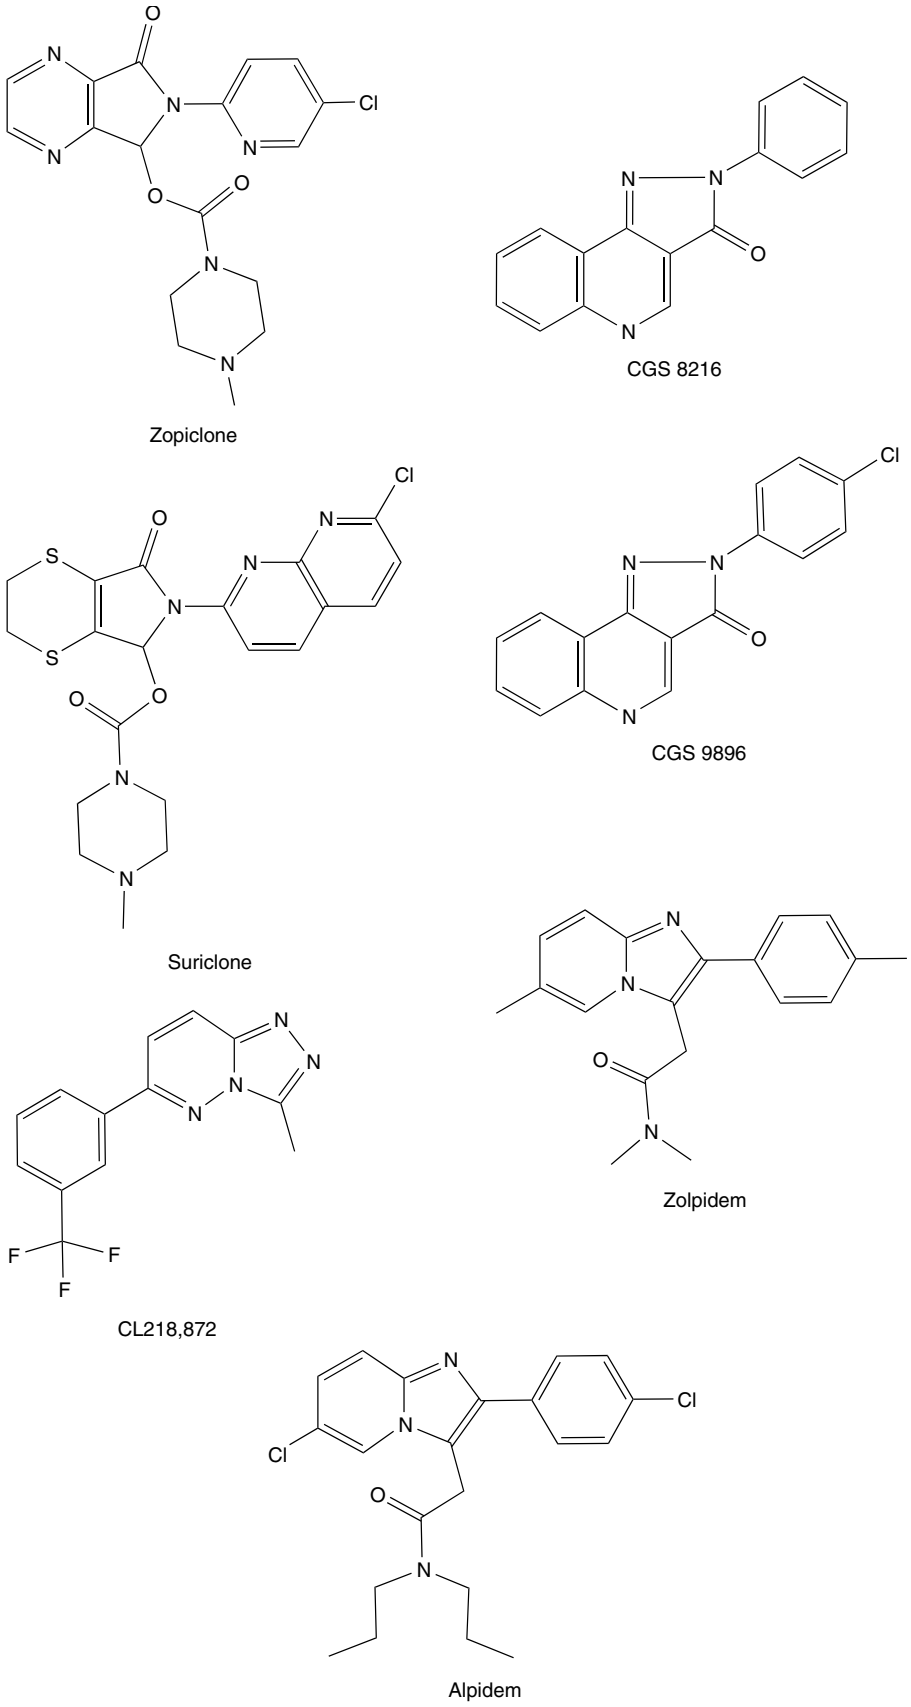

Figure XIX-3.6 Chemical structure of zopiclone, suriclone, CL 218,872, alpidem, zolpidem, CGS 9896 and CGS 8216

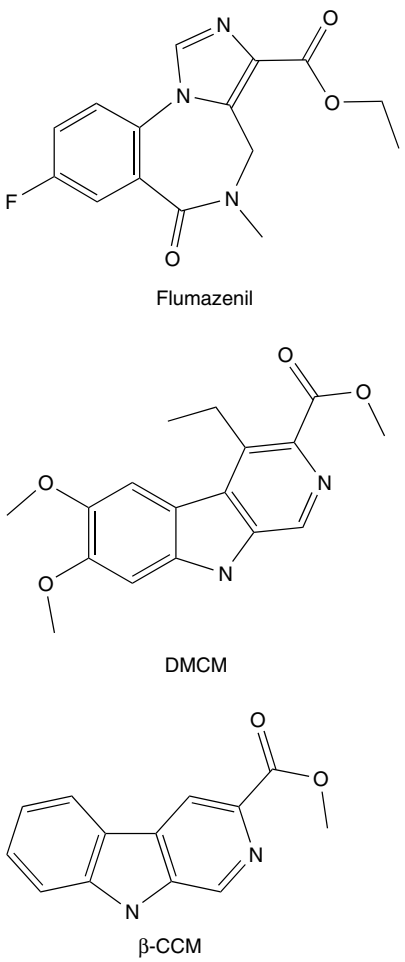

Figure XIX-3.7 Chemical structure of the BZ antagonist flumazenil and of the BZ inverse agonists DMCM and β-CCM

of BZs to the BZ receptors, of barbiturates to the barbiturate binding site, of steroids such as metabolites of progesterone to the neurosteroid site, or of loreclezole to the loreclezole site, are all associated with an anticonvulsant effect underlined by a positive modulation of GABAergic neurotransmission, that is an increase in GABA function. By contrast, binding of picrotoxin to the picrotoxin site induces convulsions, an effect related to the ability of this compound to block GABA-evoked Cl^- conductance. Furosemide, a loop diuretic, inhibits GABA function in some (for example in the cerebellum) but not all neuronal population (for example not in hippocampal neurons) via a mechanism independent of the other allosteric sites.

None of these sites are associated with anxiolytic or anxiogenic effects. As mentioned above, BZs and barbiturates are potent anxiolytics. Antagonists of the picrotoxin site such as etifoxin also induce anxiolysis: this effect is not blocked by flumazenil, thereby indicating that it is not linked to an action at BZ receptors. Some endogenous steroids such as progesterone and its 3α-reduced metabolite produce a dose-dependent anxiolytic response in animal models of anxiety. However, negative modulators of the neurosteroid site, such as pregnenolone sulphate have not been shown to induce the opposite effect in a consistent manner. Finally, some data suggested that loreclezole may induce anxiolytic effects in the rat: these effects are not blocked by flumazenil, suggesting that they are not related to the BZ site. To our knowledge, no data have shown any effect of ligands at the furosemide binding site on anxiety. Moreover, facilitation of GABAergic neurotransmission by the $GABA_A$ receptor agonist THIP or the GABA transaminase inhibitor γ-acetylene GABA (a compound that increases GABA function by inhibiting the degradation enzyme of GABA) does not elicit anxiolytic effects in the rat while drugs that have the opposite action, such as GABA synthesis inhibitors or $GABA_A$ receptor antagonists fail to induce anxiogenic effects (Ågmo *et al.*, 1991).

Molecular Biology of GABAergic Pentamer

The findings mentioned in the precedent chapter can appear contradictory as GABA mimetic drugs are not able to elicit an anxiolytic effect, while the positive modulation of allosteric sites linked to this receptor induce anxiolysis. An explanation of this apparent discrepancy is related to the molecular structure of the $GABA_A$ receptor complex. Indeed, molecular biology has revealed that the GABA receptor is composed of five subunits that co-assemble. Six classes of subunits have been described : $\alpha, \beta, \gamma, \delta, \varepsilon$ and ρ (for a review, see Hevers and Lüddens, 1998). Within each type of subunit, several isoforms are possible: in mammals, these are $\alpha 1-6$, $\beta 1-3$, $\gamma 1-3$, δ, ε and $\rho 1-3$. The $\rho 1-3$ subunits do not seem to co-assemble with α or β subunits within $GABA_A$ receptors and are mainly described in the retina. As to the ε subunit, little information is available because it has only been recently described. The most frequent stochiometric combination

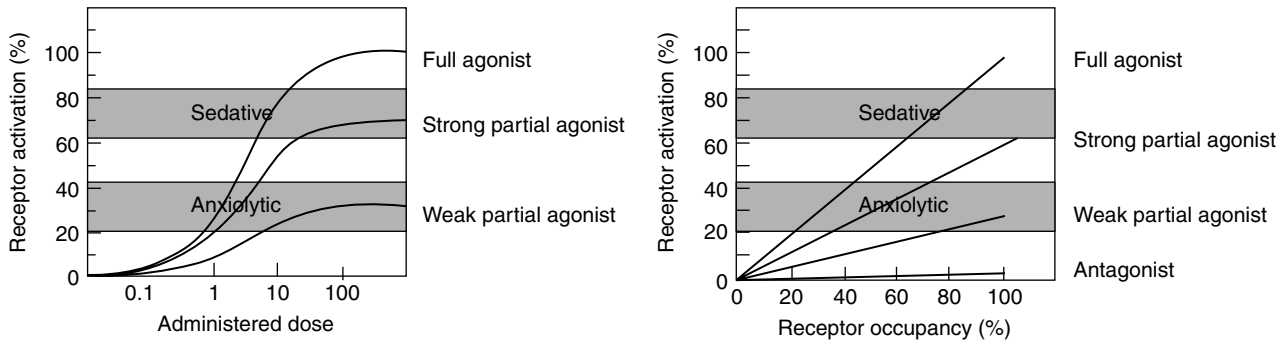

Figure XIX-3.8 Receptor occupancy–activity relationships for full and partial agonists. Left: receptor activation as a function of receptor occupation. Right: receptor activation as a function of dose administered. Reproduced by permission from Doble, A. and Martin, I.L., 1996. The $GABA_A$/Benzodiazepine Receptor as a Target for Psychoactive Drugs. Springer

includes 2 αi, 1 βj and 2 γk as well as 2 αi, 2 βj and 1 γk (with $i = 1–6$, $j = 1–3$ and $k = 1–3$). However, other stoichiometries have been described, such as 3 αi, 1 βj and 1 γk. Thus, the number of possible isoforms of the $GABA_A$ receptor may exceed 100 000. However, not all of the possible isoforms have been described within the central nervous system and approximately 20 isoforms seem to represent the most abundant ones.

Among the $\alpha 1–6$ subunits, the $\alpha 1$ is the most frequent and it has been described in almost all brain areas. It is often co-localized with $\beta 2$ and $\gamma 2$. Clustering is characteristic of GABA-A receptor genes on human chromosomes. In humans, the $\alpha 1$ subunit maps on Chr5q34-q35, in a cluster including the gene for the $\gamma 2$ and the $\alpha 6$ subunit. The human gene for $\alpha 1$ does not appear to have any mutations associated with disease entities. The $\alpha 2$ subunit is mainly localized in the cortex, in limbic areas and in the striatum (where it represents the only α subunit reported). None are found in the cerebellum. It often co-localizes with $\beta 3$ subunits. $\alpha 2$ (with $\alpha 4$ and $\gamma 2$) is expressed at low levels during early development, with a significant increase about one week after birth. However, the biological importance of that is not well understood for the moment. The $\alpha 2$ and the $\beta 1$ subunits map close together Ch4 p13-p12. The human gene for this subunit does not appear to have any mutations associated with anxiety disorders or other diseases. The $\alpha 3$ subunit is mainly localized in the monoaminergic nuclei, particularly on serotoninergic cell bodies in the raphe nuclei, as well as on cholinergic neurons of the basal forebrain. The gene coding for the $\alpha 3$ subunit is located in the central region of chromosome X and has been suggested as a candidate for X-linked manic depression, a psychiatric disease that has some comorbidity with anxiety disorders. The $\alpha 4$ subunit is localized in the hippocampus and the thalamus and the gene encoding for this subunit is located on chromosome 4 in humans. The $\alpha 5$ subunit is located quasi exclusively in the hippocampus and the gene encoding for this subunit is located on human chromosome 15, in the region of the Angelman and Prader–Willi syndromes. In fact, a single paternal allele of this gene is found in cases of Angelman syndrome, and a single maternal allele in cases of Prader–Willi syndrome. However, evidence of abnormal anxiety in these disorders is scarce. Finally, the $\alpha 6$ subunit is located mainly in the cerebellar granule cells and the cochlear nuclei. The gene encoding for this subunit forms a cluster on chromosome 5 with the genes encoding for the $\gamma 2$ and $\alpha 1$ subunits. All these data are summarized in Table XIX-3.3.

Interestingly, the α subunits seem to determine the ability of the BZ receptors to respond to BZ. Indeed, receptors containing $\alpha 4$ or $\alpha 6$ subunits lack the modulation by classical BZs. Classical BZs such as chlordiazepoxide interact indiscriminately with receptors containing $\alpha 1$, $\alpha 2$, $\alpha 3$ or $\alpha 5$ subunits, that are termed benzodiazepine-sensitive. These receptors have a histidine at a conserved position ($\alpha 1$-H101, $\alpha 2$-H101, $\alpha 3$-H126 and $\alpha 5$-H105) while the benzodiazepine insensitive receptors containing $\alpha 4$ or $\alpha 6$ subunit have an arginine in the corresponding position. Therefore, diazepam-sensitive receptors can be rendered insensitive by replacing this histidine by an arginine while the regulation of this receptor by GABA is preserved. Recent data show that replacement of histidine by arginine at the 101 position of the gene encoding for the murine $\alpha 1$ subunit gene has rendered the $\alpha 1$-type $GABA_A$ receptors insensitive to diazepam ($\alpha 1$-knock-in mice). These $\alpha 1$-knock-in mice display no overt change in spontaneous behaviour and bred normally but they failed to show the sedative, amnesic and anticonvulsant action of diazepam. By contrast, the anti-anxiety and myorelaxant properties of the BZ are fully retained (Rudolph *et al.*, 1999). A similar point-mutation technique has been used to render $\alpha 2$ and $\alpha 3$ insensitive to BZs. As for the $\alpha 1$-knock-in mice, no obvious modification of basal behaviour was observed. However, pharmacological challenge with diazepam failed to induce anxiolysis in the $\alpha 2$-knock-in mice (Low *et al.*, 2000). No similar modification could be found with the $\alpha 3$-knock-in mice. These observations point to new strategies for drug design, as one can imagine drugs of the future acting specifically on some α-subunit subtypes, that is on BZ receptors within a particular brain area. For example, drug acting in an agonistic way specifically on $\alpha 2$-type $GABA_A$ may elicit an anxiolysis not accompanied by sedation or amnesic effects (see below).

As to the β subunits, they seem to have little influence on the action of BZ receptor ligands. Indeed, *in vitro* studies showed that the type of β isoform did not modify the ability of diazepam to increase GABA-activated Cl^- currents. In fact, they seem to be involved in brain development as they are all expressed in the developing mouse cerebellum, the $\beta 2$ and $\beta 3$ subunits being present at birth, and displaying spatial correspondence with areas of GABAergic synapses. The $\beta 1$ subunit mRNA does not appear until the second week after birth, and may be associated with Bergmann glia or basket cells.

More data suggest that the γ subunits may be involved in the action of BZ. When compared to the $\gamma 2$ isoform, the $\gamma 3$ isoforms displays a marked decrease in affinity for the BZ antagonist flumazenil or the inverse agonist DMCM while replacement of the $\gamma 2$ isoform with a $\gamma 1$ isoform results in an agonistic affinity of DMCM. By using targeted mutation, $\gamma 2$ knock-out mice have been generated ($\gamma 2$ $-/-$). These mice display severe growth retardation, sensorimotor abnormalities and a reduced life span as survival was never superior to 17 days of postnatal life. They are insensitive to BZs, indicating that this subunit is critical for BZ sensitivity. As no behavioural studies could be undertaken in such young mice, features of anxiety-related disorders have been investigated in $\gamma 2$ $+/-$ mice. These mice exhibited a region-specific reduction of BZ receptors. This decrease was more pronounced in some areas of the hippocampus (reduction of 35% in CA1 and 28% in CA3), in the cingulate cortex (-25%), in the frontal cortex (-23%), in the piriform cortex (-25%) and in the lateral septum (-30%) than in other brain areas such as the striatum (-6%), the globus pallidus (-13%) or the amygdala. These mice exhibited enhanced state and trait anxiety that was reversed by diazepam. Furthermore, they displayed a bias for threat cues, resulting in an increased sensitivity

Table XIX-3.3 The properties of different types of α subunits

Type of α subunit	Ability to bind BZ	CNS localization	Human chromosome	Mouse chromosome	Cluster
$\alpha 1$	Yes	All brain areas	Chr 5q34-q35	Chr 11	$\gamma 2$ and $\alpha 6$
$\alpha 2$	Yes	Cortex, limbic areas, striatum	Chr 4p13-p12	Chr 5	$\beta 1$
$\alpha 3$	Yes	Raphe nuclei Basal forebrain	X q28	Central part of X	No
$\alpha 4$	No	Hippocampus, thalamus	Chr 15 p14-q12	Chr 5	No
$\alpha 5$	Yes	Hippocampus	Chr 15q11–q15	Chr 7	$\beta 3$ and $\gamma 3$
$\alpha 6$	No	Cerebellar granule cells, cochlear nuclei	Chr 5q31.1-q35	Chr 11	$\gamma 2$ and $\alpha 1$

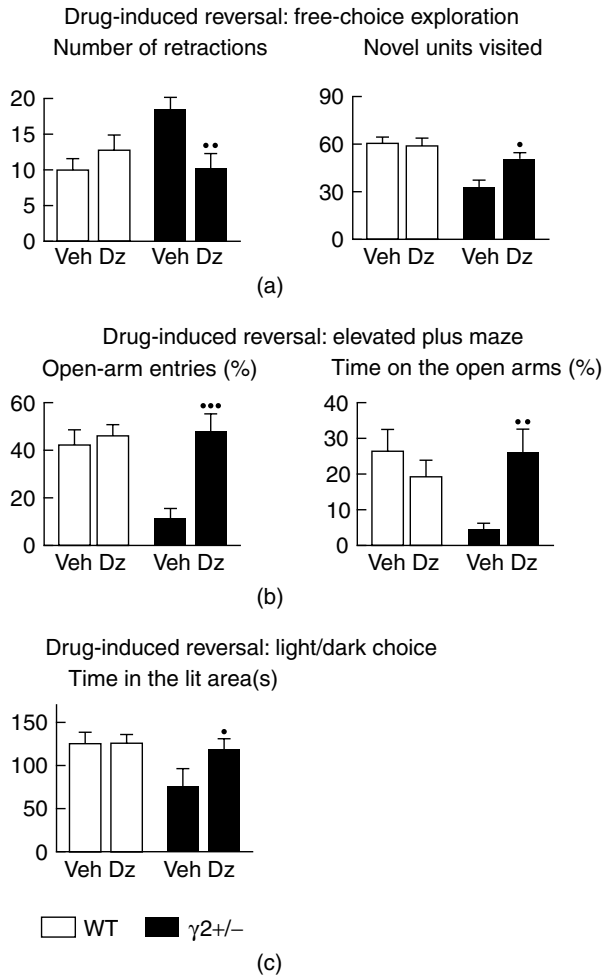

Figure XIX-3.9 Behaviour of wildtype (WT) and $\gamma 2$ +/− mice subjected to three tests of anxiety ((a) the free exploratory test; (b) the elevated plus maze; (c) the light/dark choice test) and treated either with vehicle or diazepam (0.3 mg kg^{-1}, i.p.). Results show that $\gamma 2$ +/− mice display increased anxiety when compared to wildtype mice as they exhibit an increased number of retraction, a decrease in novel units visited, a decrease of entries and time spent on the open arms and a decreased time spent in the lit box. At the dose used, diazepam did not elicit anxiolysis in vehicle-treated WT while it reversed the anxiogenic pattern observed in $\gamma 2$ +/− mice. Reproduced by permission from Crestani, F., Lorez, M., Baer, K., Essrich, C., Benke, D., Laurent, J.P., Belzung, C., Fritschy, J.M., Luscher, B. and Mohler, H., 1999. Decreased $GABA_A$-receptor clustering results in enhanced anxiety and a bias for threat cues. *Nature Neuroscience*, **2**, 833–839

to negative associations (Figure XIX-3.9) (Crestani *et al.*, 1999). Alternate RNA splicing produces two alternative forms of the $\gamma 2$ subunit ($\gamma 2$L and $\gamma 2$S) that are expressed in different brain regions, more $\gamma 2$L being found in the cerebellum, while $\gamma 2$S is in the ascendant in the cerebral cortex. Moreover, $\gamma 2$S is expressed at a more or less constant level throughout brain development, while $\gamma 2$L production increases with maturation. Mice lacking $\gamma 2$L ($\gamma 2$L −/−) display increased sensitivity to BZ agonists associated with a decreased sensitivity to BZ inverse agonists, indicating a possible shift of the BZ receptor from an inverse agonist, leaning towards an agonist preferring configuration (Quinlan, Firestone and Homanics, 2000). However, in that case, one might expect a decrease of anxiety levels in those mice, while the contrary was observed. Surprisingly, $\gamma 2$ over-expression did not elicit any changes in several animal models of anxiety (Wick *et al.*, 2000).

Little information is available concerning the relevance of the δ subunit in the $GABA_A$ receptor in relation to anxiety. A $GABA_A\delta$ null mutant (δ −/−) mouse has been described that did not exhibit any modification of anxiety in animal models. However, the neuroactive steroid ganaxolone was unable to elicit anxiolytic action in the knock-out mice, as it does in wildtype mice suggesting a possible involvement of this subunit in the anti-anxiety-like effect modulators of the neurosteroid site of the $GABA_A$ receptor.

Drugs of the Future Acting at the $GABA_A$ Receptor Subtypes

The search for compounds chemically unrelated to the BZs with more specific therapeutic actions and without their concomitant unwanted effects has led to the development of drugs that selectively bind to a specific $GABA_A$ receptor subtype, display low efficacies at each $GABA_A$ receptor subtype, or combine selective affinity and differential intrinsic activity at these receptors (Griebel, Perrault and Sanger, 2000).

While there are $GABA_A$ receptor ligands claimed in patents or shown to bind selectively for all BZ-sensitive $GABA_A$ receptor subtypes, only compounds selective for the α_1 subtype have been studied extensively. These latter include compounds with greatly varying chemical structures. The most widely studied selective α_1 subtype ligands include the imidazopyridine zolpidem (see Figure XIX-3.6), the β-carboline abecarnil (Figure XIX-3.10) and the pyrazolopyrimidine zaleplon. These compounds are either marketed (zolpidem, zaleplon) or pre-registrated (abecarnil). In animal studies, zolpidem and abecarnil were found to produce sedative activity at much lower doses than those producing ataxia and myorelaxation, and after repeated treatment, did not produce tolerance and physical dependence as was observed with most BZs. However, selective $GABA_A$ α_1 subtype agonists are generally found to display weaker (if any) anxiolytic-like activity in animals than non-selective agents, thereby confirming the findings with α_1 knock-in mice which showed that this subtype is not primarily involved in the anxiolytic effects of $GABA_A$ receptor agonists (Rudolph *et al.*, 1999).

Unlike selective $GABA_A$ α_1 subtype agonists, non-selective $GABA_A$ receptor partial agonists such as bretazenil, imidazenil and Y-23684 (Figure XIX-3.10) were found to display comparable or even greater efficacy in anxiety models than BZs. In addition, they had lower liabilities for sedation and muscle relaxation compared to conventional BZs.

Based on the findings from experiments using mice with point-mutated diazepam-insensitive $GABA_A$ receptor subtypes, that the anxiolytic effects of $GABA_A$ receptor agonists are mediated by the α_2 $GABA_A$ receptor, research for anxioselective compounds acting at the $GABA_A$ receptor subtypes has focused on the development of ligands that display functionally selective agonist activity at the α_2 $GABA_A$ receptor subtype. The recently discovered pyridoindole derivative, SL651498 fulfils this criterion. Although the drug has also high affinities for the α_1 and α_3 subtypes, it displays higher intrinsic efficacy at the α_2 subtype as compared to the other $GABA_A$ receptor subtypes. In animal experiments, SL651498 elicited anxiolytic-like activity qualitatively and quantitatively similar to that of BZs, but unlike these latter, it induced central depressant effects at doses much higher than those producing anxiolytic-like activity. Moreover, in contrast to BZs, SL651498 did not produce tolerance to its anticonvulsant activity or physical dependence, and was much less active than BZs in potentiating the depressant effects of ethanol. The 'anxioselective' profile of SL651498 is in agreement with the idea that $GABA_A$ α_2 subtype plays a major role in regulating anxiety, and suggests that targeting selectively $GABA_A$ receptor subtypes can lead to drugs with increased clinical specificity (Low *et al.*, 2000).

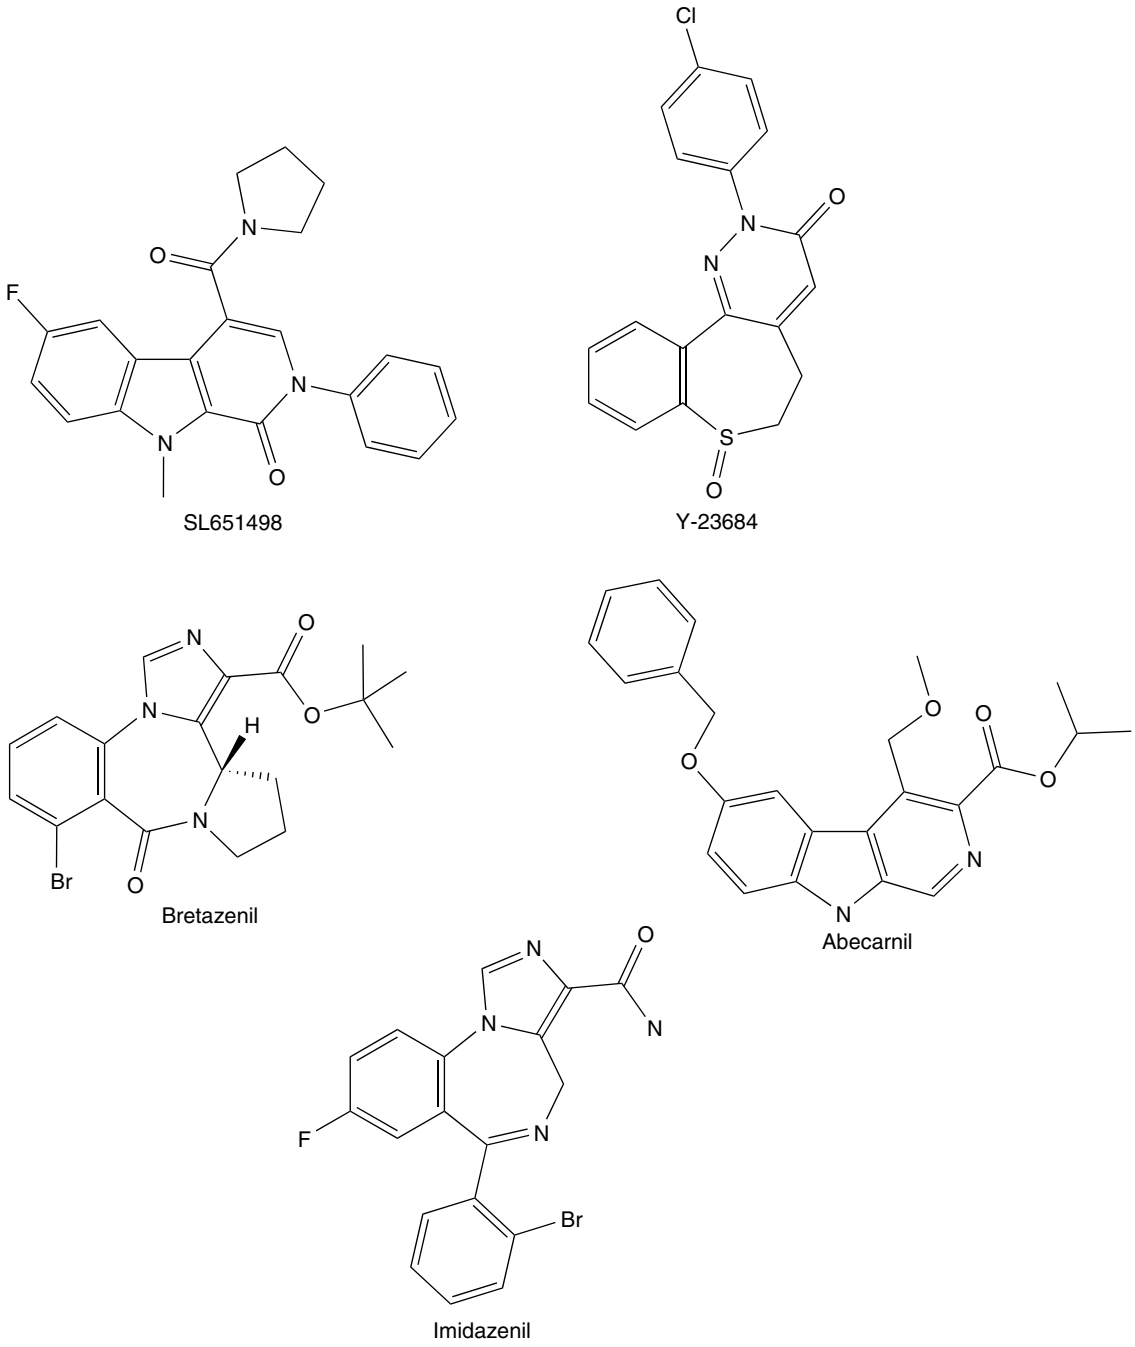

Figure XIX-3.10 Drugs of the future. Chemical structure of the partial agonists bretazenil, imidazenil and Y-23684, of the $\alpha 1$ selective agent abecarnil and of the $\alpha 2$ selective compound SL 651498

AMINO ACID NEUROTRANSMITTER SYSTEM IN ANXIETY DISORDERS

Anxiety Disorders

Anxiety can be considered as an everyday life emotion that ones experiences when subjected to threatening or stressful situations. However, in certain cases anxiety can become excessive, as in anxiety disorders. Anxiety disorders have a lifetime incidence of 16% (Walley, Beebe and Clark, 1994) and it is considered that in any six-month period, 9% of Americans are affected by such an affliction. Anxiety disorders include generalized anxiety disorder (GAD), panic disorder, obsessive–compulsive disorders, phobias and post-traumatic stress disorder (PTSD). In this chapter, we shall not consider dissociative and somatoform disorders as they are studied in further chapters of this book.

Generalized Anxiety Disorder (GAD)

GAD is considered to be a constant state of anxiety, worries occurring for almost any ordinary event. It frequently has other associated disorders accompanied by apprehension, increased tension

and hyperalertness. Even if it is the most common anxiety disorder, (14.80% worldwide incidence), little research has been carried out on investigating the underlying psychobiological features of that affliction. It has been shown that platelet and lymphocyte BZ receptors have low binding in GAD. As for cerebral BZ receptor binding in subjects with GAD, the findings are contradictory. Some have found a decrease (Tiihonen *et al.*, 1997), while others did not see any difference (Abadie *et al.*, 1999).

BZs are largely prescribed in the treatment of GAD (Hoehn-Saric and McLeod, 1991). Patients are generally treated with BZ having long elimination half-life, so that they do not have to take the treatment several times a day to prevent rebound anxiety. The main risk is linked to the ability of BZs to elicit tolerance and to have abuse potential. As patients need long-term medication, there is a high risk to elicit withdrawal symptoms when the treatment is discontinued. It should be noted that these compounds do not only relieve anxiety, but they are also effective in reducing hyperalertness, insomnia, tension and some somatic symptoms. However, one has to keep in mind the fact that some symptoms of GAD, such as tension, somatic modifications or hyperalertness may in fact contribute to the increase in anxiety, as suggested by some emotion theoricians. In that case, neither anxiety nor other symptom of GAD can be suppressed by compounds that are not acting on the somato-visceral perception.

Panic Disorder and Conditioned Fears

Though the delineation of panic disorder as a specific category had heuristic value, it has also left other fruitful conceptions in the dark (Marks, 1987), which are now implicitly coming back when categorizing panic disorder as a fear-conditioned disorder (Gorman *et al.*, 2000). Indeed, in order to understand the onset of panic disorder (characterized by episodic paroxystic anxiety states, phobic fears, and several autonomic- and endocrine-related symptoms) beside heritable aetiological factors, environmental disruption is needed. Several studies have shown an association between disruptions of early attachment to parents and the development of panic disorder (Tweed *et al.*, 1989; Stein *et al.*, 1996).

When the term 'panic attacks' was introduced in the DSM-III in 1980, the prevalent view was that the anxiety disorder characterized by severe spontaneous panic attacks was mainly alleviated by tricyclic antidepressants, while the anxiety disorder corresponding to the absence of such acute crisis (GAD) was treated by BZs. This was the rationale for splitting anxiety neurosis in two different anxiety disorders in the DSM-III. This historical background led to the prejudice that BZs may be ineffective in panic attacks. This view was reinforced by the observation that imipramine was more effective than chlordiazepoxide in panic attacks (McNair and Kahn, 1981). However, the dose of chlordiazepoxide used in that study was rather low. More recently, the contribution of amino acids in panic disorders has been evoked by the demonstration of the efficacy of higher doses of BZs in blocking panic attacks. The prototypical BZs used in the treatment of panic are alprazolam and clonazepam, even if other BZs are also effective agents. Clonazepam has a longer half-life than alprazolam, which allows a decrease in the number of daily administrations and thus avoids interdose rebound anxiety. However, many clinicians continued to claim that BZs had weak antipanic efficacy when compared with antidepressants. This prompted some researchers to compare the potency of alprazolam with imipramine and placebo in a double-bind study (Sheehan and Raj, 1990). Results showed that alprazolam was as effective as imipramine (except for the depressive symptoms that are often co-morbid with panic disorder, which were only treated by imipramine), both compounds being superior to placebo. Alprazolam was also effective in attenuating lactate-induced panic attacks. The common problem is related to the abuse potential observed with BZs. Therefore, these compounds are often prescribed for their short-term effects and then dosage is rapidly tapered and antidepressant treatment initiated. BZ are not the sole treatment of panic attack involving increase in GABA function. Indeed, when patients do not respond to BZ or to antidepressants, a medication with valproic acid can be prescribed. Valproic acid increases GABA function by stimulating the activity of glutamic acid decarboxylase, the enzyme responsible for GABA synthesis, and by inhibiting GABA degradation enzymes such as GABA transaminase. Three studies show that valproic acid was superior to placebo on various components of panic attacks and was able to block lactate-induced panic attacks.

Moreover, psychobiological data have also revealed some abnormalities in GABA neurotransmission in patients with panic disorder, suggesting that pharmacological treatments with BZs or valproic acid may in fact act on these abnormalities. For example, patients with panic disorder have been shown less sensitive to BZs on several psychophysiological measures (Roy-Byrne *et al.*, 1996). Furthermore, pre-clinical findings suggested that a decrease of GABA transmission in a network centred in the amygdala — and involving hippocampus and prefrontal cortex — with projections to midbrain central grey and hypothalamus, leads to paroxystic anxiety responses (LeDoux *et al.*, 1988; Davis, 1992). Finally, intravenous lactate, which induces panic attacks, produces a decrease in circulating plasma GABA levels.

However, most studies of binding at the BZ-$GABA_A$ receptor are contradictory. Indeed, some findings suggest global reduction of binding (Malizia *et al.*, 1998); other findings affirm only local or state-related panic anxiety reduction (Bremner *et al.*, 2000); and further studies found no peculiarity or increase in BZ receptor density in association with up-regulation hypotheses (Brandt *et al.*, 1998; Abadie *et al.*, 1999). The idea that in this disorder the subject has difficulty in protecting himself in a state of stress could bring forward new hypotheses (Kellner and Yehuda, 1999; Strohle *et al.*, 1999).

Obsessive Compulsive Disorder (OCD)

OCD is characterized by repetitive thoughts or behaviour that are felt by the subject and are difficult to prevent. Most of the time the behaviour or thoughts are absurd, and consume so much time that they alter social functioning of the subject.

The psychobiological approach accumulates arguments — including those from lesional models (Laplane *et al.*, 1989) — for abnormalities associated with obsessive and compulsive manifestations in frontocortico-striatal-thalamic networks. Indeed, a hyperactivity of this axis has been shown within orbito-frontal and anterior cingulate cortex, as well as caudate nucleus and thalamus, and a decrease of N-Acetyl-Aspartate (NAA), a putative marker of neuron viability, within striatal areas — which could be sites of primary pathology — and thalamus, a site of integration and relay, especially involved in compulsions (Fitzgerald *et al.*, 2000).

Functional neuroimaging studies in OCD patients during symptom provocation suggests increased glutamatergic activity. Current psychobiological research on OCD puts forward that *basal ganglia* dysfunctions could contribute to the aetiology of the symptoms. Indeed, it has been suggested through functional imaging techniques on subjects with OCD, before and after treatment by Selective Serotonin Reuptake Inhibitors (SSRIs), (substances known for their positive effect on OCD symptomatology) that *caudate nucleus* seems primarily involved in the medication's efficacy on OCD (Baxter, Schwartz and Bergmam, 1992). The interrelations of amino acids such as *γ-aminobutyric acid* (GABA) or *glutamate* with serotonin (5-HT) pathways could be enlightened by some findings. First, the 5-HT_{2a} stimulation on GABA neurons opposes the glutamate action on the striatum, an area known for being rich in neurons

with serotonin synthesis (Chugani *et al.*, 1998). Second, the prefrontal cortex highly innervates the caudate nucleus (Modell *et al.*, 1989) by glutamatergic projections. Third, glutamate can decrease the release of 5-HT in the caudate nucleus in humans (Becquet, Faudon and Hery, 1990) and be at the same time affected in its action by serotonin neurons (Edwards *et al.*, 1996).

As BZs are effective in the treatment of anxiety, their efficacy in OCD has also been evaluated. In fact, BZs are devoid of anti-obsessive–compulsive effect *per se* but they can alleviate the high anxiety or insomnia that are in some case associated with OCD. In this way they can be considered as a symptomatic treatment of OCD. They can also provide a short-term relief for the distress of the patients, before the anti-obsessive–compulsive effects of serotonin reuptake inhibitors can be observed, or before a cognitive therapy can be undertaken. It should be noted that this observation is not true for all BZs. In fact, there is an exception as the BZ clonazepam has been shown significantly more effective as a monotherapy than some antidepressant after 3-week treatment (Hewlett, Vinogradov and Agras, 1992). A proposed explanation as to the superiority of clonazepam over other BZs in the treatment of OCD is related to the fact that this drug may have specific effects on the serotoninergic system.

Post-Traumatic Stress Disorder

Post-traumatic stress disorder (PTSD) is a condition specified by repetition in thoughts, nightmares, physical and mental re-experiencing of the traumatic experience. It is associated with a negative semiology, such as numbing or amnesia, related to the dissociative field. Preclinical data put forward that stress induces cortico-limbic release of glutamate. Clinical observations suggest that N-methyl-D-aspartate antagonists may also induce glutamate release while provoking dissociative-like symptoms. Some authors then hypothesized that hyperglutamatergic states could contribute to acute and chronic consequences of trauma (Chambers *et al.*, 1999).

Among the psychobiological alterations observed in PTSD, the neuroendocrinological peculiarities in the hypothalamic-pituitary-adrenal axis, including cortisol decrease and reactivity alterations are documented the most. Specificities of GABA function have been studied in subjects with PTSD. The failure of the benzodiazepine antagonist flumanezil to produce flashbacks in PTSD suggest a weak role of attention deficit in the chronic disorder. The background of this topic includes the fact that $GABA_A$ receptors inhibit meso-prefrontal dopamine neurons, that BZs and neurosteroids enhance $GABA_A$ inhibition, that altered BZ receptors or a diminution of an endogenous ligand may decrease GABA inhibition and lead to excessive anxiety, and that PTSD may deplete an endogenous ligand and produce receptor alteration.

Morris and his colleagues (Morris *et al.*, 2000) presented an interesting positron emission tomography (PET) study to estimate the binding potential (BP) of $GABA_A$ benzodiazepine receptors *in vivo* using the BZ receptor antagonist radioligand C^{11}-flumanezil, comparing 13 subjects with PTSD and 13 without disorder. B_{max} was the same for subjects both with and without PTSD; K_d was lower in PTSD cases, and the B_p constant of the BZ receptor was higher in PTSD cases, especially in cerebellar, latero-temporal, occipital and prefrontal areas.

BZ medication in PTSD is still controversial. A study has shown that alprazolam induces a slight improvement in anxiety on the Hamilton scale in PTSD patients but there is no superiority of alprazolam over placebo on the PTSD scale. Moreover, alprazolam and clonazepam have positive effects on hyperarousal, as does valproic acid. The GABA transaminase vigabatrin has also been shown to ameliorate the exaggerated startle response that is found in PTSD. These observations suggest that increasing the GABA function may be a treatment of some symptoms of PTSD such as anxiety, increased startle or hypervigilance, rather than a treatment of PTSD *per se*. Furthermore, PTSD is co-morbid with other anxiety disorders such as GAD so that BZ may in fact alleviate some symptoms related to GAD, rather than treat PTSD.

Phobias

The main characteristic of phobias is marked and persistent fear of some specific situations (for example enclosed spaces) or objects/animals (small animals such as mice). Here we may emphasize on a particular type of phobia — social phobia — which is characterized by fear of social situations in which embarrassment may occur, as some arguments suggesting an involvement of the GABAergic system have been proposed. Indeed, compounds potentiating the action of GABA such as benzodiazepines and conventional anticonvulsants have been evaluated as treatments for social phobia. Among the benzodiazepines, clonazepam is the best studied, and showed efficacy in several studies. Among the anticonvulsants, gabapentin and pregabalin, which are analogues of GABA, have been shown to be more effective than placebo in double-blind studies. Furthermore, subjects with social phobia showed abnormalities in peripheral benzodiazepine receptors, which suggests that these receptors may play a role in the pathophysiology of this disorder.

BZ and Anxiety Disorders

With the exception of GAD and, to a lesser extent panic attack, it is noteworthy that BZs or drugs that increase GABA transmission may alleviate some symptoms associated with anxiety disorders (including anxiety, insomnia, tension, startle), rather than treat anxiety disorders *per se*. In these disorders, anxiety is often a symptom subsequent to a core semiology resulting mainly from cognitive activations, for instance 're-experiencing' in PTSD or 'obsession' in OCD, rather than a primary autonomic dysregulation and first rank therapeutic target. This is the reason why the ICD-10 classification of the World Health Organization (WHO) preferred to call the chapter from the DSM-IV 'Somatoform, stress-related and neurotic disorders' rather than 'Anxiety disorders'.

Peptidergic Transmitter System and Anxiety Disorders

Michel Bourin, Martine Hascoët, Denis David and Bríd Áine Nic Dhonnchadha

INTRODUCTION

Since their introduction in the beginning of the 1960s benzodiazepines (BZD) have been mainly used in treating anxiety disorders. With the exception of general anxiety disorder (GAD) the identity of the specific anxiety disorder for which each drug is most effective has been hindered by early clinical trials and psychiatric classification. Few proficient drugs have been launched since, the exception being buspirone a 5-HT_{1A} partial agonist. The recent utilization of 5-HT reuptake inhibitors is mainly in the field of panic disorder, social phobia, post-traumatic stress disorder and possibly GAD. Nevertheless, the treatment of anxiety disorders remains a very active field of research and there are some promising results in animal research with neuroactive peptides in the modulation of anxiety behaviours. This section reviews the literature on the potential effects of cholecystokinin (CCK), corticotrophin-releasing factor (CRF), neuropeptide Y (NPY), substance P (SP) and neurokinin (NK) and natriuretic peptides (NP) in anxiety disorders in various animal and human models.

CHOLECYSTOKININ AND ANXIETY

Cholecystokinin (CCK) is synthesized *de novo* in the brain (Goltermann, Rehfeld and Roigaard-Petersen, 1980). CCK has been shown to induce excitation of central neurons. However, inhibitory postsynaptic effects have been also recorded (Dodd and Kelly, 1981; Mac Vicar, Kerrin and Davison, 1987). CCK receptors have now been classified as CCK1 and CCK2 independent of their localization replacing CCK-A and CCK-B. CCK receptors are widely distributed throughout the CNS, with high densities in the striatum and nucleus accumbens (Hill *et al.*, 1987).

Animal Models

Evidence suggests that CCK is implicated in the regulation of anxiety. The peripheral administration of CCK agonists induces anxiety in various animal species, including mouse, rat, cat and monkey (Bourin *et al.*, 1996; Shlik, Vasar and Bradwejn, 1997). This effect is apparently mediated via CCK-2 receptors (previously named CCK-B) since the selective CCK-2 receptor agonists (CCK-4 and pentagastrin) are effective. Moreover, the anxiogenic action of CCK agonists is reversed by preferential CCK-2 receptor antagonists (L-365,260, Cl-988). It should be noted that CCK is active in ethological, but not in conditioned, models of anxiety. However, several studies were unable to reveal the anxiogenic action of CCK agonists in ethological models either. The anxiolytic action of CCK-2 receptor antagonists is even more doubtful since recent studies did not establish any significant action when CCK-2 receptor antagonists were given as single treatments (Dawson *et al.*, 1995).

Some evidence exists that CCK-induced anxiety may be dependent on the level of pre-experimental stress in animals (Koks *et al.*, in press). Therefore, an attempt was made to reveal the significance of pre-experimental stress on CCK-induced anxiety in the elevated plus-maze. Male Wistar rats were divided into four different groups. Two groups of rats were handled in the experimental room for three consecutive days before the experiment. The other two groups of animals were brought to the experimental room immediately before the beginning of the experiment. The handled and non-handled rats were divided into two groups after the injection of caerulein ($5\,\mu g\,kg^{-1}$), a CCK receptor agonist. Half of the animals were isolated after the injection, whereas the other half were returned to their home cage. The anxiogenic action of caerulein was strongest in the rats brought to the experimental room immediately before the plus-maze exposure and kept isolated after the injection of CCK agonist. By contrast, caerulein did not cause any anxiety in the handling habituated and non-isolated rats. Accordingly, the anxiogenic action of caerulein was dependent on the level of pre-experimental stress in rats. The anxiogenic action of caerulein in the stressed rats was dose-dependently reversed by L-365,260 ($1-100\,mg\,kg^{-1}$), a CCK-B receptor antagonist.

In another study the behavioural and neurochemical effects of long-term treatment with L-365,260, a CCK-B receptor antagonist, were investigated. L-365,260 ($100\,mg\,kg^{-1}$) was administered twice daily for 14 days. The repeated treatment with L-365,260 did not change locomotor activity, but it did reduce the exploratory behaviour of rats in the elevated plus-maze test (Koks *et al.*, in press). The neurochemical studies performed demonstrated that L-365,260 induced a sufficient blockade of CCK-B receptors in the brain. Namely, the density of CCK receptors was increased in the frontal cortex and the serum levels of thyrotrophin were reduced due to the repeated administration of L-365,260. Collectively, it is unlikely that CCK is directly involved in the neural networks mediating anxiety. The anxiogenic effect of CCK is rather mediated via other neurotransmitter systems like CRF, GABA, 5-hydroxytryptamine, noradrenaline and nitric oxide.

Human Studies

The starting point for human studies was in 1984 with the electrophysiological experiment of Bradwejn and de Montigny (1984), which demonstrated that benzodiazepine receptor agonists selectively and specifically antagonized sulphated CCK-8-induced excitation of hippocampal pyramidal neurons in rats. These studies provided evidence that anxiolytic benzodiazepines could antagonize the central action of a neuropeptide and it was proposed that benzodiazepine-mediated antagonism of CCK-induced excitation might be an important mechanism by which benzodiazepines exert

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

their clinically relevant action. More importantly, the observation that an anxiolytic drug could block the excitatory action of CCK raised questions about whether CCK might be an endogenous anxiogenic compound.

De Montigny first reported that exogenous CCK-4 produced panic-like attacks in healthy volunteers and that these effects could be attenuated by pretreatment with lorazepam (de Montigny, 1989). Bradwejn and co-workers (1990) administered CCK-4 to patients with a current-point diagnosis of panic disorder using a double-blind placebo-controlled methodology. Bolus injections of CCK-4 (50 mg) precipitated a panic attack, as defined by DSM-III criteria and patient self-report, within one minute following administration in 11 trial patients studied, whereas none of the patients panicked following placebo. CCK-4 treatment elicited an average of 12 symptoms per patient, the most common symptoms being dyspnoea, palpitations/rapid heart, chest pain/discomfort, faintness, dizziness, paresthesia, hot flushes/cold chills, nausea/abdominal distress, anxiety/fear/apprehension and fear of losing control. It has been found that response to CCK-4 reliably differentiates panic disorder patients from healthy controls with no personal or family history of panic attacks. In a double-blind placebo control study, the patients with panic disorder experienced a greater number of symptoms and more intense symptoms following challenge with two doses of CCK-4 (25 and 50 mg) (Bradwejn, Koszycki and Shriqui, 1991). In addition, the incidence of panic attacks was markedly higher in patients than controls following injection of 25 mg (91% vs 17%) and 50 mg (100% vs 47%) of the peptide. Interestingly, the number and intensity of symptoms as well as the symptom profile were remarkably similar in both patients and normal subjects who panicked with the 50 mg dose of CCK-4, suggesting that the enhanced response in patients could not be readily attributed to a tendency to overendorse symptoms. These results are corroborated by studies of Abelson and colleagues (1991) and by van Megen and colleagues (1994) who used pentagastrin, a CCK agonist which incorporates the identical 4-amino acid sequence of CCK-4. Moreover, patients with panic disorder have been shown to have decreased concentrations of CCK-8s in the cerebrospinal fluid relative to control subjects (Lydiard *et al.*, 1992). Concentrations of CCK-8 in lymphocytes were also significantly reduced in patients with panic disorder compared to healthy controls (Brambilla *et al.*, 1993). These findings are also in favour of anomalies in the CCK system due to panic disorder. It is also likely that systemic administration of CCK-4 produces prominent respiratory and cardiovascular alterations in humans through a direct action on the brainstem (Bradwejn *et al.*, 1994).

Antipanic drugs and not other compounds, block the effect of CCK-4 (Bradwejn, 1995). Recently, it was demonstrated that the panic-induced effects of CCK-4 can be antagonized by chronic treatment with imipramine (Bradwejn and Koszycki, 1994). In one study, the pretreatment of patients with the selective CCK-B receptor antagonist L-365,260 dose-dependently blocked CCK-4-induced panic attacks (Bradwejn *et al.*, 1994). In a different study, the action of another CCK-B receptor antagonist Cl-988 was evaluated. There was a significant decrease in sum intensity scores and panic attack frequency following Cl-988 treatment (Bradwejn, 1995). These data apparently support the role of CCK-B receptors in the mediation of panicogenic-like action of CCK-4. Nevertheless, a placebo-controlled trial of L-365,260 did not result in any clinically significant improvement in patients with panic disorder (Kramer *et al.*, 1995). The possible reasons for lack of effect with L-365,260 are not clear, but the poor pharmacokinetic properties of the drug is the most plausible explanation.

A comparison of the neuronal responses to cholecystokinin tetrapeptide between younger and older patients was examined by Flint and colleagues (2000). In both age groups, maximum increase in prolactin Adrenocorticotrophic hormone ACTH and cortisol was significantly greater with CCK-4 than with placebo. Following administration of CCK-4, younger and older groups did not significantly differ in maximum increase in prolactin, ACTH or cortisol; older subjects had a statistically significant smaller increase in Growth Hormone GH compared with younger subjects but the magnitude of the difference was small and of doubtful clinical relevance. Older subjects who had a panic attack had significantly greater elevations of all hormones compared with those who did not panic, and younger panickers had a significantly greater elevation of GH compared with young non-panickers. For the most part, maximum changes in hormonal levels were not correlated with symptom severity, suggesting that other factors may have contributed to the differential effect of panic on the hypothalamic-pituitary-adrenal (HPA) axis.

More recently, the role of the HPA system in panic disorder was investigated (Ströhle, Holsboer and Rupprecht, 2000). Twenty-four patients with panic disorder were given injections of CCK-4 (25 μg). Panic attacks, psychological changes as well as ACTH and cortisol secretion were recorded. Fifteen of the 24 patients experienced a panic attack after CCK-4. ACTH secretion was significantly higher in the patients with CCK-4-induced panic attacks than in those without such attacks. The patients without CCK-4-induced attacks had a brief but less pronounced increase in ACTH concentrations. Cortisol concentrations were not significantly increased after CCK-4 administration. The increased ACTH concentrations suggest that the activation of the HPA system in CCK-4-induced panic attacks plays a physiological role. Corticotrophin-releasing factor (CRF) may be involved in experimentally and perhaps, naturally occurring panic attacks as well (see section on CRF). Several studies have found that the incidence and prevalence of panic disorder decline in later life (Flint, Cook and Rabins, 1996). The reason for this decline is unknown, but it has been hypothesized that age-related changes in brain neurotransmitter function may contribute.

CORTICOTROPHIN-RELEASING FACTOR AND ANXIETY

Corticotrophin-releasing factor (CRF) is a neuropeptide that plays a prominent role in the endocrine, autonomic, behavioural and immune responses to stress, through its action on the major physiological regulator of the HPA axis (Arborelius *et al.*, 2000). In response to stress, CRF released from the paraventricular nucleus (PVN) of the hypothalamus activates CRF receptors on anterior pituitary corticoreceptors, resulting in release of ACTH into the bloodstream. CRF induces various behavioural changes related to adaptation to stress, including food intake suppression, increase in locomotor activity and grooming in familiar environments, induction of aggression and enhancement of arousal.

CRF is widely distributed in the brain, with highest concentrations found in the hypothalamus. Moderate and low levels of CRF are also found in cortical and limbic structures. The amygdala is densely innervated by CRF neurons, which exert excitatory influences on various fear-circuit brain nuclei, including the locus coerulus (Coplan and Lydiard, 1998; Le Doux, 1998).

The effects of CRF are mediated by two specific G-protein receptors called CRF_1 and CRF_2. Tissue distribution analysis showed that CRF_1 receptor expression is most abundant in neocortical, cerebellar and limbic structures, whereas CRF_2 receptor expression is generally localized in subcortical structures, notably in the later septum and various hypothalamic areas (Chalmers, Lovenberg and De Souza, 1995). The CRF_1 receptor displays a high affinity for CRF, while the CRF_2 receptor shows a lower affinity (Grigoriadis, Lovenberg and De Souza, 1996; Radulovic *et al.*, 1999). This anatomical information provides a basis for functional hypotheses related to CRF receptor subtypes, suggesting that CRF may contribute significantly both to behavioural responses to stress and to emotional behaviour itself.

Animal Models

The hypothesis that CRF plays a role in the pathophysiology of anxiety disorders derives mainly from preclinical findings (Arborelius *et al.*, 1999). There are several studies supporting the hypothesis that hypersecretion of CRF is a crucial factor in anxiety disorders (Nemeroff *et al.*, 1984). A number of researchers showed that when CRF was injected into the brain of rats, it produced many of the signs and symptoms seen in patients with anxiety disorders (Arborelius *et al.*, 1999; Koob and Heinrichs, 1999).

A vast literature indicates that intracerebroventricular (i.c.v.) administration of CRF, which presumably increases the concentrations of CRF in the central nervous system, produces physiological and behavioural alterations virtually identical to those obtained in laboratory animals in response to stress, including changes in heart rate and mean arterial pressure, changes in gastrointestinal function, suppression of exploratory behaviour, induction of grooming, reduction of feeding and food intake and disruption of reproductive behaviour. Further actions of centrally administered CRF include the potentiation of acoustic startle responses, the facilitation of fear conditioning and the enhancement of shock-induced freezing and fighting behaviour. These actions of CRF are indicated not to involve the activation of the pituitary-adrenal axis but are mediated by CRF receptors present in the CNS (Griebel, 1999). Micro-injected of CRF directly into the locus coerulus of rats has been found to produce defensive withdrawal responses from a novel environment (Butler *et al.*, 1990) and to reduce drinking behaviour in a brightly illuminated area (Weiss *et al.*, 1994). Similarly, intra-amygdala infusion of CRF has been reported to produce anxiogenic-like behaviour in the open-field test and increase grooming in rats (Liang and Lee, 1988; Lee and Tsai, 1989; Elkabir *et al.*, 1990).

Several peptide and non-peptide CRF receptor antagonists have been studied extensively in experimental models of anxiety. Treatment with antagonists that selectively block CRF_1 receptor action was shown to promote anxiolytic responses in the elevated plus-maze, the light–dark box, the mouse defense test battery and the fear-potentiated startle test (Lundkvist *et al.*, 1996; Schulz *et al.*, 1996; Griebel, Perralut and Sanger, 1998; Okuyama *et al.*, 1999). Alpha-helical CRF, a non-specific CRF receptor antagonist, reduced anxiety-like behaviour in the elevated plus-maze whereas astressin, an antagonist with a higher *in vitro* potency, did not (Brauns *et al.*, 2001). Administration of CP-154,526, a specific CRF_1 receptor antagonist, to rats blocked both the acquisition and expression of conditioned fear, thus suggesting that the CRF_1 receptor might be related to anxiety (Hikichi *et al.*, 2000). The acute administration of CP-154,526, or its analogue antalarmin was demonstrated as blocking CRF- and stress-induced elevations in plasma adrenocorticotrophin and to possess anxiolytic activity in the elevated plus-maze (Lundkvist *et al.*, 1996; Deak *et al.*, 1999), in the light/dark test and the mouse defensive test battery, but not in conflict tests (Griebel, Perralut and Sanger, 1998). After 9 to 10 days of chronic treatment with CP-154,526 ($3.2\,mg\,kg^{-1}$), defensive withdrawal behaviour was also significantly decreased, indicating anxiolytic activity (Arborelius *et al.*, 2000). CP-154,526 was also shown to reduce separation-induced vocalization in rat pups (Kehne *et al.*, 2000).

Antagonism of CRF_2 receptors produces a consistent anxiolytic-like behavioural profile in a number of different animal models. Antisauvagine-30 (anti-SVG-30), a high affinity CRF_2 peptide antagonist was found to produce a dose dependant reduction in the duration of conditioned freezing, increase the level of open-arm exploration and increase the time spent in an open field in rats (Takahashi *et al.*, 2001).

It has been demonstrated that central administration of CRF increases anxiety-like behaviour in rodents and that transgenic mice that overexpress CRF exhibit anxiogenic behaviour. Two recent studies using CRF transgenic mouse lines overexpressing CRF further emphasized the anxiogenic properties of CRF, since these mice exhibited a behavioural state resembling that produced by anxiety (Stenzel-Poore *et al.*, 1996; Koob and Gold, 1997). Studies using CRF_1 receptor knockout mice have revealed that the anxiogenic effects of CRF appears to be mediated by the CRF_1 receptor subtype (Heinrichs *et al.*, 1997; Smith *et al.*, 1998; Timpli *et al.*, 1998). CRF_1 knockout mice show increased anxiolytic-like activity in the elevated plus-maze and a tendency to enter the illuminated region of a light–dark box (Smith *et al.*, 1998; Timpli *et al.*, 1998). Varying results have been observed with CRF_2 knockout mice. Using open-field exploration as a measure, one study reported that CRF_2 knockout mice showed increased centre activity (Kishimoto *et al.*, 2000), another found a decrease in centre scores (Bale *et al.*, 2000) and a third study found no effects of CRF_2 knockout on anxiety behaviour (Coste *et al.*, 2000). In another model of anxiety a decrease in open-arm exploration, suggesting an increase in anxiety was reported (Bale *et al.*, 2000; Kishimoto *et al.*, 2000).

There is considerable evidence that CRF is involved in the anxiogenic and aversive effects of withdrawal from abuse drugs such as cocaine (Basso *et al.*, 1999). Since CRF is suggested to play a critical role in the development of stress and because anxiety is recognized as an important result of cessation of chronic drug administration, it is possible to postulate that brain CRF modulates the neurobiological mechanisms that underlie the anxiety and stress associated with drug withdrawal (Lu, Liu and Ceng, 2001). Lu and colleagues (2001) have suggested that the CRF_1 receptor, but not type 2, mediated the stress-induced reactivation of cocaine-conditioned place preference, as only the CRF_1 antagonist CP-154,526 but not the CRF_2 antagonist, AS-30 was capable of the reactivation.

Suggestions of an inverse relationship between the CRF_1 and CRF_2 receptor systems have been reported using an anxiety model based on adverse early-life experience (Skelton *et al.*, 2000). Thus CRF neuronal systems may be comprised of two separate, but interrelated, subdivisions that can be coordinately and inversely regulated by stress, anxiety or anxiolytic drugs.

Human Studies

Although there is no direct evidence that CRF or CRF receptor ligands may modulate anxiety in humans, clinical data suggesting a role for CRF in anxiety disorders have been accumulating over recent years. Clinical studies have not revealed any consistent changes in cerebrospinal fluid (CSF) CRF concentrations in patients with anxiety disorders; however preclinical findings strongly implicate a role for CRF in the pathophysiology of certain anxiety disorders (Arborelius *et al.*, 1999). CSF levels of CRF have been shown to be elevated in patients suffering from obsessive compulsive disorder (Altemus *et al.*, 1994), post-traumatic stress (Stout, Kilts and Nemeroff, 1995; Holsboer, 1999) but not panic disorder (Jolkkonen *et al.*, 1993). Fossey *et al.* (1996) examined the CSF concentrations of CRF in a group of patients with anxiety disorders and found no difference between four diagnostic categories: panic disorder, generalized anxiety disorder, obsessive compulsive disorder and normal comparison subjects.

The findings that CRF stimulation increases anxiety-related behaviours in a variety of animal models suggest that agents acting at CRF receptors may have therapeutic effects in anxiety- or stress-related disorders. CRF receptor antagonists may represent a new option for pharmacotherapy of stress-related disorders and some of these CRF receptor antagonists are currently undergoing clinical trials to determine their efficacy and tolerability in patients

with anxiety disorders as well as testing of the hypothesis that CRF hypersecretion is responsible for certain features of anxiety disorders.

NEUROPEPTIDE Y AND ANXIETY

Neuropeptide Y (NPY) is widely distributed throughout the peripheral and central nervous system. In the brain high concentrations of NPY are found in most cerebral regions including the cerebral cortex, hippocampus, thalamus and brainstem. However, regarding NPY receptors designated Y1, Y2, Y3, Y4, Y5 and Y6 (Gehlert *et al.*, 2001), the distribution varies. Y1 receptors are essentially present in high density in the cerebral cortex, thalamus and in some parts of the amygdala. Y2 receptors are found in the hippocampus, substantia nigralateralis, hypothalamus and brainstem. The so-called Y3 receptors may only be present in the brainstem but are not well characterized and have not as yet been cloned (Lee and Miller, 1998), and so far their existence remains controversial (Ingenhoven and Beck-Sickinger, 1999). Y4 receptor mRNA is mainly expressed in the peripheral nervous system, in the colon, small intestine and prostate (Michel *et al.*, 1998). Both the human and rat Y5 receptor have been cloned and with its mouse analogue, the Y6 receptor, form the latest members of the neuropeptide Y receptor family. Y5 receptor mRNA has been found in a number of brain regions implicated in the regulation of emotion (Nichol *et al.*, 1999) including hypothalamic nuclei, lateral septum, locus coeruleus and the amygdala.

The presence of NPY receptors in many regions implicated in the regulation of stress and the anxiolysis process provides the hypothesis of the implication of NPY in such mechanisms, leading to studies in animal models of anxiety.

Animals Models

Exogenous neuropeptide Y (NPY) reduces experimental anxiety in a wide range of valid animal models. The i.c.v. administration of NPY induces anxiolytic-like effects in various animal models of anxiety including ethological models such as the elevated plus-maze and social interaction test, models based on fear suppression of behaviour, including non-operant punished drinking, i.e. the Vogel's test (see Griebel (1999) for review), and operant food reinforced paradigm, as well as fear-potentiated startle. Heiling *et al.* (1989) have demonstrated using two rat models of anxiety, namely the Montgomery's conflict and the Vogel's drinking conflict test that NPY (0.4 to 2 nmol i.c.v.) induced anxiolytic-like effects with sedation and ataxia at higher doses. Increased plasma levels of immunoreactive NPY are observed following multiple aversive stimuli such as cold stress and handling (Zukowska-Grojec *et al.*, 1991), hypoxia (Cheng *et al.*, 1992) and emotional stress (Castagne *et al.*, 1987). NPY has an anticonflict effect when micro-injected into the amygdala (Heiling *et al.*, 1993). Micro-injected of NPY into the basolateral nucleus of the amygdala produced an increase in social interaction time in rats (Sajdyk, Vandergriff and Gehlert, 1999). The discovery and use of specific NPY agonists have demonstrated that the Y1 receptors are likely to be involved in the anxiolytic action of NPY (Broqua *et al.*, 1995). In this study the central administration of NPY increased the time spent in the open arms of an elevated plus-maze in the rat. Furthermore the administration of the NPY agonists, NPY_{2-36} and [Leu^{31}, Pro^{34}] NPY was found to increase the percentage of time spent in the open arms of the maze, while the Y2 receptor agonist NYP_{13-36} failed to do so. In the fear-potentiated startle model, a conditioned paradigm which is totally different from the precedent model, NPY, PYY and the agonists NPY_{2-36} or [Leu^{31}, Pro^{34}] NPY had similar effects to those of conventional anxiolytic drugs such as diazepam or even buspirone. Taken together these results are in agreement with the hypothesis that the antianxiety effects of NPY are mediated through Y1 receptors. The use of specific antagonists could help in understanding the involvement of endogenous NPY in the regulation of anxiety in animals. A highly selective, non-peptide NPY1 receptor antagonist, BIBP3226 induced an anxiogenic-like effect in the elevated plus-maze at a dose of 0.5 μg i.c.v. (Kask, Rago and Harro, 1996). This supports the hypothesis that endogenous NPY could reduce anxiety and/or neophobia through Y1 receptors. The anxiolytic-like effect of NPY in the rat social interaction test was antagonized by the specific Y1 receptor antagonist, ((R)-N-[[4-(aminocarbonylaminomethyl)phenyl]methyl]-N2-(diphenylacetyl)-argininamide trifluoroacetate) 3304 (Sajdyk, Vandergriff and Gehlert, 1999). In order to confirm the participation of endogenous NPY in regulating anxiety, Wahlestedt *et al.* (1993) synthesized an antisense 18-base-oligodeoxynucleotide on the basis of the sequence of the rat Y1 receptor. The i.c.v. administration of this antisense via chronic implanted guide cannulas (injection of 50 μg, four times over 2 days) produced an anxiogenic-like effect in the rat elevated plus-maze with more than 60% decrease in the activity in open arms, with no difference in overall locomotor activity. After testing, rats were killed and binding was performed on cortical and striatum tissue. The Y1-type binding site was decreased by almost 60%.

On the other hand, BIBP3226-induced anxiogenic effects is counteracted by the administration of 0.5 μg mg^{-1} of the benzodiazepine diazepam (Kask, Rago and Harro, 1996). This suggests that the neuropeptidic Y neurotransmission is connected to the GABAergic system. However, Britton *et al.* (1997) have demonstrated that flumazenil, a benzodiazepine receptor antagonist and picrotoxin, a GABA receptor antagonist, failed to alter NPY-induced punished responding in a rat conflict paradigm. These results confirm that the anxiolytic action of NPY is independent of a direct implication of the GABA/benzodiazepine receptor complex. On the other hand, the hypothesis that the opioid system may interact with NPY, is supported by the fact that naloxone (0.25 to 2 mg kg^{-1}) antagonized the effects of NPY in a conflict test and that central administration of the selective mu opiate antagonist CTAP partially blocked NPY-induced conflict responding (Britton and Southerland, 2001). Furthermore, concerning NPY neurotransmission interaction with other systems, a study reported that the anxiogenic effect of a selective Y1 receptor was prevented by the blockade of CRF receptors, suggesting antagonistic effects of endogenous NPY and CRF in shaping the response to novelty (Kask, Rago and Harro, 1997; Britton *et al.*, 2000).

A recent study, (Kask, Rago and Harro, 1998) reported new data on the mechanism of action of NPY. In fact, NPY has an anticonflict effect when micro-injected into the central nucleus of the amygdala but NPY is also found in other brain structures including the locus coeruleus. Interestingly, the anxiolytic-like effect of NPY in the vicinity of the locus coeruleus may involve the Y2 receptor subtype instead of Y1, as the Y2 agonist NPY_{13-36} was active and the Y1 agonist [Leu^{13}, Pro^{34}] was without effect. One explanation is that NPY transmission in the locus coeruleus modulates noradrenergic transmission via Y2 receptors in response to stress or novelty. Neuropeptide Y_{13-36} was found to be a mixed Y2/Y5 receptor agonist. Taken together these data suggest that the anxiolytic-like effect of NPY is not mediated via the single Y1 receptor subtype and that other receptors such as Y2 and Y5 may be involved. Using the Y5 receptor antagonist CGP71683A, Criscione *et al.* (1998) have shown that high doses of this compound induce conditioned taste aversion suggesting that Y5 receptor antagonism may cause anxiety or sickness behaviour. Recently, Kask *et al.* (2001) have demonstrated that CGP71683A failed to induce anxiogenic-like effects in the elevated plus-maze or decrease social interaction under testing conditions that were appropriate to detect anxiogenic-like effects of the drug. Nevertheless, rats stressed by prior exposure

to an elevated plus-maze test session have shown increased anxiety in the open-field test (Kask *et al.*, 2001). It is suggested that Y1 receptor mediates tonic NPY-induced anxiolysis and that the Y5 receptor contributes to adaptive changes that occur after stress exposure.

A role for endogenous NPY in the control of anxiety and stress is suggested by the fact that acute restraint stress suppresses NPY mRNA and peptide levels, within the cortex and the amygdala (Möller *et al.*, 1997). In the same way, repeated exposure to the same stressor chronically for 10 days leads to behavioural habituation and to an upregulation of amygdala NPY expression. One hypothesis is that endogenous NPY may contribute to the behavioural adaptation of stress. The use of NPY-transgenic (NPYtr) rats in a model of anxiety has provided an important tool in understanding the role of NPY in anxiety. Centrally injected exogenous NPY produced anxiolytic-like effects in the elevated plus-maze; the same effect was found with NPYtr rats only when the elevated plus-maze session was preceded by a stressor (Thorsell *et al.*, 2000). This presumes that neuronal activation may be needed for endogenous release of NPY.

Human Studies

Neuropeptide Y attenuates the action of CRF and other stress-released peptides. Preliminary trials with military personnel undergoing arduous basic training have shown that those individuals with the highest NPY levels tolerated excessive stress better than those with low levels (Morgan *et al.*, 2000). These findings suggest that it could be possible to treat post-traumatic stress disorder (PTSD) with a pharmacological agent promoting higher NPY levels (Friedman, 2000).

SUBSTANCE P AND NEUROKININS

The mammalian Tachykinin TKs are a group of neuropeptides comprised of substance P (SP), Neurokinin A (NK-A), and Neurokinin B (NK-B). These three endogenous peptides bind to G-protein coupled receptors, designated NK1, NK2 and NK3 respectively, to mediate their effects (Regoli, Boudon and Fauchere, 1994). The NK receptors are located in the central nervous system (CNS). NK1 and NK3 are widely distributed in the CNS (septum, striatum, amygdala, periaqueductal grey matter) whereas NK2 is distributed with lower levels in the CNS (Otsuka and Yoshioka, 1993; Maggi, 1995).

Animals Studies

Data suggests that SP may play a physiological role in the modulation of anxiety as this peptide is released after aversive environmental stimuli. The behavioural effects of SP have been investigated in animal models of anxiety (e.g. elevated plus-maze, social interaction). The effect of SP in anxiety models may be dependent on dose and specific brain regions (Griebel, 1999). Indeed, the administration of SP into various brain areas (the lateral ventricles, the region of the nucleus basalis magnocellularis, the bed nucleus of stria terminalis or the basolateral nucleus of the amygdala), produces anxiogenic-like effects in the elevated plus-maze in rodents (rats or mice) (De Lima and Ribeiro, 1996; Jentiens *et al.*, 1996; Teixeira *et al.*, 1996) whereas 1 mg of SP administered in the nucleus basalis magnocellularis showed anxiolytic-like properties in the rat social interaction test (Hasenöhrl *et al.*, 1996; Jentiens *et al.*, 1996).

The effect of NK2 agonists in animal models of anxiety show an anxiogenic-like profile. The endogenous ligand for NK2 receptors (NK-A) or the selective NK2 receptor agonist [β-Ala^8]NK-A-(4-10), a fragment of NK-A have been reported to produce anxiogenic-like effects in the mouse elevated plus-maze (De Lima *et al.*, 1995; Teixeira *et al.*, 1996). Studies are still lacking concerning the effects of NK-B on NK3 receptors, but De Lima *et al.* (1995) showed that senktide (a NK-B analogue) produces an anxiolytic-like effect in the elevated plus-maze, suggesting that NK3 receptors could play a modulatory role in anxiety (Griebel, 1999).

The potential of NK receptor antagonists as a novel treatment for anxiety and depression has been investigated (Kramer *et al.*, 1998). During 6 weeks, in a double-blind placebo-controlled study in patients with major depression, the NK1 antagonist MK 869 (300 mg per day), produced a positive outcome as measured by both the Hamilton depression (HAM-D21) and anxiety (HAM-A) scales.

There is clinical evidence that TK NK1 receptor antagonists may represent an important advance in the search for novel treatments of anxiety (Nutt, 1998). A wide range of chemically diverse SP receptor antagonists have now been synthesized, but vary markedly in their ability to cross the blood–brain barrier. Poor brain penetrant compounds include SR 14033, LY 303870, RPR 100893 and CGP 49823, while good brain penetrant compounds include the piperidines CP 99,994 and GR 203040, the piperidine ether L-733,060, and morpholines such as L-742,694 (Rupniak *et al.*, 1996, 1997; Kramer *et al.*, 1998). L-733,060 also exhibits a long duration of central NK1 receptor binding ($t_{1/2} > 6$ h), compared with the piperidine CP 99,994, making it particularly suitable for chronic administration studies in appropriate species (Rupniak *et al.*, 1996).

In preclinical studies evidence has been limited by the prevalence of tests utilizing rats and mice, whose NK1 receptor pharmacology differs to that of the human receptor (Beresford *et al.*, 1991; Gitter *et al.*, 1991). The majority of NK1 antagonist compounds display only low affinity for the rat receptor whereas they have high affinity for the human NK1 receptor. For example, L-733,060 in species that possess the human-like NK1 receptor (notably gerbils and guinea pigs), displays sub-nanomolar affinity while it does not possess affinity for the rat NK1 receptor (IC50nM) (Rupniak *et al.*, 1993). A small number of compounds have been described that possess nanomolar affinity for the rat receptor (RP 67580 and SR 140333), but their utility for *in vivo* studies is severely limited by their short half-life and poor brain penetration (Rupniak *et al.*, 1997). Nonetheless, data show an anxiolytic-like profile of the TK receptor antagonist in rodents. MK-869 reduces vocalization in guinea pig pups after maternal separation, suggesting an involvement in the integration of emotional responses to stress by amygdala or related brain areas (Saria, 1999). (±)-CP-96,345 has been reported to increase the time spent in the more aversive light compartment in the mouse light/dark test, albeit at high doses which caused sedation and motor impairment (Zernig, Troger and Saria, 1993). File (1997) also reported the anxiolytic activity of the TK NK1 antagonist, CGP 49823, in the rat social interaction test.

However, the picture is less clear with other selective NK1 receptor antagonists such as FK 888. Although the drug produced anxiolytic-like activity in the mouse elevated plus-maze (De Lima *et al.*, 1995; Teixeira *et al.*, 1996), these effects were not confirmed in a subsequent experiment in rats (De Lima and Ribeiro, 1996). Only at non-consecutive doses and only on one index of anxiety (time on open arms) was there an anxiolytic-like activity found after FK 888 administration in studies. Chronic treatment of NK1 antagonists were also studied in animal models of anxiety (File, 2000). After NKP608 administration, rats were tested in various conditions of the social interaction test. NKP608 administration had significant anxiolytic effects at 0.01, 0.03 and 0.01 mg kg^{-1} (p.o.) in an unfamiliar arena lit by both high and low light test conditions,

but was without effect in the familiar arena under low light illumination. The anxiolytic effect of 0.03 mg kg^{-1} remained after 3 weeks of chronic treatment and there was no anxiogenic effect after 24 h of drug withdrawal. At 6 weeks tolerance had developed, but no anxiogenic withdrawal effect was seen 24 h after the last dose.

Foot taping may be elicited in gerbils (a species whose NK1 receptor resembles that of the human (Beresford *et al.*, 1991; Gitter *et al.*, 1991)), by an aversive stimulus, i.e. electroshock and notably by cues paired with unconditioned stimulus. Recently, data supported the view that shock-induced foot taping in the gerbil is robustly inhibited by two NK1 antagonists. MK-869 (0.3–3 mg kg^{-1}, i.p.) dose-dependently blocked this foot tapping response and CP-99,994 (3 mg kg^{-1}, i.p.) inhibited foot tapping whereas its less active enantiomer (CP-100,263) had no effect (Ballard, Sänger and Higgins, 2001).

In contrast with NK1 studies, which can have contradictory results, NK2 antagonist studies show more reliable results. However, all results were obtained in exploration and social investigation procedures, but not conflict tests. Indeed, NK2 antagonists could possess antianxiety activity. The selective NK2 antagonist, SR 48968, increased the time spent in open arms and also increased the frequency of entries into the open arms in the mouse elevated plus-maze (Teixeira *et al.*, 1996). GR 159897, another non-peptide NK2 receptor antagonist was evaluated in two models of anxiety (the mouse light–dark box and the marmoset human intruder response test) and demonstrated in both rodent and primate species the ability to restore behaviour which had been suppressed by novel aversive environments (Walsh *et al.*, 1995). The effects of GR 159897 (0.0005–50 μg kg^{-1}, s.c.) are similar to SR 48968 (0.0005–50 μg kg^{-1}, s.c.) and diazepam (1–1.75 mg kg^{-1}, s.c.), as the three molecules increased time spent in the light compartment, without affecting locomotor activity. In the marmoset human intruder response, GR 159897 (0.2–50 μg kg^{-1}, s.c.), SR 48968 (10–50 μg kg^{-1}, s.c.) and chlordiazepoxide (0.3–3.0 mg kg^{-1}, s.c.) significantly increased the amount of time marmosets spent at the front of the cage during confrontation with humans. In fact, GR 159897 and SR 48968 produced similar effects to the classical antianxiety agents diazepam or chlordiazepoxide, but these two molecules produced positive effects over a wide dose range, with minimum dose levels in the microgram range. Another compound tested in the light–dark paradigm, GR 100679 (0.02–200 μg kg^{-1}, s.c.) which dose-dependently increased the time mice spent in the light side of the light–dark paradigm, had a similar effect to diazepam (Stratton *et al.*, 1993).

The present review suggests that centrally acting NK antagonists may have clinical utility in a number of psychiatric disorders that are currently treated with benzodiazepines and 5-HT1A agonists. The variable effects produced by NK1 receptor ligands in various anxiety models requires further investigation. The use of NK1 receptor knockout mice could be an alternative for this investigation.

Humans Studies

Investigators in a study undertaken by Merck Research Laboratories, studying 213 patients over 6 weeks, reported antidepressant effects for MK-869, a selective NK-1 antagonist, in the first week. By contrast, the study by California Clinical Trials, which took place also over a similar period, reported that statistically significant antidepressant activity of MK-869 was initially observed at week 4 and was maintained at week 6. The Californian trial formed part of a multicentre study comparing MK-869 to placebo in patients with Major Depressive Disorder (Hung, 2000).

NATRIURETIC PEPTIDES AND ANXIETY

There are at least three peptides constituting the natriuretic peptides (NP) system, namely the atrial natriuretic peptide (ANP), the brain natriuretic peptide (BNP) and the C-type natriuretic peptide (CNP). These peptides are natriuretic factors in the periphery and have a role in regulation of homeostasis of body fluid electrolytic balance and blood pressure in the CNS (Nicholls, 1994). The corresponding natriuretic peptide receptors NPR-A, NPR-B and NPR-C have been identified in the brain (Imura, Nakao and Itoh, 1992). In the CNS of rodents NPR-A is found mainly in the cortex and hippocampus, whereas NPR-B is present in the amygdala and several brainstem regulatory sites. NPR-C is found widely within the CNS, i.e. in the neocortex, limbic cortex, the hippocampal area and the amygdala. These peptides and their receptors represent an important neuromodulatory system within the CNS which is involved not only in the regulation of fluid homeostasis but also directly influences emotional behaviour such as anxiety and arousal.

Animal Models

Strohle *et al.* (1997) studied the effects of the central and peripheral administration of atriopeptin II, an aminoacid residue peptide of atrial natriuretic peptide (Ser103-Arg125), on anxiety-related behaviour and locomotor activity. Its behaviour on the elevated plus-maze after social deficit stress indicated that i.c.v. (2.5 and 5 μg) and i.p. (50 μg) administration of atriopeptin II produced anxiolysis. A low dose of 0.25 μg atriopeptin II administered bilaterally into the central nucleus of amygdala was also found to be anxiolytic.

The anxiolytic effects observed after central and peripheral administration support the hypothesis that atrial natriuretic peptide, which is increased in panic anxiety, may be involved in the tapering of anxiety-related behaviour. In contrast, ANP failed to diminish punished responses in the Geller–Sefter conflict test in rats (Heilig *et al.*, 1992). It was previously found that i.c.v. administration of ANP, PNP and CNP increased the exploratory activity of rats in the elevated plus-maze (Biro, Toth and Telegdy, 1995, 1996; Bhattacharya *et al.*, 1996). ANP-induced anxiolysis was also observed in the open field, social interaction and novelty-induced feeding suppression tests in rats (Bhattacharya *et al.*, 1996).

Isatin is an endogenous indole which has been shown to counteract some of the effects of ANP both *in vitro* and *in vivo*. Given intraperitoneally isatin reduced the effects of both BNP and CNP in a model of passive-avoidance learning in rats (Telegdy, Adamik and Glover, 2000) and the anxiolytic effect of ANP in the elevated plus-maze (Bhattacharya *et al.*, 1996). On the other hand small amounts of isatin are anxiogenic in rodent models. Furthermore, isatin has a wide spectrum of biological properties: a marker of stress and anxiety, an antiseizure agent, an inhibitor of benzodiazepine receptors and ANP binding to its receptors (Hamaue, 2000).

Human Studies

It has been suggested that ANP receptor modulation may have antipanic activity in patients with panic disorder. A double-blind placebo-controlled study was conducted in nine patients presenting with panic disorder and nine healthy control subjects. After pretreatment with an infusion of 150 μg ANP or placebo in random order, each subject received 50 μg CCK-4 (Wiedemann *et al.*, 2001). After pretreatment with ANP, the number of CCK-4-induced panic attacks decreased from eight to six in patients and from five to two in controls. Infusion of ANP significantly curtailed

the CCK-4-induced release of corticotrophin in patients. ANP exerts anxiolytic-like effects on patients with panic disorder. These results are supported by another study (Strohle *et al.*, 2001) using 25 μg CCK-4 in 10 panic disorder patients. These two studies support the antipanic activity of ANP, however it is possible that non-peptidergic ANP receptor ligands may be ultimately used to treat anxiety disorders.

CONCLUSION

The pharmacological, behavioural and molecular investigations of neuropeptides has advanced remarkably the knowledge of the peptidergic transmitter system in recent years. This knowledge has led to the development of new compounds with potential clinical interest and development has reached clinical studies in some examples of anxiety disorders. Although there is little clinical evidence so far of peptidergic involvement in human anxiety, the results from animal studies are encouraging. However, much research is required to address the hypotheses that neuropeptides may represent a new option for pharmacotherapy of stress-related disorders.

Neuroendocrinology of Anxiety Disorders: Post-traumatic Stress Disorder

W.S. de Loos

INTRODUCTION

History of Neuroendocrinology

The General Adaptation Syndrome

Endocrinology has strongly been linked to stress since Hans Selye formulated his concept of the 'general adaptation syndrome' (GAS) in his initial description of 'A syndrome produced by diverse nocuous agents' in *Nature* in 1936 (Selye, 1936a). He connected the initial response under the name 'alarm reaction' to the stage of resistance during continued exposure to the stressor and the subsequent stage of exhaustion ultimately followed by death. Shortly thereafter, he put the word 'stress' on stage as a concept of 'the nonspecific response of the body to any demand made upon it'. He drew the attention to the hypertrophic response of the adrenal glands, especially their cortical layers, and named the hormonal substances derived from them 'corticoids', such as 'cortisone'. Ever since, the glucocorticoids (cortisol/hydrocortisone and, in rodents, corticosterone) have figured as the stress hormones *in optima forma* and taken a role as the biological parameters or 'proof' of the stress response. Selye did not deny the role of the adrenal medulla and its main product adrenaline/epinephrine (EP) but the scientific community became very much focused on cortisol as the hallmark of the stress response.

Interestingly, Selye's attention was primarily drawn by physical causes of stress such as injuries, cold, restraint, hunger and numerous chemical substances (atropine, morphine, formaldehyde, epinephrine) (Selye, 1936b). Already in this and a further publication, he outlined the role of the pituitary gland in exerting the effect on the adrenal (cortical) hypertrophy marking the road to our present-day interest in the hypothalamo-pituitary-adrenocortical (HPA) axis in psychoneuroendocrinology (Selye and Collip, 1936). He also made the link to the immune system in his observations on thymicolymphatic atrophy laying the base for modern psychoneuroimmunology.

The Defence Reaction

Selye's original focus at physical causes of the GAS is of great value as it draws our attention to the unconditional stimuli that provoke it. Twenty-five years earlier, Walter B. Cannon had already described the physical (= unconditional) and psychological (= conditional) stimuli for adrenomedullary activation (Cannon and de la Paz, 1911; Cannon and Hoskins, 1911). He extended his observations to a concept of the emergency response of the individual by changes that are 'directly serviceable in making the organism more efficient in the struggle which fear or rage or pain may involve' (Cannon, 1914). His description of the 'Bodily Changes in Pain, Hunger, Fear and Rage' (Cannon, 1915) has become classical as the immediate response to the perception of threat mediated by epinephrine which is *sensori strictu* as much a hormone as cortisol. He described these changes here as 'The organic preparation for action ... in fight or conflict — either one requiring perhaps the utmost struggle'. This emergency response has later been named the 'defence reaction' (Hess and Brügger, 1943) and has its organizational centre in the amygdala (LeDoux, 1998).

The defence reaction consists of both behavioural and physiological components. The behavioural components are species specific; the physiological ones are more general, such as: pupillodilation; pilo-erection; increase of muscle tone, ventilation, cardiac output, oxygen consumption and muscle blood flow; decrease of blood flow in the skin, intestine and kidneys; bladder and bowel emptying; and many others like neurohumoral, hormonal, immunological and haemostatic changes. Understanding of the ethology and comparative physiology of the defence reaction permits excellent understanding of the psychophysiology of alarm and anxiety in humans, both under normal and pathological conditions.

The other important survival response is the above-described GAS which is characterized by behavioural inhibition when active ways of surviving a challenge have been blocked off. It can be compared to the psychodynamic concept of unsolvable conflict or to Seligman's behavioural model of learned helplessness (Abramson, Seligman and Teasdale, 1978), while Henry described it from a comparative physiological and ethological point of view as conservation-withdrawal expressing subordinate behaviour (Henry, 1992). The corresponding neuroanatomy has important organizing centres in the septum and hippocampus and has every right to be acronymized as the LHPA axis, for limbic-hypothalamo-pituitary-adrenocortical (Sapolsky, Zola-Morgan and Squire, 1991; López, Akil and Watson, 1999), including important physiological outflow through the vagal motor system. The effect of chronic mild stress on the HPA axis is organized in the hippocampus by modulation of hippocampal inhibition on the paraventricular nucleus (PVN) of the hypothalamus (Bratt *et al.*, 2001).

The emergency, or alarm, or defence reaction and the general adaptation, or conservation-withdrawal, or inhibition syndrome have been renamed 'allostasis' (Charles Kahn, see Sterling and Eyer (1988). Allostatic responses are temporary encroachments on homeostasis, a term we owe to Walter B. Cannon.

Looking back on almost a century of stress hormone research (EP and cortisol), we conclude that EP is a hormone that increases energy expenditure acutely and mobilizes quickly available resources (glucose, free fatty acids). It generates a metabolic response that can only last for a rather short time and should be followed by recuperation under better circumstances. Cortisol,

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

however, is a hormone that becomes useful under prolonged circumstances of adversity and generates a slowly catabolic response of long duration which can be used by the organism to consume its own structure as a resource for energy. It causes slow but general breakdown of the entire organism ultimately leading to death.

Syndromal Versus Matrix Diagnosis

Biological Parameters

Although challenging and even inspiring, the parallels between animal models and human disorders are defective. It remains to be seen, however, whether the clinical diagnosis of human psychiatric disorder is so much superior to ethological observation of animal behaviour or the biological responses referred to in the previous paragraph. Certainly, at group level interesting biological properties of psychiatric syndromes have been discovered, one of them the escape from dexamethasone feedback suppression of the HPA axis in major depressive disorder (MDD), a well-known phenomenon nowadays (see Gutman and Nemeroff in this book; Mitchell, 1998). Still, at the individual level this has not given us a tool to 'prove' whether a patient is suffering from MDD or not. We are far from using biological parameters to support psychiatric clinical diagnosis. Often, confusing findings have been reported, even at a group level (*vide infra*), which makes us doubt, at times, the validity of syndromal diagnosis. Biological parameters seem not to parallel the syndromal level and syndromal diagnoses inadequately predict the success of therapeutic strategies, as one of the founders of biological psychiatry, Herman M. van Praag, has pointed out (van Praag *et al.*, 1987). It is even highly questionable what the relevance is of the syndromal diagnostic constructs we use to work with. They seem to be based on a nineteenth century disease model that has been derived mainly from the paradigm of infectious diseases, a one pathogen — one disease model that is not valid any more in a world where this model of syndromal diagnosis is becoming less effective with the growth of our physiological, biochemical and genetic insights. In many cases we should speak, in fact, of common final pathways or end points with heterogeneous aetiologies or initiators. Concerning common final pathways, we know that different mutations within a single gene will often cause the same genetic defect. Different genetic defects may still lead to similar phenotypical disease expressions. Diseases that have been known for ages under a single name, had to be split into sub-groups with significant differences.

Co-morbidity

Another artifact of modern diagnostic classification is that of co-morbidity suggesting that psychiatric diagnoses can simply be added up like we do with somatic pathology, e.g. juvenile diabetes plus hypothyroidism plus Addison's disease, or hypertension plus osteoarthritis plus colorectal cancer. Not without reason van Praag again — 'rebel with a cause' — writes about 'classificatory inflation', a nosological doctrine hanging around psychiatry's neck as an albatross (van Praag, 2000). It seems more fruitful to follow a system of developmental elements as they have emerged during phylogeny and ontogeny, the natural history of biology, to form the basis of nosological diagnosis (de Loos, 2001). A matrix of relevant elements would form a diagnostic matrix that is less sensitive to unvalidated constructs and taxonomic changes.

A Diagnostic Matrix

- Dimension I: the genetic code, the set of unchangeable biological properties is at the basis of this system. It includes not only the structural floorplan and homeostatic regulatory mechanisms but also the inborn psychophysiological responses initially described by Cannon and Selye (*vide supra*). Such responses cannot be learnt or suppressed voluntarily; they can be enhanced by conditioning.
- Dimension II: acquired automated mechanisms (organizing effects, imprinting, long-term potentiation/depression, pruning and dendrite plasticity, association). Imprinting and learning are processes directly based on the genetic make-up of an individual. Imprinting is the creation of read-only-memories (ROMs), a biological parallel of computer 'firmware', and happens at a developmental stage when the nervous system is receptive for information that fulfils certain specifications. It is a process that occurs under circumstances created by the first dimension.
- Dimension III: the declarative faculty (reflexive consciousness, emotional declaration). From a heuristic point of view it seems logical to separate linguistic development from the second dimension considering the phylogeny of homo sapiens. Reflexive consciousness and the development of emotional expression are representations of the declarative faculty including aspects of relational behaviour, literature, etc.
- Dimension IV: complex language-dependent systems (science, logic, mathematics, philosophy and political systems). They can be seen as the present ultimate development of phylogeny and ontogeny. They constitute what we use to call human 'civilization' including structures based on semantically explicit cognition. Although scientific theory development requires economy in calling in assumptions or abstractions, it seems appropriate and efficacious to categorize this level of development in a separate dimension.

Construction of an individual matrix for every patient may seem tedious at first glance but respects individual variability more than our present-day system of syndromes and co-morbidity. Modern DNA technology is unravelling genetic codes of adaptive (healthy) polymorphisms and maladaptive mutations. Although still costly at present, DNA diagnostics are becoming available at the individual patient's level and may fill in Dimension I at a certain time. Dimension II can already be filled in with traits like hypervigilance, increased startle, increased impulsiveness, dissociation, sympathoadrenomedullary activation, (L)HPA activation, intrusive memory, etc. For many of these we have knowledge about neural circuits, transmitters and neuromodulators that are involved and drugs that can or cannot interfere.

Changes or disturbances in the regulation of the HPA axis (Dimension II) do not parallel the classificatory division between mood and anxiety disorders (for an overview see Heim and Nemeroff (1999) Table 1). Within the group of anxiety disorders differences are found between panic disorder (PD) and post-traumatic stress disorder (PTSD) (*vide infra*) while somatoform disorders like chronic fatigue syndrome (Demitrack *et al.*, 1991) and fibromyalgia (Griep, Boersma and De Kloet, 1993) resemble PTSD in the down-regulation of HPA axis activity (Heim, Ehlert and Hellhammer, 2000; Altemus *et al.*, 2001). Chronic fatigue syndrome overlaps with major depressive disorder (MDD) but shows opposite HPA axis regulation (Demitrack, 1997). It would thus be more helpful to assess and value HPA axis regulation as a dimensional feature as it seriously confounds syndromal diagnosis.

Dimension II of the matrix is also the domain of interaction between developmental conditions and the influence of environmental factors on adult outcome. What this implies for rodents, especially the responsiveness of the HPA axis, has been reviewed by numerous authors. The HPA axis of developing rats is, in part, regulated by maternal factors like feeding, licking and grooming the pup after a separation, which all seem to act in concert to limit and prevent the so-called stress hormones and more specifically corticosterone from exceeding some optimal level. The pattern of ACTH releasing factors is affected, not only corticotrophin releasing hormone (CRH) gene (hnRNA and mRNA) and AVP gene

activation, but also immediate early genes (the transcription factor c-*fos* and the growth factor NGF-1a) in a differentiated way demonstrating a significant plasticity of the system (Levine, 2001). Differences between mothers are fairly stable over subsequent litters and are transmitted to the next generation by environmental as well as genetic factors. Environment can thus alter the genetic trajectory demonstrating the adaptive value of plasticity (Francis *et al.*, 1999). Numerous retrospective studies in humans support these animal studies with consistent results suggesting sensitization of the neuroendocrine stress responses after early life stress in humans. Differences found between childhood versus adulthood stress on the results in adulthood underscore the interaction with the developmental stage (Heim and Nemeroff, 2001).

General Principles of Endocrine Regulatory Systems

Classical and Clinical Endocrinology

Base line values of hormonal secretions have limited value in endocrinology as they may be confounded by many factors such as inter-individual variability of normal values while intra-individual variability is much smaller in general. Base line values can be more dependent on unrecognized environmental or intra-individual circumstances than is generally acknowledged. This is known, for instance, for 'normal' morning cortisol values taken from outpatients in hospital surroundings and considerable variation has been recorded in studies with 'base line' 24-hour urine cortisol in patients with PTSD (*vide infra*).

Other problems are met with the difference in analogous (continuous) versus digital (pulse frequency) regulation of end-organ function. Releasing hormones from the hypothalamus and pituitary hormones generally are of the latter type, steroid hormones have properties of both while thyroid hormone may be the most continuous in level. An important role is being played by hormone binding proteins. They strongly dampen the oscillations in total hormone concentrations found but this can be unmasked by measuring free hormone levels in plasma or saliva. Only the free hormone can act biologically.

Understanding of hormone function and assessment of normality of function is often better achieved by stimulation or blocking (feedback sensitivity) tests. The difficulty with the tests generally applied is, however, that at least in clinical endocrinology they are of a pharmacological kind using doses far exceeding physiological levels. This may have value in detecting organ failure in autoimmune or post-operative endocrine disease, or of endocrine tumors but is of very limited value in detecting changes in set point of a regulatory system, or even in so-called subclinical thyroid disease. Modifications have been found by applying 1 in stead of 250 μg of i.v. $ACTH_{1-24}$ for adrenal stimulation and 0.5 or 0.25 instead of 1.0 mg of dexamethasone for the 'overnight' suppression test.

Many problems arise from the existence of pre- and pre-pro-hormones and from split products that may be biologically active or inactive. Examples are pro-opio-melano-corticotropin (POMC), the endorphins and enkephalins and, the endocrinologist's nightmare, parathyroid hormone. Laboratory assays may not find the difference and local transformation may mask the 'visibility' of the substance, e.g. of tri-iodothyronine (T_3) in brain tissue where it is being transformed from its biologically almost inactive precursor L-thyroxine (T_4). Also, the sensitivity of assays may be a serious problem in the range of normal function as it has been with thyroid stimulation hormone or thyrotropin (TSH) until the third generation assay became available. The transformation of pro-hormones may be regulated at multiple levels and differently in different tissues as is the case with thyroid hormone of which only 20% is readily produced in its active form T_3 in the thyroid gland itself. Deiodination from T_4 to T_3 occurs intracellularly in many tissues while especially the liver exports T_3 to the general circulation. Half-life of these substances varies considerably, in the case of T_4 and T_3 from 7 days to a few hours only.

The classical hormones are defined by their signal function transported through the general circulation. The releasing hormones and the intra-cerebral and intra-medullary peptides can hardly be found in the peripheral circulation and even in the cerebrospinal fluid the levels found must be considered as spillover from tissue to the gutter of the brain which helps to clear this organ from products that have not been degraded locally or removed by presynaptic reuptake. Lastly, psychoneuroimmunological research has shown that peptide hormones like CRH and the cytokines are being secreted by lymphocytes at the femtomolar level (10^{-15} mol l^{-1}) where they have a paracrine function and still can influence the brain that way by uptake through the blood–brain barrier at specific sites and connection to specific neuronal circuits (Breder, Dinarello and Saper, 1988).

Neuroendocrinology

Still, when we have taken into account all these technical points, we must realize that by studying a few substances we are only looking to a few links in a long chain of events. In classical ('clinical') endocrinology, hormone systems are described as separate domains. In neuroendocrinology the limitations of this way of thinking become obvious: there are important connections with other neurochemical and neurophysiological systems. The classical hormone concept is also too limited. CRH, for instance, has endocrine, autonomic, behavioural and immune effects. It acts as a classical hormone in the hypothalamo-pituitary portal system, as a neuromodulator in widespread areas of the central nervous system (CNS) confirming David de Wied's neuropeptide concept (de Wied and Jolles, 1982) and paracrine in the immune system.

POST-TRAUMATIC STRESS DISORDER

Neuroendocrinology, Psychophysiology and Post-Traumatic Symptoms

Early Biological Predictors

Peri-traumatic dissociation has been found to be a good predictor of the development of PTSD, better and stronger than depression, anxiety and intrusive symptoms (Shalev *et al.*, 1996). Heart rate in the peri-traumatic phase, i.e. in the emergency room after traffic accidents etc., was also positively correlated to the development of PTSD (Shalev *et al.*, 1998a). In an extension of the study, again peri-traumatic dissociation and heart rate predicted the development of PTSD and were associated with more intrusive symptoms and exaggerated startle (Shalev *et al.*, 1998b). Heart rate is controlled by two extracardial mechanisms. EP increases it and the vagal nerve lowers it. The sympathetic innervation only influences electrical conductance (induction of arrhythmia's), stroke volume and coronary artery blood flow. No acute studies, in the emergency room, have been done on EP production, but assessment after one and six months after an accident has shown elevated EP production rates in men with PTSD symptoms. Catecholamine rates were also associated with intrusive thoughts at one month and avoidance at six months. In this study urinary cortisol production rates were elevated in men at one month and normal at six months. Both in men and women, greater emotional numbing predicted a lower cortisol production rate at six months (Hawk *et al.*, 2000). This is a finding that seems to be confirmed by Mason *et al.* (2001) who linked lower cortisol levels with disengagement defence mechanisms (numbing) in combat veterans with PTSD.

A negative correlation between serum cortisol immediately after traumatization and the development of PTSD was found in two different settings, namely sexual assault and motor vehicle accidents (Resnick *et al.*, 1995; McFarlane, Atchison and Yehuda, 1997). Significantly lowered urinary cortisol over 15 hours at acute assessment in the emergency room predicted PTSD at one month and especially the occurrence of intrusive and avoidant thoughts (Delahanty, Raimonde and Spoonster, 2000). These psychophysiological factors raise the issue of pre-traumatic vulnerability in the development of PTSD (Yehuda *et al.*, 1998).

Acute stress disorder (ASD) is characterized by dissociation and strongly predicts the development of PTSD (Brewin *et al.*, 1999; Koren, Arnon and Klein, 1999). No specific neuroendocrine research focused on ASD *per se* has been done. Studies on initial cortisol responses predicting development of PTSD may be seen as relevant to ASD as such. When combining the elements of dissociation and stress-induced analgesia with the known effects of opioids, it is suggestive to infer a central opioid effect as a core mechanism in the initiation of this disorder (*vide infra*).

Psychophysiological Testing: Heart Rate and Epinephrine

Reference has been made to increased EP production at early stages after traumatic accidents. Analysis of heart rate variability by means of power spectrum analysis in PTSD patients many years after traumatization again showed higher heart rates and lower heart rate variability at rest. This was interpreted as an indication for lower cardiac parasympathetic (vagal) tone and elevated sympathetic activity (Cohen *et al.*, 1997).

In laboratory settings cardiovascular and other psychophysiological responses, mainly galvanic skin response (GSR) and electromyography (EMG), to stimuli of various kind have been studied extensively. Many studies have demonstrated strong specific responses of blood pressure and especially heart rate to startling unspecific noises and to individually significant sensory input in subjects with PTSD, combat veterans from various war theatres (Pallmeyer, Blanchard and Kolb, 1986; Pitman, Orr and Steketee, 1989; Blanchard *et al.*, 1990, 1991a), and in other populations of trauma survivors (Shalev *et al.*, 1993, 1997). Also in Rorschach testing the projection of traumatic content elicited significant increases in skin conductance (sympathetic activation) and heart rate (Goldfinger, Amdur and Liberzon, 1998).

Yohimbine, an α_2-adrenergic receptor antagonist that activates noradrenergic neurons, e.g. in the locus coeruleus, hippocampus and amygdala, increased systolic blood pressure significantly more in PTSD subjects than in healthy controls, especially when they had a flashback and/or a panic reaction after administration of this drug. The same occurred with heart rate which showed no significant response in the controls (Southwick *et al.*, 1993). None of these studies discriminates between sympathetic mediated decrease of vagal tone versus EP mediated cardioacceleration. A role of the latter can only be inferred by the above-mentioned study by Hawk *et al.* (2000). But all these point to a strongly increased sympatho-adrenomedullary activation in PTSD.

Vasopressin and Oxytocin

Vasopressin and oxytocin are two hormones of the central nervous system (neuropeptides) that are of special importance in memory processing. Behavioural and cardiovascular conditioning in animals has shown that vasopressin increases the retention of both appetitive and aversive memory while oxytocin in low doses has the opposite effect (Bohus, Kovacs and De Wied, 1978; Wan *et al.*, 1992). Similar results have been demonstrated in humans with PTSD with respect to psychophysiological parameters in relation to personal traumatic imagery, most specifically exerted by vasopressin on EMG (Pitman, Orr and Lasko, 1993).

Opioids

'Addiction' to the trauma, a strong need to return to memories, memorials and other symbols of the trauma, is a clinical phenomenon in many PTSD patients that was poorly understood until the role of the opioid peptides was discovered. It may also be related to novelty/sensation seeking or risk taking behaviour (Van der Kolk *et al.*, 1985). Pain-induced analgesia was known as an experimental model in pharmacology for a considerable time and has been extended, later, to stress-induced analgesia. In animal experiments it has been connected to learned helplessness (*vide supra*) and shown to be dependent on μ-opioid mechanisms at the time of initial uncontrollable footshock (Hemingway and Reigle, 1987). It can be blocked with the classical morfine antagonist naloxone. These mechanisms have been associated with post-traumatic symptoms, such as numbing (Van der Kolk and Saporta, 1991; Glover, 1992). There are indications that flashbacks and other dissociative phenomena in PTSD patients and also emotional numbing are opioid mediated phenomena that can be blocked by naloxone (Van der Kolk *et al.*, 1989; Pitman *et al.*, 1990). Improvement of many PTSD symptoms has been reported after the administration of nalmefene (Glover, 1993), a relative pure opioid μ-receptor antagonist more potent than naloxone (Reisine and Pasternak, 1996). It is possible although speculative at this moment that clinical phenomena like dissociation, auto-mutilation and conditioned or self-induced analgesia like the fakir syndrome are mental states in which the opioids play an important role. A puzzling finding is that plasma levels of β-endorphin, both in the morning and the evening, were found in one study to be lower than in controls (Hoffman *et al.*, 1989). In this same study morning cortisol levels in PTSD subjects were higher than in controls which is at variance with most later findings (see below). The above reported opioid responses to traumatic flashbacks were not accompanied in that study by detectable changes of opioids in the general circulation (B.A. van der Kolk, personal communication). The effects are confined to the CNS compartment exclusively as was shown in a study in which subarachnoid cerebrospinal fluid (CSF) sampling was compared to peripheral plasma. It was shown that PTSD patients have significantly increased CSF levels of β-endorphin and that higher levels corresponded with less intrusive and avoidance symptoms (Baker *et al.*, 1999). Also, the connection to the hypothalamic-pituitary-adrenal axis is to be considered in the light of its inhibition by opioids at the hypothalamic level (Hockings *et al.*, 1994).

The HPA Axis

Interaction with the Sympatho-Adrenal System

Many studies have addressed the complex interplay between the sympatho-adrenomedullary system and the hypothalamic-pituitary-adrenocortical (HPA) axis. In most studies PTSD is characterized by increased norepinephrine (NE) spillover (Kosten *et al.*, 1987; Blanchard *et al.*, 1991b) on one hand but decreased total daily cortisol production (Mason *et al.*, 1986; Yehuda *et al.*, 1990a, 1995b) and decreased circulating cortisol levels on the other (Yehuda *et al.*, 1996a; Boscarino, 1996; Kanter *et al.*, 2001). Urinary cortisol was also found to be lower in adult offspring from Holocaust survivors with PTSD while offspring with parental PTSD and own lifetime PTSD had the lowest levels (Yehuda *et al.*, 2000).

Daily free cortisol excretion was found to be normal at group level but to correlate inversely with intrusive PTSD symptoms in one study (Baker *et al.*, 1999) while it was increased similarly to patients with major depression and without any correlation to

symptoms in another (Maes *et al.*, 1998). One difference between the last study and the previous ones is that it was done on civilians with a majority of females without control for menstrual cycle phase while most of the previous studies were done on male combat veterans. The study by Hawk *et al.* (2000) has the same limitation mainly due to the set-up, namely emergency room assessment of accident victims. A study that did control for menstrual cycle phase showed no effect of phase on total urinary-free cortisol output, and no effect of PTSD although there was a trend towards an increased cortisol output in PTSD (Rasmusson *et al.*, 2001). It was also argued that single traumatic events might cause an increased HPA axis response while repetitive and prolonged trauma might do the opposite. Some support for this view can be found in other research but this problem has not been solved satisfactorily.

In concordance to the release rates reported above, α_2-adrenergic receptors are down-regulated (Perry, Giller and Southwick, 1987; Yehuda *et al.*, 1990b) and glucocorticoid receptors (GRs) are up-regulated (Yehuda *et al.*, 1991, 1995c). Norepinephrine release and the up-regulation of GRs correlate with the severity of PTSD symptomatology (Kellner, Baker and Yehuda, 1997). A significant negative correlation between 24-hour urinary-free cortisol and PTSD symptoms reported in another study confirmed this (Baker *et al.*, 1999).

Feedback Systems

In PTSD the efficacy of glucocorticoid feedback is increased as demonstrated by a significantly enhanced dexamethasone suppression in comparison to normals (Kudler *et al.*, 1987; Yehuda *et al.*, 1993; Stein *et al.*, 1997b; Heim *et al.*, 1998) and it is opposite to depression which is known for its dexamethasone non-suppression. One would even conclude that PTSD and biological depression as defined in this neuroendocrine way exclude one another. Yet, many studies describe co-morbidity of PTSD and major depressive disorder (MDD) (Shalev *et al.*, 1998b), not merely dysthymia. It should be kept in mind that a biological definition of depression is not by itself concordant with a psychological one. Individuals with PTSD and co-morbid depression are still better than normal suppressors, but less than having PTSD alone (Yehuda *et al.*, 1993). The enhanced negative feedback of dexamethasone is not reflected by lower levels of circulating adrenocorticotropic hormone (ACTH) but the pituitary capacity to release ACTH is markedly enhanced which excludes pituitary insufficiency and confirms the increased feedback sensitivity (Yehuda *et al.*, 1996b).

The high levels of NE in PTSD are interpreted as to reflect high sympathetic activity which corresponds with many findings on cardiovascular stimulation and galvanic skin response (GSR) reactivity. A positive correlation between intrusive PTSD symptoms and urinary excretion of the catecholamines dopamine and EP points in the same direction (Yehuda *et al.*, 1992). Thus, PTSD with or without accompanying symptoms of depression seems to be characterized, on one hand, by sympatho-adrenal arousal which is reflected by increased cardiovascular responsiveness and sweat gland activation as signs of the defence reaction, the paradigm of active survival strategy; on the other hand, it is characterized by a turn-down of the conservation-withdrawal response and its catabolic survival hormone cortisol that induces the organism to consume its intrinsic resources while waiting for a better time.

CRH, the 'Stress Superhormone'

CRH Testing

The response of ACTH to CRH has been found to be blunted in male PTSD patients as in depression and to result in slightly but not significantly lower cortisol responses (Smith *et al.*, 1989) while in panic disorder (PD) enhanced and blunted responses have been reported (Heim and Nemeroff, 1999). In PTSD this cannot be understood as a feedback effect of functional hypercortisolism, as in the case of depression (Gold, Goodwin and Chrousos, 1988). In premenopausal women ACTH response to CRH was increased and slightly prolonged with an increased and prolonged cortisol response. Cortisol response to $ACTH_{1-24}$ was tested in the follicular phase (high progesterone) and also showed an increased response. The cortisol responses correlated to each other and to 24-hour urinary cortisol excretion (Rasmusson *et al.*, 2001). It demonstrates once more the importance of accounting for sex and, as we will see, age.

Children: CRH Testing and Urine Sampling

The neuroendocrine pattern in children has not been investigated as intensively as in adults. In one study CRH testing was performed in children of 7–15 years old who were living in a stable and safe environment but who had been sexually abused 1–12 years earlier. Some of them had concurrent dysthymia and suicidal ideation and had attempted suicide but none of them was reported to have PTSD. They showed smaller than normal ACTH responses but nonetheless normal cortisol responses to this (De Bellis *et al.*, 1994), which resembles the result found in male adults.

A very different finding is the increased ACTH response to CRH in abused children who experienced ongoing chronic adversity and were rated as depressed. They differed from abused depressive children living in a stable environment, depressive non-abused controls and healthy children who all showed the same ACTH response. The increased ACTH response in the first group was not followed by an increased cortisol response which thereby was the same in all four groups (Kaufman *et al.*, 1997).

A group of children of the same age (8–13) with PTSD was compared to normal controls and children with overanxious disorder. Childhood PTSD was associated with greater co-morbid psychopathology including depressive and dissociative symptoms, lower global assessment of functioning and increased suicidal ideation and suicide attempts. The children in this group excreted significantly greater amounts of urinary dopamine and norepinephrine per day than in both comparison groups. Their free cortisol excretion was equal to that of the overanxious group but exceeded the controls. Catecholamine and cortisol excretion was correlated to the duration of traumatization and to PTSD symptoms (De Bellis *et al.*, 1999).

It is unclear what the discrepancies between these studies and the results found in adults imply. One of the possibilities is that the psychobiological development stage is a critical factor. Also in a broader sense, age may be a factor influencing the HPA axis response to challenge (Seeman and Robbins, 1994). Repetition or perseverance of traumatization is likely to influence the neurohumoral response to it as has been observed in rape victims (Resnick *et al.*, 1995). Other possibilities accounting for the discrepancies are that the studies were done on non-patients and patients with different diagnoses (diagnosing PTSD in young children poses its own difficulties), sample sizes, time of the day and baseline values.

Systems Integration

No convincing correlations have been found between HPA axis activity in the morning, when it is as high in PTSD patients as in controls, and circulating catecholamines or psychophysiologic parameters like GSR (which reflects sympathetic activity), heart rate or frontalis EMG (Liberzon *et al.*, 1999). The conclusion was drawn, then, that no integrated, multisystem stress response occurred in PTSD and this conclusion is supported by other

findings when the HPA axis response was studied in connection with CNS noradrenergic activity as represented by 3-methoxy-4-hydroxyphenylglycol (MHPG or MOPEG) spillover (Goenjian *et al.*, 1996; Yehuda *et al.*, 1998) which can be considered a metabolic parameter of central NE turnover reflecting spillover from the CSF compartment into the systemic circulation (Webster, 1989). This may seem, but is not necessarily, at variance with the above-described findings on the HPA axis and catecholamine activity. It means that within an individual these systems are not being coupled per single event. This conclusion is in concordance with the insight that the sympatho-adrenal response system and the HPA axis are not connected to each other through the activation of CRH, as this neurohormone or neuromodulator acts at different locations in the CNS independently, in different circuits and functions (Schulkin, Gold and McEwen, 1998). CRH gene expression in the central nucleus of the amygdala and the bed nucleus of the stria terminalis (BNST) is dissociated from that of the paraventricular nucleus of the hypothalamus which is the classical top of the HPA axis organization. Direct application of CRH by infusion into the third ventricle induces multiple physiological stress responses like increase of plasma epinephrine, norepinephrine, glucose and glucagon, of mean arterial blood pressure and heart rate, and inhibition of gastric acid production, all by autonomic nervous system activation (Lenz *et al.*, 1987). The gastric inhibition could, in part, be inhibited by naloxone or a vasopressin antagonist. This implies involvement of an opioid neuropeptide as a neuromodulator, e.g. a pro-opiomelanocortin (POMC)-derived endorphin (De Wied, 1999). The possibility of a relation with dissociation and flashback-related analgesia is intriguing within this context (Pitman *et al.*, 1990). The role of vasopressin is interesting from the viewpoint of its role in the consolidation of memory (Bohus, Korac and De Wied, 1978; Chepkova *et al.*, 1995), including the psychophysiologic concomitants of emotional memory (Bohus *et al.*, 1983; Pitman, Orr and Lasko, 1993) and its role in the potentiation of CRH-induced ACTH release (Scott, Medbak and Dinan, 1999).

The Role of CRH

The question of the specificity of CRH activity in the CNS is of special importance in the case of PTSD as higher levels of this neurohormone have been found in the cerebrospinal fluid of patients compared to controls, which may seem paradoxical at first sight given the increased feedback sensitivity of the system (Bremner *et al.*, 1997b; Baker *et al.*, 1999). CRH in the CSF is mainly of extrahypothalamic origin, not related to HPA axis activity (Garrick *et al.*, 1987). Interestingly, this was accompanied in patients, but not in controls, by positively correlated CSF levels of somatostatin which often acts as an inhibitory hormone or neuromodulator both in the CNS and peripherally, but its role in these particular circumstances remained unclear. It is also unclear, at this point, what actually causes the increased feedback sensitivity within the HPA axis and whether stimulation of this axis at the level of CRH production by the paraventricular nucleus (PVN) of the hypothalamus is decreased. As mentioned above, the elevated CRH levels in the cerebrospinal fluid are not likely to be generated by the PVN but to be due to spillover from the central amygdala, the bed nucleus of the stria terminalis and the locus coeruleus. The latter three nuclei have important roles in organizing or mediating vigilance, arousal and anxiety reactions and they activate both the central norepinephric system and the sympathetic nervous system (Lenz *et al.*, 1987). Central norepinephric system activation has not systematically been demonstrated (Yehuda *et al.*, 1998). However, frequently repeated activation of the sympathetic nervous system is a general feature of chronic PTSD. Similarly to PTSD symptoms, of panic and flashbacks, yohimbine challenge has indeed produced increases in systolic blood pressure and heart rate, but also MHPG spillover as a putative parameter of central norepinephrine activation (Southwick *et al.*, 1993).

Hippocampal Glucocorticoid Receptors

One of the options for increased HPA feedback sensitivity is increased GR function in the hippocampus which is an important centre for control over the HPA axis function (Meaney *et al.*, 1989). The hippocampus with its dense population of GRs is now broadly recognized as the top of the system by exerting inhibitory control over hypothalamic CRH production (Jacobson and Sapolsky, 1991). GRs may have been up-regulated conforming to a theory derived from the model of neonatal handling in rats in which attenuation of stress responses in adulthood has been observed (Levine, 1957; Denenberg, 1964). This model has been differentiated by more recent studies showing that individual differences in caring behaviour by the mother animal after separation from the litter are responsible for differential effects of such handling. The better the caring attention of the mother after replacement of the pup into the litter, the higher the GR density in the hippocampus and the more efficacious the feedback of circulating glucocorticoid hormone (Liu *et al.*, 1997; Sapolsky, 1997). This process is thought to have a protective effect on the hippocampus against later damage by high glucocorticoid responses under environmental stress or allostasis. The hippocampal atrophy found in PTSD, like in depression and Cushing's disease (Sapolsky, 1996), is not compatible with such protection if, indeed, the damage is due to high glucocorticoid responses under traumatic circumstances.

Hippocampal GRs may respond differently to cortisol than to dexamethasone. This has been shown in an intravenous cortisol inhibition study in PTSD patients in whom adrenal cortisol synthesis was partly blocked with metyrapone. Its precursor, 11-deoxycortisol, can be measured as a parameter of ACTH stimulation of the adrenal cortex. No significant difference in ACTH response to cortisol was found in the PTSD subjects who had lower baseline cortisol and 11-deoxycortisol conforming to the expected HPA axis down-regulation. The PTSD subjects showed no increased feedback sensitivity to cortisol, contrary to expectations from the dexamethasone studies (Kanter *et al.*, 2001). This difference could be based on the lack of effect of dexamethasone on the hippocampus and the PVN as it does not penetrate into the CNS. It implies that the enhanced feedback sensitivity is not present at the level of hippocampal or PVN GR. Other mechanisms must be responsible for the HPA axis down-regulation.

Atrophy of the Hippocampus

A smaller volume of the hippocampus found in several PTSD studies (Bremner *et al.*, 1995, 1997a, 1997b; Stein *et al.*, 1997a), which is enigmatic in the light of the atrophy found in MDD and Cushing's disease with their increased levels of cortisol (Sapolsky, 2000), is the opposite of what is thought to be happening in PTSD. The finding has been confirmed with more sensitive neurochemical methods independent of gross neuroanatomical morphology (Schuff *et al.*, 2001). There is not much doubt about the potential harm of glucocorticoids for the hippocampus, especially the granulosa cells and the dendritic outgrowths and sprouting of the pyramidal cells (McEwen, Gould and Sakai, 1992; Gould and Tanapat, 1999). It has been postulated that the impact of the initial adversive experience may trigger damaging levels of glucocorticoid release thus causing the observed atrophy in PTSD (Bremner, 1999). Other causes for neuronal damage are excitatory amino acid neurotransmitters, especially glutamate, via its N-methyl-D-aspartate (NMDA) receptor and possibly also its kanainate-type feedforward autoreceptor, and serotonin which may also potentiate the NMDA receptor (McEwen and Magariños, 1997; Gould and Tanapat, 1999). Neuroprotection

by GABA-ergic inhibition or by neurotrophins (NT) such as brain-derived neurotrophic factor (BDNF) and NT-3 may decrease under certain stressful circumstances.

A postulated consequence of hippocampal atrophy with respect to the striking down-tuning of the HPA axis is the putative disinhibition of CRH release from the PVN which, then, should result in CRH receptor down-regulation in the pituitary and thereby cause a decrease of ACTH stimulation. From the viewpoint of classical endocrinology, however, it seems improbable that this would result in an absolute decrease of ACTH release from the pituitary, instead of an attenuated increase, and hence produce a decrease of cortisol release from the adrenal and, lastly, an enhanced glucocorticoid feedback effect. Continuous hormonal overstimulation at a pharmacological level produces receptor down-regulation and a sharp and almost complete decline of end-organ activity. This is applied in the treatment of prostatic cancer by the use of a long-acting gonadotropin-releasing hormone agonist that down-regulates testosterone production to almost zero, but in physiological circumstances it is not known to occur and the neuroendocrinology of major depression with its increased activity of the HPA axis does not confirm this either. Moreover, experiments in primates examining the effects of lesions of the hippocampus and other related structures produced chronic glucocorticoid hypersecretion lasting 6 to 15 months (Sapolsky, Zola-Morgan and Squire, 1991).

Vasopressin, Somatostatin and the HPA Axis

Thus, there must be other reasons for the opposite characteristics of PTSD and MDD with respect to the HPA axis. Vasopressin is one candidate for discriminating between PTSD and MDD although this may be part of a very complex pattern of interaction. Vasopressin potentiates the release of ACTH (Antoni, 1993; Aguilera, 1998) and it has been shown to co-occur with CRH in the median eminence in a way modulated by neonatal handling and stress (Bhatnagar and Meaney, 1995). It also has an important role in the consolidation of memory (De Wied, 1999) and could play a role in the conditioned physiologic responses found in PTSD (Pitman, Orr and Lasko, 1993). Arginine vasopressin (AVP) is secreted into the median eminence where it enters the portal blood circulation that brings it to the pituitary. Experiments in rats have shown that this is controlled indepently from CRH by axonal transport through AVP-containing versus AVP-deficient CRH neurons, and that under conditions of chronic or repeated stress plastic changes in hypothalamic CRH neurons evolve resulting in increased AVP stores and co-localization in CRH nerve terminals (De Goeij *et al.*, 1991). Also under conditions of chronic or intermittent stressful stimulation, a shift in hypothalamic signals for ACTH release in favour of AVP may ensue as it has been found in rats (De Goeij, Binnekade and Tilders, 1992). Experimental analysis in rats at the level of CRH and AVP responses in the PVN measured by primary transcript (heteronuclear) RNA and messenger RNA has confirmed that there is a desensitization of CRH, but not AVP transcription responses to repeated restraint stress. It has also been demonstrated that animals that adapted to a chronic homotypic stress show a greater response of CRH and AVP gene transcription in the parvocellular PVN after a novel, heterotypic stress. The hypothalamus clearly has the flexibility to adapt to homotypic stress while at the same time maintaining its ability to respond to novel stressors (Ma, Lightman and Aguilera, 1999). These experiments show that, with regard to the responses of the HPA axis, vasopressin is a mediator for the discrimination between chronic (homotypic) and acute (heterotypic) stressors, which can to some extent be controlled independently from CRH. In human depression not only an increase in CRH expressing neurones in the PVN was found, but also an increased co-expression of AVP and of AVP *per se* (Hoogendijk *et al.*, 2000). If PTSD is indeed the mirror image of depression it seems to be, the feedback of cortisol on the hypothalamus should be enhanced through parallel inhibition by another central mechanism.

CSF levels of the inhibitory neuropeptide somatostatin have been found to be elevated and to be correlated with the elevated CRH levels in PTSD patients but not in controls (Bremner *et al.*, 1997b). Somatostatin is known to inhibit the release of both CRH and ACTH (Richardson and Schonbrunn, 1981; Heisler *et al.*, 1982; Brown, Rivier and Vale, 1984). This points to the possibility that somatostatin is a pivotal link in the down-regulation of the LHPA axis.

The question that remains unanswered is what the advantage for survival of these lowered cortisol responses could be. The answer may be given by the fact that CRH gene expression in the brain is differentially stimulated by glucocorticoids. In the parvocellular region of the PVN, CRH gene expression is inhibited but in the central nucleus of the amygdala and in the lateral bed nucleus of the stria terminalis it is elevated. The elevation of CRH gene expression in these two nuclei may underlie a number of fear/anxiety or pathological states (Schulkin, Gold and McEwen, 1998). This is clearly applicable to PTSD, as we have seen, and it is almost too attractive as an explanation to presume that the organism has found a way to contain this limbic CRH fly-wheel by counter-regulation in order to protect the amygdala from unlimited positive feedback.

Glucocorticoid Receptor Gene Polymorphism

A possibility that has not been considered by researchers in the field of the psychobiology of PTSD until now, is the existence of a receptor polymorphism accounting for lower than expected circulating levels of cortisol and increased dexamethasone feedback sensitivity. In an epidemiological field study of an elderly population a close relationship was found between basal cortisol levels and the feedback sensitivity of the HPA axis to a low dose of dexamethasone, lower cortisol corresponding with higher feedback effect which looks the same, so far, as in PTSD. This suggested a genetic influence on the set point of the HPA axis. Over a two-and-a-half year follow-up period, individual characteristics remained fairly constant denying an effect of ageing on HPA activity or feedback sensitivity (Huizenga *et al.*, 1998a). Among 216 elderly people 13 heterozygotes for the N363S GR gene polymorphism (codon 363) were identified as showing increased cortisol suppression to 0.25 mg dexamethasone but no differences in GR number or ligand binding affinity on peripheral mononuclear leucocytes (Huizenga *et al.*, 1998b). In PTSD patients increased receptor numbers on lymphocytes have been found and a correlation with specific symptomatology which suggests that this is indeed a disease-specific phenomenon (Yehuda *et al.*, 1991). Nevertheless, this finding calls for control of receptor polymorphism in studies on the HPA axis of PTSD patients.

Overall View of HPA Axis Regulatory Abnormalities in PTSD

- The enhanced sensitivity of HPA feedback at the pituitary level and a down-regulation of the set point seem to be consistent.
- The anxiety-related CRH system which is intimately connected to central noradrenergic neurotransmission, is activated and is probably driven by the amygdala.
- The limbic-HPA down-regulation may be mediated by somatostatin and may serve as a counter-regulation to protect the amygdala from too much CRH gene expression by cortisol stimulation.

The Hypothalamo-Pituitary-Thyroid Axis

Much less work has been done on thyroid function in PTSD compared to the HPA axis. The first publication that is relevant

to cite in this work is from John W. Mason's group, which has accumulated the work on this topic so far (Mason *et al.*, 1994, 1995). Mason and his collaborators have substantiated their initial findings in several subsequent studies of which the highlights are that PTSD is accompanied by an increased level of free T_3 which is the biologically active form of thyroid hormone (*vide supra*). It was also correlated with hyperarousal (Wang *et al.*, 1995) and with novelty/sensation seeking and this finding coincided with positive correlations with urinary total NE and NE/cortisol ratio while it correlated negatively with urinary total cortisol (Wang *et al.*, 1997). It was not restricted to the population of American Vietnam veterans but was also found in Israeli veterans (Mason *et al.*, 1996) and older Second World War veterans who had suffered from PTSD over decades (Wang and Mason, 1999). The latter finding was accompanied by slightly, although not statistically significant, higher levels of TSH. The long duration of the psychiatric disorder made it unlikely that it was men with this pattern of thyroid axis hormones that were especially vulnerable to PTSD. Probably these changes are the result of the disorder, or part of the process (Prange, 1999).

In conjunction with the above discussion on CRH and hippocampal function in PTSD it is relevant to note that thyroid hormone causes long-lasting increases in hippocampal GR numbers through intermediate serotonergic projections (Sapolsky, 1997). On the other hand, there is an intricate relationship of thyroid function with noradrenergic neurotransmission which thus seems to support the arousal response and confirms the catecholamine findings by Mason's group. It is suggested that the excess of free T_3 is produced in the thyroid gland itself by direct sympathetic nervous control (Prange, 1999) but an increase of de-iodination by any of the multiple mechanisms that control it, such as transmembrane transport and tissue-specific de-iodinase, cannot be excluded. Free T_3 production has been reported to follow rapidly on the TSH surge after thyrotropin-releasing hormone administration before T_4 responds, which makes it indeed functional as an emergency response hormone.

GENERAL CONCLUSION

PTSD is one of the most extensively studied of the anxiety disorders concerning their psychoneuroendocrine properties. It consists of response patterns that are pathological in the sense that they continue and even may manifest themselves long after the initial stimulus has occurred. They show all features of the emergency response and these are detectable at all levels of neurobehavioural and metabolic regulation. The response patterns have become fixed like fossil imprints in stone although they may not be continuous but many of them phasic in nature. The marker hormones do not always act as we would have expected and this forces us to differentiate our understanding of these substances and their dynamics. The study of PTSD has enriched our knowledge substantially in this respect. It is highly probable that this will also lead to therapeutic innovations of which the CRH antagonists are among the most promising given the central role this neuromodulator plays in the congealed emergency response of post-traumatic stress disorder.

Neuroimmunology of Anxiety Disorders

Palmiero Monteleone

INTRODUCTION

There is unequivocal evidence that stress is both causally related and a concomitant of most psychiatric disorders, including anxiety syndromes. For example, the post-traumatic stress disorder typically arises after unusual stress life experiences. Panic disorder is a syndrome with anxiety as the core of the disease and panic attacks possibly representing repeatedly recurring stress episodes. The obsessive–compulsive disorder involves recurrent thoughts (obsessions), that are experienced as intrusive and senseless, and/or repetitive seemingly purposeful behaviours (compulsions); both obsessions and compulsions cause marked distress. In phobic disorders, the phobic fear is a potent stressor.

There is agreement in the literature that stress profoundly affects immune function. Therefore, since patients with anxiety disorders endure considerable stress, it is plausible to expect alterations of immune competence in these subjects. On the other hand, it has been demonstrated that immune elements, namely some cytokines, are able to induce 'ansiogenic-like' and/or 'depressive-like' effects in the animal (Anisman *et al.*, 1998; Dantzer *et al.*, 1998); hence, it is likely that changes in immune parameters following real-life stress may be involved in the aetiopathology of anxiety syndromes and/or symptoms. Conversely, one would expect that if alterations of immunity occur in anxiety disorder patients, treatments aiming to alleviate anxiety symptoms should restore immune parameters.

The purpose of this review is to first consider the effects of stress on immune function; then, the changes in immune system that are associated with different anxiety syndromes will be discussed; finally, the effects of both pharmacological treatments and psychotherapeutic interventions on immune parameters will be analysed.

STRESS AND IMMUNE FUNCTION

Early evidence for an association between stress and immune function in humans came from the demonstration that human susceptibility to infections was increased by stress events. Kissen (1958) suggested a link between recent loss of a love object and the morbidity and mortality of pulmonary tuberculosis. Other authors suggested that hypnotically induced stress reactivates herpes simplex infection in susceptible individuals (Ullman, 1947), whereas hypnosis itself was found to be able to reverse both immediate-type and delayed-type hypersensitivity to tuberculin (Black, 1963; Black, Humphrey and Niven, 1963).

There is a large body of literature showing that stress has a significant impact on immune function. Initially, human studies examining the effects of experimental (speech task and mental arithmetic task) and real-life stressors (academic examination stress, bereavement, unemployment, divorce, caring for patients with chronic diseases) suggested that stress is associated with reduced immune responsiveness, and therefore it may compromise immune function (Dantzer and Mormede, 1995). However, there is now agreement in the literature that stress may even enhance immune activity.

In bereaved widows and widowers, a suppression of mitogen-induced lymphocyte proliferation was noted (Schleifer *et al.*, 1983); similarly, divorce, separation and unemployment were reported to decrease lymphocyte mitogen reactivity (Arnetz *et al.*, 1987; Kiecolt-Glaser *et al.*, 1987). A blunted unstimulated proliferation of peripheral blood mononuclear cells (PBMC) was observed in Israeli civilians during the period of Scud missile attacks (Weiss *et al.*, 1996), while recently released prisoners of war in Bosnia showed altered immune functions with reduced number of natural killer (NK) cells (Dekaris *et al.*, 1993).

Subacute or chronic real-life stressors were shown to decrease the number or the percentage of T-helper ($CD4^+$) cells, the T-helper/T-suppressor ($CD4^+/CD8^+$) cell ratio, and the number of NK cells in peripheral blood (Glaser *et al.*, 1985; Bachen *et al.*, 1992). To the contrary, acute laboratory and naturalistic stressors were reported to transiently elevate the number of total T and B lymphocytes, $CD8^+$ cells and the NK cells in the peripheral blood of healthy subjects (Fittshen *et al.*, 1990; Brosschot *et al.*, 1992). Moreover, Maes *et al.* (1999a) reported that students who responded to academic examination stress with a strong psychological reaction showed an increased number of activated T cell leukocyte subset profile. Furthermore, in those students, modifications of immune profile were positively and significantly associated with the stress-induced increase in self-rated severity of perceived stress and negative emotions.

Similarly to what occurs in cell-mediated immunity, increases or decreases in humoral immune parameters were reported after stress experiences. Some authors found increased salivary levels of immunoglobulin (Ig) A, while others reported reduced salivary concentrations of these Igs after exposure to acute or subacute stressors (Jemmott and Magloire, 1988; Bosch *et al.*, 1996). Increased concentrations of serum IgA, IgM and IgG were found by Maes *et al.* (1997a) in students with high levels of stress perception following academic examination, but not in those with low stress perception. Moreover, academic examination stress significantly increased serum levels of the C3 complement factor as well as those of the acute phase (AP) protein α_2-macroglobulin. Furthermore, students with high stress perception had a trend toward significant increases in serum levels of the complement C4 factor and AP proteins haptoglobin and α_1-acid glycoprotein, whereas students with low stress perception exhibited a reduction of these immune parameters (Maes *et al.*, 1997a).

Several studies assessed the effects of stress on cytokine production in humans. Early reports showed that psychological stress did not affect plasma interleukin-1 (IL-1) or interleukin-6 (IL-6) concentrations (Dugué *et al.*, 1993) or decreased the production of interferon-γ (IFγ) or increased that of IL-1β (Dobbin *et al.*,

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

1991). Maes *et al.* (1998) and Song *et al.* (1999) found that academic examination stress significantly enhanced the production of proinflammatory cytokines, such as IL-6, tumour necrosis factor-α (TNFα) and IFγ, but decreased that of the 16kd Clara cell (CC-16) protein, a natural anti-inflammatory secretory protein. These data support the idea that the immune response to psychological stressors resembles that of organic stressors (injury, infection, necrosis), being characterized by the secretion of proinflammatory cytokines (IL-1, IL-6, TNFα) which, in turn, activate an AP response in order to cope with stress and minimize its impact on the homeostasis of the organism.

In sum, this brief review emphasizes that stress may suppress or enhance immune function depending on a number of variables, including the acute or chronic nature of stressors, the severity of the triggered stress response, the immune variable under consideration, the individual's perception of the stressor, the personality characteristics of the subject, and the nature of the stress-induced affective states.

SUBCLINICAL ANXIETY AND IMMUNE FUNCTION

Studies examining the relationships between subclinical anxiety and immunity are sparse. Linn, Lin and Jensen (1981) reported a negative correlation between anxiety and lymphocyte responses to mitogens in hospitalized patients. Decreased levels of salivary IgA were found in nurses with subclinical anxiety as compared to those without anxiety (Graham *et al.*, 1988); similar results were reported in dental students (Jemmott, Borysenko and Chapman, 1983). Moreover, healthy male students with high levels of subclinical anxiety had a significantly lower lymphocyte proliferative response to concanavalin A (ConA) as well as lower levels of circulating IL-1β (Zorrilla, Redel and DeRubeis, 1994). Among women undergoing adjuvant chemotherapy for breast cancer, those with high trait anxiety evidenced a reduced number of monocytes and $CD4^+/CD8^+$ T cell ratio, and a compromised activity of NK cells (Fredrikson *et al.*, 1993). Finally, a decreased lymphocyte proliferative response to phytohaemoagglutinin (PHA) was observed in healthy students with high anxiety scores independently from a previous history of life events (Gonzales-Quijano *et al.*, 1998).

On the contrary, a few studies suggested that subclinical anxiety may increase immune function. Indeed, a positive correlation was found between NK cell activity, IL-2 production and scores on the SCL-90-R anxiety subscale during an examination period in medical college students (Koh, 1996, 1997).

GENERALIZED ANXIETY DISORDER

La Via, Workman and Lydiard (1992) first reported that subjects with generalized anxiety disorder (GAD) and/or panic disorder (PD) had a significantly higher frequency of upper respiratory infections as compared with normal controls, which suggests a decrease of the immune defences in these individuals. Moreover, the same group of investigators (La Via *et al.*, 1996) showed that a 72-hour stimulation of peripheral lymphocytes with anti-$CD3^+$ induced a significantly lower expression of $CD25^+$ cell subtype in GAD patients with respect to healthy subjects.

Castilla-Cortazar, Castilla and Gurpegui (1998) investigated several immune parameters in 16 patients with GAD and five patients with obsessive–compulsive disorder (OCD). As compared to a control group, anxiety disorder patients showed increased number of monocytes and $CD13^+$ cells, normal counts of T lymphocytes, $CD4^+$ and $CD8^+$ T cell subtypes, and decreased number and activity of $CD16^+$ (NK) cells with a blunted lymphoproliferative response to PHA, and a normal *in vitro* production of IFγ from peripheral blood mononuclear cells (PBMC). Moreover, patients with anxiety displayed an anergy to candidin and tuberculin, alterations in the expression of both monocyte surface HLA-DR molecules (involved in the mechanisms of antigen presentation) and membrane CR1 receptors (important in phagocytosis of opsonized particles and microrganisms) as well as a reduced number of monocytes expressing cytoplasmic vimentin filaments, which are implicated in the cytoskeletal organization. Incubation *in vitro* of these monocytes with naloxone normalized the number of cells expressing vimentin filaments and their ability to ingest *Candida albicans*. These findings suggest that at least some immune alterations detected in patients with GAD may be dependent on an increased opioid tonus. Indeed, plasma levels of β-endorphins were found to be elevated in those patients.

Koh and Lee (1998) investigated cell-mediated immunity in a cohort of 31 patients, 20 with GAD and 11 with PD, and 31 healthy subjects. They found that both GAD patients and subjects with PD had reduced blastogenic responses to PHA and decreased PHA-induced IL-2 production. No significant differences were found in NK cell activity between the two patient groups and healthy subjects.

SIMPLE PHOBIA

It has been recently shown that phobic fear is a potent stressor, which results in increases of autonomic activity, NK cell percentages and cytotoxicity (Gerritsen *et al.*, 1996). These immune effects, however, seem to be influenced by the individual's level of worry. Indeed, people with spider or snake phobia who experienced high levels of trait worry showed a blunted increase in the number of peripheral NK cells after exposure to the phobic stimulus, whereas those with normal levels of worry showed a marked increase in this immune parameter (Segerstrom *et al.*, 1999).

One study reported that patients with agoraphobia had normal counts of peripheral $CD3^+$, $CD4^+$, $CD8^+$ and $CD57^+$ cells, normal value of the $CD4^+/CD8^+$ ratio and an increased frequency of $CD14^+$ cell types (monocytes) (Covelli *et al.*, 1990). Moreover, *in vitro* phagocytosis and killing of *Candida albicans* exerted by polymorphonuclear cells and monocytes were reduced in those patients. After an 8-week treatment with the synthetic thymic hormone, thymopoietin, the phagocytic capacity of monocytes significantly increased, whereas that of polymorphonuclear cells remained unchanged. Moreover, treatment with the thymic hormone led to a significant recovery of polymorphonuclear and monocyte killing capacity, even if values remained below the normal range (Covelli *et al.*, 1990).

SOCIAL PHOBIA

A limited number of studies investigated immune function in people with social phobia.

Rapaport and Stein (1994a) found normal levels of serum IL-2 and soluble IL-2 receptor (sIL-2R) in 15 patients with generalized social phobia, and suggested that these patients do not have evidence of T-lymphocyte activation. This hypothesis was supported by the findings of a subsequent study, in which patients with social phobia exhibited normal values of peripheral $CD3^+$, $CD4^+$, $CD8^+$, $CD19^+$, $CD25^+$ lymphocyte subtypes and B cells expressing HLA-DR molecules, with only a slight increase in the number of NK ($CD16^+$) cells (Rapaport, 1998).

PANIC DISORDER

The studies of circulating lymphocyte phenotypes in patients with PD have provided conflicting results. In particular, no difference in

total lymphocytes, leukocytes, T cells and B cells or decreased total lymphocytes and increased total T cells have been reported in PD patients (Schleifer *et al.*, 1990; Ramesh *et al.*, 1991; Andreoli *et al.*, 1992; Marazziti *et al.*, 1992). The number of $CD4^+$ and $CD8^+$ cell subtypes and the $CD4^+/CD8^+$ ratio were found to be normal in three studies (Schleifer *et al.*, 1990; Perini *et al.*, 1995; Rapaport, 1998), but decreased in another study (Marazziti *et al.*, 1992). The peripheral NK cell number has been reported to be mostly normal, with only one study reporting an increased value (Schleifer *et al.*, 1990; Marazziti *et al.*, 1992; Perini *et al.*, 1995; Koh and Lee, 1998; Rapaport, 1998). Two groups of investigators found increased values of $CD19^+$ B cells and lymphocytes expressing the HLA-DR antigen (Perini *et al.*, 1995; Rapaport, 1998), whereas Marazziti *et al.* (1992) detected normal values of these cells. Similarly, the $CD57^+$ cell number was reported to be normal in two studies (Marazziti *et al.*, 1992; Rapaport, 1998), but was decreased by another study (Perini *et al.*, 1995). Finally, $CD56^+$ cells and lymphocytes expressing the CD25 molecule, which is the surface receptor for IL-2, were not increased in patients with PD (Perini *et al.*, 1995; Rapaport, 1998).

The *in vitro* mitogen response of lymphocytes from PD patients has been found to vary within a wide range. Two studies reported normal blastogenic responses to PHA (Surman *et al.*, 1986; Brambilla *et al.*, 1992), two others found a reduced proliferative responses to ConA, Pokeweed mitogen (PWM) and PHA (Schleifer *et al.*, 1990; Koh and Lee, 1998), and one found increased blastogenic responses to PHA and ConA (Andreoli *et al.*, 1992).

Serum levels of immunoglobulins were investigated by Ramesh *et al.* (1991) who found increased concentrations of IgA, but normal values of IgM, IgG and IgE in PD patients as compared to normal controls. Brambilla *et al.* (1994) detected increased plasma concentrations of IL-1β in PD patients both before and after successful alprazolam therapy, whereas Rapaport and Stein (1994b) found normal serum levels of IL-1β, IL-1α and sIL-2R, with a slight but not significant increase in serum IL-2 levels. The finding of normal serum sIL-2R is consistent with the normal values of $CD25^+$ lymphocytes reported in these patients (Rapaport, 1998). Moreover, blood levels of TNFα in people with PD were reported to be the same as those from normal controls (Brambilla, Bellodi and Perna, 1999). Finally, *in vitro* experiments have shown a decreased production of PHA-induced IL-2 and a normal unstimulated synthesis of IL-2 and IL-3 from PBMC of panic patients (Koh and Lee, 1998; Weizman *et al.*, 1999).

The patient selection is likely the most relevant factor accounting for this discrepancy. Indeed, studies widely differed in the patient populations since they included subjects with or without agoraphobia, previous histories of major depression, and concomitant depressive disorders.

OBSESSIVE–COMPULSIVE DISORDER

Several lines of evidence suggest that some cases of children-onset obsessive–compulsive disorder (OCD) may have an autoimmune aetiology. Swedo *et al.* (1989, 1998) reported an increased incidence of OCD in paediatric patients with Sydenham's chorea, an autoimmune disease of the basal ganglia. These investigators showed that some children may develop obsessive–compulsive symptoms with motor and/or vocal tics in the aftermath of group A beta-haemolytic streptococcal infection, presumably on the basis of antineuronal antibodies, and introduced the term of paediatric autoimmune neuropsychiatric disorders associated with streptococcal infection (PANDAS) to characterize these patients. As in Sydenham's chorea, the pathogenesis of PANDAS is thought to be autoimmune. This idea is supported by the following: (a) autoimmune antibodies reactive with nuclei of the basal ganglia have been detected in some of these patients (Black, Lamke and Walikonis, 1998); (b) a temporal link between symptom exacerbation and streptococcal infection has been described (Allen, Leonard and Swedo, 1995); (c) a progressive clinical improvement has been observed in those patients undergoing antibiotic prophylaxis at dosages effective in preventing recurrent streptococcal infections (Leonard and Swedo, 2001). Furthermore, Murphy *et al.* (1997) found that the B lymphocyte antigen D8/17, a marker of vulnerability to rheumatic fever, was more common in patients with childhood-onset OCD than in comparison subjects, despite the absence of documented Sydenham's chorea or rheumatic fever.

Very recently, a case of a 25-year-old man who developed OCD after a severe antibiotic-responsive pharyngitis and exhibited increased levels of antibodies to group A beta-haemolytic streptococci has been described (Bodner, Morshed and Peterson, 2001). This subject had elevated serum D8/17 lymphocytes, positive antistriatal antibodies and positive anticytoskeletal antibodies. This case report suggests that post-streptococcal OCD may occur also in adult individuals.

Similarly to patients with major depression who produce antibodies against β-endorphin and somatostatin-14 (Roy *et al.*, 1988), patients with OCD have been shown to exhibit high circulating levels of antibodies for somatostatin-14 and prodynorphin 209–240, although the pathophysiological significance of these immune changes has not been clarified (Roy *et al.*, 1994). Finally, Khanna *et al.* (1990, 1997) documented higher levels of IgG in the blood and increased antibodies to herpes virus type-1 in the cerebrospinal fluid of subjects with OCD.

Investigations of cell-mediated and humoral immunity in people with OCD have provided conflicting results. Plasma levels of IL-1β have been reported to be normal by both Maes, Meltzer and Bosmans (1994) and our group (Monteleone *et al.*, 1998), but decreased by Brambilla *et al.* (1997). Serum levels of IL-6, sIL-2R, soluble IL-6 receptor (sIL-6R) and transferrin, an AP protein, have been found to be unchanged (Maes, Meltzer and Bosmans, 1994; Monteleone *et al.*, 1998), whereas plasma concentrations of TNFα have been detected to be reduced (Brambilla *et al.*, 1997; Monteleone *et al.*, 1998). *In vitro* assessment of IL-1β, IL-2 and IL-3 production from unstimulated PBMC of OCD patients did not display any alteration (Weizman *et al.*, 1996). Finally, Barber *et al.* (1996) did not find any change in T-lymphocyte subsets in a small sample of obsessive–compulsive patients, whereas Marazziti *et al.* (1999), in a study involving a larger group of adult patients with OCD, reported a significant increase in $CD8^+$ and a decrease in $CD4^+$ lymphocytes.

POST-TRAUMATIC STRESS DISORDER

Among the anxiety syndromes, post-traumatic stress disorder (PTSD) may be considered the prototype of stress-induced diseases. In fact, by definition, PTSD occurs in response to unusually stressful life events (extreme and catastrophic stresses). Given the above-mentioned relationships between stress events and immune activity, one would expect dramatic changes in immune parameters in people with PTSD.

Watson *et al.* (1993) first reported that Vietnam combat veterans with chronic PTSD, compared with healthy control subjects, had enhanced cell-mediated immunity, as assessed by means of delayed skin responsivity to a panel of antigens (CMI multitest). Ironson *et al.* (1997), instead, found that NK cell cytoxicity, $CD4^+$ and $CD8^+$ cell counts were significantly lower in PTSD patients, while the number of white blood cells was positively and significantly related to the severity of PTSD symptoms. Normal counts of $CD2^+$, $CD4^+$, $CD8^+$, $CD16^+$, $CD20^+$ and $CD56^+$ cell subtypes, and increased activity of NK cell activity were detected by Laudenslager *et al.* (1998) in combat veterans with long-term PTSD. Finally, significantly increased counts of total leukocytes, total lymphocytes,

T cells, $CD4^+$ and $CD8^+$ cell subtypes were reported by Boscarino and Chang (1999) in Vietnam veterans with current PTSD; moreover, in this study, patients exhibited a delayed cutaneous hypersensitivity, as assessed by the CMI multitest. This finding confirmed the occurrence of a delayed skin hypersensitivity in PTSD patients, previously reported by Watson *et al.* (1993). Recently, a normal lymphoproliferative response to PHA, but a reduced blastogenic response to tetanus toxoid (a specific recall antigen recognized by memory T cells) has been found in Gulf War veterans with a diagnosis of PTSD (Everson, Kotler and Blackburn, 1999).

With regard to humoral immunity, increased levels of serum IL-1β and normal values of sIL-2R have been detected in Israeli male veterans with PTSD (Spivak *et al.*, 1997). In this study, serum levels of IL-1β were positively correlated with the duration of the illness. Finally, Maes *et al.* (1999b) reported normal plasma levels of soluble IL-1 receptor antagonist, CC-16, glycoprotein 130 (gp130) and soluble CD8 antigen, but increased concentrations of IL-6 and sIL-6R in subjects with PTSD following accidental man-made traumatic events. Since serum sIL-6R mediates IL-6 signals, while serum gp130 has the potential to inhibit IL-6 signalling, the findings of Maes and coworkers suggest an increased IL-6 signal transducing and, consequently, an activation of the inflammatory response system in PTSD. These results, together with the above-reported observation of increased production of IL-1β in war veterans with PTSD (Spivak *et al.*, 1997), support the idea that proinflammatory cytokines may play a role in the development of anxiety subsequent to stressful traumatic events.

ANTIANXIETY TREATMENTS AND IMMUNE FUNCTION

Drug Treatments

Although several pharmacological agents are commonly used in the treatment of anxiety syndromes, we will focus exclusively on the immune effects of benzodiazepines (BDZs) and selective serotonin reuptake inhibitors (SSRIs), that are actually the most widely prescribed drugs for these disorders.

Benzodiazepines

Evidence that BDZs influence immune function emerged from studies showing the presence of BDZ receptors on immune cells. Peripheral-type BDZ receptors have been detected on immune cells of the experimental animal (Zavala, Haumont and Lenfant, 1984) and on human monocytes, polymorphonuclear neutrophils, B cells, NK cells, $CD4^+$ and $CD8^+$ cells (Canat *et al.*, 1992). It has been shown that activation of these receptors stimulates chemotaxis of human monocytes (Ruff *et al.*, 1985), enhances the production of reactive oxygen species (an essential step in oxygen-dependent phagocytic defence against pathogens) (Zavala and Lenfant, 1988), and modulates the production of proinflammatory cytokines such as IL-1β, TNFα, IL-6, IL-8 and granulocyte/macrophage-colony stimulating factor (Taupin *et al.*, 1991; Zavala *et al.*, 1991). Moreover, peripheral-type BDZ receptors have been detected also on microglial cells, which are considered the resident macrophages of the brain (Bender and Hertz, 1985), and their activation has been shown to enhance the production of IL-1, TNFα and IL-6 in the rat cortex after a fluid percussion trauma (Taupin *et al.*, 1993).

A number of studies suggest that anxiolytic BDZs reverse or attenuate the stress-induced immunosuppression. For example, chronic treatment with alprazolam, diazepam or imidazolam protects mice against the stress-induced decreases in thymus cellularity and weight, blastic response to ConA and NK cell activity (Freire-Garabal *et al.*, 1991a, 1991b). Partially consistent with animal data, Lechin *et al.* (1994) recently reported that chronic BDZ users without psychotic or depressive symptoms had lower-than-normal $CD3^+$, $CD4^+$ and $CD16^+ + CD56^+$ (NK) cell counts with a reduced $CD4^+/CD8^+$ ratio, and enhanced NK cell activity and $CD57^+$ cell number. After 15 days of BDZ discontinuation, some of these immune parameters ($CD3^+$, $CD4^+$ cell counts and NK cell activity) returned to normal values, others ($CD16^+$ cell number) persisted significantly lower than controls, while $CD4^+/CD8^+$ ratio and $CD56^+$ cell number exceeded normal values.

Selective Serotonin Reuptake Inhibitors

There are some indications that both acute and chronic administration of SSRIs may compromise cellular immune responses in the animal. For instance, fluoxetine administration has been reported to increase tumour growth and tumour formation following tumour transplantation and exposure to chemical carcinogens in rodents (Brandes *et al.*, 1992). In addition, acute fluoxetine has been shown to decrease immune cell infiltration and inflammation in rats following exposure to irritants (Bianchi *et al.*, 1995). Finally, either fluoxetine or sertraline have been shown to decrease NK cell cytolytic activity and lymphocyte proliferative responses (Pellegrino and Bayer, 1998; Pellegrino and Bayer, 2000).

Other studies, however, point to an immunopotentiating effect of prolonged administration of SSRIs to experimental animals. Indeed, chronic administration of sertraline has been shown to increase the percentage of neutrophils and enhance the proliferative activity of T-lymphocytes (Song and Leonard, 1994), while chronic treatment with fluoxetine has been reported to inhibit the growth of induced and spontaneous neoplasms in rodents (Bendele *et al.*, 1992; Abdul, Logothetis and Hoosein, 1995). It has been suggested that, at least in animals, SSRIs may exhibit both immunoenhancing and immunosuppressive effects depending on the type of drug and the duration of its administration (Kubera *et al.*, 2000).

With regard to human studies, although a direct assessment of the immune effects of SSRIs in people with anxiety disorders is lacking, there are some data *in vitro* and in depressed patients that support an immunosuppressive action of these drugs. For example, *in vitro* studies have shown that SSRIs decreased splenic lymphocyte proliferation (Berkeley *et al.*, 1994), while coincubation of mitogen-stimulated human immunocytes with fluoxetine, sertraline or citalopram significantly reduced the production of proinflammatory cytokines IL-1β, IL-6, IFNγ and TNFα and/or increased the production of IL-10, an anti-inflammatory cytokine, with a consequent decrease of the IFNγ/IL-10 ratio (Xia, DePierre and Nassberger, 1996; Maes *et al.*, 1999c). Moreover, it has been reported that some patients receiving fluoxetine for the treatment of a depressive condition experienced a reactivation of a herpes simplex infection or developed cutaneous pseudolymphoma lesions, that promptly reverted when the drug was discontinued (Reed and Glick, 1991; Crowson and Magro, 1995). In patients chronically treated with SSRIs, a significant reduction in the number of leukocytes and neutrophils, but no significant changes in the absolute number of PBMC and $CD4^+/CD8^+$ cell ratio have been reported (Maes *et al.*, 1997b; Kubera, Van Bockstaele and Maes, 1999). Moreover, subchronic treatment with fluoxetine has been shown to normalize the pathologically elevated blood levels of IL-6, α_1-acid glycoprotein and IL-2R in major depression (Maes *et al.*, 1995; Sluzewska *et al.*, 1995). To the contrary, a 12-week treatment with sertraline has been reported to not affect the abnormally increased plasma concentrations of IL-1β in dysthymic subjects (Anisman *et al.*, 1999), while both fluoxetine and fluvoxamine, administered for 3 months, did not influence plasma levels of IL-1β, IL-6 and TNFα in people with eating disorders (Brambilla *et al.*, 1998).

The exact mechanisms by which SSRIs exert their activity on immune functions are still unknown. It has been suggested that the immune effects of SSRIs are mediated by endogenously released serotonin (5-HT). Indeed, in animals depleted of endogenous 5-HT

stores, the administration of both fluoxetine and sertraline was not able to reduce lymphocyte proliferative responses (Pellegrino and Bayer, 2000). Moreover, it has been shown that T-lymphocytes constitutively express 5-HT receptors as well as the high-affinity 5-HT transporter system (Aune, Golden and McGrath, 1994; Faraj, Olkowski and Jackson, 1994).

Psychotherapeutic Interventions

Further to initial reports of immune effects of hypnosis (Ullman, 1947; Black, 1963; Black, Humphrey and Niven, 1963), the effects of psychotherapeutic interventions on immune function have been assessed in two categories of subjects: (a) patients dealing with different types of cancer; (b) healthy subjects exposed to different kinds of stressors.

The effects of short-term (6 weeks) structured cognitive-behavioural therapy on immune parameters were evaluated by Fawzy *et al.* (1990) in patients with post-surgical malignant melanoma. At the sixth-month evaluation point, along with a reduction in levels of psychological distress and greater use of active coping methods, patients in the intervention group exhibited significant increases in the percent of large granular lymphocytes and NK cells along with an increase in NK cytotoxic activity and a small decrease in the percent of $CD4^+$ cells. In post-surgical early-stage breast cancer patients, a 10-week cognitive-behavioural intervention programme induced a significant increase in the number of circulating lymphocytes (Schedlowski *et al.*, 1994). Finally, in the study of van der Pompe *et al.* (1997), cancer patients who had been treated for early-stage breast cancer and were diagnosed with either positive axillary lymph nodes or distant metastases, were assigned to a 13-week experimental–existential group psychotherapy (EEGP) or to a waiting list control condition (WLC). EEGP patients with a higher percentage of $CD4^+$, $CD8^+$ and $CD16^+/56^+$ T-lymphocytes at baseline had lower post-treatment percentages than their counterparts in the WLC with similar initial levels. Similarly, those EEGP patients with the highest lymphoproliferative response to PWM at baseline had smaller post-treatment responses than patients in the WLC. These authors, on the basis of literature suggestions showing that lower percentages of NK and $CD8^+$ cells were associated with a better prognosis in cancer patients, speculated that EEGP by normalizing increased immune parameters may positively affect the outcome of these patients.

Several groups have studied the effects of psychotherapeutic interventions on stress-induced immune changes. After a 1-month intervention period, geriatric patients who received relaxation training reported a decrease in distress symptoms coupled with increased NK cell cytotoxicity and decreased antibody titres to latent herpes simplex virus (Kiecolt-Glaser *et al.*, 1985). In a study by Peavy, Lawlis and Goven (1985), in subjects with high life stress scores coupled with poor phagocytic capacity, a biofeedback-assisted relaxation training significantly enhanced neutrophil activation capacity, suggesting a qualitative improvement of phagocytic ability. In a subsequent study (Green and Green, 1987) a single 20-minute relaxation session resulted in a significant increase in salivary IgA concentrations. Finally, in males at high risk for HIV-1 infection, significant positive correlations were found between the frequency of relaxation procedures and the number of $CD4^+$, $CD8^+$, NK cells and the $CD4^+/CD8^+$ ratio during the high stress week of serostatus determination (Antoni *et al.*, 1990).

Two studies examined the effects of self-hypnosis/relaxation intervention on immune changes induced by academic examination stress in medical students. The first one (Kiecolt-Glaser *et al.*, 1986) showed that the hypnosis/relaxation programme prevented exam-related increases in distress symptoms, but did not influence immune parameters. Indeed, both the intervention and control groups showed significant decreases in the percentages of $CD4^+$ lymphocytes and NK cell activity at the examination time; however, the frequency of the relaxation procedures was a good predictor of the increases in the $CD4^+/CD8^+$ cell ratio during the exam period. The second study (Whitehouse *et al.*, 1996) demonstrated that significant increases in the number of B lymphocytes, activated T-lymphocytes, PHA-induced and PWM-induced blastogenesis and NK cytotoxicity occurred during the examination period in both students assigned to a self-hypnosis/relaxation intervention and in those assigned to the control group. Nevertheless, within the self-hypnosis group, the quality of relaxation exercises predicted both the number of NK cells and their cytotoxicity.

Finally, it has been very recently reported that, in medical students undergoing academic examination, massage therapy induced a significant increase in the total number of white blood cells with a decrease in the percentage of T cells, no significant changes in the lymphocyte responses to mitogens and a significant increase in the killing activity of NK cells (Zeitlin *et al.*, 2000).

CONCLUSIONS

The existing literature is highly controversial and fraught with several methodological problems. The diagnostic heterogeneity of the subject samples is certainly one of the most relevant factors contributing to the inconsistency of the results. Indeed, in some studies patients were suffering from pure anxiety disorders, in others patients had concomitant major depressive disorder or positive histories of previous depressive episodes. Moreover, most of the studies did not include healthy controls matched to patients on age and gender; as there may be age-dependent alterations (Weksler, 1983) and gender-specific differences (Oyeyinka, 1984) in immune function, these factors must be taken into account in this kind of research. Furthermore, patients differed on the duration and/or severity of the illness, personality characteristics and treatment status. This last variable is particularly relevant in light of the immune effects of both BZD and psychotherapeutic techniques. Differences in both methodology (e.g., evaluation of absolute number of lymphocytes versus lymphocyte percentages, assay techniques) and/or immune parameters investigated may also add to the variability of results. Finally, smoking, excessive drinking, disturbed sleep and poor nutrition are known to affect immune function (Locke and Gorman, 1989), hence variations of these behaviours may further explain controversies among the studies.

All these factors limit the interpretation and generalization of the findings. Notwithstanding, there is unequivocal evidence that immune changes do occur in anxiety disorders, with the majority of studies suggesting an impairment of the immune function in these syndromes. Only PTSD seems to be associated with an immune enhancement rather than immunosuppression. It has been suggested that the increase in immune activity in patients with PTSD may have a pathogenetic role (Spivak *et al.*, 1997; Maes *et al.*, 1999b). Moreover, there is consistent evidence that at least some cases of childhood-onset OCD may have an autoimmune aetiology, possibly linked to the streptococcal infection and rheumatic fever. Finally, it has been almost uniformly reported that psychotherapeutic interventions aiming to alleviate anxiety symptoms potentiate immune functions, whereas antianxiety drugs may have both immunoenhancing and immunosuppressive effects.

In conclusion, whether in anxiety disorders immune changes occur as a consequence of the psychological distress or are primitive and aetiopathogenetically linked to the disorders themselves, it becomes more evident every day that they are part of the biological substrate of these syndromes and, as such, they are worthy of every effort by both clinicians and researchers in order to better

understand their implications in the course and the treatment of anxiety disorders.

Psychophysiology of Anxiety Disorders

G. Wiedemann and A. Mühlberger

INTRODUCTION

The use of psychophysiological methods in the assessment of a condition and the evaluation of treatment can be separated from research on mechanisms in the aetiology of fear (see also Hugdahl, 1989). In the following section, we will focus on condition assessment and treatment evaluation. For an extended discussion of experimental research on the mechanisms of fear, we refer you to the corresponding section in this book or to the *Handbook of Psychophysiology* (Bradley, 2000; Öhman, Hamm and Hugdahl, 2000).

The investigation of anxiety in psychophysiological research has a long history and is based on the dualistic view of emotions as consisting of both a cognitive and a somatic component (James, 1884). Obvious changes in different physiological systems, such as pounding of the heart, sweaty palms, and trembling hands upon confrontation with fear-eliciting stimuli, indicate the importance of physiological assessments, especially in anxiety disorders. The physiological reactions may tell us not only about the intensity of fear, but also about the quality of fear responses. In current psychophysiology research, a three-system concept of fear and emotion (Lang, 1968; Foa and Kozak, 1993) is widely accepted. The phobic reaction is seen as consisting of three loosely coupled components: psychophysiological responses, cognitive reports, and avoidance behaviour (Lang, 1971). As the three systems do not always react to the same extent or in the same temporal course (e.g. Rachman, 1977), the assessment of fear responses in all three component levels is recommended (e.g. Hugdahl, 1989). Many of the issues arising regarding one anxiety disorder may be equally applicable to other anxiety disorders. Research on panic disorder, for instance, may be difficult because of diagnostic co-morbidity, particularly with depression. On the other hand, the issue of the nature of the stimuli used to elicit physiological responses is illustrated by disorders such as post-traumatic stress disorder.

This paper is subdivided according to the Diagnostic and Statistical Manual (DSM-IV, American Psychiatric Association, 1994) diagnoses of the different anxiety disorders: (1) phobias; (2) panic disorder (PD); (3) generalized anxiety disorder (GAD); (4) post-traumatic stress disorder (PTSD); and (5) obsessive–compulsive disorder (OCD).

PHOBIAS

Phobias are subdivided into three subcategories: specific phobia; social phobia and agoraphobia.

Specific Phobia

No evidence of abnormal reactions of subjects (Ss) with specific phobia was found if no phobic context was present (Klorman, Weissberg and Wiesenfeld, 1977; Lang, Cuthbert and Bradley, 1998b). However, there is clear evidence for differences during exposure to phobic stimuli. The most established paradigm is to compare phobic Ss with control Ss in their reactions to phobic stimuli (e.g. spider pictures) in contrast to neutral, pleasant, or unpleasant stimuli. Early investigations focused on responses of the autonomic nervous system (ANS, e.g. heart rate (HR), skin conductance (SC) and respiration). More recently, focus was drawn to protective reflexes (e.g. startle response (SR), measured by corrugator electromyography (EMG) upon exposure to electric shocks or loud noise) and direct central nervous system (CNS) parameters, e.g. EEG/EP (evoked potentials). Spontaneous EMG measures were most frequently used to measure frontalis or forearm extensor muscle activity. The results were inconsistent (see e.g. review by Sartory and Lader (1981). Hamm *et al.*, (1997) found no significant group-specific differences in corrugator EMG in animal and mutilation phobic Ss during perception of phobic or neutral pictures. This seems to reflect heterogeneity of EMG reactions among subjects. This would be confirmed by subjective evaluations. Phobic Ss quite commonly experience mixed feelings of muscles becoming weak or tense (Hugdahl and Öst, 1985).

Many studies dealing with specific phobias investigated selected fearful, but non-clinical Ss. Since these Ss were comparable to diagnosed phobic Ss in many measures, selected investigations including analogous samples will be included in this section. Fearful samples without a clinical diagnosis are described as fearful Ss whereas diagnosed samples are described as phobic Ss.

According to the DSM IV, phobias can be subdivided in five types: animal type; natural environment type; blood-injection-injury type; situational type and other type. Most research was done on the animal type, the blood/injection/injury type and the situational type (e.g. flight phobia). The following sections will deal with these three types only.

Animal Type Specific Phobia

The autonomic system activity profile is dominated by a strong activation of the sympathetic branch. SC level (SCL) is considered a good candidate for measuring sympathetic activation, because the electrodermal system is thought to be controlled exclusively by the sympathetic part of the autonomic nervous system (Bradley, 2000). Nevertheless, there are some drawbacks. Firstly, sweat gland activity relies on a cholinergic mechanism rather than an adrenergic mechanism like most other sympathetic actions. Secondly, it is assumed that there are different types of sweating (e.g. Dawson, Schell and Filion, 2000). It is possible, for example, that sweating of the palms, which is most commonly measured, is an effect of parasympathetic regulation (Guyton and Hall, 1996). Nevertheless, SC reaction (SCR) is reliably modulated by emotional arousal in perception, anticipation and imagination (Bradley, 2000) and

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

many publications used SCL as an index of sympathetic activation (Sartory, 1983; Hugdahl, 1989; Bradley, 2000). In laboratory settings, the SCR upon presentation of emotional (e.g. phobic) pictures is widely investigated. Geer (1966) showed an increased SCL for spider phobic Ss compared to control Ss during the perception of spider pictures. Wilson (1967) was able to show the same effects when pictures were presented tachistoscopically. This suggests that conscious perception is not necessary for this type of reaction.

Special focus was drawn to the underlying mechanism of these autonomic responses. Öhman and Soares (1994) exposed selected snake- and spider-fearful Ss to masked- and non-masked phobic and control pictures in a backward masking paradigm. SCR of phobic Ss was enhanced in the unmasked as well as the masked condition only upon exposure to their phobic stimuli (snakes or spiders). Further, snake phobic Ss rated snakes as more arousing and more negative in valence (with similar results for spider phobic Ss upon exposure to spider stimuli). This suggests that SCRs are individual rather than evolutionally prepared. Guided by these results, Öhman and Soares (1994) proposed a pre-attentive perceptual analysis of physical stimuli characteristics by a supposed '*physical feature detector*'. This feature detector can activate the arousal system. Van den Hout and co-workers (2000) tested the hypothesis of the '*physical feature detector*' (Öhman and Soares, 1994) by exposing spider phobic Ss (DSM-IV) to words (fear-related, general threat and neutral) instead of pictures. Control Ss were not included. As expected, the researchers found the strongest reaction of phobic Ss to phobia-related words, followed by progressively milder reactions to common threat words and neutral words during unmasked presentation. In the masked condition, spider phobic Ss reacted more strongly to general threat words and phobia-related words than to neutral words, but reactions did not differ between spider words and threat words. It was concluded that pictures are processed as words semantically, that the hypothetical significance evaluator (Öhman and Soares, 1994) directly influences the arousal system and that for this process, no conscious perception is required (Van den Hout, De Jong and Kindt, 2000).

Additionally, cardiovascular measures verify the sympathetic dominance in animal phobic Ss during anticipation or perception of phobic pictures. Spider or snake phobic Ss show strong HR acceleration, whereas control Ss show HR deceleration (e.g. Klorman, Weissberg and Wiesenfeld, 1977; Cook *et al.*, 1988). The HR acceleration in phobic subjects is accompanied by an increase in peripheral resistance in skin blood vessels (vasoconstriction measured by a decrease in digit pulse amplitude) and a decrease in peripheral resistance in muscle blood vessels (vasodilatation, measured by an increase of forearm blood volume) (e.g. Kelly, 1980). Furthermore, an increase in average blood pressure was found (Hamm *et al.*, 1997). To summarize, cardiovascular responses and SCR suggest that confrontation with phobic stimuli results in a defensive reaction (DR) (Sokolov, 1963) in phobic Ss, but an orientation reaction (OR) Sokolov, 1963) in non-phobic comparison Ss. For a review of the OR/DR literature see for example Öhman and co-workers (2000). According to the idea that the phobic reaction is a DR and includes the activation of a fight–flight system (Lang, 1968), not only the sympathetic nervous system should be activated, but also behavioural avoidance as well as protective reflexes (e.g. acoustic SR (ASR)) should be facilitated (Lang, Bradley and Cuthbert, 1990). To test this hypothesis, Hamm *et al.* (1997) assessed blood pressure (BP), HR, and eyeblink reflex (ASR, measured by orbicularis occuli EMG reaction to sudden, loud noise) during the perception of spider/snake pictures. In a second part of the experiment, subjects were able to stop the presentation themselves. An increased ASR during the perception of phobic stimuli was found only in animal fearful Ss, but not in control Ss. No differences between groups were found for neutral, pleasant or unpleasant pictures. Additionally, fearful Ss showed a strong avoidance reaction. While control Ss looked at spider/snake pictures and neutral pleasant/unpleasant pictures for the same length of time, fearful Ss stopped examining spider/snake pictures after a few seconds. Globisch *et al.* (1999) studied the temporal course of ASR potentiation. The researchers found a *relative* potentiation of the ASR beginning 300 ms after the onset of phobic pictures in animal fearful Ss. Furthermore, increased SCR, HR and average BP reaction were found. Similar results were observed when pictures were shown only for 150 ms, with the exception of the blood pressure (BP) reaction. Further research is necessary to differentiate whether this fast onset of relative startle potentiation is a result of reduced pre-pulse inhibition due to rapid encoding of the threat cue, or due to the fast onset of fear-potentiated startle response (Globisch *et al.*, 1999).

Central nervous measurements of phobic responses focus on alpha activity (8–13 Hz) and different features of Event-Related Potentials (ERPs). Within the ERPs, the Contingent Negative Variation (CNV), which occurs between signal stimulus, and target stimulus, e.g. in conditioning paradigms, and the P300 after stimulus presentation were investigated. Unfortunately, results are inconsistent. Larger (more negative) CNVs were observed in phobic subjects anticipating phobic stimuli compared to subjects awaiting neutral stimuli (e.g. Dubrovsky, Solyom and Barbas, 1978); however, smaller (less negative) CNVs have also been observed under these conditions (e.g. Lumsden, Howard and Fenton, 1986). To summarize, it seems that smaller CNVs may be associated with phobic fear states (Hugdahl, 1989).

Not only the perception of phobic stimuli results in physiological reactions. Memory retrieval or imagery of phobic stimuli (spiders/snakes) in animal phobic Ss results in sympathetic activation. Imagery is typically realized by presenting a script to the subject with instructions to imagine the presented situation. Scripts can be standardized or created with respect to individual fear stimuli (Cuthbert and Lang, 1989). Different investigations showed that even very short scripts of a few seconds in duration can induce subjective anxiety as well as physiological activation (e.g. Vrana, Cuthbert and Lang, 1986; Bradley, Land and Cuthbert, 1991).

Lang and co-workers (1970) showed accelerated HR in snake phobic Ss during imagery. This acceleration was linearly correlated with subjective fear, and could be enhanced by including more extensive use and description of text portions describing a reaction to stimuli in the imagery script (Lang *et al.*, 1980, 1983). In addition to this HR acceleration, Watson and Marks (1971) and Marks and co-workers (1971) verified an acceleration of spontaneous SC fluctuations (SCF) correlated with the extent of reaction-describing material in imagery scripts. Hamm *et al.* (1992) showed increased HR along with enhanced ASR in spider/snake phobic Ss during presentation of short, 12-second scripts. Compared to control Ss and neutral scripts, this increase was even higher during a period of imagery following the script presentation. This study also involved presentation of different picture categories (e.g. phobic, neutral). No differences between perception and imagination were found.

Another important application of psychophysiology is the evaluation of treatment outcome. As the presentation of real spiders within the laboratory is relatively inexpensive, *in vivo* confrontation as well as Behaviour Avoidance Tests (BAT) have been quite thoroughly investigated. Öst (1996) compared the effects of small and large therapy groups in a one-session exposure treatment of spider phobia. Significant time effects, but no group differences were found in any variable. Self-rating anxiety, assessor's rating of anxiety severity and BAT performance as well as systolic BP (SBP), diastolic BP (DBP) and HR during the BAT were improved after the therapy. The improvements were maintained up to a 6-month follow-up.

Watts, Trezise and Sharrock (1986) compared treated and untreated spider phobic Ss in a modified Stroop Test (Stroop, 1938). In this reaction time paradigm, they presented spider-related and control words in different colours. The Ss' task was to name

the colour while ignoring the semantic word. Untreated Ss were severely retarded in naming the colour only for spider-related words (see also Mathews and MacLeod, 1985), while treated Ss were not. This effect probably is suppressed when measured directly before or during exposure treatment (Armir *et al.*, 1996). This paradigm allows the investigation of attentional aspects through psychophysiological methods. De Jong *et al.* (1992) additionally showed that the amount of covariation bias (Tomarken, Mineka and Cook, 1989), which is found in untreated spider phobic Ss, has decreased in treated Ss. The covariation bias seems to measure cognitive changes and may be used in outcome or relapse prediction (De Jong *et al.*, 1992). Another noteworthy predictor of treatment success is the initial HR response during perception of phobic pictures, as found by Lang (Lang, Bradley and Cuthbert, 1998a).

Blood/Injection/Injury Type Specific Phobia

Symptoms such as weakness, dizziness, and fainting or near-fainting while being confronted with phobic stimuli are more common in blood/injury phobia than in any other type of phobia. This very different type of reaction is also shown in psychophysiological measures. Enhanced sweat gland activity, measured by SC, was not found in blood/injury phobic Ss as compared to control Ss (e.g. Hamm *et al.*, 1997). Furthermore, no HR accelerations were found, as had been observed in other phobia types. However, after a short acceleration phase, strong HR decelerations were found, accompanied by a drop in mean BP (e.g. Hamm *et al.*, 1997). Blood/injury fearful subjects do not respond with a relative enhancement of sympathetic activation when exposed to their fear-relevant pictures, as do other phobic Ss. Interestingly, enhanced ASR was also found in blood/injury phobic Ss (e.g. Hamm *et al.*, 1997). Therefore, Hamm *et al.* (1997) concluded that the startle probe methodology provides important information for the clinical assessment and the evaluation of treatment outcome in phobias.

Situational Type Specific Phobia

We would like to present flight phobia as one prevalent and specific situational phobia. In the investigation of flight phobia, excellent ambulatory psychophysiological studies have been recently conducted by Wilhelm and Roth at Stanford University.

One study investigated the effect of benzodiazepine (alprazolam) on acute subjective and physiological responses during and following real flights in 28 flight phobic women (Wilhelm and Roth, 1997). Interestingly, alprazolam reduced self-reported anxiety and symptoms more than placebo, but induced an increase of HR and respiratory rate. In a second flight two weeks later, none of the Ss received alprazolam. However, subjects who had received alprazolam before the first flight indicated more anxiety, experienced panic attacks more often, and showed further increased HR during the second flight, compared to the placebo group. Wilhelm and Roth concluded that alprazolam increases physiological activation during acute stress situations and hinders therapeutic effects of exposure.

Another goal was to establish valid measures of HR response due to emotional activation. Therefore, the ability to distinguish whether HR increases are due to exercise or due to emotional response is necessary. This is especially important in ambulatory settings, where body movements or speech behaviour cannot be prevented. These sources of potential artefacts (e.g. walking, speaking) are essential to realize a natural setting. An early attempt to discriminate emotionally induced from exercise-induced HR increases involved an estimate of exercise-induced HR increases by measurement of oxygen consumption (Blix, Stromme and Ursin, 1974). By regression analysis, this source of variance was excluded and the resulting *additional* HR was attributed to emotional activation. Wilhelm and Roth (1998b) substituted the estimation of exercise due to oxygen consumption for practical reasons with a measurement of respiratory minute ventilation. Twenty-eight flight phobics and 15 control Ss were examined in different situations before and during a real flight. Previously, Ss completed different exercise tasks in the laboratory to obtain a function for the estimation of exercise-induced HR increases. The computed additional HR could be used to distinguish the phobic group from the control group during the walk to the airplane, which was not possible by examining HR or HR difference. During the flight, there were no differences, because exercise variation was negligible. One shortcoming of this technique is that anxiety-induced hyperventilation may distort the results. In another article, Wilhelm and Roth (1998a) described different physiological measures that were recorded in flight phobics and control Ss before, during and after a real flight. They were able to distinguish flight phobics from control Ss by measuring increased additional HR, more SC fluctuations, and less respiratory sinus arrhythmia during flight. By using the additional HR measure, they were able to classify 90% of flight phobics correctly. No differences between groups were found when respiratory rate or minute ventilation was recorded. For comparison, Sartory, Roth and Kopell (1992) also found encouraging results while investigating ambulatory assessment of driving phobia. They compared driving phobic Ss (e.g. avoidance of freeway drives for more than one year) with control Ss while performing different driving-related tasks within a BAT. Increased HR and respiratory minute volume were observed, but no differences in T-wave amplitude, respiratory sinus arrhythmia or respiratory rate were observed.

A new tool for the investigation and treatment of phobias is virtual reality. Virtual reality makes it possible to investigate states of phobic anxiety within a naturalistic, but highly controllable and repeatable setting. Mühlberger *et al.* (2001) compared the effect of repeated exposure to flights in virtual reality (VR) on flight phobics with effects resulting from relaxation training (RT). To test the effects, fear reports and physiological response were assessed during additional short virtual flights before and after the treatment. A decrease in subjective fear, SCL and HR reaction was found in both groups, but SCL and fear reports in the VR group were reduced compared to the RT group. Furthermore, a stronger initial HR response correlated highly with post-treatment fear of flying reduction at least up until a 3-month follow-up. Substantial correlations were only found in the VR group, and not in the RT group (Mühlberger, 1997). This may be in part due to the smaller changes within this group. However, it may also be the case that the predictive value of initial HR response is especially high in exposure-based treatments.

Social Phobia

An overview of earlier research on psychophysiology in social phobia is given by Öst (1989). Typically, giving a speech (e.g. in the paradigm of public speaking) or having a conversation with an unknown person (especially of opposite sex) is used as an anxiety-provoking stimulus in laboratory settings. Turner, Beidel and Larkin (1986) compared 26 socially anxious Ss and 26 non-socially anxious Ss with a clinical sample of 17 social phobics. During an impromptu speech, both the anxious and phobic group had higher SBP than the non-socially anxious Ss. DBP and HR did not differ between groups. In selected socially anxious and non-socially anxious students, Panayiotou and Vrana (1998) found no HR differences due to self-focus instructions while performing a digit rehearsal task, and an increased ASR only in socially anxious Ss. Lang (1993) compared speech fearful Ss with spider-fearful Ss during an impromptu speech *in vivo*

as well as *in sensu*. Increased HR was found in speech fearful Ss and also in spider-fearful Ss, with no difference between the two groups. McNeil *et al.* (1993) were able to verify these results in a clinical sample. They found an increase in HR during the imagination of a scene most fearful for the individual being tested, but observed no difference in HR increase compared to dental phobic Ss. In a second analysis, Ss were divided based on questionnaires into two subgroups: a fear group and an avoidance group. The fear group (14% assigned) showed a strong increase in HR correlating with their subjective fear, whereas the avoidance group (71% assigned) showed only a small increase. However, both groups subjectively stated experiencing strong anxiety and vivid imaginations. Turner and Beidel (1985) also found a high correlation between strong physiological reactions (BP) and subjective fear as major symptom after splitting their sample into high and low physiological responders. Similar results were described by Heimberg *et al.* (1990). They found stronger HR accelerations but less subjective fear in speech fearful Ss giving a talk or interacting socially than in Ss with a diagnosis of social phobia of the *generalized type* (Specifier of DSM-IV diagnosis). Levin *et al.* (1993) replicated these results by comparing specific social phobics and generalized social phobics. Hofmann *et al.* (1995) compared social phobics with and without avoidance personality structure and control Ss. Phobics without personality disorder reacted with a stronger HR increase than the other two groups, whereas phobics with additional personality disorder reacted with more subjective anxiety than the other two groups while presenting a public speech.

In treatment outcome studies, usually a decrease in physiological response, but no differences in treatment comparison tests were found. Jerremalm, Jansson and Öst (1986) divided 38 patients into physiological or cognitive reactors and assigned them either to applied relaxation (AR), self-instructional training (SIT), or waiting list (WL) group. They found a reduced HR reaction during a conversation test after AR and SIT compared to the WL group in physiological reactors, but no treatment group differences.

One major challenge in research involving social phobia or agoraphobia is the confusion of cognitive demand or motor exercise with emotional activation. One strategy for dealing with this difficulty is to disentangle these two sources of variance by manipulating the anxiety (e.g. Ss are observed by authorities or not) or the demand parameters (e.g. known or unknown speech topic (e.g. Erdmann and Baumann, 1996). Another strategy is to simply use the anticipatory anxiety, measuring the physiological states during expectation of giving an impromptu talk (e.g. Davidson *et al.*, 2000). Recently, Davidson *et al.* (2000) published an interesting article comparing the ANS responses and spontaneous EEG alpha power values of 18 social phobics with those of 10 control Ss. HR was elevated among phobics in most conditions. Furthermore, a marked increase in right-side activation of the anterior temporal and lateral prefrontal brain regions was found in social phobics. These EEG and HR measures explained more than 48% of the variance of the negative affect during speech anticipation. Like the results of Wilhelm and Roth, this indicates that when using physiological parameters within the correct paradigm, subjective anxiety can be predicted very well.

The results indicate that based on the phobic reaction, social phobia can be divided into two subgroups, simple phobia-like and generalized or agoraphobia-like. The two subgroups seem to reflect the different diagnoses in social phobia. One subgroup may reflect the simple diagnosis social phobia, the other one the diagnosis social phobia with specifier *generalized* (or even the additional diagnosis of a personality disorder). These promising results in distinguishing different types of social phobia might prompt a broader use of psychophysiology in further research of social phobia.

Agoraphobia

An overview of the earlier research on the psychophysiology in agoraphobia is given by Öst (1990). In some laboratory assessments, a general increased ANS activation without anxiety-eliciting stimulation could be found (Öst, 1990). This increase is accompanied by reduced habituation. Interestingly, the reactions to phobic stimuli or imagery tend to be less intensive than in specific phobia. Cook *et al.* (1988) compared the reaction of specific phobic, social phobic and agoraphobic (with PD) patients during imagery of phobic scripts describing their most feared scene. It was found that all three groups of patients rated their subjective fear-related cues as very arousing and highly unpleasant. However, when ANS responses were examined, simple phobics showed the largest and agoraphobics the smallest overall reactivity (HR and SCL changes). Specific phobics also showed a strong correlation between subjective anxiety and physiological reactions, whereas agoraphobic Ss did not. Cuthbert *et al.* (1994) replicated these results and found in addition a general increased level of ASR reactions during phobic and neutral imagery as well as between imageries, but the modulation of the ASR by emotional content as in social or specific phobics was not found (see Figure XIX-7.1, adapted by permission of the author). The presentation of external stimuli led to the same results as *in vivo* exposure (e.g. Fisher and Wilson, 1985). Unfortunately, like in social phobia, *in vivo* exposure or ambulatory assessments are often confounded by motor exercise. For instance, having a walk is a common paradigm in the assessment of agoraphobia. As discussed above, it is difficult to disentangle the different sources of physiological changes. It is not possible to state whether the HR acceleration during *in vivo* exposition (e.g. having a walk) commonly found not only in agoraphobics but also in control Ss is due to artefacts or the lack of differences between these groups. Therefore, the use of different physiological measurements (e.g. including respiratory) and methodological improvements in ambulatory measurements (see e.g. Wilhelm and Roth, 1998b) is strongly recommended in the assessment of agoraphobia.

In treatment studies, an overall HR reduction during different tasks was found (see Öst, 1990). Öst, Jerremalm and Jansson (1984) found a reduction of HR reactivity through both exposure and relaxation training. Bonn, Readhead and Timmons (1984) found (upon follow-up measurement) *in vivo* exposition combined with breathing retraining to be superior to *in vivo* exposition alone. Michelson *et al.* (1990) compared paradoxical intervention (PI), graduated exposure (GE) and relaxation training (RT). Only RT and

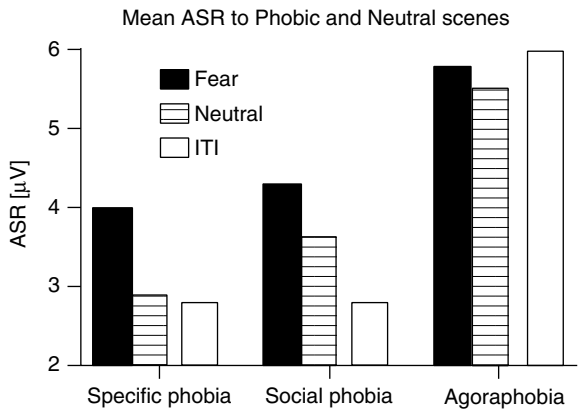

Figure XIX-7.1 Average acoustic startle responses (ASR) during the imagery of phobic or neutral scenes and during the Inter-Stimulus-Interval (ITI) for patients of these phobias. Adapted by permission from Cuthbert *et al.*, © 1994 by B. Cuthbert

GE led to substantial reductions in HR reactivity. No correlation between pre-treatment physiological reactivity and therapy outcome was observed. Additionally, the authors categorized persons with improvements across all three systems of phobic reactions (physiology, behaviour, self-report; see e.g. Lang, 1968) as synchronizers. Ss that exhibited discrepant patterns of improvement and worsening were classified as desynchronizers. Treatment outcome of synchronizers (e.g. Michelson *et al.*, 1990) was found to be superior to that of desynchronizers (e.g. Michelson *et al.*, 1990) in all but the physiological (HR) measures. In a comparison of behavioural and pharmacological (imipramine) treatment, Michelson, Mavissakalian and Marchione (1985) observed substantial decreases in HR through the behavioural treatment. Conversely, HR increases in imipramine-treated Ss were found.

Interestingly, in some investigations a substantial correlation of pre-treatment HR and post-treatment as well as follow-up treatment response was found (e.g. Craske, Sanderson and Barlow, 1987; Roth *et al.*, 1988), but also contrary results were reported (see Michelson *et al.*, 1990).

To summarize, strong evidence has been found that psychophysiological measures in agoraphobia are important. Nevertheless, there is still a dearth of investigations using psychophysiological measures in assessment or outcome prediction.

Direct Comparison of Phobias

Some studies were able to show in direct comparisons that different phobias are related to different physiological reactivity (Cook *et al.*, 1988; Cuthbert *et al.* 1994; Lang, Bradley and Cuthbert, 1998a). *Specific phobia* is generally characterized by a marked sympathetic activation and potentiated protective reflexes (e.g. ASR) during presentation or imagination of phobic stimuli. This was attributed to the activation of a DR (Lang, Bradley and Cuthbert, 1997), which protects against potentially dangerous stimuli. The phobic reactions were very reliable and accompanied by strong avoidance tendencies. However, no abnormal signs have been found in baseline reactions. Also, in *social phobia*, no abnormal ANS or ASR baseline reactivity was found (Lang, Bradley and Cuthbert, 1998a). Reactions upon phobic cues were somehow less salient than in simple phobia. In *agoraphobia*, more baseline ANS activation and enhanced ASR accompanied by smaller reactions during the presentation or the imagery of phobic stimuli was discovered (see Figure XIX-7.1, adapted by permission of the author) (Lang, Bradley and Cuthbert, 1998a).

Recent findings in animal research led to the conclusion that different neurophysiological pathways are involved in fear behaviour under different paradigms. It was assumed that fear can be divided into cue-explicit fear and more generalized context-related fear (Lang, Bradley and Cuthbert, 1998a). This implies that object-related phobias (e.g. snakes, spiders phobia) differ fundamentally from more general phobias (e.g. agoraphobia). They differ not only in a quantitative matter, i.e. in amount of subjective, physiological and behavioural reactions, but also in a qualitative matter, in the underlying mechanisms of fear processing. This would imply that very different therapy strategies may be effective for different types of anxiety disorders.

PANIC DISORDER WITH OR WITHOUT AGORAPHOBIA

Discrepant Findings in Resting Heart Rate as an Example for Different Explanations

Many studies of panic disorder (PD) have found higher resting heart rates (HR) among patients in comparison to healthy control participants (Freedman *et al.*, 1984; Liebowitz *et al.*, 1985; Ehlers *et al.*, 1986; Castellani *et al.*, 1988; Aronson *et al.*, 1989; Nutt, 1989; Uhde *et al.*, 1989; Yeragani *et al.*, 1990; Hoehn-Saric, McLeod and Zimmerli, 1991; Stein, Tancer and Uhde, 1992). However, several other authors did not find such differences (Charney, Heninger and Breier, 1984; Cowley *et al.*, 1987; Villacres *et al.*, 1987; Gaffney *et al.*, 1988; Stein and Uhde, 1991; Stein, Tancer and Uhde, 1992; Gurguis, Vitton and Uhde, 1997). Some authors claim underlying physiological differences are responsible (Stein and Uhde, 1998; Ballenger, 1990), others suggest that these discrepant findings may result from anticipatory anxiety in response to the experimental environment (Margraf, Ehlers and Roth, 1986; McNally, 1994). Ambulatory monitoring studies have found that the resting HR of patients with PD did not differ from those of healthy control individuals (Freedman *et al.*, 1985; Cameron *et al.*, 1987; Taylor *et al.*, 1987; Pauli *et al.*, 1991). Therefore, Larson *et al.* (1998) compared the resting HR of patients with PD, social phobia, and healthy control participants during two consecutive laboratory sessions. The authors found no significant differences in resting HR between groups on either day. Patients with PD had significantly higher mean resting HR during their first laboratory session, which may be due to elevated anticipatory anxiety in these patients. This study highlights a potential confounding factor in many studies. It suggests that anticipatory anxiety and its effect on baseline physiological reactivity in patients with PD may be reduced by pre-exposing them to the experimental environment.

Theoretical Models for the Development of Panic Disorder and Psychophysiological Response Patterns

A uniform theoretical model for the development of panic disorder and/or phobia has not yet been established, but according to research thus far, two important theories have emerged: a learning-theory based conditioning model and a cognitive model. Classic conditioning processes and dysfunctional cognitions are thought to be vulnerability factors for the development of panic disorders with or without agoraphobia (Beck, Emery and Greenberg, 1985; Ehlers *et al.*, 1986; Clark, 1988; Carr, Lehrer and Hochron, 1992).

Mowrer (1939) developed a two-factor theory. Firstly, common and naturally triggering factors for an anxiety response become linked to neutral stimuli by spatial and temporal association. Thus, these neutral situations are able to set into action an anxiety reaction without necessitating the presence of a 'natural' trigger (classical conditioning). Secondly, avoidance behaviour is developed, which prevents the learned anxiety reaction from becoming habituated. According to operant conditioning models, this avoidance behaviour acts as negative reinforcement and thus maintains the pathological anxiety response. In fact, retrospective assessments of agoraphobia cases point to conditioning experiences as triggering factors (Öst and Hugdahl, 1983).

Ehlers *et al.* (1986) were able to show that patients with a panic disorder exhibit altered perception of their normal interoceptive stimuli, such as heart beat. This selective focusing on bodily reactions did not correspond to a real improvement in their ability to appraise such changes (Rapee *et al.*, 1992), but this readiness to appraise physical experiences as anxiety-provoking events leads to fears which themselves provoke psychophysiological changes, such as even further accelerated heart beat or hyperventilation. These observations again confirm the original fear and act as reinforcement. Thus, a vicious circle has been established, which ultimately leads to a panic attack. These theories are based on studies examining psychophysiological response patterns in patients with panic disorders compared to healthy, depressive, or somatically ill control participants (e.g. Hoehn-Saric, McLeod and Zimmerli, 1991; Yeragani *et al.*, 1993; Klein *et al.*, 1995).

Respiratory Psychophysiology and its Explanatory Capacity in Panic Disorder

In the context of respiratory psychophysiology, Ley outlined a dyspnoea/suffocation-fear theory of panic which later led to a tripartite categorization of panic attacks (Hibbert and Pilsbury, 1988; Ley, 1989; Sanderson, Rapee and Barlow, 1989; Craske and Barlow, 1990; Ley, 1994a, 1994b). In contrast, Klein's false suffocation alarm theory hypothesizes a deranged suffocation monitor, which is assumed to trigger a hypothetical suffocation alarm (Klein, 1993; Taylor and Rachman, 1994; McNally, Hornig and Donnell, 1995; Stein *et al.*, 1995). This hypothesis relies on the physiological mechanism whereby potential suffocation is detected by increasing P_{CO_2} and brain lactate.

In his critique of Klein's theory, Ley emphasizes the distinction between dyspnoea, the sensation of difficulties in breathing, and suffocation, the condition that may give rise to dyspnoea (Ley, 1998).

Asmundson and Stein (1994) found an association between a measure of pulmonary function, the forced expiratory flow rate, and the severity of panic symptoms in patients with PD. Thus, they provided relatively strong support for the dyspnoea/suffocation-fear theory, stating that uncontrollable dyspnoea is the source of panic fear. On the contrary, Spinhoven, Onstein and Sterk (1995) did not succeed in replicating these findings; however, this study was criticized by Ley as containing flawed methodology and statistical anomalies. Although the significant findings of Asmundson and coworkers might be subject to type I error, the study of Spinhoven and co-workers cannot be seen as proof for this.

Papp *et al.* (1997) challenged patients with PD and healthy individuals with 5% and 7% CO_2 inhalation and hyperventilation of room air. Patients were more sensitive to the anxiogenic effects of CO_2 compared to healthy participants. Furthermore, CO_2 was a more potent panic stimulus than hyperventilation. The authors identified several respiratory abnormalities, and concluded that patients with PD are behaviourally and physiologically more sensitive to CO_2 inhalation. Panic attacks are explained by inefficient compensatory mechanisms of respiratory rate.

In summation, many studies have shown that patients with PD have a greater propensity to experience increased anxiety and more panic attacks during inhalation of CO_2 compared to healthy participants (Griez *et al.*, 1987; Sanderson and Wetzler, 1990; Perna *et al.*, 1994; Gorman *et al.*, 1994, 1997). In patients with PD, rates of panic during CO_2 inhalation decrease after successful treatment of the disorder (Sanderson, Wetzler and Asnis, 1994; Perna *et al.*, 1997; Bocola *et al.*, 1998). Some authors even claim that CO_2-induced panic is specific to patients with PD (Griez *et al.*, 1990; Perna *et al.*, 1995a, 1995b), but others could show that other patients are also susceptible, e.g. in social phobia (Caldirola *et al.*, 1997) or premenstrual dysphoric disorder (Harrison *et al.*, 1989).

CO_2 sensitivity is increased even in clinically asymptomatic, first-degree relatives of patients with PD (Perna *et al.*, 1995c; Coryell and Arndt, 1999). This could represent a specific abnormality in the afferent neural pathways that respond to increased levels of CO_2 (Klein, 1993). Others argue that the non-specific somatic distress produced by CO_2 inhalation triggers the panic attack (Roth *et al.*, 1992), but studies that addressed this controversy led to conflicting results (Gorman *et al.*, 1988; Pain, Biddle and Tilter, 1988; Papp *et al.*, 1995, 1997). As a result, the mechanism of action is still a matter of intense debate.

Therefore, Gorman *et al.* (2001) investigated differences in respiratory response to CO_2 breathing by comparing patients with PD, healthy control participants, patients with major depression (MD), and patients with premenstrual dysphoric disorder (PMDD). Both latter groups had no co-morbidity with panic disorder. Patients with MD generally do not respond to panic-producing agents such as CO_2, whereas patients with PMDD do.

In sum, patients with PD exhibit higher rates of panic attacks during CO_2 inhalation than other groups, but have no fundamental abnormality in their ventilatory physiology. The exaggerated respiratory responses are more a function if a panic attack occurs than the diagnostic group. The panic response to CO_2 involves a generalized fear response that is not specific to PD. These results are compatible with preclinical fear conditioning models.

These CO_2 studies have pointed the way for neuroimaging studies of cortical and subcortical sites.

Is Regional Brain Asymmetry Associated with (Different) Anxiety Disorders?

Evidence has accumulated from non-psychiatric and psychiatric populations, that individual differences in electroencephalogram (EEG) resting frontal brain asymmetry are associated with differences in basic dimensions of emotion, i.e. in dispositional mood and temperament (see Davidson, 1992; for review, Schaffer, Davidson and Saron, 1983; Henriques and Davidson, 1990; Tomarken *et al.*, 1990; Henriques and Davidson, 1991; Wheeler, Davidson and Tomarken, 1993; Heller, Etienne and Miller, 1995). In particular, increased relative activation of right hemisphere anterior regions is linked to negative affects, such as depressive or sad emotions. In contrast, relatively higher activation of the left frontal area is associated with positive affects, i.e. cheerful emotions. Davidson (1992) has conceptualized this frontal brain asymmetry as reflecting specialized systems in the right hemisphere for withdrawal behaviour coupled with negative emotions and in the left frontal region for approach behaviour associated with positive affects. Much of the data supporting this relationship comes from studies measuring EEG alpha activity during different emotional states (Davidson *et al.*, 1990; Tomarken *et al.*, 1992).

Hemisphere Asymmetry and General Negative Emotional Dispositions

Davidson found that sub-clinically as well as clinically depressed individuals have significantly higher right frontal hemispheric activation than non-depressed subjects (Schaffer, Davidson and Saron, 1983; Henriques and Davidson, 1991, 1992). This difference did not depend on the acute phase of the disorder. Also, remitted depressives that were upon examination normothymic showed increased right frontal activation (Henriques and Davidson, 1990). Thus, this seems to be a trait marker of individuals reacting with negative affect.

Hemisphere Asymmetry and Negative Emotional States

However, individuals differ dramatically in their affective responses to emotional provocations, as they do in their propensity to approach or withdraw from unfamiliar situations. These differences in action have been linked with corresponding differences in emotional reactivity. Therefore, in response to elicitors of dimensions of positive emotion, there should be more intense positive affect and less intense negative affect in subjects with strong left-sided frontal activation. The opposite pattern of reactivity should occur in individuals with stronger right frontal activation. So, increased right frontal hemisphere activation is not only a trait marker for depressives, but also a state marker in conditions predominated by negative affect.

Laterality Findings in Anxiety Disorders

Tucker and co-workers found that anxiety-producing conditions in healthy volunteers were linked to significantly more left than right lateral eye movements (Tucker *et al.*, 1977) and resulted specifically

in decreased performance in the right visual field (Tucker *et al.*, 1978). Tucker *et al.* (1978) also showed that high trait-anxious subjects reported tones at the right ear as significantly louder compared to low trait-anxious people with the same tone in quantity and quality (Tucker *et al.*, 1978). Moreover, high trait-anxious individuals showed reduced left lateral eye movements. So, Tucker and co-workers argue that anxiety is associated with greater left-hemisphere activation. Therefore, left-hemisphere tasks are more poorly performed, as there is a concomitant processing overload. In contrast, further studies with imaging techniques during anxious states revealed more right than left activation in parietotemporal regions (Buchsbaum and Wu, 1987; Naveteur *et al.*, 1992), while others found no asymmetry (Fredrikson *et al.*, 1993). One EEG study even showed increased left brain activation (Carter, Johnson and Borkovec, 1986).

These patterns of hemisphere activation therefore also vary as a function of anxious mood. The findings, however, have been inconsistent (Heller, Etienne and Miller, 1995), and this variability has made generalizations difficult. According to reviews by Heller (1990, 1993), this could be due to the possibility that anxiety and depression may be linked to opposite patterns of activation in the cerebral hemispheres. Depressive mood might be associated with right-hemisphere activation and anxiety with left-hemisphere activation. In populations with much co-morbidity of anxiety and depression, these patterns might suppress each other. Such opposing tendencies could account for the variable patterns in different studies, depending on the ratio of these two emotional states in the particular sample. Because studies of anxiety-depressive conditions and depression studies do not account for anxiety, this might have led to confounded effects. More so, because the co-morbidity of depression and anxiety is high: 40% to 80% of patients with panic disorder have had an episode of major depression (Katon and Roy-Byrne, 1991). However, the overlap between symptoms of anxiety and depression decreases, as the severity of symptoms increases (Hiller, Zaudig and von Bose, 1989).

Heller and co-workers (1995) classified more than 1000 subjects as either high- or low-depressive and high- or low-anxious, and gave a face-processing task that elicits left hemispatial bias (chimeric faces task, CFT). High-depressed probands showed smaller left hemispatial biases than low-depressed ones (corresponding to lower right hemisphere activation), whereas high-anxious subjects had larger left hemispatial biases than low-anxious individuals (corresponding to higher right hemisphere activation). As there was no interaction effect, the number of depressive symptoms cannot be made responsible for the right or left hemispheric asymmetry of anxiety.

Consequently, Heller and co-workers (1995) hypothesize that different kinds of anxiety might be associated with different patterns of hemispheric asymmetry. Left-hemisphere functions may be linked to experiences of worry involving verbal rumination, i.e. cognitive and anticipatory anxiety (Öhman, 1993), whereas right hemisphere activation may be associated with fear or panic responses, i.e. more autonomic and physiological changes (Spence, Shapiro and Zaidel, 1996). These subtypings have been based primarily on behavioural data from lateralized tasks and on lateralized EEG findings. Beyond Heller and colleagues, this distinction has not yet been systematically assessed.

Right frontal brain activation seems to represent an activation of an avoidance–withdrawal system and appears to be associated with negative emotions. Since panic patients are characterized by negative emotions and by avoidance behaviour, this hemispheric asymmetry might be expected. Therefore, Wiedemann *et al.* (1999) compared the spontaneous EEG of 23 panic patients and 25 healthy control subjects during resting phases and while being confronted with neutral, panic-relevant, anxiety-relevant but panic-irrelevant, or anxiety-irrelevant but emotionally relevant stimuli, or when performing a motor task. This study showed that in

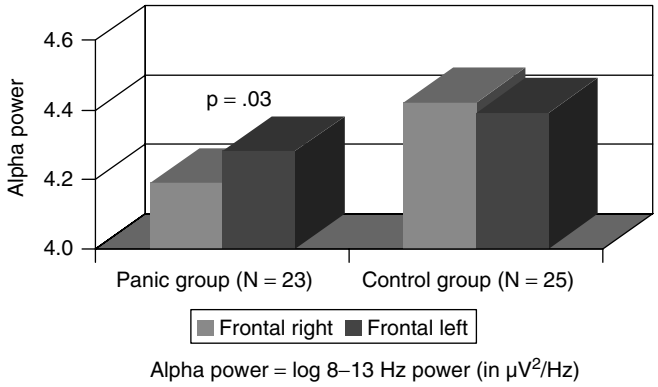

Figure XIX-7.2 Frontal alpha power during resting phases in patients with panic disorder. Adapted by permission

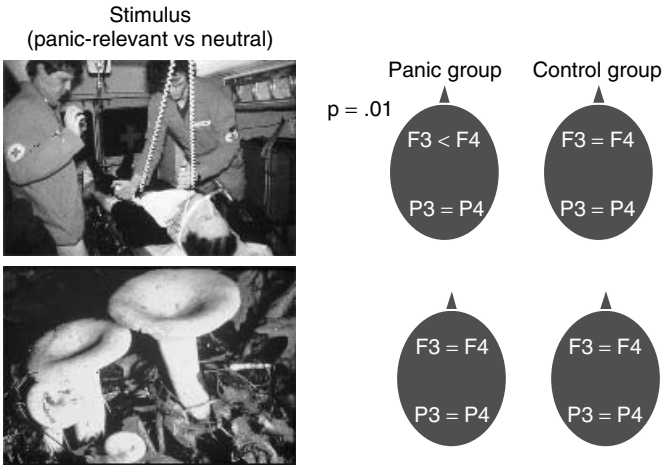

Figure XIX-7.3 Frontal and parietal hemispheric activation in patients with panic disorder when being confronted with panic-relevant and neutral stimuli. Adapted by permission

the spontaneous electroencephalogram of panic patients there are asymmetries in frontal hemispheric activation during resting phases (see Figure XIX-7.2, adapted by permission of the author) and when being confronted with anxiety-relevant stimuli (see Figure XIX-7.3, adapted by permission of the author).

The right frontal alpha power was significantly decreased in these patients compared to that of the left side, while control subjects did not show a frontal asymmetry during these phases.

There was no frontal asymmetry when patients observed an emotionally neutral picture or while performing a motor task. Thus, panic patients were characterized by greater activation of a right frontal avoidance–withdrawal system in negatively valenced situations.

Studies that investigate both central and autonomic measures are warranted to further develop the theory of distinct, psychophysiologically defined subtypes of anxiety disorders.

GENERALIZED ANXIETY DISORDER

In generalized anxiety disorder (GAD), persistent, uncontrollable worry represents the central defining feature. This state of apprehension is maintained by defensive attentional mechanisms such

as pre-attentive bias for threat information and poor habituation to novel stimuli (Mathews, 1990). The persistent cognitive anxiety of GAD may be based on an adaptive coping strategy gone awry. Thayer *et al.* (2000) tried to bridge the attentional and physiological underpinnings of GAD by examining phasic heart period responses to cued threat and non-threat word stimuli in an S1–S2 procedure. The GAD group showed HR acceleration in response to threat stimuli, and a conditioned anticipatory HR deceleration to threat stimuli over repeated trials, in comparison to healthy control participants. Additionally, the GAD group showed smaller and impaired habituation of cardiac orienting responses to neutral stimuli. These findings are interpreted as a diminished global adaptive variability in GAD patients.

Although it is reasonable to assume that patients with GAD exhibit physiological hyperarousal at rest and heightened responses to stressors, this is not the case. Patients with GAD show increased muscle tension (Hoehn-Saric, McLeod and Zimmerli, 1989; Hazlett, McLeod and Hoehn, 1994), but not autonomic hyperarousal. Interestingly, GAD patients under stress show less efficient and more rigid but not higher autonomic responses compared to healthy individuals (Hoehn-Saric, 1998). This physiological rigidity may result from a physiological adaptation to chronic arousal, or represent a constitutional predisposition. On the other hand, a patient with GAD may not be aware of stressful situations that are not incorporated into his pathological preoccupations. Furthermore, the relationship between physiological changes and their perception is weak. This inconsistency may be due to alterations of body sensations by psychological factors. Excessive attention to and expectation of body states may exaggerate body sensations on the one hand, but may on a long-term basis (in the long run) lead to a perceptual distortion and to a disregard of the body states.

POST-TRAUMATIC STRESS DISORDER (PTSD)

According to the American Psychiatric Association's Diagnostic and Statistical Manual of Mental Disorders (DSM-IV) symptoms of PTSD include irritability, hypervigilance, exaggerated startle response, and intense physiological reactivity upon re-exposure to events that symbolize or resemble an aspect of the traumatic event (American Psychiatric Association, 1994). In a series of studies, heart rate (HR), blood pressure (BP), skin conductance (SC), and electromyogram (EMG) have been used as outcome measures. The paradigms differed in the nature of the stimulus used to elicit physiological responses: external stimuli reminiscent of the trauma, internal (mental) imagery of the trauma, and intense but neutral stimulations, e.g. auditory startle stimulus (Shalev, Orr and Pitman, 1993a). Following this subdivision, the corresponding studies will be described.

Psychophysiological Responses to External Stimuli

World War II veterans with ($n = 8$) and without ($n = 13$) decompensated combat neurosis and student control individuals ($n = 10$) were exposed to a tape of artillery barrage, small arms fire, and aerial bombardment sounds (Dobbs and Wilson, 1960). While only one of the student control subjects showed a moderate or marked increase in pulse rate, eight of the healthy veterans did so, and five of the decompensated veterans even asked that the tape be turned off. Vietnam veterans with PTSD and non-veteran control individuals underwent mental arithmetic and combat sounds from an audiotape (Blanchard *et al.*, 1982). The mental arithmetic aroused both groups (heart rate, electromyogram, and blood pressure responses), whereas the combat sounds did so only in the PTSD group. However, this study did not differentiate the effect of combat from that of PTSD, as there was no control group with combat exposure.

Therefore, Malloy, Fairbank and Keane (1983) compared the physiological responses of Vietnam veterans with PTSD, psychiatric inpatients, and veterans without PTSD. The audio-visual presentation of combat sounds resulted in significantly greater heart rate and skin conductance responses to combat scenes in the group with PTSD only.

The methodology was further refined by comparing Vietnam veterans with PTSD, veterans with other psychiatric disorders, veterans with combat experience, Vietnam-era veterans, and non-veterans patients with anxiety disorders (Pallmeyer, Blanchard and Kolb, 1986). Physiological responses (HR, BP, SC) were compared during rest, mental arithmetic, and combat sounds. Larger HR responses to combat sounds were found in the PTSD group compared to all other groups. McFall *et al.* (1990) used additional outcome measures by comparing the group's (Vietnam veterans with and without PTSD) HR, BP, subjective responses, and plasma epinephrine upon viewing of combat and non-combat stress films. Greater increases in all outcome measures were found in the PTSD group during the combat films.

Blanchard *et al.* (1991) tested the reliability of the psychophysiological measures. They compared HR and BP responses to combat sounds in two large samples ($n = 104$ and 96, respectively) of Vietnam veterans with and without PTSD. The cumulative difference in HR and BP response to combat sounds correctly classified 80% in the first and 83% in the second sample of testees as individuals with or without PTSD.

These studies resulted in a neuropsychological hypothesis explaining PTSD (Kolb, 1987). The disorder was defined as a conditioned emotional response to overwhelming stressful exposure. Excessive stimulation was thought to result in permanent neuronal changes. These might lead to impairment of learning, habituation, and stimulus discrimination. Thus, the disorder results from strong associative learning. Originally, individuals react to a traumatic event (unconditioned stimulus, UCS) with arousal and fear (unconditioned response, UCR). Associative learning implies that finally, individuals show the same response to external cues associated with the stressful experience. By then, these cues have become conditioned stimuli (CS). The physiological response generated by these cues represents the equivalent of a conditioned response (CR).

However, combat is only one condition capable of provoking PTSD. Rape, motor vehicle accidents, torture, natural disasters etc., are other conditions considered to be potential stimuli.

Psychophysiological Responses to Mental Imagery

Brende (1982) found that hypnotically induced imagery of past traumatic events in PTSD patients was associated with increased electrodermal response of the left side of the body. According to Brende, this lateralization might be explained by the preferential processing of images by the right brain hemisphere.

Pitman hypothesized that in PTSD, there is a pathological emotional network, which can be provoked by mental imagery, resulting in physiological and other responses (Pitman, 1988). Lang and co-workers had shown that emotionally loaded imagery correlates with HR, SC, and EMG responses in general (Lang *et al.*, 1983). According to their theory, emotional memories are stored as an associative network. These networks consist of memory traces of the sensory input, the meaning derived from this input, and the physiological response.

Following this theoretical approach, Pitman and co-workers conducted a series of studies. Vietnam veterans with and without PTSD listened to recorded scripts describing traumatic events. Some of these were standardized, others were based on the

individual's own experience. Imagery of the personal events resulted in strong HR, SC, and EMG responses in PTSD patients only (Pitman *et al.*, 1987). In a further study, Pitman and co-workers compared Vietnam veterans with PTSD and Vietnam veterans with other anxiety disorders (Pitman *et al.*, 1990). The response to combat imagery was specific to PTSD. Shalev and co-workers assessed the psychophysiological response to traumatic imagery in Israeli trauma survivors. These subjects were of both sexes with PTSD of different origin, i.e. rape, road accidents, terrorist acts (Shalev and Rogel-Fuchs, 1993b). In subjects whose disorder was the result of non-military events, increases in HR and EMG in response to traumatic imagery were observed compared with the response of survivors without PTSD, the same trend seen in the studies of Pitman *et al.*

Response to mental imagery was also used as a measure of treatment outcome. Keane and Kaloupek (1982) treated a Vietnam veteran suffering from PTSD with imaginal flooding. The heart rate response to imaginal scenes of combat memories was reduced after therapy. Similarly, Fairbank and Keane (1982) showed that imaginal flooding reduced heart rate and skin conductance response to combat-related imaginal scenes in PTSD patients. Boudewyns and Heyr (1990) compared direct therapeutic exposure and counselling in Vietnam veterans with PTSD. Regardless of treatment protocol, clinical improvement as an outcome measure is correlated with decreases in physiological responses to combat imagery. However, Shalev *et al.* (1992) also showed that such reductions might not generalize to recollections of other traumatic events, although their treatment of desensitization of the specific trauma resulted in a decrease of HR, SC, and EMG responses to that trauma.

In a further study, Shalev (1997) explored the physiological responses of PTSD patients to reminders of a significant stressor that had preceded the onset of the disorder and was not related to its cause. They compared outpatients with PTSD, survivors of traumatic events who had not developed PTSD, panic disorder patients, and mentally healthy individuals with no history of trauma. PTSD individuals showed higher SC and EMG responses than the other groups. The authors concluded that PTSD patients may acquire and maintain prolonged conditioned responses to various stressors during their lifetime or become sensitized to reminders of past traumata following the onset of their illness. Heightened susceptibility to acquire conditioned responses or an inability to extinguish such responses may be expressed before the trauma in individuals who are liable to develop PTSD.

In a recent study, Orr *et al.* (2000) found evidence that individuals with PTSD show greater conditionability than those without. This stronger conditionability could reflect pre-trauma vulnerability to developing PTSD.

Keane *et al.* (1998) were able to show that more severe PTSD symptomatology is associated with greater physiological responsivity to trauma-related cues.

Blanchard *et al.* (1996) found that higher physiological responsivity to imagery one-to-four months after a motor vehicle accident predicted the persistence of chronic PTSD after one year.

In a recent study, Orr *et al.* (1998) showed that PTSD and non-PTSD groups do not differ in the magnitude of their physiological responsivity to standard stressors (mental arithmetic, postural challenge).

The consistency of the results across various studies suggests that the method of using responses to mental imagery represents a good measurement of the traumatic experiences. Mental representations of the trauma may constitute a mental network of recollections, verbal representations and images. These may be able to reinforce learning and conditioning even in the absence of external reinforcement. Thus, cogitations and nightmares of recollections may result in endless sequences of self-induced reinforcement of the conditioned emotional response.

Psychophysiological Responses to Intense but Neutral Stimulation (Auditory Startle)

The acoustic startle response (ASR) consists of a characteristic sequence of muscular and autonomic responses to sudden, intense stimuli. It is measured as the magnitude of the eyeblink reflexes.

The ASR is modified by non-startling effects that precede the startling stimulus. Such warning stimuli may facilitate or inhibit the magnitude of the ASR. If such a stimulus had previously been paired with a shock, the presence of such a cue augmented the amplitude of the ASR. Conditioning of this type is called fear-potentiated startle effect.

Affective valence and arousal can be induced by background information. Lang and co-workers (1990) studied the extent to which this modulates the acoustic startle response. They found that the ASR is associated with affective valence, whereas the skin conductance response is reflective of arousal.

Increased ASR is one of the cardinal features of PTSD.

Ornitz and Guthrie (1989) found impaired pre-pulse modulation, i.e. a significant loss of normal inhibitory modulation of the ASR by warning stimuli, in children with PTSD compared to age-matched, healthy control children.

In a group of Vietnam veterans with combat-related PTSD, Butler *et al.* (1990) found a higher eyeblink EMG response to an acoustic stimulus of intermediate intensity compared to a group of Vietnam veterans without PTSD. Paige *et al.* (1990) found larger HR responses to ASR in Vietnam veteran PTSD patients. Ross *et al.* (1989), however, found no difference in habituation of the ASR to a series of 100 dB tones between PTSD patients and healthy volunteers.

A study by Morgan *et al.* (1995) showed that infusion of yohimbine, which stimulates noradrenaline transmission in the brain, facilitated the acoustic startle response in combat veterans with PTSD. Another study by Grillon *et al.* (1997) found that darkness facilitated the acoustic startle reflex in combat veterans both with and without PTSD in comparison to non-combat control individuals. There seem to be important influences of contextual fear on the startle response.

Shalev *et al.* (1992) compared autonomic (ANS)- and central nervous system (CNS)-mediated responses to ASR in Israeli PTSD patients, patients with other anxiety disorders, healthy individuals with past traumatic experiences, and healthy individuals having experienced no traumatic event. They found a larger HR and SC response, and an impaired habituation of the SC response to the consecutive presentation of auditory stimuli in the PTSD patients compared to all other groups.

In a recent study, Shalev *et al.* (2000) showed that patients showed differential effects after a psychologically traumatic event. Patients who developed PTSD showed increased HR responses and slower habituation of SC responses to startling stimuli one and four months after the trauma. However, these responses were not seen one week after the trauma. These results suggest a progressive sensitization of the autonomic response to startling stimuli. These studies of ASR in PTSD have some characteristics which differentiate them from the previously mentioned studies. Firstly, the startle reflex represents an elementary stimulus, which is not associated with the traumatic experience and for which previous conditioning is unlikely. Secondly, ASR studies do not require deliberate mental activity by the individual. Thus, confounding by (un)conscious manipulations is less likely. Thirdly, it reflects impairments in structures such as the amygdala and other mesocortical areas, which are responsible for evaluation of the stimulus, memory, and arousal. Therefore, these studies suggest that in PTSD, there is an alteration of the responsiveness of the central nervous system to elementary stimuli. In addition, the capacity to effectively appraise intensive but redundant stimuli and to regulate the arousal response seems to be impaired, as habituation of the SC response is slow.

Summary

The studies using external stimuli support the associative learning paradigm, studies using the imagery technique extend the conditioning paradigm to mental representations of traumatic experiences, and studies of intense but neutral stimulations (ASR) show the abnormal responsiveness to elementary stimuli in PTSD patients.

Event-Related Electroencephalographic Potentials (ERPs)

The latency and amplitude of ERP components index specific aspects of stimulus and information processing. In contrast to responses by the autonomic nervous system, which occur within seconds, those of the central nervous system occur within milliseconds. The studies of Paige *et al.* (1990) and Lewine *et al.* (1997) showed an augmentation–reduction of P2 responses. Increases in acoustic stimulus intensity are normally directly correlated to increasing P2 amplitude responses. In contrast to such an augmenting response pattern, PTSD combat veterans showed a decreasing response pattern, i.e. decreasing P2 amplitudes. Such a pattern reflects a protectively tuned sensory system that dampens increased stimulation. Similar to findings in other diseases (schizophrenia, cocaine abusers), combat veterans with PTSD exhibited less habituation of the P50 potential to the second click in comparison to control individuals (Gillette *et al.*, 1997). This auditory P50 habituation was inversely correlated with re-experiencing symptoms within the PTSD group.

In the auditory oddball paradigm, PTSD patients were exposed to a series of high-frequency non-target tones, low-frequency distractor tones, and low-frequency target tones. PTSD patients showed longer reaction times, delayed N2, and attenuated P3 amplitudes to target and distractor stimuli (McFarlane *et al.*, 1993; Charles *et al.*, 1995; Metzger *et al.*, 1997a, 1997b). It is unclear whether this response abnormality is secondary to a motivational deficit or reflects a higher order cognitive impairment.

In summation, ERP findings provide evidence for increased cortical inhibition in response to high-intensity stimuli, auditory gating deficits, impairments in memory and concentration, and increased selective attention to trauma-related stimuli.

This psychophysiological research into PTSD supports the validity of the diagnostic entity, but more work needs to be done to test the robustness of the various results. Some of the stimulus presentation techniques are now being incorporated into neuroimaging symptom provocation studies. These are described elsewhere in this book.

OBSESSIVE–COMPULSIVE DISORDER (OCD)

Two loosely related goals have been pursued in the research of OCD. Firstly, the search for the biological basis of OCD led to an intense investigation of the EEG properties of OCD sufferers. Secondly, ANS measures were used in the assessment of OCD and in the treatment evaluation. An overview of the earlier research on psychophysiology in OCD is given by Sartory (1989).

EEG Studies

In OCD patients, some abnormalities in sleep EEG have been found. OCD patients have longer Stage 1 sleep and reduced Stage 3 and 4 sleep, which is indicated by the amount of delta activity (review by Sartory, 1989). However, these findings are not disorder-specific and have been found in depression and schizophrenia as well.

Furthermore, awake resting EEG measurements are variable and conflicting (Sartory, 1989; Towey *et al.*, 1994; Simpson *et al.*, 2000). One possible reason is that different subgroups of OCD patients exist. All show the symptoms of OCD, but perhaps differ in psychophysiological measures. Prichep *et al.* (1993) assumed two distinct groups of OCD patients. One group of patients is thought to be characterized by an excess in relative theta power and a second group by increased relative alpha power. By dividing 27 patients into two groups according to this classification, the response to treatment with serotonin reuptake inhibitors (fluvoxamine, fluoxetine, or clomipramine) could be predicted. Eighty percent of patients characterized by increased theta power were non-responders, whereas 82% of patients characterized by increased alpha power were responders. Interestingly, this result is consistent with the finding that serotonin reuptake inhibitors decrease alpha activity, but increase slow and fast activity (Prichep *et al.*, 1993). It might be helpful to follow-up on such a differentiation, in order to ensure more validity in further research results. Once established, such psychophysiological measures may be for use in clinical treatment assignment and the prediction of treatment response.

Symptom provocation studies constitute a further area of research. Possibly the first symptom provocation study including EEG measures was done by Simpson *et al.* (2000). Significant changes in alpha activity during live exposure were found. Unfortunately, only six patients and no control group were investigated so, as yet, no concrete evidence for specific EEG changes has been given. Future research is necessary to identify potential differences in power bands and to specify activated brain regions during sensitive stimulation.

In the investigation of event-related potentials (ERPs), consistent results were found for some components. Different studies found reduced latencies of the N200 and the P300 components (see Sartory, 1989; Towey *et al.*, 1990, 1994). The increase in N200 and P300 latency as a function of task difficulty, which is found in control Ss, was not found in OCD patients (Sartory, 1989; Towey *et al.*, 1990). These results are interesting, since other psychiatric disorders (depression, schizophrenia) are not accompanied by reduced, but rather by increased, ERP latencies. The reduced ERP latencies are interpreted as indicators of cortical hyperarousal. Towey *et al.* (1994) also found that attention-related processing negativity (PN) began earlier, lasted longer and was increased in OCD patients compared to control Ss. This may be interpreted as overfocused attention in OCD patients (Towey *et al.*, 1994). Another well-established finding is the enhanced contingent negative variation (CNV) during preparation of a (motor) response. This enhanced CNV also seems to be specific for OCD patients (Sartory, 1989). Sartory and Master (1984) found that with an interval of 5 s between warning and imperative stimulus, only the late, but not the early component of the CNV was affected. They proposed that this is due to the uncertainty of the situation and that this reflects the doubts of OCD patients regarding the requirements made of them.

ANS Activity

Emotional arousal or anxiety is a common observation in OCD during exposure to obsession-related stimuli, prevention of ritual behaviour, or while experiencing obsessive thoughts. The most effective therapy for OCD is exposure with response prevention, as is effective in severe phobias (Foa and Kozak, 1985). Therefore, the relevance for investigation of ANS responses is obvious.

One hypothesis was that OCD patients are in a state of abnormal arousal which, in the end, results in a failure to adapt to unwanted thoughts (Beech, Ciesielski and Gordon, 1983). This should lead to elevated baseline ANS activation, or at least to an elevated responsiveness to stressful stimuli. Although earlier studies found a generally increased ANS activation (e.g. Kelly, 1980; Insel, Zahn and Murphy, 1985), more recent studies were not able to confirm the hypothesis of a general hyperactivation (Berg *et al.*, 1986; Hoehn-Saric *et al.*, 1995; Zahn *et al.*, 1996). The hypothesis of a general

hyper-responsiveness of OCD patients to stress was investigated during stressful mental activity. Despite some positive results (e.g. Insel, Zahn and Murphy, 1985), this hypothesis remains empirically unconfirmed (Kelly, 1980; Zahn *et al.*, 1996). On the contrary, patients with OCD react with less physiological flexibility to general stressful tasks (Hoehn-Saric, McLeod and Hipsley, 1995), but this is not specific for OCD patients, having also been found in other anxiety disorders (Hoehn-Saric, McLeod and Hipsley, 1995). Nevertheless, a significant positive correlation between symptom severity and general ANS reactivity was found in children and adolescents with OCD (Zahn *et al.*, 1996).

However, disorder-specific stimuli as well as obsessive thoughts increase ANS activity (SCF, SCL, HR) in OCD patients (Rabavilas and Boulougouris, 1974; Boulougouris, Rabavilas and Stefanis, 1977; Haines *et al.*, 1998). Patients with obsessional ruminations react with HR accelerations during the presentation of sensitive words in the same way as phobic Ss do (Eves and Tata, 1989). Words that are used to neutralize the obsessions evoked no HR reactions, whereas neutral words resulted in an HR deceleration (OR) (Eves and Tata, 1989).

A few studies investigated the effect of psychological treatment on ANS responses. A substantially greater reduction of HR and SCF was found for long-duration *in vivo* exposition compared to short-duration *in vivo* exposition (Boulougouris, Rabavilas and Stefanis, 1977). A study by Grayson, Foa and Steketee, (1982) focused on the investigation of the treatment process. A group of patients with washing compulsions performed *in vivo* exposure with focused attention, while a second group was distracted during exposure by playing a video game. Interestingly, HR reactions were attenuated during exposure in both conditions. The improvement was maintained in the focusing condition, but not in the distraction condition between the sessions (Grayson, Foa and Steketee, 1982).

Recent studies focused on the changes occurring during a pharmacological treatment. One major challenge in these studies was to disentangle disorder-independent drug effects from clinical changes, as psychoactive substances are known to induce changes in the ANS. In one study, clomipramine (a tricyclic antidepressant and serotonin reuptake inhibitor) effectively decreased symptoms in patients with OCD (Hoehn-Saric *et al.*, 1993). But tricyclic antidepressants are also known to generally induce HR accelerations (Sartory 1989). Zahn, Insel and Murphy, (1984) were able to demonstrate more clinical benefits and a marked reduction of SCL in clomipramine compared to placebo or clogyline (a monoamine oxidase (MAO) inhibitor) treatment time periods (crossover design). The number of non-specific SCR was reduced after clomipramine and clogyline compared to placebo periods. This was found during rest and during a threshold discrimination task. Additionally, after clomipramine periods, the OR (measured in amplitude of SCR) to startle-like loud noise was reduced and habituation was hastened. In contrast to the reduction in SC activity, a substantial increase of HR was found after treatment with clomipramine (12 beats per minute) and clogyline (six beats per minute), compared to placebo periods. In another study, Hoehn-Saric *et al.* (1993) found no effects of clomipramine during rest in a broad range of ANS measures. The only exception was the HR, which increased during clomipramine treatment and decreased during placebo treatment. However, the ANS reactivity to non-specific and to pathology-specific stressful stimuli compared to placebo was reduced. The conclusion was that the ANS effect of clomipramine is not disorder-specific. The effect might reflect a generally heightened indifference to psychological stressors.

It would be interesting to observe whether ANS reactivity differences can be found in subgroups of OCD patients (with groups divided, e.g. according to EEG power).

In summary, the hypotheses of a general hyperactivity or a general hyper-reactivity in OCD patients were not confirmed. Future research may focus on symptom provocation studies, to determine differences in OCD patient reactions to obsessive cues compared to control Ss and Ss suffering from other anxiety disorders. Especially interesting will be the investigation of EEG differences within symptom provocation studies. ANS measures may be valuable for complete assessment of OCD and evaluation of treatment outcome.

The Neuropsychology of Anxiety Disorders: Affect, Cognition, and Neural Circuitry

Jack B. Nitschke and Wendy Heller

INTRODUCTION

In attempting to construct a neuropsychology of anxiety, findings can be drawn from several related, yet often perceived as separate, domains of research, including cognitive science and neuroscience. The relatively new fields of cognitive neuroscience and affective neuroscience are concerned with very similar questions regarding brain–behaviour relationships as were fundamental to the older field of neuropsychology, and the neuroimaging tools central to those disciplines are no less pertinent to neuropsychology than are traditional neuropsychological test batteries or cognitive/behavioural paradigms. Thus, this review of the neuropsychological findings in anxiety disorders covers a wide array of methods that together inform knowledge of the brain mechanisms involved in the circuitry governing pathological forms of anxiety.

Although often overlooked by neuroscientists studying brain function in anxiety, cognitive research over the past two decades has contributed substantially to knowledge about brain function in anxiety. A large body of work demonstrates that anxiety disorders are characterized by cognitive biases, indicating a heightened response to the possibility of threat (for review, see McNally, 1998). Attentional biases have been elicited very reliably across a variety of paradigms in which potentially threatening information is associated with greater attentional capture in individuals with anxiety disorders than in controls. The interference of this attentional capture with other cognitive processing serves as the operationalization of this bias in research studies. Furthermore, attentional biases have been found to disappear upon remission (for review, see McNally, 1998), suggesting that such biases are state-dependent. Cognitive biases have also been observed in the form of interpretation and memory biases. Across a number of different paradigms involving ambiguous stimuli that can be interpreted as threatening or neutral, anxious people choose the threatening meaning. Accruing evidence suggests that anxiety disorders are also accompanied by enhanced memory for negative or threatening information under certain conditions. These cognitive data suggest dysfunctional activation of a right hemisphere system involved in threat perception (for review, see Nitschke, Heller and Miller, 2000; see also Compton *et al.*, 2000, 2002).

In addition to these cognitive biases, cognitive deficits have been documented in anxiety disorders. One is a tendency to do poorly on tasks that require selective attention and concentration. This deficit has been suggested to reflect a general problem of preoccupation and distraction due to worry or rumination that interferes with other mental processes (for review, see Nitschke, Heller and Miller, 2000). Compromised visual–spatial functioning has also been reported. In addition, individuals with posttraumatic stress disorder often exhibit deficits in explicit memory. Taken together, these cognitive deficits suggest aberrant frontal, anterior cingulate, right parietal, and hippocampal functioning. Building on this cognitive research as well as on behavioural and electroencephalographic (EEG) findings (for review, see Nitschke, Heller and Miller, 2000) and an extensive literature in non-human animals examining fear and anxiety (for reviews, see LeDoux, 1996; Davis and Lee, 1998), haemodynamic neuroimaging research has implicated a number of the suggested regions.

Although emotional, cognitive, and neural commonalities are apparent, the diversity of findings also warrants the importance of respecting unique patterns and heterogeneity both among and within the various anxiety disorders. An observation that has become increasingly salient in the burgeoning neuropsychological literature on anxiety and its disorders is the lack of clarity and specificity about what anxiety is. Views of anxiety range from its usage in contemporary clinical research as a rubric term that encompasses fear, panic, worry, and all the anxiety disorders listed in the DSM-IV to its very specific operationalization referring to context conditioning and long-term sensitization (e.g., Davis and Lee, 1998) to a more generic personality dimension closely linked to neuroticism (e.g., Gray, 1982). Further, the heterogeneity within each of the different anxiety disorders has become increasingly apparent and represents a major problem for investigators attempting to uncover the neurobiological correlates of individual anxiety disorders. Inconsistencies across studies may be explained by the fact that anxiety is not a unitary phenomenon and that different types and symptoms of anxiety are associated with particular cognitive patterns (Heller and Nitschke, 1998; Nitschke, Heller and Miller, 2000). An important mission of neuroscience research in this area is to help unravel the inchoate notions of anxiety that currently exist. Thus, although it is important to look for generalizations regarding the neural mechanisms of anxiety, it is also necessary to consider the possibility of heterogeneity by being as specific as possible regarding the disorder or type of anxiety under investigation.

The aim of this chapter is to assess what is known about the neuropsychology and neural circuitry of anxiety disorders by examining the relevant cognitive research. Structural and functional neuroimaging data will also be reviewed, including morphometric magnetic resonance imaging (MRI), functional MRI (fMRI), positron emission tomography (PET) using various radiotracers such as [^{18}F]fluorodeoxyglucose (FDG) for glucose metabolism and ^{15}O-labelled water for blood flow, single-photon emission computed tomography (SPECT) with ^{133}Xenon or ^{99m}Tc-HMPAO, and scalp-recorded EEG. This review of the cognitive and neuroscience literatures reveals that the anxiety disorders engage brain regions involved in threat perception (e.g., right hemisphere

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

regions; Compton *et al.*, 2000, 2002; Nitschke, Heller and Miller, 2000), anxious arousal (right posterior regions; Nitschke, Heller and Miller, 2000), fear (e.g., amygdala; LeDoux, 1996), vigilance for motivationally salient events (e.g., amygdala; Whalen *et al.*, 1998; Davis and Whalen, 2001), decoding of motivationally relevant emotional information such as the reward and punishment value of a stimulus [e.g., orbital frontal cortex (OFC); Rolls, 1999], worry (e.g., left-hemisphere regions; Nitschke, Heller and Miller, 2000), response conflict [e.g., anterior cingulate cortex (ACC); Carter *et al.*, 1999, 2000; Davidson *et al.*, 2002], and memory (e.g., hippocampus; Squire, 1992). The aforementioned heterogeneity should also lead to some diverse findings for the different anxiety disorders. The focus here is on the anxiety disorders as defined by the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) although consistent patterns have emerged in studies using nonclinical and brain-lesioned human populations (for review, see Nitschke, Heller and Miller, 2000).

OBSESSIVE–COMPULSIVE DISORDER

The most widely investigated anxiety disorder from a neuropsychological perspective has been obsessive–compulsive disorder (OCD). The emphasis on obsessions and compulsions in connection with the experienced anxiety and distress reported by individuals suffering from OCD is unique among the anxiety disorders and can be linked to a number of neuropsychological abnormalities.

Cognitive Studies

An extensive cognitive literature on OCD points most strongly to non-verbal memory and other visual–spatial deficits (e.g., Boone *et al.*, 1991; Zielinski, Taylor and Juzwin, 1991; Christensen *et al.*, 1992; Cohen *et al.*, 1996; Purcell *et al.*, 1998; Savage *et al.*, 1996, 1999; see also McNally and Kohlbeck, 1993; Constans *et al.*, 1995). No evidence of a verbal memory deficit has been found (Foa *et al.*, 1997). There is also ample documentation of impaired executive functions (e.g., Head, Bolton and Hymas, 1989; Veale, Owen and Marks, 1996; Abbruzzese, Ferri and Scarone, 1997; Purcell *et al.*, 1998), with trends reported by Cohen *et al.* (1996) for several neuropsychological tests. It is possible that problems in executive function could account for at least some of the visual–spatial deficits found. For example, Savage *et al.* (1999) found that poor organizational strategies for copying a figure mediated the non-verbal memory deficit for reproducing a figure among OCD patients. Morphometric data for OCD subjects by the same group suggests that larger right prefrontal volumes are associated with worse non-verbal memory using the same task (Grachev *et al.*, 1998). Should this finding be replicated, one possible explanation is that the heightened threat perception and negative affect accompanying OCD occupy the resources in the right prefrontal cortex (PFC) that are normally dedicated to non-verbal memory and also lead to structural changes.

Of additional relevance to cognitive functioning in OCD, Foa *et al.* (1993) documented that the attentional bias toward threat-related material seen across all the anxiety disorders for the emotional Stroop paradigm also emerges in OCD. In this paradigm, subjects are asked to name the colour of words varying in emotional content while ignoring their meanings. Foa *et al.* (1993) found that OCD patients with washing rituals took longer to name the colour for contamination words than for neutral words, suggesting that the threatening nature of the contamination words interfered with the task of naming the colour. They also had longer response latencies to contamination words than did OCD non-washers or non-psychiatric controls. On the other hand, OCD non-washers had longer latencies to negative than neutral words, whereas the opposite pattern was seen in controls. In a similar study in which the contamination words did not reflect the primary concerns of the OCD patients, no interference effects were observed (McNally *et al.*, 1990). These attentional findings implicate the involvement of right hemisphere regions important for threat perception (Compton *et al.*, 2000, 2002; Nitschke, Heller and Miller, 2000).

With regard to memory biases, Foa *et al.* (1997) found no bias for contamination sentences for either explicit or implicit memory. However, they did replicate the finding that OCD patients are less confident than non-psychiatric controls about memory-related judgements (McNally and Kohlbeck, 1993; Constans *et al.*, 1995). Thus, the cognitive literature is fairly conclusive in demonstrating that the memory concerns frequently voiced by OCD patients (e.g., 'Did I lock the door?') are not the result of a memory deficit or a memory bias but rather a lack of confidence in their memory. This lack of confidence is likely to be related to the characteristic fear of forgetting some activity that has become a target for compulsive behaviour, and thus is a reflection of the underlying anxiety in OCD. As such, the degree to which confidence is lacking might correlate with activity in neural structures associated with fear and other anxiety-related features.

Neuroimaging Studies

The most common finding to emerge in morphometric MRI studies to date is a reduction in caudate volume (Robinson *et al.*, 1995; Rosenberg *et al.*, 1997), with a trend also reported by Jenike *et al.* (1996). However, Aylward *et al.* (1996) found no caudate differences, and Scarone *et al.* (1992) reported an increase in right caudate volume (see Table XIX-9.3A in Martis *et al.*, Chapter XIX-9). Similar inconsistencies for the caudate have emerged in functional imaging studies examining resting states using PET and SPECT to measure glucose metabolism and blood flow. Increases were reported in three samples (Baxter *et al.*, 1987, 1988; Rubin *et al.*, 1992), with Perani *et al.* (1995) reporting a trend in the same direction. However, Lucey *et al.* (1997a, 1997b) found a reduction, and others observed no differences from non-psychiatric controls (e.g., Swedo *et al.*, 1989). In contrast, symptom provocation paradigms employing PET (McGuire *et al.*, 1994; Rauch, Jenike and Alpert, 1994) and fMRI (Breiter *et al.*, 1996) have consistently shown caudate activation.

The cortico-striatal model of OCD proposed by Rauch *et al.* (1998) posits that pathology within the caudate results in OFC and ACC hyperactivity via inefficient thalamic gating. An OFC-caudate loop may comprise much of the neural circuitry associated with the repetitive and perseverative nature of obsessions and compulsions (see also Alexander, Crutcher and DeLong, 1991). Further pursuing the evidence of caudate abnormalities, Rauch and colleagues employed PET and fMRI while OCD patients performed an implicit learning task shown to be dependent on striatal function in non-psychiatric volunteers (Rauch *et al.*, 1995b, 1997c). As noted by Martis *et al.* (Chapter XIX-9), the striatum was not activated in OCD subjects (Rauch *et al.*, 1997a), suggesting that OCD symptoms pertinent to perseveration occupy the resources normally allocated to implicit learning. The caudate activation observed in the symptom provocation studies suggests that inconsistencies in other reported findings may be due to heterogeneity in the degree of symptom severity among OCD patient samples. Taken together, these data suggest that augmented caudate activation is associated with the perseverative nature of obsessions and compulsions, which also may serve to enlarge that structure.

Haemodynamic studies of OCD have implicated a number of other regions, most consistently OFC and ventral ACC, areas of the brain frequently found to be involved in aspects of emotion and

attention. PET and SPECT studies using protocols not involving a task have revealed that patients with OCD have more blood flow or glucose metabolism than non-psychiatric controls in OFC (Baxter *et al.*, 1987, 1988; Swedo *et al.*, 1989; Rubin *et al.*, 1992; but see Machlin *et al.*, 1991; Busatto *et al.*, 2001) and ventral ACC (Machlin *et al.*, 1991; Perani *et al.*, 1995; but see Busatto *et al.*, 2001; see Table XIX-9.3B in Martis *et al.*, Chapter XIX-9).

Similar findings for the OFC were also observed during an auditory continuous performance task in a PET study measuring glucose metabolism (Nordahl *et al.*, 1989). OFC and ventral ACC activations have also been reported in fMRI (Breiter *et al.*, 1996; Adler *et al.*, 2000) and PET (Rauch, Jenike and Alpert, 1994) studies employing symptom provocation paradigms with actual obsessional stimuli. In another study employing symptom provocation via presentation of individually specified contaminants in OCD patients, McGuire *et al.* (1994) found symptom intensity to be correlated with right inferior frontal/OFC but not ACC activation. Busatto *et al.* (2001) also found that obsessive–compulsive symptoms correlated positively with left OFC blood flow. A less potent experimental elicitation of symptoms via auditory presentation of obsessional material did not induce blood flow changes in these areas using PET (Cottraux *et al.*, 1996).

With the amygdala often highlighted in models of the neural circuitry of fear, anxiety and emotion (e.g., LeDoux, 1996; Charney, Grillon and Bremner, 1998), it is worth noting that amygdala activation has been documented in only one study examining OCD, that conducted by Breiter *et al.* (1996), who exposed 10 OCD subjects to stimuli highly relevant to their obsessions. One of the subjects studied by McGuire *et al.* (1994) also showed amygdala activation, as did two of the seven OCD patients examined by Adler *et al.* (2000). Further evidence of frontal and ACC dysfunction in OCD can be inferred from two EEG studies examining event-related potentials (ERPs) in a Go–NoGo task (Malloy *et al.*, 1989) and a selective attention task (Towey *et al.*, 1994).

Treatment studies further inform the neural circuitry characterizing OCD (see also Martis *et al.*, Chapter XIX-9). Both cognitive-behavioural and pharmacological therapies have been associated with normalized (i.e., decreased) glucose metabolism in the caudate nucleus (Benkelfat *et al.*, 1990; Baxter *et al.*, 1992; Schwartz *et al.*, 1996; Saxena *et al.*, 1999; but see Baxter *et al.*, 1987; Swedo *et al.*, 1992), OFC (Benkelfat *et al.*, 1990; Swedo *et al.*, 1992; Saxena *et al.*, 1999; but see Baxter *et al.*, 1987, 1992; Schwartz *et al.*, 1996), and ventral ACC (Perani *et al.*, 1995; marginally significant in Baxter *et al.*, 1992, and Swedo *et al.*, 1992). Similar findings have emerged for blood flow measured by SPECT in the OFC (Rubin *et al.*, 1995) and ventral ACC (Hoehn-Saric *et al.*, 1991). Baxter and colleagues have reported that pre-treatment correlations between caudate and orbital regions ranging from 0.44 to 0.74 decreased significantly after effective treatment (Baxter *et al.*, 1992; Schwartz *et al.*, 1996). In addition, lower pre-treatment OFC glucose metabolism may be associated with better response to medications, whereas the converse may be true for psychotherapy (Swedo *et al.*, 1989; Brody *et al.*, 1998; Saxena *et al.*, 1999). Response to pharmacotherapy has also been predicted by glucose metabolic reductions in the ACC (Swedo *et al.*, 1989) and left caudate (Benkelfat *et al.*, 1990); however, Brody *et al.* (1998) did not replicate those findings Saxena *et al.*, 1999, only reported conducting tests for the OFC). Overall, treatment studies further implicate the caudate, OFC, and ACC in OCD. They suggest that the hyperactivity of these structures in OCD is state-dependent and that pre-treatment levels of activity may have prognostic value. The inconsistencies in findings remain to be addressed in further research.

The cognitive data implicating right hemisphere regions suggest the importance of threat perception and evaluation in OCD. The functional significance of the caudate, OFC, and ACC hyperactivity often reported prior to treatment are consistent with their roles in the perseverative nature of obsessions and compulsions, in decoding reward and punishment values of perceived and real events (c.f. Rauch, in press), and in response conflict about whether to perform some mental activity or compulsive behaviour. As noted above, the cognitive data suggest the engagement of right hemisphere regions involved in threat perception. The absence of more right-sided effects in the imaging data should be interpreted with caution, as it may be due to the difficulty of conducting adequate tests of asymmetry (Davidson and Irwin, 1999).

A final important consideration is the high level of comorbid depression in people with OCD. Visual–spatial (including non-verbal memory) and executive deficits in depression are well established and are congruent with the reduced activity in right parietal and bilateral frontal regions often reported for depression (Heller and Nitschke, 1997, 1998). The extent to which the non-verbal memory and executive deficits in OCD can be attributed to depression, anxiety, obsessions, or compulsions has not been determined, in part because the co-occurrence of these various symptoms makes disentangling their effects exceedingly difficult. Furthermore, the pronounced brain abnormalities accompanying depression (for reviews, see Davidson *et al.*, 2002; Mohanty and Heller, 2002, Chapter XVIII-7) certainly have consequences for the neuropsychology of OCD. For example, Martinot *et al.* (1990) reported a bilateral diminution of PFC glucose metabolism in 16 OCD patients as compared to eight non-psychiatric controls and no effects for OFC; however, despite not meeting criteria for DSM-III current major depressive episode, these patients were characterized by significantly higher levels of depression than the controls.

POSTTRAUMATIC STRESS DISORDER

The past decade has witnessed an explosion of research examining the neurobiological mechanisms and neuropsychological, behavioural, and cognitive concomitants of posttraumatic stress disorder (PTSD). The diagnostic requirement of exposure to a traumatic event makes this disorder an ideal candidate for testing aetiological hypotheses based on the rich conditioning literature, including classical cue conditioning, operant conditioning, and context conditioning. However, the array of re-experiencing, avoidance, and arousal symptoms and the common comorbidity with depression (and substance abuse in war veterans) add layers of complexity that make unraveling the neural circuitry of PTSD seem an intractable enterprise. Moreover, classification of PTSD remains a highly controversial topic, not only with regard to prototypic symptoms and subtyping but also with regard to whether it should be considered an anxiety disorder at all. Despite these obstacles, the emerging body of research is contributing to understanding this elusive condition.

Cognitive Studies

As with OCD, a commonly reported cognitive abnormality in PTSD is an attentional bias towards threat-related stimuli on tasks such as the emotional Stroop test. This effect has been reported for rape victims (e.g., Foa *et al.*, 1991), combat veterans (e.g., McNally *et al.*, 1990, 1993, 1996; Kips *et al.*, 1995; Vrana, Roodman and Beckham, 1995), motor vehicle accident victims (Bryant and Harvey, 1995), and people involved in a ferry disaster (Thrasher, Dalgleish and Yule, 1994). Recovery from PTSD has been shown to eliminate the attentional bias (Foa *et al.*, 1991), whereas PTSD patients who have not recovered continue to show the bias toward threat cues when retested (McNally and Kohlbeck, 1993). A memory bias toward trauma-relevant material has also been found in PTSD patients for explicit memory (Vrana, Roodman and Beckham, 1995) and conceptual implicit memory (Amir, McNally and Wiegartz, 1996c), suggesting a more pervasive proclivity towards

threat-related material that is not confined to the frequently reported attentional effect. No bias was found on an implicit-memory task that depended more on physical, perceptual features of the words than on their meaning (McNally and Amir, 1996). Consistent with these cognitive data, a recent ERP study using threat words as the low-probability stimulus type in an oddball paradigm reported that PTSD patients had larger P3 amplitudes than non-psychiatric controls for trauma-relevant but not trauma-irrelevant threat words (Stanford *et al.*, 2001). The oddball paradigm is comprised of frequent presentations of one stimulus type and infrequent presentations of a second stimulus type, which typically elicits an enlarged ERP component known as P3 or P300. Taken together, these data are suggestive of right hemisphere abnormalities pertinent to threat perception.

The other salient cognitive finding in PTSD is an explicit memory deficit. Compromised memory performance has been observed in combat veterans (e.g., Bremner *et al.*, 1993; Uddo *et al.*, 1993; McNally *et al.*, 1994, 1995; Yehuda *et al.*, 1995), rape victims (Jenkins *et al.*, 1998), and adult survivors of childhood abuse (e.g., Bremner *et al.*, 1995b; but see Stein *et al.*, 1997). These data corroborate the reports of reduced hippocampal volume in PTSD to be reviewed next.

Neuroimaging Studies

As covered by Martis *et al.* (Chapter XIX-9), the handful of studies examining structural abnormalities in PTSD consistently implicate the hippocampi, with reduced volume ranging from 8% to 30% (Bremner *et al.*, 1995a, 1997; Gurvits *et al.*, 1996). A 5% reduction in the left hippocampus was observed by Stein *et al.* (1997) in 21 adult survivors of childhood abuse, 15 of whom met DSM-IV criteria for PTSD. Schuff *et al.* (1997) also reported a trend for a 6% right hippocampal reduction in combat veterans. It is not known whether this smaller hippocampal size is due to cell loss, cell atrophy, or to some other cause (Rajkowska, 2000; Sapolsky, 2000; Sheline, 2000). Controversy persists with regard to the role of cortisol as a causative factor in the hippocampal reductions observed in PTSD (Yehuda, 1997). Regardless of this, these hippocampal data are clearly linked to the aforementioned explicit memory deficit in PTSD. Indeed, Bremner *et al.* (1995a) reported a strong correlation ($r = 0.64$) between verbal memory and right hippocampal volume in combat veterans with PTSD.

In contrast to the above morphometric data, functional neuroimaging studies examining PTSD have implicated a host of structures (see Table XIX-9.1B in Martis *et al.*, Chapter XIX-9). Two recent symptom provocation studies used script-driven imagery in conjunction with PET in adult female victims of childhood sexual abuse with and without PTSD (Bremner *et al.*, 1999a; Shin *et al.*, 1999). Bremner *et al.* (1999a) found that personalized traumatic scripts were associated with less blood flow in the right hippocampus and more blood flow in ventral ACC, PFC, insula, posterior cingulate, and motor cortex for women with PTSD than those without. Shin *et al.* (1999) reported more blood flow in the ventral ACC, OFC, and insula for childhood abuse victims with PTSD than those without. Two studies reported activation of the ventral ACC in combat veterans with PTSD as well as in combat controls without PTSD (Bremner *et al.*, 1999b; Liberzon *et al.*, 1999). Using SPECT, Liberzon and coworkers observed activation of the ventral ACC/medial PFC in non-psychiatric controls as well. Another report from this group indicated that only PTSD subjects showed more blood flow in the medial PFC, whereas both PTSD subjects and non-psychiatric controls showed a trend for increased blood flow in the ventral ACC (Zubieta *et al.*, 1999). Using PET, Bremner *et al.* (1999b) also found PTSD to be associated with increased blood flow in parietal, posterior cingulate, and motor areas. It remains to be seen whether activation in some of these regions (e.g., ventral ACC) is specific to PTSD, or has more to do with task demands or other phenomena (e.g., mood, comorbid depression, the presence of other types of anxiety).

Several symptom provocation studies of PTSD have found amygdala activation (Rauch *et al.*, 1996; Shin *et al.*, 1997; Liberzon *et al.*, 1999). Other areas implicated by Rauch *et al.* (1996) in a PET study using script-driven imagery were the ventral ACC and right OFC, insula, and temporal cortex. The same group also found increased blood flow in the ventral ACC in another sample of combat veterans for a paradigm involving combat, negative, and neutral pictures (Shin *et al.*, 1997a, 1997b). Both those studies also reported a blood flow decrease in Broca's area (see also Fischer, Wik and Fredrikson, 1996), perhaps indicative of downregulation of this verbal generation region in the service of more effective recruitment of phylogenetically older structures more appropriate for the extreme fear and horrific traumas experienced by people who go on to develop PTSD.

The importance of the amygdala and OFC for the circuitry implicated in PTSD is further underscored by research not targeting symptom-related stimuli. Using fMRI and a backward masking paradigm previously shown to activate the amygdala in non-psychiatric volunteers (Whalen *et al.*, 1998), Rauch *et al.* (2000) found that combat veterans with PTSD had larger right amygdala responses to fearful faces masked by neutral faces than did combat controls without PTSD. These responses to fear expressions are consistent with cognitive biases toward threat discussed above for PTSD patients. An older study conducted by Semple *et al.* (1993) reported more OFC blood flow as measured by PET during an auditory continuous performance task and a word generation task in combat veterans with PTSD and substance abuse than non-psychiatric controls. Less parietal blood flow during the continuous performance task was also observed (Semple *et al.*, 1996). A newer study from that group found that a similar sample of PTSD patients had more right amygdalar and left parahippocampal blood flow during the same continuous performance task than non-psychiatric controls (Semple *et al.*, 2000), adding further support to the symptom provocation findings above.

In sum, both cognitive and neuroimaging findings suggest the engagement of several right hemisphere regions, consistent with evidence that these areas are differentially involved in responding to threat. In addition, the neuroimaging data highlight a distributed array of structures not clearly lateralized, including the OFC, ACC, amygdala, and hippocampus, regions associated with decoding motivationally salient material, response conflict, fear and vigilance for motivationally salient events, and memory. As with OCD, the OFC and ventral ACC appear to be involved in the brain circuitry associated with the pathogenesis and expression of PTSD. Important points of divergence between the two disorders emerge in the subcortex, with the caudate specific to OCD and the amygdala and hippocampus implicated in numerous studies examining PTSD. It is unclear whether the decrease in Broca's area is unique to PTSD, in part because deactivations often are not reported. As with OCD, the rates of depressive disorders in PTSD populations is extremely high, which again warrants attention to the known cognitive and neurobiological correlates of depression in any discussion of the brain circuitry central to PTSD.

PANIC DISORDER

Characterized by recurrent unexpected panic attacks that share many features with basic fear responses, panic disorder has been viewed as the pre-eminent candidate condition for postulating dysfunction of the fear circuitry identified in research with non-human animals. However, the literature has shown this to be

a disappointing enterprise, and the neural machinery involved remains largely a mystery. It is important to note that even in the majority of individuals experiencing frequent panic attacks (once or more per day), more time is spent worrying about having future attacks or about the implications of those attacks than having actual attacks. For obvious reasons, animal models are not particularly conducive to tracking the circuitry associated with worry, although research on context conditioning, long-term sensitization, and anticipatory anxiety is certainly relevant (e.g., Davis and Lee, 1998; Nitschke *et al.*, 2001). The various neuropsychological research tools now available with humans may hold the most promise for identifying the circuitry affected in panic disorder.

Cognitive Studies

Cognitive reports in the literature on panic disorder have been more sparse than for OCD or for PTSD. The most common finding is a bias for panic-relevant words on implicit and explicit memory tasks (e.g., McNally, Foa and Donnell, 1989; Cloitre and Liebowitz, 1991; Cloitre *et al.*, 1994; Amir *et al.*, 1996b; Becker *et al.*, 1994, 1999), although negative findings have been reported (Otto *et al.*, 1994; Rapee, *et al.*, 1994). Perceptual asymmetry on a dichotic listening task suggestive of more left than right hemisphere activity was associated with better memory for threat words in panic disorder patients but not in non-psychiatric controls (Otto *et al.*, 1994). These results suggest a pattern of brain activity akin to that found for generalized anxiety disorder (see below), anxious apprehension, and worry (for review, see Nitschke, Heller and Miller, 2000). There is also evidence of a bias towards threatening words in a priming task involving lexical and non-lexical word pairs, one presented above the other (McNally *et al.*, 1997). Panic patients showed faster reaction times in naming the threat targets following the threat prime but only when the target was in the bottom position. Emotional Stroop interference has also been observed in panic disorder patients (Ehlers *et al.*, 1988; McNally *et al.*, 1990, 1994). These cognitive biases again point to the involvement of right hemisphere systems corresponding to threat, with dichotic listening data suggesting left-hemisphere engagement, perhaps reflecting anxious apprehension.

Neuroimaging Studies

The one known quantitative morphometric study found that panic disorder patients had smaller temporal lobes than non-psychiatric controls but no hippocampal differences (Vythilingam *et al.*, 2000). Evidence for temporal lobe aberrations has also been documented using qualitative grading methods (Fontaine *et al.*, 1990). Eleven patients exhibited abnormal signal activity in the temporal lobes, which was most prominent at the interface of the right medial temporal lobe and parahippocampal cortex (see Table XIX-9.2A in Martis *et al.*, Chapter XIX-9).

Consistent with these data, haemodynamic imaging studies have repeatedly implicated abnormalities in hippocampal and parahippocampal regions. The first report was a PET study finding more right than left parahippocampal blood flow in panic disorder patients who responded to lactate infusion (Reiman *et al.*, 1984). This finding held for the full sample, with right-sided parahippocampal asymmetries also observed for blood volume and oxygen metabolism (Reiman *et al.*, 1986). Differential hippocampal asymmetries in the same direction were found for glucose metabolism in panic disorder patients while engaged in an auditory continuous performance task (Nordahl *et al.*, 1990, 1998; see Table XIX-9.2B in Martis *et al.*, Chapter XIX-9). In the first study, patients also exhibited more right frontal and occipital metabolism and less left parietal metabolism than non-psychiatric controls. An inferior frontal asymmetry with more right than left metabolism was observed in both patient samples. Similar group differences in inferior PFC asymmetry (right > left), right frontal (marginally significant), and occipital cortex were reported in a SPECT study conducted by De Cristofaro *et al.* (1993). There were no differences in hippocampal asymmetry, but rather patients showed bilateral decreases.

Consistent with the reports of hippocampal and parahippocampal asymmetries, Bisaga *et al.* (1998) found that panic disorder patients exhibited more glucose metabolism in the left hippocampus and parahippocampal area than non-psychiatric controls. Those patients also had less metabolism in right inferior parietal and right superior temporal regions, which could be due to comorbid depression (Heller and Nitschke, 1998). In light of hippocampal involvement in explicit memory, these findings suggest that hippocampal and parahippocampal asymmetries may play a role in the explicit memory bias toward threat emerging in the cognitive literature.

The first quantitative EEG study on panic disorder documented abnormal patterns of asymmetry in both frontal and parietal regions, with patients exhibiting relatively more right-sided activity than non-psychiatric controls (Wiedemann *et al.*, 1999). More right than left frontal activity was documented for the patients but not the controls, whereas the patients did not exhibit the parietal left > right asymmetry observed in controls. Furthermore, the same frontal asymmetry was also present while the patients viewed a spider, an erotic, and an emergency picture, but not a mushroom.

Symptom provocation studies of panic disorder employing haemodynamic methods have assumed the form of pharmacological challenges. Using SPECT during sodium lactate infusion that induced global blood flow increases, Stewart *et al.* (1988) found that patients who panicked following infusion exhibited larger occipital increases, especially on the right, than non-panicking subjects, whereas the non-panicking subjects showed larger global increases, especially over the left hemisphere. In a PET study, Reiman *et al.* (1989) found no blood flow increases following sodium lactate infusion among non-panicking subjects, whereas the panic disorder patients who had panic attacks exhibited increased blood flow in anterior temporal, insula/claustrum/putamen, superior colliculus/periacquenductal grey, and cerebellar vermis regions (see also Table XIX-9.2C in Martis *et al.*, Chapter XIX-9). Of note, the anterior temporal findings may be an artifact of muscular contraction of the jaw (Drevets, Videen and MacLeod, 1992; Benkelfat *et al.*, 1995), such that recent imaging studies on anxiety often employ teeth-clenching control conditions (e.g., Rauch *et al.*, 1996; Reiman, 1997; Javanmard *et al.*, 1999).

The parallel between the most frequently observed cognitive and neuroimaging findings is noteworthy. As the only anxiety disorder with a memory bias toward threat just as reliable as an attentional bias, if not more so, panic disorder also is unique with regard to the consistent hippocampal findings across several functional imaging studies. With the hippocampus known to be the critical structure for explicit memory function, these findings suggest that the commitment of certain right hemisphere regions to threat may extend to the hippocampus. Consistent with the argument forwarded for OCD and PTSD, the involvement of broader right hemisphere systems encompassing various territories governing threat perception corresponds to findings of memory and attentional biases. The PFC asymmetry observed in three studies using different technologies is in concordance with that position. The OFC, ACC, and caudate regions highlighted in the above sections for OCD and PTSD have not emerged with any consistency in research on patients with panic disorder.

Again, the issue of comorbidity with depression deserves mention, because the explicit memory bias and the PFC asymmetry are commonly seen in depression. However, evidence reviewed above suggests that increases in right PFC activity are driving this asymmetry in panic disorder, whereas the preponderance of literature on

major depressive disorder indicates that decreased left PFC activity likely contributes to that asymmetry in depression.

SPECIFIC PHOBIA (SIMPLE PHOBIA)

Characterized by a persistent, excessive, and unreasonable fear of a specific object or situation, this disorder is very amenable to research investigation both with regard to experimental designs (e.g., presenting subjects with phobic stimuli) and subject sampling due to the prevalence of specific phobias and the relatively low rates of comorbidity with other mental disorders. However, studies with phobics are few, perhaps due to minimal public health interest in specific phobias because they generally do not compromise the occupational or social functioning of affected individuals to the same extent as other anxiety disorders. The preponderance of physiological research to date has focused on peripheral psychophysiological measures such as skin conductance, cardiovascular, and neuroendocrine activity (for review, see Fyer, 1998). No structural imaging data are available for specific phobias, and other neuropsychological research has been quite limited.

Cognitive Studies

The handful of studies investigating cognitive function in phobic individuals has documented the presence of an attentional bias but no memory bias. In women with spider phobia, Van den Hout *et al.* (1997) documented interference for both masked and unmasked words associated with spiders on a modified Stroop task similar to those employed in the OCD, PTSD, and panic disorder studies above. Using Stroop tests involving spider, general negative, and neutral words, Watts *et al.* (1986) and Lavy, Van den Hout and Arntz (1993) found larger interference for the spider words in spider phobics than matched non-anxious controls. No Stroop interference effects were observed in driving phobics for motor vehicle accident words; however, the words did not reflect their primary concerns but rather were designed for accident victims who developed PTSD (Bryant and Harvey, 1995). Evidence of a memory bias in spider phobia has not been reported (Watts and Coyle, 1993).

Neuroimaging Studies

Consistent with the conclusion drawn by Martis *et al.* (Chapter XIX-9), functional neuroimaging data have been inconsistent across studies. When small animal phobics were exposed to containers housing the feared animal, Rauch *et al.* (1995a) found blood flow increases using PET in a number of regions implicated in the above studies for OCD and PTSD (see Rauch *et al.*, 1997b), including the right ACC, left insular cortex, and left OFC. Conversely, two earlier PET studies by Fredrikson and colleagues using film clips of the feared stimuli with snake and spider phobics did not find blood flow increases in any region except the secondary visual cortex (Fredrikson *et al.*, 1993, 1995; Wik *et al.*, 1993). The only other PET study conducted with specific phobics found that confronting animal phobics with their feared animal did not elicit blood flow changes in any region of the brain although significant cardiovascular and self-reported anxiety changes were observed (Mountz *et al.*, 1989). They also reported no resting baseline differences between the phobics and non-psychiatric controls. In a SPECT study of women with spider phobia, those reporting panic while watching a video of spiders exhibited less frontal blood flow, especially on the right side, than during a neutral film (Johanson *et al.*, 1998). The remaining phobic women who reported anxiety but did not panic showed more right frontal blood flow to the spider film (although significance level was not reported). The sole published EEG study of specific phobia found more right than left parietal activity to be associated with higher pre-treatment spider phobia scores, whereas frontal activity was not related to pre-treatment or post-treatment clinical measures (Merckelbach *et al.*, 1998). There have been no published findings of amygdala activation in specific phobia despite the clear relevance of that structure for the fear response evoked by confronting phobic stimuli.

Due to the dearth of cognitive and neuroimaging research investigating specific phobias, little is known about the neuropsychology accompanying such intense, long-standing fear of an object that is often harmless. The attentional bias suggests the involvement of right hemisphere regions oriented towards threat; however, the imaging data are inconsistent. Although the structures implicated in the study by Rauch *et al.* (1995a, 1997b) suggest some commonality with other anxiety disorders, those findings have not been supported by the other studies examining specific phobia. It may be that the circuitry implicated is much less pronounced or complex than appears to be the case for the other anxiety disorders, just as the impact on everyday functioning is on average far less than for the others.

SOCIAL PHOBIA (SOCIAL ANXIETY DISORDER)

Now often referred to as social anxiety disorder, social phobia can be viewed as a variant of specific phobia that pertains to social or performance situations. Individuals suffering from social phobia fear that they will act in a humiliating or embarrassing way when in the presence of other people. Recent epidemiological studies have identified it as the third largest psychological disorder in the United States, after depression and alcoholism. Accordingly, the past five years has witnessed an explosion of research interest in the disorder, with efforts to identify the affected neural circuitry very much in their infancy.

Cognitive Studies

Cognitive research has implicated a number of abnormalities in social phobia, the majority of which are consistent with the information processing biases described in other anxiety disorders. The numerous studies examining attention, interpretation, and memory biases in social phobia have recently been reviewed (Heinrichs and Hofmann, 2001). This literature abounds in evidence of attention and interpretation biases towards social threat across multiple different paradigms.

One relevant study not reviewed by Heinrichs and Hofmann (2001) examined attention bias for facial expressions in generalized social phobia (Gilboa-Schechtman, Foa and Amir, 1999). Consistent with the dot probe and Stroop studies reviewed, phobic subjects showed an attentional bias toward angry faces as measured via several metrics using the face-in-the-crowd paradigm, whereas non-anxious controls did not. Moreover, successful treatment has resulted in the attenuation of attention (e.g., Mattia, Heimberg and Hope, 1993) and interpretation (e.g., Foa *et al.*, 1996) biases.

In other findings, Amir *et al.* (1996a) found suppression of Stroop interference to social-threat words in social phobics but not non-psychiatric controls prior to giving a speech (see Mathews and Sebastian, 1993, for comparable findings in snake-fearful subjects when in the presence of a snake they are told they will have to approach upon completion of the Stroop task). The authors suggested that subjects might increase their efforts when anxious, thereby compensating for the interference. Another possibility is that the right hemisphere resources devoted to threat might all be allocated to the situation surrounding the impending social performance, such that the threat words no longer are perceived as threatening (relative to the impending speech) to the same degree as they are under non-anxious experimental conditions.

Research eliciting anticipatory anxiety in interpretation/judgement bias paradigms is needed to determine if this phenomenon extends to other domains of information processing.

Until very recently, it was widely accepted that social phobia was not accompanied by a memory bias (e.g., Rapee *et al.*, 1994). However, recent evidence suggests otherwise (Amir *et al.*, 2000, 2001). Two reports using face stimuli provide further evidence for an explicit memory bias in social phobia. Lündh and Öst (1996) first documented the effect in a paradigm where social phobics and non-psychiatric controls were asked to judge faces as either critical or accepting. Unlike the controls, the phobics showed a memory bias for faces they had previously judged as critical. In two elegant experiments following up the seminal report by Lündh and Öst (1996), Foa *et al.* (2000) found that social phobics recognized more angry and disgust faces than happy or neutral ones, whereas no differences were observed for non-anxious controls. The same pattern was seen for reaction time data, with social phobics showing longer latencies in making a decision about the negative than the non-negative facial expressions. Furthermore, phobic subjects had longer latencies for angry than disgust faces, whereas controls did not. Similar specificity was observed in the attentional paradigm employing faces mentioned above, with social phobics detecting anger faces faster than disgust ones, whereas controls showed no difference (Gilboa-Schechtman, Foa and Amir, 1999). Taken together, data from these face paradigms suggest a general negativity bias (e.g., all negative emotion expressions) that is amplified by faces connoting threat (e.g., anger expressions), again implying that the right hemisphere regions involved in threat perception should be involved.

Consistent with cognitive findings for OCD, visual–spatial impairment including non-verbal memory deficits has been documented in social phobia (Cohen *et al.*, 1996; Hollander *et al.*, 1996), as has executive dysfunction (Cohen *et al.*, 1996). Along with other findings of left-sided neurological soft signs (Hollander *et al.*, 1996), these visual–spatial deficits are consistent with right hemisphere dysfunction in social phobia. Possibly, these deficits are produced by the augmented engagement of the right hemisphere in threat perception with a consequent lack of resources for other processes lateralized to the right hemisphere such as visual–spatial functions.

Neuroimaging Studies

Structural abnormalities of the brain have not been observed in social phobics (Potts *et al.*, 1994); however, a set of recent functional neuroimaging studies point to several critical regions. Surveying EEG at the scalp, Davidson *et al.* (2000) found that social phobics exhibited a larger anterior temporal right > left asymmetry (marginally significant for lateral frontal and parietal sites) during anticipation of making a public speech than non-psychiatric controls. Using PET to measure blood flow in social phobics, Reiman (1997) reported that singing in front of observers activated a number of cortical and subcortical regions, including lateral PFC, anterior temporal, and posterior cingulate regions, with trends noted in the ACC, medial PFC, amygdala, and hippocampus. In another PET study, Tillfors *et al.* (2001) found that social phobics exhibited larger blood flow increases than non-psychiatric controls in the right amygdaloid complex (extending into the hippocampus) while speaking in front of an audience. On the other hand, controls had larger increases in right parietal, restrosplenial, and right secondary visual cortices than social phobics did.

An fMRI study found that social phobics showed greater amygdala activation bilaterally to neutral faces than did non-psychiatric controls despite no differences in subjective ratings of the faces, whereas both groups showed the expected activation of the amygdala to aversive odors (Birbaumer *et al.*, 1998). However, it appears that this effect for the amygdala did not maintain for the full sample (Schneider *et al.*, 1999), with social phobics only exhibiting greater amygdalar and hippocampal activation than controls when the neutral faces were paired with the aversive odors (see Table XIX-9.4A in Martis *et al.*, Chapter XIX-9). Three additional neuroimaging reports presented pilot or preliminary data with mixed results for the structures implicated in the above studies on social phobia (Stein and Leslie, 1996; Van Ameringen *et al.*, 1998; Van der Linden *et al.*, 2000).

Overall, these cognitive and neuroimaging data point most strongly to the right cortical regions and the amygdala, especially in paradigms involving methods that are ecologically relevant to social phobia such as face stimuli and social performance. The concordance of the cognitive findings with the right-sided brain activation reported by Davidson *et al.* (2000) suggests that the circuitry of social phobia includes right hemisphere regions involved in threat perception. The involvement of the amygdala in fear and in vigilance for motivationally salient events is certainly applicable for the paradigms involving anticipatory anxiety and social performance.

GENERALIZED ANXIETY DISORDER

The salience of worry and verbal rumination in generalized anxiety disorder (GAD) suggests the involvement of left-hemisphere structures dedicated to language. In contrast to the other anxiety disorders which may involve varying degrees of worry about disorder-specific content, worry is the hallmark of GAD. Although worry about everyday problems is not pathological in itself, the person with GAD worries excessively, has difficulty controlling the worry, and experiences significant distress and impaired social and occupational functioning as a result. The exceedingly high rates of comorbidity with depression have made it very difficult to isolate brain abnormalities in GAD. Both cognitive and neuroimaging studies have therefore often been quite compromised in terms of diagnostic specificity.

Cognitive Studies

As with the other anxiety disorders covered above, GAD is characterized by an attentional bias towards threat in Stroop (Mathews and MacLeod, 1985; Mogg *et al.*, 1987, 1993; Martin, Williams and Clark, 1991; Bradley *et al.*, 1995; Mathews *et al.*, 1995), dot probe (MacLeod, Mathews and Lata, 1986), distractor (Mathews *et al.*, 1990, 1995), and dichotic listening (Mathews and MacLeod, 1986) paradigms. Consistent findings have emerged in two newer paradigms using emotional faces. Using a variant of the dot probe task, Bradley *et al.* (1999) reported that GAD patients had slower reaction times for threatening than neutral faces, compared to controls. Using a similar probe detection task, Mogg, Miller and Bradley (2000) measured eye movements and found that GAD subjects showed a bias toward threat faces for the two eye-movement metrics employed, but they did not replicate the reaction time differences documented by Bradley *et al.* (1999). Several of these studies reported the absence of an attentional bias in comparison groups with clinical depression (Mogg *et al.*, 1993, 2000) or with comorbid GAD and depression (Bradley *et al.*, 1995). Evidence for general rather than threat-specific distractibility has also been found (Bradley *et al.*, 1999; see also Mathews *et al.*, 1990, 1995), although even these studies found results for threat conditions to be more robust than for non-threat conditions. Despite earlier evidence to the contrary (Mathews *et al.*, 1990), recovery from GAD does not appear to be accompanied by a residual attentional bias (Mathews *et al.*, 1995; see also Mogg, Mathews

and Eysenck, 1992), consistent with findings reviewed above for other anxiety disorders.

Findings of a memory bias in GAD have been mixed. A bias towards threat has generally not been observed for explicit memory tasks (Mogg, Mathews and Weinman, 1987; Mathews *et al.*, 1989a; Otto *et al.*, 1994; MacLeod and McLaughlin, 1995; Becker *et al.*, 1999). However, Friedman, Thayer and Borkovec (2000) found an explicit memory bias in two separate GAD samples with extremely low rates of comorbid depression (although comorbidity with social phobia was 60%). Several important methodological differences from earlier studies (e.g., incidental learning task, no imagery instructions, longer stimulus exposure) suggest the presence of an explicit memory bias in GAD under conditions optimal for detecting memory biases in clinical anxiety (see Becker *et al.*, 1999). In addition, Otto *et al.* (1994) documented the same relationship between auditory perceptual asymmetry and memory bias toward threat discussed above for panic disorder in a sample of GAD patients. The inferred pattern of more left than right hemisphere activity was associated with better memory for threat words, consistent with left-sided neuroimaging findings for GAD reviewed below.

Implicit-memory bias has emerged for GAD under some conditions (MacLeod and McLaughlin, 1995; Mathews *et al.*, 1989a) but not others (Mathews *et al.*, 1995), a discrepancy that cannot be explained by the type of implicit-memory tested (see above discussion contrasting conceptual and perceptual implicit-memory in PTSD). There is also evidence that GAD patients have a bias to interpret ambiguous stimuli as threatening (Mathews, Richards and Eysenck, 1989b; Eysenck *et al.*, 1991). Recovered patients do not show implicit memory or interpretive biases (Mathews, Richards and Eysenck, 1989b; Eysenck *et al.*, 1991). Again, the cognitive bias literature suggests state-dependent recruitment of right hemisphere regions involved in threat perception, perhaps superimposed upon the left-sided perceptual asymmetry and neuroimaging findings also observed in GAD patients.

There is some indication of mild cognitive deficits in GAD that are consistent with the notion that worry occupies cognitive resources that otherwise might be deployed for various experimental tasks and everyday functions. Wolski and Maj (1998) documented performance deficits on a modified Sternberg memory task in a group of 87 anxiety patients, 77 of whom had GAD. The general distractibility effects reviewed above (e.g., Bradley *et al.*, 1999) provide further support for this position. However, overall performance deficits are generally not seen on attention and memory tasks (e.g., Mathews *et al.*, 1990; Otto *et al.*, 1994).

Neuroimaging Studies

The one published morphometric MRI study on GAD was conducted with children and adolescents (De Bellis *et al.*, 2000). The right amygdala was larger in patients than in matched non-psychiatric controls. No differences were found in the temporal lobe, hippocampi, corpus callosum, or basal ganglia or for total intracranial or total cerebral volumes.

In contrast to the other anxiety disorders covered here, functional neuroimaging studies are older, with no work published in the past decade. Wu *et al.* (1991) found that patients had less glucose metabolism in the basal ganglia (comprised of caudate, putamen, and globus pallidus) and more in left inferior frontal, left inferior occipital, right posterior temporal, and right precentral regions than non-psychiatric controls during a passive viewing task. The left inferior frontal finding and concomitant greater left than right frontal metabolism are in line with the hypothesis that language centres involved in worry (e.g., Broca's area) are activated. During a visual continuous performance task using degraded stimuli performed only by the patients, basal ganglia and right parietal metabolism increased, whereas decreases were seen in right temporal and occipital lobes. Consistent with their earlier report (Buchsbaum *et al.*, 1987), which they claimed was on the same GAD sample (the gender breakdown was slightly different), benzodiazepine therapy resulted in decreased occipital, basal ganglia, and limbic system (comprised of the amygdala, hippocampus, and cingulate) metabolism. In a SPECT study, GAD patients showed increased left orbital frontal blood flow when asked to freely associate about threatening pictures presented prior to rCBF measurement (Johanson *et al.*, 1992). The specificity of the effects to GAD in the latter two studies is not clear because neither one included a control group.

Involvement of different brain areas in GAD can also be gleaned from several EEG studies. EEG topography from 32 sites revealed no baseline differences between GAD patients and non-psychiatric controls (Grillon and Buchsbaum, 1987). When presented with neutral lights in a basic orienting response paradigm, patients showed less alpha suppression (presumably reflecting decreased mental activity) than controls, especially over the occipital lobe, perhaps reflecting a diminution of attention to external stimulation because of competing processes devoted to worry. An earlier EEG study by the same group examined benzodiazepine treatment effects in patients with random assignment to placebo or drug group and in non-psychiatric controls (Buchsbaum *et al.*, 1985). Using 16 midline and left-hemisphere sites, they found that patients had less delta and alpha (more activity) than controls, especially over left posterior temporal cortex. Drug effects were seen in different bands across several regions of the brain but were of limited utility in isolating patterns of brain activity critical for GAD because only four of the nine patients administered benzodiazepines showed clinical improvement as measured by the Hamilton Anxiety Scale (none of the 11 patients taking placebo improved). However, correlational analyses revealed that increased left frontal alpha (decreased activity) was associated with clinical improvement for patients in the drug group, consistent with above findings of left frontal involvement in GAD and worry.

Of relevance to imaging research despite only recording from three midline electrodes, a recent treatment study of GAD explored frontal midline theta activity, which is thought to reflect reduction of anxiety during task performance (Suetsugi *et al.*, 2000). Criteria for frontal midline theta at the midfrontal site were not met for any of the 28 patients at the initial visit. The 26 patients for whom frontal midline theta appeared following psychotherapy or pharmacotherapy showed dramatic clinical improvement, whereas the remaining two individuals continued to exhibit high levels of anxiety. Although these data are certainly preliminary, they again implicate the frontal cortex and suggest that worry interferes with the production of frontal midline theta.

The dearth of recent neuroimaging data for GAD — also noted by Martis *et al.* (Chapter XIX-9) — is striking when compared to the proliferation of such research conducted with the other five anxiety disorders covered in this review. The few studies conducted, along with the more extensive cognitive science literature examining GAD, point to several brain regions deserving further investigation. Based on the cognitive deficit and left-sided neuroimaging findings, the circuitry involved in worry and the structures overlapping with attention and working memory (e.g., PFC, parietal regions, particularly left hemisphere) are conspicuous candidates for uncovering brain aberrations in GAD. In addition, the right hemisphere territories implicated by the cognitive biases accompanying GAD are also likely constituents of the brain circuitry involved in the pathophysiology of GAD.

DISCUSSION

Across the many cognitive and neuroimaging studies reviewed here, cognitive biases toward threat is the one attribute common to all six

anxiety disorders covered. Attentional biases have been observed in all disorders, whereas data for explicit and implicit-memory biases have been mixed. Findings of a memory bias have been replicated most consistently for panic disorder, with substantial evidence also reported for PTSD, social phobia, and GAD. On the other hand, no studies have found a memory bias in OCD or specific phobia. Interpretation (i.e., judgement) biases have not been extensively examined among clinical populations, although there is ample evidence of such a bias in OCD, social phobia, and GAD. This orientation towards threat in anxiety disorder populations suggests the involvement of particular anterior and posterior right hemisphere regions (for reviews, see Compton *et al.*, 2000, 2001; Nitschke, Heller and Miller, 2000). As described by Nitschke and coworkers (2000), these biases may be related to an emotion surveillance system of the right hemisphere designed to evaluate the presence of a threat in the external environment. This right hemisphere system may correspond to the cortical processes that McNally (1998) postulated to accompany a subcortical circuit involved in attentional biases toward threat. The hyperactivation of this right hemisphere system may interfere with visual–spatial functions for which right posterior regions are specialized, as seen in OCD and social phobia. The right-sided increases in activation reported in many of the neuroimaging studies examining anxiety disorders — with the notable exception of GAD, which likely invokes left-hemisphere regions devoted to verbal processes needed for worry — may be a manifestation of the heightened reliance on this emotional surveillance system governing threat perception and evaluation.

The anxiety disorders covered here are further characterized by a number of divergent neuropsychological patterns. In contrast to the morphometric and functional studies on OCD, the caudate nucleus is not implicated in any other anxiety disorders. PTSD is the only disorder to be accompanied by memory deficits and by reduced hippocampal volume. Findings of hippocampal asymmetries have been reported exclusively for panic disorder. Unlike the other disorders, the preponderance of imaging findings for GAD implicates left-hemisphere regions. Amygdala activation has not been observed with any inconsistency, except in PTSD and social phobia. OFC and ventral ACC activations have been reliably found only in OCD and PTSD. Finally, visual–spatial deficits have been observed for OCD and social phobia but not the others. This summary of the findings points to the substantial heterogeneity among the anxiety disorders.

Although anxiety is often referred to as a homogenous construct, neuropsychological data clearly indicate the importance of noting distinctions and variable symptom expression both across and within diagnoses. Several useful neurobiological models have been proposed, including one proposed by Rauch *et al.* (1998) on OCD and another proposed by Charney, Grillon and Bremner (1998) concentrating primarily on PTSD. We have proposed a neuropsychological framework positing a distinction between two types of anxiety (e.g., Nitschke *et al.*, 2000). Anxious apprehension is characterized primarily by worry and relies on left-hemisphere processes, whereas anxious arousal is characterized by immediate fear and panic symptoms and closely aligned with the emotion surveillance system of the right hemisphere. In general, GAD is characterized more strongly by anxious apprehension than are the other disorders, whereas panic disorder is likely accompanied by the highest levels of anxious arousal. However, it is important to note that these two forms of anxiety are not mutually exclusive and likely exist in all individuals with anxiety disorders to varying degrees. Pronounced individual differences within a disorder in the expression of both forms of anxiety are also likely, as are intra-individual differences across time. Although several models explain some of the variability in the neuropsychological findings, no current formulation can account for all the heterogeneity.

Attending to psychological and biological mechanisms should inform this heterogeneity that impedes attempts to unravel the neuropsychology and neural circuitry of clinical anxiety. One means of accomplishing this is research with clinical populations that rigorously examines the brain correlates of specific anxiety symptoms, such as worry, contamination obsessions, and avoidance of feared objects or situations. Another approach is to appeal to knowledge about which brain regions govern specific functions relevant to anxiety pathology (see Davidson *et al.*, 2002). Basic research with humans and non-human animals has uncovered some of the circuitry involved in those psychological phenomena central to anxiety disorders and showcased in this review (e.g., threat evaluation, fear, response conflict). This emphasis on mechanisms is also promising for research examining the interface with other neurobiological systems shown to be critical for the expression of fear and to manifest irregularities in anxiety disorders, such as cortisol, corticotropin-releasing factor (CRF), cholecystokinin (CCK), tachykinins, neuropeptide-Y, serotonin, norepinephrine, gamma-aminobutyric acid (GABA), and *N*-methyl-D-aspartate (NMDA). These are some of the areas that await synthesis with the neuropsychological concomitants of anxiety that have been identified in the large corpus of cognitive and neuroimaging research examining anxiety disorders.

ACKNOWLEDGEMENTS

We gratefully acknowledge the assistance of Kristen Mackiewicz with the preparation of this chapter.

Functional Neuroanatomy of Anxiety Disorders

Brian Martis, Andrea Malizia and Scott L. Rauch

INTRODUCTION

In this chapter, current hypotheses regarding the functional neuroanatomy of anxiety disorders are examined. Initially, the concepts of anxiety and stress as well as anxiety disorders are discussed. Next, relevant research on animal fear conditioning as well as human anxiety studies are briefly reviewed. This provides the necessary foundation for the ensuing coverage of human data on anxiety disorders and related contemporary neurobiological models.

Anxiety and Fear

In humans, anxiety is a normal unpleasant affective state with experiential, cognitive, autonomic, neuroendocrine and behavioural components. Fear behaviour is the response to specific environmental stimuli that are perceived as potentially dangerous. Though details are still debated, fear behaviour refers to a stimulus-bound response while anxiety is understood as a state of anticipatory apprehension and dread in humans (Davis, 1998; Nitschke, Heller and Miller, 2000). Fear processes are innate and mediated by rapid-response neurobiological systems in animals and humans. It is appealing to consider that these adaptive mechanisms have evolved to enable harm avoidance and enhance chances of survival. Animal research findings suggest that the fear system is a dynamic, integrated network of neural circuits, comprised of processing nodes (specific brain areas), that detects and responds to danger (LeDoux, 2000a). Given the wealth of behavioural and neurobiological similarities between fear responses in animals and humans, animal research in this area plays an important role in guiding anxiety research in humans. However, the conscious and cognitive aspects of human anxiety are undeniably complex and unique, thereby warranting caution when extrapolating from fear research in animals to the neurobiology of anxiety in humans. Similarly, there are substantial inferential leaps to be acknowledged when moving from theories regarding normal human anxiety to the anxiety disorders, which are complex, multifactorially determined syndromes.

Stress

Stress is generally defined as a circumstance that disturbs the normal physiological or psychological functioning of an individual, as well as the disturbed state that results (derived from The Oxford English Dictionary, Second Edition, 1989). Physiological stress responses are coordinated, multisystem (e.g. autonomic, neuroendocrine and immune) adaptive changes in organisms. Stress inducing stimuli or 'stressors' can be positive or adverse. Stress research in humans is particularly challenging due to the convergent and less well described effects of psychological, social and cultural stressors on biological systems. Excessive stress in humans contributes to increased morbidity and mortality and is a significant predictor of adverse outcomes in many medical and psychiatric disorders, e.g. ischaemic heart disease and major depression (Chrousos and Gold, 1998; O'Connor, Gurbel and Serebrauny, 2000; Monroe *et al.*, 2001). Stress responses are closely related to anxiety disorders; this being inferred mainly from overt exposure to stressful life events or trauma. The effects of chronic low level stress are less well established in relation to psychiatric disorders. In the current Diagnostic and Statistical Manual of Mental Disorders (DSM-IV; APA, 1994), two disorders, Acute Stress Disorder and Post-Traumatic Stress Disorder, specifically require exposure to overt traumatic stress as a diagnostic criterion.

Anxiety Disorders

Anxiety disorders, (DSM-IV, (APA, 1994); ICD 10, under 'neurotic, stress-related and somatoform disorders', Chapter V (F), WHO, 1992), are characterized by exaggerated anxiety and fear responses occurring either spontaneously or to relatively innocuous stimuli. Additional hallmarks of these disorders include hypervigilance, hyperarousal, ritualized avoidance and subjective distress. When severe, these manifestations can be disabling. Sufferers tend to display attention and interpretation biases resulting in hypervigilance and overestimation of risk (Nitschke, Heller and Miller, 2000). Psychiatric comorbidity is common among individuals who suffer from an anxiety disorder; the most prevalent comorbid conditions include another anxiety disorder, depression, and substance use disorders. People with anxiety disorders are also at increased risk of suicide and exhibit increased medical service utilization (Regier *et al.*, 1998; Dunner, 2001). Discrete anxiety disorder diagnoses in the DSM-IV include: panic disorder (with and without agoraphobia), acute stress and post traumatic stress disorder, specific and social phobias (social anxiety disorder), generalized anxiety disorder and obsessive compulsive disorder (APA, 1994). Emerging neurobiological evidence provides an opportunity to critically review and refine these nosological constructs, though making sense of inconsistent evidence from studies that involve different modalities and paradigms in heterogeneous populations is a challenge.

FUNCTIONAL NEUROANATOMY OF FEAR AND ANXIETY

Fear Conditioning: Animal Research

The fear-conditioning behavioural paradigm has been a centrepiece for advancing science in this domain via hypothesis-driven research in both animals and humans. Fear conditioning involves the temporal pairing of a neutral stimulus (known as a conditioned stimulus (CS); e.g. a tone), with an aversive stimulus (the unconditioned stimulus (US); e.g. a shock) that can innately elicit fear responses.

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

After one or several paired presentations, the CS alone can trigger the fear responses. This process can be shown to habituate (i.e. repeated presentations cause decremental intensity in the response). Moreover, if the CS is subsequently repeatedly presented without the paired US, the fear responses decline and cease, a process referred to as 'extinction'. These phenomena and pathways subserving them have been reliably demonstrated in multiple animal species as well as in humans (LeDoux, 2000a).

Evidence accumulated from neuroanatomical tract tracing, ablation, and unit-recording studies of animal fear conditioning implicates the amygdala as central in the 'fear network'. The critical role of the amygdala is further supported by evidence of its abundant reciprocal connections with other brain areas (e.g. sensory thalamus, primary somatosensory cortex, prefrontal cortex, striatum, and brain stem) that comprise the fear network, subserving the various elements of the characteristic fear response (see below).

The amygdala also houses an internal circuitry, involving its various nuclei. Based on animal findings (best mapped out in the context of auditory CS in rats), sensory information from the sensory thalamus is rapidly conveyed to the lateral nucleus of the amygdala (LA). Further transmission occurs from the LA to the central nucleus of the amygdala (CeA), both directly and via the accessory basal (abA) and basal (bA) amygdalar nuclei. The CeA has projections to multiple output areas which subserve the characteristic components of the conditioned fear response such as autonomic activity (subserved by the brainstem autonomic centres including the locus caeruleus), the stress neuroendocrine response (lateral hypothalamic nuclei), attentional processes and response choice (the anterior cingulate cortex) as well as templates of action tendency and overt response behaviour (periaqueductal gray, the striatum) (Kapp *et al.*, 1992; Maren and Fanselow, 1996; LeDoux, 2000b; Davis, 2000).

Animals thus conditioned also express similar responses to the context in which the conditioning occurred. This phenomenon, called 'contextual fear conditioning' is evidenced when the same characteristic fear responses can be elicited following fear conditioning, simply by exposing the subject to the situation where conditioning occurred, even in the absence of re-exposure to a discrete CS. Lesion studies have demonstrated the crucial role of the hippocampal projections to the amygdala in contextual fear conditioning (Maren and Fanselow, 1995).

The neurobiology of fear conditioning has been further elucidated by studies that assess changes occurring at the cellular and molecular levels within the amygdala, hippocampus and other relevant structures. Plasticity has been studied via cell recordings in various amygdalar nuclei as well as at other nodes within the fear-conditioning network. Long-term potentiation (LTP) has been demonstrated in the amygdalo-hippocampal pathways in fear conditioning though these results are mixed and less well characterized. Specifically, the NMDA receptor activation is implicated in the mediation of LTP in some subnuclei of the amygdala (Chapman and Chattarji, 2000). The amygdala is considered to be essential in fear-related learning and thus may have an important role in decision making (by emotional weighting) and in the early stages of memory formation for emotionally salient events. However, much remains to be understood about the role of the amygdala and relevant neural pathways in fear learning and memory in humans.

The orbitofrontal cortex (OFC) is implicated in the extinction of conditioned fear response. There is evidence for a dynamic interaction between the OFC and the amygdala with regard to processing of fear-conditioning responses. When the potentially threatening nature of a particular stimulus diminishes, the OFC is purported to attenuate responses to that stimulus via projections to the amygdala. Thus prefrontal connections of the amygdala are believed to modulate threat-related information (Wilson and Rolls, 1990; Morgan, Romanski and LeDoux, 1993; Morgan and LeDoux, 1995), conferring flexibility and adaptability needed to successfully navigate a rapidly changing environment.

Primate Studies

Extending fear-conditioning work in rats to primates could be viewed as an essential intermediate step in the understanding of human anxiety and fear. The seminal work of Kluver and Bucy (1939) in describing the behavioural effects of bilateral anterior temporal lobectomy in monkeys set the stage for more detailed investigations into amygdala involvement in fear behaviour. It is important to note that subsequent studies, involving more selective lesions of the amygdala, have shown the ensuing deficits to share some but not all features of the Kluver–Bucy syndrome, confirming that some of the features were due to lesions in the adjacent brain regions. Contemporary data from primates has, however, strengthened the argument that the amygdala is critically involved in stimulus–affect association (i.e. in the elicitation of learned emotional responses; see Baxter and Murray (2000) for a detailed review of these newer studies).

Much of the work on fear conditioning in rodents with specific reference to the role of the amygdala in stimulus-reinforcer associations has been extended in primates. The amygdala neurons have been shown to respond to primary reinforcers (e.g. taste), visual stimuli previously paired with rewarding primary reinforcer, novel stimuli and faces (Rolls, 1999). The interactions between the OFC and amygdala have been demonstrated to similarly contribute to acquisition and extinction of fear conditioning. However, more recent studies highlight the anticipated difficulty in making inferential leaps across different species towards human brain functioning. For example, Kalin *et al.* (2001) reported that rhesus monkeys with previously characterized 'anxious temperament' endophenotype, demonstrated blunted acute unconditioned fear responses in the face of >70% bilateral amygdalar destruction, but were unchanged on unconditioned trait-like anxiety-fear responses in the face of >95% bilateral amygdala destruction. Thus, caution must be exercised while using findings from animal research to hypothesize about human anxiety and its disorders.

Studies of Humans with Brain Lesions

Brain lesions that arise in humans are rarely neuroanatomically configured to involve only the entirety of a brain region of interest. Furthermore, the capacity of spared regions to compensate for lost structures complicates meaningful interpretation of regional function. Nevertheless, the study of humans with discrete brain lesions offers valuable clues to functional neuroanatomy.

Adolphs *et al.* (1994, 1995) reported studies with a single subject (SM), a 32-year-old lady with a rare heritable disorder of primarily epithelial tissue, the Urbach–Wiethe syndrome, characterized by avascular/atrophic mineralizations of medial temporal tissue including the amygdala. SM was reported to have selective, complete and stable bilateral amygdalar damage (as well as minor damage to anterior entorhinal cortices) by magnetic resonance imaging (MRI). Extensive testing on SM revealed a persistent deficit in recognition of fear expression despite the cognitive ability to describe fear and what it entailed. This has been replicated in subsequent studies on humans with bilateral amygdala damage (Calder *et al.*, 1996; Broks *et al.*, 1998; Adolphs *et al.*, 1999b). In humans with discrete lesions of the amygdala or more extensive temporal lobe lesions that include the amygdala, deficits have also been demonstrated involving fear conditioning (Bechara *et al.*, 1995; LaBar *et al.*, 1998). The few studies in subjects with varying amounts of amygdala damage using a task of emotional prosody recognition have yielded mixed results: impairment (Scott *et al.*, 1997) vs no deficits (Anderson and Phelps, 1998; Adolphs *et al.*, 1999a). Thus, taken together, human

lesion studies have extended the research in animals, by demonstrating amygdala involvement in the recognition of facial expressions of negative emotions including but not limited to, fear.

Based on these findings it has been hypothesized that the amygdala is an important component in a specialized human neural system that detects and responds to danger-related stimuli (with or without a social context). The role of the amygdala in this system is to detect the emotional relevance of stimuli and help trigger rapid behavioural responses and conscious awareness of aversive stimuli through its subcortical and cortical connections (Adolphs and Tranel, 2000).

Human brain lesion studies involving other regions germane to the purported fear network, provide further information to guide contemporary circuitry models of anxiety disorders. For instance, OFC lesions are associated with disruption in the rapid flexible response to changes in rule set. This may parallel the established role of the OFC in dynamic response attenuation when stimulus salience has changed (i.e. extinction). This is consistent with a broad role for the OFC in top-down control over subcortical structures in fear processing. Thus, OFC dysfunction in top-down control may lead to an inflexible persistence of fear responses, manifesting as pervasive cognitive misinterpretation of danger even in the face of relatively innocuous stimuli (or conversely a lack of recognition of danger).

Neuroimaging Studies of Anxiety in Healthy Subjects

It is important to understand the neural processing of normal anxiety to gain insight into anxiety disorders where this mechanism is presumably dysfunctional. Recent positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) studies have attempted to map the mediating neuroanatomy associated with perception of threat-related or emotionally valenced stimuli (mainly faces) as well as behaviourally or pharmacologically induced anxiety (see Rauch and Shin, 2002 for review). Such studies of anxiety in healthy volunteers have demonstrated relatively consistent patterns of brain activation in the anterior paralimbic cortical structures (i.e. posterior medial orbitofrontal, anterior temporal, anterior cingulate, and insular cortex) and the amygdala.

Much of the work in this area has involved mapping brain activity in healthy volunteers when presented with emotionally expressive faces (fear, happy, angry and disgust). Perception of fearful faces has been reported to be associated with amygdala activation both when the stimulus was overtly (Breiter *et al.*, 1996a; Morris *et al.*, 1996, 1998a; Phillips *et al.*, 1997) or covertly presented with a backward masking technique (Whalen *et al.*, 1998). Extending this work, Morris, Öhman and Dolan (1998b, 1999) demonstrated significant correlation of right amygdala neural activity (to masked fear-conditioned faces) with activity in visual structures implicated in non conscious processing (pulvinar nucleus of thalamus and superior colliculus). Based on this the authors suggest that processing of behaviourally relevant unseen visual stimuli may be subserved by a right-sided subcortical pathway in parallel to a cortical route necessary for conscious identification.

Habituation in the brain represents an adaptive mechanism by which resources can be preferentially allocated to survival-relevant (e.g. threat-related) stimuli by rapid attenuation of response to stimuli that are no longer salient. Lack of habituation may help to explain some symptoms of anxiety such as persisting anxiety beyond the point of stimulus relevance. Investigators have attempted to demonstrate habituation in fMRI studies of healthy subjects by showing response decrements in various brain areas activated by emotionally relevant stimuli (e.g. faces bearing emotional expressions) (Breiter *et al.*, 1996a; Whalen *et al.*, 1998; Fischer *et al.*, 2000a, 2000b). Although preliminary there seem to be lateralized differences in habituation of amygdala responses (significant signal decrement over time in right but not left amygdala) and differential habituation to emotional valence in the left prefrontal cortex (greater signal decrement to positive vs negatively valenced stimuli) (Wright *et al.*, 2000, 2001).

The phenomena of fear conditioning and extinction are relevant to models of anxiety disorders. Innovative functional neuroimaging paradigms have been employed to study the neural substrates of fear conditioning in humans. Morris *et al.* (1997, 1998a, 1998b) reported association of the fear-conditioned state with increased activity in bilateral amygdala, right thalamus and OFC, further demonstrating lateralized amygdala activation based on subjects' awareness of the fear-related stimuli (right-sided with covert stimuli and left-sided with overt stimuli). Other groups using different conditioning paradigms, have demonstrated anterior paralimbic activation and habituation of conditioning-related signals in the amygdala and hippocampal region (Büchel *et al.*, 1998, 1999; LaBar *et al.*, 1998).

ANXIETY DISORDERS

Overview

The anxiety disorders share many common core features (hypervigilance, excessive anxiety, and avoidance); yet, they are also distinguishable from one another clinically (e.g. spontaneous attacks of terrifying anxiety in panic disorders versus a pervasive state of anxiety in GAD). It is appealing to consider that common neurobiological substrates may underlie the spectrum of anxiety disorders, while unique pathophysiological mechanisms exist that distinguish among them. Investigators have developed tentative models regarding the neurobiology of anxiety disorders drawing from animal research and human imaging data as outlined above.

Currently, neurobiological and neuroanatomical hypotheses for some of these disorders (e.g. PTSD, OCD and PD) are more coherent than for others (e.g. GAD, phobias). A logical starting point is to identify core characteristics of specific anxiety disorders and based on animal and human research findings, test hypotheses of regional dysfunction in specific disorders. Advances in neuroimaging have accelerated this effort. Structural as well as neutral state and symptom provocation functional neuroimaging studies are giving way to more sophisticated cognitive, pharmacological and multimodal paradigms.

In the following section, research findings and current hypotheses pertaining to the functional neuroanatomy of specific anxiety disorders will be discussed. Note that a comprehensive model requires an integration between neurocircuitry and relevant neurochemistry/neuropharmacology of the implicated brain pathways. For clarity of organization, these complementary topics have been addressed in a separate chapter in this volume (Malizia *et al.*, Chapter XIX-10).

POST-TRAUMATIC STRESS DISORDER (PTSD)

PTSD is characterized by a triad of symptom clusters that occur in the aftermath of a precipitating traumatic event: (1) recurrent intrusive 're-experiencing' of the trauma (2) hypervigilance/hyperarousal and (3) emotional numbing/avoidance (DSM-IV; APA, 1994). Neurobiological research in PTSD has mostly involved patients with combat or childhood abuse related PTSD. In fact, there are a wide variety of types of trauma that can cause PTSD, and it is not clear whether different characteristics of the trauma history are reflected in different neurobiological subtypes of the disorder. For instance, the trauma can be a single event, or a series of multiple events; it can occur over a brief time or chronically; the

exposure can occur in childhood or adulthood; and it can be perpetrated by humans or not. Regardless of the aetiology of the PTSD, patients are prone to comorbidities such as mood and substance-abuse disorders. Despite these numerous sources of heterogeneity in PTSD, findings from human studies seem to converge with data from animal research in certain areas discussed below.

Stress, Glucocorticoids/HPA Axis and the Hippocampus in Animals and Humans

Rodent and non-human primate studies have demonstrated neural damage such as apical dendrite atrophy (CA3 neurons), degeneration of CA3 hippocampal neurons, and decreased hippocampal blood flow in response to a variety of chronic stressors (social, restraint, physical) (Uno *et al.*, 1989; Watanabe, Gould and McEwen, 1992; Endo *et al.*, 1999). These effects appear to be a consequence of stress-related excessive glucocorticoid (GC) secretion which in part seems to be mediated by an excess of excitatory amino acids (EAA's) such as glutamate, producing NMDA receptor mediated excitotoxic effects (Sapolsky, Krey and McEwen, 1985; Woolley, Gould and McEwen, 1990; Gould and Tanapat, 1999).

Smaller hippocampal volumes have also been demonstrated in human subjects with PTSD, due to combat as well as childhood sexual abuse (in both sexes, ranging from 5–26%) (see Table XIX-9.1A for structural studies in PTSD) with the exception of one study involving children/adolescent subjects with PTSD (De Bellis *et al.*, 1999). Bremner *et al.* (1995), reported smaller right hippocampal volumes in 26 veterans with PTSD (vs 22 civilian controls without PTSD). In the PTSD subjects, lower percent retention scores on a standard test of verbal memory were associated with lower right hippocampal volumes. Gurvits *et al.* (1996) found smaller bilateral hippocampal volumes in seven Vietnam combat veterans with PTSD (vs seven Vietnam combat veterans without and eight civilians without PTSD). The hippocampal volumes across the 14 veterans were inversely correlated with the extent of combat exposure and PTSD symptom severity. This raises the question of the specificity of the volumetric reductions to the PTSD process. Thus the basis for these volumetric differences is still unclear. Several possibilities exist including volume loss being the effect of the traumatic exposure vs sequelae of the development of the PTSD symptoms, or that people with smaller hippocampi are predisposed to developing PTSD following trauma (Pitman, 2001).

Clinical research has revealed decreased hippocampal volumes and elevated cortisol levels in Cushing's syndrome, which was reversed with treatment (Starkman *et al.*, 1992, 1999). Smaller hippocampal volumes and high cortisol levels have also been reported in major depressive disorder (for review see Brown, Rush and McEwen, 1999). The hippocampus is also involved in the modulation of the hypothalamic-pituitary-adrenal (HPA) axis, and lesions of the hippocampus appear to increase the release of glucocorticoids during stress which in turn may further damage the hippocampus (Feldman and Conforti, 1980; Sapolsky, Krey and McEwen, 1986; Herman *et al.*, 1989). However, hypo and not hypercortisolaemia has been frequently reported in patients with PTSD (Newport and Nemeroff, 2000), which is harder to reconcile with the GC mediated hippocampal volume loss theory. One hypothesis that attempts to explain this apparent disparity suggests GC hypersensitivity in PTSD patients resulting in hypocortisolaemia (due to feedback inhibition) and reduced hippocampal volumes (Yehuda, 1998).

Fear Conditioning, PTSD Symptoms and Functional Neuroimaging Studies in PTSD

The fear-conditioning paradigm seems relevant to the understanding of some PTSD symptomatology. For example, certain aspects of the response to environmental triggers of past trauma strongly resemble the animal fear-conditioning response. However, the indelibility of the trauma-related memory and resistance to extinction of the fear response in PTSD is distinct from normal fear conditioning in animal studies. Simple experimental noxious stimuli currently used in animal research provide a suboptimal comparison to the real life complexity of the human post-traumatic stress response. Thus, one of the challenges in PTSD research is to disentangle pre-existing neurobiological factors that might predispose to developing PTSD in the face of trauma exposure (i.e. risk factors) from fundamental pathophysiological elements of the disease process as well as non-specific consequences of traumatic exposure.

According to the 'amygdalocentric' model of PTSD, hyperresponsivity within the amygdala to threat-related stimuli, in the face of disrupted functional connectivity between the OFC, amygdala and hippocampal regions may explain some of the cognitive, affective and psychomotor manifestations of PTSD (Rauch and Baxter, 1998; Rauch and Shin, 2002). According to this theory the hyperresponsivity of the amygdala results in characteristic symptoms of hyperarousal. Dysfunctional governance of the amygdala by the prefrontal cortex (specifically the affective division of the anterior cingulate cortex) is implicated in the inappropriate assessment of and response to threat and the persistence of this beyond the relevant period (i.e. inflexibility and dysfunctional 'extinction'). Hippocampal dysfunction may contribute to contextual avoidance, difficulty in identifying safe contexts and explicit memory deficits

Table XIX-9.1A Structural neuroimaging studies in PTSD

Authors	Subjects	Methods	Findings
Bremner *et al.*, 1995	26 Vet-PTSD vs 22 healthy civilians	MRI morphometry	R-hippo. volumes 8% ↓ in vets vs controls. ↓ scores on a standard measure of verbal mem. correlated directly with ↓ R-hippo. volumes.
Gurvits *et al.*, 1996	7 Vietnam vets with PTSD; 7 Vets. and 8 nonvet. controls without PTSD	MRI morphometry	Significantly ↓ B/L-hippo. volumes in PTSD vs both control groups. Hippo. volume inversely correlated with extent of exposure (14 vets.)
Bremner *et al.*, 1997a	17 adults with PTSD (childhood abuse) vs 21 non abused controls	MRI morphometry	12% ↓ L-hippocampal volumes.
Stein *et al.*, 1997	21 adults with PTSD vs 21 non abused controls	MRI morphometry	5% smaller L-hippo. volumes in abused subjects. Total hippo. volumes ↓ in abused with ↑ PTSD symptom severity than those with ↓ severity.
DeBellis *et al.*, 1999	44 maltreated children and adolescents vs 61 healthy controls	MRI morphometry	No differences in hippocampal volumes PTSD group had ↓ intracranial and cerebral volumes.

Table XIX-9.1B Functional neuroimaging studies in PTSD

Authors	Subjects	Methods	Findings
Semple *et al.*, 1993	6 combat PTSD and substance abuse vs 7 normal controls	PET-Auditory CPT and word generation	PTSD group exhibited ↑ rCBF in orbitofrontal cortex during auditory CPT and word generation.
Rauch *et al.*, 1996	Mixed gender, 8 PTSD subjects	PET-Symptom provocation with script-driven imagery	Provoked vs control: ↑ rCBF in ACC, R-OFC, insula, Ant. Temp. and visual cortex and right amygdala. ↓ rCBF decreases in L Brocas and L middle temporal cortex. No comparison group.
Shin *et al.*, 1999	8 F with PTSD (childhood sexual abuse) vs 8 trauma controls with out PTSD	PET-Symptom provocation with script-driven imagery	Trauma tic vs neutral contrast: Anterior paralimbic activation in both groups. Group by condition interaction: PTSD group showed significantly > rCBF increases within ant. temp. and OFC. > rCBF increase within ACC in controls than PTSD group.
Bremner *et al.*, 1999a	10 F with PTSD (childhood sexual abuse) vs 12 trauma controls without PTSD	PET-Symptom provocation with script-driven imagery	↓ recruitment of ACC in PTSD group.
Bremner *et al.*, 1999b	10 Vietnam vets. with PTSD vs 10 Vietnam vets. without	PET-Responses to trauma-related pictures and sounds	PTSD group showed ↑ rCBF in medial PFC (subcallosal gyrus) and ACC.
Liberzon *et al.*, 1999	14 Viet. Vets. With PTSD, 11 vet controls, 14 healthy nonvets	SPECT-Study	Combat sound vs. white noise: All three groups showed activation of ACC/MPFC. PTSD group showed activation in L amygdaloid region.
Bremner *et al.*, 1997b	10 combat vets. With PTSD vs 10 nonvets, no PTSD	PET-Yohimbine (Y) challenge	Y administration associated with increased anxiety and panic symptoms and widespread decreased ↓ CBF in PTSD group.
Shin *et al.*, 1997	7 vets. With combat PTSD and 7 matched trauma exposed vets. without	PET-Cognitive activation: neutral, negative, combat pictures perception and imagery	Combat imagery vs control: PTSD group showed ↑ rCBF in R-amygdala and ventral ACG and ↓ rCBF in L-Inf. frontal gyrus (Brocas).
Rauch *et al.*, 2000	8 combat vets. with PTSD vs 8 control combat vets	fMRI-Study Fearful and happy faces masked temporally by neutral faces	> amygdala activation in PTSD group than control. Magnitude of activation correlated with PTSD severity.

(especially for the traumatic event/s). Conscious appreciation of trigger stimuli may not be necessary to trigger symptomatology. Rauch *et al.* (2000) have previously demonstrated that subjects with PTSD have hyperactive amygdalar responses to emotional facial expression even when subjects were unaware of seeing them (using a backward masking technique).

Functional neuroimaging studies in PTSD have involved symptom provocation studies and neurocognitive probes of specific areas implicated in the pathophysiology of PTSD. Upon exposure to reminders of their traumatic event (script-driven imagery or trauma-related pictures and sounds), patients with PTSD have been shown to exhibit abnormal activity in the anterior paralimbic areas (OFC, ACC) as well as subcortical circuitry involving the amygdala (Rauch *et al.*, 1996; Shin *et al.*, 1999; Bremner *et al.*, 1999b; see Table XIX-9.1B for other functional neuroimaging studies in PTSD).

Semple *et al.* (1993) using an auditory continuous performance test (CPT) and word generation task with PET, reported increased rCBF in the orbitofrontal cortex in six veterans with combat PTSD and substance abuse (vs seven healthy controls). Using a Yohimbine challenge PET study Bremner *et al.* (1997b), reported increased anxiety and panic symptoms and widespread decreased rCBF in 10 combat vets with PTSD (vs 10 healthy controls). Rauch *et al.* (2000), probing amygdala function using fearful and happy faces masked by neutral faces, found greater amygdala activity in the PTSD subjects (vs controls) to masked fearful faces. In this study, the magnitude of amygdala activation correlating with PTSD severity.

Thus some of these studies provide positive evidence for the amygdalocentric hypothesis in the genesis/maintenance of PTSD symptoms. Neuroimaging advances provide an attractive method of testing hypotheses regarding other brain structures in PTSD.

PANIC DISORDER (PD)

PD is one of the most extensively studied of the anxiety disorders, in part due to occurrence of discrete characteristic symptoms, familial segregation, response to specific pharmacological agents and demonstration of the panicogenic effects of specific agents. PD is characterized by mostly spontaneous discrete attacks of terrifying anxiety with cognitive, affective and autonomic hyperarousal. In between attacks, the patient often experiences significant anxious apprehension, in anticipation of the next attack. Contextual avoidance completes the picture and contributes to most of the disability. A comprehensive theory of PD should explain the genesis of spontaneous recurrent panic attacks and associated symptom states such as anticipatory anxiety, agoraphobia and avoidance behaviour.

Panic disorder could be viewed as a result of a normal threat-related system being repeatedly inappropriately triggered/governed by a dysfunctional threat detection system, or a threat response system gone awry, responding excessively to minor or innocuous stimuli. An attractive hypothesis of the genesis of spontaneous panic attacks, is the possibility of subconscious processing of threat-related stimuli by a hyperresponsive amygdalar system, resulting in

a full blown panic attack. There is evidence in healthy subjects for amygdalar recruitment while viewing fear-related stimuli (Whalen *et al.*, 1998) and hyperresponsivity to masked fearful stimuli has been demonstrated in subjects with PTSD (Rauch *et al.*, 2000). According to this model, one of the major processes in PD may be hyperresponsivity of the amygdala circuitry to environmental cues processed without consciousness, resulting in the characteristic panic response without an apparent context (Rauch and Shin, 2002). This remains to be demonstrated in panic disorder.

Phenomenological similarities between panic symptoms and fear-conditioned responses in animals have drawn attention to analogous brain pathways in humans. A deficit in the relay and coordination of upstream (cortical) and downstream (brainstem) sensory information is hypothesized in PD (Gorman *et al.*, 2000). This may result in a hypersensitive amygdalar network, which could inappropriately trigger the brainstem and hypothalamic autonomic and stress neuroendocrine centres causing the characteristic acute panic symptoms (akin to the fear-conditioned response in rats). Cognitive misattribution and contextual fear may result from the involvement of the OFC and hippocampus respectively. The therapeutic effects of serotonergic medications may be explained by their general transmission damping effect in the subcortical and brain stem areas while cognitive therapies may work by enhancing the top-down control of the OFC over the amygdala and related subcortical structures (Gorman *et al.*, 1989, 2000).

Neuroimaging research in subjects with PD has employed diverse modalities. In one qualitative MRI study, the frequency of gross structural abnormalities has been reported to be greater in the PD group (40%) than in the control group (10%; Fontaine *et al.*, 1990; see Table XIX-9.2A). Resting state neuroimaging studies in patients with PD (including those vulnerable to lactate-induced panic), have suggested abnormal hippocampal activity (Reiman *et al.*, 1986; and Table XIX-9.2B), One group has reported post clomipramine treatment normalization of abnormally low left/right asymmetry in hippocampal activity in subjects with PD (Nordahl *et al.*, 1990, 1998). Symptom provocation studies (with pharmacological challenges) have revealed reduced activity in widespread cortical regions, including the prefrontal cortex, during symptomatic states (Reiman *et al.*, 1989; and Table XIX-9.2C). Magnetic resonance spectroscopy studies have reported greater brain lactate levels in response to hyperventilation and lactate infusions (Dager *et al.*, 1995, 1999).

Table XIX-9.2A Structural neuroimaging studies in panic disorder

Authors	Subjects	Methods	Findings
Fontaine *et al.*, 1990	31 patients with PD vs 20 matched controls	Qualitative MRI study	Frequency of gross structural abnormalities: PD group (40%) > control group (10%).
Vythilingam *et al.*, 2000	13 with PD vs 14 control subjects	Quantitative volumetric methods	Sig. smaller mean vols. of L and R-temporal lobes in PD vs controls (normal hippo. volumes).

Table XIX-9.2B Functional neuroimaging studies in panic disorder (PD)

Authors	Subjects	Methods	Findings
Reiman *et al.*, 1986	16 patients with PD and 25 controls	PET-Neutral state study	In patients vulnerable to lactate-induced panic ($N = 8$), abnormally low left/right ratios of parahippo. blood flow.
DeCristofaro *et al.*, 1993	7 treatment-naive with PD vs 5 age-matched controls	SPECT-rCBF at rest	PD (vs control) group showed ↑ rCBF in L-occipital cortex, and ↓ rCBF in the B/L-hippo. areas.
Nordahl *et al.*, 1990	12 PD patients vs 30 controls	PET-FDG while engaged in an auditory CPT	PD group exhibited a lower left/right hippo. rCMRGlu ratio.
Nordahl *et al.*, 1998	IMI-treated subjects with panic disorder	PET-FDG Follow-up study (1990): same methods	R-shift in rCMRglu symmetry within hippo. and post. inf. frontal cortex. IMI-treated group showed ↓ rCMRglu in post. OFC.
Bisaga *et al.*, 1998	6 F with PD and 6 matched controls	PET-FDG	PD subjects showed ↓ rCMRglu in the L-hippo. and parahippo. area.

Table XIX-9.2C Symptom provocation studies in panic disorder

Authors	Subjects	Methods	Findings
Stewart *et al.*, 1988	10 with PD vs 5 controls	SPECT-xenon inhalation r CBF during lactate infusion	PD subjects who had lactate-induced panic attacks ($n = 6$) displayed global cortical CBF ↓.
Woods *et al.*, 1988	6 patients with PD vs 6 controls	SPECT-Yohimbine (Y) infusions	PD group: Y administration increased anxiety and decreased rCBF in bilateral frontal cortex.
Reiman *et al.*, 1989	17 patients with PD vs 15 controls	PET-rCBF during lactate infusions	Patients who had lactate-induced panic ($n = 8$) had ↑ rCBF in B/L temporopolar cortex and B/L insula/claustrum/putamen. Controls and PD patients without lactate-induced panic did not display these changes.
Fischer *et al.*, 1998	Case report	Spontaneous panic attack	↓ rCBF R-orbitofrontal, prelimbic (area 25) ant. cingulate, and ant. temp. cortex.

Consistent with prevailing neurobiological models of PD, it is possible that fundamental abnormalities in monoaminergic neurotransmitter systems, originating in the brain stem, underlie the abnormalities of metabolism, haemodynamics, and chemistry found in widespread territories of cortex. Further, regional abnormalities within the medial temporal lobes provide some support for theories regarding hippocampal or amygdala dysfunction in PD.

OBSESSIVE COMPULSIVE DISORDER (OCD)

The cardinal manifestations of OCD are recurrent, intrusive, egodystonic thoughts, images and urges portending adverse consequences leading to feelings of anxious dread. Patients therefore engage in mental and motor compulsions (repetitive ritualized thoughts or acts) in an attempt to 'neutralize' the obsession/adverse consequence. They often spend many hours a day engaged in these symptoms, leading to significant distress and potential disability. OCD is considered a group of heterogeneous neuropsychiatric disorders. Characteristic neuropsychological dysfunction on tests of organizational strategy and memory, purportedly subserved by the OFC, has been described in OCD patients (Savage *et al.*, 2000). This may explain symptoms of doubt as well as cognitive inflexibility especially related to risk assessment often seen in OCD.

Current animal models are unsatisfactory and have proved of limited value in elucidating OCD pathophysiology. Much of our understanding of functional neuroanatomy implicated in OCD comes from neuroimaging evidence (Rauch and Baxter, 1998). The results of several morphometric MRI (mMRI) studies done in OCD have suggested abnormalities in the volume of the caudate nucleus, though findings between studies have been inconsistent (Scarone *et al.*, 1992; see Table XIX-9.3A for mMRI studies in OCD). Neutral state PET and SPECT paradigms have most consistently reported increased activity in the OFC and ACC areas in OCD subjects versus controls (Baxter *et al.*, 1988; Swedo *et al.*, 1989; see Table XIX-9.3B for other neutral state studies in OCD). Importantly, pre/post treatment studies have reported a treatment-related decrease of activity in the OFC, ACC and CN, regardless of treatment modality (i.e. both for pharmacotherapy with serotonergic reuptake inhibitors, and cognitive behaviour therapy) (e.g. Baxter *et al.*, 1992; Schwartz *et al.*, 1996; and Table XIX-9.3B). Studies designed to investigate predictors of treatment response have yielded impressively consistent results: lower activity within OFC at the pretreatment time point is associated with a positive response to treatment with SRIs while higher left OFC activity predicted a better response in the behavioural therapy responders (Swedo *et al.*, 1989; Brody *et al.*, 1998; Saxena *et al.*, 1999). PET and fMRI symptom provocation studies have shown increased activity in the anterior/lateral OFC, ACC and CN during the provoked state (Rauch *et al.*, 1994; Breiter *et al.*, 1996b). More recently investigators have used neurocognitive probes to study brain areas implicated in OCD. One such task used is the serial reaction task, which leads to implicit or procedural learning demonstrated by shortening reaction times without the subjects' conscious knowledge. Implicit/procedural learning has been shown to be subserved by the striatum, while the medial temporal lobes have been demonstrated to be preferentially involved in explicit or conscious learning. Rauch *et al.* (1997) in a PET study of implicit sequence learning, reported failure of OCD subjects to normally recruit striatum like healthy controls, instead recruiting the medial temporal lobes typically associated with explicit processing (see Table XIX-9.3B for summary of the various functional studies in OCD).

On the basis of evidence from neuropsychiatric disorders effecting the basal ganglia, together with brain imaging data, contemporary models of OCD focus on medial orbitofrontal-striatal-thalamo-cortical circuits (Rauch and Baxter, 1998). According to this scheme striatal dysfunction leads to inefficient thalamic gating, resulting in hyperactivity within the OFC and cingulate cortex. This could result in the intrusive cognitive phenomena and the associated anxiety. Extending this line of thought, compulsions could be conceptualized as repetitive mental and motor behaviours performed to recruit the striatum so as to ultimately achieve thalamic gating (ultimately transiently neutralizing the anxiety and thoughts; Rauch and Shin, 2002).

OCD also provides a more direct approach to investigating functional neuroanatomy, through study of patients undergoing specific neurosurgical lesions for refractory OCD. Rauch *et al.*, (2001) reported a hypermetabolic focus in the posterior cingulate (PET-FDG) to predict better response in refractory OCD patients undergoing stereotactic MRI guided cingulotomy. Ongoing Deep Brain Stimulation studies in OCD (Greenberg, personal communication), involving indwelling electrodes in the anterior limb of the internal capsule, may yield crucial functional neuroanatomic information.

SOCIAL PHOBIA (SoP) AND SPECIFIC PHOBIAS (SpP)

The phobic syndromes involve an excessive, irrational fear of relatively innocuous and usually non-threatening stimuli. Two subtypes of social phobia (also known as social anxiety disorder) are generally recognized, namely, the generalized type and performance-related type. In the generalized subtype, patients experience excessive and irrational fear of negative social scrutiny in most unfamiliar social situations. In the performance subtype the

Table XIX-9.3A Structural neuroimaging studies in OCD

Authors	Subjects	Methods	Findings
Scarone *et al.*, 1992	20 patients with OCD (mixed gender) vs 16 matched controls	MRI morphometry	↑ right caudate volume in OCD group.
Robinson *et al.*, 1995	26 patients with OCD (mixed gender) vs 26 matched controls	MRI morphometry	B/L ↓ caudate volumes in the OCD group.
Jenike *et al.*, 1996	10 F patients with OCD vs matched controls	MRI morphometry	Trends toward a R-shift in caudate volume ($p = 0.06$) as well as overall ↓ caudate volume ($p = 0.10$) in OCD group.
Aylward *et al.*, 1996	24 patients with OCD (mixed gender) vs 21 matched controls	MRI morphometry	No significant differences in striatal volumes.
Rosenberg *et al.*, 1997	19 treatment-naive children with OCD vs 19 matched controls	MRI morphometry	↓ striatal volumes in the OCD group, and inverse correlation between striatal volume and OCD symptom severity.

Table XIX-9.3B Functional neuroimaging studies in OCD

Authors	Subjects	Methods	Findings
Neutral State			
Baxter *et al.*, 1987	14 OCD vs 14 controls and 14 MDD	PET-FDG	OCD: metabolic rates were significantly ↓ in the L-orbital gyrus and B/L in the caudate nuclei. ↑ C/H ratio B/L in treatment responders.
Baxter *et al.*, 1988	10 OCD vs 10 age and sex matched controls	PET-FDG	↑ rCMRGlu in whole cerebral hemispheres, heads of caudate, OG and O/H ratio similar to previous study.
Machlin *et al.*, 1991	10 OCD vs 8 controls	SPECT	OCD group had higher medial-frontal/whole cortex ratio, negatively correlated with anxiety.
Nordahl *et al.*, 1989	8 OCD vs 30 controls	PET-FDG	Higher norm. rCMRGlu in R-OFC and L-ant. OFC in OCD vs controls.
Rubin *et al.*, 1992	10 OCD (adult males) vs 10 age-matched controls	SPECT Xe-133 rCBF and 99mTc-HMPAO	No difference in rCBF with Xe-133. OCD group had ↑ 99mTc uptake in B/L parietal and OFC and L-posterofrontal regions.
Swedo *et al.*, 1989	18 adults with OCD (childhood onset) vs matched controls	PET-FDG	OCD group had ↑ rCMRglu in the L-OF, R-sensorimotor, and B/L prefrontal and ACC. Significant correlation between CMRGlu and OCD severity.
Pre/post Rx			
Baxter *et al.*, 1992		PET-FDG	R-C/H ratio significantly ↓ post Rx (Fluoxetine and CBT).
Benkelfat *et al.*, 1990	8 OCD subjects before and on CMI	PET-rCMRGlu	Significant ↓ in L-caudate rCMRglu in responders vs non responders.
Hoehn-Saric *et al.*, 1991	6 drug free OCD subjects before and during fluoxetine	SPECT	Rx. significantly ↓. symptoms and associated with ↓ medial-frontal/whole brain ratio.
Perani *et al.*, 1995	11 OCD subjects before and after SSRI; 15 age-matched controls	PET [18F]FDG	rCMRGlu significantly ↑ in CC, thalamus and basal ganglia. Post Rx YBOCS improvements associated with B/L ↓ rCMRGlu in CC.
Schwartz *et al.*, 1996	9 OCD before and after 10 weeks of ERP	PET-rCMRGlu	Significant ↓ in B/L-caudate rCMRGlu in ERP responders.
Swedo *et al.*, 1992	Repeat scans in 13 OCD subjects (10 on meds. at least $\times 1$ year)	PET-FDG	Significant ↓ in norm. rCMRGlu in B/L-OF areas. R-OFC rCMRGlu partially correlated with symptom improvement.
Predictors of response			
Brody *et al.*, 1998	27 OCD Before and after 10 ± 2 wks. of BT ($n = 18$) or fluoxetine (F) ($n = 9$)	PET-FDG	↑ norm. rCMRGlu in L-OFC predicted better treatment response in BT group but worse outcome in F group.
Saxena *et al.*, 1999	20 OCD before and after 8–12 weeks of paroxetine (P) 40 mg per day^{-1}	PET-FDG	Paroxetine responders had significant ↓ in rCMRGlu in R-ant. Lat. OFC and caudate. Lower B/L-OFC rCMRglu predicted better improvement in OCD Sx.
Swedo *et al.*, 1989	18 adults with OCD (child onset) and matched controls	PET-FDG	OCD group had ↑ rCMRglu in L-OF, R-SM, and B/L PF and ACC. Significant correlation between rCMRGlu and OCD severity.
Symptom provocation			
McGuire *et al.*, 1994	4 OCD patients	PET H2 15 O	Significant correlation between Sx. severity and rCBF in R-IFG, caudate, parietal, globus pallidus and thalamus and L-hippo and PCG. Also neg. correlation in R-sup. PFC and T/P junction.
Rauch *et al.*, 1994	8 OCD	PET O 15 CO_2 rest and provoked	Sig. ↑ in rCBF during OCD state vs rest in R-caudate, B/L-OFC and L-ACC.
Breiter *et al.*, 1996b	10 OCD and 5 controls	fMRI/control and provoked	Most OCD subjects showed activations in OFC, ACC, insula, caudate and amygdala.
Cognitive activation			
Rauch *et al.*, 1997	OCD vs normal	PET-FDG: Serial Reaction Time task	Both groups showed implicit learning. However OCD group recruited B/L medial temporal areas rather than ventral striatum (seen in controls).

R = Right, L = Left, B/L = Bilateral, M = Male, F = Female, OFC = orbitofrontal cortex, mPFC = medial prefrontal cortex, OG = orbital gyri, O/H = orbital/hemispheric ratio, PCG = posterior cingulate gyrus, T/P = Temporo-parietal, C/H = caudate/hemispheric ratio, ACC = anterior cingulate cortex, Hippo. = hippocampus, PET = Positron Emission Tomography, fMRI = functional Magnetic Resonance Imaging, SPECT = Single Photon Emission Computed Tomography, rCBF = regional cerebral blood flow, rCMRglu = regional cerebral metabolic rate (glucose), Norm. rCMRglu = Normalized regional cerebral metabolic rate (glucose).

phobic symptoms are circumscribed around performance in specific social situations such as public speaking. In specific phobias, the feared object could be animate or inanimate (APA, 1994). Symptoms of anticipatory anxious apprehension, anxiety and panic symptoms and avoidance of triggering situations are common to both disorders. The subtype of blood injury phobia, differs in part from the other phobias, due to a vasovagal syncopal response to blood exposure (Marks, 1988).

Currently, there are no cohesive functional neuroanatomically based models for the phobias (Stein, 1998). Phobias could be viewed as learned aversive responses to specific stimuli or situations, resembling fear conditioning in animals. From a

Table XIX-9.4A Neuroimaging studies in social phobia (SoP)

Authors	Subjects	Methods	Findings
Potts *et al.*, 1994	22 SoP subjects and 22 matched controls	MRI morphometry: Total cerebral, caudate, putaminal and thalamic volumes	The groups did not significantly differ on any of these measures.
Stein *et al.*, 1996	SoP subjects and healthy controls	SPECT-study Neutral state	No significant between-group differences in rCBF.
Birbaumer *et al.*, 1998	7 SoP subjects and 5 controls	fMRI: exposure to neutral human faces or aversive odours	Compared to controls, the SoP group exhibited human face specific amygdalar hyperresponsivity.
Schneider *et al.*, 1999	12 SoP subjects and 12 controls	fMRI classical conditioning paradigm: neutral faces (CS) paired with negative odour and odourless air (US) s	In response to conditioned stimuli associated with the negative odour, the SoP group displayed signal ↑ within amygdala and hippo., whereas controls displayed signal ↓ in these regions.

Table XIX-9.4B Neuroimaging studies in specific phobias (SpP)

Authors	Subjects	Methods	Findings
Mountz *et al.*, 1989	7 small-animal phobics vs 8 controls	PET	Phobics exhibited increased HR, RR and subjective anxiety during exposure to phobic stimuli. No changes in rCBF measurements were observed.
Wik *et al.*, 1993	6 patients with snake phobias	PET exposure to neutral, generally aversive, and snake-related scenes (videotapes)	Phobic condition was associated with significantly ↑ rCBF in secondary visual cortex and ↓ rCBF in prefrontal, post. cingulate and ant. temporopolar cortex, and hippocampus.
Rauch *et al.*, 1995	7 subjects with a variety of small-animal phobias	PET *in vivo* exposure	Provoked vs control condition: ↑ rCBF within multiple ant. paralimbic territories (R-ant. cingulate, R-ant. temporal pole, L-post. orbitofrontal and L-insular cortex), L-somatosensory cortex, and L-thalamus.

neuroanatomical perspective, phobias could represent the product of dysregulated threat detection systems for detecting potentially threatening stimuli or situations. Ongoing studies are actively investigating such hypotheses (Rauch and Shin, 2002).

More recently, contribution from animal research on attachment and affiliative behaviour, social subordination stress and environmental rearing have provided a partial yet useful framework to investigate social phobia (for reviews see Stein, 1998; Mathew, Coplan and Gorman, 2001). Surprisingly few neuroimaging studies exist in this area (see Table XIX-9.4A). In the only morphometric study published to date, Potts *et al.* (1994) compared the total cerebral, caudate, putaminal and thalamic volumes in 22 subjects with SoP vs 22 matched controls and found no differences. More recently Birbaumer *et al.* (1998), used fMRI to study seven SoP subjects and five healthy controls while they were exposed to slides of neutral human faces or aversive odours. The SoP group showed human face specific amygdalar hyperresponsivity compared to the control group. In another fMRI study, Schneider *et al.* (1999) presented 12 subjects with SoP and 12 healthy controls with paired conditioned (CS; neutral facial expressions) and unconditioned stimuli (US; negative odour vs unmanipulated air). The SoP group showed signal increases within the amygdalar and hippocampal in response to the CS paired with the negative odour while controls showed signal decreases in these regions. These findings, while in need of replication, suggest that hyperresponsivity of the medial temporal lobes may be one of the candidate neural substrates for SoP.

It is appealing to try to understand specific phobias from the viewpoint of conditioned fear studies in animals. This is supported by the fact that behavioural therapy for the phobias involving exposure and desensitization (akin to 'extinction') has been used to effectively treat many patients. While this perspective clearly does not explain aetiology or pathophysiology, the resemblance of components of these disorders to animal fear conditioning should trigger a closer look at analogous brain circuits. In a PET-symptom provocation study, Rauch *et al.* (1995) reported increased activity in prefrontal, posterior cingulate, anterior temporopolar, hippocampal and secondary visual areas as well as in multiple anterior paralimbic territories in seven subjects with small-animal phobias. These findings may reflect a hypersensitive threat detection and response network (therefore triggered by relatively innocuous stimuli). However, as is evident in Table XIX-9.4B, the few symptom provocation studies in SpP report inconsistent findings and are hard to meaningfully interpret. More work is clearly needed in this area.

GENERALIZED ANXIETY DISORDER (GAD)

GAD is, in some sense, the prototypical anxiety disorder. Patients usually have pervasive anxiety symptoms pertaining to, but not confined to, two or more life areas for at least a 6 month period. However, 'free-floating' anxiety and pervasive anxious dread is harder to characterize objectively. Perhaps consequently, genetic evidence and biological evidence in GAD is less compelling.

Rodent experiments involving the fear potentiated acoustic startle response (fear-like; conditioning dependent, shows 'extinction') vs the light-enhanced startle response (anxiety-like; unconditioned, slow onset and rate of decay, reduced by anxiolytics) show that these processes are subserved by different neural systems. Based on these findings, it is hypothesized that the bed nucleus of the stria terminalis (BNST) may subserve the anxiety-like phenomena, while the CeA subserves fear phenomena and may not contribute directly to anxiety. Stress (fear)-induced phasic release of CRH by

the neurons in the CeA may lead to long-term activation of the BNST (Davis, 1998). Thus by extension, hypersensitivity of the BNST pathway may be manifested by a state of chronic generalized anxiety with generalization to many innocuous stimuli (internal and external). This remains to be tested in humans with GAD. Neuroimaging evidence is scant and preliminary at this stage. In a recent MRI volumetric study in 12 children with GAD (compared with 24 matched controls), De Bellis *et al.* (2000) reported that the right and total amygdala volumes were significantly larger in those with GAD, all other volumes not differing significantly. The implications of these findings are currently unclear.

Thus no coherent neurocircuitry model exists currently for GAD. Chronic hyperactivity of the danger assessment and response circuits may underlie GAD. However, it is not known if this may be common to all anxiety disorders or could be a process specifically related to GAD.

DISCUSSION AND FUTURE DIRECTIONS

Anxiety disorders are common and are associated with considerable comorbidity (Regier *et al.*, 1998). A better understanding of the neural mechanisms of adaptive as well as pathological anxiety and fear promises to enhance the development of more effective preventive and therapeutic strategies. Advances in animal fear research provide a springboard to related research in humans. The advent of sophisticated neuroimaging techniques promises to accelerate progress in this field, by providing a means for probing human functional anatomy non-invasively.

Based on animal research, the subnuclei of the amygdala have emerged as the central component of the early, rapid processing of danger-related stimuli. The rich connections between the subnuclei of the amygdala and the sensory thalamus, the orbitofrontal and sensory cortices, the hypothalamus and brainstem areas as well as the striatum have been shown to subserve the various characteristic components of the fear response. The amygdala is a crucial component in stimulus-reinforcer association learning and possible modulation of other relevant brain areas. The cellular and molecular basis of fear conditioning and emotional learning and memory are being vigorously investigated. Of specific interest are the processes of plasticity, kindling, LTP and at a cellular level, NMDA receptor and voltage gated calcium channel mediated signal transduction (LeDoux, 2000b).

In healthy human volunteers, induced transient states of anxiety and fear are associated with increased activity in anterior paralimbic regions and decreased activity in heteromodal association cortex (Rauch and Shin, 2002). These findings are in need of further refinement given that other experimentally induced emotions (such as anger and guilt) also activate overlapping pathways (Dougherty *et al.*, 1999; Shin *et al.*, 2000). The processes of habituation and extinction of fear responses, explored via novel functional neuroimaging paradigms, are relevant to the understanding of normal and pathological anxiety, as well as therapies that rely on desensitization.

Functional neuroimaging studies, combined with specific human brain lesions, implicate the amygdala and associated structures in the innate processing of fear-related faces. The medial frontal and OFC are implicated in the top-down governance of the amygdala and related structures. The anterior cingulate cortex is important in attention and choice making, the brain stem nuclei and lateral hypothalamus in the control of the somatic reactions to stress and anxiety, and the striatal regions in mediating automated response routines, as well as influencing gating at the level of the thalamus (Rauch and Shin, 2002). The insular cortex, which has rich connections with the amygdala, is commonly activated in anxiety-related studies. However, most work has implicated the insula in functions related to taste, including the perception of disgust (Phillips *et al.*, 1997, 1998). Its role in fear and anxiety is less clear.

The convergence of different modes and fields of inquiry are enabling growth from simple to more complex models befitting the nature of human anxiety/fear mechanisms. This increased sophistication also reflects an integration of data across scales — from the systems level to the molecular level. In the area of PTSD, evidence from animal fear conditioning and stress research, clinical traumatology as well as innovative neuroimaging paradigms in patients have helped to increase our understanding of the PTSD syndrome. Thus, the amygdala in functional connectivity with the OFC, hippocampus, the hypothalamus as well as brainstem regions, are thought to mediate the characteristic symptoms of the disorder. The contemporary neurocircuitry model of OCD has been derived from the neuropsychiatry of the basal ganglia as well as from neuroimaging studies (Rauch and Savage, 1997; Saxena and Rauch, 2000). Abnormal activity in the orbitofrontal-thalamo-striato-cortical circuits has been shown to normalize with clinical response to both drug and behavioural treatments. With the emergence of deep brain stimulation as an experimental treatment modality for OCD, there is the potential for learning much about the implicated circuitry in human subjects. In PD, panic attacks accompanied by anticipatory anxiety and avoidance suggest involvement of the amygdala, the medial temporal lobes (specifically hippocampus) and functional connections with the OFC and brainstem areas (Gorman *et al.*, 2000). Currently, neurocircuitry models for the phobic disorders and GAD are less coherent, although preliminary, contemporary neurocircuitry models of anxiety disorders facilitate hypothesis-driven research in this domain. While delineating the functional neuroanatomy of psychiatric diseases is extremely important, these neural substrates must be understood in the context of interdigitating environmental influences. The interactions between genetic/temperamental predisposition of individual neural systems with environmental events (e.g. trauma during early neurodevelopment, stressful life events) are important in the development and maintenance of anxiety disorders.

Further research across modes of inquiry and across scales is required to understand the neural substrates of normal relevant brain functions as well as the pathophysiology of anxiety disorders. An integrated approach combining animal studies, molecular biology, genetics, clinical psychiatry, behavioural neurology, cognitive neuroscience, and neuroimaging is essential to make meaningful progress in this field. Ultimately, the hope is for better preventive and therapeutic options to help people who might otherwise suffer from anxiety disorders.

In Vivo Functional Neurochemistry of Anxiety Disorders

Andrea L. Malizia, Brian Martis and Scott L. Rauch

INTRODUCTION

Human anxiety disorders are the most prevalent psychiatric conditions affecting at least two fifths of the population in their lifetime. About one in 20 of the population has enduring or recurrent anxiety disorders and therefore these conditions are responsible for the highest societal global (medical and social) costs of any psychiatric condition. For instance, out of 92 million working days lost in the UK. due to mental illness in 1993 (18% of all lost days), 49% were due to anxiety or stress representing a cost of over £3 billion (approximately ∈/$ 4.5 billion).

In order to understand the aetiology of these disorders, possibly leading to better treatments, research has been carried out on the biological basis of healthy and pathological anxiety. Compared with other emotions and other psychiatric conditions, anxiety and fear (as defined in Martis *et al.*, Chapter XIX-9) are constructs which have a reasonable mapping between animals and man. Therefore, the study of anxiety and fear in preclinical experiments can provide leads for human research. Animal experiments have generated two overlapping sets of information. One set describes the sufficient or necessary neuroanatomical structures underlying the expression of these emotions (whether innate or conditioned) in animals and the other the neurochemical changes which predispose to or accompany the behavioural changes. However, despite the similarities in anxiety expression between man and other animals, data from preclinical experiments are not sufficient to understand the biology of human anxiety or anxiety disorders.

Direct human experimentation has also contributed to increase our knowledge about brain function and anxiety. Yet, the traditional investigation of human brain processes *in vivo* has many constraints related to the inaccessibility of the tissue under study and to functional complexity whereby understanding of individual modules from lesion studies, pharmacological challenges and electrophysiological recordings cannot provide sufficiently comprehensive hypotheses of system architecture. Indeed, up to the late 1980s, the most informative experimental strategies employed in clinical psychopharmacology recorded behavioural, physiological and cognitive responses to pharmacological probes where the aim was to characterize the central neurochemical changes underlying particular processes or diseases based on preclinical knowledge. These challenges were, and are, limited by their intrinsic inability to characterize neural networks in detail and by the fact that ligand binding and neurotransmitter release cannot be quantified *ex vivo* or by microdialysis in man (except recently in very selected samples of neurosurgical patients). These limitations prevent the conduct of any quantitative human research which aims to relate changes in physiology or behaviour to synaptic parameters. Further, many of the probes used to selectively affect one system or one subset of receptors have often subsequently been discovered to be relatively less selective than originally postulated.

Since the late 1980s, human imaging (Table XIX-10.1) has been used to describe the functional anatomy (discussed in Chapter XIX-9), pharmacology and functional neurochemistry (this chapter) of human anxiety and anxiety disorders with macroanatomical (up to about 1 cm) brain resolution. The use of these technological advances is still in its infancy as novel paradigms and analytical methods are developed; however, the vision for the future is that their utilization should lead to a more robust understanding of the brain mechanisms underlying disease and response to treatments.

This chapter has two aims: a brief commentary on the technical issues related to pharmacological imaging and a review of the current human psychopharmacology imaging knowledge regarding anxiety and anxiety disorders, including some preliminary data.

PHARMACOLOGICAL IMAGING

Two strategies can be employed to detect drug effects on the brain: detection of changes in brain metabolism or activation induced by pharmacological agents and radioligand assay of binding to receptors, transporters, enzymes and of tracer kinetics of precursor pools.

Changes in Brain Metabolism or Activation

The paradigms used here depend on the detection of changes in regional brain metabolism or blood flow following the administration of pharmaceuticals. The principles are as follows.

- Changes in local brain metabolism are mostly induced by changes in neuronal activity; while there is debate on the cellular location of the metabolic changes (i.e., neurons or glia), energy is mostly expended at synaptic sites.
- Changes in local metabolism are tightly linked to changes in local blood perfusion, which overcompensates for the increases in oxygen demands by delivering an excess of deoxyhaemoglobin.
- Imaging techniques can measure changes in local metabolism ([^{11}C] glucose PET or ^{18}fluorodeoxyglucose (FDG) PET), in local perfusion ($H_2{}^{15}0$ PET or $C^{15}O_2$ PET or [^{11}C]butanol PET; ^{99}Tc HMPAO SPECT; ASL (arterial spin labelling) or gadolinium MRI), in local deoxyhaemoglobin concentration (fMRI), in oxygen extraction ($^{15}O_2$ PET) or in local blood volume ($C^{15}O$ PET).

One complicating factor in the interpretation of these techniques is the fact that pharmacological manipulations have effects not only on the brain processes of interest but also on other neuronal or

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

Table XIX-10.1 Types of human imaging used for investigating *in vivo* neurochemical processes in the human brain. Note that the significant parameters are derived from the primary measures by using mathematical and statistical models

Imaging modality	Technique	Primary measure	Deduction/physiological significance
MRI	Functional MRI	Deoxyhaemoglobin signal	Change in perfusion.
	Spectroscopy	Specific spectral signal	Total concentration of molecule of interest (GABA, lactate) in whole brain.
PET	Water, butanol	Radioactive counts	Perfusion or change in perfusion.
	Fluorodeoxyglucose (FDG)	Radioactive counts	Regional integrated (over time) glucose analogue transport into brain tissue.
	Receptor binding	Radioactive counts	Binding potential or volume of distribution (related to B_{max}/K_d).
	Labelled precursor	Radioactive counts	Local brain transport of precursors. Relationship with transmitter synthesis unproven.
	Enzyme binding	Radioactive counts	Regional enzyme concentration.
	Transporter binding/uptake	Radioactive counts	Regional transporter availability.
SPET	HMPAO	Radioactive counts	Change in perfusion.
	Receptor binding Transporter binding	Radioactive counts	Relative binding potential or volume of distribution. (related to B_{max}/K_d) or transporter availability.

glial processes and on the innervation to the cerebral vasculature (adventitia). Further, the signal associated with pharmacological modulation of specific brain activations is often very small and the statistical techniques needed to detect these changes have to be more sensitive than ones often employed in simple activation experiments. Newer strategies will improve the quality of data generated. These include the following.

- Comprehensive evaluation of the cerebral effects of the drugs under study using more than one imaging modality and detailing a number of the physiological responses. This strategy would measure changes in regional metabolism as well as in perfusion, or measure changes in magnitude and distribution of activation with control tasks as well as with tasks of interest or compare metabolic maps with maps of changes in radioligand binding. In the few occasions where such combinations of data have been acquired in the past, important differences between changes in regional metabolism and regional perfusion have been detected.
- The inclusion of other measured physiological responses in the analysis, thus allowing detection of the relationship between changes in regional brain activity and another physiological parameter of interest such as saccadic eye movement parameters.
- Use of statistical methods such as path or network analysis which are more sensitive to small predicted changes in activity.

Measure of Radioligand Binding

The principle of these studies is that a ligand is administered which is labelled with a radioactive nucleus. The time course of the distribution of radioactivity in the tissue of interest is recorded with SPET or PET cameras and the data is analysed with an appropriate mathematical model (Gunn, Gunn and Cunningham, 2001) in order to obtain the parameters of interest. Since the signal recorded is a tomographic, time dependent measure of radioactivity in a particular image segment or voxel, it is made up of a number of components (Figure XIX-10.1) comprising free and bound ligand and metabolites in the blood and tissue of interest. Thus the identifiability of the measure of interest depends on a number of factors (Table XIX-10.2) mostly related to radioligand properties. These factors explain why there are very few PET/SPET radioligands that can be successfully used to measure brain chemistry *in vivo* in man despite the fact that thousands have been developed.

Radioligand binding can be used to measure a number of processes.

- Receptor density and affinity. Often a composite measure of these is used such as binding potential or volume of distribution. These are proportional to B_{max}/K_d. Composite parameters are used because a measure can be obtained by doing only one scan and without the injection of significant amounts of cold ligand (Mintun *et al.*, 1983). A number of receptors have thus been measured including dopamine D1 and D2, serotonin 1A, 2 and 2A, $GABA_A$ benzodiazepine, substance P (NK1) and opiate.
- Changes in neurotransmitter concentration. This is deduced by measuring the change in binding potential as receptor availability increases or decreases with changes in neurotransmitter release. So far this strategy has only been successful in measuring dopamine and possibly opiate release.
- Precursor pools — this method has been used to measure the concentration of radiolabelled fluoroDOPA and alpha-methyl-L-tryptophan in the brain. The interest in these measures is that they are thought to relate to precursor pool and rate of synthesis of derivative neurotransmitters such as dopamine and serotonin. The demonstration that they are more likely to be measuring local brain uptake than any other process (Shoaf *et al.*, 2000) recommends caution in the interpretation of results obtained when using these techniques.
- Transporter density. This technique has been used successfully to measure dopamine (Laruelle *et al.*, 1997) and to a lesser extent serotonin reuptake sites.
- Enzyme concentrations. So far this technique has been used to measure MAO in the brain.
- Occupancy or inhibition of any of the above.

NEUROCHEMISTRY OF ANXIETY DISORDERS *IN VIVO* IN MAN

Studies in this area have been scarce to date with most of the effort being concentrated on the $GABA_A$ benzodiazepine receptor. In the receptor binding arena, this has been in part due to practical issues related to the availability of good radiotracers. Preclinical work indicates that investigation of the ascending monoaminergic systems (dopamine, serotonin, noradrenaline), of some peptidergic transmitters such as substance P and the NK1 receptor and CCK, of adenosine receptors and of benzodiazepine-GABAergic activity

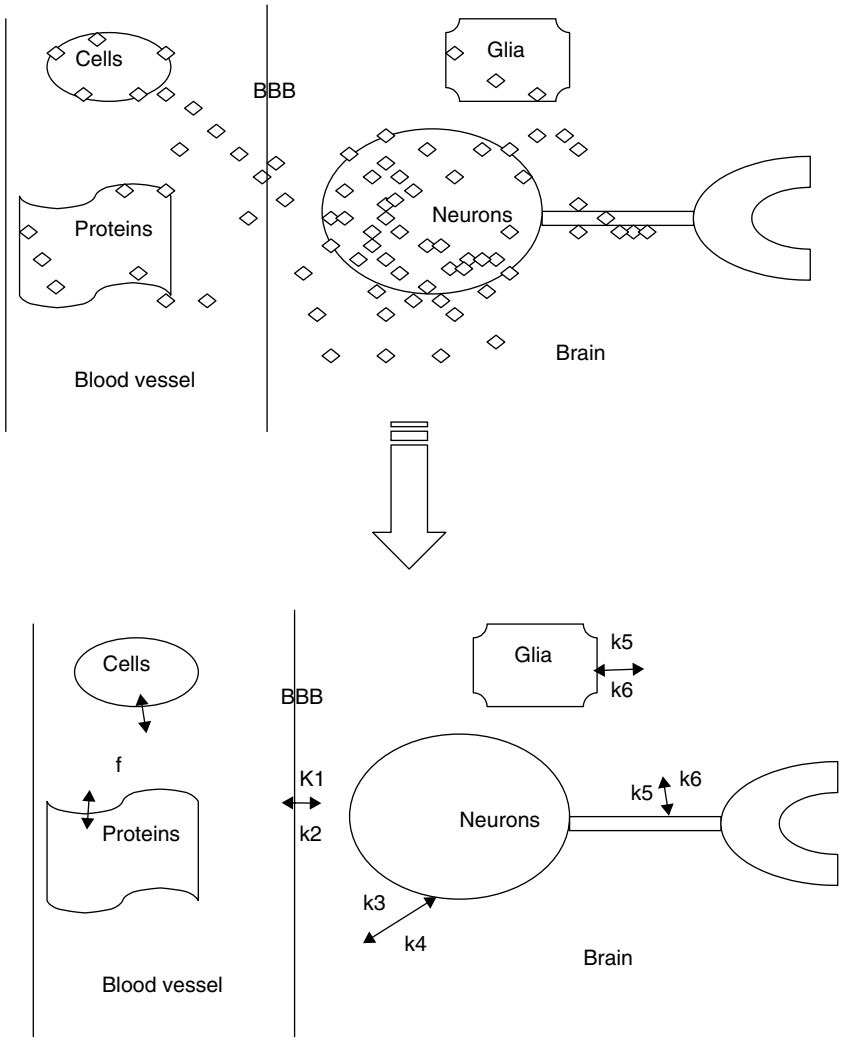

Figure XIX-10.1 (Upper panel) Schematic representation of radioligand (◇) topography. In the vasculature the radioligand is partly bound to cells and proteins. Once it crosses the blood–brain barrier (BBB) it may bind to specific sites on the neurons and sometimes glia and to non-specific sites on neurons and glia. In addition it can exist in the interstitial spaces. (Lower panel) The same scheme with processes as described by common symbols. f is the free fraction in plasma. K1/k2 represents the constants characterizing movement to and from tissue, k3/k4 describes the rate constants for specific binding and k5/k6 the rate constants for non-specific binding

Table XIX-10.2 Necessary characteristics of radioligands for pharmacological imaging in the brain. The essential feature is that the signal recorded is from the whole of the tissue and vasculature *in vivo* and therefore the radioligand characteristics are stringent in order to make it interpretable

Essential and desirable characteristics	Significance
Radioligand crosses blood–brain barrier easily	Allows measurement of total brain concentration of radioligand.
Radioligand specific binding is at least 3× non-specific binding	Allows measurement of specific binding and changes in specific binding.
Radioligand has no radioactive metabolites **OR**	Signal becomes very difficult to model mathematically if radioactive metabolites
Radioactive metabolites do not cross blood–brain barrier	are present in the tissue.
Radioligand has no metabolites which also bind to receptor of interest	*Avoids potential for displacement by metabolite*.
Radioligand has high affinity (low K_d)	*Mean transit time in tissue has to be of same order of magnitude as timing of imaging*.
Radioligand binds to one receptor only **OR**	Resolution of signal specific to one site of specific binding is otherwise not
If to multiple receptors, these have distinct anatomical distribution	possible.
Radioligand has no physiological actions at injected concentrations	Pharmacodynamic effects may affect pharmacokinetic parameters.
Radioligand has high specific (radio) activity	Must inject tracer doses of radioligand (<2% occupancy) for tracer kinetics to apply.
Appropriate reference activity can be obtained from plasma or tissue	Separation of parameters depends on being able to account for signal which is not specific.

would be the most relevant for human anxiety disorders. However, only some of the above can be currently explored in terms of receptor binding. This section of the chapter will examine the extant data, organized by neurotransmitter system and disease.

$GABA_A$ BENZODIAZEPINE

Benzodiazepines, first discovered in the 1950s, were found in the 1970s and 1980s to act by modulating GABA chloride ionophores, thus increasing the effectiveness of local neuronal inhibition. Benzodiazepines and GABA potentiation are known to have an immediate effect on anxiety in man and therefore investigation of their binding in the brain is a field of interest (Nutt and Malizia, 2001). The $GABA_A$ ionophore is a structure made up of five subunits; benzodiazepines in clinical practice bind to receptors expressing $\alpha1$, $\alpha2$, $\alpha3$, and $\alpha5$ subunits. This includes iomazenil and flumazenil, two benzodiazepine antagonists routinely used to image these receptors in man with SPET and PET respectively. Further, other agents that bind at these sites are being developed, which have differential affinity for some of the subtypes (e.g., Ro 15-4513 which has higher affinity for $\alpha5$-containing receptors). In addition, GABA concentrations can now be measured with MR spectroscopy. Three conditions have been investigated: Panic Disorder, Generalized Anxiety Disorder and Post Traumatic Stress Disorder.

Panic Disorder

Benzodiazepine Binding

The separation of Panic Disorder (PD) from other anxiety disorder followed the observation that PD patients did not respond clinically to benzodiazepines but were treated by adequate courses of tricyclic antidepressants. It is now known that higher doses of benzodiazepines or compounds with higher potency at the $GABA_A$ benzodiazepine site are effective at treating PD; however, the original findings were an indication that PD patients have a lower sensitivity to these compounds. Further experimental evidence was produced, showing that PD patients are less sensitive to benzodiazepines on a number of psychophysiological measures, such as saccadic eye movements to target and suppression of noradrenaline appearance rate (Roy Byrne *et al.*, 1989). These findings, coupled with the observation that FG 7142 (a benzodiazepine site exogenous inverse agonist) is panicogenic in man and the discovery of putative endogenous inverse agonists in man (DBI (Elsworth *et al.*, 1986) and tribulin (Corda *et al.*, 1984)) led to theories which postulated that panic attacks were precipitated by the pathological production of a putative endogenous inverse agonist. However, Nutt and colleagues (1990) discovered that flumazenil, a benzodiazepine site antagonist, which has neutral anxiety effects in control subjects, provokes panic attacks in patients with PD. This disproved the putative benzodiazepine receptor inverse agonist theory and two possible explanations were put forward. The first is that fundamental changes at the $GABA_A$ benzodiazepine receptor result in changed receptor binding/function which alter the effects of flumazenil so that it behaves like an inverse agonist. The second is that flumazenil blocks a putative endogenous agonist which is present in a compensatory function in anxiety disorders and that this endogenous ligand is, however, insufficient to prevent the emergence of panic attacks. Following these leads, a number of investigators have sought to determine benzodiazepine receptor density using Iomazenil SPECT or Flumazenil PET. Many of these studies have considerable methodological shortcomings that prevent the formation of robust conclusions. In particular, early scanning after injection of iomazenil (thus contaminating the data with effects due to brain delivery), inappropriate control groups (for example patients with epilepsy who may themselves have alterations at the benzodiazepine site), comorbidity with other affective conditions and the study of patients who have been treated with benzodiazepines (thus inducing changes in regulation of the site) are the most common problems.

Schlegel *et al.* (1994) were the first to report decreased benzodiazepine receptor binding in panic disorder using Iomazenil SPECT comparing, at 90–110 min post-injection, 10 patients with PD with 10 patients with epilepsy on carbamazepine. The decreases were significant in the occipital and frontal lobes and maximal in the temporal lobes. Kaschka, Feistel and Ebert (1995) studied nine medicated patients with PD *and* comorbid depression with a matched group of medicated patients with dysthymia using Iomazenil SPECT (2 h). Decreases in binding were seen in the inferior temporal lobes both medially and laterally and in the inferior frontal lobes. These changes were already detectable at 10 min post-injection reflecting changes dominated by delivery effects. All participants were on antidepressants. Tokunaga *et al.* (1997) published an elegant technical study, having followed a very rigorous scanning methodology. However, their demonstration of reduced benzodiazepine binding in anxiety patients is limited by the uncertainty associated with the fact that he did not use a standard psychiatric classification. On the other hand, Kuikka *et al.* (1995) using two different SPECT cameras (at 90 min post-injection) studied 17 unmedicated patients with PD and 17 healthy age and sex matched controls using Iomazenil and found an increase in Iomazenil signal bilaterally in the temporal cortex and in the right middle/inferior lateral frontal gyrus, while Brandt *et al.* (1998) showed that patients with PD have a significant increase of benzodiazepine receptor binding in the right supraorbital cortex and a trend to an increased uptake in the right temporal cortex. Both these studies are however also likely to be contaminated by ligand delivery issues. Finally, Bremner *et al.* (2000a) showed a relative decrease in measures of benzodiazepine receptor binding in left hippocampus and precuneus in panic disorder patients relative to controls. The group further observed that panic disorder patients who had a panic attack compared with patients who did not have a panic attack at the time of the scan also had a decrease in benzodiazepine receptor binding in prefrontal cortex. They also reported an increase in benzodiazepine binding in the right caudate, in the occipital lobes, in the middle temporal and in the middle frontal cortex. Although patients were drug free at the time of the scan none of them were benzodiazepine naïve.

In summary, most SPECT studies demonstrate decreases in benzodiazepine binding in panic disorder. However, the direction and location of these changes is not consistent across all studies, probably due to methodological issues.

In the only fully quantitative study of benzodiazepine naïve subjects, Malizia *et al.* (1998) employed [^{11}C]flumazenil PET and found a global decrease in binding in benzodiazepine naive, drug-free patients with PD who had no comorbid conditions and did not abuse alcohol (Colour Plate XIX-10.2). These changes were maximal in ventral basal ganglia, orbitofrontal and temporal cortex. Having corrected for the global decrease in binding, PD patients showed a further statistically significant regional decrease in binding in the inferior parietal temporo-occipital areas which was maximal in the lateral posterior temporal lobes as well as decreases in orbitofrontal cortex and ventral striatum. Decreased binding in thalamus, dorso-lateral and medial prefrontal, medial temporal and cerebellar cortex and vermis were accounted for by the global changes. Another PET study (Abadie *et al.*, 1999) compared patients with a number of anxiety disorders and healthy volunteers using flumazenil PET and a tissue reference technique which is semi-quantitative. The variance of the reference areas was such that the data had to be pooled across subjects in order to avoid dealing with negative binding in the pons. No significant differences were

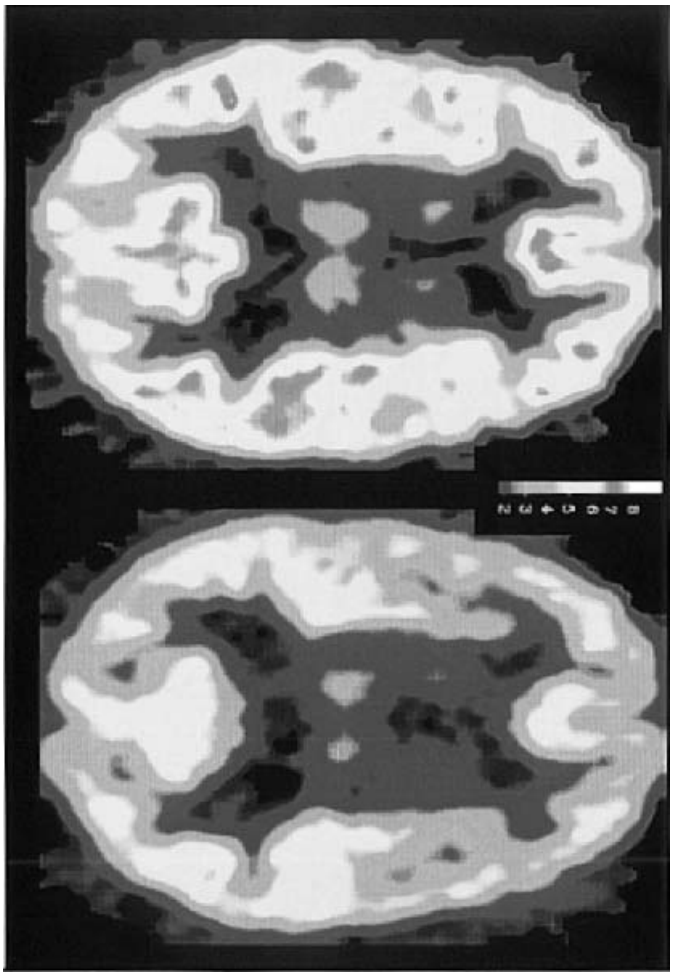

Figure XIX-10.2 A comparison of flumazenil binding between controls and panic disorder patients. The image shows a coloured scale of volume of distribution of flumazenil. The horizontal brain slice is through the middle of the brain showing occipital cortex (left) thalami amd basal ganglia (centre) temporal cortex (middle rim) and frontal cortex (right). A decrease in flumazenil binding is seen throughout the cortex and subcortical structures on the bottom which is the median map for panic disorder patients. The median map for controls is on the top (See Colour Plate XIX-10.2)

found between individual brain areas because of this large variance but for each area examined benzodiazepine receptor density was lower in patients with anxiety disorders.

Decreased benzodiazepine receptor binding is consistent with the idea that panic disorder is due to a deficiency in brain inhibition that leads to, or allows, paroxysmal elevations in anxiety during panic attacks. The peak decreases in benzodiazepine binding are in anatomical areas (e.g., orbitofrontal cortex and insula) thought to be involved in the experience of anxiety in man and could represent a primary pathology. The reduction in binding not only explains some of the known features of benzodiazepine receptor function in panic disorder but is also congruent with animal data showing that chronic stress decreases benzodiazepine binding (Inoue *et al.*, 1985; Weizman *et al.*, 1989, 1990) and that animals with genetically decreased flumazenil binding experience more anxiety (Crestani *et al.*, 1999). It is thus possible that this finding could be the result of experiencing repeated panic attacks or the consequence of one or more of the aetiological factors such as genetic predisposition or life events.

BRAIN GABA CONCENTRATIONS

One of the possible mechanisms by which benzodiazepine $GABA_A$ receptor subunit composition could be altered or downregulated is via a change in brain GABAergic activity. Goddard *et al.* (2001) have demonstrated that patients with panic disorder have a 22% reduction in total occipital cortex GABA concentration (GABA plus homocarnosine) compared with controls. GABA concentration was measured by using MR spectroscopy of occipital cortex *in vivo*; the selection of this area of the brain was dictated by current constraints in data acquisition using this method. This remarkable finding was present in 12 of the 14 patient–control pairs but there were no significant correlations between occipital cortex GABA levels and measures of illness or state anxiety. Clearly, further studies will be needed to determine what the GABA concentration is in areas more germane to the expression of anxiety, but these data provide an interesting model of pathophysiology in panic disorder which may be consistent with reduced flumazenil binding.

Post Traumatic Stress Disorder (PTSD)

Exposure to chronic stress decreases benzodiazepine binding which is maximal in the frontal cortex in some animal experiments (Weizmann *et al.*, 1989). The Yale group (Bremner *et al.*, 2000b) investigated Vietnam veterans with PTSD using Iomazenil SPECT and found that there was a significant decrease in the volume of distribution of benzodiazepine $GABA_A$ receptors in the frontal cortex of these patients in an area which corresponds to Brodmann Area 9. This finding may be of particular significance as this area is involved in extinction of conditioned responses, thus misfunction of local inhibitory circuits could be either a consequence or a predisposition to developing inappropriate responses to trauma.

Generalized Anxiety Disorder

Benzodiazepine binding was also investigated in Generalized Anxiety Disorder using ^{123}I NNC 13-8241 SPECT in Finland where Tiihonen *et al.* (1997) compared 10 patients with 10 age and sex matched healthy volunteers finding decreased benzodiazepine $GABA_A$ binding in the left temporal pole. In addition they found a difference in fractal dimensions of the binding parameters which the authors interpreted as a decrease in variation of cortical receptor density akin to the decrease variability of some heart rate parameters seen in cardiovascular disease. While intriguing, this interpretation is premature as the significance of changes in fractal parameters for binding have not been mapped to cellular or histological differences.

Two papers reported studies of changes in brain metabolism during a vigilance task in patients with generalized anxiety disorders before and after benzodiazepine or placebo administration (Buchsbaum *et al.*, 1987; Wu *et al.*, 1991). Reductions in anxiety could not be mapped to specific changes in cerebral metabolism for the drug group and the usual pattern of benzodiazepine-induced global reductions in metabolism emerged. These types of experiments, however, need to be repeated with more sophisticated analyses as it is likely that detection of the smaller specific modulatory signal is obscured by the global changes.

SEROTONIN (5HT)

Since the discovery of the anxiolytic therapeutic action of $5HT1_A$ agonists and selective serotonin reuptake inhibitors (SSRIs), changes in serotonergic function have been postulated in all anxiety disorders with some authors detailing possible differences in

mechanisms between generalized anxiety and panic (Deakin and Graeff, 1991). Further, polymorphisms at the $5HT1_A$ site have been reported to contribute to variance in human anxiety disorders (Lesch *et al.*, 1992) and other receptor subtypes have been implicated in preclinical anxiety experiments. It may therefore seem surprising that the serotonergic system has been relatively underinvestigated.

Panic Disorder

Two sets of data are available in panic disorder. One relates to $5HT1_A$ binding and one to the effects of SSRI treatment on resting brain metabolism and on activations. $5HT1_A$ receptors are of particular interest as they have functional significance in decreasing raphe firing until functionally downregulated and are thought to mediate the cortical effects of increased serotonergic transmission.

[^{11}C]WAY100635 has been available as a useful PET radioligand to investigate $5HT1_A$ receptors. Following the demonstration of global decreases in benzodiazepine binding, global decreases in cortical and subcortical $5HT1_A$ binding in panic disorder patients when compared with controls have also been demonstrated by the same research group (Sargent *et al.*, 2000). These patients were, however, on active SSRI treatment when scanned and therefore the findings could be a consequence of the therapeutic interventions rather than a correlate of the psychopathology. In this light the findings of an inverse correlation between $5HT1_A$ binding and anxiety trait scores in healthy volunteers (Tauscher *et al.*, 2001) is however intriguing, as it may indicate that low $5HT1_A$ receptor density predisposes to anxiety in man.

The effect of serotonin transporter inhibition on brain metabolism in panic disorder was studied in nine patients successfully treated with imipramine by comparing their resting cerebral metabolism measured via ^{18}FDG PET with healthy volunteers and untreated panic disorder patients (Nordahl *et al.*, 1998). Compared with healthy volunteers, treated PD patients had lower Left/Right hippocampal and prefrontal metabolic ratios (but no difference with untreated PD patients). Lower posterior orbitofrontal metabolism was found in treated patients when compared with healthy volunteers or untreated patients and this effect was ascribed to antidepressant treatment since it was similar to effects observed with the tricyclic imipramine in OCD (Benkelfat *et al.*, 1990). *Post hoc* comparisons revealed that treated patients were no different from controls in the left parietal and left Rolandic areas which were however hypometabolic in untreated panic disorder patients.

Social Phobia

One leading group has employed [^{11}C]5hydroxy-L-tryptophan PET to investigate serotonergic basal metabolism in the brain of patients with social phobia (Marteinsdottir *et al.*, 2001) and has described decreases in signal in the basal ganglia and parts of the limbic system. However, signal with this ligand is closely linked to local transport into the brain (Shoaf *et al.*, 2000) and therefore the significance of these findings will have to be interpreted cautiously.

NORADRENALINE

While the status of noradrenergic manipulation as anxiogenic in preclinical experiments is much debated, there is a considerable body of evidence that $\alpha 2$ antagonists induce anxiety and $\alpha 2$ agonists decrease anxiety in patients with anxiety disorders. This has been mapped as noradrenaline release being anxiogenic while decreases are anxiolytic as activation of the $\alpha 2$ receptors in the locus coeruleus decreases firing. There are no viable noradrenergic ligands to study binding in the human brain *in vivo* but two experiments have been reported which observe brain metabolic changes after the administration of yohimbine (an $\alpha 2$ antagonist) in anxiety disorders.

PTSD

An investigation by the Yale group (Bremner *et al.*, 1997) examined the differences in regional metabolic rate after the administration of yohimbine to patients with PTSD and healthy volunteers. This study demonstrated that yohimbine generated a global small increase in grey matter metabolism in healthy volunteers, while patients with PTSD respond with a moderate global decrease in grey matter metabolism. These effects were maximal in the orbitofrontal cortex and significant in the prefrontal, parietal and temporal cortices and were accompanied by significant behavioural activation in PTSD patients. The authors interpreted this observation as evidence of increased sensitivity to the noradrenergic releasing properties of yohimbine in PTSD, in line with their previous pharmacological observations in this patient group.

Panic Disorder

The same group reported briefly (Woods *et al.*, 1988) on the effects of yohimbine on cerebral blood flow in panic disorder patients. In this study yohimbine provocation of panic resulted in large decreases in HMPAO-SPECT signal in the frontal cortex. The study has however not been described in more detail elsewhere so that a thorough critique is not possible.

DOPAMINE

Dopaminergic manipulation can alter the response to stress in animals and to some extent in man. The evidence for dopaminergic involvement in anxiety disorders is however scanty, both in the treatment and in the aetiology literatures. This may explain why few human imaging studies exist in this arena, despite the fact that there are some very robust dopaminergic radioligands for human work.

Social Phobia

Dopaminergic underactivity and social anxiety have been postulated to be related from animal models, human diseases such as Parkinson's and the effects of dopamine modulating agents (reviewed by Bell, Malizia and Nutt, 1999). Two studies have provided evidence for dopaminergic dysfunction in social phobia by measuring the density of dopamine transporters and D2 (mainly post synaptic) receptors in the basal ganglia of patients with this condition and controls, using SPET. The first study, using ^{123}I β CIT, demonstrated that 11 Finnish Social Phobia patients had decreased binding potential for the dopamine transporter in the striatum (Tiihonen *et al.*, 1997). This was followed by a study by Schneier *et al.* (2000) who demonstrated that 10 New York patients with Social Phobia had lower D2 binding potential than controls. These data suggest three possibilities:

- downregulation of both sites as a trait associated with possible dopaminergic hypofunction;
- increased dopaminergic tonic release, which would decrease the proportion of sites available for radioligand binding;
- mild atrophy of the basal ganglia.

PEPTIDES

CCK 4 and pentagastrin have been demonstrated to be powerful anxiogenic agents in patients with anxiety disorders and in particular with panic disorder. Imaging studies have demonstrated that induction of anxiety in volunteers using these agents activates brain areas thought to be germane to the experience of anxiety (Benkelfat *et al.*, 1995; Javanmard *et al.*, 1999). Further recent data suggests that SSRI treatment of PD patients modifies the brain activation pattern upon infusion of pentagastrin (Boshuisen *et al.*, 2001). These changes are most pronounced in frontal and limbic cortices, but to date it is not clear whether these changes are dominated by the change in anxiety experience after treatment.

SUMMARY AND CONCLUSION

Some human brain imaging techniques are mature and can be used to investigate a number of pharmacological systems in the human brain *in vivo*. While preclinical data have provided useful leads, some of the most striking results have come from investigating hypotheses suggested by observing human disorders. The demonstration of reduced benzodiazepine and $5HT1_A$ binding and reduced GABA concentrations in panic disorder and of dopaminergic dysfunction in the basal ganglia of patients with social phobia are the most notable examples.

It is increasingly important therefore that human imaging should be seen as able to provide leads which can be further validated and explored using preclinical methods. An intriguing example is the demonstration of reduced benzodiazepine binding in panic disorder which was almost immediately complemented by genetic experimentation in mice demonstrating that alterations in $\gamma 2$ and $\alpha 2$ subunits at the benzodiazepine receptors (Crestani *et al.*, 1999; Low *et al.*, 2000) can induce changes such as increased anxiety, decreased sensitivity to benzodiazepine agonists and decreased binding to flumazenil that are also observed in humans with anxiety disorders. Similarly, the demonstration that $5HT1_A$ knockout mice have increased anxiety and decreased flumazenil binding (Sibille *et al.*, 2000) also seems to link the reduced $5HT1_A$ binding seen in panic disorder to benzodiazepine site abnormalities in man and provides a link between the two systems which needs to be further explored.

It is therefore important that these techniques should be increasingly used in biological psychiatry research, as part of a strategy that aims to integrate preclinical and clinical data in a symbiotic cycle of enquiry. The responsibility that human brain imaging researchers face is to use methodology that is robust enough to allow appropriate interpretations of the studies.

ACKNOWLEDGEMENTS

ALM was in part supported from grants from the departments of psychopharmacology, old age medicine and clinical medicine of the University of Bristol while writing this chapter.

Neurogenetics of Anxiety Disorders

Ronit Weizman and Abraham Weizman

INTRODUCTION

Family and twin studies show that distinct and/or common genetic factors may play a role in anxiety disorders, although the magnitude of the genetic effect in each of the anxiety disorders is as yet unclear. A genetic liability apparently underlies the phenotypic expression of some of them; however, like other mental disorders, anxiety disorders exhibit a complex inheritance. That is, their transmission most likely requires the interaction of several genes and environmental factors that may predispose individuals to the disorder but do not always lead to its full clinical expression. Anxiety disorders may share a common genetic background with depression, as evidenced by the frequent coexistence of depressive and anxiety symptoms and the response of the anxiety disorders to antidepressant agents. The advances in genetic molecular technology and genetic epidemiology may help researchers to identify the genes contributing to the predisposition to these disorders and to clarify the interaction between genetic and environmental factors. However, in addition to the common difficulties of the molecular genetics of complex diseases, namely, non-Mendelian inheritance patterns, incomplete penetrance, possibility of phenocopies, genetic heterogeneity, and variable expressivity (Lander and Schork, 1994), the major problem in the neurogenetic study of anxiety disorders is the definition of the heritable phenotype (Tsuang, Faraone and Lyons, 1993; Smoller and Tsuang, 1998).

PANIC DISORDER

Family Studies

Family studies have consistently shown that panic disorder (PD), with or without agoraphobia, is a familial phenotype (Tsuang, Faraone and Lyons, 1993; Vieland *et al.*, 1996). First-degree relatives of probands with PD show a 3- to 21-fold higher lifetime risk of the disorder than relatives of unaffected probands. Goldstein *et al.* (1997) found that the risks of PD in adult first-degree relatives of probands was 17-fold higher when the age of onset in the proband was 20 years or less, but only six-fold higher when onset was after age 20 years.

First-degree asymptomatic relatives of patients with PD have a tendency to be more reactive to the CO_2 challenge test (Perna *et al.*, 1996). Furthermore, Perna *et al.* (1996) showed that PD probands with CO_2 hypersensitivity accounted for most of the familial loading. It seems that CO_2 hypersensitivity may be due to a particular genetic dysfunction and individuate a genetically homogeneous subgroup of patients with PD (endophenotype).

Twin Studies

Twin and adoption studies serve as a powerful tool in genetic research. The comparison of concordance rates between monozygotic (MZ) and dizygotic (DZ) twins can help clinicians estimate heritability, which is an index of the contribution of genetic factors to vulnerability to a disorder.

An effect of genetic factors in PD was shown in an early study by Torgersen (1983) who found that PD and agoraphobia with panic attacks were five times as frequent in MZ than in same-sex DZ twins. Ten years later, Kendler *et al.* (1993) assessed 2163 women from a population-based twin registry and noted only a modest familial aggregation of PD on multifactorial-threshold analysis, the best estimates of the heritability of liability ranged from 30% to 40%. In a subsequent study, this team examined the structure of the genetic and environmental risk factors for six major psychiatric disorders (phobia, generalized anxiety disorder, panic disorder, bulimia, major depression, and alcoholism) in an epidemiologic sample of 1030 female–female twin pairs with known zygosity (Kendler *et al.*, 1995). The estimated heritability of PD was 44%. The twin concordancerate for PD was also studied by Bellodi *et al.* (1998) in a sample of 90 same-sex twin pairs. They found that the probandwise concordance rates for PD were significantly higher in the MZ than in the DZ pairs (67% vs 0%), as were the concordance rates for spontaneous panic attacks (71% vs 18%). For CO_2-induced PD, the rates were 55.6% and 12.5%, respectively. These data suggest a relevant role of genetic factors in CO_2-induced panic attacks. The marked differences indicate that the genetic relationship is complex and not simply additive.

Segregation Studies

Segregation analysis of pedigrees determines the mode of transmission of a disorder using mathematical methods. The inclusion of twin pairs or adoptive relatives enables quantification of the degree and nature of environmental effects. Pedigree analyses of PD have suggested that a single major locus contributes to the inheritance of the disorder, although the possibility of polygenic inheritance has not been completely ruled out. Pauls *et al.* (1980) analyzed 19 kindreds of PD patients and found that the disorder is transmitted as a Mendelian autosomal dominant trait with an allele frequency of 0.014, age-dependent penetrance, and average age of onset 21.9 years. Crowe *et al.* (1983), in a preliminary genetic analysis, tested the single major locus and multifactorial polygenic transmission models, and was unable to exclude either one. The best-fitting single-locus model predicted a disorder gene with an allele frequency of 0.05 and a penetrance of 45.5% in women and 24.6% in men. Vieland *et al.* (1996) performed a simple segregation analysis in 126 families of probands

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

with DSM-III-R panic disorder and found comparable support for autosomal dominant and recessive models. The best-fitting dominant model predicted a disorder gene with an allele frequency of 0.01, a heterozygote penetrance of 50% and a phenocopy rate of 0.01. The best-fitting recessive model predicted a disorder gene with an allele frequency of 0.20, a homozygote penetrance of 70%, and a phenocopy rate of 0.01 among heterozygotes and normal homozygotes.

Finally, Cavallini and colleagues (1999b) performed a complex segregation analysis on a sample of 165 families of PD probands and on the subgroup homogeneous for CO_2 hypersensitivity. Their results fit a Mendelian hypothesis without distinction between different models of transmission. The analysis of the probands of 134 families found to be hypersensitive to CO_2 supported the existence of a single major locus model with a best fit for a dominant model.

Parent-of-Origin Effect

Since the lifetime risk of developing PD is higher in women than men (2 : 1), researchers have suggested it may be affected by the pattern of maternal vs paternal transmission. Using narrow and broad diagnostic models in a sample of 64 PD pedigrees, Haghighi *et al.* (1999) reported that the proportion of affected children born to a transmitting mother did not differ from the proportion born to a transmitting father, and there was no difference in the frequency of affected offspring from maternal or paternal transmission. However, when a subset of 'pure' pedigrees (including only maternal or paternal transmission of PD) was included under the broad diagnostic model, a significant difference was noted in the proportion of affected females and males from maternal (111 females and 23 males) and paternal (nine females and six males) transmissions. Furthermore, when affected and unaffected children were included in the analysis (excluding individuals with unknown status) the cumulative lifetime risk of PD for offspring of transmitting mothers was significantly higher than that of offspring of transmitting fathers. This finding may indicate that maternal transmission confers an increased susceptibility to PD on female offspring. Apparently, PD has a complex mode of inheritance, though further confirmation of the possibility of genomic imprinting or mitochondrial inheritance is still needed. By contrast, in a study of 38 families unlineally affected with PD and agoraphobia, Battaglia *et al.* (1999) noted no differences in sex distribution between offspring of transmitting mothers and offspring of transmitting fathers, nor was there a significant difference in the anticipation of age at onset of PD. The authors concluded that at least in their sample, there was no evidence of a parent-of-origin effect.

Molecular Genetics

Linkage Studies

As mentioned, some segregation analyses have suggested the involvement of a major gene in the aetiology of PD (Pauls *et al.*, 1980; Crowe *et al.*, 1983; Vieland *et al.*, 1996). These findings have prompted linkage analyses in families with multiple affected individuals. The aim of these studies is to pinpoint disease genes by showing that a genetic marker with a known genetic location tends to be transmitted along with the disease within families (Faraone, Tsuang and Tsuang, 1999).

Crowe *et al.* (1987b) studied 26 families segregating PD for linkage to 29 polymorphic blood group antigens and found a suggestion of linkage to the alpha-haptoglobin locus. However, this locus was later excluded by testing additional families with DNA markers (Crowe *et al.*, 1990). The candidate genes pro-opiomelanocortin (Crowe, Noyes and Persico, 1987a), tyrosine hydroxylase (Mutchler *et al.*, 1990), adrenergic receptor genes ($\alpha 1/\beta$ 2 pair on chromosome 5q32-q34, the $\alpha 2/\beta$ 1 pair on chromosome 10q24-q26, and a second $\alpha 2$ locus on chromosome 4) (Wang, Crowe and Noyes, 1992), Cys311 variant of dopamine receptor 2 (DRD2) (Crawford *et al.*, 1995), DRD4 and dopamine transporter (DAT) (Hamilton *et al.*, 2000a), the GABA-Aâl receptor (Schmidt, Zoega and Crowe, 1993) and GABA α1-5, β1, β3, γ2 (Crowe *et al.*, 1997) and the functional polymorphism in the promoter of the gene for serotonin transporter (5-HTT) (Hamilton *et al.*, 1999) have all been excluded.

Knowles *et al.* (1998) conducted a large-scale study on first-pass genomic screen for PD. They collected 23 multiplex families consisting of 368 individuals, of whom 269 were directly interviewed, and used 540 microsatellite DNA markers for genotyping. The data were analyzed with both a dominant and a recessive model. The authors failed to detect definitive evidence of linkage to PD (no lod scores exceed 2.0 for either dominant or recessive parametric model): they ruled out linkage over more than 95% of the genetic length of the autosomes under the homogeneous dominant model with reduced penetrance, and over 60% under the homogeneous recessive model with reduced penetrance. This team is currently trying to enlarge their sample size, refine the phenotype using an endophenotype (CO_2 sensitivity) (Perna *et al.*, 1996), and look for segregation of comorbid disorders. Since they failed to detect loci that contribute to the predisposition to develop PD in the genome-wide genetic screen, the authors concluded that the genetic structure of the disorder seems to be more complex than the simple autosomal and dominant recessive models. Crowe *et al.* (2001) performed a genome scan of 23 multiplex families of panic disorder, including 90 family members with PD and 23 members who had recurrent, spontaneous panic attacks that did not satisfy the full PD diagnostic criteria. Two-point lod scores were calculated with both a dominant and a recessive model, and maps of lod scores < -2.00, assuming genetic homogeneity, were constructed by using DSM-III-R panic disorder as the affected phenotype. The greatest lod score was 2.23 (theta = 0.15) at the D7S2846 locus, located at 57.8 cM on chromosome 7p.

A 10 cM linkage genome scan, in a set of 20 American pedigrees (153 subjects), ascertained through probands with panic disorder (PD), pointed towards two genomic regions which met criteria for suggestive linkage. One of these regions is on chromosome 1 (LOD score = 2.04) and the other (LOD score = 2.01) is located on chromosome 11p. For agoraphobia, the most promising potential linkage was on chromosome 3. The authors suggested that PD and agoraphobia are complex traits that share some, but not all, of their susceptibility loci (Gelernter *et al.*, 2001).

Association Studies: Candidate Genes

In this approach, candidate genes are selected on the basis of the biology of the disease, and molecular variants are sought. The distribution of different alleles of the candidate genes is compared between affected individuals and a non-related ethnically similar healthy population. If a particular allele is found to occur significantly more often among the affected persons, the researchers assume an association between the disease phenotype and a particular molecular variant of the gene. To overcome the pitfalls of case-control studies, some researchers perform family-based association studies wherein the control group is composed of the parents or siblings of affected individuals. In the haplotype relative risk (HRR) design, the untransmitted alleles of the parents serve as the ethnically matched controls (Stefanos, Dikeos and Papadimitrious, 1996) on the assumption that a variation in the distribution of alleles of the candidate genes can influence the

expression of the genes or its properties. However, it is possible that this variation is not the actual cause of the biological expression but is in linkage disequilibrium with another molecular change (a mutation) which is the primary cause. While one advantage of association studies is their enhanced power to detect genes with small effects, their major disadvantage is the increased likelihood of false-positive results. One way to reduce the probability of first-order errors is to look for replication in an independent sample or verification in family-based internal controls allowing for linkage disequilibrium analysis using the HRR or transmission disequilibrium test (TDT).

Serotonin Transporter and Receptors

The serotonin transporter (5-HTT) regulates the sodium-dependent reuptake of serotonin into the presynaptic neuron. Platelet-binding studies have suggested a disruption in 5-HTT function in PD (Pecknold *et al.*, 1995). The 5-HTT is encoded by a gene (solute carrier six, member four; SLC6A4) on chromosome 17q11.1-q12 and is organized in 14 exons spanning about 13 kb. Recently, a functional deletion/insertion polymorphism was identified within the promoter of the 5-HTT gene (Heils *et al.*, 1996). *In vitro* research has shown that a polymorphism in the 5-HTT promoter region has an effect on gene expression wherein the long (L) allele of 5-HTT produces expression levels three times greater than the short (S) allele. Some researchers have claimed that this polymorphism (the S allele) may play a role in susceptibility to anxiety-related traits and affective disorders (Collier *et al.*, 1996; Lesch *et al.*, 1996). However, when the 5-HTT gene-linked promoter polymorphic region (5-HTTLPR) genotype and allele frequencies were compared between patients with PD and a control group, no differences were observed (Deckert *et al.*, 1997; Ishiguro *et al.*, 1997; Matsushita *et al.*, 1997). In a family-based study, 74 haplotype relative risk 'trios' were genotyped at the polymorphic locus, which consists of a 44 base pair deletion/insertion in the promoter region. There were no significant differences in allele frequencies or occurrence of genotypes within the triads (Hamilton *et al.*, 1999).

A challenge with m-chlorophenylpiperazine (mCPP), a non-selective 5-HT2C receptor agonist, is associated with emergence of panic attacks more frequently in PD patients as compared to normal controls (Germine *et al.*, 1994). Thus, 5-HT2C gene is a candidate genes for association studies in PD. The association between PD and two adjacent polymorphisms [(GT) 12-18 and (CT) 4-5] in the 5′-regulatory region of the X-chromosomal 5-HT2C was studied in German and an Italian sample (combined $n = 211$) of PD patients and compared it with allele frequencies in two ethnically matched control samples (combined $n = 226$) (Deckert *et al.*, 2000). In the German sample, a comparison of female genotypes containing the short polymorphism haplotype vs female genotypes containing only long haplotypes showed a significant difference ($p = 0.01$), However, such a difference could not be replicated in the Italian sample ($p = 0.54$). Thus it seems that these promoter-associated 5-HT2C receptor gene length polymorphisms do not have a major role in the genetics of PD.

Cholecystokinin

Cholecystokinin (CCK) is the most abundant neuropeptide in the mammalian brain and, in humans, it is expressed in significant quantities in all regions of the brain (Bradwejn and Koszychi, 1994a). The CCK receptors have been classified into two subtypes, CCK-A and CCK-B. A line of evidence suggests a possible role of the CCK system in the neurobiology of PD. The CCK receptor agonist CCK-tetrapeptide (CCK-4) has been found to provoke panic attacks in about half of all normal individuals and almost all patients with PD (Bradwejn, Koszycki and Shriqui, 1991). Furthermore, CCK-4-induced panic attacks can be blocked by imipramine (Bradwejn and Koszycki, 1994b), a tricyclic antidepressant which is efficacious in the treatment of PD. Patients with PD also show lower cerebrospinal fluid (CSF) and lymphocyte CCK concentrations than normal controls (Bradwejn, Koszycki and Shriqui, 1991). A search for mutations in the CCK gene in 30 probands of multiplex PD pedigrees was conducted by Wang *et al.* (1998). They identified a C → T transition at position-36 ($CCK_{-36C/T}$) in a GC box, a binding site for transcription factor Sp1, in the promoter region of the gene. However, a study on the function of the $CCK_{-36C/T}$ polymorphism in the human CCK gene promoter (Hansen, Rehfeld and Nielsen, 2000) showed that the C to T polymorphism does not affect CCK transcription or function, and therefore does not play a direct role in the pathogenesis of PD. The putative association of this polymorphism to PD is likely to be the result of co-segregation with a linked mutation. Another study of CCK polymorphism in 99 patients with PD compared to healthy controls matched for gender and ethnicity showed no significant differences in the CCK peptide gene or the CCK-A gene markers (Kennedy *et al.*, 1999). However, there was a significant association of a CCK-B polymorphism with PD, suggesting a role for this gene in the susceptibility to PD. A later study (Yamada *et al.*, 2001) including 91 unrelated Japanese patients and 100 matched controls did not find evidence for an association between PD and four confirmed polymorphic sites in the CCK-B receptor gene, i.e., three at exon 3 : 1550 G → A, 1962 T → C and 1985 G → A and one at intron 4 : 2491 C → A.

In a recent study (Hattori *et al.*, 2001) a polymorphic compound short tandem repeat (STR) stretch located in the 5′-upstream region of the cholecystokinin gene, approximately −2.2 to −1.8 kb from the cap site was identified. This STR was found to be with 10 different allele lengths. Dividing the STR alleles into three classes (Long: L, Medium: M, and Short: S) produced strong genotypic (MM) (nominal $P = 0.0014$) and allelic (M) (nominal $P = 0.0079$) associations with panic disorder. No such association was found with three single nucleotide polymorphisms (SNPs) in the CCK promoter region: −36C > T and −188A > G, and the rare −345G > C. Haplotypic distributions of the STR and SNPs −188 and −36 were significantly different between panic disorder patients and controls ($P = 0.0003$). The authors suggest that the novel STR or a nearby variant may confer susceptibility to the development of panic disorder.

Monoamine Oxidase-A

The monoamine oxidase-A (MAO-A) inhibitor moclobemide, like other antidepressants, has been reported to be effective in the treatment of PD (Tiller, Bouwer and Behnke, 1999). This makes the MAO-A gene, which is localized on chromosome X (Xp21-p11) (Ozelius *et al.*, 1988), a candidate gene for PD.

A possible association between a functional polymorphism in the MAO-A gene promoter and PD was investigated in two independent German ($n = 80$) (Sabol, Hu and Hamer, 1998) and Italian ($n = 129$) (Deckert *et al.*, 1999) samples. Four alleles [3, 3a, 4 and 5 30 base pair (bp) repeats] of the MAO-A gene promoter polymorphism were observed in both samples. The 3a allele contained three repeats plus 18 bp of the repeated motif. An additional rare fifth allele (two 30 bp repeats) was detected in the Italian sample. Functional characterization in a luciferase assay demonstrated that the longer alleles (3a, 4 and 5) were more active than allele 3. In both the German and Italian samples, the longer alleles were significantly more frequent in females with PD compared with female controls; no such significant difference was observed for males. The authors calculated that in females, homozygosity for the long alleles increases the relative risk over heterozygosity as well as homozygosity for the short alleles by factors of 1.4 and 1.8. They suggested that the discrepancy between the males and females may be related to the relatively smaller number of males, so that the

statistical power to display significant differences of the magnitude found in females was very low (~14%). The discrepancy between the male and female patients with PD may also be related to gender differences in the genetic background of PD. The consistency of this finding in two independent samples from different geographic areas makes it unlikely that the association between long alleles of the MAO-A gene promoter polymorphism and PD was a false-positive finding. However, replicative studies as well as verification in haplotype relative risk samples with family-based internal controls are still required. Indeed in one recent family-based study including 620 individuals in 70 multiplex families and 81 triads consisting of proband (62 female and 19 male), mother and father, the authors failed to demonstrate a genetic linkage or association between the same functional promoter polymorphism in the MAO-A gene and PD (Hamilton *et al.*, 2000b). From the pathophysiological and pharmacological points of view, the association between genotype-related high MAO-A activity and PD symptoms (panic attacks, anticipatory anxiety or phobic avoidance) as well as the therapeutic response to MAO-A inhibitors merits further investigation.

α_2 Adrenergic Receptor

Three different genes coding for human α_2 receptor subtypes α_{2A}, α_{2B} and α_{2C} have been cloned and localized on chromosomes 10, 2 and 4, respectively (Bylund *et al.*, 1994). The α_{2A} receptor subtype is expressed in the central nervous system and peripheral tissues, the α_{2B} in the liver and kidneys, and the α_{2C} only in the brain (Lorenz *et al.*, 1990). Yohimbine, an α_2 adrenergic receptor antagonist, has been found to induce marked anxiety and panic attacks in patients with PD (Charney *et al.*, 1987). However, in a study of a polymorphism of the α_{2A} receptor gene in the promoter region at position −1291 in 55 patients with PD and 114 healthy control subjects, Ohara *et al.* (2000) reported no statistically significant difference between the groups in either genotype or allele frequency. These results are in accordance with the linkage study of Wang, Crowe and Noyes, (1992) which revealed no evidence to support the possibility that a genetic mutation at the α_{2A} and α_{2C} receptor loci is responsible for PD.

Adenosine Receptor

The rationale for searching for adenosine receptor gene mutations or polymorphisms in PD is based on the finding that the adenosine receptor antagonist caffeine can provoke panic attacks in patients with PD, and on the similarity between symptoms of caffeine intoxication and anxiety (Boulenger *et al.*, 1984). Deckert *et al.* (1998) screened 38 patients with PD for mutations in the coding sequence of the A_1 and A_{2a} adenosine receptor genes. One silent mutation (716T/G) in the A_1 receptor gene and two silent mutations (432C/T and 1083C/T) in the A_{2a} receptor gene were detected. Thereafter, an association study between the identified DNA sequence variants and PD was performed in an extended sample of 89 patients and matched controls, and it yielded a significant association between PD and the 1083T allele and 1083T/T genotype of the A_{2a} receptor gene. These findings support the hypothesis that the A_{2a} receptor gene, or a locus in linkage disequilibrium with it, confers susceptibility to PD. Yamada *et al.* (2001) in a case-control study in Japanese population did not find evidence for an association between the 1083C → T polymorphism in the A_{2a} receptor gene and PD. Hamilton *et al.* (2001) in a family-based design, employing 596 individuals in 70 panic disorder pedigrees, as well as 77 haplotype relative risk 'triads', examined any linkage or association between the single nucleotide polymorphism in the SP1 site of the CCK gene (in the promoter region) and a simple sequence repeat in the CCK-B receptor, and panic disorder. Employing a variety of diagnostic and genetic models, linkage analysis produced no significant lod scores at either locus. Family-based tests of association, the HRR statistic and the TDT, were likewise non-significant. These two recent studies provide little support for the role of these polymorphisms in CCK and CCK−B receptor in PD.

Dopamine Transporter and D4 Receptor

Challenge studies with dopaminergic agonists such as apomorphine (Pitchot *et al.*, 1992) and epidemiological data associating the use of the dopamine agonist cocaine with PD (Anthony, Tien and Petronis, 1989) provide modest evidence for the possible involvement of a dopaminergic component in PD. A family-based design, with 622 individuals in 70 families, as well as 82 HRR 'triad' families, was employed to detect a possible association between either dopamine transporter (DAT) or dopamine receptor 4 (DRD4) gene polymorphisms and PD (Hamilton *et al.*, 2000a). Three common polymorphisms were studied; two were in DRD4, a 12 bp insertion/deletion in exon 1 and a 48 bp repeat in exon 3, and one was a 40 bp repeat in the three untranslated regions of DAT. Alleles in the triad families were analyzed with the HRR method as well as the TDT statistic. There were no significant differences in allele frequencies or occurrence of genotypes within the triads for any of the three polymorphisms, indicating the absence of involvement of these polymorphisms in susceptibility to PD.

Table XIX-11.1 demonstrates the association studies reported in patients with PD.

PHOBIC DISORDERS

Family Studies

In a direct-interview study of first-degree relatives of probands with social phobia (SP) ($n = 83$) and never mentally ill controls ($n = 231$), Fyer *et al.* (1993) reported that the study group had a significantly increased risk of SP (16% vs 5%, relative risk = 3.12), but not of other anxiety disorders. In a subsequent study, the same authors assessed the rates of phobic disorders in first-degree relatives of four proband groups: simple phobia, SP, agoraphobia with panic attacks, and healthy controls (Fyer *et al.*, 1995). They found a moderate (two- to four-fold increased risk) but specific familial aggregation for each of the three phobic disorders (10% for agoraphobia, 15% for SP and 31% for simple phobia). The relative risk for agoraphobia was 2.7, for SP 3.1, and for simple phobia 3.3. The moderate elevations in familial risk indicate a familial contribution to each of the disorders. The mode of transmission is unknown and seems to be multifactorial complex.

In a direct-interview family study, Stein *et al.* (1998) assessed the familial liability for the discrete (performance-only), non-generalized [performance-only, limited-interactional-only (one or two socially interactive situations), or performance-plus-limited-interactional types of phobia], and generalized subtypes (DSM-IV criteria) of SP in 23 probands with generalized SP and their first-degree family relatives ($n = 106$) and 24 healthy subjects and their relatives ($n = 74$). The generalized subtype of SP was found to be present in 26.4% of the relatives of probands with generalized SP but only 2.7% of the relatives of probands in the comparison group. By contrast, the relative risks for discrete SP and non-generalized SP were not significantly different between the two groups. The authors concluded that only the generalized type (and its probable Axis II counterpart, avoidant personality disorder) occurs more often among the families of probands with generalized SP.

Twin Studies

The genetic epidemiology of phobias was studied in a population-based sample of 2163 female twins (Kendler *et al.*, 1992). The familial aggregation of agoraphobia, SP, situational phobia, and

simple phobia appeared to be due to genetic and not familial-environmental factors, with estimates of heritability of liability ranging from 30% to 40%. The authors concluded that the best-fitting multivariate genetic model indicates the existence of genetic and individual-specific environmental aetiologic factors. Nonspecific shared environmental experiences were most important for agoraphobia and SP, and unique environmental experiences for simple phobias. Genetic factors were most important in the predisposition to animal phobia and least important for agoraphobia. Thus, the simple phobias seem to result from the common effect of a modest genetic vulnerability and phobia-specific traumatic event in childhood, whereas agoraphobia and SP result from the combined effect of a more pronounced genetic influence and nonspecific environmental experiences.

Molecular Genetics

Linkage and Association Studies

A line of evidence from molecular genetics studies support the claim that SP, particularly the generalized form, is familial, and is frequently associated with at least one other anxiety disorder and with major depressive disorder. Furthermore, its apparent responsiveness to treatment with selective serotonin reuptake inhibitors (SSRIs) suggest the possible involvement of the serotonergic system in the genetic susceptibility to SP. Stein *et al.* (1998) excluded a possible genetic linkage of generalized SP to the serotonin transporter protein (promoter region) and $5HT_{2A}$ receptor genes. Seventeen multiplex families (122 subjects) were included in the study. In additional studies, the MspI silent T → C 102 polymorphism at the HTR2A gene (Warren *et al.*, 1993) and the insertion/deletion polymorphism in the promoter region of the serotonin transporter gene (Heils *et al.*, 1996) were genotyped, and LOD scores for pairwise analyses were calculated. Linkage studies to other 5-HT receptor subtypes as well as other regions of the genome were not performed as yet.

Gratacòs *et al.* (2001) identified a polymorphic interstitial duplication of human chromosome 15q24-26 (named DUP25), which is significantly associated with panic/agoraphobia/social phobia/joint laxity in families, and with panic disorder in non-familial cases. The authors proposed that DUP25, which is present in 7% control subjects, is a susceptibility factor for a clinical phenotype that includes panic and phobic disorders and joint laxity.

OBSESSIVE–COMPULSIVE DISORDER

The concept of a spectrum of OCD disorders has recently been suggested, including Tourette's syndrome, body dysmorphic disorder hypochondriasis, trichotillomania, pathological gambling, and other impulse control disorders (Hollander *et al.*, 1996). This broader definition of OCD poses problems in defining the phenotype of OCD in family and twin studies as well as in molecular genetic studies. Future research on age of onset, comorbidity, treatment, neuropsychological functioning, personality characteristics and neuroimaging will help to elucidate subsets of endophenotypes of the disorder, and these will broaden our understandings of its neurobiological and genetic mechanisms.

Family Studies

Lenane *et al.* (1990), who interviewed 145 first-degree relatives (89 parents and 56 siblings) of 46 children and adolescents with OCD, found that the familial rate of OCD was higher than the expected rate in the general population (30% of patients had at least one first-degree relative with OCD). Furthermore, there was

a difference in the presenting symptoms of OCD in the probands and their relatives, indicating the possibility of genetic involvement rather than simple social or cultural transmission.

A possible aetiologic relationship between Tourette's disorder and OCD has been shown by several researchers. Leonard *et al.* (1992) re-evaluated 54 children with OCD, of whom 57% also had a lifetime history of tics, 2–7 years after the initial diagnosis of OCD. The presence or absence of tics and Tourette's disorder was also assessed in their first-degree relatives ($n = 171$). At follow-up, 59% ($n = 32$) of the probands were found to have a lifetime history of tics, including eight, all males, who met the criteria for Tourette's disorder. This subgroup had a younger age at onset of OCD. Tourette's disorder was noted in 1.8% of their relatives, and a tic disorder, in 14%. These results indicate that in some cases, OCD and Tourette's disorder may be alternative manifestations of the same underlying illness. In a similar study, Pauls *et al.* (1995) as well as Nestadt *et al.* (2000b) also demonstrated the heterogeneity of OCD, including familial tic-related OCD, familial tic-unrelated OCD, and sporadic OCD.

The familial relationship between OCD and other OCD spectrum disorders was investigated in 80 patients with OCD and their 343 first-degree relatives compared to 73 control probands and their 300 first-degree relatives (Bienvenu *et al.*, 2000). Body dysmorphic disorder, hypochondriasis, eating disorders, nail biting, skin picking, and trichotillomania all occurred more frequently in the case probands and their relatives, whether or not the case probands also had the same diagnosis. These data indicate that these conditions are part of the familial OCD spectrum. However, Black *et al.* (1994), in an earlier study, failed to find significant differences in the lifetime prevalences of anorexia nervosa, bulimia nervosa, or pathologic gambling between first-degree relatives of patients with OCD and first-degree relatives of control subjects.

Twin Studies

Inouye (1965) found an 80% concordance for OCD between pairs of MZ twins ($n = 10$) compared to 20% concordance between pairs of DZ twins ($n = 4$). Higher concordance rates in MZ than DZ twins were also reported by Carey and Gottesman (1981) (87% and 47%, respectively). In addition, the nature of the symptoms and response to treatment were more similar for the MZ twins (Kim, Dysken and Kline, 1990). Unfortunately, all these studies were performed in small samples and did not use blind methodology, so definite conclusions concerning the contribution of genetic factors cannot be made.

Segregation Studies

Cavallini *et al.* (1999a) performed a complex segregation analysis on a sample of 107 Italian families of OCD probands. Based on the hypothesis that OCD shares common underlying genetic factor(s) with Tourette's disorder (Pauls *et al.*, 1986), the authors applied two phenotypic definitions of affected subjects: OCD with and without Tourette's disorder/chronic motor tics. Analysis of the transmission of OCD alone (wherein relatives with Tourette's disorder or chronic motor tics were considered healthy) provided support for a major gene effect. However, when the phenotype was widened, the pattern of inheritance (dominant, recessive or additive) could not be established. Given the phenotypic heterogeneity observed in OCD, Alsobrook *et al.* (1999) studied inheritance patterns using symptom-based factor scores. Analyses limited to families with symmetry and ordering (high factor 3) probands led to a rejection of the polygenic model. Additionally, the relative risk of OCD or subclinical OCD was 1.7 for relatives of probands with a high factor 3 score compared with relatives of probands with a low factor 3 score. In this study patients were defined as having subclinical OCD if they met all DSM-III-R criteria for OCD except one of the following: their obsessions/compulsions consumed less than one hour per day, or they lacked insight into the unreasonable nature of their obsessions and compulsions. The authors suggested that these symptoms may constitute a genetically symptomatic subtype of OCD. In a recent large-scale study with a well-characterized sample, Nestadt *et al.* (2000a) analyzed 80 case families (423 subjects, including adult OCD probands and their first-degree relatives), and 73 control families (373 subjects, including probands and their first-degree relatives) for mode of inheritance. OCD was the only affected phenotype. The results provided further evidence of a Mendelian inheritance of a dominant allele. However, Mendelian factors alone could not fully explain the familial aggregation of this phenotype, and residual familial and sex effects probably play a role in the inheritance of the disorder. Thereafter, polygenic factors may also contribute to the aetiology of OCD. It is of note that this study included both case and control families; thus, the estimated disease frequencies and penetrances were likely less biased.

Molecular Genetics

The family, twin and segregation studies have consistently suggested that the underlying mechanisms of OCD involve genes of major effect. The recent progress in molecular genetic methods has encouraged the search for genes that confer susceptibility to complex diseases, including OCD.

Linkage Studies and Mutation Screening

In a study of a large British kindred multiply affected with Tourette's syndrome, chronic motor tics, and obsessive–compulsive behavior, Brett *et al.* (1995) reported no evidence to support the hypothesis that a genetic variation in the serotonin 5-HT1A receptor and tryptophan oxygenase genes causes susceptibility to Tourette's syndrome and chronic multiple tics.

Interaction between the glutamatergic and serotonergic systems within the striatum suggests the glutamate transporter protein as a functional candidate in OCD. The gene (SLC1A1) for this protein is localized in chromosome 9. Genomic organization of this gene and mutation screening was investigated in families of patients with early-onset OCD (Veenstra-VanderWeele *et al.*, 2001). No evidence was found for a functional mutation and capillary electrophoresis single-stranded conformational polymorphism (SSCP) analysis of a haplotype consisting of two common SNPs within this gene revealed no significant linkage disequilibrium.

Association Studies

The findings of the association studies in OCD are summarized in Table XIX-11.2.

The Serotonergic System

Pharmacological and neurochemical studies point to a dysregulation of the serotonergic system in OCD. SSRIs are effective in the treatment of OCD; exacerbations are common when SSRIs are discontinued (McDougle, Gordman and Price, 1993). Challenge with meta-chlorophenyl-piperazine (mCPP), a mainly serotonin 2C receptor agonist, can induce the emergence of symptoms in patients with OCD (Zohar *et al.*, 1987). Finally, OCD patients have lower platelet serotonin transporter (5-HTT) density than normal controls (Weizman *et al.*, 1986, 1992). It is of note that recent studies have reported an association between a polymorphism in the serotonin transporter gene regulatory region and anxiety-related

traits (Lesch *et al.*, 1996) as well as susceptibility to affective disorders (Collier *et al.*, 1996).

Serotonin Transporter

McDougle *et al.* (1998) found evidence of linkage disequilibrium between the serotonin transporter protein gene (SLC6A4) in the promoter region and OCD. The investigators used the TDT design, which examines linkage in the presence of association in affected probands and their biological parents and thereby controls for the stratification effect. The study included 34 European–American family trios, 30 unrelated and four extracted from an extended pedigree. Of the 35 heterozygous parents, 24 transmitted the long (L) allele and 11 transmitted the short (S) allele ($p < 0.03$) to the OCD probands. Separate analysis of the SRI non-responders ($n = 13$) yielded 10 parents who transmitted the L allele and three who transmitted the S allele ($p = 0.052$). Bengel *et al.* (1999) reported an association of a functional polymorphism in the 5-HTTLPR with OCD in a population-based study of 75 Caucasian patients with OCD and 397 ethnically matched individuals. The patients were found to be more likely to carry two copies of the long allele (L) (46.7% vs 32.3%: $\chi^2 = 5.19$, $p = 0.023$). However, this finding did not agree with the study of Billet *et al.* (1997) of 72 patients with OCD and 72 matched controls, which revealed no significant between-group difference in either genotype count or allele frequencies. Furthermore, no significant 5-HTT genetic difference was observed between the patients who responded to SSRIs and those who did not. The possible association of OCD with the insertion/deletion polymorphism in the promoter area of the serotonin transporter gene was also analyzed by Frisch *et al.* (2000) in 77 biologically unrelated OCD patients and ethnically matched controls (Ashkenazi and Sephardic Jews). There was no difference between patients and controls in the allelic distribution of the 5-HTT gene promoter region polymorphism. Similar negative results were reported also in a relatively genetically homogeneous Afrikaner population of South Africa (Kinnear *et al.*, 2000).

A case-control study of a possible association between 5-HTTLPR polymorphism and Tourette syndrome with and without OCD was

carried out by Cavallini *et al.* (2000). The study included 52 patients (53.84% with OCD) and 63 healthy control subjects. No association was found, even when the study sample was divided by the presence or absence of OCD or family history of OCD or tics.

Ohara *et al.* (1999) compared the variable-number-tandem-repeat (VNTR) in the second intron of the 5-HTT gene between 103 patients with anxiety disorders and 106 controls. They found that the frequency of the allele containing 12 copies of the VNTR element (5-HTTin2.12) was significantly higher in the patients with OCD ($n = 15$) and that the presence of the 5-HTTin2.12 allele was significantly associated with the risk of OCD (odds ratio = 10.2, 95% CI 1.34-77.4).

Serotonin Receptors and Tryptophan Hydroxylase

Variants of the genes encoding the serotonin receptors 5-HT2A and 5-HT2C are not associated with OCD. Nicolini *et al.* (1996) studied 5HT2A gene polymorphisms in 67 OCD patients and 54 healthy controls and found no statistically significant between-group differences in either genotype or allele frequencies. Cavallini *et al.* (1998) investigated the role of the Cys23Ser mutation of the 5-HT2C receptor gene in OCD in a case-control study of comparing 109 OCD patients with 107 healthy control subjects. Again, no allelic or genotypic association was revealed. Furthermore, in a subsample of 39 patients with OCD who had previously undergone a challenge test with clomipramine, no association was noted between the 5-HT2C receptor gene mutation and the response to the test. This finding excludes any specific role for the Cys23Ser mutation of the 5-HT2C receptor gene in the aetiology of OCD.

The 5-HT1Dβ is a terminal autoreceptor, involved in the regulation of 5HT release, and it is expressed mostly in the limbic region and in the striatum. It is encoded by an intronless gene located on chromosome 6 (6q14-15) (Demchshyn *et al.* 1992). There are at least three polymorphisms known for this gene: the G861C, the T-261G, and the T371G (Lappalainen *et al.*, 1995; Mundo *et al.*, 2001). Gross *et al.* (1998) reported that acute administration of sumatriptan, a selective agonist of the 5-HT1Dβ receptor, was associated with acute worsening of obsessive–compulsive symptoms in patients with OCD. However, OCD patients resistant to conventional pharmacotherapy have shown improvements with chronic administration of sumatriptan (Stern *et al.*, 1998). Mundo *et al.* (2000) investigated the possibility of a linkage disequilibrium between the 5-HT1Dβ receptor gene G861C polymorphism and OCD using a combination of the TDT, which examines alleles preferentially transmitted from parents to affected offspring, with the sib-TDT, which compares the marker genotypes in affected and unaffected siblings. Sixty-seven OCD probands and their biological parents and siblings participated in the study. After genotyping, 32 families were found suitable for the TDT/sib-TDT procedure. Twenty-two were triads that showed heterozygosity at the marker, and 10 were sibships with one affected and one unaffected sibling. The authors found a significant linkage disequilibrium between the G861C variant of the 5-HT1Dβ receptor gene and OCD, with preferential transmission of the G allele to the affected subjects.

In a case-control study no association was found between OCD and polymorphism in the gene coding tryptophan hydroxylase (TPH), the key enzyme in the synthesis of 5-HT (Frisch *et al.*, 2000).

Dopamine Receptors and Transporter

The involvement of dopamine in the pathophysiology of OCD has been suggested by several pharmacological studies. Addition of dopamine receptor blockers seem to be effective in some SRI-resistant patients with OCD, especially those with comorbid tic disorder or psychotic features (McDougle, Goodman and Price, 1994). Accordingly, cocaine, which blocks the presynaptic dopamine transporter, can aggravate obsessive–compulsive symptoms in patients with OCD and induce such symptoms in subjects with a family history, but not a personal history, of OCD (Satel and McDougle, 1993).

Catalano *et al.* (1994) studied the D3 dopamine receptor gene polymorphisms in 97 patients with OCD and 97 control subjects. No statistically significant differences in allele or genotype frequencies were found. Negative results were reported also by Frisch *et al.* (2000) in a study of the possible association between OCD (75 patients and 172 controls), the D4 dopamine receptor gene and dopamine transporter gene.

In another case-control association study of 100 OCD patients and matched controls, Billett and his group (1998) examined a 40-base-pair repeat in the dopamine transporter gene; the TaqIA polymorphism and the serine/cysteine variation in the D2 dopamine receptor gene; the MscI polymorphism in the D3 dopamine receptor gene; and a 48-base-pair repeat in the D4 dopamine receptor gene. Significant differences in allele frequencies were found between patients and controls only for the D4 receptor gene.

Catechol-O-Methyltransferase

Catechol-O-methyltransferase (COMT) is an Mg^{2+}-dependent enzyme that catalyzes the transfer of methyl groups from S-adenosyl methionine to a hydroxyl group of a catecholic substrate. COMT is widely distributed in the mammalian brain. The gene for COMT, which is involved in the inactivation of catecholamines including the neurotransmitters dopamine and norepinephrine, has been mapped to the 22q11 region (Grossman, Emanuel and Budarf, 1992). In humans, a common functional polymorphism is associated with a three- to four-fold variation in COMT enzyme activity. This variation in activity is due to a GA transition at codon 158 of the COMT gene that results in a valine (high-activity allele, COMT*H)-to-methionine (low-activity allele, COMT*L) substitution (Lachman *et al.*, 1996).

Karayiorgou *et al.* (1997), in a study of 73 Caucasian patients with OCD (42 males and 31 females) and 148 ethnically matched and unrelated control subjects (75 males and 73 females), found that the COMT*L allele was significantly associated in a recessive manner with susceptibility to OCD, particularly in males. Furthermore, the COMT*L/COMT*L genotype was apparently a risk factor for OCD, with an estimated relative risk of 5.91 (95% CI: 2.40-14.53) versus the nonCOMT*L/COMT*L. These findings were later confirmed by the same group in a family-based study (Karayiorgou *et al.*, 1999) wherein the inheritance of the two functional variants of the COMT gene was investigated in 110 nuclear OCD families (affected proband and both biological parents). Both the TDT and HRR analyses revealed a preferential transmission of the low-activity COMT allele from the heterozygous parents of male (but not female) probands. This finding indicates a sexually dimorphic pattern of genetic susceptibility to OCD. Another family-based population study, in a group of 72 North American and Canadian OCD patient/parent trios, using the HRR TDT analyses, did not identify an association between a particular allele and OCD. Furthermore, no evidence was found to support the findings of a gender-based association for COMT. However, a genotype analysis demonstrated a tendency for association between homozygosity at the COMT locus and OCD (Schindler *et al.*, 2000). In contrast, a case-control study in Afrikaner community population found that heterozygosity (COMT*H/COMT*L genotype) was significantly more common than expected in OCD patients ($P = 0.0017$) (Niehaus *et al.*, 2001). No association was found between OCD and a novel polymorphism adjacent to the oestrogen response element (ERE 6) in the promoter region of the COMT gene (Kinnear *et al.*, 2001).

In a recent study by Cavallini *et al.* (2000) of 52 patients with Tourette disorder with or without OCD and 63 healthy control subjects, no association between the val-158-met substitution was noted in the COMT in any of the patients.

Monoamine Oxidase-A

Monoamine oxidases (MAOs) are flavin-containing enzymes that degrade a variety of biogenic amines, including the neurotransmitters norepinephrine, dopamine, and serotonin. Two forms of the enzyme, MAO-A and MAO-B, are encoded by two adjacent genes (Hsu *et al.*, 1989) located at the p11.23-11.4 region of the X chromosome. MAO inhibitors seem to have a beneficial effect in a subset of OCD patients (Liebowitz *et al.*, 1990). Karayiorgou *et al.* (1999), in their sample of 110 nuclear OCD families, found a sexual dimorphic association between OCD and an allele of the *MAO-A* gene (*MAO-A**297CGG allele of the *Fnu*4H1 marker), previously linked to high MAO-A enzymatic activity. This association was detected particularly among male OCD probands with comorbid major depression.

MAO-A/EcoRV polymorphism was examined in a sample of 122 Mexican OCD patients and 124 healthy subjects (Camarena *et al.*, 2001). An excess of allele 1 in OCD females with major depression disorder was confirmed as previously reported (Camarena *et al.*, 1998). This difference was more strongly associated with OCD females than males in the total sample. Additionally, an HRR analysis of the inheritance of the MAO-A variants was performed in a sample of 51 OCD trios. An allelic association between OCD and MAO-A gene was found in the female probands, i.e., 14 out of 19 transmitted the allele 1.

GENERALIZED ANXIETY DISORDER

Family Studies

A study by Noyes *et al.* (1987) demonstrated a higher frequency of GAD among first-degree relatives ($n = 123$) of GAD probands ($n = 20$) compared to first-degree relatives of control subjects ($n = 20$) and of PD ($n = 40$) and agoraphobia probands ($n = 40$). Among the relatives of GAD patients, more women (24.2%) than men (14%) had GAD. The categorization of GAD as a distinct entity was further confirmed by the distribution of anxiety disorders among the families.

Twin Studies

Kendler *et al.* (1995) addressed the possible interrelationship of genetic and environmental risk factors in six major psychiatric disorders (phobia, GAD, PD, bulimia, major depression and alcoholism). The study included 1030 female–female twin pairs with known zygosity, derived from the population-based Virginia Twin Registry. Major depression was found to be the most frequent comorbidity of GAD. On factor analysis, the authors found statistical evidence of two genetic factors: phobia, PD and bulimia loaded heavily on the first factor, and major depression and GAD on the second. A disorder-specific additive gene was present only for GAD and alcoholism. Individual-specific environmental influences on the risk of GAD and major depression were best explained by a single factor and played a strong aetiological role.

In a recent study, the genetic and environmental contributions to GAD and PD were investigated in 6724 MZ and DZ male–male twin pairs taken from the Vietnam Era Twin Registry (Scherrer *et al.*, 2000). The presence of a non-additive genetic factor specific to PD supports a distinction of PD from GAD. The authors suggested that the common genetic and unique environmental influences in GAD and PD may be partially responsible for the high lifetime co-occurrence of these disorders.

Association Studies: Candidate Genes

Serotonin Transporter

Ohara *et al.* (1999) studied the 5-HTTin2.12 polymorphism in 103 patients with anxiety and 106 control subjects. The frequency of the 5-HTTin2.12 allele was significantly higher compared with controls in both the whole group of anxious patients ($p = 0.027$; odds ratio = 2.06, 95% CI 1.09-3.90) and in the GAD patients separately ($p = 0.0123$; odds ratio = 3.61, 95% CI 1.23-10.6).

Serotonin Receptors

Fehr *et al.* (2000a), using a candidate gene approach, genotyped 50 patients with GAD, 209 patients with alcoholism, 108 patients with major depression, 32 patients with PD, 58 patients with narcolepsy, and 74 healthy volunteers for the serotonin HTR1B receptor gene 861G → C polymorphism. This common *Hinc*II polymorphism had been linked to antisocial alcoholism in a Finnish sample and a sample derived from an American-Indian tribe (Lappalainen *et al.*, 1998). A higher frequency of the HTR1B 861G allele was detected among the male alcohol-dependent patients, but not in the patients with other mental disorders, compared to the control subjects. The same group (Fehr *et al.*, 2000b) also genotyped patients with GAD, alcohol dependence, PD without agoraphobia, and narcolepsy and normal healthy volunteers ($n = 173$ females and 298 males) for the 5-HT2C Cys23Ser polymorphism, but no difference in frequencies and genotypes were found between patients and controls. No association was found between GAD and 5-HT2A receptor polymorphism (T102C), as well as the intron 7 TPH (A218C) polymorphism (Fehr *et al.*, 2001).

POST-TRAUMATIC STRESS DISORDER

Family Studies

Reich, Lyons and Cai (1996) investigated familial vulnerability factors to PTSD in male military veterans by examining family history of four proband groups: PTSD, mixed anxiety disorders, coexisting anxiety and depressive disorders, and screened normal controls. The pattern of psychopathology in the families of the PTSD probands most closely resembled that in the families of the coexisting anxiety and depressive disorders probands.

In a family history study of 36 patients with chronic post-traumatic stress disorder, Davidson *et al.* (1985) reported a positive history of familial psychopathology, mostly alcoholism, depression, and anxiety disorders, in 66% of the patients. Subsequently, these authors investigated the relationship between chronic PTSD and family psychiatric morbidity in first-degree relatives ($n = 285$) of 81 female rape survivors with or without lifetime PTSD, 31 major depressive disorder controls, 20 anxiety disorder controls, and 39 healthy controls (Davidson *et al.*, 1998). Information was also available by family history for 639 relatives. An increased risk of depression was noted in family members of PTSD probands with depression but not in relatives of PTSD probands without lifetime depression. The authors concluded that PTSD following rape seems to be associated with familial vulnerability to major depression, which may thus serve as a risk factor for PTSD.

Twin Studies

Male–male veteran MZ twin pairs ($n = 2092$) who were discordant for military service in southeast Asia were investigated to evaluate the impact of military service on PTSD (Goldberg *et al.*, 1990). The prevalence of PTSD was over three-fold higher in the twins who served in southeast Asia than in their co-twins who did not (16.8% vs 5.0%) and nine-fold higher in the twins who experienced high levels of combat (95% CI: 4.8-17.6). The same group (True *et al.*, 1993) also performed a twin study of genetic and environmental contributions to liability for PTSD. The sample included 4042 Vietnam-era veteran MZ and DZ male twin

pairs. Quantitative genetic analysis revealed that inheritance had a substantial influence on liability for symptoms of re-experiencing the trauma (13%–30%), avoidance of stimuli related to the trauma (30%–34%), and increased arousal (28%–32%). The family environment did not have a significant effect on any of the variables. Another twin study by this group (Lyons *et al.*, 1993) on a similar sample ($n = 4029$) studied genetic and nongenetic factors that influence wartime exposure to traumatic events. Specific events examined were volunteering for service in Vietnam, actual service in southeast Asia, a composite index of 18 combat experiences, and awards for combat. Heritability estimates ranged from 35% to 47%. There was no evidence that shared environment had a significant effect on any of the variables.

Association Studies

The Dopaminergic System

Increased levels of 24-hour urine dopamine excretion have been reported in PTSD (Yehuda *et al.*, 1992), and higher than normal levels of 24-hour urine homovanillic acid have been found in sexually abused girls (Debellis *et al.*, 1994; Putnam and Trickett, 1997). Plasma dopamine was also found to be elevated in a small cohort of combat veterans compared to controls (Hamner and Diamond, 1993). Deutch and Young (1995) suggested that PTSD is associated with a dopamine dysregulation which limits the ability of patients to cope with trauma and increases their susceptibility to trauma-related contextual stimuli.

Using a case-control design, Comings *et al.* (1991) investigated the association of PTSD and the DRD2 TaqI polymorphism in 35 European–American patients with PTSD, all with drug or alcohol abuse. The control group was comprised of 314 subjects, 69 of them non-alcoholics. Among the total group of controls, 77 (24.5%) carried the A1 allele, whereas among the non-alcoholic controls, only 10 (14.5%) did so. An increased prevalence of the A1 allele (45.7%) was demonstrated in the PTSD patients compared to the controls. However, after correction for multiple comparisons, the statistical significance was lost. In a subsequent study (Comings, Muhleman and Gysin, 1996) of 56 combat-exposed subjects with ($n = 37$) and without ($n = 19$) PTSD who were hospitalized in an addiction treatment unit, the same authors noted an association between PTSD and the DRD2*A1 allele (59.5% vs 5.3%; $p < 0.0001$). Though this study has an advantage of the inclusion of both PTSD and non-PTSD subjects who were exposed to combat, its small sample size limits the conclusions. Further, a later case-control study conducted by Gelernter *et al.* (1999) failed to demonstrate such an association. The authors noted no allelic association between the DRD2 TaqI 'A1' as well as in the 'B' and 'D' alleles in 52 European-American PTSD patients. Furthermore, the DRD2 haplotype frequencies also did not differ between the patients with PTSD and healthy control subjects. The authors concluded that the DRD2 gene variants do not contribute significantly to the risk of PTSD.

CONCLUDING REMARKS

The pattern and repertoire of behaviors and emotions are determined by gene–environment interactions. Genomic and non-genomic factors influence the risk of emergence of anxiety disorders in individuals and across generations. In addition to the common difficulties in molecular genetics of complex diseases, namely, non-Mendelian inheritance patterns, incomplete penetrance, possibility of phenocopies, genetic heterogeneity, and variable expressivity (Lander and Schork, 1994), the neurogenetic study of anxiety disorders is hampered by the problem of defining the heritable phenotype, including subsets of endophenotypes of the disorders (Tsuang, Faraone and Lyons, 1993; Smoller and Tsuang, 1998). The human genome project, combined with other novel strategies, such as DNA microarrays (Watson *et al.*, 2000), functional magnetic resonance imaging (fMRI) (Rosenberg and Hanna, 2000), and identification of genes and proteins implicated in the brain neurocircuitry of anxiety and fear hold great promise in furthering our understanding of the cellular and molecular mechanisms involved in the pathogenesis of anxiety disorders and developing specific and efficient treatments.

Gender Differences in Anxiety Disorders

Teresa A. Pigott and Lai T. Lac

ANXIETY DISORDERS: INTRODUCTION

Though rarely appreciated, anxiety disorders represent one of the most common psychiatric disorders. Nearly one out of four Americans will meet criteria for an anxiety disorder during their lifetime. Inexplicably, women are much more likely than men to develop anxiety disorders. In fact, lifetime prevalence estimates based on large-scale population surveys conducted within the US suggest that women are two to three times more likely than men to develop panic disorder (7.7% vs 2.9%), agoraphobia (9.0% vs 3.0%), simple phobia (13.9% vs 7.2%), or post-traumatic stress disorder (PTSD) (11.3% vs 6.0%). Lifetime prevalence estimates also suggest that women are 1.5 times more likely than men to develop obsessive–compulsive disorder (OCD) (3.1% vs 2.0%) or social anxiety disorder (16.4% vs 11.2%) (Robins *et al.*, 1984; Bourdon *et al.*, 1988; Breslau, Davis and Andreski, 1990; Regier, Narron and Rae, 1990; Kessler *et al.*, 1994; Leon, Portera and Weissman, 1995; Magee *et al.*, 1996; Yonkers and Ellison, 1996).

Results from the international epidemiological surveys also confirm that anxiety disorders are very common and that women have much higher prevalence rates than men. Although prevalence rates tend to decrease with advancing age, anxiety disorders remain more common in women throughout the life span (Krasucki, Howard and Mann, 1998). There is some evidence that the gender difference for anxiety disorders narrows after the age of 65. This finding, however, may represent an artifact from the combined effects of cumulative, anxiety-related mortality as well as the complex differentiation between anxiety and cognitive impairment. The narrowing of the gender difference may also result from the attenuation of hormonal factors that occurs with advancing age (Krasucki, Howard and Mann, 1998).

The presence of an anxiety disorder has important implications. A lifetime diagnosis of an anxiety disorder is associated with increased functional impairment, diminished educational and occupational opportunities, and elevated morbidity and mortality rates in comparison to the absence of an anxiety disorder. Elevated utilization rates for emergency medical and mental health care services are also linked to the presence of an anxiety disorder. Despite these adverse consequences, very few individuals with an anxiety disorder receive any type of psychiatric treatment (Lindal and Stefansson, 1993; Dick *et al.*, 1994a, 1994b; Kessler *et al.*, 1994, 1997; Weissman *et al.*, 1994; Leon, Portera and Weissman, 1995).

Low recognition rates for anxiety disorders represent a significant obstacle in delaying effective treatments. Somatic symptoms, a cardinal feature of excess anxiety, may effectively obscure their primary psychiatric basis. Most anxiety disorders initially present in a general medical rather than mental health setting. Unfortunately, results from numerous studies confirm that a primary anxiety disorder is unlikely to be considered in a primary care setting until the late stages of a routine diagnostic assessment (Hohmann, 1989; Kennedy and Schwab, 1997; Roy-Byrne and Katon, 1997; Bland, Newman and Orn, 1997b; Fleet *et al.*, 1998). Instead, anxiety is routinely relegated to the position of a diagnosis of exclusion. A number of studies have also suggested that gender differences in the presentation, attribution, and expression of anxiety symptoms may further delay the prompt recognition of anxiety disorders. Results from several studies also suggest that primary care physicians are more likely to attribute anxiety to a mood disorder, even when an anxiety disorder is primary (Rogers *et al.*, 1994).

Anxiety and mood disorders have extensive comorbidity. Lifetime prevalence estimates, in fact, suggest that more than two thirds of anxiety disorder patients will also develop a mood disorder, particularly depression (Kessler *et al.*, 1994). There is also substantial comorbidity between the anxiety disorders. For example, 40% of patients with OCD will also meet criteria for an additional anxiety disorder diagnosis during their lifetime (Rasmussen and Eisen, 1990; Pigott *et al.*, 1994; Hollander *et al.*, 1996a; Antony, Downie and Swinson, 1998). The frequent co-existence of mood and anxiety conditions may also further hinder the prompt and accurate diagnosis of anxiety disorders.

It remains unclear why anxiety disorders are so much more common in women than men. Genetic, biological, developmental, and environmental factors have all been implicated. Since anxiety and depression are both more prevalent in women than men, a shared or similar genetic basis may exist. Results from female twin studies provided some compelling support for a shared genetic diathesis between GAD and depression (Kendler *et al.*, 1992a, 1992b). However, available evidence suggests that the remaining anxiety disorders are characterized by less genetic homogeneity (Kendler *et al.*, 1992c, 1995).

Developmental and environmental factors are also likely to be important in the pathogenesis of anxiety disorders. Histories of childhood trauma or early separation anxiety increase the risk for both sexes that an anxiety disorder will subsequently occur (Young *et al.*, 1997; Stein *et al.*, 1998; Sutherland, Bybee and Sullivan, 1998). There is some intriguing evidence, however, that women may be differentially susceptible to the adverse consequences associated with childhood abuse. Breslau and colleagues have extensively investigated the impact of gender on PTSD. Their results suggest that when exposure rates are similar, women are more likely than men to develop PTSD after the occurrence of trauma. Moreover, a history of childhood trauma is a more reliable predictor in women than men that PTSD will be present as an adult (Breslau *et al.*, 1990, 1997a, 1997b). There is also evidence that gender differences exist in the type of anxiety disorder that may develop in response to chronic environmental stress. Galbaud and colleagues investigated the potential association in psychiatric diagnoses between spouses. They found that a diagnosis of depression, drug addiction, or antisocial personality disorder in one spouse increased the chances that the spouse would meet criteria for an anxiety disorder. However, a different anxiety disorder occurred in the women versus men spouses. That is,

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

spouses with drug addiction or antisocial personality disorder were more likely to meet criteria for GAD if men, but PTSD if women (Galbaud-du-Fort *et al.*, 1998).

Although genetic and environmental factors are likely to be important in the development of anxiety disorders, the role of women gonadal hormones may be particularly critical in the pathogenesis of anxiety disorders. Women gonadal steroids, particularly oestrogen and progesterone, can elicit potent biological effects within the central nervous system. In addition, dramatic and cyclical fluctuations in gonadal hormone concentrations routinely occur throughout the female reproductive life span. These unique features may contribute to the finding that women have an increased risk for anxiety disorders. Despite the significant gender differences identified for prevalence rates, remarkably little research has focused on detecting any further gender differences in anxiety disorders. With these issues in mind, this chapter will provide a review of the available data concerning: (a) the potential impact of gender on the epidemiology, phenomenology, and clinical course of anxiety disorders; and (b) the impact of reproductive cycle events on the clinical course of anxiety disorders.

GENERALIZED ANXIETY DISORDER (GAD)

GAD is one of the most common of the anxiety disorders with most estimates suggesting a lifetime prevalence rate of between 5% and 6%. Women are two to three times more likely than men to meet lifetime criteria for GAD. The onset of GAD is typically during late adolescence or early adulthood and most studies suggest that a chronic, persistent course is most common (Boyd *et al.*, 1990; Kessler *et al.*, 1994; Wittchen *et al.*, 1994; Yonkers *et al.*, 1996; Woodman *et al.*, 1999). Although results from most population surveys suggest that anxiety disorders tend to decrease with increasing age, the prevalence rate for GAD remains at a constant rate throughout life (Krasucki, Howard and Mann, 1998).

GAD most commonly presents in the primary care setting (Woodman *et al.*, 1999). A diagnosis of GAD is associated with elevated rates of functional impairment. GAD is also linked to greater levels of medically unexplained symptoms and over-utilization of health care resources. Roy-Byrne and Katon suggest that the increase in health care utilization reported with GAD does not occur by a direct path, but instead by acting as a catalyst that modifies the presentation of other psychiatric disorders that more directly affect health care costs (Roy-Byrne and Katon, 1997). Patients with GAD are also more likely to be prescribed psychotropic medication in comparison to patients without GAD (Wittchen *et al.*, 1994).

In addition to being associated with considerable disability and morbidity, remission rates with GAD are reported to be fairly low. For example, preliminary results from the large, prospective HARP Study indicate that after two years of follow-up only 8% of the patients with GAD were considered symptom-free (Yonkers *et al.*, 1996). A recent systematic comparison of GAD and panic patients revealed similarly dismal results. The GAD patients reported an earlier age of onset and a longer duration of illness. Moreover, significantly lower remission rates were noted in the patients with GAD (18%) than in the panic (45%) patients during the five-year study (Woodman *et al.*, 1999).

Gender Differences in GAD

More than 85% of patients with primary GAD will meet criteria for an additional lifetime psychiatric disorder (Boyd *et al.*, 1990; Kessler *et al.*, 1994; Wittchen *et al.*, 1994). Women with GAD are significantly more likely than men to meet criteria for an additional lifetime psychiatric condition (complicated GAD). Since results from population surveys and prospective studies suggest that complicated GAD has a worse prognosis and reduced chance of remission than GAD alone, this finding may help to explain why women with GAD are reported to have a more chronic course and greater symptom severity than men with GAD (Yonkers *et al.*, 1996). Women with GAD are also more likely than men with GAD to meet criteria for a depressive disorder, especially dysthymia (Wittchen *et al.*, 1994). This finding may also have important consequences since the presence of depression in patients with GAD has been associated with increased functional impairment and a greater risk of suicide in comparison to a diagnosis of GAD alone (Robins *et al.*, 1984; Wittchen *et al.*, 1994; Breslau, Schultz and Peterson, 1995; Bakish, 1999). Preliminary evidence also suggests that women with GAD are more likely to seek treatment with a health care professional than men, especially if comorbid diagnoses are also present (Bland, Newman and Orn, 1997a).

The finding that gender differences exist in GAD may have additional ramifications. The frequent co-occurrence of depression and GAD in women may also provide an important clue in understanding their underlying pathophysiology. That is, their common co-existence may reflect an enhanced vulnerability that is in part mediated by factors distinct to the women gender. While earlier investigations into the preponderance of anxiety disorders in women have tended to emphasize psychosocial and environmental factors, recent research has also investigated the potential role of genetic factors. Kendler and colleagues have investigated these issues by analysing data obtained from bivariate female twins. The female twin pair data provides compelling support for the role of genetic transmission as a primary mediating factor for GAD. The female twin data also suggests that GAD and depression may arise from the same genotype. That is, if a certain genotype is present within an individual, Kendler and colleagues hypothesize that either GAD or depression may develop as determined by a variety of environmental and biological influences (Kendler *et al.*, 1992a, 1992b, 1995).

The pathophysiology of GAD remains undetermined although serotonergic, noradrenergic, and GABAergic dysregulation are commonly implicated (Brawman-Mintzer and Lydiard, 1997). However, a neuroimaging study conducted in GAD patients demonstrated evidence of a more homogeneous distribution of benzodiazepine receptors throughout the cerebral hemispheres in the GAD patients versus control subjects. The reduced heterogeneity in cerebral blood flow associated with a diagnosis of GAD may be similar to the finding of reduced heterogeneity in myocardial blood flow associated with ischaemic heart disease (Tiihonen *et al.*, 1997). Unfortunately, the potential impact of gender on brain function in GAD has not been systematically assessed.

Medications reported to be effective for GAD include buspirone, benzodiazepines, venlafaxine and the SSRI antidepressants (Brawman-Mintzer and Lydiard, 1997). Data derived from animal models of anxiety suggest that response to anxiolytic medication, especially benzodiazepine anxiolytics, may be significantly influenced by gender as well as the phase of the oestrous cycle (Fernandez-Guasti and Picazo, 1990). While these results suggest that important gender differences in treatment response may occur in GAD, systematic data is not available. Unfortunately, the potential impact of gender on brain function in GAD has also not been systematically assessed.

There is some evidence that GAD symptoms become more severe during the premenstrual period in women with GAD and co-existing premenstrual syndrome (PMS). However, no change in symptom severity during the menstrual cycle was detected in the women with GAD who did not have co-existing PMS according to the same report (McLeod *et al.*, 1993). Further information about the impact of the menstrual cycle, pregnancy, or the menopause on the symptoms or course of GAD has not been reported at this time.

These findings indicate that important gender differences exist in the prevalence, clinical features, and comorbid conditions that may complicate GAD. There is some evidence that GAD symptom severity may be influenced by female reproductive hormone cycles but further information, especially about the potential impact of pregnancy and the post-partum period on GAD, is currently absent. Since preliminary evidence suggests that women with GAD have a more chronic course and a worse outcome, systematic data concerning gender differences in underlying pathophysiology and/or treatment response is clearly needed.

PANIC DISORDER

Estimates derived from large-scale community surveys suggest a 1.5%–2.0% lifetime prevalence rate for panic disorder. Women are two to three times more likely than men to meet lifetime criteria for panic disorder (Regier *et al.*, 1988, 1990; Eaton, Dryman and Weissman *et al.*, 1991; Kessler *et al.*, 1994; Dick, Bland and Newman, 1994b). Panic onset is typically during adolescence or early adulthood and is very rare after the age of 40. Men and women have a similar age of onset for panic disorder (Dick, Bland and Newman, 1994b). Despite substantial fluctuations in severity over time, most patients with panic disorder report a chronic clinical course (Joyce *et al.*, 1989; Keller and Hanks, 1993).

A diagnosis of panic disorder has been linked to a number of adverse consequences including increased utilization of medical and mental health services and elevated rates of suicidal behaviour (Weissman *et al.*, 1989; Katerndahl, 1990; Hollifield *et al.*, 1997; Katerndahl and Realini, 1997). Data from the largest prospective study of patients with anxiety disorders to date, the HARP study, confirm that 40% of panic patients will be in treatment at one year and 30%–40% are likely to require long-term, maintenance medication (Keller and Hanks, 1993).

Gender Differences in Panic Disorder

Several significant gender differences have been identified for panic disorder. As previously noted, panic is two to three times more common in women than in men. In addition, the occurrence of panic attacks even in the absence of meeting full criteria for panic disorder may represent a significant development, especially in women. For example, 63% of women and 40% of men that experienced panic attacks subsequently developed an additional psychiatric disorder in one report (Reed and Wittchen, 1998). Gender differences have also been identified in the phenomenology of panic disorder. Women with panic disorder report more individual panic symptoms and greater levels of phobic avoidance in comparison to men with panic disorder (Dick, Bland and Newman, 1994b). They are also more likely to report that leaving home alone or using public transportation triggers their panic attacks. Women with panic disorder are also more likely than men to report that they rely on family members to enter fearful situations. The apparently increased level of dependence on others endorsed by women with panic disorder may help to explain the finding that women with panic have a greater degree of functional impairment in comparison to men with panic (Weissman *et al.*, 1997; Starcevic *et al.*, 1998; Turgeon, Marchand and Dupuis, 1998).

Women with primary panic disorder are more likely than men to meet criteria for an additional lifetime psychiatric disorder (Yonkers *et al.*, 1998). Gender also appears to have a significant impact on the type of comorbid psychiatric diagnosis that will present during the course of panic disorder. Comorbid agoraphobia depression, GAD, simple phobia, and somatization disorder are more likely to complicate panic disorder in women than in men (Katerndahl, 1990; Andrade, Eaton and Chilcoat, 1996; Marshall, 1996; Yonkers *et al.*, 1996, 1998). In contrast, men with panic disorder have greater rates of comorbid alcohol abuse. Alcohol-related disorders are not uncommon in women with panic disorder, however, as illustrated by the finding that women with panic disorder are at an increased risk of developing alcohol abuse or dependence in comparison to women without panic disorder (Otto *et al.*, 1992; Cox *et al.*, 1993; Kessler *et al.*, 1994). Interestingly, preliminary evidence suggests that women with panic disorder may have an elevated rate of relatives with alcohol dependence. Although further research is needed, this and additional findings has resulted in considerable speculation concerning a possible genetic link between panic and alcohol abuse in women (Battaglia *et al.*, 1995; Kendler *et al.*, 1995).

The data suggesting that women with panic disorder have an elevated risk for comorbid psychiatric disorders in general and certain comorbid disorders in particular may have critical implications. The presence of agoraphobia in panic disorder is associated with a less favourable outcome than the presence of panic disorder alone. Since agoraphobia is more common in women than in men with panic disorder, women with panic disorder might be expected to have a worse prognosis. There is evidence supporting this finding. For example, women with panic disorder and agoraphobia report greater phobic avoidance, more catastrophic thoughts, and a heightened awareness of body sensations in comparison to men that have panic disorder with agoraphobia. Women with panic disorder complicated by agoraphobia are also more likely to meet criteria for social anxiety disorder and/or PTSD (Stein *et al.*, 1989; Turgeon, Marchand and Dupuis, 1998). The increased prevalence of agoraphobia in women with panic disorder may also contribute to the consistent finding of a more chronic and severe clinical course for panic disorder in women in comparison to men (Boyd *et al.*, 1990; Hollifield *et al.*, 1997; Katerndahl and Realini, 1997; Joyce *et al.*, 1989; Yonkers *et al.*, 1998). Recent prospective data also suggests that if a period of remission occurs during the course of panic disorder, women have an increased risk for recurrence of panic disorder (Yonkers *et al.*, 1998).

These findings indicate that a diagnosis of panic disorder in women in comparison to men is associated with a more complicated course and an overall poorer outcome. Since the aetiology of panic disorder remains obscure, it is difficult to explain why women have a greater risk and a more malevolent course for panic disorder than men. Numerous neurobiological and psychological theories have been proposed for panic disorder. Most psychological theories emphasize the importance of cognitive misinterpretation and 'false threat alarms' as the basis for the subsequent development of panic disorder (Windmann, 1998). Biological theories, in contrast, implicate altered brain function and an abnormal ventilatory response in the pathophysiology of panic (Klein, 1993; Bell and Nutt, 1998). Neural circuits within the amygdala and its ascending cortical pathways are most often speculated to represent the functional neuroanatomy of panic disorder. Altered dysregulation of the ventilatory response and associated neurovascular instability may also be important factors in the pathophysiology of panic disorder (Coplan and Lydiard, 1998). Both physiological (e.g., CO_2 sensitivity) and psychological (anxiety sensitivity) factors have been suggested as predisposing factors in the development of panic disorder (Coplan and Lydiard, 1998; Stein, Jang and Livesley, 1999). Despite the striking gender differences identified in the prevalence and clinical features associated with panic disorder, evidence of significant gender differences in the purported pathophysiology of panic disorder have not been detected.

Results from covariate female twin studies suggest that genetic or familial factors play a role in panic disorder, although their contribution is estimated to be relatively modest (Kendler *et al.*, 1993, 1995). There is some evidence that genetic factors may be particularly critical in determining risk for panic disorder in

women. That is, the presence of a specific genetic polymorphism in women may convey an increased risk for panic disorder. Women with panic disorder are reported to have a higher occurrence of a novel repeat genetic polymorphism on chromosome X than control subjects. This genetic polymorphism is thought to mediate expression of monoamine oxidase A. Since monoamine-oxidase-inhibiting antidepressants are known to be effective anti-panic agents, this finding has been interpreted as evidence that altered monoamine oxidase A activity may be a risk factor for panic disorder, at least in women (Deckert *et al.*, 1999).

Important gender differences in the presentation, clinical features, and overall course of panic disorder have been identified. Women with panic disorder are more likely to have agoraphobia and other comorbid conditions than men with panic disorder. The elevated risk for comorbid conditions likely contributes to the poorer prognosis reported for women than men with panic disorder. However, the potential contribution of differential avoidance strategies and other clinical characteristics that may influence prognosis in panic disorder requires further study.

Panic Disorder and Female Reproductive Cycles

Oestrogen and progesterone have complex effects on the CNS. Oestrogen is generally considered a facilitator of neurotransmission via its ability to reduce MAO enzyme activity and enhance serotonergic tone. Oestrogen's biological actions are thought to convey some mood-enhancing or antidepressant effects. In contrast, progesterone increases MAO enzyme activity. Pregnanolone, a major metabolite of progesterone, enhances GABA tone via its effects as an allosteric modulator at the GABA-benzodiazepine receptor complex. Since GABA represents one of the major inhibitors of neurotransmission within the CNS, progesterone's biological effects may convey an anxiolytic action (Shear, 1997; Stahl, 1997; Warnock and Bundren, 1997).

The female reproductive cycle (menstruation, menopause, and pregnancy) is characterized by relatively dramatic fluctuations in oestrogen and progesterone concentrations. These hormonal fluctuations may have a role in determining the overall risk for panic disorder and may also have a substantial impact on the clinical course of panic disorder in women. The dramatic decline in oestrogen and progesterone levels that characterizes the mid-luteal phase of the menstrual cycle has been linked to the emergence or worsening of anxiety symptoms in women (Yonkers and Ellison, 1996). Several reports, primarily retrospective in nature, confirm that women with panic disorder report an increase in their anxiety and panic symptoms during the mid-luteal or premenstrual phase of the menstrual cycle (Cook *et al.*, 1990; Griez *et al.*, 1990). This finding, however, has not been replicated in studies conducted on a prospective basis. Instead, prospective studies reported to date have failed to detect any significant association between menstrual cycle phase and ratings of panic or anxiety symptoms in women with panic disorder (Stein *et al.*, 1989; Cook *et al.*, 1990).

In contrast, biological challenge paradigms conducted in women with panic disorder have detected some evidence of changes in anxiety sensitivity across the menstrual cycle. Acute ingestion of carbon dioxide (CO_2) is often used as a provocative challenge to precipitate anxiety and panic attacks in experimental conditions (Griez *et al.*, 1990). Women with panic disorder have been reported to demonstrate evidence of menstrual cycle phase (follicular vs luteal)-dependent changes in anxiety sensitivity in at least one report (Fishman *et al.*, 1994). In this report, women with panic disorder demonstrated elevated anxiety responses during the mid-luteal phase of the menstrual cycle in comparison to the earlier follicular phase when serially administered CO_2. The women control subjects did not demonstrate any significant relationship between CO_2-induced anxiety and phase of the menstrual cycle during the same study (Perna *et al.*, 1995). Interestingly, subsequent treatment of the same group of women with panic disorder with alprazolam was associated with apparent 'normalization' of the CO_2-induced anxiety response in the same report (Fishman *et al.*, 1994).

Precipitous oestrogen withdrawal, whether physiological or induced by medication or surgical intervention, has also been linked to the subsequent emergence of panic disorder. In a large study ($n = 390$) of peri-menopausal women with new-onset but 'ill-defined' psychological and somatic symptoms, 7% were found to meet criteria for panic disorder (Ushiroyama and Sugimoto, 1994). Moreover, results from another report indicate that a diagnosis of panic disorder should be considered in peri-menopausal women with hot flashes that fail to attenuate during hormone replacement therapy (van der Feltz-Cornelis, 1999). Medical interventions that have primary progesterone-like effects, such as birth control pills or Norplant implants, have also been associated with the acute development of panic disorder (Wagner and Berenson, 1994). Ovarian suppressants utilized for the treatment of endometriosis such as leuprolide may also elicit panic attacks and other psychiatric disturbances (Warnock and Bundren, 1997).

Pregnancy and the post-partum period are marked by particularly dramatic fluctuations in gonadal hormone concentrations. Pregnancy is characterized by 2–3-fold increases in oestrogen and a dramatic elevation (80–100 times) in progesterone concentration (Altshuler, Hendrick and Cohen, 1998). Progesterone is a potent stimulant for oxygen drive and as previously noted its metabolite, allopregnanolone, has GABA-enhancing effects. With these actions in mind, women with pre-existing panic disorder might be expected to experience a substantial attenuation or remission in panic during pregnancy. Available data, however, suggests a more variable course for pre-existing panic disorder during pregnancy. Summarizing available data, it appears that about half (40%–45%) will not have a significant change in their panic symptoms, whereas 30%–35% will experience improvement and a substantial worsening in panic will occur in 20%–30% of patients with pre-existing panic disorder during the course of pregnancy (Cohen *et al.*, 1994a, 1994b; Northcott and Stein, 1994). Interestingly, the course of panic disorder during successive pregnancies is often markedly different (Villeponteaux *et al.*, 1992; Cohen *et al.*, 1994a, 1994b; Northcott and Stein, 1994).

Post-partum worsening (35%–63%) is a much more consistent finding demonstrated in women with pre-existing panic disorder (Sholomskas *et al.*, 1993; Cohen *et al.*, 1994a, 1994b; Northcott and Stein, 1994; Beck, 1998). The post-partum period may also be associated with an increased risk for the onset of panic disorder. According to available data, 11%–29% of women with panic disorder report onset during the post-partum period (Sholomskas *et al.*, 1993; Wisner, Peindl and Hanusa, 1996). Since this rate is significantly greater than the expected age-corrected rate for panic onset in women, it is unlikely to represent a coincidental event (Sholomskas *et al.*, 1993). In patients with pre-existing panic disorder, pregnancy does not appear to increase the likelihood that medication for panic can be successfully discontinued (Cohen *et al.*, 1994a, 1994b). Instead, there is some rational for continuing or re-starting pharmacotherapy during the latter part of pregnancy. Cohen and colleagues demonstrated that pregnant women with pre-existing panic disorder who receive anti-panic medication are significantly less likely to experience a post-partum exacerbation than those who did not receive treatment during pregnancy (Cohen *et al.*, 1994b).

Selective serotonin reuptake inhibitors (SSRI), monoamine oxidase inhibitors (MAOI), and tricyclic (TCA) antidepressants have all demonstrated efficacy in the treatment of panic disorder (Sheehan, 1999). High-potency benzodiazepine medications such as lorazepam, alprazolam, and clonazepam are also effective anti-panic agents. Each of the anti-panic medications (SSRI, MAOI, TCA, and benzodiazepines) is associated with a similar rate of

improvement (60%–70%) in panic symptomatology. However, buspirone and other medications with primary serotonergic effects do not appear to be more effective than placebo for panic disorder (Bell and Nutt, 1998). Little information is available concerning the potential impact of gender on treatment response in panic disorder. Results from one study (Kalus *et al.*, 1991) suggest that the TCA, desipramine, may be less effective in men than in women with panic disorder.

These findings indicate that important gender differences exist in the prevalence, clinical features, and overall course of panic disorder. Women are more likely to have panic disorder with comorbid conditions, especially agoraphobia. They are also more likely than men to suffer a recurrence of panic symptoms after remission of panic disorder. Available data also suggests that the female reproductive cycle, especially pregnancy and the postpartum period, can have an important impact on the course of panic disorder. Moreover, declining female hormone levels associated with the ageing process or as a consequence of medical or surgical interventions can precipitate or elicit an exacerbation in panic disorder. Although preliminary evidence also suggests that treatment response may be different in men versus women with panic disorder, further studies that focus on this critical issue are clearly needed. The potential contribution of differential avoidance strategies and other clinical characteristics that may influence prognosis in panic disorder also requires further investigation.

SIMPLE PHOBIA

Results from large-scale population surveys confirm that simple phobias represent one of the most common psychiatric disorders. More than 20% of adults are estimated to meet criteria for simple phobia (Eaton, Dryman and Weissman, 1991; Kessler *et al.*, 1994). Simple phobias encompass a wide range of situations and 'feared' objects. Women are twice as likely as men to meet criteria for simple phobia (Bourdon *et al.*, 1988; Boyd *et al.*, 1990; Dick *et al.*, 1994a). Depression, substance abuse, and OCD are frequently comorbid with simple phobias (Bourdon *et al.*, 1988; Regier, Narron and Rae, 1990; Eaton, Dryman and Weissman, 1991; Kessler *et al.*, 1994; Magee *et al.*, 1996). Some authors have suggested that simple phobias can be sub-classified into three primary classes: (a) situational phobias (e.g., claustrophobia, acrophobia); (b) animal phobias (e.g., fear of spiders, insects, snakes, etc.); and (c) health-related phobias (e.g., fear of injections, blood, dental procedures, etc.). Using this schemata for simple phobia, situational phobias are most common, followed by animal and then health-related phobia, respectively. Women reportedly are two to three times more likely than men to meet criteria for situational and animal phobia, whereas health-related phobia appears to occur at a similar rate in women and men (Fredrikson *et al.*, 1996).

In addition to increased prevalence rates, women may also have an earlier age of onset for simple phobia than men (Dick *et al.*, 1994a). Although they tend to have a chronic course, the associated disability is generally reported as minimal and relatively few (20%–25%) people with simple phobias seek treatment (Boyd *et al.*, 1990; Lindal and Stefansson, 1993). Data derived from female twin studies suggest that environmental factors are more critical than genetic factors in the development of simple phobia (Kendler *et al.*, 1992c). Additional data concerning potential gender differences or the possible influence of reproductive cycles on simple phobia is currently lacking.

SOCIAL ANXIETY DISORDER

Although an initial population study reported that it was relatively rare, data from subsequent population surveys estimate that more than 13% of people will meet lifetime criteria for social anxiety disorder (Boyd *et al.*, 1990; Schneier *et al.*, 1992; Kessler *et al.*, 1994; Stein, Walker and Forde, 1994; Stein and Chavira, 1998). Women are slightly (1.5 times) more likely than men to meet criteria for social anxiety disorder (Kessler *et al.*, 1994; Dick *et al.*, 1994a). Two subtypes (generalized and discrete) of social anxiety disorder are generally recognized. The generalized subtype of social anxiety disorder is comprised of individuals with pervasive performance and interact ional fears in a broad range of social activities, whereas the discrete subtype is limited to anxiety in only certain, focal situations. The two subtypes of social anxiety disorder appear remarkably similar in terms of age of onset, family history, and certain socio-demographic correlates (Kessler *et al.*, 1994; Stein, Walker and Forde, 1994; Stein and Chavira, 1998). However, considerable differences have been identified between the subtypes in terms of clinical course and complications. Discrete social anxiety is associated with an episodic course and minimal functional impairment (Stein, Walker and Forde, 1994) In contrast, generalized social anxiety is more likely to be chronic, complicated by comorbid psychiatric conditions, and associated with substantial functional impairment (Kessler, Stein and Berglund, 1998). Despite the considerable disability associated with generalized social anxiety disorder, relatively few (20%–25%) patients enter treatment (Boyd *et al.*, 1990; Kessler *et al.*, 1994; Schneier *et al.*, 1994).

The low treatment rates reported may in part reflect the difficulties encountered in rapidly and accurately diagnosing social anxiety disorder. Most studies suggest that as many as 5% of patients evaluated in primary care meet criteria for social anxiety disorder, but very few are properly identified. Results from a recent primary care study illustrate the enormity of this problem. Their primary care physicians recognized less than half of the patients with social anxiety disorder as having 'a psychiatric illness'. Overall during the study, the physicians failed to identify 85% of the patients who met criteria for social anxiety disorder (Lecrubier and Weiller, 1997; Bisserbee *et al.*, 1996).

Comorbid disorders are extremely common and may help to obscure the primary diagnosis of social anxiety disorder. Since onset frequently occurs during adolescence, comorbid disorders generally develop after the emergence of social anxiety disorder (Schneier *et al.*, 1992; Stein and Chavira, 1998; Kessler, Stein and Berglund, 1998). Agoraphobia probably represents the most common comorbid psychiatric condition (odds ratio 10 : 4) in social anxiety disorder. Comorbid depression (60%–90%) and alcohol abuse (30%–40%) also frequently complicate generalized social anxiety disorder (Kessler *et al.*, 1994, 1998; Dick *et al.*, 1994a; Stein and Chavira, 1998). Patients with generalized social anxiety disorder have elevated rates of drug abuse including an increased risk for prescription drug abuse (Bisserbee *et al.*, 1996; Lecrubier and Weiller, 1997).

A considerable overlap in diagnostic criteria exists between avoidant personality and social anxiety disorder. It is not surprising, therefore, that 70%–90% of patients with generalized social anxiety have co-existing avoidant personality disorder. The co-occurrence of social anxiety disorder and avoidant personality disorder appears to convey an increased risk for depressive disorder as well as a greater degree of functional impairment in comparison to social anxiety alone (Alpert *et al.*, 1997).

Childhood behavioural inhibition is implicated as a non-specific risk factor for the development of an anxiety disorder in adults. However, social anxiety disorder, in particular, is most strongly associated with a history of behavioural inhibition during childhood (Mick and Telch, 1998). Childhood selective mutism may represent a precursor to the development of social anxiety disorder. In fact, 70% of the first-degree relatives of children with selective mutism were reported to have social anxiety disorder in one study (Black and Uhde, 1995).

The neurobiology of social anxiety disorder is poorly understood, although preliminary research has identified evidence of several different biological abnormalities. Challenge paradigms comparing social anxiety disorder patients and control subjects after acute administration of carbon dioxide, cholecystokinin, or caffeine have detected evidence of enhanced sensitivity and potential cardiovascular and adrenergic abnormalities in the social anxiety disorder patients. Serotonergic dysfunction is implicated by pharmacological challenge results as well as the efficacy of the SSRI antidepressants in the treatment of social anxiety disorder (Nutt, Bell and Malizia, 1998; Ballenger *et al.*, 1998; Davidson, 1998). Patients with social anxiety disorder administered serotonergic probes demonstrate evidence of altered neuroendocrine and behavioural responses in comparison to control subjects. Functional neuroimaging studies reveal evidence of altered dopaminergic function in social anxiety subjects. In particular, a significant reduction in striatal dopamine reuptake has been detected in social anxiety disorder patients versus control subjects (Nutt, Bell and Malizia, 1998).

A number of pharmacological treatments, including the MAOIs, reversible inhibitors of MAO-A, beta-blockers, high-potency benzodiazepines, and the SSRIs have all demonstrated efficacy in the treatment of social anxiety disorder (Ballenger *et al.*, 1998; Davidson, 1998; Pollack, 1999). In the largest multicentre, placebo-controlled trial reported to date, paroxetine was more effective than placebo in both moderate and severe social anxiety disorder (Stein *et al.*, 1998). According to the International Consensus Treatment Guidelines for Mood and Anxiety Disorders, SSRI antidepressants are considered first-line therapy for social anxiety disorder. These guidelines also advocate long-term (>12 months) treatment for patients with generalized social anxiety disorder that have: (a) persistent symptoms despite treatment; (b) a comorbid psychiatric condition; (c) a history of relapse after treatment discontinuation; or (d) a very early onset of social anxiety disorder (Ballenger *et al.*, 1998). However, little information is available concerning the potential impact of gender on treatment response in social anxiety disorder.

Gender Differences in SAD

Evidence of significant gender differences has been reported in patients with SAD. As previously noted, women (15.5%) have a slightly elevated risk for SAD than men (11.1%). Interestingly, men with SAD appear more likely to seek treatment than women with SAD (Weinstock, 1999). Turk and colleagues systematically assessed the potential impact of gender on SAD in a recent report. They failed to detect evidence of gender differences in the prevalence of SAD subtype, the occurrence of comorbid disorders such as additional anxiety disorders, mood disorders, or avoidant personality disorder, or in the clinical course of a group of patients with SAD. However, Turk and colleagues did identify some significant gender differences in the phenomenology of SAD. Women with SAD exhibited more severe social fears than men with GAD. In addition, data derived from self-report measures revealed that the SAD women endorsed more severe fear in a wide range of activities including talking to authority figures, acting/performing/speaking/working in front of others or while being observed, being the centre of attention, expressing disagreement or disapproval to people they do not know very well, or giving a party. Women were also more likely than men to report that going to a party was a trigger for SAD symptoms. In contrast, the men with SAD endorsed more severe symptoms in only two distinct situations: urinating in public bathrooms and returning goods to a store. Men more frequently reported fear of urinating in a public restroom than women in the same group of SAD patients (Turk *et al.*, 1998). Although no gender differences in comorbid conditions were detected in the report by Turk and Co-workers, results from two other studies (Dick *et al.*, 1994a; Lecrubier and Weiller, 1997) have that agoraphobia may be more frequent in women than in men with SAD.

Results from bivariate female twin studies and family studies provide support for the importance of genetic factors in the development of generalized SAD (Kendler *et al.*, 1992c; Stein *et al.*, 1998, 1999). Patients with generalized SAD are 10 times more likely to have relatives with SAD than control subjects (Stein *et al.*, 1998). Results from the Stein and Co-workers study (1998) also imparted strong support for the validity of separating SAD into generalized versus non-generalized groups for research purposes. Data derived during the same study failed to support the role of genetic or familial effects as primary factors in the transmission of the non-generalized form of SAD. Little information is available concerning the impact of female reproductive cycle events and SAD. However, since depression, panic, and substance abuse are frequent complications of untreated SAD, further research appears indicated (Weinstock, 1999).

These results suggest that women are slightly more likely to meet criteria for SAD during their lifetime and that the clinical features associated with SAD may be substantially influenced by gender. The presence of comorbid conditions in primary SAD may also be impacted by gender, although conflicting findings have been reported. Probably the largest vacuum in knowledge about SAD exists in the areas of treatment response and in the potential impact of reproductive hormone cycle events on the onset and/or clinical course of SAD in women. Given the significant psychosocial burden associated with a diagnosis of SAD, future research efforts should focus on these important issues.

OCD

Results from the ECA and the subsequent Cross-National OCD Collaborative Group Study confirm that the lifetime prevalence rate for OCD is between 2% and 3% worldwide. These studies also demonstrate that women are 1.5 times more likely than men to meet lifetime criteria for OCD (Karno *et al.*, 1988; Weissman *et al.*, 1994). The onset of OCD is generally during adolescence or young adulthood. Baer has demonstrated that OCD symptoms can be subdivided into three primary symptom factors: 'symmetry/hoarding', 'contamination/cleaning', and 'pure obsessions' (Baer, 1994). Sixty to seventy percent of patients with OCD endorse substantial psychosocial and occupational dysfunction (Koran, Thieneman and Davenport, 1996; Hollander *et al.*, 1998). An OCD diagnosis is also associated with elevated utilization of medical and mental health services (Kennedy and Schwab, 1997; Hollander *et al.*, 1998). The total annual cost of OCD-related impairment is estimated to exceed $8 billion dollars (Dupont *et al.*, 1995). Unfortunately, OCD remains vastly under-diagnosed and persistently under-treated. Moreover, results from a recently published survey of OCD patients suggest that the average time between symptom onset and initial treatment contact in OCD exceeds 10 years (Hollander *et al.*, 1998).

OCD has historically been considered to be chronic in course, but recent data suggests that the course may be more variable than previously appreciated. An episodic clinical course may occur in as much as 1/3 of OCD patients (Perugi *et al.*, 1998; Antony, Downie and Swinson, 1998; Steketee *et al.*, 1997; Thomsen and Mikkelsen, 1995). Factors reported to be associated with an episodic course of OCD include lower rates of checking rituals and an increased risk of relatives with mood disorders (Perugi *et al.*, 1998). Sustained remission, however, appears to be fairly rare in OCD with either an episodic or chronic clinical course (Hollander *et al.*, 1996b; Bland, Newman and Orn, 1997b; Perugi *et al.*, 1998).

Most patients with OCD will have comorbid psychiatric disorders. Major depressive disorder appears to be the most common

comorbid diagnosis with a 60%–80% lifetime prevalence rate. Additional anxiety disorder diagnoses (40%) also frequently co-exist in OCD, especially panic disorder and social anxiety disorder (Rasmussen and Eisen, 1992; Pigott *et al.*, 1994; Weissman *et al.*, 1994; Antony, Downie and Swinson, 1998). Other conditions that frequently occur in OCD include substance abuse, schizophrenia, body dysmorphic disorder, hypochondriasis, Tourette's Syndrome, and anorexia nervosa (Rasmussen and Eisen, 1990, 1992; Pigott *et al.*, 1994; Weissman *et al.*, 1994; Antony, Downie and Swinson, 1998). Interestingly, the presence of comorbid mood or anxiety disorders does not appear to convey any additional burden in terms of the phenomenology, course, or prognosis of OCD (Demal *et al.*, 1993; Steketee *et al.*, 1997). In a systematic assessment of over 300 OCD patients, Perugi and colleagues found that 16% were comorbid for bipolar disorder. The OCD patients with co-existing bipolar disorder had a more gradual onset and a more episodic course. An elevated rate of sexual and religious obsessions was also associated with the presence of bipolar disorder in OCD (Perugi *et al.*, 1998).

Numerous challenge studies with serotonergic (5-HT) probes have revealed evidence of altered behavioural or neuroendocrine responses in OCD patients in comparison to control subjects. In contrast, OCD patients do not appear to exhibit evidence of altered noradrenergic and/or dopaminergic function in comparison to control subjects using various challenge paradigms (Zohar and Insel, 1987; Goodman *et al.*, 1990; Pigott, 1996). The preferential efficacy of serotonin-selective medications for OCD coupled with the evidence of selective serotonergic dysfunction in challenge studies provides fairly compelling evidence for the importance of serotonin in OCD.

Data from epidemiological and familial-genetic studies provide strong support for an important association between OCD and tic disorder/Tourette's syndrome (Karno *et al.*, 1988; Leonard *et al.*, 1992; Rasmussen and Eisen, 1992; Santangelo *et al.*, 1994). Tic disorder occurs in approximately 10%–15% of patients with OCD and patients with tic disorders have extremely high rates of comorbid OCD. In fact, most estimates suggest that 40%–60% of patients with TS or tic disorder will also have OCD. The considerable overlap in occurrence between OCD and tic disorders has elicited considerable interest. Several investigators have explored potential differences between patients with OCD and those with OCD and comorbid tic disorder (Pauls *et al.*, 1995). In terms of phenomenology, OCD patients with comorbid TS are more likely than OCD patients without TS to report obsessions involving non-violent images, excessive concern with appearance, and need for symmetry. Touching, blinking or staring, and counting compulsions are also reported to be more common in OCD patients with comorbid TS than in those with OCD alone. Preliminary evidence also suggests that a childhood history of ADHD is more common in OCD patients with tic disorder than in those without comorbid tic disorder (Petter, Richter and Sandor, 1998). In addition, OCD patients with co-existing TS have higher rates of bipolar disorder, social phobia, body dysmorphic disorder, attention deficit hyperactivity disorder (ADHD), and substance use disorders in comparison to those with OCD alone or TS alone (Coffey *et al.*, 1998). Family studies also provide support for the contention that OCD with comorbid tic disorder represents a distinct subtype of OCD. OCD is much more prevalent than tic disorder in the first-degree relatives of patients with OCD, whereas the risk for tic disorder is two times greater than the risk for OCD in the first-degree relatives of patients with OCD and tics (Yang and Liu, 1998).

These putative differences in clinical features have resulted in considerable speculation concerning potential differences in the underlying pathophysiology of OCD versus OCD with comorbid TS or tic disorder. In particular, OCD without tic disorder may arise primarily from serotonergic abnormalities, whereas dysfunction in the dopaminergic and serotonergic systems may occur in those with OCD comorbid for tic disorder (Petter, Richter and Sandor, 1998). Recent investigations using genetic association techniques have explored dopaminergic (D) function in OCD. Polymorphic variations have been identified in the genes that determine the expression of the D2, D3, and D4 receptors, respectively. Patients with OCD have been reported to have an increased frequency of the allele associated with a polymorphic variant of the D4 receptor; no differences were detected between the OCD and control subjects in the distribution of alleles in the genotypes for the D2 and D3 receptors (Billett *et al.*, 1998). However, results from another recent report suggest that future genetic association studies conducted in OCD should consider the presence of a comorbid tic disorder as a potential confounding factor. Patients with OCD and tic disorder were noted to have an increased frequency of the variant alleles identified for both the D2 and D4 receptor genes when compared to patients with OCD alone (Nicolini *et al.*, 1998). These findings provide further evidence that dopamine function may be altered in OCD, especially in OCD patients with comorbid tic disorder who may represent a genetically distinct subtype of OCD.

The SSRI antidepressants and the TCA, clomipramine, remain the cornerstone of the pharmacological treatment for OCD (Orloff *et al.*, 1994; Jefferson *et al.*, 1995; Stein, Spadaccini and Hollander, 1995). Although these medications effectively reduce OCD symptoms, the average improvement is fairly modest (30%–40%). Patients who developed OCD later in life had a better chance of response than do those who became ill earlier, independent of length of illness (Ackerman *et al.*, 1994). Re-analysis of data from the multicentre, placebo-controlled, fixed-dose trials of fluoxetine in OCD revealed that response rates and overall improvement were greatest for patients with histories of remission, lack of previous drug treatment, and more severe OCD (especially with greater interference and distress from obsessions) (Ackerman, Greenland and Bystritsky, 1998). Non-response to either clomipramine or fluoxetine treatment has been linked to the presence of: (a) concomitant schizotypal personality disorder; (b) prominent compulsions; and (c) a longer illness length (Ravizza *et al.*, 1995).

Gender Differences in OCD

The impact of gender has been extensively investigated in OCD in comparison to the other anxiety disorders. In addition to the gender difference noted in lifetime prevalence rates for OCD, results from community surveys have consistently demonstrated that the mean age of OCD onset is significantly earlier in men (20 years) than in women (25 years). Data from clinical samples also support the finding that OCD onset is earlier in males than in females, although the age of onset in clinical samples is typically during adolescence rather than young adulthood (Rasmussen and Eisen, 1990, 1992).

Children often manifest OCD-like behaviours as part of their normal development. For example, a standardized assessment for OCD symptoms was administered to a large community sample of children aged 9 to 15 years. The girls and the boys endorsed similar amounts of obsessive–compulsive behaviours during the study. The boys were more likely to admit to checking behaviours and cleaning behaviours were more common in the girls. OCD-like behaviours were more common in the 9- to 12-year-olds than in the 13–15-year-old children. Elevated anxiety levels were reported in the few subjects that continued to have persistent OCD behaviours during adolescence (Zohar and Bruno, 1997). These results suggest that OCD-like behaviours are common in elementary aged children, but persistence into adolescence is rare and may represent the initial symptoms of clinical OCD.

Childhood-onset OCD appears to have some unique features in comparison to adult-onset OCD. As previously noted, boys are two to three times more likely than girls to have OCD during childhood. Comorbid psychiatric disorders, especially ADHD and other developmental disorders, are very common in childhood-onset

OCD. Neuropsychological deficits and familial loading for OCD are also common in childhood-onset OCD. Long-term studies indicate that childhood-onset OCD may also be associated with a graver prognosis. Most reports suggest that patients with childhood-onset OCD rarely experience remission (Demal *et al.*, 1993; Thomsen and Mikkelsen, 1995; Hantouche and Lancrenon, 1996; Steketee *et al.*, 1997). In fact, Leonard and colleagues conducted one of the largest ($n = 54$) and longest (up to seven years) prospective follow-up study of children and adolescents with OCD. They reported that after an average of three years of follow-up, 81% of the patients treated with clomipramine were significantly improved, but only 6% of the subjects were considered to be in remission. Predictors of worse outcome for the childhood-onset OCD patients were: (a) more severe OCD symptoms score after 5 weeks of clomipramine therapy; (b) a lifetime history of a tic disorder; and (c) the presence of a parental Axis I psychiatric diagnosis (Leonard *et al.*, 1992).

As previously noted, men typically have an earlier onset of OCD than women. In fact, three times as many boys as girls meet diagnostic criteria for OCD. Recent investigations have identified a potential variant of OCD designated as early onset OCD. This variant is characterized by the onset of OCD before the age of 10, occurs predominantly in boys, and is strongly associated with tic disorder and a positive family history (Leonard *et al.*, 1992; Pauls *et al.*, 1995). The data concerning the potential link between OCD and tic disorder has already been reviewed; however, it is important to note that men are much more likely to have OCD with a comorbid tic disorder as well as an earlier onset of illness. This finding may also suggest that gender differences may exist in the pathophysiological mechanisms that underlie OCD. Dopamine dysregulation may be more prominent in men with OCD, whereas women gonadal steroid hormones and their complex interactions with serotonin may be more critical to the development of OCD in women. The dramatic shift that occurs in gender prevalence rates for OCD after the onset of puberty provides support for the importance of female reproductive hormones. Women begin to develop OCD at a much greater rate than men after menarche; the increase is sufficiently robust that the overall prevalence rate in OCD is greater for women (1.5 : 1.0) than men (Weissman *et al.*, 1994; Karno *et al.*, 1988).

Gender differences have also been identified in the phenomenology and clinical course of OCD. Aggressive obsessions and cleaning compulsions may occur more frequently in women with OCD (Noshirvani *et al.*, 1991; Castle, Deale and Marks, 1995; Lensi *et al.*, 1996). In a systematic assessment of adolescents with OCD, females endorsed a greater amount of compulsive rituals, whereas obsessions were more common in the males with OCD (Valleni-Basile *et al.*, 1994). Women with OCD may also have a more episodic clinical course and less severe symptoms (Thomsen and Mikkelsen, 1995; Hantouche and Lancrenon, 1996).

Women with OCD may also have a greater risk of certain comorbid conditions than men with OCD. Comorbid panic disorder and eating disorders such as anorexia nervosa or bulimia nervosa are reported to occur more frequently in women than men with OCD (Noshirvani *et al.*, 1991; Rubenstein *et al.*, 1992; Tamburrino, Kaufman and Hertzer, 1994; Castle, Deale and Marks, 1995; Kendler *et al.*, 1995; Yaryura-Tobias, Neziroglu and Kaplan, 1995; Lensi *et al.*, 1996). Since anorexia and bulimia nervosa are associated with marked alterations in female reproductive hormone function, the frequent association of OCD with eating disorders also provides indirect evidence for the importance of the female reproductive cycle in the course of OCD.

Gender differences may also exist in response to serotonergic probes during challenge studies conducted in OCD patients. Women with OCD administered the serotonergic probe fenfluramine have an attenuated cortisol response in comparison to men with OCD and control subjects (Monteleone *et al.*, 1997). Acute intravenous administration of clomipramine is also used as a probe of 5-HT function. Results from clomipramine challenge studies conducted in OCD also suggest gender differences in response. Men with OCD experienced an increase in symptoms during the clomipramine challenge, whereas no substantial change was detected in the OCD women. The OCD women also demonstrated a better antiobsessional response during a subsequent 10-week trial with either clomipramine or fluvoxamine. Interestingly, the gender difference detected in antiobsessional response was more pronounced after clomipramine than fluvoxamine treatment (Mundo *et al.*, 1999). Potential gender differences in treatment response have been explored from the data derived from the multicentre, placebo-controlled treatment trials of clomipramine and fluoxetine, respectively. Both analyses failed to detect any evidence of gender differences in medication response in OCD (Ackerman *et al.*, 1994, 1998). Given the differences highlighted between OCD and OCD with tic disorder, future studies should explore the potential relationship between distinct OCD subgroups and medication response.

OCD and Female Reproductive Cycle Events

There are numerous reports suggesting that the female reproductive cycle may have a substantial influence on OCD. The striking increase in prevalence rates for OCD that occurs in women after the onset of puberty has already been reviewed. Several reports suggest a relationship between menstrual cycle and OCD. Undergraduate women without demonstrable OCD have been reported to engage in more OCD-like behaviours such as 'excessive cleaning or cleaning of things not usually cleaned' during the luteal phase than at any other time during the menstrual cycle (Dillon and Brooks, 1992), Moreover, the premenstrual (late-luteal phase) period may be associated with an exacerbation in symptoms in women with OCD (Yaryura-Tobias, Neziroglu and Kaplan, 1995; Williams and Koran, 1997). In the largest study to date, the impact of the menstrual cycle on the course of their OCD symptoms was retrospectively examined in 57 women with OCD. Nearly half (42%) of the women reported premenstrual worsening in their OCD symptoms and a substantial number (21%) also noted premenstrual dysphoria (Williams and Koran, 1997).

Several case series suggest that a substantial portion (13%–36%) of women with OCD report the onset of their illness during pregnancy or the post-partum period (Buttolph and Holland, 1990; Sichel *et al.*, 1993; Neziroglu *et al.*, 1994; Williams and Koran, 1997; Altshuler, Hendrick and Cohen, 1998). A number of case reports suggest that women with pre-existing OCD will experience a worsening in symptomatology during pregnancy (Brandt and Mackenzie, 1987; Buttolph and Holland, 1990; Stein *et al.*, 1993; Neziroglu *et al.*, 1994; Weiss *et al.*, 1995; Chelmow and Halfin, 1997; Altshuler, Hendrick and Cohen, 1998). However, in the largest reported study to date concerning the impact of pregnancy on OCD, most of the women with pre-existing OCD (69%) reported no significant change in symptoms during pregnancy. Relatively few of the OCD patients reported a significant worsening (17%) or a substantial improvement (14%) in OCD symptoms during pregnancy. Relatively few (13%) of the women reported the onset of OCD during pregnancy. Substantial changes in OCD symptoms, however, were likely to occur during the post-partum period. Post-partum worsening of OCD (29%) and post-partum depression (37%) was a frequent finding in the OCD women (Williams and Koran, 1997). The exacerbation noted during the post-partum period is a fairly consistent finding in women with pre-existing OCD. Most studies have reported that 20%–30% of women with OCD will experience a significant post-partum worsening in OCD symptoms (Buttolph and Holland, 1990; Sichel *et al.*, 1993; Williams and Koran, 1997; Altshuler, Hendrick and Cohen, 1998).

These results provide further evidence that changes in female reproductive hormone concentrations can substantially influence the severity and course of OCD. Pregnancy and the post-partum period may represent a time of increased vulnerability for the initial emergence of OCD or for significant worsening in women with pre-existing OCD.

POST-TRAUMATIC STRESS DISORDER (PTSD)

Although many individuals are exposed to trauma, only one out of four will develop PTSD (Breslau, Davis and Andreski, 1990). Community surveys consistently report that the lifetime prevalence rate for PTSD is two times greater in women (12.5%) than men (6.2%) (Drummond, 1993). The most common cause of PTSD in men is combat exposure. In contrast, women are most likely to develop PTSD as a consequence of sexual assault, sexual molestation, or childhood physical abuse (Kessler *et al.*, 1995). PTSD is often complicated by comorbid conditions such as depression and alcohol abuse (Breslau *et al.*, 1997b). PTSD can occur at any age, but certain traumatic events are associated with an especially high risk of subsequent PTSD development. For example, Foa reported that 95% of rape victims and 75% of victims of non-sexual assaults develop PTSD symptoms within 2 weeks of the traumatic event (Foa, 1997).

Although exposure to life-threatening traumatic events is fairly common, a number of studies confirm that PTSD is poorly recognized in a variety of clinical settings. For example, Davidson *et al.* (1998) found that 81% of new patient referrals to an outpatient psychiatric clinic had a positive history of significant trauma. Although almost 30% of the patients with exposure to trauma met criteria for PTSD, only 8% were correctly diagnosed with PTSD. Unfortunately the low rates of recognition typically associated with PTSD can have catastrophic consequences. Comorbid conditions are extremely common in PTSD, especially mood and substance use disorders. In fact, the presence of PTSD has been associated with an elevated risk for major depression, dysthymia, and mania. According to the National Comorbidity Survey, comorbid alcohol and substance abuse occur twice as often in the presence of PTSD in comparison to patients without PTSD (Kessler *et al.*, 1995; Breslau *et al.*, 1997b).

Cumulative evidence indicates that the SSRI antidepressants constitute first-line pharmacotherapy for PTSD (Nagy *et al.*, 1993; Rothbaum, Ninan and Thomas, 1996; Marshall *et al.*, 1998; Davidson and Connor, 1999). TCA and MAOI antidepressants are also effective for PTSD and should be considered for patients with PTSD who fail to respond to SSRI treatment. The SSRI antidepressants appear to have a broad spectrum of activity in PTSD. Common PTSD symptoms such as anxiety, insomnia, and an exaggerated startle response are reported to improve during SSRI treatment. Moreover, SSRI treatment may also ameliorate PTSD symptoms such as intrusive trauma-related recollections, feelings of emotional numbing, and avoidance behaviours (Davidson and Connor, 1999). Pharmacotherapy for PTSD should be initiated at a relatively low dose and maintained for at least 12 months before discontinuation is considered.

Gender Differences in PTSD

The gender difference in prevalence rate for PTSD has been linked to a differential rate of exposure to trauma. However, this assumption appears to be incorrect. In a sample of over 1000 young adults, Breslau and colleagues found similar rates of exposure to traumatic events, but substantially more women than men met criteria for PTSD (Breslau *et al.*, 1997b). Potential confounding factors such as the increased prevalence of pre-existing anxiety or major depressive disorders in women were examined, but failed to account for the observed gender difference noted in the prevalence of PTSD. Instead, women appeared to have a markedly increased susceptibility for PTSD development, especially if the trauma occurred prior to age 15 (Breslau *et al.*, 1990, 1995, 1997b; Kessler *et al.*, 1994). Results from the National Comorbidity Survey also implicate multiple factors in the elevated risk of PTSD in women. However, there was substantial overlap between factors that predicted an increased risk for trauma exposure and development of PTSD. Once the overlapping risk factors are excluded, only one risk factor (history of affective disorder) predicted PTSD in women, whereas two (history of anxiety disorder and parental mental disorder) factors were associated with an increased risk of PTSD in men (Bromet, Sonnega and Kessler, 1998). These findings suggest that most variables identified as predictive of PTSD are actually more indicative of trauma exposure than PTSD.

Major depression and generalized anxiety disorder are common comorbid disorders in PTSD regardless of gender, whereas co-existing somatoform pain disorder is more common only in women with PTSD. Pre-existing depression appears to convey an increased risk for subsequent exposure to traumatic events as well as the development of PTSD once trauma occurs (Breslau *et al.*, 1997a, 1997b). Certain traumatic experiences are more likely to precipitate PTSD. Women who are victims of sexual assault have an extremely high risk of subsequent development of PTSD. For example, Foa and colleagues found that 3 months after the trauma, women rape victims were twice as likely as women victimized by non-sexual crimes (48% vs 25%) to have PTSD (Foa, 1997). Women may be particularly susceptible to the long-term complications of abuse that occurs during childhood. In fact, women with histories of childhood abuse are reported to have a level of functional impairment that is commensurate with that of women with recent abuse (McCauley *et al.*, 1997). Women victimized by domestic violence are more likely to develop anxiety symptoms as well as PTSD, whereas male victims of domestic violence are at greater risk of developing substance use disorders. An elevated risk of depression and an increased number of physical and psychological health problems have also been reported in women exposed to ongoing domestic violence. This finding appears to be independent of the severity of domestic violence or the presence of injuries sustained. That is, women who sustain severe injuries do not appear more likely to develop psychiatric symptoms or PTSD (Sutherland, Bybee and Sullivan, 1998). While this finding may seem counter-intuitive, it likely reflects the importance of 'perceived threat' in the formation of PTSD. That is, a victim's perception of danger or possibility of death during an assault or exposure to trauma may be more important subsequent risk for PTSD as compared to more objective or realistic assessments of life-threatening events. These findings suggest that sexual assault, childhood abuse, and individual assessment of threat during the occurrence of trauma may represent the strongest predictors of subsequent PTSD development in women.

These findings suggest that sexual assault and childhood sexual abuse represent significant risk factors for the development of PTSD in women. They also confirm that childhood abuse has particularly devastating complications that are likely to persist into adulthood in women. Certain factors appear to substantially increase the risk of development of PTSD and other complications in women. These factors include: (a) exposure to sexually related trauma or aggression; (b) occurrence of abuse or severe trauma during childhood or prior to the age of 15; and (c) perception within the victim that the traumatic event is life threatening or escape is unlikely. With these issues in mind, future research efforts should focus on identifying the biological correlates associated with childhood trauma and/or sexual abuse/assault.

Gender differences have also been identified in the biological alterations associated with PTSD. An elevated norepinephrine-to-cortisol ratio has been reported in men with PTSD, whereas women with PTSD have demonstrated significantly elevated levels of urinary norepinephrine, epinephrine, dopamine, and cortisol on a daily basis (Lemieux and Coe, 1995). The HPA axis has strong, multi-level inhibitory effects on the female reproductive hormones. Since HPA axis alterations are implicated in PTSD, the marked fluctuations in oestrogen and progesterone levels that characterize the female reproductive cycle may well have a significant impact on the course of PTSD. The relative hypercortisolism that occurs during the third trimester of pregnancy is speculated to cause a transient suppression of the adrenals during the post-partum period (Chrousos, Torpy and Gold, 1998). This finding suggests that women with pre-existing PTSD may experience substantial changes in symptomatology during pregnancy or the post-partum period. Unfortunately, very little systematic information is available concerning the potential impact of the reproductive cycle on PTSD.

SUMMARY

Women are much more likely than men to meet lifetime criteria for GAD, panic disorder, simple phobia, SAD, OCD, and/or PTSD. Potentially important gender differences have also been identified in the phenomenology and clinical course for each of the anxiety disorders. Women with GAD are more likely to meet criteria for a comorbid psychiatric disorder, seek treatment, and experience a more severe clinical course in comparison to men with GAD. Phobic avoidance, an elevated risk for comorbid conditions, and a less favourable clinical outcome are associated with female gender in patients with panic disorder. Women, in comparison to men, with simple phobia are more likely to have an earlier age of onset and a situational or animal-related simple phobia; men and women have a similar risk for developing health-related simple phobia. Men are more likely to seek treatment for SAD than women, but women with SAD endorse a wider range of activities that elicit severe anxiety and/or avoidance behaviours. Numerous gender differences have been identified in OCD including an earlier age of onset in males, gender-related symptom manifestations (cleaning compulsions more common in women, obsessions more common in men) and comorbid conditions (eating disorders common in women with OCD, tics more common in males with OCD), and a more episodic clinical course for women with OCD. Women appear to be more susceptible to the development of PTSD after the occurrence of severe trauma such as sexual assault or childhood abuse, whereas men are more likely to develop PTSD as a consequence of combat exposure.

The gender differences that have been identified are likely to arise from a variety of factors including genetic, environmental, and neurobiological influences. However, increasing evidence also suggests that the female reproductive hormone cycle may also have a substantial influence in the development and/or perpetuation of anxiety disorders in women. Despite the fact that the majority of people afflicted by anxiety disorders are women of childbearing potential, relatively little data is available concerning the impact of female reproductive hormone cycle events on the onset and/or clinical course of anxiety disorders. Much of the available information focuses on women with either panic disorder or OCD. Information concerning the impact of the menstrual cycle on panic disorder is somewhat mixed, but there is mounting evidence suggesting that the post-partum period, and perhaps the peri-menopause, are associated with exacerbations in panic symptomatology. Menarche appears to increase the prevalence of OCD in females and the post-partum period is often associated with an increased risk of OCD onset and/or symptom worsening in women with pre-existing OCD. While these results are intriguing, further research is clearly needed to further clarify these important relationships. Lastly, there is some evidence suggesting that gender differences may exist in the neurobiological and/or genetic basis of anxiety disorders. While preliminary in nature, these findings suggest that further research efforts should focus on delineating these potential gender differences as well as their subsequent impact on treatment response and functional outcome. Hopefully, such investigations will lead to improved prevention strategies and/or treatments that will eventually result in eliminating the finding that women afflicted with anxiety disorders often have a more severe clinical course and a worse overall outcome than men with anxiety disorders.

Therapeutic Armamentarium in Anxiety Disorders

J.A. den Boer, B.R. Slaap, G.J. ter Horst, T.I.F.H. Cremers and F.J. Bosker

INTRODUCTION

For decades benzodiazepines have been the mainstay in the treatment of anxiety disorders. It is only during the last decade that this situation has changed. With the introduction of serotonin reuptake inhibitors (SSRI's), 5-HT receptor-specific drugs like 5-HT_{1A} agonists and recently, dual action antidepressants, new possibilities have been created for the treatment of panic disorder, obsessive compulsive disorder, social phobia, generalized anxiety disorder and post-traumatic stress disorder. In this chapter the pharmacotherapeutic options for the treatment of these anxiety disorders will be reviewed. We will focus on new developments and not reiterate all the studies performed with old tricyclic antidepressants (TCAs) such as imipramine, as these studies have been mentioned and reviewed in many other textbooks and papers.

PANIC DISORDER

Panic disorder (PD) is a chronic and recurring syndrome which requires long-term treatment. The disorder encompasses five essential domains: the panic attacks themselves, the associated anticipatory anxiety, phobic avoidance, and the resultant functional impairment and effects on quality of life. However, the complete resolution of panic attacks, the signal feature of panic disorder, is clearly important to patients. Modern studies on the efficacy in PD should measure symptoms domains outlined above (Shear and Maser, 1994).

Originally, tricyclic antidepressants (TCAs) like imipramine and clomipramine were the first found to be beneficial in panic disorder. Imipramine originally played a role in the sixties in the pharmacological dissection of panic and anxiety, as it was discovered that in patients suffering from anxiety neurosis, panic attacks disappeared during treatment with imipramine. The efficacy of imipramine has been the subject of many studies and this drug was used as a reference drug for years. TCAs, in spite of their proven efficacy, have many drawbacks, including high rates of non-compliance due to anticholinergic side-effects, weight gain, daytime sedation, orthostatic hypotension, lethality in overdose and withdrawal reactions (Wolfe, 1997; Bennett *et al.*, 1998; den Boer, Bosker and Slaap, 2000). After six months treatment with imipramine dry mouth, constipation, sweating was still present as a substantial burden to patients (Mavissakalian and Perel, 2000). It is questionable whether by current standards, TCAs would be marketed if they were introduced today. Many studies have also been performed with BDZs in PD and there is a large database indicating that high potency BDZs such as clonazepam and alprazolam are efficacious in PD. Due to developments in psychopharmacology during the last decade it has, however, been questioned whether BDZs should be the first choice in the treatment of PD in view of their serious side-effects and withdrawal reactions.

Benzodiazepines in Panic Disorder

There are several placebo-controlled studies suggesting that clonazepam has therapeutic effects in PD. In one of the largest studies with clonazepam conducted so far, Rosenbaum and co-workers (1997) included 413 patients with PD in a fixed-dose placebo-controlled study in a 6-week study followed by a 7-week discontinuation phase. They used dosages ranging from 0.5 mg to 4.0 mg clonazepam daily and found that dosages of clonazepam of 1.0 mg were equally effective in reducing the number of panic attacks. During the discontinuation phase most patients worsened and reported increases in the number of panic attacks. Recently, Valenca *et al.* (2000) undertook a 6-week placebo-controlled study in 24 PD patients. They found that 11% of the placebo-treated patients were panic free after six weeks, whereas 62% of the clonazepam treated patients were panic free. Because treatment with BDZs has been associated with severe withdrawal reactions, Moroz and Rosenbaum (1999) treated PD patients with 0.25 up to 4.0 mg per day clonazepam for 6 weeks in a double-blind placebo controlled design, followed by a 7-week discontinuation phase during which the doses were gradually tapered. They observed no symptoms suggestive of withdrawal syndrome, nor evidence for rebound during the gradual tapering of clonazepam, but some patients did show worsening of symptomatology, most notably a recurrence of panic attacks. These data show that in the short-term clonazepam is efficacious but treatment in this study was probably too short to achieve full remission of panic attacks. On the other hand, a naturalistic follow-up study for 2 years in 204 patients showed that improvement in global severity of PD did not change during treatment with stable dosages of clonazepam, indicating that there was no development of tolerance (Worthington *et al.*, 1998). In spite of the fact that clonazepam has been marketed in the US for PD, the two pivotal studies did not fulfil all the criteria that were set forth by Shear and Maser (1994), moreover, there is evidence that the higher dosages that are required in many patients are associated with withdrawal symptoms (Davidson *et al.*, 1998).

Two large studies investigating the anxiolytic effects of alprazolam have been conducted in more than 1600 patients suffering from PD. The Cross-National Collaborative Panic Study and the Philadelphia study, which was a maintenance study (Ballenger *et al.*, 1988; Noyes *et al.*, 1988; Pecknold *et al.*, 1988; Rickels *et al.*, 1993; Schweizer *et al.*, 1993). The results of these studies suggested that alprazolam was an effective drug in reducing the number of panic attacks. In spite of these results, these studies were criticized for several points; there was a very high placebo drop-out rate and the average dose was high (mean dose at week 8: 5.6 to 5.8 mg per day). These are important issues as even lower dosages have been shown to lead to impaired recall and other cognitive disturbances (Pomara *et al.*, 1998). In addition, cessation of alprazolam treatment induces

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

severe withdrawal reactions, for which PD patients appear to be very vulnerable compared to patients suffering from generalized anxiety disorder (Klein *et al.*, 1994). Cognitive-behavioural therapy (CBT), prescription of drugs such as trazodone, valproate and carbamazepine have all been shown to facilitate alprazolam discontinuation (Rickels *et al.*, 1999; Bruce, Spiegel and Hegel, 1999). In addition, there is a relapse rate of 44% to 56% after discontinuation of alprazolam (Spiegel, 1998).

One placebo-controlled study compared alprazolam with exposure and relaxation, either alone or in combination (Marks *et al.*, 1993). In this study, alprazolam plus exposure was more effective than alprazolam plus relaxation, although the number of panic-free patients did not differ between placebo (plus either relaxation of exposure) and alprazolam plus relaxation. There is evidence from placebo-controlled studies that diazepam could also be effective in the treatment of PD. However, in most studies conducted with diazepam very high dosages have been used. In a placebo-controlled 8-week study comparing diazepam with alprazolam, the mean dose of diazepam was 40 mg per day, which according to European standards is considered extremely high (Noyes *et al.*, 1996). Diazepam was found to be as effective as alprazolam in reducing the number of panic attacks, but throughout the study sedation was more severe for patients taking diazepam or alprazolam than for those taking placebo.

In sum, there is evidence that the high-potency BDZs clonazepam and alprazolam are effective in the treatment of PD. The onset of efficacy on BDZs in rapid, but due to the high number of side-effects and withdrawal reactions we would not consider them as first-line treatment of PD.

Table XIX-13.1 Percent of patients free from panic attacks at endpoint in placebo-controlled studies of SSRIs and clomipramine

Study	Duration (weeks)	Percent panic-free			
		N	SSRI	Clomipramine	Placebo
Paroxetine					
Oehrberg *et al.*, 1995[†]	12	120	36%*	—	16%
Lecrubier *et al.*, 1997a	12	367	51%*	37%~	32%
Lecrubier *et al.*, 1997b	36	176	85%*	72%~	59%
Ballenger *et al.*, 1998	10	278	86%*	—	50%
Bakker *et al.*, 1999	12	131	75%	59%"	37%
Fluvoxamine					
Hoehn-Saric *et al.*, 1993	8	50	61%*	—	22%
Black *et al.*, 1993	8	75	73%*	—	25%
Citalopram					
Wade *et al.*, 1997	8	475	43–58%*	50%*	32%
Sertraline					
Pohl *et al.*, 1998	10	168	62%*	—	46%
Pollack *et al.*, 1998	10	176	57%~	—	47%
Londborg *et al.*, 1998	12	178	57%~	—	41%

*Significantly different from placebo; [†]one or zero panic attacks in a three week period; ~not significantly different from placebo; CT = cognitive therapy.

SELECTIVE SEROTONIN REUPTAKE INHIBITORS

Resolution of Panic Attacks

The SSRIs are effective in the treatment of panic disorder for which they are increasingly considered as first-line treatment. Comprehensive data has been published for SSRIs in particular, and the proportion of patients achieving panic-free rates have been reported in patients treated with paroxetine, fluvoxamine, citalopram, and sertraline in placebo-controlled studies (Table XIX-13.1).

Paroxetine

There is an extensive clinical database available for paroxetine — the largest data set among the SSRIs — which comprises data for over 700 patients with panic disorder treated with paroxetine for periods ranging from 10 to 36 weeks (Oehrberg *et al.*, 1995; Lecrubier and Judge, 1997; Lecrubier *et al.*, 1997; Ballenger *et al.*, 1998a). In a 12-week, double-blind, placebo-controlled comparison of paroxetine and clomipramine in 367 patients with panic disorder, paroxetine reduced the number of panic attacks to zero in 51% of patients, compared with 37% of patients treated with clomipramine and 32% of those on placebo (Lecrubier and Judge, 1997). In a two-centre study, Bakker *et al.* (1999) included 131 patients in a placebo-controlled double-blind study comparing paroxetine, clomipramine and cognitive therapy. They found that 37% of placebo treated patients were free from panic attacks in the last three week interval of this 12 weeks study. In the clomipramine and cognitive therapy group, this number was 17% and 54% and respectively. Interestingly, they reported a very low response-rate to clomipramine, in contrast to other studies. The highest response was found in the paroxetine treated patients: 75% from the patients were panic-free from week 10–12 or earlier. In this study, cognitive therapy did not differ from placebo on the pivotal measures.

Fluvoxamine

Fluvoxamine has been shown to reduce the number of panic attacks to zero in two, 8-week, placebo-controlled studies (125 patients in total): up to 73% of patients treated with fluvoxamine were panic free by the end of study, compared with approximately 25% of patients on placebo (Black, Uhde and Tancer, 1992; Hoehn-Saric *et al.*, 1993).

Citalopram

Citalopram has been compared with clomipramine in an 8-week, placebo-controlled study in 475 patients with panic disorder, with or without agoraphobia (Wade *et al.*, 1997). At the most effective citalopram dose (20–30 mg per day), approximately 58% of patients were panic-free compared with 50% of patients receiving clomipramine and 32% of placebo patients.

Sertraline

The results from a 12-week, double-blind, placebo-controlled, study of sertraline in 178 outpatients with panic disorder have recently been published (Londborg *et al.*, 1998). At study endpoint, 57% of the pooled sertraline sample were panic free compared with 41% of the placebo subjects; a non-significant difference. A large increase in the placebo response from week 9 onwards may have masked the treatment response. In a study with a similar design Pohl and associates (1998) found that significantly more sertraline-treated patients (62%) than placebo-treated patients were free of panic attacks at the end of treatment. From the analysis of the pooled results from these two studies it was concluded that the mean frequency of panic attacks was very high in this sample

(10 panic attacks per week), but this did not preclude superiority of sertraline over placebo, which was present in all dosages used (50 mg, 100 mg and 200 mg). In addition, analysis of the pooled data set showed that illness severity, chronicity or the presence of clinically relevant depressive symptomatology did not influence treatment results (Sheikh *et al.*, 2000). As yet there are no published comparative data for sertraline against other active treatments.

Fluoxetine

Fluoxetine was for a long time the least well-studied of the SSRIs in panic disorder, but a large multisite double-blind placebo-controlled study including 243 patients suffering from PD has now been published (Michelson *et al.*, 1998). In this study 10 and 20 mg per day were used in an acute 10 weeks treatment phase and responders to the acute phase were randomly assigned to a 24-week continuation-phase using the same double-blind design. Fluoxetine 20 mg appeared to be slightly superior to 10 mg, but both dosages led to statistically significant superior effects compared to placebo on the number of panic attacks, overall anxiety (20 mg better), phobic symptoms, depression and overall impairment.

Long-Term Efficacy

Of the SSRIs, only paroxetine, fluvoxamine and citalopram have demonstrated long-term efficacy in the treatment of panic disorder. A 9-month extension of an acute treatment study with paroxetine in 176 patients with panic disorder showed that, not only was the efficacy of paroxetine maintained, but the proportion of patients who became free of panic attacks continued to increase: after 9 months 85% of patients were panic-free compared with 72% of patients on clomipramine (Lecrubier *et al.*, 1997). Similarly, in a second study, 80 patients with panic disorder who responded to three months' maintenance treatment with paroxetine were randomized to paroxetine or placebo for a further 3 months (Judge and Steiner, 1996). Only 5% of those who continued to take paroxetine experienced a relapse compared with 30% of patients switched to placebo. Seventy-three patients with panic disorder underwent 12 months' further treatment with fluvoxamine in an open extension of two placebo-controlled studies (Holland *et al.*, 1994). Patients who had been transferred from placebo and those continuing on fluvoxamine continued to improve indicating that the effect of fluvoxamine in panic disorder is probably sustained in the long term. In a double-blind placebo-controlled long-term study lasting one year comparing citalopram (fixed dose ranges: 10 or 15 mg per day; 20 or 30 mg per day; 40 or 60 mg per day) vs clomipramine, it was found that all drug-treatment groups treatment outcome was better than placebo. Only the lowest dose of citalopram was less effective. In almost all patients remaining in the study ($N = 279$) panic attacks tended to disappear during active treatment (Lepola *et al.*, 1998).

Anxiety Levels

Reductions in global anxiety ratings with paroxetine, fluvoxamine, and citalopram have been reported in treatment studies in panic disorder (den Boer *et al.*, 1987, 1988; Black *et al.*, 1992; Hoehn-Saric *et al.*, 1993; Oehrberg *et al.*, 1995; Lecrubier and Judge, 1997; Lecrubier *et al.*, 1997; Wade *et al.*, 1997; Ballenger *et al.*, 1998a). All three SSRIs demonstrated comparable efficacy to clomipramine with respect to this endpoint measure (den Boer *et al.*, 1987; Lecrubier and Judge, 1997; Wade *et al.*, 1997).

Sertraline significantly reduced the time spent with anticipatory anxiety compared with placebo in a multicentre comparison in outpatients (Londborg *et al.*, 1998; Pohl, Wolkow and Clary, 1998), but in the study of Pollack *et al.* (1998) sertraline was not significantly different from placebo on measures for anticipatory anxiety. Limited data are available for the reduction of global anxiety in panic disorder with fluoxetine. It has been compared with desipramine in one small 10-week study where it was found to reduce anxiety levels (Bystritsky *et al.*, 1994). In the study by Michelson and co-workers (1998) it was found that fluoxetine 20 mg per day (but not 10 mg per day) significantly reduced global anxiety.

Phobic Avoidance

Paroxetine

Paroxetine produced a significant reduction in overall phobic score compared with placebo during a 12-week, placebo-controlled study in 367 patients (Lecrubier and Judge, 1997). The reduction was similar to that observed in patients on clomipramine. Further improvements in phobic avoidance were evident during the long-term extension phase of this study (Lecrubier *et al.*, 1997).

Fluvoxamine

Fluvoxamine was also found to be efficacious in the reduction of phobic avoidance in patients with panic disorder in several studies (den Boer *et al.*, 1987, 1988, 1990; van Vliet, Westenberg and den Boer, 1996). In all studies, although phobic avoidance was reduced, patients on fluvoxamine were still exhibiting signs of avoidance at study endpoint.

Fluoxetine and Citalopram

Fluoxetine reduced phobic avoidance in a small comparative study with desipramine (Bystrisky *et al.*, 1994). In the large double-blind study by Michelson *et al.* (1998) fluoxetine reduced phobic avoidance better than placebo. In the 12 months extension follow-up period of the study by Lepola *et al.* (1998) in which citalopram was compared to clomipramine and placebo, it was found that the reduction in total phobia score as assessed with the Phobia Scale was significantly greater in all patients receiving citalopram by month 9 and 12 compared to the group receiving placebo. Using the same scale, the group treated with clomipramine did not differ from placebo at month 12 (Leinonen *et al.*, 2000). In this study, however, no mention was made of the number of panic attacks, so that it is unclear whether clomipramine and citalopram showed comparable efficacy on this measure.

Overall Impairment

The effect of SSRIs on overall impairment in patients with panic disorder has been assessed in placebo-controlled clinical trials conducted with paroxetine (Lecrubier and Judge, 1997; Lecrubier *et al.*, 1997), fluvoxamine (Black, Uhde and Tancer, 1992; Hoehn-Saric *et al.*, 1993) sertraline (Pohl, Wolkow and Clary, 1998; Pollack *et al.*, 1998) and fluoxetine (Michelson *et al.*, 1998). Reductions in overall impairment, as assessed by the Sheehan Disability Scale in work, social and family life items, have been observed with both paroxetine, fluvoxamine and fluoxetine, whereas sertraline treated patients did significantly better than placebo on the Quality of Life Enjoyment and Satisfaction Questionnaire.

SSRI's Compared with Cognitive-Behavioural Therapy

There is limited data about the combination of cognitive therapy and pharmacotherapy in the short- and long-term treatment of PD. In order to evaluate whether drug therapy or psychosocial therapies are efficacious for PD, Barlow and co-workers conducted

a double-blind placebo controlled study in 312 patients suffering from PD (Barlow *et al.*, 2000). Patients received imipramine (up to 300 mg per day), CBT only, placebo only, CBT plus imipramine, or CBT plus placebo. Patients were treated for 12 weeks, responders were seen monthly for 6 months. Both imipramine and CBT were found to be significantly superior to placebo in the acute phase (12 weeks) and during the 6 months continuation phase. Combining CBT with imipramine did not increase response rates in the acute phase, but by the end of maintenance (6 months) the combination led to more substantial advantage compared to either condition alone.

Two studies have compared the efficacy of fluvoxamine and cognitive-behavioural therapy (CBT) in PD (Black, Uhde and Tancer, 1992; Sharp, Power and Simpson, 1996). In dosages up to 300 mg per day for 8 weeks, fluvoxamine reduced anxiety levels significantly more effectively than CBT or placebo alone (Black, Uhde and Tancer, 1992). The percentage of patients who were panic free at the end of study was higher in patients receiving fluvoxamine than CBT of placebo alone. In usual dose-levels of 150 mg per day, fluvoxamine was not better than CBT, whereas an additive effect was seen when the two treatments were combined (Sharp, Power and Simpson, 1996). Although the number of studies combining exposure *in vivo* with pharmacotherapy was limited, van Balkom *et al.* (1997) concluded from a meta-analysis from studies pertaining to different treatment conditions, that in the short-term treatment of PD the combination is superior. De Beurs and co-workers (1995) compared fluvoxamine (150 mg per day) plus exposure therapy, placebo plus exposure, panic management plus exposure or exposure alone in a 12 week, double-blind study. They found that fluvoxamine plus exposure therapy reduced agoraphobic behaviour more than the other three treatment conditions. Also after a two-year follow-up study of patients from this study, it was found that the beneficial effects of combination therapy was maintained long term, although the differences between the treatment condìtions were no longer significant (de Beurs *et al.*, 1999).

Dual Action Antidepressants in Panic Disorder

Although the aetiology of PD is unclear, it has been suggested that besides serotonergic dysfunction noradrenergic dysfunction is also associated with PD. Although SSRI's appear to be consistently effective in relieving the symptoms of PD the results of studies with selective noradrenergic agents are generally negative. Maprotiline (a selective noradrenergic agent) for example was found to be ineffective in PD (den Boer and Westenberg, 1988). On the other hand a small anxiolytic effect was seen during the use of the selective noradrenalin reuptake inhibitor reboxetine (Phillips *et al.*, 2000). In addition, a recent pilot study conducted in SSRI-resistant panic disorder found reboxetine to be efficacious in reducing the number of panic attacks (Dannon, Iancu and Grunhaus, 2001).

New drugs have been developed to combine noradrenergic and serotonergic sites of action. Mirtazapine is one of these drugs. It is an antidepressant with a different mode of action than the SSRI's and thus with a different side effect profile. The mechanism of action is enhancement of both noradrenergic and serotonergic neurotransmission without reuptake inhibition (den Boer *et al.*, 1994, 1995).

A number of placebo controlled studies have proven the efficacy of mirtazapine in major depressive disorder (Gorman, 1999; Thompson, 1999; Kent, 2000). Efficacy in moderate to severe depression is equivalent to that of TCAs and SSRIs. The tolerability and the safety profile of mirtazapine are more favourable than that of TCAs. The efficacy of mirtazapine in the treatment of anxiety symptoms has been described (Fawcett *et al.*, 1998; Connor *et al.*, 1999a, 1999b; Goodnick *et al.*, 1999; Nutt, 1998). So far, one open label study was published showing efficacy for mirtazapine in PD (Carpenter *et al.*, 1999). We recently completed a larger open-label study in 23 patients with PD according to DSM-IV (Boshuisen *et al.*, 2001). Patients were treated for 15 weeks including a three-week placebo run-in period. As primary efficacy measures we studied the decrease in the number of panic attacks and the number of patients being panic free in the last three weeks of the study. 73.6% were considered responders (decrease of at least 50% in panic attack frequency). The results of this open label study in panic disorder suggest that mirtazapine seems to be a fast and effective treatment in panic disorder with a different side effect profile from SSRI's. Double-blind studies with mirtazapine in PD are ongoing.

Experience with venlafaxine in PD is limited. Two open-label study reported complete cessation of panic attacks in patients suffering from PD (Geracioti, 1995; Papp *et al.*, 1998). In the only double-blind placebo-controlled study published so far, Pollack *et al.* (1996) evaluated the efficacy of immediate-release venlafaxine for the treatment of PD in an 8-week trial. In this small-scale study 25 outpatients suffering from PD were included. Based on endpoint analysis venlafaxine-treated patients showed significantly greater improvement than the placebo group on the CGI, whereas the difference in the mean number of panic attacks was not significant between the two treatment conditions.

5-HT RECEPTOR AGONISTS

Evidence regarding the efficacy of the partial 5-HT_{1A} receptor partial agonists, buspirone and gepirone in panic disorder has been conflicting. Buspirone has shown antipanic activity in two placebo-controlled trials (Robinson *et al.*, 1989; Sheehan *et al.*, 1993), but has not demonstrated superior efficacy to placebo on all outcome measures. Similarly, an 8-week placebo-controlled study of buspirone and imipramine in 52 patients with panic disorder showed that buspirone was not significantly superior to placebo in its anxiolytic effects (Sheehan *et al.*, 1990). There have been no reports supporting the ability of buspirone to reduce the number of panic attacks to zero in a population of patients with panic disorder. In contrast, 59% of patients ($n = 21$) on gepirone reached panic-free status by the end of a 6-week open trial (Pecknold *et al.*, 1993). However, the potent and selective 5-HT_{1A} agonist, flesinoxan did not reduce the number of panic attacks in two small pilot studies (20 patients in total) (van Vliet, Westenberg and den Boer, 1996). Furthermore, treatment with flesinoxan produced a profound increase in symptoms of anxiety in these patients.

Buspirone in combination with cognitive-behavioural therapy (CBT), has demonstrated greater efficacy than CBT and placebo, suggesting that buspirone may be an effective adjunct to CBT (Bouvard *et al.*, 1997), however, this effect was not maintained in the long term.

5-HT RECEPTOR ANTAGONISTS

Electrophysiological experiments in anaesthetized animals have highlighted the role of somatodendritic 5-HT_{1A} autoreceptors in the delayed onset of action of antidepressants (Blier, de Montigny and Chaput, 1987). Microdialysis experiments in conscious animals have shown that the increase in extracellular 5-HT following reuptake inhibition by SSRIs is counteracted by activation of these autoreceptors (Invernizzi, Belli and Samanin, 1992; Hjorth and Auerbach, 1994). Repeated administration of SSRIs is thought to desensitize the somatodendritic autoreceptors, resulting in an enhanced availability of serotonin (Chaput, de Montigny and Blier, 1991). Arguably, this desensitization process can be mimicked instantaneously by blockade of the autoreceptors with 5-HT_{1A}

receptor antagonists. Consequently, coadministration of SSRIs with 5-HT_{1A} antagonists would hasten the therapeutic effect of SSRIs (Artigas, 1993). Several studies have indeed reported beneficial effects of this augmentation strategy with pindolol (e.g. Artigas, Perez and Alvarez, 1994; Blier and Bergeron, 1995) in major depression.

A preliminary report suggested that augmentation with pindolol is also effective in treatment resistant panic disorder (Dannon *et al.*, 1997). However, an augmentation study by van Vliet *et al.* (2001) with panic disorder patients was negative. In this open-label study patients were treated with either fluvoxamine and pindolol (7.5 mg daily) or fluvoxamine alone. The results of this study show that pindolol as add-on medication to fluvoxamine does not hasten the anxiolytic or antipanic effects of fluvoxamine. In a recent study 25 therapy-resistant PD patients received fluoxetine (20 mg per day) and additionally either placebo or pindolol (2.5 mg t.i.d.). Patients treated with the combination of pindolol and fluoxetine showed a significantly better treatment response over patients treated with fluoxetine plus placebo (Hirschmann *et al.*, 2000). Although preliminary in nature, this study is at odds with the findings with fluvoxamine. It is possible that pharmacological differences among the SSRI's could explain these differences, on the other hand it should be noted that there were differences in the inclusion criteria among the studies: in the study by van Vliet and co-workers treatment resistance was not a prerequisite for inclusion, whereas the other two studies did include only treatment resistant patients.

Preliminary open studies with the 5-HT_2 antagonists ritanserin and trazadone suggested that both agents may have antipanic and antiphobic activity (Griez, Pols and Lousberg, 1988; Charney *et al.*, 1986). However, placebo-controlled studies with a larger patient sample in which ritanserin was compared with fluvoxamine (den Boer and Westenberg, 1990), and trazodone with imipramine and alprazolam (Charney *et al.*, 1986) showed no reduction in panic attack frequency for either agent. Preliminary evidence has been reported for the efficacy of nefazodone in a small open, 8-week study of 14 patients with panic disorder and comorbid depression (DeMartinis, Schweizer and Rickels, 1996). Another open-label study reported beneficial effects of nefazodone in nine out of 10 patients (Bystritsky *et al.*, 1999). In spite of these promising open-label studies, these results have not been confirmed in well designed placebo controlled studies.

The 5-HT_3 antagonist ondansetron demonstrated only limited efficacy in a small pilot study of 31 patients with panic disorder and agoraphobia (Schneier *et al.*, 1996). The response rate of 48% was not beyond the upper limit of placebo response rates and, in the absence of a placebo control group, it was not possible to attribute the response rate to an improvement in panic attacks. As a result, the use of ondansetron in panic disorder is no longer being actively pursued.

Inositol

Inositol is a natural isomer of glucose and a precursor for the second-messenger phosphatidyl–inositol system. There is one recent double-blind comparative study versus fluvoxamine in which inositol has been investigated in panic disorder. In this study 20 patients were treated with inositol up to 18 mg per day for one month and the clinical outcome was compared to patients treated with fluvoxamine up to 150 mg per day (Palatnik *et al.*, 2001). The results of this preliminary study suggest similar efficacy for inositol and fluvoxamine in reducing the number of panic attacks. When replicated in larger studies treatment with inositol might offer an alternative for patients who are sensitive to the side-effects of SSRI's, as inositol is almost devoid of side-effects.

Conclusion

The only serotonergic agents which have clearly demonstrated efficacy as antipanic agents in both short and long-term investigations are the SSRIs. The SSRIs produce improvements in anticipatory anxiety and phobic avoidance. In addition, the SSRIs proven ability to enable patients with panic disorder to achieve panic-free status indicates that, as a first-line treatment in panic disorder, the SSRIs are a good therapeutic choice. In contrast, the 5-HT agonists and antagonists have demonstrated equivocal efficacy in panic disorder. Most of our judgements about the therapeutic efficacy of SSRIs (and other antidepressants) are based upon double-blind placebo controlled studies. To what extent the results of randomized clinical trials apply to everyday care cannot be judged without regular measurement of outcomes in daily practice. In a three-year naturalistic prospective study in PD, Toni *et al.* (2000) described the evolution of panic and agoraphoba in 326 DSM-IIIR PD patients. The main antidepressants used were paroxetine, imipramine and clomipramine. Although efficacy did not show major differences during the entire follow-up period, paroxetine-treated patients suffered significantly less from jitteriness and anticholinergic side-effects, thus reducing barriers to compliance for the SSRI treated patients. Preliminary results with inositol may appear promising, although the evidence for its efficacy is still circumstantial.

OBSESSIVE COMPULSIVE DISORDER

Introduction

The 'Serotonin Hypothesis of OCD' evolved from the speculation that the unique efficacy of the TCA, clomipramine, in OCD was due to its effects in facilitating 5-HT neurotransmission (Insel *et al.*, 1985; Zohar and Insel, 1987; Jenike *et al.*, 1989; Goodman *et al.*, 1990; Murphy and Pigott, 1990; Rasmussen, Elsen and Pato, 1993; Zohar *et al.*, 2000). Clomipramine was the first drug reported to be effective in OCD (Fernandez and Lopez-Ibor, 1967). The efficacy of clomipramine has been reviewed in many publications and will not be repeated here. OCD patients respond specifically to drugs that influence the serotonergic system; noradrenergic drugs like nortryptiline or drugs with weaker 5-HT reuptake inhibiting properties like imipramine and amitryptiline appear to be without effect on OCD symptomatology (Leonard *et al.*, 1989, 1991). The potential role of 5-HT in the pathogenesis of OCD has led to the investigation of other agents, in particular the SSRIs.

SSRIs in the Treatment of OCD

Paroxetine, fluvoxamine, sertraline and fluoxetine have all been investigated in large placebo-controlled trials and their efficacy as anti-obsessional agents is well established. A 12-week, fixed-dose study of paroxetine versus placebo in 263 patients with OCD demonstrated that paroxetine (40 and 60 mg per day) was significantly more effective than placebo in reducing OCD symptoms (mean reduction as assessed with the Yale–Brown Obsessive Compulsive Inventory (Y-BOCS), 25% and 29% versus 13% respectively) (Wheadon, Bushnell and Steiner, 1993).

Similarly, fluvoxamine was reported to be more effective than placebo in reducing OCD symptoms in a number of randomized double-blind studies (for review see Figgett and McClellan, 2000; Vythilingum, Cartwright and Hollander, 2000). In four placebo-controlled studies fluvoxamine at dosages of 100 to 300 mg per day was found to significantly reduce symptoms of OCD compared to placebo (Mallya, White and Waternaux, 1992; Greist, Jenike and Robinson, 1995a; Goodman *et al.*, 1996; Mundo, Bianchi and Bellodi, 1997). In most of these studies the response rate as

measured with the Y-BOCS was in the range of 40–52%. As with the other SSRI's, the average dose for fluvoxamine in OCD is higher than in other anxiety disorders and depression and is in the range of 150–300 mg per day.

Greist and colleagues (1995b) reported the results of a 12-week, placebo-controlled, fixed-dose study of sertraline in 324 patients with OCD; the active treatment (50 and 200 mg per day) was significantly more effective than placebo in reducing OCD symptoms (mean Y-BOCS reduction, 24% and 28% versus 15%). In a follow-up study of 40 weeks duration Greist and colleagues (1995b) reported continued improvement of sertraline over time. Interestingly, the occurrence of side-effects subsided throughout the year of treatment. A recent double-blind placebo-controlled study using a flexible dose schedule of sertraline (50–200 mg per day) in 167 patients with OCD confirmed the anti-obsessional/compulsive effects of this SSRI (Kronig *et al.*, 1999). Also, in patients suffering from OCD who also met the criteria for major depression, sertraline was found to be more effective in reducing both OCD and depressed symptomatology compared to the noradrenaline reuptake inhibitor desipramine (Hoehn-Saric *et al.*, 2000).

In a double-blind, fixed-dose study 217 OCD patients were treated with fluoxetine (20, 40 or 60 mg) or placebo for 8 weeks (Montgomery *et al.*, 1993). Only the 40 and 60 mg dosages were found to be statistically superior to placebo, indicating that also with fluoxetine higher dosages are required. In a 13-week, multicentre, placebo-controlled, fixed-dose study of 355 patients with OCD, fluoxetine (20, 40 and 60 mg per day) was significantly more effective than placebo (mean Y-BOCS reduction, 20%, 22%, and 27% versus 3%) in reducing OCD symptoms (Tollefson *et al.*, 1994a). The trend may suggest greater efficacy with increasing dosage.

The efficacy of citalopram has been less well-studied in OCD than the other SSRIs. Recently, however, citalopram has also demonstrated efficacy in OCD in two open studies (Mundo, Bianchi and Bellodi, 1997; Koponen *et al.*, 1997). In one of these studies, a 24-week pilot study in 29 patients with OCD, 76% of patients showed alleviation of symptoms in comparison with baseline (Koponen *et al.*, 1997).

SSRIs vs Clomipramine

The efficacy of the SSRIs in the treatment of OCD has been compared with clomipramine, which for a long time was considered the gold-standard treatment for this anxiety disorder. Paroxetine, fluoxetine and fluvoxamine have been shown to be at least as effective as clomipramine in the treatment of patients with OCD, but better tolerated (Wheadon, Bushnell and Steiner, 1993; Zohar and Judge, 1996; Goodman *et al.*, 1997; Koran, Mueller and Maloney, 1996). The first multicentre, placebo-controlled study of an SSRI versus clomipramine, in 399 patients with OCD, was performed with paroxetine (Zohar and Judge, 1996). Both paroxetine and clomipramine were associated with similar efficacy at weeks 6, 8, and 12. Furthermore, during a multicentre, flexible dose, 10-week study in 66 patients with OCD, significant and similar reductions in OCD symptoms were seen for fluvoxamine and clomipramine (mean Y-BOCS reduction, 33% and 31%) (Freeman *et al.*, 1994). Similar results were obtained in a recent double-blind comparison of fluvoxamine and clomipramine in 133 patients suffering from OCD. In terms of efficacy as measured with the Y-BOCS, no statistically significant differences were found between the two treatment conditions but the side-effect profile was more favourable in the fluvoxamine treated patients (Mundo, Maina and Uslenghi, 2000).

In a 16-week comparative study of sertraline and clomipramine in 86 patients with OCD a significantly greater reduction in OCD symptoms was found for patients on sertraline compared with clomipramine (mean Y-BOCS reduction, 51% versus 43%; $p < 0.05$) (Bisserbe *et al.*, 1997). However, a fair comparison may have been precluded because of the greater number of clomipramine subjects who withdrew early in the study (18 clomipramine versus three sertraline within 28 days). When compared with clomipramine in a 26-week, double-blind, crossover study in 11 patients with OCD, fluoxetine was associated with significant reductions from baseline in OCD symptoms which were comparable with clomipramine (Pigott *et al.*, 1990). Similar results were observed in an 8-week double-blind comparative study of fluoxetine vs clomipramine in 55 OCD patients (Lopez-Ibor *et al.*, 1996). Interestingly, a 10-week, double-blind study comparing fluvoxamine, paroxetine and citalopram demonstrated that there were no significant differences between the three treatments in terms of efficacy (Mundo, Bianchi and Bellodi, 1997).

Despite the chronicity of OCD and the recommendation that pharmacotherapy should exceed 9–12 months' duration, there are comparatively few published data on the efficacy of SSRIs or clomipramine for periods longer than 20 weeks (Jenike *et al.*, 1990a, b; Rasmussen, Elsen and Pato, 1993). It has been demonstrated that OCD symptoms continued to improve for up to 6 months of paroxetine therapy. Furthermore, patients on placebo relapsed three times faster than those on paroxetine during the extension phase of one placebo-controlled study.

In terms of long-term efficacy, a two-year, open-label follow-up of responders to clomipramine and fluvoxamine, found both maintenance treatments to be significantly superior to placebo in preventing relapse in patients with OCD (Ravizza *et al.*, 1996). Seventy-six patients with OCD who responded to treatment with fluoxetine during an acute treatment study maintained symptom improvement during a 24-week continuation study (Tollefson *et al.*, 1994b). Similarly, in a two-year, open-label follow-up of responders to clomipramine and fluoxetine, both maintenance treatments were found to be significantly superior to placebo in preventing relapse (Ravizza *et al.*, 1996). There is no data available on the long-term efficacy of citalopram or sertraline in OCD.

Several meta-analyses have addressed the question of the differential efficacy of clompiramine and SSRI's in OCD (e.g. Picinelli *et al.*, 1995; Greist *et al.*, 1995c). The main conclusion of these meta-analyses was that clompiramine had a somewhat better effect on OCD-symptomatology than the SSRI's, although the side-effect profile of the SSRI's was superior to clomipramine. These findings stand in sharp contrast with the direct head-to-head comparative studies vs clomipramine reviewed above: in these studies similar efficacy of the SSRI's was found. We should, however, remain aware of the methodological problems encountered in meta-analyses. Variables such as study design, time period, chronology and site-specific factors, which may have impact on the results, cannot be considered in meta-analyses.

In sum, there is substantial evidence from head-to-head comparisons of paroxetine, fluoxetine, sertraline and fluvoxamine with clomipramine to conclude a similar efficacy and a lower incidence of side-effects with the SSRI (see also Pigott and Seay, 1999).

Anti-compulsive or Antidepressant Action?

Symptoms of depression often co-occur with OCD raising the possibility that non-specific antidepressant and anxiolytic effects may determine the success of SSRI's in OCD (e.g. Marks *et al.*, 1980). In subsequent studies discussed above it has been shown that initial depression was not predictive, nor related in any way to the degree of improvement in OCD (e.g. Price *et al.*, 1987). Moreover, if the anti-obsessional and anti-compulsive effects were in fact related to antidepressant efficacy, that other antidepressants such as nortryptiline should also be effective in the treatment of OCD, and this clearly is not the case.

5-HT RECEPTOR AGONISTS

The 5-HT_{1A} receptor agonist buspirone has demonstrated equivocal results in efficacy studies in patients with OCD. Buspirone was ineffective in a small, 8-week, open study in 14 patients with OCD (Jenike and Baer, 1988). However, Pato and colleagues (1991) demonstrated that buspirone and clomipramine produced significant improvements in symptoms in 18 patients with OCD; no differences were noted between the active treatments (Pato *et al.*, 1991). There is no published evidence of the efficacy of gepirone or ipsapirone in OCD.

Evidence for the augmenting effect of buspirone in SSRI treatment-refractory patients with OCD is also equivocal. In a 20-week, open study with fluoxetine, clinical response was enhanced in 50% of patients by addition of buspirone during the last 8 weeks of the study (Jenike, Baer and Greist, 1991). In contrast, however, in a double-blind study in which 13 fluoxetine-treated patients with OCD were given adjuvant buspirone or placebo for 4 weeks, there were no significant differences in improvement of OCD symptoms between the two treatment groups (Grady *et al.*, 1993).

5-HT RECEPTOR ANTAGONISTS AND TREATMENT REFRACTORY OCD

There is a paucity of data with respect to the treatment options in treatment refractory OCD. There is circumstantial evidence from open-label studies that adding another SSRI to ongoing treatment with clomipramine could lead to further improvement, but the evidence is not compelling (Pallanti *et al.*, 1999).

A small number of patients with SSRI treatment refractory OCD have been given open trials of risperidone (an atypical antipsychotic agent with potent dopaminergic and serotonergic antagonist activity) (Saxena *et al.*, 1996; Jacobsen, 1995). In the largest of these studies, 21 patients were treated openly with the combination of an SSRI (paroxetine, fluvoxamine, sertraline or fluoxetine) and risperidone (Saxena *et al.*, 1996). Sixteen patients tolerated the combined treatment and, of these, 87% had substantial reductions in OCD symptoms within 3 weeks. Similar results were reported in a recent open label study with risperidone as add-on to ongoing treatment with SSRIs (Pfanner *et al.*, 2000). In a recent double-blind placebo-controlled study it was found that adding risperidone for 6 weeks to ongoing therapy with SSRIs in treatment refractory patients led to a 50% response rate, which was not present in the placebo treated patients (McDougle *et al.*, 2000). There has also been a preliminary report that the 5-$HT_{2A/2C}$ receptor antagonist ritanserin was effective as an adjunct to fluoxetine treatment in OCD patients with psychotic features (Bach, Aigner and Lenz, 1997).

Experience with other atypical antipsychotics in treatment refractory OCD is limited and studies are ongoing. There is one open-label study in which olanzapine (5 mg per day) was added to treatment with fluvoxamine (300 mg per day). It was found that this augmentation led to a significant decrease in the Y-BOCS (Bogetto *et al.*, 2000).

Open studies suggest that pindolol has shown some merit as an adjuvant to SSRIs (paroxetine, fluvoxamine, sertraline or fluoxetine) in OCD (Blier and Bergeron, 1995). In a recent study 14 patients who were nonresponders to previous treatment with two SSRIs and were currently unresponsive to treatment with paroxetine (60 mg per day) were included in a double-blind placebo-controlled pindolol (2.5 mg t.i.d.) augmentation study (Dannon *et al.*, 2000). As measured with the Y-BOCS, significant differences were noted in favour of pindolol compared to placebo, whereas no differences were present between placebo and pindolol on measures of anxiety and depression.

There is anecdotal evidence that treatment-refractory patients might respond to treatment with the 5-HT_{1D} agonist sumatriptan (Stern *et al.*, 1998). In a recent study, however, we were not able to show involvement of the 5-HT_{1D} receptor in OCD in a double-blind placebo controlled challenge study using the selective 5-$HT_{1D/1B}$ receptor agonist zolmitriptan and therefore treating patients with 5-HT_{1D} agonists should not be encouraged before further clinical studies have been performed (Boshuisen and den Boer, 2000).

Finally, inositol augmentation to SSRI treatment did not lead to significant improvement in 10 OCD patients in an open-label study (Seedat and Stein, 1999).

THE LAST RESORT: PSYCHOSURGERY

In a small number of cases, OCD is refractory to irrespective which conventional treatment, and uncontrolled evidence suggests that such cases may respond to different types of psychosurgery. In spite of the fact that only a limited number of operations are performed, a variety of surgical techniques are used. They involve: capsulotomy, cingulotomy, subcaudate tractotomy, combined orbitofrontal/cingulate lesions.

During capsulotomy stereotactic lesions are produced in the anterior limb of the internal capsule. Cingulotomy involves stereotactic lesions of the anterior cingulate cortex. Subcaudate tractotomy involves placement of radioactive rods beneath and in front of the caudate nucleus.

All surgical treatments appear to be effective in approximately 30–40% of the patients, but no reliable clinical studies have been performed based upon which predictive indicators for good outcome can be defined. In addition, the site and size of the lesion remains to be established (for review, see Jenike, 1998). Cummings and co-workers (1995) studied 17 patients with OCD using a neuropsychological test battery after psychosurgery. The psychosurgery group appeared to perform more poorly only on the Wisconsin Card Sorting Test (WCST), indicating the impact of frontal lobe lesions on abilities mediating the formation and shifting of response sets. In another study 18 patients with intractable OCD who underwent cingulotomy participated in a follow-up study. In this small sample, 28% were responders, whereas 17% were partial responders (Baer *et al.*, 1995).

In one of the very rare studies investigating the effects of specific lesion sites in OCD, Irle *et al.* (1998) conducted a long-term follow-up of patients who underwent ventromedial frontal leukotomy during the seventies. Eight out of 11 subjects with lesions of the ventral striatum had developed substance dependence. Subjects with frontostriatal lesions showed most clinical improvement. In all patients, neuropsychological testing only revealed abnormalities on the WCST, whereas subjects with lesions of the dorsolateral frontal convexity showed other cognitive impairments such as attentional problems and memory problems.

In countries where psychosurgery is applied it is advised that an independent multidisciplinary legally constituted review board selects patients who apply for psychosurgery (Rosenfield and Lloyd, 1999).

Conclusion

The SSRIs have demonstrated efficacy in the treatment of OCD while the 5-HT agonists have shown equivocal results. Data from studies of the 5-HT antagonists in patients with OCD suggest that these agents may be useful as augmenting agents in treatment-refractory patients. However, drugs such as risperidone and olanzapine have mixed serotonergic and dopaminergic functions and the efficacy of these agents in OCD may be correlated with their action on more than one neurotransmitter.

Until recently, the placebo response in many studies using antidepressants in OCD has been very low (5–10%). In more recent studies, higher placebo responses were observed (up to 30%). The reason for this could be that patients who participated in the original clomipramine studies could distinguish placebo from clomipramine because of the severe side-effects. It is possible that the newer drugs can be less clearly distinguished from placebo thus yielding a greater placebo response. Lastly, it is conceivable that due to competing studies investigators may be inclined to include patients with mild OCD.

GENERALIZED ANXIETY DISORDER (GAD)

Introduction

Since 1968, the diagnostic and statistical manual, second edition (DSM-II) delineated anxiety neurosis. This category was abolished in the DSM-III from 1980, in which generalized anxiety disorder (GAD) and panic disorder were delineated. In the DSM-III GAD was considered a 'residual' mental disorder which was diagnosed by exclusion. In the DSM-III-R it was defined by the presence of excessive/unrealistic worry as the core symptoms plus additional associated anxiety symptoms. In the DSM-IV, GAD was redefined to include the A-criterion symptoms of excessive uncontrolled anxiety and worry for at least 6 months plus three or more additional somatic and psychological anxiety symptoms (which is consistent with ICD-10 criteria). These include among others: muscle tension, restlessness, fatigue, difficulty in concentrating, irritability, and sleep disturbance.

Usually GAD is considered to be a chronic disorder. The study by Yonkers *et al.* (1996) of 166 GAD patients reported a man duration of GAD of more than 20 years and a likelihood of GAD symptom remission of only 15% and 25% at 1 and 2 years, respectively. This chronicity is consistent with a previous study of a large group of anxiety disorder patients with different diagnoses which reported that GAD patients were symptomatic for 56% of their lives after onset compared with much lower proportions in anxiety disorders traditionally thought to be more severe (Roy-Byrne, 1996) (16% for panic and 29% for agoraphobia with panic).

Differences in Cognitions between GAD and PD: the Role of Worrying

McNally (1994) considered that the distinction between GAD and panic disorder in DSM-III-R was blurred in two ways. Firstly, eliminating the diagnostic hierarchies of DSM-III allowed for very high rates of comorbidity, and revealed that GAD was rarely diagnosed as a single disorder. Secondly, unexpected panic attacks often occur in GAD patients, but few of these patients suffer from panic disorder (Sanderson and Barlow, 1990). The most important worry for PD patients is focused on fear of having another panic attack, as opposed to any other worry (Adler *et al.*, 1989; McNally, 1992, 1994). Worry in GAD patients is usually associated with exaggerated predictions of external catastrophic events (Borkovec and Roemer, 1995; Lydiard, 2000).

In view of the high degree of comorbidity associated with GAD, it has been argued that GAD could be a trait-like 'platform' that sets the stage and confers the vulnerability for the development of major depression, panic and other anxiety disorders. Recent evidence, however, challenged this notion and suggests that initial concerns about extremely high degrees of comorbidity among patients with GAD are misplaced. Wittchen and co-workers showed that comorbidity is a high predictor of help-seeking behaviour in patients with GAD indicating that in earlier studies this sample was over-represented and constitutes a selection bias (Wittchen *et al.*, 1994). In a recent review Kessler (2000) concluded that GAD does not stand out in any particular way with respect to other disorders in predicting other anxiety or depressive disorders (see also Wittchen *et al.*, 2000). Therefore there is no reason to question the validity of GAD as a separate disorder, because this doubt should also apply to any other anxiety or mood disorder.

Benzodiazepines in GAD

Benzodiazepines (BDZs) are frequently prescribed for the treatment of GAD by general practioners. They are widely accepted by both patients and general practitioners because of their rapid onset of action and good tolerability. However, withdrawal symptoms hamper successful discontinuation after prolonged treatment and thus BDZs should not be recommended as first-line monotherapy for the long-term management of anxiety disorders. Interestingly, several studies have shown that BDZs are effective on specific GAD symptoms such as somatic/autonomic symptoms in contrast to the psychic symptoms cluster including apprehensive worry and irritability (for review see Connor and Davidson, 1998). Side-effects of BDZs include sedation, memory difficulties, additive effects on alcohol and severe withdrawal reactions. Several treatment strategies such as cognitive therapy (Otto *et al.*, 1993) and concomitant prescribing of pharmacological agents like carbamazepine (Schweizer *et al.*, 1991) have been employed to assist patients to overcome their severe withdrawal syndrome induced by tapering off BDZs. In a recent study Rickels *et al.* (2000a) studied 107 patients with GAD who were long-term BDZs users. They were enrolled in a BDZs withdrawal programme assessing the efficacy of concomitant imipramine (mean dose: 180 mg per day) vs buspirone (mean dose: 38 mg per day) in a double-blind placebo controlled study. The success of the taper was significantly higher for patients treated with imipramine (82.6%), compared to either buspirone (success rates of taper 67.9%) and placebo (success rate taper: 37.5%). There is also evidence that prior treatment with BDZs is a negative predictor for therapeutic effects of subsequent treatment with buspirone. In a recent study DeMartinis and co-workers (2000) found that clinical improvement with buspirone was similar to BDZs treatment in GAD if patients had no prior treatment of BDZs. When patients were recently treated with BDZs, the effects of buspirone could not be distinguished from placebo.

During the last few years many studies have been performed using SSRIs, dual action antidepressants, 5-HT_{1A} receptor agonists and mixed SSRI/$5HT_{2A/C}$ receptor antagonists like nefazodone in the treatment of GAD. Older antidepressants like imipramine have also been shown to reduce anxiety in patients with GAD, although few clinicians would favour imipramine due to its severe side-effect profile compared to modern antidepressants. Based upon a large review of the published randomized double-blind studies up to 1997, Casacalenda and Boulenger (1998) concluded that imipramine, trazodone and paroxetine displayed similar efficacy in the treatment of GAD. At that time there was, however, a paucity of data of the effects of SSRIs and dual action antidepressants in GAD.

In a recent study it was found that clinical improvement with imipramine in GAD was present in patients with the lowest plasma levels of desipramine. In addition, there was a strong relationship with desipramine and anticholinergic levels, indicating that imipramine may have properties that result in physiological states counteracting its therapeutic effects (McLeod *et al.*, 2000). In addition, there are tolerability limitations using TCAs like imipramine and clomipramine in the treatment of GAD (Wingerson, Nguyen and Roy-Byrne, 1992).

Selective Serotonin Reuptake Inhibitors

There have been few studies to date on the use of the SSRIs in the treatment of GAD. Rocca and colleagues investigated the

efficacy of paroxetine, imipramine and 2′-chlordes-methyldiazepam in 81 patients with GAD (Rocca *et al.*, 1997). Both paroxetine and imipramine treatment resulted in more improvement than 2′-chlordes-methyldiazepam by the fourth week of treatment as measured by HAM-A and COVI Anxiety Rating Scale (CARS). At the end of the study, 68% of patients in the paroxetine group, 72% of those in the imipramine group, and 55% of those in the 2′-chlordes-methyldiazepam group showed a decrease of 50% or more on the HAM-A score. The efficacy of paroxetine in GAD (defined according to DSM-IV criteria) was evaluated in three other placebo-controlled 8-week studies and a long-term (32 week) relapse prevention study. In a multicentre study in 331 patients suffering from GAD paroxetine was found to be statistically superior to placebo on the HAM-A ($p < 0.01$). In addition, impairments in family and social life were beneficially influenced by paroxetine as assessed with the Sheehan disability Scale (McCafferty *et al.*, 2000). In a study in 566 GAD patients the results of treatment with placebo or paroxetine on the HAM-A and health related quality of life was investigated using the EuroQol (EQ)-5D questionnaire. This group reported that patients treated with 20 and 40 mg paroxetine not only showed significantly larger reductions in the HAM-A ($p < 0.001$), but also that improvement in GAD symptomatology is accompanied by improvement in health-related quality of life (Bellew *et al.*, 2000a, 2000b). The final multicentre study in 372 GAD patients treated with paroxetine or placebo provides supportive data for the efficacy of paroxetine in the treatment of GAD (SKB, data on file).

Stocchi and associates (2001) also studied the long-term efficacy of paroxetine (20–50 mg) in 652 patients with GAD. Patients received paroxetine (20–50 mg) for 8 weeks. Patients whose CGI scores had decreased by at least two points (to a score of three or less) at the week 8 visit were then randomized to double-blind treatment with either paroxetine ($n = 278$) or placebo ($n = 288$) for a period of 24 weeks. The results of this study showed that significantly fewer paroxetine- than placebo-treated patients (10.9% vs 39.9%, respectively, $p < 0.001$) relapsed during the 24 weeks of double-blind therapy indicating that anxiolytic efficacy in GAD is maintained during long-term treatment.

Dual Action Antidepressants in GAD

Venlafaxine

The therapeutic potential of venlafaxine extended release (XR) has been investigated in GAD and venlafaxine XR is the first antidepressant which has been registered for this indication. Three large placebo-controlled multicentre studies have been performed using venlafaxine XR in the treatment of GAD (for review see Hackett, 2000). A summary of these studies is shown in Table XIX-13.2.

The main conclusion of the 6-month flexible-dose study of Gelenberg and co-workers (2000) is that venlafaxine XR was significantly more effective than placebo on the main efficacy measures. Hackett, Parks and Salinas (1999a) performed a 24-weeks fixed-dose study of venlafaxine XR and found significant reductions of the HAM-A which were apparent after two weeks of treatment (for dosages and other details, see Table XIX-13.2). In a study with a similar design but a shorter study period Rickels *et al.* (2000b) found beneficial effects of venlafaxine XR in GAD. In addition there are two comparative studies with buspirone and diazepam as comparators (Davidson *et al.* 1999; Hackett, Desmet and Salinas, 1999b [the latter study is only available as a poster-presentation]).

In an 8-week randomized double-blind placebo-controlled multicentre study, venlafaxine XR (75 or 150 mg) was compared to buspirone 30 mg per day. At endpoint, there was a higher mean reduction in the main efficacy variable (HAM-A) in the venlafaxine-treated patients, but the difference with buspirone was not statistically significant (for detailed discussion, see Barman Balfourand and Jarvis, 2001). Reductions in psychic anxiety scores and score for anxious mood and tension were significantly lower for venlafaxine XR treated patients compared to placebo. The effects of buspirone on these measures, however, were not statistically different from placebo.

In sum, venlafaxine is the first antidepressant to be approved by the Food and Drug Administration of the USA and authorities in Europe for the treatment of GAD. It appears to be consistently better than placebo in the treatment for GAD in terms of inducing reductions of psychometric scales measuring severity of anxiety symptoms. There is substantial evidence from long-term studies that this improvement sustained over 6 months of treatment. Further studies are warranted to establish whether this improvement remains in time and contributes to improvements in the quality of life of these patients.

Mirtazapine

There is only one study in which mirtazapine was studied in GAD. In this open-label study patients with a DSM-IV diagnosis of major depressive disorder with comorbid GAD were prescribed mirtazapine for 8 weeks. In addition to its antidepressant effects, mirtazapine led to a significant reduction on the Hamilton Anxiety Rating Scale, indicating that mirtazapine could have potential value in the treatment of GAD (Goodnick *et al.*, 1999).

5-HT Agonists

Buspirone has been shown to be effective in the treatment of GAD in the short term. A 4-week single-blind study of 23 patients with GAD showed that, when titrated to a daily dose of 30 mg, buspirone provided effective anti-anxiety therapy as assessed by standard psychometric rating scales (Cohn, Wilcox and Meltzer, 1986). It needs to emphasized, however, that several of the studies of buspirone were conducted before proper criteria for GAD were defined, and therefore it cannot be stated that buspirone is effective in GAD according to DSM-IV criteria, because there simply are no studies of buspirone treatment in GAD according to DSM-IV criteria.

Concomitant depression occurs in at least 50% of patients with a primary diagnosis of GAD. A composite analysis of five placebo-controlled studies with buspirone in 382 patients with major depression and associated GAD showed significant improvements in anxiety (Robinson *et al.*, 1990). Interestingly, a 6-week, placebo-controlled efficacy study with buspirone in 121 patients with GAD and mild depression reported a significant reduction from baseline in anxiety and depression for patients on buspirone in comparison to those on placebo (Sramek *et al.*, 1996). In addition, a double-blind study in patients with GAD and depression showed that buspirone was equally effective as diazepam in reducing both anxiety and depression (Feighner *et al.*, 1982). These results suggest that buspirone may be suitable for the treatment of patients with GAD and comorbid depression. Furthermore, a meta-analysis of eight placebo-controlled studies in 520 patients with GAD demonstrated significant improvements over baseline for anxiety and depression for patients on buspirone in comparison with those on placebo (Gammans *et al.*, 1992). Similar results were also obtained when the efficacy of buspirone was assessed in comparison with clorazepate (Goldberg and Finnerty, 1982) and alprazolam (Enkelmann, 1991).

Gepirone is also effective in the treatment of GAD, however it has been suggested that the anxiolytic response to gepirone may be delayed: an 8-week, double-blind study in 198 patients

Table XIX-13.2 Efficacy of once-daily venlafaxine XR (VEN) in patients with generalized anxiety disorder without comorbid major depressive disorder in multicentre, randomized, double-blind, placebo-controlled studies

with GAD reported that clinical improvement was significant from week 6 for patients on gepirone compared with significant relief from week 1 onwards for patients on diazepam (Rickels *et al.*, 1997). A 5-week, placebo-controlled, dose-finding efficacy study in 267 patients with GAD has also suggested that ipsapirone represents a viable treatment option for GAD (Cutler, Hesselink and Sramek, 1994).

In a recent study weak anxiolytic effects were observed of the 5-HT_{1A} receptor agonist lesopitron in a double-blind placebo-controlled study vs lorazepam (Sramek *et al.*, 1996; Fresquet *et al.*, 2000). These findings need replication in larger trials.

In terms of long-term therapy, buspirone has been demonstrated to be effective as maintenance therapy: a 12-month, open study in 700 patients with GAD reported a significant reduction in anxiety in patients treated with buspirone (Feighner, 1987).

5-HT Antagonists

Early evidence with the 5-$HT_{2A/2C}$ receptor antagonist ritanserin indicated that it may be an effective anxiolytic agent: 24 patients with GAD treated for 6 weeks with ritanserin or lorazepam showed comparable improvements in symptoms (Bressa, Marini and Gregori, 1987). The efficacy of nefazodone was studied in an 8-week open trial in 21 patients with GAD. Fifteen of the patients completed the study, and of these 80% were rated as 'much' or 'very much' improved as measured by the CGI scale (Hedges *et al.*, 1996). Although promising, these results have not yet been substantiated in placebo-controlled, double-blind trials. Similarly, controlled data with the 5-HT_3 antagonist ondansetron are not yet available.

Conclusion

The 5-HT_{1A} agonists are the most studied of the serotonergic drugs in the treatment of GAD. It is questionable whether newly developed 5-HT1A receptor agonists like lepisetron will be able to conquer a niche in the treatment of GAD in view of the fact that several studies indicate that the efficacy of venlafaxine is better than buspirone. Evidence is also emerging for the efficacy of paroxetine in GAD, but further investigation is warranted for the SSRI drug class. Similarly, only preliminary data are available with the 5-$HT_{2/3}$ receptor antagonists.

SOCIAL ANXIETY DISORDER

Introduction

The majority of individuals will admit to recognizing an element of anticipatory anxiety on specific occasions when they are under public scrutiny, such as prior to giving a speech or playing a musical instrument; this has been called 'normal' social discomfort (Rosenbaum *et al.*, 1994). However, social anxiety disorder is the excessive fear harboured by some people that their performance or social interaction will be viewed as inadequate, to the point of causing them embarrassment or humiliation. These people experience extreme distress in, or will completely avoid, the feared social setting.

Social anxiety disorder is a common mental disorder, yet it is one of the least investigated and most misunderstood (Judd, 1994). Therefore, we will devote more attention in this introduction to diagnostic and epidemiological issues before we discuss the pharmacotherapeutic options. The avoidance of everyday social situations by patients with social anxiety disorder can cause considerable disruption to patients' work, relationships and normal functioning (Schneier *et al.*, 1992; den Boer, 1997; Lépine and Lellouch, 1995). Many patients with social anxiety disorder are single, divorced or separated (Magee *et al.*, 1996). In addition, they may have a lower educational attainment and a lower socioeconomic status; in an epidemiologic study, over 50% of patients with social anxiety disorder did not complete secondary school, more than 70% were in the lowest two quartiles in terms of socioeconomic status, and approximately 22% were receiving welfare payments, suggesting that they were unable to work (Schneier *et al.*, 1992). This level of functional disability imposes an economic burden on society, not only because of sufferers' financial dependency and lack of gainful productivity, but also because of the increased risk of suicide attempts, particularly if there is a comorbid disorder (Schneier *et al.*, 1992). This disabling condition therefore necessitates early recognition and treatment.

Defining and Diagnosing Social Anxiety Disorder

The updated DSM (DSM-IV) (APA, 1994) and the ICD-10 criteria can be used to define social anxiety disorder. Both criteria state that social anxiety disorder is a distinct disorder involving a marked fear or anxiety of behaving in an embarrassing or humiliating manner while under the gaze of other people, which then leads to avoidance of the situations that stimulate this fear (Lépine and Lellouch, 1995; den Boer, 1997). Two distinct subtypes of social anxiety disorder are recognized: non-generalized and generalized. Non-generalized social anxiety disorder involves one or two social or performance situations, such as public speaking, whereas individuals with generalized social anxiety disorder fear a multitude of social and performance situations (Heimberg *et al.*, 1990).

Other conditions from which social anxiety disorder should be distinguished are panic disorder, separation anxiety (in children), and atypical depression, although fear or avoidance of social or performance situations in a public setting should identify the patient with social anxiety disorder. Diagnoses of social anxiety disorder and avoidant personality disorder (APD) have arisen from different historical sources; however, the difference between these conditions has become indistinct with the introduction of the DSM-III-R criteria. Schneier *et al.* (1991) found that most (89%) of the patients with generalized social anxiety disorder were also diagnosed with APD. This co-occurrence of social anxiety disorder and APD may indicate a more severe form of social anxiety disorder (Holt, Heimberg and Hope, 1992).

Management Options

As the need for treatment of social anxiety disorder has been recognized only recently, optimum treatment strategies have not yet been defined. The SSRIs have been recommended as the pharmacologic treatment of choice (Ballenger *et al.*, 1998b) but the role of combined or sequential psychotherapeutic and pharmacologic treatment has still to be clarified (Heimberg, 1993). Drug treatment may relieve the symptoms of social anxiety disorder but habitual patterns of avoidant behaviour may take longer to respond; therefore, a combined strategy may be more effective than either alone (Marshall, 1992).

Pharmacological Approaches

Pharmacological treatment of social anxiety disorder has become established only in the past decade. The most recently investigated drug class is the SSRIs, for which there is growing support (Jefferson, 1995; van Ameringen, Mancini and Oakman, 1999a). Other explored drug classes include tricyclic antidepressants, monoamine oxidase inhibitors (MAOIs), benzodiazepines, and β-blockers (Davidson, 1998).

Table XIX-13.3 Summary of studies of SSRIs in patients with social anxiety disorder

Drug	Type of study	No. Patients	Outcome	Reference
Paroxetine	12 week, double-blind, placebo-controlled study	384	Relative to baseline, paroxetine produced significantly greater improvements than placebo in endpoint Leibowitz Social Anxiety Scale (LSAS) total scores ($p < 0.001$) for the 20 mg dose with similar degrees of improvement exhibited by the 40 mg and 60 mg doses. The proportion of responders CGI-I (score 1 or 2) was higher for paroxetine (20 mg 45%, 40 mg 47%, 60 mg 43%) than placebo (28%) with a statistically significant difference at the 40 mg dose.	Baldwin, 2000
Paroxetine	12-week, double-blind, placebo-controlled study	187	Relative to baseline, paroxetine produced significantly greater improvements than placebo in endpoint Liebowitz Social Anxiety Scale (LSAS) total scores ($p < 0.001$), subscale scores ($p < 0.001$), Social and Anxiety Distress Scale scores (SADS; $p < 0.001$) and Sheehan Disability Inventory social and work item scores (SDI; $p < 0.001$ and $p < 0.05$, respectively). The proportion of responders with paroxetine (55%) was significantly higher than with placebo (24%; $p < 0.001$) based on a CGI global improvement score of 1 or 2.	Stein *et al.*, 1998
	12-week, double-blind, placebo-controlled study	290	Patients receiving paroxetine experienced a significantly greater reduction in LSAS total score compared with placebo ($p \leq 0.001$). The proportion of responders (based on a CGI global improvement score of 1 or 2) in the paroxetine group was significantly greater than in the placebo group (65.7% vs 32.4%; $p < 0.001$). Paroxetine also produced significant improvements in social avoidance (as measured by the SADS) ($p < 0.032$) and in patients' family ($p < 0.001$), social ($p < 0.05$), and work ($p < 0.001$) lives (as measured by the SDI) compared with placebo.	Baldwin *et al.*, 1999
	Randomized, double-blind, placebo-controlled, 12-week trial	99	At week 12, 70.5% of paroxetine-treated patients and 8.3% of placebo-treated patients were responders ($p = 0.0001$). Paroxetine produced significantly greater improvements than placebo in endpoint LSAS total scores ($p = 0.0001$). Paroxetine was also significantly superior to placebo in terms of improvements in Brief Social Phobia Scale ($p = 0.0001$), Fear of Negative Evaluation Scale ($p = 0.0003$), and SDI work ($p = 0.0065$), social ($p = 0.0048$), and family life ($p = 0.0092$) scores.	Allgulander, 1999
	11-week, open study	36	23/30 patients (77%) were 'much' or 'very much' improved on the Clinical Global Impression scale. Baseline/Week 11 reductions on the Duke Social Phobia Scale and Liebowitz Social Phobia Scale were 36/20 ($p < 0.0005$) and 75/37 ($p < 0.0005$), respectively.	Stein *et al.*, 1996
	12-week, open study	18	Paroxetine produced an 83% response assessed by a moderate-to-marked symptomatic improvement on the Liebowitz Panic and Social Phobia disorders rating Scale.	Mancini and Ameringen, 1996
	12 week single-blind; 24 week double-blind	437	A significantly greater proportion of patients in the paroxetine group were 'much improved' or 'very much improved' (as assessed with the CGI) at the end of the study, and that significantly fewer patients relapsed with paroxetine (14%) compared to placebo (39%, $p < 0.001$) during the 24-week follow-up.	Hair *et al.*, 2000; Stein *et al.*, 2001
Sertraline	6-week, open study	24	After 4 and 6 weeks, sertraline produced significant improvements compared with baseline ($p < 0.05$) on the Davidson Brief Social Phobia Rating Scale and Clinical Global Impression Severity and Change scales. 58% responded to treatment.	Martins *et al.*, 1994
	12-week, open study	22	16/20 responded to treatment. All measures of social anxiety and functioning and depression significantly improved compared with baseline.	van Ameringen *et al.*, 1994
	20-week, randomized, double-blind, crossover study	12	Scores on the Liebowitz Social Anxiety Scale significantly improved with sertraline ($p = 0.001$) but not with placebo. 6/12 moderately or markedly improved while taking sertraline compared with 1/12 while taking placebo.	Katzelnick *et al.*, 1995
	12-week, open study	11	5/7 completers substantially responded to treatment.	Munjack *et al.*, 1994/95
Citalopram	12-week, open study	22	19 out of 22 were responders to treatment.	Bouwer and Stein, 1998

Table XIX-13.3 (*continued*)

Drug	Type of study	No. Patients	Outcome	Reference
Fluoxetine	12-week, open study	13	10 patients had a moderate-to-marked improvement independent of changes on the Beck Depression Inventory.	van Ameringen *et al.*, 1993
	6–40 weeks, open study	14	10 patients moderately or markedly improved.	Black *et al.*, 1992
	12 week, open study	20	13 out of 20 patients were responders.	Perugi *et al.*, 1995
Fluvoxamine	12-week, double-blind, placebo-controlled study with 12-week follow-up	30	Fluvoxamine significantly better than placebo on Symptom Checklist 90 ($p < 0.05$) and superior to placebo on social anxiety item of Social Phobia Scale. Further improvements observed during follow-up period.	van Vliet *et al.*, 1994
	Double-blind, randomized, placebo-controlled, 12-week trial	92	At week 12, 53.3% of the fluvoxamine group and 23.5% of the placebo group were responders ($p = 0.01$). Compared with placebo, fluvoxamine produced significantly greater improvements on the BSPS ($p < 0.05$), the Social Phobia Inventory (SPIN; $p < 0.05$), LSAS ($p < 0.05$), and the work and family life items of the SDI ($p < 0.05$).	Stein *et al.*, 1999

Serotonin-Selective Reuptake Inhibitors

Four large, double-blind, placebo-controlled 12-week trials and one long-term relapse prevention study have recently reported a significant improvement of patients with social anxiety disorder prescribed paroxetine compared with those given placebo (Allugander, 1999; Baldwin *et al.*, 1999; Stein *et al.*, 1999; Baldwin, 2000; Stein *et al.*, 2001). Two double-blind placebo-controlled trials of fluvoxamine have also demonstrated the efficacy of this SSRI against the symptoms of social anxiety disorder (Stein *et al.*, 1999; DeVane *et al.*, 1999). Data for other SSRIs are limited to mainly open and small scale trials. The results of open and double-blind studies using SSRIs to treat patients with social anxiety disorder are shown in Table XIX-13.3.

SSRIs also provide effective and well tolerated treatment for depression and panic disorder, both of which may be comorbid with social anxiety disorder. In a recent meta-analysis conducted along the methods set forth by the Cochrane Collaboration, van der Linden and co-workers (2000) concluded that SSRIs as a group were effective for the treatment of social phobia. In addition, SSRIs had a larger response-rate and effect-size compared to the reversible monoamine oxidase inhibitors. There is a paucity of data on the long-term pharmacotherapy of SAD. In order to study the effectiveness of long-term paroxetine treatment in the prevention of relapse in patients with SAD, Stein and co-workers (2001) studied 437 patients in a placebo-controlled, multicentre study. The study comprised a 12 week single-blind treatment phase (paroxetine 20–50 mg) with responders ($n = 323$) being randomized to double-blind treatment with paroxetine or placebo for a further 24 weeks. Stein and co-workers found that a significantly greater proportion of patients in the paroxetine group were 'much improved' or 'very much improved' (as assessed with the CGI) at the end of the study, and that significantly fewer patients relapsed with paroxetine (14%) compared to placebo (39%, $p < 0.001$) during the 24-week follow-up. This study lends support to the widely held belief that patients should at least be treated for a period of one year.

One study has recently been published on the efficacy of sertraline in SAD. In this study 204 patients suffering from SAD were randomly allocated to treatment with either placebo or sertraline (50–200 mg per day; van Ameringen *et al.*, 2001). As assessed with the social phobia subscale of the Marks Fear Questionnaire, 32.6% of the patients using sertraline and 10.8% using placebo were considered responders. The mean reductions of the score on the Brief Social Phobia Scale yielded statistical superiority of sertraline over placebo (34.3% and 18.6% respectively), indicating that also sertraline is an effective treatment for SAD.

There is hardly any information about the efficacy of dual action antidepressants in social phobia. In a 12-week open-label study in which the effects of mirtazapine were evaluated in 16 patients van Vliet and co-workers (2000) found significant reductions in social anxiety and avoidance. Further placebo-controlled studies are necessary to confirm these preliminary findings.

Tricyclic Agents

Studies published more than 20 years ago reported positive results for clomipramine in the treatment of phobic disorders (Beaumont, 1977; Gringras, 1977). However, these were open studies and the patient population was not well defined. A further small study found that clomipramine significantly improved some aspects of social anxiety disorder and agoraphobia compared with diazepam but the patient population was again ill-defined (Allsopp, Cooper and Poole, 1984). A recent small open trial of imipramine did not support its efficacy as a treatment for social anxiety disorder (Simpson *et al.*, 1998).

Monoamine Oxidase Inhibitors

Double-blind, placebo-controlled trials have shown that patients with social anxiety disorder respond better to phenelzine, an irreversible MAOI) than with alprazolam (Gelernter *et al.*, 1991) atenolol (Liebowitz *et al.*, 1992) or placebo (Gelernter *et al.*, 1991; Liebowitz *et al.*, 1992). Earlier studies also suggested that phenelzine was more effective than placebo but these studies suffered from methodologic problems, making interpretation of the results difficult (den Boer, van Vliet and Westenberg, 1995). However, the use of phenelzine is limited due to the potentiation of the tyramine pressor effect, which can lead to hypertensive crises.

Conflicting results have been obtained with reversible MAOIs, such as brofaromine and moclobemide, which do not exhibit the tyramine pressor effect. Brofaromine appeared to significantly improve the symptoms of social anxiety disorder compared with placebo (van Vliet, den Boer and Westenberg, 1992; Lott *et al.*, 1997) but is now no longer in development. Moclobemide also appeared to be statistically significantly more effective than placebo after 8 weeks' treatment in a small double-blind study (Versiani *et al.*, 1992) and a large ($n = 578$), 12-week trial in patients with social anxiety disorder (The International Multicenter Clinical Trial Group on Moclobemide in Social Phobia, 1997). However, a further large ($n = 583$), 12-week, double-blind, placebo-controlled

trial in patients with social anxiety disorder failed to find a significant difference between moclobemide and placebo (Noyes *et al.*, 1997).

Benzodiazepines

Clonazepam and alprazolam have been evaluated in a few open studies and found to be effective in social anxiety disorder (Davidson, Tupler and Potts, 1994). Bromazepam was significantly superior to placebo in a 12-week double-blind study (Versiani *et al.*, 1997). In small controlled trials, clonazepam was significantly superior to placebo (Davidson *et al.*, 1993) while alprazolam was also superior to placebo, but inferior to phenelzine (Gelernter *et al.*, 1991). However, the putative efficacy of phenelzine in social anxiety disorder may partly be due to its sedative effect rather than due to true anxiolysis. Furthermore, since alcohol abuse is a common comorbid condition in social anxiety disorder, benzodiazepines should be avoided due to the risk of excessive sedation. Long-term use may also lead to dependency.

Beta-Blockers

Beta-blockers may alleviate anxiety as a secondary consequence of the reduction in autonomic symptoms (tremors, palpitations). These drugs have been effective in the short-term for performance anxiety (Laverdure and Boulenger, 1991; den Boer, van Vliet and Westenberg, 1994; Jefferson, 1996). Despite promising early work with atenolol, subsequent investigations have not established efficacy for β-blockers in generalized social anxiety disorder (den Boer, van Vliet and Westenberg, 1994).

Other Drugs

A recent randomized placebo-controlled trial involving 69 patients demonstrated the efficacy of the anticonvulsant, gabapentin, in the treatment of social anxiety disorder (Pande *et al.*, 1999). After 14 weeks of treatment, patients receiving gabapentin experienced a significant reduction in the symptoms of social anxiety disorder compared with those receiving placebo. In an open trial of nefazodone, 69% of patients ($n = 23$) showed moderate or marked improvement after 12 weeks of treatment (van Ameringen, Mancini and Oakman, 1999b). Venlafaxine has also produced improvements in social anxiety disorder symptoms in a small open study involving 12 patients (Altamura *et al.*, 1999). Larger placebo-controlled trials are required to fully determine the efficacy of these agents.

Non-Pharmacologic Approaches

Cognitive-Behavioural Therapy

Cognitive-behavioural treatment aims to help people to overcome anxiety reactions in social and performance situations and to alter the beliefs and responses that maintain this behaviour.

One type of treatment, cognitive-behavioural group therapy, is given in 12 weekly sessions, each lasting about two and a half hours. It has six elements: cognitive-behavioural explanation of social anxiety disorder; structured exercises to recognize maladaptive thinking; exposure to simulations of situations that provoke anxiety; cognitive restructuring sessions to teach patients to control maladaptive thoughts; homework assignments in preparation for real social situations; and a self-administered cognitive restructuring routine (Heimberg and Juster, 1994).

Cognitive-behavioural group therapy was associated with long-term benefit in moderately impaired patients, and compared well with pharmacologic treatment (phenelzine, alprazolam) (Heimberg, 1993). Group therapy has been shown to be an effective treatment of social anxiety disorder in comparison with control groups or pill placebo (Heimberg and Juster, 1994; Donohue, van Hasselt and Hersen, 1994).

Impact of Comorbidity on Treatment Strategies

Comorbidity may reflect a more severe psychopathology, with more disability and impaired functioning than in the absence of comorbidity. This may create the expectation of a more difficult treatment course and a less favourable outcome, resistance to treatment, the need to treat each disorder effectively, and extended or long-term maintenance treatment to prevent relapse (Rosenbaum and Pollock, 1994).

Empirically, there are four general principles for dealing with comorbid disorders: tailor treatment to individual patients; use monotherapy in preference to polypharmacy, provided that the chosen drug is effective in both disorders and the comorbid disorder is secondary to the social anxiety disorder; consider compatible drugs for some patients; and administer a combination of psychotherapy and pharmacotherapy (Rosenbaum and Pollock, 1994). Social anxiety disorder comorbid with alcoholism is a special case because of the risk of excessive sedation with concomitant medication (benzodiazepines, for example), and patients should be carefully questioned about their use of alcohol, as well as the amount and the pattern of intake (Marshall, 1994). Comorbidity affects the choice of treatment, as well as its efficacy. A treatment scheme for comorbid conditions is outlined in Table XIX-13.4 (Jefferson, 1995).

Table XIX-13.4 Treatment scheme for comorbid conditions

Disorder	Suggested treatment		
Social anxiety disorder and major depression	SSRI or MAOI		
Social anxiety disorder and panic disorder	SSRI, MAOI or benzodiazepine		
	One drug/both disorders	*One drug per disorder*	*Combined approach*
Social anxiety disorder and obsessive–compulsive disorder (OCD)	SSRI or MAOI	Clonazepam for social anxiety disorder, clomipramine for OCD	SSRI, clomipramine or MAOI and behaviour therapy
Social anxiety disorder and alcoholism	—	SSRI for social anxiety disorder, disulfiram for alcohol abuse	SSRI, disulfiram and Alcoholics Anonymous
Social anxiety disorder with *no* comorbidity	—	—	SSRI, MAOI or benzodiazepine (with or without cognitive-behavioural therapy)

Based on Rosenbaum and Pollock, 1994; Jefferson, 1995.

Conclusions

Social anxiety disorder was recognized as a condition separate from other phobias and panic disorders as recently as the 1960s (Marks and Gelder, 1966). Three decades later, there is still much to learn about the causes and treatment of the disorder.

While social anxiety disorder is common in the general population, it is probably under-reported in general practice because, by its very nature, patients are reluctant to seek treatment. The delay in seeking help for social anxiety disorder may lead to the development of other psychiatric disorders such as major depression, and consequently a greater disability and risk of suicide. In addition, the inability of the patient to function as a normal, productive member of the community places an economic burden on the sufferer and on society. Early diagnosis and treatment of social anxiety disorder may help to alleviate the burdens imposed by the condition.

Optimum treatment strategies for social anxiety disorder have not been clearly defined. However, no one would disagree that treatment should be aggressive in view of the potential disability caused by the disorder. SSRIs show the most promise for the treatment of social anxiety disorder.

POST-TRAUMATIC STRESS DISORDER

There is a sparse but expanding literature on treatment options for PTSD. Most studies in PTSD have been performed in combat-related trauma victims and other serious traumas including rape, sexual molestation and assault. Until recently, the role of pharmacotherapy in PTSD was more of an adjunctive therapy to alleviate depressive and other comorbid symptoms. During the last few years, however, several double-blind studies have been performed which studied the effects on core symptoms of PTSD.

There is a great need for better treatments in this disorder as a recent study has shown that in spite of consistent treatment efforts, more than 30% of patients with episodes of PTSD do not recover even after several years (Kessler *et al.*, 1995). It was recommended by the Expert Consensus Panel for PTSD that the first-line treatment should be psychotherapy, whereas in cases complicated by comorbid psychiatric conditions (which is often the case) a combination of psychotherapy and pharmacotherapy is recommended (The Expert Consensus Panel on PTSD, 1999). PTSD is characterized by different groups of symptoms: intrusive thoughts (recurrent flashbacks and nightmares), avoidance behaviour (active avoiding memories of the traumatic events, numbness) and hyperarousal (insomnia, concentration difficulties). These symptoms are rather specific for PTSD, but it should not be overlooked that many patients also report other symptoms not assessed by DSM-IV criteria such as feelings of shame and guilt and ruminations on existential fear (Wenzel *et al.*, 2000).

Together with the high degree of comorbidity there is the issue of symptom subtypes. If the different symptom-complexes are mediated by different underlying neurobiological systems, it is conceivable that they respond to different psychotropic drugs. Considering the limited number of studies in PTSD this question will be difficult to answer. In addition, we still do not know which scales are the most useful in establishing effective pharmacotherapy in PTSD.

Tricyclics and MAO-Inhibitors in PTSD

Older antidepressants like amitryptiline and desipramine have been shown to be only slightly better than placebo (Davidson *et al.*, 1990; Reist *et al.*, 1989). Only depressive symptoms associated with PTSD responded to treatment in these studies.

The irreversible and nonselective MAOI phenelzine was found to be effective in a number of studies. In comparative studies versus imipramine and placebo in male veterans, phenelzine led to significant improvements in intrusive thought and nightmares. Emotional numbing, however, was not affected (Frank *et al.*, 1988; Kosten *et al.*, 1991). Needless to say, the dietary restrictions posed upon patients during treatment with phenelzine are a disadvantage to this type of drug. The newer generation of MAO-A inhibitors, for which dietary restrictions are not necessary, has been scarcely investigated in PTSD. There are some controlled studies with brofaromine in PTSD with mixed results (e.g. Baker *et al.*, 1995), but since brofaromine has not been registered these studies will not be discussed. Moclobemide, another selective and reversible MAO-A inhibitor which has been marketed for depression was investigated in a 12-week open-label study in 20 patients suffering from PTSD (Neal, Shapland and Fox, 1997). Typical PTSD symptoms subsided and symptoms severity was diminished in most of the patients. Double-blind placebo controlled studies have, however, not been performed with moclobemide.

Benzodiazepines

The use of BDZs in PTSD has been described by several authors, but there are hardly any well designed studies. Clonazepam was found to reduce anxiety and depression in an open-label study (Lowenstein *et al.*, 1988). In a 5-week crossover trial, Braun *et al.* (1990) studied the efficacy of alprazolam in a mixed population ($N = 16$) of therapy-resistant combat-related and civilian PTSD patients. Alprazolam dosages were increased up to 6 mg per day. Although a modest anxiolytic effect (measured with the HAM-A) was described, alprazolam failed to improve typical PTSD symptoms.

SSRIs in the Treatment of PTSD

Fluvoxamine has been studied in three small studies in PTSD: two trials were conducted in war veterans and one in civilians; all studies used an open-label design and included only a small number of patients (Marmar *et al.*, 1996; Davidson *et al.*, 1998; de Boer *et al.*, 1992). The results of these studies suggest that fluvoxamine can diminish the severity of specific PTSD symptoms such as survival guilt, nightmares, insomnia, intrusive recollections and fear. Placebo-controlled studies of fluvoxamine in PTSD are warranted to evaluate the potential role of fluvoxamine in PTSD.

Fluoxetine has been more extensively investigated in PTSD. There are both open-label and double-blind placebo-controlled studies evaluating the effects of fluoxetine in PTSD. Here we will confine the discussion to the placebo-controlled studies. Van der Kolk and co-workers (1994) conducted a 5-week placebo-controlled study and found that fluoxetine was significantly more effective in both combat veterans and civilian casualties. They found the typical PTSD symptoms to respond to treatment with fluoxetine: numbing and arousal. Interestingly, the treatment effect was most robust in the civilian group who suffered from acute traumas, indicating that fluoxetine is perhaps less effective in chronic PTSD. In a more recent study Connor *et al.* (1999a) included 54 civilian PTSD patients (most notably females) and found that fluoxetine up to 60 mg per day had beneficial effects on all typical PTSD symptoms. In a reanalysis of the data it was found that fluoxetine has a broad spectrum effect on the symptomatology of PTSD. The symptoms who were found to be most responsive to treatment with fluoxetine were: being physically upset at reminders of the trauma, avoiding thoughts of the trauma, anhedonia, feeling distant and impaired concentration (Meltzer-Brody *et al.*, 2000). A recent small placebo-controlled study also reported improved quality of

life as a result of fluoxetine treatment as assessed with the Short-Form Health Survey (SF-36; Malik *et al.*, 1999). In a small placebo-controlled study in severe PTSD male combat veterans fluoxetine could not be distinguished from placebo, indicating that severity or gender could influence treatment outcome (Hertzberg *et al.*, 2000).

Two open-label studies evaluated the effects of sertraline in PTSD and most of the core PTSD symptomatology showed a significant decrease (Brady, Sonne and Roberts, 1995; Rothbaum, Ninan and Thomas, 1996). In a 12-week double-blind placebo-controlled multicentre study Brady *et al.* (2000) studied the efficacy of sertraline (50–200 mg per day) in 187 outpatients suffering from non-combat-related PTSD. On three of the main efficacy parameters (Clinician Administered PTSD-scale; Clinical Global Impression Severity and Improvement Scales), sertraline showed a significantly better treatment effect compared to placebo. Around 53% of the patients were considered responders to treatment with sertraline and 32% responded to placebo. Significant efficacy was evident for sertraline on symptoms of avoidance/numbing, increased arousal, but not on re-experiencing traumatic events. Davidson and co-workers (2001) included 208 outpatients suffering from PTSD in a double-blind placebo controlled study. Although their study was not powered enough to evaluate clinical variables such as sex, type of trauma, duration of illness, or presence of comorbidity on treatment response, they reported a 60% response-rate for sertraline and a 38% response rate for placebo.

It has been argued that repeatedly responding to PTSD-related questions can possibly evoke an element of exposure and desensitization (Krakow, Hollifield and Warner, 2000). Thus, since there was a considerable placebo response in this study, this might have been achieved by covert cognitive-behavioural therapy. If this were true, then this reasoning should also apply to other syndromes for which CBT is an effective treatment (e.g. PD, OCD) and since many placebo-controlled studies have been performed yielding significant differences between active treatment and placebo it is almost impossible to disentangle the relative contribution of 'covert' CBT to the treatment. Nevertheless, in PTSD there is a need for studies exploring the interface between pharmacotherapy and psychotherapy.

Paroxetine was found to be effective in a small open-label study in chronic non-combat-related PTSD (Marshall *et al.*, 1998). All typical symptom clusters were improved and there were also beneficial effects of paroxetine on anxiety and depression-scores. Very recently, a number of placebo-controlled studies has been conducted with paroxetine in PTSD. Ruggiero and associates (2001) included 307 patients suffering form PTSD according to DSM-IV criteria in a flexible-dose study. As primary efficacy parameters they used the clinician administered PTSD scale (CAPS-2) and the Clinical Global Impression Scale. Their study showed that paroxetine in a dosage of 20–50 mg was more efficacious than placebo in reducing the symptom clusters of the CAPS-2 and in improving psychosocial functioning. In a 12-week double-blind fixed dose study in 550 outpatients with PTSD, Beebe and co-workers (2000) found paroxetine (20 and 40 mg) to be effective in reducing PTSD symptoms in all symptom domains including re-experiencing, avoidance, intrusion and hyperarousal. A further 12 week double-blind flexible-dose (20–50 mg per day) in 322 outpatients with PTSD showed similar efficacy (unpublished data). Interestingly, when PTSD patients were exposed to individual trauma scripts, another group found autonomic functioning (heart rate and blood-pressure) to be improved after treatment with paroxetine in a 10-week open-label study (Tucker *et al.*, 2000), indicating that a wide range of PTSD symptoms are affected by paroxetine.

In view of the repeatedly reported finding that PTSD patients often suffer from comorbid depression, Stein *et al.* (2001) pooled the data of the three mentioned double-blind placebo-controlled studies described here and found that both the depressed and the non-depressed subgroups showed a statistically significant improvement in the CAPS-total score and the CGI for paroxetine compared to placebo.

Dual Action Antidepressants in PTSD

There is only one small open-label study in which mirtazapine has been studied in PTSD. Six outpatients with chronic PTSD were treated with mirtazapine and three of them were responders (Connor *et al.*, 1999b). Due to the small sample any conclusion would be premature. One case study reported therapeutic effects of venlafaxine in a PTSD patient who did not respond to various serotonergic antidepressants (Hamner and Frueh, 1998).

Serotonin Receptor Antagonists in PTSD

There are a number of open studies in which therapeutic effects of trazodone and nefazodone in PTSD has been investigated. Trazodone was found to be effective in just one open-label study in six combat-related PTSD patients (Hertzberg *et al.*, 1996), but there are no published controlled studies of this compound. The therapeutic potential of nefazodone, an antidepressant which blocks 5-HT_2 receptors and 5-HT reuptake was studied in the beginning of the 1990s in six open-label studies (data pooled and reviewed by Hidalgo *et al.*, 1999). Both civilians and combat veterans were included in these studies, and results indicate beneficial effects on a broad range of typical PTSD symptoms. In chronic therapy-resistant Vietnam veterans, nefazone showed therapeutic effects in depression-scores and typical PTSD symptoms like intrusive recollection, avoidance and hyperarousal in an open-label study (Zisook *et al.*, 2000). Many patients with chronic combat-related PTSD also suffer from comorbid depression. Available evidence indicates that antidepressants affecting 5-HT reuptake are associated with a better outcome compared to compounds predominantly affecting noradrenalin reuptake (Dow and Kline, 1997).

A Role for Atypical Antipsychotics or Antiepileptics in PTSD?

In some cases of severe emotional turmoil in PTSD dopamine blockers can be prescribed and there are case reports indicating beneficial effects of atypical antipsychotics. Leyba and Wampler (1998) report therapeutic effects on nightmares and flashbacks in four cases of PTSD, and another case report describes the use of risperidone in the treatment of intrusive thoughts and subsequent emotional reactivity in combat-related PTSD (Krashin and Oates, 1999). Also in acute stress disorder after physical trauma, preliminary evidence indicates beneficial effects of risperidone on flashbacks (Eidelman, Seedat and Stein, 2000).

In view of the fact that symptoms of PTSD may point to sympathetic hyperarousal and hyperreactivity, it has been suggested that stress-induced limbic kindling could play a role. Consistent with this view is the reported efficacy in PTSD of carbamazepine and valproate. There are only a few open-label studies but all of them support the therapeutic efficacy of carbamazepine and valproate in this condition (Lipper, 1988; Wolf, Alavi and Mosnaim, 1988; Fesler, 1991; Looff *et al.*, 1995). More recently, Clark and co-workers (1999) studied divalproex in 16 combat-related PTSD patients and found reduced intrusion and diminished hyperarousal. Interestingly they also reported significant decreases in depression and anxiety.

Future Directions in the Treatment of PTSD

Based upon the studies described above there is evidence that rarely does a single medication benefit all symptom clusters equally or produce complete remission of the syndrome. Therefore it appears

reasonable to further study the role of specific classes of drugs for particular symptom clusters.

As mentioned before, there is also a need for combination studies using pharmacotherapy and psychotherapy. A number of studies have shown that applying CBT and other psychotherapeutic techniques can reduce core PTSD symptoms in both acute stress disorder and PTSD (Bryant *et al.*, 1998; Devilly and Spence, 1999; Hembree and Foa, 2000). These additional therapeutic strategies probably have additive or synergistic effects on ongoing pharmacotherapy as they focus on the processing of traumatic events, emotional engagement of the traumatic memory, the organization of the trauma narrative and correction of dysfunctional cognitions that often follow traumatic experiences. Therefore, studies combining pharmacotherapy and CBT are clearly needed.

In depression, several studies have suggested potential therapeutic effects of augmentation strategies. The number of augmentation studies in PTSD is limited. One study suggested modest effects of clonidine augmentation to imipramine (Kinzie and Leung, 1989), another open-label study suggested additive effects of buspirone augmentation to SSRIs (and other antidepressants) in combat-related chronic PTSD (Hamner, Ulmer and Horne, 1997). In order to evaluate the therapeutic potential of these augmentation strategies, placebo-controlled studies are warranted.

There is a growing body of literature indicating that there exist dysfunctions in the regulation of the hypothalamic-pituitary axis (HPA) in PTSD (Baker *et al.*, 1999). Dysregulation of CRH is regarded the key component of the human stress response. Based upon a growing body of neurobiological studies it has been shown that other key components of the stress response include changes in the adrenergic system, serotonergic system, neuropeptide Y, opioid system and glutamatergic system. In addition, kindling/sensitization could play a role in developing PTSD. Based upon these findings it has been suggested that in addition to SSRIs future treatment possibilities for PTSD could include CRH antagonists, neuropeptide Y, β-adrenergic blockers, substance P, drugs that influence NMDA receptors and antiepileptics (Friedman, 2000).

If indeed developments in pharmacotherapy of PTSD and other anxiety disorders would be based upon the pathophysiology of the disorder this could lead to a more rational drug design which would greatly influence clinical practice and contribute to the well-being of our patients.

EPILOGUE

Serotonergic drugs have been developed and extensively investigated during the last decade in a range of depressive and anxiety disorders. As a result, a clinical database has been formed which allows us to view, and compare, their efficacy.

Of the serotonergic agents examined in this review, the SSRIs stand out with proven efficacy in the treatment of a wide spectrum of disorders including depression, panic disorder, OCD, PTSD and social anxiety disorder. Initial results with paroxetine have indicated that it may also be a suitable treatment for GAD.

The 5-HT_{1A} agonists have been used extensively in the treatment of GAD and depression, but reports of their efficacy in the treatment of panic disorder, OCD and social anxiety disorder have been equivocal, although they may prove useful in these anxiety disorders as augmenting agents for SSRI treatment-refractory patients.

The 5-HT antagonists are the least well-studied of the agents and have not yet been fully investigated in many of the psychiatric disorders discussed in this article. While they may have activity in the treatment of depression, the initial results in the treatment of panic disorder are disappointing. There are insufficient data concerning the 5-HT antagonists in GAD and social anxiety disorder to draw conclusions on their efficacy in these disorders, but preliminary reports have suggested that the drug class may be of use as adjuvants to the SSRIs in treatment refractory patients with OCD.

Large scale epidemiological studies such as the National Comorbidity Survey have clearly demonstrated that the rate of comorbidity between depression and anxiety disorders is high. Therefore, pharmacotherapy which is effective against a broad range of depressive and anxiety disorders could be of considerable utility to clinicians. The activity profile of the SSRIs in the treatment of depression and anxiety make this class of drug an attractive option for initial monotherapy in these disorders.

It should be stressed, that despite their attractive therapeutic profile, SSRIs have unwanted side effects and that response rates in clinical studies vary between 50% (e.g. OCD) and 70% (e.g. major depression and PD). Future research should focus on much overlooked items, such as pharmacokinetics, sex and ethnic differences and response prediction. Moreover, a sensible combination of clinical and preclinical research into the biological mechanisms is likely to provide information to further enhance (augment) pharmacotherapy of anxiety and depressive disorders.

Psychobiology of Somatoform Disorders

Winfried Rief and Cornelia Exner

INTRODUCTION: UNEXPLAINED PHYSICAL SYMPTOMS AND THE HEALTH CARE SYSTEM

Unexplained physical symptoms are one of the major problems of the health care system. Depending on the medical setting under investigation, between 15% and 80% of doctor visits are due to persons with physical symptoms which cannot be accounted for by a clear organic cause. Most common symptoms are pains and aches, gastrointestinal complaints, and cardiovascular symptoms. Kroenke and Mangelsdorff (1989) demonstrated that only about 16% of the most common physical symptoms can be explained by a clear organic pathology. In their longitudinal study, patients with multiple unexplained physical symptoms and with an illness duration of more than four months had the worst prognosis. As will be shown below, unfortunately this is the most frequent combination of features in patients with somatoform disorders. Accordingly, this group of patients is one of the most expensive subgroups in the health care system. Fink (1992) analysed a subgroup of high utilizers of the health care system who had had at least ten inpatient treatments during the last eight years. He found that about 20% of these frequent hospitalizations were due to unexplained physical symptoms.

Some experts believe that illness behaviour is the most typical feature of somatization. Typical features of illness behaviour are frequent doctor visits, wandering around from doctor to doctor and from treatment unit to treatment unit, taking unnecessary medication, urging doctors to do unnecessary investigations which may lead to complications, avoidance behaviour and reduction of social activities, a high number of sick-leaves, and reduced social functioning. Health anxiety is a frequent, but not a necessary condition for the development and maintenance of unexplained physical symptoms. It is unclear whether these features are consequences of the disorder or else maintaining factors, or even the cause of additional physical problems.

Patients with somatoform disorders are also characterized by a specific cognitive–perceptual style. Barsky *et al.* (1993) emphasized that patients with hypochondriasis and somatoform symptoms have an over-exclusive concept of being healthy. They conceive health as a state of perfect physical well-being without any physical discomfort. However, physical discomfort is a common sensation even to healthy persons. Therefore persons with somatoform disorders are concerned about normal bodily perceptions; they focus their attention on bodily processes, which leads to an amplified perception of physical changes. This can encourage the interpretation of physical discomfort as illness symptoms.

While Barsky's concept of somatosensory amplification (Barsky and Wyshak, 1990) related primarily to patients with *hypochondriasis*, our own group demonstrated that patients with somatization syndromes without *hypochondriasis* also tend to catastrophize their perception of physical processes (Rief *et al.*, 1998). Patients with somatization syndromes have a bias to interpret minor physical changes (e.g., heart beat acceleration while taking a hot bath) as a possible sign of a severe illness (e.g., cardiomyopathy). This cognitive–perceptual style leads to the behavioural consequences described above. Moreover, the cognitive and behavioural features of somatization interact with biological properties of the disorder and maintain a vicious circle (see Figure XX.1). Affective consequences such as demoralization, negative affectivity, or depression might present a negative feedback loop that helps to maintain the problem.

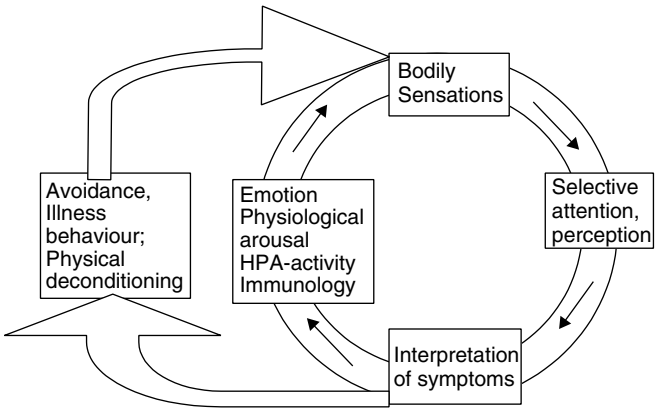

Figure XX.1 Somatization from a cognitive–psychobiological perspective (Rief and Nanke, 1999)

SYNDROMES OF SOMATIZATION AND THEIR CLASSIFICATION

The common feature of the somatoform disorders is the presence of physical symptoms which are not fully explained by a general medical condition, by the direct effect of a substance, or by another mental disorder. The symptoms must cause clinically significant distress or impairment in social functioning. Seeking medical help or para-medical consultation is very frequent. Historically, these syndromes have been labelled 'hysteria', a term which is presently less used because of stigmatizing effects.

Despite the fact that single physical complaints are very common, persons with multiple physical complaints represent the most serious subgroup for the health care system. The Diagnostic and Statistical Manual of Mental Disorders (DSM-IV) (APA, 1994) suggests the diagnosis of *somatization disorder* for polysymptomatic pictures of somatization. The disorder starts typically before age 30 years, extends over a period of years and is characterized by a

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

combination of pain, gastrointestinal, sexual, and pseudoneurological symptoms. Eight physical symptoms out of a list of 33 suggested symptoms have to be present or had to be present in medical history. While persons with multiple somatoform symptoms are very frequent, especially in medical settings, they only rarely fulfil the complete criteria of *somatization disorder*. This is one of the most critical points concerning current classification rules of *somatization disorder*. Therefore, following DSM-IV, most patients with polysymptomatic somatoform complaints are diagnosed in the two rest categories *undifferentiated somatoform disorder* or *somatoform disorder not otherwise specified*.

Another subgroup of somatoform disorders refers to clinical pictures with a circumscribed physical symptomatology. The most frequent diagnosis of this subtype is *pain disorder*. To fulfil the criteria for this diagnosis, pain in one or more anatomical sites has to be the predominant focus of the clinical presentation; the pain causes clinically significant distress or impairment, and psychological factors are judged to have an important role in the onset, severity, exacerbation, or maintenance of pain. Especially for the diagnosis of *pain disorder*, it is nearly impossible to differentiate between the influence of psychological factors and a general medical condition. If both psychological factors and a general medical condition are judged to have important roles, the associated medical condition or anatomical site of the pain is coded on axis III. This also applies to pains where an underlying general medical condition is not yet clearly established, for example low back pain, pelvic pain, headache, joint pain, abdominal pain, and urinary pain.

Similar to pain disorder, *conversion disorder* is also characterized by circumscribed physical symptoms without sufficient organic explanation, but the typical symptoms involve voluntary motor or sensory functions. *Conversion disorder* typically suggests a neurological condition and is sometime difficult to diagnose with sufficient certainty.

The following diagnoses are not so much characterized by physical complaints, but by anxiety and cognitive preoccupations. The typical feature of *hypochondriasis* is health anxiety. The unwarranted fear or idea of having a disease persists despite medical reassurance. It can be very difficult to differentiate *hypochondriasis* from somatic delusions that may occur in psychotic disorders.

The essential feature of *body dysmorphic disorder* is the preoccupation with an imagined or exaggerated defect in physical appearance. If a slight physical anomaly is present, the person's concern is markedly excessive. While this disorder can have a dramatic course, and might have high health care relevance (e.g., cosmetic surgery), profound research relating to the condition is still rare.

Table XX.1 presents a brief guideline for the diagnostic process if a somatoform disorder is suspected. Following this guideline, three questions have to be answered.

- Does the patient describe a history of multiple somatoform complaints?
- Does the patient describe focussed, circumscribed symptoms?
- Is health anxiety or concern about the physical appearance a predominant feature?

SOMATIZATION-ASSOCIATED DISORDERS: OVERLAPPING OR DISTINCT FEATURES?

Unexplained physical symptoms are common in all disciplines of medicine. Accordingly, all disciplines have created unique terms for the description of patients with physical complaints which cannot be accounted for by a known medical condition. Examples are cephalgia, dorsalgia, recurrent abdominal pain, vulvodynia, hypomeralgia, chronic fatigue syndrome, fibromyalgia, irritable bowel syndrome, functional disorders, psychosomatic disorder, neurasthenia, multiple chemical sensitivity syndrome, somatized depression. It is

Table XX.1 The three major subgroups of somatoform disorders

Focus on multiple unexplained physical symptoms	Focus on single physical symptoms	Focus on anxiety or concerns
Somatization disorder (DSM-IV; ICD-10)	Pain disorder (DSM-IV; ICD-10)	Hypochondriasis (DSM-IV; ICD-10)
Somatoform autonomic dysfunction (ICD-10)	Conversion disorder (DSM-IV; ICD-10)	Body dysmorphic disorder (DSM-IV)
	(Somatoform autonomic dysfunction; ICD-10)	

Table XX.2 Case definitions for chronic fatigue syndrome

	CDC-1988	CDC-1994	Australia	UK
Minimum duration (month)	6	6	6	6
Functional impairment	50% decrease in activity	Substantial	Substantial	Disabling
Cognitive or neuropsychiatric symptoms	May be present	May be present	Required	Mental fatigue required
Other symptoms	6 or 8 required	4 required	Not specified	Not specified
New onset	Required	Required	Not required	Required
Medical exclusions	Extensive list of known physical causes	Clinically important	Known physical causes	Known physical causes
Psychiatric exclusions	Psychosis, bipolar disorder, substance abuse	Melancholic depression, substance abuse, bipolar disorders, psychosis, eating disorder	Psychosis, bipolar, substance abuse, eating disorder	Psychosis, bipolar, eating disorder, organic brain disease

obvious that there is an enormous overlap between these syndromes as well as with somatoform disorders. Despite the critique of current classification approaches to somatoform disorders, one of the major advantage of the new concept may be the provision of the one term 'somatoform' for a variety of related concepts. One common feature of all these syndromes is that although some symptoms may be the predominant focus of the clinical presentation, most of the patients also report many unspecific physical complaints. Buchwald and Garrity (1994) compared physical complaints of patients with chronic fatigue syndrome, fibromyalgia and multiple chemical sensitivity. Physical complaints that were common in chronic fatigue were also frequent symptoms of fibromyalgia and multiple chemical sensitivity. Wessely (1996) investigated the frequency of somatic symptoms in patients with chronic fatigue and reported that these patients described an enormous amount of unspecific physical complaints. The more chronic the fatigue syndrome was, the more physical complaints patients described.

To summarize, it seems that diagnoses such as fibromyalgia, chronic fatigue syndrome, multiple chemical sensitivity syndrome, etc. cannot be differentiated on the basis of somatic symptoms. The principal difference between these groups are theoretical assumptions on psychophysiological and psychobiological interactions. For some of these syndromes, well-established criteria have been defined which are useful for further research (see Table XX.2 for the example of CFS).

NEW APPROACHES TO THE CLASSIFICATION OF SOMATOFORM DISORDERS

There has been growing concern that current diagnostic concepts of *somatization disorder* fail to cover the large majority of patients presenting with unexplained somatic symptoms (Escobar *et al.*, 1989; Kroenke *et al.*, 1997). Several researchers have therefore suggested alternative diagnostic criteria for *somatization disorder* that require a smaller number of somatic symptoms and also take into consideration the higher symptom report rates of women (see below).

If the number of unexplained physical symptoms presented by the patient is the central diagnostic criterion, the first question is which symptom list should be used. Symptoms that are to be incorporated into a total score should have a sufficient base rate and a sufficient item–total correlation. In an empirical analysis Rief and Hiller (1999) demonstrated that many pseudoneurological symptoms do not fulfil these requirements. Moreover, sexual and menstruation symptoms had an insignificant item–total correlation which was due to unspecifity. These symptoms have comparable base rates in patients with somatization syndromes and in patients with other mental disorders. Our results suggest that for the diagnosis of polysymptomatic somatoform disorder one should focus on pain symptoms, gastrointestinal symptoms, cardiovascular symptoms and a reduced list of pseudoneurological symptoms.

Fink (1996) emphasized that symptom counting should not be the principal part of the diagnostic process, but that further psychological and psychobiological features should be considered, which might present additional aspects for the diagnosis of somatization disorder. In the following sections we will review the evidence concerning the possible psychobiological changes that underlie the chronic tendency to experience bodily complaints.

Abnormal Illness Behaviour

Pilowsky (1993) has outlined the concept of abnormal illness behaviour, which seems to be a predominant feature of somatization. The concept includes an abnormal behavioural reaction to physical discomfort. Doctor visits even for minor reasons, a continuous tendency to search for diagnostic evaluation and interventions, avoidance of physical demands, high number of sick-leave occasions are only some of these aspects.

Sustained Focussed Attention on Bodily Processes

Those patients with somatization syndrome show a tendency to focus attention on bodily processes. This internal attention focusing is often accompanied by a reduction of interests for external events.

Catastrophizing Interpretation of Bodily Sensations

Patients with *hypochondriasis* show a general tendency to misinterpret bodily sensations as evidence for physical illness (Barsky *et al.*, 1993; Rief *et al.*, 1998). While healthy controls can generate many normal attributions for bodily sensations, somatizing patients have a bias towards using only catastrophizing interpretations.

Self-Concept of Being Weak

Many somatizing patients (yet not all) have a self-concept of being weak which is not founded on a physical basis (Rief *et al.*, 1998). A self-concept of being weak is highly associated with disability and abnormal illness behaviour.

Following these empirical analyses, we proposed the diagnosis of *polysymptomatic somatoform disorder*. To fulfil criteria, persons should describe at least seven to eight physical symptoms affecting multiple body sites during the past two years. At least one of the psychological factors which had been mentioned above should be present as a maintaining factor. Further criteria resemble DSM-IV criteria of *somatization disorder* (symptoms not sufficiently explained by any pathological physical condition; symptoms cause clinically significant distress, etc.).

Escobar and colleagues (Escobar *et al.*, 1987, 1989) suggested using the Somatic Symptom Index (SSI) as a classification approach. The criteria for SSI-4/6 are fulfilled if men have at least four physical symptoms and women at least six physical symptoms out of the list of 35 somatoform symptoms suggested for DSM-III-*somatization disorder*. The SSI-4/6 concept of Escobar has been used in a number of studies. However, there are concerns that it may be over-inclusive and the empirical basis of this concept still needs to be improved. Kroenke *et al.* (1997) suggested a new diagnosis of *multisomatoform disorder*. The criteria for this disorder were derived from primary care studies. Patients have to present with at least three current somatoform symptoms out of a 15-symptom checklist along with at least a two-year history of somatoform symptoms. The 15 physical symptoms were chosen because they account for more than 90% of outpatient visits attributable to physical complaints. The major advantage of the Kroenke approach is its feasibility for use in primary care.

COMORBIDITY PATTERNS

Already centuries ago the high overlap between unexplained physical symptoms and depression/melancholia was described (Burton, 1621). Kielholz (1973) has postulated that depression may be the underlying disorder in many patients with bodily complaints, and that functional physical symptoms might be just epiphenomena. Empirical analyses of comorbidity patterns underline the close association of depression and somatization syndrome. In 90–100% of patients seeking help in health care settings and fulfilling the complete criteria of *somatization disorder* a comorbid affective disorder can be found. A history of major depression is reported by 65–80%

Table XX.3 Comorbidity diagnoses of distressed high users of primary care (Katon *et al.*, 1991)

Somatization syndrome	Major depression (lifetime)	Panic disorder (lifetime)
<SSI-4/6	45%	3%
SSI-4/6	75%	20%
SSI-9	71%	19%
Somatization disorder	82%	48%

of patients with *somatization disorder* (Katon *et al.*, 1991; Rief *et al.*, 1996). Despite these findings, the association between somatization and depression should be interpreted with caution. First, high prevalence of comorbid depression (especially in patients in health care settings) is not only common in somatization, but also in most other mental disorders (anxiety disorders, eating disorders and others). Second, the stricter the criteria applied for the diagnosis of *somatization disorder*, the higher is the base rate of comorbid depression (Katon *et al.*, 1991; Hiller *et al.*, 1995). Third, onset and course of depression are quite different from onset and course of somatization with somatoform symptoms having an earlier onset and very frequently a stable and chronic course (Rief *et al.*, 1992). And fourth, there seem to be significant psychobiological differences between depression and somatization, as will be shown in subsequent sections.

Somatization is not only associated with depression, but patients with somatization syndromes are at increased risk also for other disorders. There seems to be a close link to anxiety disorders (Rief *et al.*, 1996). In some studies, patients with *hypochondriasis* showed higher comorbidity rates with anxiety than with affective disorders (Barsky *et al.*, 1992). Therefore *hypochondriasis* was suggested to represent the link between somatoform disorders and anxiety disorders. Other authors emphasize the association of *hypochondriasis* and *body dysmorphic disorder* with obsessive–compulsive disorder (Starcevic, 1990; Simeon *et al.*, 1995; Bienvenu *et al.*, 2000).

Table XX.3 presents comorbidity patterns of somatoform disorders with other mental disorders. Summarizing these results, it seems that somatization, anxiety and depression (as well as other features) are risk factors one for the other.

EPIDEMIOLOGY

Patients who present with multiple physical symptoms that lack an adequate somatic explanation are commonly seen in primary care settings (Rief *et al.*, 2001). This is in contrast to the low prevalence rates of somatoform disorders according to current diagnostic systems (ICD-10 and DSM-IV). Depending on study design, diagnostic criteria (ICD-10 versus DSM-IV) and catchment area *somatization disorder* is estimated to have a lifetime prevalence between 0.03% and 3% (Escobar *et al.*, 1989; Gureje *et al.*, 1997). If less restrictive concepts are used for *somatization disorder* (SSI 4/6 or 3/5), prevalence rates are in the range of 10–20% in the general population (Escobar *et al.*, 1989; Rief *et al.*, 1996, 2001; Gureje *et al.*, 1997).

Reliable information on the prevalence rates of other diagnostic subgroups of somatoform disorders is still lacking. Hypochondrial concerns are present in at least 10–15% of the general population (Kroenke and Spitzer, 1998; Rief *et al.*, 2001). However, only 1–4% meet full diagnostic criteria for *hypochondriasis* (Faravelli *et al.*, 1997; Gureje *et al.*, 1997; Kroenke and Spitzer, 1998).

Pain is probably the most frequent complaint in medical practice. In a representative German sample, for instance, up to 30% of subjects complained about back pain in the last two years (Rief *et al.*, 2001). Pain symptoms often lack an adequate medical explanation. However, little is known about the prevalence of *somatoform pain disorder* according to current diagnostic criteria and reported rates vary from under 1% up to 5% in the general population (Gureje and Obikoya, 1992; Faravelli *et al.*, 1997).

Body dysmorphic disorder (BDD) affects approximately 1% of the general population; however, this is thought to be an underestimate because BDD is frequently underdiagnosed. In clinical populations the frequency might be much higher. Thirteen per cent of psychiatric inpatients were reported to suffer from BDD (Grant *et al.*, 2001). In dermatological patients and those seeking cosmetic surgery the rate of BDD was estimated to be between 7% and 12% (Sarwer *et al.*, 1998; Phillips *et al.*, 2000).

Reported prevalence rates of *conversion disorder* vary widely, ranging from 11/100,000 to 300/100,000 according to DSM-IV. However, in neurological patients the prevalence rates have been reported to be as high as 20% (Mace and Trimble, 1991).

GENDER EFFECTS

Unexplained physical symptoms have consistently been shown to be more frequent in women than in men (Piccinelli and Simon, 1997; Kroenke and Spitzer, 1998; Ladwig *et al.*, 2000; Rief *et al.*, 2001). Kroenke and Spitzer (1998) for instance reported the results of a mental health survey in 1000 primary care patients in the USA. Results showed that physical symptoms in general and somatoform symptoms more specifically were more common in women than in men. Odds ratios adjusted for age, race, education, medical and psychiatric comorbidity were in the range of 1.5 to 2.5. Although anxiety and depression were both strongly associated with symptom reporting the effect of gender on symptom reporting was independent of psychiatric comorbidity. While women in the general population are approximately twice as likely as men to report physical symptoms that lack an adequate somatic explanation the ratio shifts even more to the female side when only patients are considered who fully meet diagnostic criteria for a somatoform disorder. The DSM-IV reports female prevalence rates for *somatization* and *conversion disorder* to be up to 10 times higher in women than in men. However, hypercondriacal concerns in the general population as well as prevalence rates for *hypochondriasis* according to DSM-IV or ICD-10 appear to be equally frequent in women as in men (Gureje *et al.*, 1997; Kroenke and Spitzer, 1998). Men are also as likely as women to suffer from *body dysmorphic disorder*; whilst symptom localization and comorbidity patterns vary between male and female patients (Perugi *et al.*, 1997; Phillips and Diaz, 1997).

The elevated frequency of somatoform symptoms in women has been explained by several authors in terms of a biopsychosocial model of symptom perception (Pennebaker, 1982; Gijsberg van Wijk and Kolk, 1997). Accordingly, symptoms do not just result from the passive registration of bodily changes but are modulated by cognitive processes that guide attention to and the attribution of somatic information. In women there might be simply more somatic information to begin with. The female reproductive process itself produces much physical information that is absent in men. It might further exert an influence on pain perception thresholds that have been shown to be lower in women (Riley *et al.*, 1998) and to vary with the menstrual circle (Riley *et al.*, 1999). Attention towards physical symptoms, attributions applied to them and the willingness to report them to medical professionals might be further influenced by differences between women and men in socialization, sex roles and social position.

NEUROIMAGING STUDIES

Functional Neuroimaging Studies

As somatoform disorders are by their very definition thought to lack an adequate somatic explanation little research has been done to elicit possible neurophysiological abnormalities associated with this type of disorder. Tiihonen *et al.* (1995) reported the case of a 32-year-old woman with a conversive left-sided paralysis and paraesthesiae who had a single photon emission tomography (SPECT) carried out during the electric stimulation of the median nerve of her affected hand. Altered cerebral blood flow was observed with hyperfusion of the right frontal and hypofusion of the right parietal region. After recovery from her conversive symptoms cerebral blood flow measures returned to normal. Results were interpreted as reflecting a simultaneous activation of frontal inhibitory areas and inhibition of somatosensory cortex. A further case study by Marshall *et al.* (1997) reported the case of a 45-year-old woman with left-sided paralysis but without somatosensory loss in whom no organic lesion had been found. Brain activity was studied by positron emission tomography (PET) when the patient prepared to move and tried to move her paralysed (left) leg. Her good (right) leg was used as a control condition. Preparing to move or moving her good leg, and also preparing to move her paralysed leg activated motor and/or premotor areas previously described as participating in movement preparation and execution. However, the attempt to move the paralysed leg failed to activate right primary motor cortex. Instead, the right orbitofrontal and right anterior cingulate cortex were significantly activated. These areas are known from previous studies in both animals and humans as 'negative motor areas' which play a crucial role in the suppression of inappropriate motor responses (Lüders *et al.*, 1995). The interpretation was put forward by Marshall *et al.* (1997) that these two frontal areas inhibited (willed) effects on the right primary motor cortex when the patient tried to move her left leg. Interestingly, the results of their study were paralleled by those of a single case study of brain activity during hypnotic paralysis. Using an identical PET design Halligan *et al.* (2000) showed that hypnotic paralysis activated similar brain areas (orbitofrontal and anterior cingulate areas) as conversive paralysis, supporting the view that hypnosis and *conversion disorder* might share common neurophysiological mechanisms.

Both prefrontal and right parietal regions are thought to be components of a distributed neural network that integrates processes of attention and awareness (Parasuraman, 1998). Thus, the results of the studies cited above are consistent with the notion that altered inhibitory mechanisms at high levels of sensory and motor processing play a role in the formation of conversive symptoms. However, findings to date are far from forming a clear picture: Yazící and Kostakoglu (1998) reported the results of five cases suffering from bilateral conversive symptoms (astasia-abasia) who had SPECT performed at rest. Perfusion decreases were found in left temporal and parietal areas. As symptoms were bilateral in all their cases and no activation paradigm was applied it is difficult to compare the results of Yazící and Kostakoglu (1998) to those of Tiihonen *et al.* (1995) and Marshall *et al.* (1997). Even more care is warranted when trying to generalize neuroimaging findings in *conversion disorder* to other somatoform disorders. Studies in *somatization disorder* patients so far have yielded inconclusive results: James *et al.* (1987) reported regional cerebral blood flow changes in 14 patients with *somatization disorder* who performed a visual matching task known to activate predominantly the right hemisphere. Compared to controls they exhibited a slightly higher right posterior activation. This was interpreted as indicating a hyperactivity of the right hemisphere and the right posterior region in particular and possibly reflecting disturbed processes of selective attention. However, in a recent SPECT study of 11 cases with *somatization disorder* Garcia-Campayo *et al.* (2001) found right hemisphere or bilateral hypoperfusion in different brain areas in the majority of their patients under resting conditions. No control group was studied and no activation paradigm was applied. The seemingly contradictory results highlight the necessity for further research in this field studying larger numbers of carefully diagnosed patients under both resting and activation conditions.

To sum up, the only conclusion that can safely be drawn from functional neuroimaging findings so far is that alternations in regional cerebral blood flow accompany the expression of physical symptoms in *conversion disorder* and *somatization disorder*. These changes might be related to altered processes of attention and awareness in sensory and motor processing.

Structural Neuroimaging Studies

Again, as the definition of somatoform disorder excludes the presence of organic brain disease only few attempts have been made to discover the prevalence of (subtle) structural changes in the brains of patients with somatoform disorders. There is, however, one related condition to which structural brain imaging techniques have been applied. *Chronic fatigue syndrome* (CFS) is a debilitating multisystem condition of unknown origin. Attempts have been made to relate the clinical findings to structural changes in the brain of affected individuals but have so far yielded ambiguous results. Some researchers found an increased frequency of white matter intensities (WMI) in MRI studies of CFS patients compared to normal age-matched controls (Buchwald *et al.*, 1992; Natelson *et al.*, 1993; Schwartz *et al.*, 1994). However, others found no differences in the frequency of WMIs between CFS patients and controls (Cope *et al.*, 1995; Greco *et al.*, 1997). Reported frequencies of white matter lesions in CFS varied greatly from 8% (Cope *et al.*, 1995) to 78% (Buchwald *et al.*, 1992) depending on catchment area, age of subjects and the presence of associated disorders. Even those investigators who found increased frequencies of white matter lesions could not identify a specific pattern of radiological abnormalities and doubt their clinical usefulness (Schwartz *et al.*, 1994). The unspecific and subjective nature of the disease combined with the absence of a known causal agent and pathognomonic abnormalities makes the condition difficult to diagnose. Thus, it seems questionable whether the different investigation carried out even related to the same population of patients.

With relation to *conversion disorder* there is some evidence that lesions of the left hemisphere may present a predisposition for the development of conversive symptoms. Drake (1993) reported that patients who had sustained left hemisphere injuries or infarctions were at greater risk of developing conversion symptoms later in life.

NEUROPSYCHOLOGICAL ASPECTS

Circumstantial evidence for disturbed brain function in somatoform disorders could derive from findings of neuropsychological deficits in affected patients. Indeed, patients with unexplained physical symptoms frequently complain of cognitive deficits such as fatigue, lack of concentration and memory failure. However, little is known about how patients with somatoform disorders perform on standardized neuropsychological tests. Patients suffering from *body dysmorphic disorder* (BDD) have been reported to show performance deficits on verbal and non-verbal learning and memory tests compared to healthy controls (Deckersbach *et al.*, 2000). Learning and memory deficits in BDD patients seemed especially due to their poor organizational strategies, an aspect of memory processing that is attributed to the frontal lobes. These findings were similar to patterns previously observed in obsessive–compulsive

disorder (OCD) and could thus point to the possible relationship between BDD and OCD that has repeatedly been suggested by other investigators (Bienvenu *et al.*, 2000). Further and more direct evidence for this claim comes from the study of Hanes (1998). BDD patients in this study were directly compared to OCD patients and both groups were found to show a similar pattern of neuropsychological performance. Patients with BDD showed normal performance on memory and motor tasks but were significantly impaired relative to normal controls on tests of executive functions, thus again pointing to the frontal lobes as a possible site of disturbances.

Flor-Henry *et al.* (1981) investigated cognitive functioning in 10 subjects with 'hysteria', who according to current diagnostic criteria would have been seen as suffering from *somatization disorder*. Ninety per cent of the test profiles of somatization patients were judged as 'abnormal' according to Reitan's approach (Reitan and Davison, 1974), thus suggestive of cerebral dysfunction. The somatization group was characterized by deficits on tests of sensorimotor, executive and visuospatial function. The test variables that best discriminated somatization patients from controls were Colored Progressive Matrices, Finger Localization (preferred hand) and Verbal Associative Learning. On the basis of these findings the authors concluded that dominant hemisphere dysfunction is related to the symptom of hysteria (today: *somatization disorder*). The high prevalence of cognitive impairment in somatization patients in the study of Flor-Henry *et al.* (1981) has never been replicated and might be partly due to the definition of 'abnormal' test profiles applied in this study. Further investigations of cognitive performance in patients with *somatization disorder* seem mandatory to clarify how prevalent objective cognitive deficits are in somatization patients.

Complaints about cognitive deficits mainly in the area of memory and concentration are also a core feature of *chronic fatigue syndrome* (CFS), a condition often seen as belonging to the 'somatoform spectrum' disorders. Any understanding, however, of the cognitive problems in CFS has to take account of the frequent comorbidity of CFS and depression. Affective disorders themselves are known to cause cognitive deficits (Murphy and Sahakian, 2001). In a recent review Wearden and Appleby (1996) reported that non-depressed CFS patients, although showing mild cognitive impairments, performed within normal limits on various standard neuropsychological tests. In most investigations they did not significantly differ from healthy controls. If impaired at all, CFS patients showed a tendency to perform slower especially on more complex and effortful tasks but there was no evidence for excessive fatigueability. On the basis of the current evidence Wearden and Appleby (1996) concluded that mild cognitive problems in CFS patients are unlikely to relate to grossly altered brain function; instead, psychological variables like motivation, effort, mood and arousal are likely to be involved in the explanation.

LATERALIZATION OF SYMPTOMS

The debate over whether unilateral somatization and conversion symptoms are lateralized dates back to the 1970s and has not yet led to any conclusive result. Psychogenic somatization symptoms in different psychiatric conditions (anxiety, depression, somatoform disorders) have been reported to occur more frequently on the left side of the body (Axelrod *et al.*, 1980; Min and Lee, 1997). Left-sided lateralization of conversion symptoms has been found by Stern (1977) and more recently by Pascuzzi (1994). Galin *et al.* (1977) also found a prevalence of left-sided conversion symptoms but for females only. However, others have found a predominantly right-sided lateralization of symptoms in *conversion disorders* in children (Regan and LaBabera, 1984) and adults (Fallik and Sigal, 1971) or no lateralization of symptoms (Keane, 1989; Roelofs *et al.*, 2000). Apart from the ambiguous results the integration of the existing findings on lateralization of somatoform symptoms is further complicated by differences in sample sizes, patient selection and symptom definition.

Different hypotheses have been put forward to explain the predominantly left-sided lateralization of conversion and somatization symptoms. The *evaluative hypothesis* suggests that the left side of the body is associated with negative connotations and might therefore be the preferred site for the development of somatization (bad) symptoms. This symbolic interpretation has received little empirical support. The *convenience hypothesis* claims that symptoms develop on that side of the body where they cause the least inconvenience. This would predict a left-sided predominance in right-handers and vice versa. However, this claim is contradicted by the finding that left-sided symptoms occur more frequently in both left- and right-handed patients (Galin *et al.*, 1977; Stern, 1977). By the same token, one could also propose the opposite of the convenience hypothesis, namely that symptoms are more frequently on the right side just because they are more incapacitating there and require more attention (Fallik and Sigal, 1971; Regan and LaBabera, 1984). Right-sided lateralization has also been explained as being related to *previous organic lesions* which more often occur on the dominant side of the body (Fallik and Sigal, 1971). Again, this claim is contradicted by the lack of any consistent relation between handedness and lateralization of symptoms. The predominant theory today explains symptom lateralization to the left side in terms of *hemispheric specialization* (Sierra and Berrios, 1999; Roelofs *et al.*, 2000). The right inferior parietal cortex is believed to be involved in higher-order processes of attention and awareness (Parasuraman, 1998). Disturbances of this system might thus compromise sensory and motor processing on the contralateral side of the body. This theory would also allow for the incorporation of current functional imaging findings (Tiihonen *et al.*, 1995; Marshall *et al.*, 1997; Halligan *et al.*, 2000). However, it does not seem necessary to restrict the proposed effects of a dysfunctional right-sided attention and awareness system to the contralateral body side.

To summarize, more investigations of symptom manifestation in somatoform disorder using representative samples are necessary to resolve the question of symptom lateralization. It seems important to stress that most patients suffer from symptoms that are not restricted or not attributable to only one side of the body and any explanation of a possible 'conversion' mechanism has to account for this fact (Roelofs *et al.*, 2000).

GENE–ENVIRONMENT INTERACTIONS

The aetiology and pathogenesis of somatoform disorders are still not well understood. It has been shown that adverse environmental factors such as low socioeconomic background, childhood experiences of death and illness, exposure to traumatic events or high levels of current stress increase the risk for the development of somatoform disorders (Hartvig and Sterner, 1985; Whitehead, 1994; Binzer *et al.*, 1997). There is also evidence that hereditary factors have some influence. Familial aggregation for somatization (Briquet's syndrome) has been reported for women but not for men (Cloninger *et al.*, 1986). Higher concordance rates for somatoform disorders in monozygotic than in dizygotic twins (29% vs. 10%) have been reported in a Norwegian twin study (Torgersen, 1986). However, the differences failed to reach statistical significance and shared environmental influences might have influenced the concordance rates. All the concordant pairs consisted of partners with two different somatoform disorders pointing to an aetiologic and nosologic similarity of the different subtypes of somatoform disorders.

The study further found a high frequency of anxiety disorders, especially generalized anxiety disorders, in the co-twins of somatoform disorder twins.

Familial aggregation and twin studies alone do not provide unequivocal evidence for a genetic aetiology, as shared environmental influences might be responsible for higher frequency of psychiatric disorders in the families of affected patients. More direct evidence can be drawn from adoption studies. A Swedish adoption study using the medical history data of female adoptees found an increased prevalence of alcohol abuse and antisocial behaviour in the biological fathers of somatizing women (Bohman *et al.*, 1984). The results confirmed those of earlier family studies suggesting that somatoform disorders in women and some forms of alcohol abuse and antisocial behaviour in men might share common aetiological factors.

Genetic–epidemiological approaches may also help in clarifying the relationship between somatoform disorders and other comorbid psychiatric diagnoses that are often diagnosed in the same individual. Recent studies suggest that *somatization disorder* and symptoms of anxiety and depression do not share a common genetic background (Battaglia *et al.*, 1995; Gillespie *et al.*, 2000).

The advantages of molecular biology offer new tools for studying those variations in genes and matching gene products that might be responsible for the genetic transmission of psychiatric diseases. So far, little is known about which part of the genome might hold candidate genes related to the aetiology of somatoform disorders. However, a number of the studies point to the involvement of the serotonin transmitter system in *fibromyalgia*, a syndrome of generalized muscular pain which shares clinical features with both *pain disorder* and depression. In patients with fibromyalgia the genotype distributions for both the 5-HT2A receptor gene and the serotonin transporter gene have been found to differ from healthy controls (Bondy *et al.*, 1999; Offenbacher *et al.*, 1999). These results suggest that altered serotonergic neural transmission might present a genetically transmitted vulnerability for the disorder.

NEUROTRANSMITTER SYSTEMS

The serotonergic system has repeatedly been discussed to be involved in the pathophysiology of somatoform disorders and related syndromes. Reduction of central serotonergic transmission has been linked to the pathogenesis of *pain disorder*. This notion is based first on the analgesic effects of tricyclic antidepressants and second on reports of reduced activity of the peripheral and central serotonin system (Van Kempen *et al.*, 1992). Serum levels of serotonin (5-hydroxytryptamine, 5-HT), its precursor tryptophan and its main metabolite 5-hydroxyindoleacetic acid (5-HIAA) have also been found to be decreased in patients suffering from *fibromyalgia*. Schwartz *et al.* (1999) found low levels of 5-HIAA and tryptophan to be related to higher pain scores and lower serum concentration of 5-HIAA to be associated with reduced quality of sleep in fibromyalgia patients. There was also a tendency of higher pain scores to be related to higher serum concentrations of the neuropeptide substance P, pointing to the antagonism of substance P and the serotonergic system in nociception. In a recent review Russell (1998) discussed the findings of low 5-HT and high substance P concentrations as signs of a pain amplification syndrome in fibromyalgia. The aetiology of *body dysmorphic disorder*, another somatoform disorder, has also been related to poor regulation and depletion of serotonin (Craven and Rodin, 1987; Barr *et al.*, 1992). However, altered serotonin physiology might be either a consequence or a marker of the disorder.

Current concepts of stress research point to the importance of the monoaminergic neurotransmitters for the response to and adaptation to acute and chronic stressful events. As emotional distress has been shown to be a powerful predictor of somatic complaints across gender, different age groups and different cultures (Piccinelli and Simon, 1997) one would predict that the monoaminergic neurotransmitter system should be involved in the pathophysiology of somatoform disorders. So far, there is only circumstantial evidence to support this claim. Gjerris *et al.* (1987) found CSF adrenaline but not noradrenaline levels to be reduced in 'somatizing' depressive patients. CSF adrenaline concentration was related to ratings of somatic anxiety symptoms and *hypochondriasis* on the Hamilton Depression Scale.

Taken together, most support is there for the involvement of the serotonergic neurotransmitter system in somatoform disorders especially those that are characterized by altered pain perception and obsessive–compulsive features. However, there seem to be few results specific to somatoform disorders as alternations in serotonergic transmission have been shown for other psychiatric conditions such as depression, anxiety, obsessive–compulsive disorder and eating disorders.

ENDOCRINOLOGICAL ASPECTS

Studies on endocrinological aspects of unexplained physical symptoms focus on the activity of the hypothalamic–pituitary–adrenal axis (HPA-axis). Parallels to post-traumatic stress disorder have been drawn as many patients with unexplained physical symptoms report traumatic experiences. Heim *et al.* (1998) examined women with chronic pelvic pain and analysed diurnal salivary cortisol levels and hormonal responses to a corticotropin-releasing factor (CRF) stimulation test as well as a low-dose dexamethasone suppression test. Women with chronic pelvic pain had increased prevalences of abuse experiences and post-traumatic stress disorder. Analysing endocrinological parameters, the authors found normal to low diurnal salivary cortisol levels, normal ACTH, but reduced salivary cortisol levels in the CRF stimulation test. The suppression of cortisol concentrations after dexamethasone was enhanced in patients with chronic pelvic pain.

Taking into account the tendency towards increased cortisol scores in depressive patients, the results for chronically stressed persons with syndromes other than depression are quite surprising. Pruessner *et al.* (1999) demonstrated that the associations between stress and cortisol are not as straightforward as had been thought earlier. In their study, perceived stress correlated with an increase of cortisol levels during the first hour after awakening. However, the overall cortical secretion of persons scoring high on burn-out scales showed lower cortisol concentrations on all sampling days in that study. Therefore the authors postulated differential effect of burn-out and perceived stress on HPA-access regulation.

Other studies have confirmed an association between vital exhaustion and lower basal cortisol levels (e.g., Nicolson and van Diest, 2000). These and other results stimulated Heim *et al.* (1998) to postulate a theory of hypocortisolism in the pathophysiology of stress-related bodily disorders. Chronic or very intense stress may lead to a hypoactivity of the HPA-axis. The authors assume that cortisol may have a protective function; a lack of these protective properties may be of relevance for the development of bodily disorders in chronically stressed individuals.

However, the finding of low cortisol scores in patients with unexplained physical symptoms is not as consistent as might be supposed. For chronic fatigue syndrome patients, Scott and Dinan (1998) confirmed lower urinary free cortisol excretion, while Scott *et al.* (1998) and Young *et al.* (1998) found normal cortisol scores in chronic fatigue patients. Vingerhoets *et al.* (1996) found a tendency towards lower cortisol levels in persons who described many stress-related bodily complaints, whereas Rief and Auer (2000) found normal urinary cortisol, normal salivary cortisol and

normal serum cortisol after dexamethasone suppression tests for persons with somatization syndrome. In another study of Rief *et al.* (1998) we even found increased scores for salivary cortisol in somatizing patients. This effect was still evident after controlling for depression. Results contradictory to the hypocortisolism theory were also reported for persons with burn-out syndrome (Melamed *et al.*, 1999).

Therefore, the theory of hypocortisolism in the pathophysiology of stress-related bodily disorders has less empirical support than proposed by Heim *et al.* (2000). Measurement artefacts, differences in study design, or differences in comorbidity patterns of examined samples might account in part for these discrepancies. If a tendency towards reduced cortisol concentrations in somatoform disorders is confirmed in the future, it is likely to be a rather weak effect.

Neeck and Riedel (1999) presented a sophisticated outline of hormonal perturbations in fibromyalgia syndrome. According to their opinion, fibromyalgia is characterized not only by pain in defined points of the musculoskeletal system, but also by numerous additional somatoform and psychological symptoms. The authors claim that not only the HPA-axis may be deregulated in fibromyalgia, but also other hormonal axes (the thyroid system, regulation of growth hormone, and other parameters). Therefore they conclude that there must be a higher-order central rather than a peripheral origin causing perturbations of the hormonal axes. They favour a model in which hypothalamic CRH neurons play a key role not only in 'resetting' the various endocrine loops, but possibly also in regulating nociceptive and psychological mechanisms as well.

Some other studies have analysed peptides in patients with functional physical symptoms or associated disorders. Jonsson *et al.* (1998) analysed gastrin, cholecystokinin, and somatostatin in blood samples of patients with functional dyspepsia. Mean hormone values did not differ between patients with functional dyspepsia and a matched healthy control sample. Patients with a high degree of dyspeptic symptoms during the week preceding the experiment had a higher mean somatostatin level than patients with a lower degree of dyspeptic symptoms. During a stress interview, cholecystokinin levels increased in patients with functional dyspepsia, but not in controls. Somatostatin increased significantly earlier in patients than in control subjects during the stress interview. Therefore the authors postulated that cholecystokinin and somatostatin may possibly link psychological reactions to the pathophysiology of functional dyspepsia. Maes *et al.* (1998) analysed prolyl endopeptidase and dipepetidyl peptidase IV in patients with fibromyalgia. They found lower serum prolyl endopeptidase in patients with fibromyalgia than in normal volunteers. Moreover, they also described significant negative correlations between serum prolyl endopeptidase and severity of pressure hyperalgesia.

Unfortunately, for patients who were classified according to the somatoform disorders section of DSM-IV, studies on peptides are so far lacking.

IMMUNOLOGICAL ASPECTS

One of the conceptual precursors of somatoform disorders, neurasthenia, was assumed to be triggered by viral infections and other diseases. Hundreds of years later, the terminus *chronic fatigue syndrome* was created and it was postulated that viral infection and subsequent immunological processes may be underlying pathophysiological mechanisms leading to the complaints. While a uniform viral aetiology of chronic fatigue syndrome has been questioned in the following years (for an overview see Wessely *et al.*, 1999), there is convincing evidence to postulate a close link between immunological processes and the perception of physical complaints. The possible trigger function of viral infections continues to be a topic of research. For example, White *et al.* (1998) demonstrated that glandular fever is a risk factor for the development of acute and chronic fatigue syndromes, whereas ordinary upper respiratory tract infections are not (Wessely *et al.*, 1999). White (1997) summarized that specific infections can trigger chronic fatigue syndromes, but these syndromes are not maintained by the infectious agent itself, but by the patient's subsequent maladaptation. This maladaptation may be mediated by changes in sleep patterns, physical deconditioning, and endocrine and immune system changes.

One of the core features of somatization is the patient's belief and self-perception of being sick. This provides a link to the body of immunological research which focuses on 'sickness behaviour'. Sickness behaviour is characterized by reduced activity, a reduction of social interactions and sexual drive and the development of depressed mood. Interestingly, the administration of cytokines in the absence of infection produces the full syndrome of sickness behaviour. For example, all symptoms of sickness were produced by human interleukin-1b administered within rat hippocampus (Linthorst *et al.*, 1994).

Illness behaviour in somatoform disorders is phenomenologically characterized by reduced physical activity, reduced social interactions, and reduced exploration behaviour. As these features are also behavioural correlates of the acute phase-response, a close link between immunological parameters of the acute phase and the symptoms of somatoform disorders can be postulated.

Circumstantial evidence for a relationship between somatization and immunological processes is provided by the stress-dependency of immune processes. Stressors lead to increases in the levels of cytokines circulating in the blood, with IL-6 being the most frequently measured (Maier and Watkins, 1998). Moreover, several reports document the role of IL-1 in the stress response, as well as increased TNF-alpha levels following stress. Thus, both primary as well as secondary cytokines are induced *in vivo* as well as *in vitro* by stressors (Black and Berman, 1999). On the other hand, acute and chronic stressors as well as low stress tolerance are typical concomitants of somatoform syndromes.

Apart from illness behaviour and stress, there is a third line of evidence suggesting a link between somatoform disorders and immune activity. This is the interaction between immunological processes and pain sensitivity. Immune stimulation seems to activate both analgesia and hyperalgesia circuitry (Maier and Watkins, 1998). Stress-induced analgesia is a very rapid response, whereas hyperalgesia follows infectious or inflammatory processes much more slowly. The peripheral administration of LPS or IL-1 results in an increase in pain sensitivity (Watkins *et al.*, 1995). Altered pain sensitivity can lead to the perception of minor physical changes that otherwise would have gone unnoticed. These results could present a framework for research into the relationship between immune system activity and somatization.

Most of the approaches outlined above postulate increased levels of proinflammatory substances in patients with somatization. Moreover, elevated levels of proinflammatory cytokines have been found for the most frequent comorbid psychiatric disorder, major depression (Maes *et al.*, 1997). Neopterin is one of the metabolically stable markers for inflammation. In some (but not all) studies, plasma neopterin levels have been increased in major depression. Bell *et al.* (1998) found that serum neopterin is correlated with variables of somatization. However, this association was only found in a subgroup of persons with chemical intolerance, not in a subgroup of patients with depression or in normal controls.

Substance P, a neuropeptide which is involved in communication between the nervous and the immune system, seems to play a major role in the process of nociception. As outlined above, nociception and alternations of pain sensitivity can be a central process involved in the development of somatoform symptoms. Elevated levels of

Table XX.4 Immunological aspects of somatization (data from Rief *et al.* (2001) and similar studies)

Parameter	Somatization	Depression
IL-6	Reduced	Increased
IL-6R	Reduced	Reduced
IL-1	Unclear	Increased
IL-1RA	Increased	Slightly increased
CD-8 cell count	Reduced	Increased

substance P have been found in cerebrospinal fluid of patients with fibromyalgia. In some studies, there was an association between substance P serum concentrations and pain in fibromyalgia patients (Schwartz *et al.*, 1999). However, a direct investigation of substance P in patients with a DSM-IV diagnosis of somatoform disorders is still lacking.

In a study of Rief *et al.* (2001) we examined serum concentrations of immunological parameters. A total of 150 persons were divided into a subgroup of patients with major depression, patients with somatization, patients with depression and somatization, and healthy controls. Patients with multiple somatoform symptoms were characterized by reduced IL-6 concentrations, increased IL-6R concentrations, increased IL-1RA concentrations and increased concentrations of the anti-cytokine Clara cell protein CC16. Moreover, the T-lymphocyte CD-8 count was reduced for somatizing patients, while patients with major depression had increased scores in comparison to controls. This is one of the few studies comparing multiple clinical groups and providing information about the specificity of the results. To summarize, there is some evidence that immunological processes may be differentially affected in major depression and somatization. In our study we found signs of increased proinflammatory capacity in depression, while some indicators were found for anti-inflammatory capacity in somatization (see Table XX.4).

As the preceding paragraphs highlight, there are reasons for investigating the interaction of immune parameters and somatoform symptoms. To date, only a few studies have been carried out, and we are just at the beginning of understanding these associations.

PSYCHOPHYSIOLOGICAL ASPECTS

Autonomic and Peripheral Physiological Activity

Lehofer *et al.* (1998) suggested a close interrelationship between brainstem centres regulating arousal and pain sensitivity. Higher 'nervousness' has been demonstrated to be associated with increased pain sensitivity. Altered pain sensitivity, on the other hand, can be assumed to be a central feature of somatization. Following this model, somatizing patients may have a reduced threshold for perceiving physiological changes and experiencing multiple unpleasant physical sensations.

However, it is also possible that somatizing patients really have abnormal physiological reactions, and not only changed perception thresholds. There may be different ways in which physiological abnormalities may contribute to an increased risk for the perception of physical symptoms. Abnormal physiological arousal could be of importance not only for the exacerbation, but also for the maintenance of somatoform symptoms. Somatization *per se* is a state of chronic stress which is accompanied by changes of autonomic and muscular activity (Melin and Lundberg, 1997). There are different ways in which an association between arousal abnormalities and perception of symptoms may work.

(a) *Permanent over-arousal*.
Patients with somatoform symptoms can be over-aroused in challenging as well as during relaxing situations. This over-arousal can lead to the subjective feeling of exhaustion which is typical for patients with somatoform disorders.

(b) *Over-activation in response to challenging events; lack of habituation*.
Somatization may be characterized by physiological hyper-reactivity. If the body perceives challenges, physiological over presentation of energy occurs. Moreover, the process of habituation describes the tendency to reduced reactions if stimuli are repeated. If over-activation or a lack of habituation occurs, this may be associated with reduced stress tolerance.

(c) *Lack of recovery and relaxation after challenging events*.
One of the principal human adaptation processes is to relax after physical, emotional, or cognitive challenges. If people are not able to use breaks for relaxation, the activity level which is typical for challenging events remains stable even in periods without demands. Again this may lead to states of exhaustion.

(d) *Increased dishabituation*.
If people are repeating sequences of comparable demands interrupted by shorter breaks, there is a typical increase of activation after the break when people restart activity. However, another process of human adaptation is that the re-increase of arousal after breaks is reduced as the person habituates more and more to the following demands. A process of amplified dishabituation would also lead to insufficient recovery of energy, and feelings of exhaustion and stress.

Some of these pathophysiological hypotheses have been tested in patients with somatization syndrome. In the study of Rief *et al.* (1998) we demonstrated that somatized patients feel more and more tense during and after periods of mental challenges, while healthy controls habituate to the situation. A physiological correlate could be found by assessing heart rate reactions. After breaks, the heart rate of somatizing patients re-accelerated even if the task was well-known and patients were familiar with it. Healthy controls did not show signs of dishabituation in heart rate reactions in this study; obviously, the adaptation process of 'habituation to challenges' is compromised in somatizing patients.

In a subsequent study, this effect was further analysed (Rief and Auer, 2001). As in the first study, a number of muscular and autonomic parameters were assessed (e.g., electrodermal activity, peripheral temperature, muscular activity, peripheral pulse amplitude and others). Again abnormal adaptation processes in heart rate activity were demonstrated in patients with somatoform symptoms. In this study, the most pronounced effects were found for the difference between task period and subsequent breaks: heart rate activity reduced significantly in healthy controls when breaks occurred, demonstrating an adaptation of physiological activity. This process was significantly less pronounced in patients with somatization indicating a reduced ability to benefit from breaks.

Further studies have pointed to the link between cardiovascular activity and somatic complaints, while relationships with other physiological systems seem to be of less importance. Kristal-Boneh *et al.* (1998) reported an association between somatic symptoms and 24-hour ambulatory blood pressure levels. There was a direct association between systolic blood pressure and somatic complaints, while the association with diastolic blood pressure was non-significant. In their study, they also replicated the association between heart rate reactivity and somatic complaints (see Table XX.5).

Yardley *et al.* (1998) confirmed that patients with somatization-associated symptoms react to the provocation of these symptoms with physiological processes which might maintain the problems. They examined persons with vestibular dysfunction with a dizziness provocation technique. After the provocation of dizziness, a

Table XX.5 Heart rate and somatic complaints (data from Kristal-Boneh *et al.*, 1998)

	Low somatic complaints	High somatic complaints	Significance
Diurnal heart rate	76 b.p.m.	81 b.p.m.	$p < 0.001$
Nocturnal heart rate	64 b.p.m.	65 b.p.m.	NS
Work time	76 b.p.m.	83 b.p.m.	$p < 0.01$
Casual	71 b.p.m.	75 b.p.m.	NS

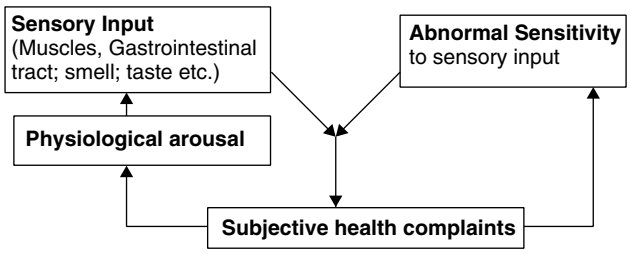

Figure XX.2 Ursin's model of a sensitization feedback loop (Ursin, 1997)

significant greater increase in respiration rate following head movements was found in those patients who complained of more somatic symptoms. These symptom-unspecific physiological effects could be associated with specific physiological changes, such as increased muscle tension or changes of blood circulation in symptom regions. Despite the face validity of the importance of these changes, they need to be better founded with empirical research.

Ursin (1997) presented a model of a psychobiological feedback loop to explain the process of somatization. Psychophysiological over-activation and the experience of complaints may lead to a sensitization of neurons. This might result in an abnormal sensitivity to sensory input from muscles or from the gastrointestinal tract, but also from smell and taste. This positive feedback loop is symbolized in Figure XX.2.

Somatoform Symptoms and the Electrophysiological Activity of the Brain (EEG, Evoked Potentials)

The perception of physical changes is a process of the central nervous system. Therefore it is possible that abnormalities of information processing in the central nervous system might be crucial for the development of somatization symptoms.

Some components of the evoked potentials are direct correlates of perceptual processes. The N1 amplitude, for example, seems to reflect processes of stimulus filtering and selective attention. Only few studies have investigated evoked potentials in somatoform disorders. However, they have yielded promising results: Gordon *et al.* (1986) used the classical 'oddball' paradigm to investigate a tone-discrimination task in *somatization disorders*. Eighty-five per cent of the tones were 1000 Hz in frequency and the remaining 15% were 2000 Hz (target tones). Participants were instructed to ignore the background tones and to count the number of target tones. The results demonstrated a trend for N1 amplitudes to be larger in the somatization group, and this was tentatively interpreted in terms of an impairment in stimulus filtering. For the other components (P1, P2, N2, P3) no significant group differences were found. The authors suggest that a more demanding task of selective attention may reveal more pronounced effects as a result of impaired stimulus processing in *somatization disorder*.

In a second study of the same group abnormalities of event-related potentials were confirmed which are thought to reflect disturbed attention processes in *somatization disorder* (James *et al.*, 1987). In this study the so-called mismatch negativity was assessed. Mismatch negativity is the difference between the potentials seen when subjects have to attend to one specific stimulus (e.g., 1000 Hz tone presented to the left ear) in comparison to potentials raised by the same stimulus when it should not be attended. Mismatch negativity starts prior to the N1 component and lasts for approximately 200 msec. This negative shift represents the difference in attention which is paid to relevant and irrelevant stimuli. In the study of James *et al.* (1987) there was less mismatch negativity in somatizers compared to normal controls at central and parietal midline sites. Somatizing patients seemed to process relevant and irrelevant stimuli more similarly than did normals; they were less capable of dividing their attention efficiently between relevant and irrelevant sensory input. This would help to explain why somatizing patients are more aware of and report more somatic symptoms.

A third study of the same group used auditory stimuli which varied in intensity (James *et al.*, 1990). The slope of P1-N1 amplitude changes as a function of stimulus intensity. This P1-N1 dependency of stimulus intensity was more pronounced in patients with *somatization disorder*, compared with controls, suggesting an enhanced central nervous system response to sensory input.

The results of these three studies are difficult to integrate. While all of them point to alternations in attention processing, the results seem not to be consistent and should be replicated and extended.

An interesting different approach was used by Wittling and colleagues (see Wittley (1997) for review). They did not investigate patients with manifest *somatization disorder*, but persons with high levels of unspecific physical complaints. Participants viewed either emotional stimuli or neutral stimuli, while topographic brain mapping procedures were used. The emotional stimuli evoked a significantly higher negativity in the period between 800 and 1200 msec over the whole posterior region. Group differences were found only for emotional stimuli, but not for the neutral stimulus conditions. Individuals with a low susceptibility to psychosomatic disorders responded to emotional stimuli with a higher negative potential than subjects with a high susceptibility to such disorders. These differences were most pronounced for the right hemisphere. Thus, these results point to abnormalities of information processing not only in simple attention tasks but also in the processing of emotional stimuli. As with other brain imaging techniques, topographic EEG can be one tool to highlight the specificities of the disturbed information processing in somatization. It would be helpful to continue this line of research.

THERAPEUTIC ARMAMENTARIUM

Management of Somatoform Disorders

In most doctor's offices, the time for diagnosis and treatment is quite limited. However, there is evidence that these few minutes can be crucial for whether the patient will be enabled to manage his complaints or whether the complaints might become chronic. Smith *et al.* (1986) and Smith *et al.* (1995) demonstrated that providing information to general practitioners on how to manage patients with somatization complaints was helpful in the avoidance of long-lasting, expensive and useless treatments. Table XX.6 contains the recommendations of Smith *et al.* (1986) as well as some extensions of our group.

Many patients with somatization symptoms are quite suspicious during the first contacts with experts. This means that the experts have to do many empathetic interventions during the first contact to install a constructive therapeutic relationship. One of these

Table XX.6 Guidelines for the management of somatization in primary care

- Confirm the credibility of the complaints
- Anticipate and inform the patient as early as possible that the most probable cause for the complaints is not a severe organic disorder, but a problem in the perception of bodily signals
- Explore the complete history and diversity of physical complaints
- Inform the patient about the next steps of investigations and about possible consequences; anticipate the time point when the procedure of organic investigations will be finished
- Avoid unnecessary investigations and alibi diagnoses
- Arrange regular dates for doctor visits of the patient; avoid spontaneous doctor visits
- Motivate for a healthy way of living and avoid physical deconditioning
- To avoid dysfunctional information processing due to the bias of the patients, use questions and ask the patient for conclusions.

steps should include the confirmation that the symptoms are 'real' for the patient and not 'just in mind'. The introduction of psychophysiological models (such as muscle over-activation, dysfunctional breathing, etc.) can be helpful at an early point in the therapeutic process. Introducing psychophysiological models only after all severe organic causes have been excluded might reduce their credibility.

Physicians may sometimes find it annoying to explore the complete history of complaints all over again. However, patients will not believe in the doctor's treatment recommendations if the doctor does not know all about the complaints. Moreover, some patients describe just those symptoms which fit in the speciality of the doctor, but do not report that they have been in gynaecological, orthopaedic or neurological treatment some weeks earlier. Therefore the diagnostician has to explore actively and ask for complaints in all parts of the body.

Some patients find it difficult to accept the doctor's opinion that no more medical investigations are necessary despite the fact that no organic reason has been found. It is easier for the patients to accept the decision to stop the diagnostic process if they have been informed in advance when this step will be taken. Unnecessary investigations increase the risk of iatrogenic harm, and unnecessary 'alibi diagnoses' reduce the probability of using successful self-help strategies.

If patients are in need of frequent doctor visits, it may be helpful to install a regular scheme for visits to avoid spontaneous, symptom-contingent procedures. The installation of regular doctor visits may be one of the first and most important steps to encourage self-help strategies for the patient: the patient knows that the doctor is still involved in the treatment process, but the patient tries to use self-help strategies in between appointments.

Some patients think that the avoidance of physical activity may be helpful to overcome the complaints. However, these patients should be informed that the avoidance of physical activity may be a helpful short-term strategy (e.g., in acute pain), but considering a long-term perspective it might increase disability. Therefore the patients should be encouraged to continue and even to expand regular physical activities.

Most patients with somatoform complaints have an information processing bias. The information provided by the doctor is transformed until it fits into the patient's reasoning. A doctor's statement of "Cancer is really improbable in your case" could be transformed into "It is probable that you have cancer" by the patient. To prevent this information transformation, the doctor can use questions and ask the patient for summaries.

As mentioned above, these simple behaviour strategies can be done even during very short-term contacts, and have a proven efficacy in the management of patients with unexplained physical symptoms. Most patients with somatoform symptoms are treated by general practitioners. Therefore it is important to transform the knowledge of experts into intervention strategies for GPs. If patients need more sophisticated psychological treatment, there are also

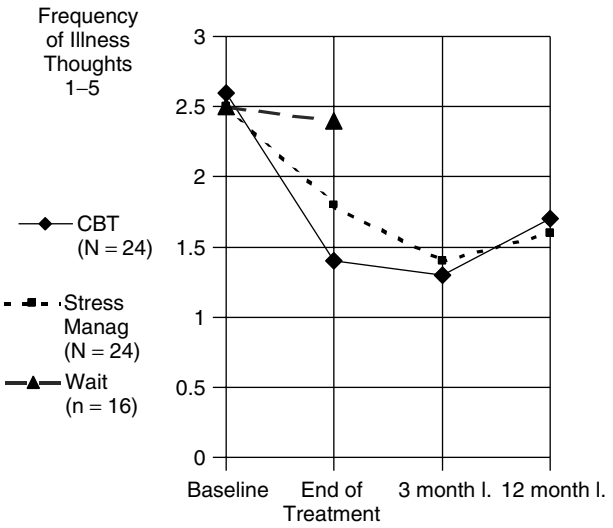

Figure XX.3 Treatment of hypochondriasis (Clark *et al.*, 1998)

some treatment studies demonstrating the efficacy of psychotherapeutic approaches. Kroenke and Swindle (2000) presented a critical review of controlled clinical trials for cognitive–behavioural therapy (CBT) in somatization. They summarized that CBT can be an effective treatment for patients with somatization or somatoform syndromes. Benefits can occur whether or not psychological distress is ameliorated. However, compared to some outstanding studies proving the efficacy of CBT in *hypochondriasis* (Clark *et al.*, 1998), the number of studies reporting psychotherapeutic approaches in other somatoform disorders is still small (see Figure XX.3).

Pharmacological Treatment

Although somatoform disorders are highly prevalent and present a rising problem to the health services there is still no standard pharmacological treatment. Only few placebo-controlled clinical trials have been performed. This might be partly due to the very concept of somatoform disorders that excludes somatic causes and therefore seems to call for other than pharmacological treatment. Further difficulties for the establishment of a standard pharmacological management of somatoform disorders arise from the heterogeneous characteristics of sub-syndromes summarized under the heading of somatoform disorders, inconsistencies in diagnostic concepts and outcome measures and generally elevated placebo response rates in somatoform disorder patients (Volz *et al.*, 1994). From the limited data base to date there is reason to believe that antidepressants are beneficial in the treatment of somatoform disorders (Volz *et al.*,

1994; Escobar, 1996). Open clinical trials suggest that selective serotonin reuptake inhibitors (SSRIs) like fluvoxamine might lead to improvement in about 60% of patients (Noyes *et al.*, 1998). In one of the few placebo-controlled clinical trials Volz *et al.* (2000) reported that the tricyclic antidepressant opipramol proved to be more effective than placebo in reducing somatic symptoms in patients with certain somatoform disorders (*somatization disorder*, *undifferentiated somatoform disorder*, *somatoform autonomic dysfunctions*). Additional improvement on other psychopathological outcome measures and the good tolerability profile further recommended the compound, especially for use in a patient group characterized by high psychiatric comorbidity and a focus on even minor body sensations.

Body dysmorphic disorder (BDD) has been considered an obsessive–compulsive spectrum disorder, owning to the features it shares with obsessive–compulsive disorder (OCD). As in OCD open trials suggest a good therapeutic response to serotonin reuptake inhibitors, such as clomipramine, fluoxetine and fluvoxamine; other pharmacological agents, such as neuroleptics, trazodone, lithium, benzodiazepines, tricyclics and anticonvulsants, have been less beneficial or ineffective in BDD (Hollander *et al.*, 1989; Phillips *et al.*, 2001; Phillips *et al.*, 2001). In a randomized, double-blind, crossover-design study of 29 BDD patients clomipramine, a potent serotonin reuptake inhibitor, was superior to the active control desipramine, a potent norepinephrine reuptake inhibitor in the treatment of BDD symptoms according to all outcome measures (Hollander *et al.*, 1999). As was later confirmed by other researchers delusional patients (which required the diagnosis of delusional disorder, somatic type) responded as well as non-delusional patients to SRI treatment (Hollander *et al.*, 1999; Phillips *et al.*, 2001). Thus, delusional patients may not require neuroleptic treatment and might be spared possible adverse side effects.

Another subtype of somatoform disorder, *hypochondriasis*, has also been related to obsessive–compulsive disorder. Although the comorbidity profile, clinical course and family history data do not support this hypothesis there is evidence that hypochondriac concerns respond to the same class of drugs that is effective in OCD: serotonin reuptake inhibitors. Open trial data suggest that SSRIs such as fluvoxamine might be useful therapy for hypochondriac patients (Fallon *et al.*, 1993; Perkins, 1999). A preliminary report of placebo-controlled trial in a small group of patients partly confirmed these results. However, due to high placebo response rates differences between fluvoxamine (66% responders) and placebo (50% responders) felt short of statistical significance (Fallon *et al.*, 1996). Tricyclic antidepressants seem not to be effective in *hypochondriasis* (Fallon *et al.*, 2000). As is the case in BDD there seems to be a spectrum of insight in *hypochondriasis* ranging from good to absent. Patients at the latter end of this continuum would require the diagnosis of delusional disorder, somatic type, formerly called monosymptomatic hypochondriacal psychosis. For those patients single case studies and small clinical series suggest that low doses of neuroleptics such as pimozide or olanzapine might be the treatment of choice (Opler and Feinberg, 1991; Weintraub and Robinson, 2000). However, as SSRIs have proved to be effective in treating delusionality in delusional BDD patients there might be reason to expect beneficial effects also on delusional *hypochondriasis* (Perkins, 1999).

The possible analgesic effects of antidepressants for the treatment of chronic pain have been evaluated in a number of double-blind studies. In a recent meta-analysis Fishbain *et al.* (1998) reviewed 11 randomized, placebo-controlled treatment studies on *pain disorder*. The results showed that antidepressants decreased pain intensity more than placebo in patients with psychogenic pain or *somatoform pain disorder* (mean overall effect size = 0.48). The authors argued that low dosage and short duration of treatment in most studies made it unlikely that the medication could have exerted an appreciable antidepressant effect. Thus, the analgesic effect of the treatment was considered not to be just a function of the antidepressant properties of the drugs.

The analgesic properties of both tricyclic antidepressants and new antidepressant compounds have also proved to be therapeutically useful in related syndromes such as the somatoform spectrum disorder *fibromyalgia* (Goldenberg *et al.*, 1986; Dwight *et al.*, 1998).

Taken together, there is evidence that antidepressant drugs have a beneficial effect in somatoform disorders, with traditional tricyclic antidepressants being especially useful in those conditions that are characterized by pain and multiple somatic complaints (*pain disorder*, *somatization disorder*) and modern SSRI antidepressants being especially effective in conditions being related to anxiety disorders and obsessive–compulsive disorder (*body dysmorphic disorder*, *hypochondriasis*). However, there is still a need for more controlled studies using larger patient samples. Issues of differential indication and long-term maintenance of treatment effects need considerably greater attention.

The Emerging Psychobiology of Trauma-Related Dissociation and Dissociative Disorders

Ellert R.S. Nijenhuis, Onno van der Hart, and Kathy Steele

INTRODUCTION

Mental dissociation is an intriguing and complex phenomenon that has been studied clinically and theoretically for more than 150 years. Major empirical studies have been conducted during the last two decades. For example, these studies have established that the prevalence rates of the DSM-IV dissociative disorders (APA, 1994) are considerable among psychiatric inpatients, with an overall prevalence among nine studies of 18.9% for dissociative disorders in general, and 4.4% for dissociative identity disorder (DID; Friedl *et al.*, 2000). Only in recent years has dissociation begun to receive attention from a combined psychological and biological perspective.

The study of dissociation has been impeded by several factors. First, conceptual confusion and controversy exist regarding the nature of this phenomenon. For example, dissociation is described as a process, as various symptoms, as mental structure, as psychological defense, and as a deficit in integrative capacity. In addition, it is confused with retraction of the field of consciousness (that which is within awareness at a given time) such as absorption, daydreaming, and states of inattention. Although negative dissociative symptoms such as amnesia are acknowledged, positive ones, such as intrusive re-experiences of trauma, are often not understood as dissociative in nature.

Second, diagnostic and aetiological issues are far from resolved in psychiatric disorders in which dissociation is an essential feature. For example, it is debatable that the DSM-IV category of dissociative disorders encompasses the actual range of dissociative disorders. As discussed below, although post-traumatic stress disorder (PTSD) is classified as an anxiety disorder, there are arguments to regard it as a dissociative disorder (e.g., Nijenhuis *et al.*, 2002b). And the ICD-10, for instance, includes dissociative disorders of movement and sensations that are defined in the DSM-IV as conversion disorders. It has been theoretically argued (Kihlstrom, 1994; Nemiah, 1991; Nijenhuis and Van der Hart, 1999a) and empirically documented (Nijenhuis, 1999) that conversion symptoms are dissociative in nature. Conversion is better conceptualized as somatoform dissociation in that the symptoms of concern are at least equally characteristic of DSM-IV dissociative disorders as dissociative symptoms that manifest in psychological variables, i.e., so-called psychoform dissociation (Van der Hart *et al.*, 2000). Moreover, somatoform dissociation correlates very strongly with psychoform dissociation (Nijenhuis, 1999; Nijenhuis *et al.*, 1996, 1997, 1999b; Sar *et al.*, 2000; Waller *et al.*, 2000), and evidence for the hypothesis that psychological conflicts can be converted into physical symptoms, and thus reduce mental strain, is lacking.

Although the DSM-IV dissociative disorders have received wide acceptance, there exists a vocal minority of clinicians and researchers who express their scepticism about the validity of the most complex dissociative disorder, DID (Spanos and Burgess, 1994). As we will discuss in more detail below, patients with DID have severe somatoform and psychoform dissociative symptoms that relate to the existence of two or more self-aware dissociative systems, i.e., dissociative systems of ideas and functions that involve a sense of self. However, sceptics doubt that dissociative personalities are genuine phenomena. Simulated or factitious cases of DID certainly exist (Draijer and Boon, 1999) along with genuine cases, and the psychobiological differences between genuine and false positive cases of DID are a fruitful area of research. Some authors have also questioned whether chronic childhood traumatization is an aetiological base for DID and other dissociative disorders, but research has converged to indicate traumatic events are a key element in the psychopathology of dissociation and dissociative disorders. Retrospective (e.g., Boon and Draijer, 1993; Coons, 1994; Kluft, 1995; Lewis *et al.*, 1997; Nijenhuis *et al.*, 1998b) and prospective studies (Ogawa *et al.*, 1997) — some of which have provided external corroboration for reported trauma — have confirmed the clinical observation that dissociative symptoms and disorders are associated with reported and factual traumatization. Studies have also demonstrated discrete and long-lasting alterations in neurobiological systems in relation to trauma and dissociation, which will be discussed below.

The current chapter focuses on dissociation related to traumatization. The first aim of the chapter is to reduce confusion about the concept of dissociation. Next, possible neuroendocrine parameters of dissociation and key brain structures that seem to be involved in the phenomenon are discussed. Several neurobiological models of dissociation will be reviewed, including Putnam's discrete behavioural states model (Putnam, 1997). Finally, the theory of structural dissociation will be presented (Nijenhuis and Van der Hart, 1999b; Van der Hart *et al.*, 1998; Nijenhuis *et al.*, 2002b; Steele *et al.*, 2001), along with supporting evidence. The theory attempts to explain trauma-related dissociation as it manifests in disorders ranging from simple PTSD to DID, and serves an important heuristic function with regard to the emerging psychobiological study of trauma-related dissociation.

THE CONCEPT OF DISSOCIATION

Dissociative symptoms are often misunderstood as indicators of other disorders or problems. Thus, it is quite common for dissociative disorder patients to hear internal voices (easily confused with psychosis); to experience disorientation to time, place and person during intrusive re-experiences (confused with intoxication, delirium, delusions, hallucinations, and psychosis); to have

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

rapidly alternating shifts in mood (confused with bipolar disorders); to experience cognitive and attentional difficulties (confused with attention deficit disorder and cognitive processing deficits); to have intractable dissociative pain and somatoform disturbances (confused with malingering, factitious disorder; hypochondriasis, drug-seeking behaviour, and somatization disorder); to have unusual sleep disturbances due to night-time dissociation (confused with disorders of sleep); and to experience lapses in awareness (confused with malingering, manipulation, organic memory dysfunction, and iatrogenic suggestibility). Therefore, efforts to define dissociation (e.g., Braude, 1995; Cardeña, 1994; Janet, 1907; Nijenhuis *et al.*, 2002b; Putnam, 1997; Van der Hart, 2000) are important, both for clinical and research purposes.

Janet (1907, p. 332) postulated that dissociation involves a lack of integration of 'systems of ideas and functions that constitute personality' due to 'a form of mental depression'. In the context of traumatic experience, dissociation ensues when the integrative capacity of the individual is not sufficient to integrate experiences and functions. As a result, (components of) experiences can be encoded and stored as discrete systems involving sensations, body movements, affects, perceptions of the environment, and factual knowledge. Because conscious experience implies a subject, dissociative systems also involve their own sense of self, however rudimentary. While integrative failure that results in fragmentation of the personality denotes the essence of dissociation, Janet did not specify the underlying psychobiological nature of the different dissociative 'systems of ideas and functions' that traumatic experience tends to evoke.

Psychoform and Somatoform, and Negative and Positive, Dissociative Symptoms

Dissociation manifests in psychoform and somatoform symptoms (Janet, 1889; Kihlstrom, 1994; Nijenhuis and Van der Hart, 1999a; Nijenhuis *et al.*, 2002b; Van der Hart *et al.*, 2000). Both categories include negative and positive symptoms. Negative symptoms manifest when the individual fails to integrate dissociative systems of ideas and functions that, at least in principle, are available. Positive symptoms occur when these systems are retrieved (e.g., flashbacks), but without integration. Negative psychoform symptoms include losses such as amnesia, depersonalization, and derealization. Positive psychoform symptoms include re-experiencing the mental contents of traumatic memories such as thoughts, images, and feelings, as well as hearing voices that are emitted by dissociative systems (e.g., as in dissociative fugue; APA, 1994). Negative somatoform dissociative symptoms involve anaesthesia of one or more sensory modalities and motor inhibitions, such as paralysis, visual disturbances like tunnelling and haziness, deafness, or inability to feel parts of the body. Examples of positive ones are pain, sexual sensations, and freeze, flight, fight and submissive states pertaining to traumatic re-experiences.

Retraction of the Field of Consciousness and Low Levels of Conscious Awareness

Phenomena such as absorption, imaginative involvement and trance-like behaviour are often referred to as normal or non-pathological dissociation (e.g., Putnam, 1997) or as dissociative detachment (Allen *et al.*, 1999). However, these experiences result from automatic and unconscious reduction of the number of phenomena in current conscious awareness, called retraction of the field of consciousness. They do not involve encoding and storage of experience, knowledge, and skills. For example, selective attention for threat cues does not necessarily imply encoding and storage of 'peripheral' cues. While retraction of the field of consciousness may accompany dissociation (Janet, 1907; Nijenhuis *et al.*, 1996), the concepts are different.

Retraction of the field of consciousness can involve different levels of conscious awareness. The level of awareness can be high when dissociative patients focus on threat cues, but low when they enter trance states during which they are only minimally aware of themselves and their surroundings, and thus fail to encode their experience at the time. Extremely high and low levels of awareness may set the stage for dissociative processes, but are not dissociative in themselves.

The conceptual confusion with regard to dissociation continues to plague the field. For example, many instruments that evaluate the severity of dissociation suffer from under-inclusion of negative somatoform dissociative symptoms, as well as positive psychoform and somatoform dissociative symptoms, and from over-inclusion of symptoms that evaluate retraction of the field of consciousness and lowering of the level of consciousness.

PTSD, DISSOCIATION, AND STRESS RESPONSES

Defining dissociation as a lack of integration among self-aware 'systems of ideas and functions' implies that dissociation also characterizes PTSD in that this psychobiological disorder (Kardiner, 1941; Van der Kolk, 1994; cf. Vermetten and Bremner, 2001a, 2001b) involves two dissociative parts of the personality that can take control over consciousness and behaviour (Nijenhuis and Van der Hart, 1999b). One is numb and avoidant of traumatic memories and trauma-related reminders, but more or less functional in daily life, and another is enmeshed in traumatic memories. The enmeshed dissociative system intermittently intrudes or replaces the numb dissociative system. As we will discuss below, this split represents a form of structural dissociation of the personality that also constitutes the basis of more complex dissociative conditions.

To the extent that this conceptualization is correct, pre-clinical and clinical studies of severe aversive stress and PTSD are also relevant for the psychobiology of trauma-related dissociation more generally. Although a review of these studies is beyond the scope of the present chapter (for reviews, see Coupland, 2000; Van der Kolk, 1994; Vermetten and Bremner, 2001a, 2001b), the main findings are briefly noted. Animal studies have contributed to the understanding of human reactions to overwhelming events. For example, they have allowed for insights into delay conditioning of fear and defensive reactions patterns in which the conditioned stimulus immediately follows the unconditioned stimulus, as well as trace conditioning, in which the conditioned stimulus and unconditioned stimulus are separated by an interval. Delay conditioning depends on long-term potentiation within the basolateral amygdala, whereas trace conditioning requires involvement of the hippocampus. These forms of classical conditioning are relevant for dissociation, since dissociation as a process (i.e., the presumed psychobiological process that yields splits among self-aware dissociative systems) can become a conditioned response to previously neutral cues. Yet, the issue is complex: clinical observations and experimental research (Nijenhuis *et al.*, 1999a; Reinders *et al.*, in preparation; Van Honk *et al.*, 1999, 2001), to be discussed below, suggest that different dissociative systems can display different psychobiological responses to identical stimuli. Somehow the associations between unconditioned aversive stimuli (UCS) and conditioned stimuli (CS), or the responses to these associations, may depend on the particular dissociative system that dominates consciousness and behaviour.

Pre-clinical studies have also been valuable in delineating other learning processes that are relevant for trauma-related dissociative disorders. These processes include contextual conditioning (i.e., learning to respond to contextual cues such as the place where a foot shock was received), sensitization (i.e., response increment with repeated exposure to aversive cues), kindling, and extinction. It was once thought that the disappearance of conditioned responses

indicated loss of the conditioned association between the CS and the UCS. However, the evidence suggests that once encoded, CS-UCS associations cannot be extinguished (Bouton, 1994), but rather become inhibited. The hippocampus and medial prefrontal and orbitofrontal cortex seem to have major roles in this process.

Animal studies provide a model for understanding a range of neurobiological alterations in PTSD, and probably are relevant for (other) dissociative disorders as well. The pathophysiology of stress reflects enduring changes in biological stress response systems with implications for learning and memory. The affected biological systems include systems mediating corticotropin-releasing factor (CRF), adrenocorticotropin hormone (ACTH), glucocorticoids (HPA-axis), neuropeptide Y (NPY), and norepinephrine (locus coeruleus/autonomic nervous system). Stressors also tend to affect serotonergic, dopaminergic, neuropeptide and central amino acid systems. Combat-related PTSD was marked by decreased benzodiazepine receptor binding in the prefrontal cortex (Bremner *et al.*, 2000b). These systems interact with brain structures involved in learning and memory, including the hippocampus, amygdala, and prefrontal cortex. Pre-clinical studies have demonstrated that the intensity and duration of the stressor, as well as the timing of the stressor in life, amplify the neurobiological effects of stressors. For example, maternal separation, lack of handling, and repetitive pain affect the developing brain of animals.

There is evidence for a number of parallels between animal responses to aversive stress and similar mechanisms in PTSD (Coupland, 2000), as well as other trauma-related disorders in humans. Thus, clinical studies of PTSD have found that brain areas such as the hippocampus, amygdala, insula, cingulate and prefrontal cortex are critically involved in responding to severe stressors, as well as in the learning from and memorization of these events (e.g., Rauch *et al.*, 1996; Van der Kolk, 1994; Vermetten and Bremner, 2001b). Some findings (to be discussed below) suggest that these brain structures are also of major importance in other dissociative conditions. Neural circuits affected in PTSD include the HPA-axis, catecholaminergic and serotonergic systems, neuropeptide systems, the hypothalamic-pituitary-thyroid axis, and neuro-immunological alterations. In both animals and humans, the HPA-axis and the autonomic nervous system are important stress response systems that, within limits, serve to maintain homeostasis during exposure to stress. Consistent with the animal studies, converging evidence has emphasized the role of early life trauma and attachment in the development of PTSD and other trauma-related disorders (Schore, 2001). Yet, there are also differences between neurobiological correlates of animal and human traumatization. An example is the finding of low cortisol levels in several studies of PTSD that contrasts with stress-induced increases of cortisol in animals (for a review see Yehuda, 2000).

POSSIBLE INVOLVEMENT OF NEUROCHEMICALS IN DISSOCIATION

Dissociation involves a failure to integrate systems of encoded and stored experiences and functions. From a biological point of view, integrative functions can be hampered by the release of neurochemicals provoked by severe threat (Ludwig, 1972; Krystal *et al.*, 1991; see also Siegel, 1999) and that are concentrated in brain regions implicated in integrative mental acts, such as the hippocampus and the prefrontal cortex.

Enhancement and Impairment of the Memory Function

The extent to which substances such as glutamate (Krystal *et al.*, 1998), norepinephrine, epinephrine, glucocorticoids, endogenous opiates, and several others (McGaugh, 1990, McGaugh *et al.*, 2000) interfere with integration is dose-dependent. For example, retention of recently learned material is enhanced when moderate doses of epinephrine are administered after training, but impaired at high doses. Memory impairment also depends on experimental conditions such as degree of arousal produced by the learning situation and the strength of the memory involved. For example, when the β-adrenergic antagonist propanolol was administered after training, memory was strongly impaired in rats that exhibited good learning during the acquisition session, but not in rats that exhibited poor learning (Cahill *et al.*, 2001, discussed in Cahill, 2000). While long-lasting exposure to threat cues such as predators may produce failure to execute previously memorized tasks (Diamond and Park, 2000; Woodson *et al.*, 2001), memories of emotional events can also be excellent, requiring little or no cognitive rehearsal (Guy and Cahill, 1999). This apparent paradox may be resolved by considering that patients with PTSD and several other dissociative conditions may alternate between hyperamnesia and memory loss. Hence, memory retrieval may depend on the dissociative part of the personality that is dominant.

Substance-Induced Dissociative-Like Symptoms in Healthy Individuals

Several substances may induce phenomena in healthy individuals that mimic dissociative symptoms, i.e., antagonists of the *N*-methyl-D-aspartate (NMDA) subtype of glutamate receptors, cannabinoids, and serotonergic hallucinogens (Krystal *et al.*, 1994a, 1994b, 1998). Because glutamate has a central role in corticocortical, thalamocortical, amygdalacortical, and hippocampocortical connectivity, higher cognitive functions could basically involve glutamatergic systems. Pre-clinical data have indeed suggested that (traumatic) stress stimulates the corticolimbic release of glutamate, and clinical studies have documented that antagonists of the NMDA receptor may transiently stimulate glutamate release, inducing symptoms that resemble dissociative symptoms in humans (Chambers *et al.*, 1999).

Ketamine blocks the NMDA receptor-mediated component of glutamatergic connections. This substance produces dose-dependent impairment of perceptual, sensory, and proprioceptive experiences that could reflect retraction of the field of consciousness, lowering of the level of consciousness, and negative dissociative symptoms. Ketamine does not seem to evoke positive dissociative symptoms, such as manifestations of dissociative parts of the personality or intrusive recollection of experiences involving negative emotions. Ketamine-induced learning and memory impairments have also been observed, as were psychotic-like symptoms such as delusions, thought disorder and negative symptoms of schizophrenia (e.g., Breier *et al.*, 1997). Hence, it seems doubtful that glutamatergic dysregulation is a *specific* inductor of dissociation, i.e., an inductor of dissociative fragmentation of the personality.

The hippocampus is implicated in the synthesis of experiences and memory encoding, and the NMDA receptor is highly concentrated in this brain structure. Since blocking of the Schaffer collateral-CA1 NMDA receptors in the hippocampus can inhibit long-term potentiation (Tsien *et al.*, 1996), ketamine could affect memory. Substances that enhance NMDA receptor function may perhaps reduce trauma-related dissociation (see Krystal *et al.*, 1998). Consistent with this hypothesis, a drug that reduces glutamate release attenuated the effects of ketamine (Chambers *et al.*, 1999). Modulatory GABAergic neurons regulate pyramidal neurons that use glutamate as their primary neurotransmitter (Krystal *et al.*, 1998). Thus, future research should assess whether substances that reduce trauma-related glutamate release or enhance gamma-aminobutyric acid (GABA) functions promote the integration of traumatic experience. Benzodiazepines are prototypical

GABA enhancers, and were useful in the treatment of some PTSD symptoms of patients with dissociative disorders (Loewenstein *et al.*, 1988). Yet, benzodiazepines can evoke positive dissociative symptoms, discussed below, and at high doses they may promote amnesia. Krystal *et al.* (1998) have proposed to evaluate whether drugs that facilitate NMDA receptor function have antidissociative effects in PTSD patients.

Depersonalization, derealization, perceptual alterations, and time distortions have also been provoked by high doses of cannabinoids (Dittrich *et al.*, 1973; Melges *et al.*, 1970), and were correlated with increased cerebral blood flow (Mathew *et al.*, 1993). Moreover, cannabinoids also produce amnestic effects due to interference with hippocampal memory functions (Hampson and Deadwyler, 1999). Some cannabinoid effects may be mediated by stimulation of glucocorticoid receptors (Eldrigde and Landfield, 1990) and blockade of NMDA receptors (Feigenbaum *et al.*, 1989). Serotonergic hallucinogens produce visual hallucinations, illusions, depersonalization, derealization, as well as body image distortion and, occasionally, emotional detachment (e.g., Freeman, 1986; Strassmann *et al.*, 1994). However, ketamine, its cousin phencyclidine, cannabinoids, and serotonergic hallucinogens do not produce dissociative disorders or positive dissociative symptoms such as hyperamnesia and flashbacks with respect to stressful and aversive experiences. As applies to ketamine, there is no evidence that the symptoms that cannabinoids and serotonergic hallucinogens produce relate to structural splits among dissociative parts of the personality.

Substance-Induced Dissociative Symptoms and States in PTSD Patients

A range of substances, including barbiturates and benzodiazepines, can reactivate traumatic memories and flashbacks in PTSD (for a review, see Krystal *et al.*, 1998). The effects of these drugs seem to be indirect, as they may reduce anxiety, and thus suppress mechanisms that inhibit access to traumatic memories (e.g., Kopelman *et al.*, 1994).

Autonomic activation, flashbacks and recall of traumatic memories can be provoked in a subset of patients with chronic PTSD using intravenous administration of sodium lactate (Rainey *et al.*, 1987), yohimbine (Southwick *et al.*, 1993), and metachlorophenylpiperazine (m-CPP; Southwick *et al.*, 1991). In some cases, yohimbine-induced flashbacks and traumatic memories were accompanied by depersonalization and derealization. Yohimbine blocks $\alpha 2$ receptors located on noradrenergic neurons that have a role in the regulation of fear and arousal. The $\alpha 2$ receptors partly mediate feedback inhibition of noradrenergic neurons (Starke *et al.*, 1975). Hence, yohimbine activates central noradrenergic neurons, producing increased release of norepinephrine in the brain. Clinical observations have suggested that autonomic arousal can reactivate traumatic memories, possibly because the autonomic arousal that was part of the traumatic experience has become a conditioned stimulus. (Thus, some PTSD patients and traumatized patients with other dissociative disorders tend to avoid aroused states, such as physical exertion, as well as negative and positive emotions.) However, Southwick (see Krystal *et al.*, 1998) reported that in some cases autonomic arousal followed yohimbine-provoked traumatic memories. This observation led Krystal and colleagues to conclude that 'noradrenergic systems might be involved in the elicitation of dissociative symptoms [i.e., traumatic memories, and accompanying features] as a direct consequence of central pharmacological actions of yohimbine on neural circuitry contributing to dissociation and memory retrieval' (p. 326). On the other hand, even small increments of arousal may perhaps trigger traumatic memories when the individual has developed a phobia for bodily arousal that originally accompanied trauma.

Norepinephrine/Locus Coeruleus

The autonomous nervous system is regulated by the locus coeruleus and its projection areas. The activity of the HPA-axis is partly mediated by the release of CRF by the paraventricular nucleus of the hypothalamus. Both systems are key players in stress responsivity and are functionally interrelated. They both have differentiated anatomical and functional responses to different kinds of stressors. For example, the hypothalamic paraventricular nucleus neuron appears to be affected by multiple sources, including brainstem aminergic and peptidergic afferents; blood-borne information; indirect input from limbic system and associated regions, including the prefrontal cortex, hippocampus, and amygdala; and local-circuit interactions (Herman *et al.*, 1996).

The locus coeruleus houses the majority of noradrenergic neurons. Exposure to chronic stress may yield long-term alterations in locus coeruleus firing and in norepinephrine release in target brain regions of the locus coeruleus (Bremner *et al.*, 1996). Norepinephrine also has a role in fear conditioning and sensitization, and there is strong evidence that noradrenergic activation of the amygdala is critical for neuromodulatory influences on memory storage (McGaugh *et al.*, 2000).

Both animal and human studies have shown that high levels of norepinephrine release are associated with a decrease in metabolism in the cerebral cortex. Following administration of yohimbine, PTSD patients had a tendency towards decreased brain metabolism in hippocampal, orbitofrontal, temporal, parietal, and prefrontal cortex areas; healthy controls had a tendency toward increased metabolism in these regions (Bremner *et al.*, 1997a).

Endorphins

Alcohol and opiate withdrawal activate central noradrenergic systems and can increase flashbacks and other PTSD symptoms (e.g., Kosten and Krystal, 1988). Many dissociative patients report that self-mutilation and substance abuse may be instrumental in temporarily reducing autonomic arousal, intrusions of traumatic memories, and internal imperative voices. These effects could be mediated by the release of β-endorphins that dampen norepinephrine firing in the locus coeruleus. Endogenous opiates contribute to stress-induced analgesia, dissociative symptoms, and possibly the high rate of opiate abuse in patients with PTSD: this disorder is associated with decreased baseline levels, but increased post-stimulation effects of β-endorphins (Newport and Nemeroff, 2000). The opioid antagonist naltrexone decreased the frequency of flashbacks and other dissociative phenomena in borderline personality disorder (Bohus *et al.*, 1999).

HPA-Axis

Several studies have suggested that PTSD involves low baseline levels of cortisol (Yehuda, 2000), and lower cortisol responses to CRF and ACTH challenge (Vermetten and Bremner, 2001b). While there is evidence for excessive CRF release from the hypothalamus in PTSD, and excessive ACTH from the pituitary, baseline cortisol is low. According to Yehuda (2000), low cortisol in PTSD is due to negative feedback inhibition in the HPA-axis. Yet, since the number of glucocorticoid receptors are high in PTSD, the HPA-axis would be very sensitive to stressors. In some studies, however, PTSD was associated with increased cortisol levels (e.g., De Bellis *et al.*, 1999; Lemieux and Coe, 1995). Bremner (1999) suggested that perhaps low cortisol characterizes chronic PTSD, and high cortisol levels the acute stages of the disorder. For example, women with a history of prior rape or assault had relatively lower cortisol levels immediately after rape than raped women without such a history (Resnick *et al.*, 1995). On the other hand, in individuals who had developed PTSD

in response to motor vehicle accidents, the cortisol response in the immediate aftermath of the accident was significantly lower than in individuals who had developed major depression. This group effect remained after controlling for covariates such as minutes post accident, time of day, severity of trauma, and past PTSD (Yehuda *et al.*, 1998).

The neuropeptide CRF and ACTH are involved in the modulation of memory functions and the stress response. Bremner *et al.* (1997b) found an increase of CRF in PTSD patients, which is consistent with the impaired memory function in PTSD (Bremner *et al.*, 1998b) and the DSM-IV dissociative disorders. Heim *et al.* (2000) documented strongly increased ACTH levels and heart rate increases in response to mild stressors, but normal cortisol levels in women who had been sexually and physically abused early in life. This increase is presumably due to CRF hypersecretion.

Interactions Among Neuropeptide Y (NPY), Corticotropin-Releasing Factor (CRF), Cortisol, and Norepinephrine

Anxiety and stress vulnerability may relate to dysregulation of interrelated neurotransmitter systems that augment and attenuate threat responses. Whereas CRF promotes anxiety, pre-clinical studies suggest that NPY has anxiolytic properties (Helig *et al.*, 1989, 1993). Chronic stress exposure may result in the development of low baseline levels of NPY, as well as a blunted NPY response to subsequent stress (Corder *et al.*, 1992). It thus seems that deficits in NPY may promote anxiety and distress, whereas augmentations in NPY can buffer these effects.

The interactions between CRF and NPY are relevant to human stress responses in that abnormalities of both CRF and NPY have been noted in individuals suffering from post-traumatic stress, anxiety, and symptoms of dissociation (Bremner *et al.*, 1997b; Rasmusson *et al.*, 2000). Compared with healthy subjects, PTSD patients reported more anxiety, had low baseline levels of NPY, and had a blunted NPY response to yohimbine (Rasmusson *et al.*, 2000). Rasmusson and colleagues also found a negative correlation between the degree of combat exposure and plasma NPY and a negative correlation between baseline NPY levels and yohimbine-induced increases in plasma 3-methoxy-4-hydroxyphenylglycol and in systolic blood pressure. Thus sympathetic dysregulation in PTSD may be related to deficits in the NPY response to stress.

Twenty-four hours after cessation of uncontrollable stress during military survival school training, NPY had returned to baseline in special forces soldiers (Morgan *et al.*, 2000). However, other soldiers exhibited a significant depletion of NPY. The stress-induced release of NPY was negatively correlated to negative dissociative symptoms. Studying healthy subjects enrolled in US Army survival school, Morgan *et al.* (2001) found that release of salivary cortisol, NPY, and norepinephrine induced by stressful military interrogation during training were positively correlated. Release of cortisol, but not of NPY, was also correlated with dissociation and military performance during stress in this study. The dissociation measure (Clinician Administered Dissociative States Scale, CADSS, Bremner *et al.*, 1998a) administered in this study is problematic, however. The CADSS includes items that evaluate retraction of the field of consciousness, and lowering of the level of consciousness, disregards positive psychoform dissociative symptoms, and includes only a few items that assess somatoform dissociation. These flaws are found in many dissociation scales.

Urinary Catecholamines and CSF Norepinephrine

De Bellis *et al.* (1999) examined the relationship between trauma, psychiatric symptoms and urinary-free cortisol and epinephrine, norepinephrine, and dopamine excretion in abused pre-pubertal children with PTSD. These subjects were compared to a group of non-traumatized children with overanxious disorder, and with healthy controls. The children with PTSD excreted significantly greater concentrations of urinary dopamine and norepinephrine over 24 hours than the other subjects, had greater concentrations of 24 hour urinary-free cortisol than control subjects, and excreted greater concentrations of urinary epinephrine than subjects with overanxious disorder. They also had more dissociative symptoms and other psychiatric symptoms than control groups. Urinary catecholamine and urinary-free cortisol concentrations showed positive correlations with the duration and severity of PTSD symptoms. However, urinary catecholamine levels bear little relation to brain activity. A recent study found presence of greater central nervous system noradrenergic activity under baseline conditions in patients with chronic PTSD than in healthy individuals (Geracioti *et al.*, 2001). While plasma norepinephrine concentrations showed no significant relationship with the severity of PTSD symptoms, CSF norepinephrine levels strongly and positively correlated with PTSD symptoms.

In conclusion, progress in the study psychobiology of dissociation depends on more sophisticated conceptualization and measurement of dissociation. Excessive glutamate could be associated with negative dissociative symptoms, whereas excessive norepinephrine may provoke positive dissociative symptoms in individuals who have been traumatized. Traumatized individuals also display ACTH hypersecretion in response to even mild stressors — probably induced by hypersecretions of CRF. Assuming that the subjects studied by Heim *et al.* (2000) had increased numbers of glucocorticoid receptors, the hippocampus would be exposed to levels of cortisol that exceed normal values. The role of cortisol in dissociation requires further study. Some studies have found low-to-normal cortisol levels in PTSD, perhaps indicating negative feedback inhibition. However, abused children with PTSD and dissociative symptoms may have increased levels of cortisol. The inconsistent findings with respect to cortisol perhaps indicate that the functioning of patients with dissociative conditions depends on the dissociative system that dominates at a given time. Consistent with this hypothesis, Mason *et al.* (2001) found an inverse relationship between urinary cortisol levels and a symptom complex composed of two closely related clinical subgroupings, i.e., 'disengagement' (emotional numbing; relatively lower cortisol levels) and 'engagement' in trauma memories (relatively higher cortisol levels). Anisman *et al.* (2001) found that one month after an ice storm, salivary cortisol levels were elevated among moderately affected victims. However, they were diminished among those with the highest Impact of Event Scale scores. It seems possible that the more seriously affected victims remained in a numbed state when tested. The hypothesis that the psychobiological functioning of patients with dissociative conditions depends on dissociative systems will be discussed in detail below.

KEY BRAIN STRUCTURES IN INTEGRATIVE FUNCTIONS

The integrative failure that is characteristic of traumatized individuals may relate to structural and functional brain changes. For example, some data suggest temporal lobe abnormalities in dissociation. EEG recordings of dissociative patients usually involved temporal and frontal slow wave activity (Putnam, 1997). Studies of psychiatric patients reporting childhood abuse (Teicher *et al.*, 1993), as well as traumatized children (Ito *et al.*, 1993) have also documented EEG abnormalities. Using SPECT tomography, Yazici and Kostakoglu (1998) found regional cerebral blood flow changes in patients with somatoform dissociative disorder involving astasia–abasia, i.e., bizarre gait and the inability to stand unaided. Four of the five patients had left temporal, and one patient had left parietal perfusion decreases.

A range of temporal lobe structures have been implicated in dissociation, including the amygdala, hippocampus, and thalamus. Cortical regions involve the orbitofrontal and medial prefrontal cortex, and the sensory association areas.

Amygdala

The amygdala plays a critical role in responding to unconditioned threat stimuli, in the acquisition and expression of classical conditioning effects (Davies, 2000; Dolan, 2000), and in encoding and retrieval of the evaluative tone of episodic memories (Dolan, 2000). For example, LeDoux (2000) stressed that inactivation of the amygdala during learning prevents classical fear conditioning from taking place, and inactivation immediately after training precludes effects on memory. These data suggest that the amygdala is essential for fear learning.

There is evidence for involvement of the amygdala in PTSD. Electrical stimulation of the amygdala and hippocampus — as components of distributed neural memory networks — may automatically retrieve memories in a rather inflexible way, including sensorimotor re-experiencing of frightening experiences (Halgren *et al.*, 1978; Penfield and Perot, 1963). Relative inflexibility and involuntary retrieval are prominent features of traumatic memories (Van der Kolk and Van der Hart, 1991). The responsiveness of the amygdala to threat cues does not depend on conscious awareness of threat: Morris *et al.* (1999) found that the amygdala is responsive to masked angry faces, and Rauch *et al.* (2000) reported functional MRI-evidence for exaggerated amygdala response to masked facial stimuli in PTSD.

Hippocampus

The hippocampus supports the integration and modulation of modality-specific information (e.g., of the sensory, motor, and visual cortices). This processing is required for the development of coherent experiences and memories (Squire and Knowlton, 1995). The hippocampus also serves to evaluate context, which is important in the context-dependent modulation of acquired associations between unconditioned and conditioned (threat) stimuli. Thus, the amygdala stores (LeDoux, 1996) and modulates (Cahill, 2000; McGaugh *et al.*, 2000) the mostly permanent CS-UCS associations, but information processing involving the hippocampus is required to evaluate whether the CS-UCS association applies in the current context. If the CS does not signal the probable occurrence of the UCS in the present circumstances, the hippocampus should inhibit (with the medial prefrontal and orbitofrontal cortex) amygdala-based responses to CS.

Stress hormones interfere with functioning of the hippocampus, and may even damage it: animal studies have shown that direct glucocorticoid exposure results in a loss of pyramidal neurons and dendritic branching in the hippocampus (Woolley *et al.*, 1990). This suggests that the organic structure of the hippocampus is affected by cortisol, probably resulting in a decrease of neuronal synapses that would facilitate integration. Glucocorticoids might have similar effects on the human hippocampus. Compared with healthy controls, patients with combat-related PTSD (Bremner *et al.*, 1995), adults reporting childhood physical and sexual abuse with PTSD (Bremner *et al.*, 1997c), as well as a patient with DID (Tsai *et al.*, 1999) exhibited smaller hippocampal volume.

Whereas trauma-reporting female patients with borderline personality disorder had smaller hippocampal volumes than control groups, levels of neuropsychological functioning were associated with severity of depression but not with hippocampal volume (Driessen *et al.*, 2000). Stein *et al.* (1997) found smaller left-sided hippocampal volume for women reporting childhood sexual abuse compared to controls, with volume correlating strongly ($r = -0.73$) with dissociative symptom severity, but not with indices of explicit memory functioning. It thus seems that the relationship between hippocampal volume and memory functioning may be mediated by dissociation. Whether smaller hippocampi constitute a premorbid risk factor for PTSD and possibly for DSM-IV and ICD-10 dissociative disorders, or whether they are caused by chronic stress exposure, is a question for further study. Recently, Bonne *et al.* (2001) reported that smaller hippocampal volume was not a necessary risk factor for developing PTSD and did not occur within 6 months of expressing the disorder. A controlled study of hippocampal volume in patients with DID is underway (Ehling *et al.*, 2001).

Medial Prefrontal Cortex

Stress hormones also interfere with the activation of the medial prefrontal cortex. For example, elevated levels of norepinephrine were associated with dysfunction of the prefrontal cortex (Arnsten, 1999). This interference presents a major problem of affect regulation in that hippocampal (McCormick and Thompson, 1982) and medial prefrontal (Armony and LeDoux, 1997) information processing are crucially involved in inhibiting the amygdala. As discussed above, yohimbine-provoked traumatic memories and reduced hippocampal and medial prefrontal blood flow in PTSD.

Bremner *et al.* (2000b) found decreased benzodiazepine receptor binding in the medial prefrontal cortex and Bremner *et al.* (1999) documented medial prefrontal and anterior cingulate dysfunction in women with and without PTSD who reported childhood sexual abuse (CSA). The participants were exposed to neutral personal memories and to descriptions of personalized CSA events. CSA scripts were associated with greater increases in regional cerebral blood flow in portions of the prefrontal cortex, posterior cingulate, and motor cortex in women with PTSD than in those women without PTSD. These scripts also induced alterations in brain metabolism in the medial prefrontal cortex, i.e., decreased blood flow in subcallosal gyrus and the anterior cingulate. Compared with women who had not developed PTSD, those with PTSD also had decreased blood flow in the right hippocampus, fusiform/inferior temporal gyrus, supramarginal gyrus, and visual association cortex.

Using SPECT, Sar *et al.* (2001) assessed regional cerebral blood flow in 15 patients with DID without structural lesions and epilepsy, and in eight healthy controls. The blood flow ratio was decreased in orbitofrontal region bilaterally and increased in the left lateral temporal region among patients with DID when compared to the control group. Comorbid diagnoses or ongoing drug treatment did not have any significant effect on perfusion in these regions, and there was no statistically meaningful difference in regional cerebral blood flow ratios among dissociative parts of the personality, also described as dissociative personalities. Sar *et al.* (2001) concluded that the persistency of the findings over different dissociative personalities suggests a trait measure for DID. As we will discuss below, until specific *types* of dissociative personalities are compared, this conclusion might be premature.

In conclusion, dysfunction in the hippocampus and the prefrontal cortex may be related to memory deficits, affect dysregulation, impaired inhibition of conditioned responses, and dissociative symptoms in PTSD and possibly in more complex dissociative disorders as well.

Thalamus

Krystal *et al.* (1998) argued that dissociative-like phenomena in healthy individuals tend to ensue when they are exposed to extremely low or high levels of sensory stimulation. This led them to propose that the thalamus might contribute to dissociation-like alterations in consciousness in that it serves as a sensory gate or filter that directly and indirectly modulates the access of

sensory information to the cortex, amygdala and hippocampus. In relay mode, the thalamus facilitates accurate transmission of sensory information to the cortex, amygdala, and hippocampus. When slow oscillatory firing patterns predominate, the flow of sensory information to amygdala, cingulate and frontal cortex is impeded, leaving the individual focused on internally generated thought processes and affective and sensory experiences. While Krystal *et al.* (1998) hold that this mode might be associated with dissociation, they have not detailed in what modes the thalamus would operate during detachment from and overengagement in trauma memories.

Cingulate Gyrus

The cingulate gyrus is responsive to shifts in thalamic sensory processing functions and is an important point of convergence for a network involving amygdala, prefrontal cortex, and mediodorsal thalamic nucleus (cf., Krystal *et al.*, 1998). The cingulate may be involved in dissociation. For example, Shin *et al.* (2000) reported that Vietnam veterans with PTSD failed to activate the affective division of the anterior cingulate during the Emotional Counting Stroop, while non-PTSD veterans did not (Whalen *et al.*, 1998). Maltreated children with PTSD also manifested metabolic abnormalities in the anterior cingulate (De Bellis *et al.*, 2000). Women with histories of childhood sexual abuse had increased anterior cingulate activity in response to trauma scripts, but those with PTSD had less regional cerebral blood flow increases in this region than those without PTSD (Shin *et al.*, 1999).

Motor Cortex

Marshall *et al.* (1997) reported that attempts of a patient with dissociative paralysis (somatoform dissociation) to move her affected leg failed to activate right primary motor cortex. Instead, the right orbitofrontal and the right anterior cingulate cortex were significantly activated. The authors suggested that these areas may inhibit willed effects on the right primary motor cortex. Preparing to move the paralysed leg produced normal brain activation. Findings by Spence *et al.* (2000) also suggest that somatoform dissociative motor symptoms involve intact ability to generate motor plans, but inhibition of actual motor action. All patients had deactivation of the left dorsolateral prefrontal cortex, regardless of the side of the symptoms. This frontal region is specifically activated by willed action. Feigning controls did not exhibit this deactivation but had hypofunction of the right anterior prefrontal cortex compared with controls. However, studying stress-related dissociative unilateral sensorimotor loss in seven patients using SPECT, Vuilleumier *et al.* (2001) found that these symptoms may represent lack of motor readiness. Compared with a resting condition, passive vibration of both hands-known to activate sensory and motor brain regions — generated bilateral and symmetrical regional cerebral blood flow increases in parietosomatosensory, frontal premotor, and anterior prefrontal cortical areas. Blood flow was reduced in the thalamus, putamen, and caudate contralateral to the side of the symptoms These hemispheric asymmetries disappeared in the four scanned patients who recovered. Vuilleumier *et al.* (2001) suggested that the decreased blood flow in circuits involving the basal ganglia and thalamus may reflect impaired motor readiness through inhibitory input from the amygdala and orbitofrontal cortex in response to emotional stressors.

Somatosensory Association Areas:

Depersonalization is related to several negative somatoform dissociative symptoms, e.g., experiencing the body as a foreign object. Comparing eight patients with depersonalization disorder and 24 healthy controls, Simeon *et al.* (2000) reported that the disorder was associated with functional abnormalities along sequential hierarchical areas, secondary and cross-modal areas of the sensory cortex (visual, auditory, and somatosensory), as well as areas responsible for an integrated body schema. More specifically, they found less metabolism in right temporal cortex (auditory association area), and more metabolism in parietal somatosensory association area and multimodal association area. Dissociation and depersonalization scores among the patients with depersonalization disorder were strongly correlated with metabolic activity in the posterior parietal association area. It thus seems that integrative failure with respect to bodily cues — which may be at the heart of basic forms of consciousness (Damasio, 1999) — is related to dysfunctioning of the temporal, parietal, and occipital association areas. Indeed, '[t]here is a hierarchy of sensory processing in the brain, from primary sensory areas to unimodal and then polymodal association areas and finally to the prefrontal cortex' (Simeon *et al.*, 2000, p. 1786). Depersonalization and negative somatoform dissociative symptoms may thus relate to dysfunction of the posterior association areas, that affects the input into the prefrontal cortex.

Insula:

Reiman *et al.* (2000, p. 399) observed that 'a region in the vicinity of anterior insular cortex [. . .] appears to be preferentially involved in the emotional response to potentially distressing cognitive stimuli, interoceptive sensory stimuli, and body sensations'. For example, regional cerebral blood flow increases have been observed in the anterior insular region during recall-generated sadness (Lane *et al.*, 1997), normal anticipatory anxiety, (Reiman, 1996), lactate-induced panic (Reiman *et al.*, 1998), and the perception of temperature and pain (Bushnell *et al.*, 1995). Based on these and other studies, Reiman *et al.* (2000) suggested that the insula participates in the evaluation of potentially distressing thoughts and body sensations with negative emotional significance, and may serve as an internal alarm centre, 'alerting the individual about potential dangers inside the body' (p. 399). The hypothesized alarm function could perhaps be executed in conjunction with the amygdala in that the insular cortex has afferent and efferent connections with the amygdala (Aggleton and Saunders, 2000).

Because traumatic memories essentially involve unintegrated emotional and somatosensory reactivity, re-experiences of trauma could be associated with altered metabolism in the insula. Indeed, exposing PTSD patients to recorded trauma memory scripts was associated with increased metabolism in the right insula (Rauch *et al.*, 1996). Other areas involved in processing these trauma scripts included a range of other right-sided limbic and paralimbic structures.

NEUROBIOLOGICAL MODELS OF DISSOCIATIVE DISORDERS

DID and Epilepsy

It has been suggested that DID actually represents epilepsy (e.g., Mesulam, 1981; Schenk and Bear, 1981). However, video EEG monitoring of DID patients previously diagnosed as cases of epilepsy documented EEG abnormalities, but not epileptiform EEG activity (Devinsky *et al.*, 1989). In addition, compared to patients with epilepsy, DID patients and patients with pseudo-epileptic seizures had more symptoms of psychoform and somatoform dissociation (Bowman and Coons, 2000; Devinsky *et al.*, 1989; Kuyk *et al.*, 1999; Loewenstein and Putnam, 1988). In some cases, epilepsy and DID may be concurrent disorders. In other cases, apparent epilepsy may represent dissociative convulsions

(WHO, 1992) reflecting a more complex dissociative disorder (e.g., Bowman, 1993; Kuyk *et al.*, 1996, 1999). Moreover, DID responds to psychotherapy, but not to the pharmacological treatment for epilepsy. The evidence thus reveals that DID does not represent epilepsy.

Dissociative Disorders and Cerebral Hemispheric Laterality

The hypothesis that dissociative personalities involve left- or right-sided hemispheric dominance (Tiihonen *et al.*, 1995) is difficult to reconcile with the fact that most DID patients encompass more than two dissociative personalities, and that these personalities display bilateral perfusion defects (Sar *et al.*, 2001). It has been suggested that dissociative disorders of movement and sensation involve symptom lateralization, and perhaps hemispheric lateralization (e.g., Marshall *et al.*, 1997; Tiihonen *et al.*, 1995). However, the results from different studies were contradictory, and a recent study of 114 cases found no evidence for lateralization (Roelofs *et al.*, 2000).

Dissociative Personalities as Discrete Behavioural States

While particular neuroendocrine substances and brain structures may be involved in trauma-related integrative failure, they do not explain why dissociation of the personality is not a random phenomenon, but tends to be orderly within limits. To account for this, Putnam (1997) has proposed that complex dissociative disorders involve discrete behavioural states. He argued that the first years of life are important in laying the groundwork of personality organization that is rather cohesive across contexts, such as place, time, and state. Infants tend to automatically move from one discrete state to another, initially lacking much integration. These states are referred to as discrete behavioural states because emotional states in young children are closely tied to behaviour, producing a highly state-dependent sense of self (Wolf, 1990; Wolff, 1987).

The relatively low integrative capacity of young children can be related to the immaturity of the brain regions that have major integrative functions, notably the prefrontal cortices and the hippocampus. Hippocampal maturity may not occur for up to three years (Seress, 1998), and full maturation of the orbitofrontal and prefrontal cortex requires many years (Benes, 1998). Furthermore, myelination in the hippocampus increases from childhood until adolescence, after which the pattern remains unchanged (Arnold and Trojanowski, 1996). As a result, emotional states involving the amygdala operate in relatively uncoordinated and unintegrated ways in early childhood, even under normal conditions.

The integrative capacity of children is also limited because of a relative absence of experience-derived templates that are helpful as 'attractors' (Siegel, 1999) to integrate new and/or emotionally charged experiences. Thus (young) children seem to be dependent on their social environment for regulation of instinctual emotional systems. In support of this hypothesis, Ogawa *et al.* (1997) found that dissociation in early childhood was a common response to disruption and stress, whereas persistent dissociation in adolescence and young adulthood was indicative of psychopathology.

Although little is known about the development of integration among emotional states, it is in interaction with caretakers that young children begin to acquire skills to sustain, modulate, and integrate states (Schore, 2001; Siegel, 1999). Social sharing of parallel or complementary states between the child and caretaker is associated with synchronizations of physiological processes between the child and the adult that assist the child in regulating states, and lack of synchronization has disruptive effects (Field, 1985). While adequate caretaking activities critically enhance integration of behavioural states in the child, inadequate or inconsistent caretaking will result in the child having difficulty integrating emotional states and constructing a stable sense of self.

Trauma may interfere with this developmental integrative process (Putnam, 1997) by compromising the integrative functions of the developing brain (Gurvits *et al.*, 2000; Teicher *et al.*, 1997; for reviews, see Bremner, 1999; Glaser, 2000; Schore, 2001; Siegel, 1999). Thus, repeated activation of trauma-related states can promote state-dependent functioning and concomitant neurobiological 'hard-wiring' of the brain (Perry, 1999; Perry *et al.*, 1995), depending on the child's life experiences, particularly before age six. While prospective studies should assess to what extent particular brain features are a risk factor for, or sequelae of traumatization and dissociation, the evidence to date suggests that maltreatment in childhood is associated with adverse influences on brain development (De Bellis *et al.*, 1999), and increased sensitivity to the effects of stress in later life (Graham *et al.*, 1999). Thus, adverse social experiences during early critical periods result in permanent alterations in CRF, opiate, corticosteroid, dopamine, noradrenaline, and serotonin receptors (cf. Schore, 2001).

Several studies suggest a potential causal relationship between severe traumatization in early childhood and compromised integrative functions. For example, younger children had more PTSD symptoms than adolescents (Anthony *et al.*, 1999), and the severity of psychoform and somatoform dissociation among DID patients and psychiatric controls were best predicted by reported trauma during the first six years of life (Draijer and Boon, 1993; Nijenhuis *et al.*, 1998b). Also, the age of onset, chronicity, and severity of childhood trauma were associated with psychoform dissociative symptoms up to 19 years later (Ogawa *et al.*, 1997). Recently, Nijenhuis *et al.* (2001a) found that adult psychiatric patients who reported more than five different types of traumatization during their lives had higher levels of PTSD symptoms, and more psychoform and somatoform dissociation than did psychiatric patients who reported fewer than five different types of trauma, only emotional abuse and neglect, or no traumatization at all. In most cases, the reported severe traumatization had commenced in (early) childhood, and severity of somatoform dissociation was associated with composite bodily threat scores, including age at onset, duration, and subjectively rated impact of the traumatization (Nijenhuis *et al.*, 2001a).

Dissociative Personalities in DID

Consistent with Putnam's theory (Putnam, 1997), dissociative systems in DID tend to display psychophysiological differences that are not reproduced by DID-simulating controls. Differences have been reported in electrodermal activity (skin conductance; Ludwig *et al.*, 1972; Larmore *et al.*, 1977), EEG — in particular in the beta 2 band (Coons *et al.*, 1982; Hughes *et al.*, 1990; Ludwig *et al.*, 1972; Putnam *et al.*, 1993), visual evoked potentials (Putnam *et al.*, 1992), regional cerebral blood flow (Mathew *et al.*, 1985; Saxe *et al.*, 1992), autonomic nervous system variables (Putnam *et al.*, 1990), optical variables (Birnbaum and Thomann, 1996; Miller, 1989; Miller and Triggiano, 1991; Miller *et al.*, 1991), and arousal (Putnam *et al.*, 1990).

While these studies are valuable, it is difficult to say what the data actually tell beyond suggesting that these physiological data sets 'are most parsimoniously explained by regarding the alter personalities as discrete states of consciousness' (Putnam, 1997, p. 138). Advances in the field critically depend on theoretical predictions with respect to the *kind* of differences that exist among different *types* of dissociative personalities. The theory of structural dissociation (Nijenhuis *et al.*, 2002) offers such predictions.

THE THEORY OF STRUCTURAL DISSOCIATION

Many individuals with PTSD or more complex dissociative disorders alternate between being fixated on the trauma and being

detached from the experience (Nijenhuis and Van der Hart, 1999a, 1999b). Using metaphors that Myers (1940) proposed, the 'emotional' personality (EP) has encoded and stored trauma, and is dedicated to defense from major threat, in particular, threat to the integrity of the body. The 'apparently normal' personality (ANP), on the other hand, is detached from trauma, experiences some degree of amnesia or is depersonalized from some or many components of the experience, and is dedicated to fulfilling functions in daily life, some of which serve the survival of the species. According to the theory of structural dissociation (Nijenhuis *et al.*, 2002b), this alternating pattern reflects failed integration between the ANP and EP.

Structural dissociation of the personality may involve constellations of one ANP and one EP, as in PTSD; one ANP and more than one EP, as in complex PTSD (Herman, 1992), also known as disorders of extreme stress (Pelcovitz *et al.*, 1997), and more than one ANP and more than one EP, as seen only in DID. According to the theory, the extent to which the personality becomes fragmented depends on the severity of the traumatization in terms of developmental age at trauma onset, chronicity and intensity of the traumatization, and factors such as the relationship to the perpetrator and lack of support and social recognition of the trauma. A limitation of the theory of structural dissociation is that it does not address structural dissociation of the personality unrelated to trauma (for a remarkable case of latent abilities, see Braude, 2000).

ANP and EP are two different psychobiological systems, each endowed with its own sense of self. According to Damasio (1999, p. 26), consciousness and sense of self are essentially grounded in 'a feeling that accompanies the making of any kind of image — visual, auditory, tactile, visceral — within our living systems' and may involve several integrative levels: (1) the *proto-self* that emerges from the activity of brain devices that continuously and nonconsciously maintain the body state within the narrow range and relative stability required for survival; (2) the *core self* that relates to core consciousness defined as conscious awareness of the here and now based on the mental representation of how the organism's own state is affected by the organism's processing of an object; and (3) the *autobiographical self* that involves extended consciousness, i.e., conscious awareness of one's personal existence across subjective time.

The existence of the EP can be limited to re-experiencing traumatic memories, i.e., sensorimotor experiences that hardly involve narrative components, if at all (Nijenhuis *et al.*, 2001b; Van der Kolk and Fisler, 1995; Van der Kolk and Van der Hart, 1991). In this case, the EP may involve little more than core consciousness and core self. Yet clinical observations suggest that with recurrent reactivations of traumatic memories and chronic traumatization (and treatment), the EP may develop a degree of extended consciousness and autobiographical self. Even in these cases, however, extended consciousness and the sense of autobiographical self tend to remain quite limited. EPs are typically fixed in past trauma with absent or only partial awareness of the present or the passage of time. ANPs typically have developed a more substantial degree of extended consciousness, yet lack personification of the traumatic past and the associated EPs. EPs and ANPs have a narrowed field of consciousness focused on issues relevant to the functions they exert. Although Nijenhuis *et al.* (2002b) use the metaphor of dissociative personalities, it should be noted that such systems range from quite simple to highly complex: some dissociative personalities encompass just one psychobiological state, others are complex assemblies of such states. Dissociative personalities involve senses of self that are different from the pretraumatic self. However, because young children encompass psychobiological systems that are still relatively unintegrated, their pretraumatic sense of self is rather inconsistent and changeable, thus sense of self may not be stable even prior to early traumatization.

A major question is what psychobiological systems drive the EP and ANP, including their sense of self? These systems should meet a range of shared criteria: (1) they must be self-organizing and self-stabilizing within windows of homeostasis, time and context to control and integrate all the rather coherent complexes of psychobiological phenomena exhibited by ANP and EP; (2) they should be functional systems that have been developed in the course of evolution, and should be rather analogous to animal biological systems. Clinical observations suggest that the ANP typically engages in tasks of daily life such as reproduction, attachment, care taking, and socialization, and avoidance of traumatic memories that supports focus on daily life issues. In contrast, the EP primarily displays evolutionary defensive and emotional reactions to the (perceived) threat on which they seem to be fixated; (3) they should be very susceptible to classical conditioning, because, as we discuss below, the EP and ANP strongly respond to unconditioned and conditioned threat cues; (4) they should involve stable characteristics, but also allow for case-dependent variation as well, as ANP and EP exhibit both invariant and idiosyncratic variations; and (5) they should be available early in life, since dissociative disorders can manifest from a very early age.

Emotional Operating Systems

The theory of structural dissociation holds that the psychobiological systems that drive EP and ANP are *emotional operating systems*, or briefly, emotional systems, described by Panksepp (1998). Defense, attachment of offspring to parents, parental attachment to and care for offspring, procreation, sociability, energy management, exploration, and play constitute the major emotional systems, and may encompass a range of subsystems. Panksepp argued that basic emotional processes arise from distinct psychobiological systems that reflect coherent integrative processes of the nervous system (cf. Ciompi, 1991). In his view, the affective essence of emotionality is organized on subcortical and precognitive levels, and each of the emotional systems involves specific patterns of activation of neural networks and associated neurochemical activity in the brain.

Emotional systems are psychobiological in nature and closely meet the five criteria of dissociative personalities described above: they are organizational, evolutionary derived, functional, flexible within limits, and inborn but epigenetic. Emotional systems are functional in that they activate various types of affective feelings which help identify events in the world that are either biologically useful or harmful, and generate adaptive responses to many life-challenging circumstances. The basic behavioural patterns involved in emotional systems are approach and avoidance. Although the resulting behaviour is unconditionally summoned by the appropriate cues, approach and avoidance are adaptable to prevailing environmental conditions within limits, rather than being mere inflexible responses. For example, flight involves not just running away from threat, but running that is adapted to the current situation in form, direction, and duration. Thus, threat as an unconditional stimulus does not evoke a single 'unconditional' response, but integrated series of psychobiological responses.

Emotional systems are epigenetic, i.e., the result of influences by nature and nurture. Experiences, especially early ones, can change the fine details of the brain forever. These experiences include learning associations between events. Emotional systems are susceptible to classical conditioning: i.e., learning that some previously neutral events predict or refer to unconditioned stimuli. These conditioned stimuli tend to reactivate a representation of the unconditioned stimuli, and thus the once unconditionally summoned emotional system. Subsystems of defense are of particular interest in dissociation because of exposure to threat. Each defensive

subsystem controls a pattern of psychobiological reactions that is adapted to meet a particular degree of threat imminence (Fanselow and Lester, 1988). This degree of imminence can be expressed in terms of the time and space that separate the subject from the threat (i.e., the distance between predator and prey), as well as in terms of an evaluation of the defensive abilities of the subject (e.g., the subject's psychosocial influence and physical force).

Pre-encounter defense involves an apprehensive state with increased arousal, potentiated startle response, interruption of 'normal life' behaviours, and nearly exclusive attentional focus on the potential threat. *Post-encounter defense* includes several subsystems: flight, freeze, with associated analgesia, and fight. *Post-strike defense* involves total submission and bodily as well as emotional anaesthesia. Upon survival, a recuperative subsystem is activated that allows for a return of affective awareness and body sensations (e.g., pain, fatigue), and that drives wound care and rest through social isolation, as well as sleep. Upon recovery, there will be a reactivation of (sub)systems that control daily life interests such as consumption of food, reproduction and taking care of offspring.

The EP is Dedicated to Survival Under Threat

According to the theory of structural dissociation, EPs are primarily manifestations of the emotional system that controls defense in the face of threat — particularly threat to the integrity of the body by a person — and potentially also of the emotional system that controls separation panic in relation to caretakers. Both systems serve survival interests and strongly influence the mental and physical experiences and actions of the EP. While EPs essentially rely on evolutionary derived mechanisms, their manifest form will be shaped by environmental conditions, especially traumatic experiences that evoke threat, in particular those that occurred in early childhood, and subsequent external and internal conditions. These conditions include the degree and quality of social support in the aftermath of trauma, repetition of trauma, and the degree of dissociation between EP and ANP.

In cases of *primary structural dissociation*, which would characterize acute stress disorder, simple PTSD, and simple cases of somatoform dissociative disorders (i.e., the ICD-10 dissociative disorders of sensation and movement), a single EP can include all defensive subsystems. *Secondary structural dissociation* is a manifestation of a range of defensive subsystems that have not, or not sufficiently, been integrated among each other. Thus the EP may become fragmented into several EPs that serve different defensive functions. In secondary structural dissociation, some EPs typically display freezing and are analgesic, others are inclined to physically resist threat and experience anger, or totally submit to threat while being severely anaesthetic. This threat often consists of re-experiencing (traumatic) memories of severe and chronic childhood abuse and neglect, or in responding to cues that are salient reminders of these events. Insecure attachment to caretakers can also become associated with one or more EPs in secondary structural dissociation. This level of integrative failure is mediated by traumatization that is more severe than that associated with simple PTSD. Secondary dissociation is characteristic of complex acute stress disorder, complex PTSD, complex cases of somatoform dissociative disorders, many cases of dissociative disorder not otherwise specified (APA, 1994), and perhaps borderline personality disorder (APA, 1994) as well.

We repeat that the literature generally refers only to states of freezing and submission as dissociative (and often these states are not regarded as different from each other), whereas sympathetic hyperarousal states are not (Perry *et al.*, 1995). However, defining dissociation as a lack of integration among emotional systems that may include single or clusters of states implies that hyperarousal states can also be dissociative. But these, as well as states involving analgesia and motor inhibition (freezing), bodily and emotional anaesthesia, disengagement from environmental cues, and submission (total submission, regulated by the parasympathetic nervous system (Porgess *et al.*, 1994; Schore, 1994)) may all be manifestations of unintegrated dissociative subsystems of defense.

The ANP Involves Systems that Manage Daily Life and Promote Survival of the Species

Clinical observations suggest that emotional systems of the ANP primarily function to direct performance of daily tasks necessary to living (work, social interaction, energy control), and of tasks related to survival of the species (reproduction; caretaking of children). Some ANPs may execute daily life emotional systems with passion, while others do so in more or less depersonalized and automatic ways (e.g., caretaking). Depersonalized functioning in caretaking and attachment may interfere with synchronizations of physiological processes between adult and child that assist the child in regulating states (Field, 1985), potentially leading to dissociation in the offspring of dissociative parents (Schore, 2001).

When trauma by caretakers begins early in the life of the child, a particular style of attachment often develops in the child, termed *disorganized/disoriented* (Liotti, 1999; Main and Morgan, 1996). In normal, middle class families about 15% of the infants develop this attachment style, but in cases of maltreatment its prevalence may be up to three times higher (Van IJzendoorn *et al.*, 1999). Thus frightened or frightening parental behaviour predicted infant disorganized attachment (Schuengel *et al.*, 1999). Prospective longitudinal research has demonstrated that disorganized and avoidant attachment in early childhood, along with age of onset, chronicity, and severity of abuse, predicted dissociation in various developmental stages, up to late adolescence (Ogawa *et al.*, 1997). Both ANP and EP may be insecurely attached to original abusive caretakers or to (positive or negative) substitute caretakers.

Disorganized attachment may neither be disorganized nor disoriented. Instead, it involves concurrent or rapid successive activation of the attachment system and the defense system when primary attachment figures are both the source of protection from threat and the threat itself for the traumatized child. Separation from attachment figures activates the innate attachment system, which evokes mental and behavioural approach to the caregiver. However, approach yields an increasing degree of imminence of threat, and therefore evokes a succession of defensive subsystems (flight, freeze, fight, submission). This approach and avoidance conflict cannot be resolved by the child and promotes a structural dissociation of the attachment and the defensive system.

In addition to secondary structural dissociation (fragmentation of the defensive system, thus of the EP), fragmentation of the ANP may also occur. Thus, this *tertiary structural dissociation* (Nijenhuis and Van der Hart, 1999b; Nijenhuis *et al.*, 2002; Van der Hart *et al.*, 1998), characteristic only of DID, involves fragmentation among two or more emotional operating systems that serve functions in daily life and in survival of the species. For example, one ANP regarded herself as the mother of her children, and another ANP engaged in a job. Remaining as the mother, the patient did not appreciate or understand the interests that she had as a worker, and vice versa. Tertiary structural dissociation does not occur during trauma, but rather emerges when certain inescapable aspects of daily life become associated with past trauma, such that systems of daily life become dissociated. Apart from extreme generalization of stimuli that reactivate traumatic memories, tertiary dissociation can also result from traumatization that started before the individual had been able to create a cohesive personality. Early and chronic traumatization may lead to some

unclear mix of ANP/EP, where neither can be clearly distinguished. Such complexes are clinically observed in more dysfunctional DID patients.

SIMILARITIES BETWEEN THE HUMAN AND ANIMAL DEFENSIVE SYSTEM

At a general level, Nijenhuis *et al.* (1998c) drew a parallel between animal defensive systems/recuperative systems and characteristic somatoform dissociative responses of trauma-reporting patients with dissociative disorders. Their review suggested that there are similarities between animal and human disturbances of normal eating patterns and other normal behavioural patterns in the face of diffuse threat; freezing and stilling when serious threat materializes; analgesia and anaesthesia when strike is about to occur; and acute pain when threat has subsided and recuperation is at stake.

Nijenhuis *et al.* (1998a) performed a first empirical test of the hypothesized similarity between animal defensive reactions and certain somatoform dissociative symptoms of dissociative disorder patients who reported trauma. All 12 somatoform dissociative symptom clusters tested were found to discriminate between patients with dissociative disorders and patients with other psychiatric diagnoses. Those clusters expressive of the hypothesized similarity between animal and human models — freezing, anaesthesia–analgesia, and disturbed eating — belonged to the five most characteristic symptom clusters of dissociative disorder patients. Anaesthesia–analgesia, urogenital pain and freezing symptom clusters independently contributed to predicted caseness of dissociative disorder. Using an independent sample, it appeared that anaesthesia–analgesia best predicted caseness after controlling for symptom severity. The indicated symptom clusters correctly classified 94% of cases that constituted the original sample, and 96% of an independent second sample. These results were largely consistent with the hypothesized similarity to animal defense systems.

Among Dutch and Flemish dissociative disorders patients, the severity of somatoform dissociation — as measured by the Somatoform Dissociation Questionnaire (SDQ-20; Nijenhuis *et al.*, 1996, 1999b) — was best predicted by threat to the integrity of the body in the form of childhood physical abuse and childhood sexual trauma (Nijenhuis *et al.*, 1998b). The particularly strong association between the SDQ-20 — which includes many items that assess anaesthesia, analgesia, and motor inhibitions — and physical abuse has also been found in a range of other populations: nonclinical subjects (Waller *et al.*, 2000), gynaecology patients with chronic pelvic pain (Nijenhuis *et al.*, 1999c), women reporting childhood sexual abuse (Nijenhuis *et al.*, 2001b), psychiatric outpatients (Nijenhuis *et al.*, 2001a), as well as North American (Dell, 1997) and Ugandan patients with dissociative disorders (Van Duyl and Nijenhuis, in preparation).

According to the theory of structural dissociation, EPs involve defensive (sub)systems. We will discuss below recent experimental research suggesting that (1) animal defense-like reactions particularly characterize the EP, and that (2) EPs and ANPs have different psychophysiological stress responses to threat-related stimuli, even if these stimuli are presented preconsciously. Future research will need to decipher whether various EP-subtypes have the hypothesized features of animal defensive subsystems.

PSYCHOBIOLOGICAL INTERFERENCE WITH INTEGRATION OF ANP AND EP

Peritraumatic Integrative Failure

Evocation of the defense system or any other psychobiological system is not dissociative in itself, rather the lack of integration between various systems and subsystems is what constitutes dissociation. As discussed above, extremely high levels of arousal may interfere with the execution of normal integrative processes (Ludwig, 1972; Krystal *et al.*, 1991; see also Siegel, 1999), and integrative functions may be compromised by long-lasting neuroendocrine instability induced by severe stress in early childhood. It is likely that some emotional systems can be integrated more readily than others. As Panksepp (1998) argued, multiple feedbacks within and across emotional systems promote synthesis of components of a system (e.g., perceptions, behaviours, sense of self) and integration across emotional systems. However, integration across emotional systems that involve quite different and sometimes conflicting functions may be far more demanding than synthesizing components of a particular emotional system or integrating functionally related systems. If this is correct, the integration of systems dedicated to daily life and survival of the species (ANP), and systems dedicated to survival of the individual in the face of that threat (EP) will fail more readily than integration across subsystems of these two complex systems. Structural dissociation between the ANP and the EP will thus be the basic type of integrative failure, i.e., primary structural dissociation, when overwhelming trauma occurs. When stress levels rise, integration of subsystems of defense may be compromised as well, yielding secondary dissociation, i.e., fragmentation of the EP.

Post-traumatic Integrative Failure

Since living organisms have a natural tendency toward integration (Siegel, 1999), what maintains dissociation when trauma has ceased and stress-induced monoaminergic reactivity has returned to baseline? According to the theory of structural dissociation, apart from integrative deficiency that relates to enduring neuroendocrine changes induced by stress in early life, integrative failure in the aftermath of trauma also involves fear conditioning.

Trauma and Classical Conditioning

Trauma-related classical conditioning involves association of stimuli that saliently signalled or accompanied the overwhelming event. As a result, these previously neutral cues will thereafter reactivate a representation of the traumatic experience. Thus the essence of classical conditioning is the development of an anticipatory (CS signals UCS) or referential response (CS refers to UCS). For example, the specific mood (e.g., anger) of the caretaker when abusive, as well as the stimuli that apparently tended to elicit this mood, will tend to become conditioned stimuli.

Phobias of Traumatic Memories and Dissociative Personalities

Classical trauma conditioning can also generate effects that support continued structural dissociation (Nijenhuis *et al.*, 2002). First of all, structural dissociation is less than perfect. When the EP's traumatic memories are reactivated by potent external (e.g., certain smells, sounds, sights) or internal (e.g., feelings or body sensations) CS, they can intrude into the experiential domain of the ANP. Since traumatic memories represent the trauma, they are formally CS. But the sensorimotor and highly affectively charged properties of these unintegrated experiences are inherently aversive for the ANP and *will therefore act as UCS.* Indeed, when traumatized patients re-experience their traumas, it is as if the trauma happens 'here and now'. When the integrative capacity of the ANP does not suffice for integration of the intruding traumatic memory, the ANP will respond to intrusions (UCS) with typical behavioural and mental defensive reactions (UCR; Nijenhuis and Van der Hart, 1999b). The ANP cannot escape from the highly stressful intrusions by behavioural means, but mental escape can be effective, as applies to factual (inescapable) trauma. Thus, typical reactions of the ANP

include retracting the field of consciousness, lowering the level of consciousness (with pseudo-epileptic loss of consciousness as an extreme), and (re)dissociating the EP and the traumatic memories. At the same time, the ANP learns to fear and avoid internal and external CS that signal or refer to the EP. As time progresses and the dissociative condition continues, there is an ever widening range of CS that the ANP will avoid due to stimulus generalization.

Evaluative Conditioning

In addition to classical fear conditioning, evaluative conditioning (Baeyens *et al.*, 1993) of external and internal stimuli may occur. This type of associative learning produces robust effects and involves the presentation of two conjointly stimuli: a neutral stimulus and a stimulus that the individual evaluates in a negative (or positive) manner. As a result of this simple procedure, the previously neutral stimulus adopts a similar negative (or positive) tone. The ANP and EP evaluate traumatic memories differently (Nijenhuis *et al.*, 1999a), and clinical observations strongly suggest that evaluative conditioning applies to trauma-related dissociation. For example, when the trauma involved a shameful event, the ANP may learn to be ashamed of the EP, and to despise it.

In cases of secondary and tertiary dissociation, EPs and ANPs may learn to fear, reject, and avoid each other along similar pathways of evaluative and classical conditioning. In tertiary structural dissociation, avoidance of different ANPs may be based on similar trauma-related issues and conflicts. In summary, many dissociative personalities become phobic of each other. These conditioned effects interfere with normal integrative tendencies. Hence, *structural dissociation involves a strong tendency toward chronicity*.

In some individuals, alternations between the ANP and EP manifests from the acute phase onward, but other individuals function apparently well for extended periods of time before displaying post-traumatic stress symptoms. However, upon close scrutiny it often appears that the latency period was marked by avoidance of the trauma and associated internal and external cues, yielding a condition of chronic depersonalization. In cases of trauma-related dissociative amnesia as a disorder (APA, 1994), access to the memory of the trauma and to other parts of one's previous non-traumatic life seem to be inhibited (Markowitsch *et al.*, 2000; Van der Hart and Brom, 2000; Van der Hart and Nijenhuis, 2001; Van der Hart *et al.*, 1999).

Relational Factors that Maintain Structural Dissociation

When significant others deny trauma instead of assisting in the integration of the painful experience, or prohibit talking about it, dissociative tendencies are enhanced. These adverse social influences prevail in intrafamilial childhood sexual abuse (Freyd, 1996), and seem to promote dissociative amnesia (Vanderlinden *et al.*, 1993). PTSD has been associated with lack of support in the aftermath of trauma (King *et al.*, 1998), and in another study, patients with complex dissociative disorders reported total absence of support and consolation when abused (Nijenhuis *et al.*, 1998b). As the structural dissociation theory predicts, social support can buffer negative effects of trauma exposure (Elklit, 1997; Runtz and Schallow, 1997). It might be that social support provides safety cues, assists the individual in modulating the affective state and biological stress levels, and thus promotes the integration of the EP and ANP.

PSYCHOBIOLOGICAL RESEARCH OF ANP AND EP

To summarize the essence of the structural dissociation theory, it proposes that (1) traumatic experiences — especially trauma that occurs early in life and involves severe threat to the integrity to bodily integrity — activate evolutionary derived defensive systems, (2) these emotional operating systems may remain unintegrated to varying degrees due to extreme stress levels, classical and evaluative conditioning to traumatic memories, approach–avoidance conflicts with regard to defense and attachment, and lack of social support. ANPs involve emotional operating systems dedicated to survival of the species and normal life, and EPs systems dedicated to survival of the threatened individual. From this theory, a range of hypotheses can be derived, some of which have been tested in pioneering studies.

Differences Between ANP and EP on Subliminal Threat Exposure

Preconscious information processing plays a key role in responding to unconditioned and conditioned threat cues and in fear-related learning (Davies, 2000; Dolan, 2000; LeDoux, 1996; Morris *et al.*, 1998). The theory of structural dissociation considers that ANPs aim to avoid this threat, and that EPs will selectively attend to these cues. Thus in an original study, Van Honk *et al.* (1999, 2001) hypothesized that dissociative personality-dependent reactivity to (un)conditioned threat will be evident following exposure to cues that are presented very briefly in order to preclude consciously aware perception. More specifically, the effects of exposing the ANP and EP in DID patients to masked neutral, fearful, and angry facial expressions were tested.

Whereas ANPs named the colour of the mask that immediately followed the experimental stimuli more quickly when this stimulus involved angry facial expressions compared to exposure to neutral facial expressions, EPs did not show differential responses to these cues. DID-simulating controls showed the reverse pattern: a tendency toward longer response latencies after exposure to angry faces when enacting ANPs, and a tendency toward shorter reaction times after exposure to angry faces when enacting EPs. The interaction 'group (genuine DID vs DID-simulators) $\times$ condition (angry vs neutral faces)' was statistically significant. Because this effect was absent when comparing fearful and neutral faces, it was specific for cues that signal an increased possibility of attack. The reaction time effects were associated with a decrease of the pre-ejection period (PEP; the interval between ventricular depolarization and ventricular ejection onset) for the EP when exposed to angry faces, indicating increased sympathetic nervous system activity in this condition.

The results are consistent with the hypothesis that ANPs avoid subliminal threat cues by means of gaze aversion, and that EPs particularly attend to bodily threat from a person, with increased sympathetic tone. The response of the EP is pathological in that angry faces represent social threat that can be reduced by gaze aversion: a social cue that signals submission to a dominant individual. On the other hand, the results of the study are at odds with the theory that DID involves effects of suggestion and role-playing.

If ANPs can preconsciously avoid externally presented (un)conditioned threat cues, it is reasonable to assume that they can also preconsciously avoid *internal* (un)conditioned threatening stimuli. Hence, it seems possible that the ANP preconsciously avoids the EP and its memories, as the theory of structural dissociation holds. Some neurobiological data are consistent with the interpretation that dissociative amnesia involves inhibited access to episodic memory. Markowitsch and his colleagues have demonstrated that trauma-related dissociative amnesia as a disorder (APA, 1994) can be associated with reduced blood flow in parts of the brain that are normally activated during retrieval of autobiographical memories (Markowitsch, 1999; Markowitsch *et al.*, 1997a, 1997b, 1998, 2000). Moreover, partial regaining of these memories was correlated with a return to normal brain metabolism in

these areas (Markowitsch *et al.*, 2000). The mechanisms of this presumed inhibitory process could be studied using functional MRI analysis.

Symptom Provocation by Exposure to Neutral and Trauma Memory Scripts in DID

In several studies, imagery of personal trauma, audiotaped descriptions of traumatic experiences, and videotaped traumatic scenes have been used to provoke post-traumatic stress reactions in PTSD patients. Compared to controls, many PTSD patients have increased psychophysiological responses (heart rate, blood pressure, skin conductance, EMG) to these types of trauma-related cues (Keane *et al.*, 1998; Orr *et al.*, 1993, 1998; Pitman *et al.*, 1999), and more severe pathology was associated with a higher magnitude of psychophysiological reactions to trauma cues (Orr *et al.*, 1998). However, using psychophysiological responses to trauma-related cues as a classificatory criterium of PTSD yielded a substantial number of false positives and false negatives (Keane *et al.*, 1998), i.e., the positive and negative predictive values of these factors were limited. It seems possible that the 'physiological nonresponders' to trauma cues remained as ANP, whereas 'physiological responders' failed to avoid cued intrusion by the EP, or switched into the EP. In this regard, it is interesting that physiological nonresponders with PTSD manifested less re-experiencing symptoms (Keane *et al.*, 1998), perhaps indicating ANP dominance.

In the first study of its kind, Nijenhuis *et al.* (1999a) assessed several sensorimotor, affective, and psychophysiological reactions in 11 women with DID, assessed by the SCID-D (Steinberg, 1994). Regional cerebral blood flow was evaluated with PET (Reinders *et al.*, in preparation). ANPs and EPs were subjected to audiotaped descriptions of neutral personal memories and traumatic personal memories. In support of the hypotheses, it was found that in response to the trauma scripts, EPs, but not ANPs displayed decreases of heart rate variability as measured by time domain variability. Stress induces reductions in heart rate variability. In response to the trauma scripts, EPs but not ANPs, also showed statistically significant increases of heart rate frequency and systolic blood pressure. Neither personality types had differential psychophysiological responses to the neutral memories. Whereas EPs experienced a wide range of affective and sensorimotor reactions to the trauma scripts, ANPs did not have these reactions, or only to a minor degree. The ANP's lack of psychophysiological reactivity to supraliminal threat (trauma scripts) could reveal inhibition of responding to threat cues by means of mental avoidance.

As hypothesized, there were statistically significant differences in regional cerebral blood flow between EPs and ANPs when they were exposed to trauma memory scripts, but not when they were exposed to neutral memory scripts (Reinders *et al.*, in preparation). There were also differences in brain metabolism for exposure of EPs to trauma memory scripts and neutral memory scripts. The observed neurobiological differences could not be explained as a result of the variability in subjective and psychophysiological reactivity, and thus reflected effects of the experimental conditions, i.e., types of memory scripts and types of dissociative personality. The PET scan results — described in more detail in Reinders *et al.* (in preparation) — converged with the subjective and psychophysiological data. Jointly, the findings were supportive of the hypothesis that EPs and ANPs have different patterns of psychobiological reactivity to traumatic memories, and that the psychobiological reactions of EPs to trauma memory scripts differ from their reactions to neutral memory scripts: EPs responded to trauma memory scripts in somatosensory and emotionally charged ways, whereas ANPs responded to these cues with a psychobiological pattern that reflects depersonalization and numbing.

POSITIVE FEEDFORWARD EXCITATION (EP) AND NEGATIVE FEEDFORWARD INHIBITION (ANP)?

As detailed above, the ANP tended to avoid masked angry faces, whereas the subliminal perception of angry faces interfered with performance for the EP (Van Honk *et al.*, 1999, 2001). This may imply that the ANP and EP involve different degrees or kinds of amygdala activity when exposed to external threat cues. One EP inadvertently recognized the angry faces, became very anxious, fixed her gaze on the screen, froze, and could not name the colour of the mask for several minutes. She finally mentioned the wrong colour. Remaining as ANP, the patient did not recognize the angry faces, however. (Note: the scores of this patient were excluded from the calculations.) The EP's fixation on threat cues is also suggested by the increased heart rate frequency and blood pressure, as well as the reduced heart rate variability of EPs in response to trauma memory scripts (Nijenhuis *et al.*, 1999a). Moreover, EPs but not ANPs, reported analgesia and strong negative evaluative reactions in response to the trauma scripts. A major riddle to solve regarding dissociation is how DID patients can display the EP-dependent and ANP-dependent psychobiological activity in response to identical threat stimuli (i.e., angry faces and trauma scripts).

Before presenting some thoughts on the issue, we remark that our experimental DID research was limited to women, which may have affected the results. Pre-clinical trials have suggested large gender differences with respect to responsivity to identical stressors, e.g., c-fos expression in the prefrontal cortex and other brain regions (Trentani *et al.*, 2002). Hence, the degree of activation of various brain structures may be dependent on gender. Next, there is evidence for differential responding of the left and right amygdala to stressors (Cahill *et al.*, 2001). For the time being, we disregarded this complexity, but remark that future research should control for gender.

EP-Dependent Responsivity to Threat

Exposure to major external threat causes rapid activation of the defensive system by the amygdala and related structures. This is mandatory for survival, as is learning and memorizing by means of classical conditioning that which signals or refers to threat. The range of threat-related responses orchestrated by the amygdala includes activation of the sympathetic nervous system and the HPA-axis, defensive behaviour (through the central grey), startle response, and stress-induced hypoalgesia (Aggleton, 2000). The lateral amygdala receives sensory inputs directly from the sensory thalamus and indirectly from the sensory cortex. The lateral amygdala projects to the central nucleus of the amygdala, which projects to structures controlling defensive behaviour (flight, freeze, fight, submission), autonomic arousal, hypoalgesia, stress hormones, and potentiated startle. Thus, the amygdala will be hyperactivated in the face of threat (UCS), will encode and store CS-UCS propositions (e.g., CS signals UCS), and will modulate trauma memories more generally. When CS (re)appear, the amygdala and other aspects of the emotional brain and the defensive systems tend to become reactivated.

Hyperactivation of the defensive system during traumatic stress may produce hyperamnesia through mediation of the basolateral nucleus of the amygdala. The basolateral amygdala has a major role in stress-mediated neuromodulatory influences on memory storage (Cahill, 2000; McGaugh *et al.*, 2000). Post-event memory consolidation for emotional experiences involves not only the basolateral amygdala, but the stria terminalis as well. This is a major afferent/efferent amygdala pathway, which interacts with peripheral stress hormone feedback locally in the amygdala, and with emotional memory storage elsewhere in the brain (Cahill, 2000).

Reactivated traumatic memories represent internal threat in that these memories are not narratives but somatosensory and

emotionally charged experiences. Findings of Reiman and his colleagues, discussed above, suggest that internal threat cues (including body signals) are associated with activity of the insula. Because the insula have afferent/efferent connections with the amygdala, internal threat cues may activate the amygdala through this path.

Hyperactivation of the amygdala in the EPs exposed to external and internal threat cues (angry faces) may be related to failed inhibition of the amygdala and insula by the hippocampus and the medial prefrontal cortex due to excessive release of stress hormones: uninhibited positive feedforward loops would seem to stabilize the defensive system, and impede the integration of EP and ANP. In this context, reactivation of traumatic memories and the defensive system (the EP) by CS implies sensitization rather than modulation of CS-UCS propositions. Finally, hyperactivation of the defensive system/limbic structures and potent somatosensory activity combined with relatively low levels of prefrontal cortical activity could perhaps explain why in most cases EPs have only developed a quite limited degree of extended consciousness.

Thus it seems that exposure of the EP to (perceived) threat cues (re)activates defensive responses with concomitant lack of contextual information processing, uninhibited conditioned emotional responding within limits of homeostasis, and hampered integration of traumatic memories. Hyperamnesia, sensitization, and maintenance of structural dissociation between ANP and EP can co-occur.

ANP-Dependent Responsivity to Threat

Now consider the ANP. Because ANPs displayed reactivity to masked angry faces (Van Honk *et al.*, 1999, 2001), it seems unlikely that the amygdala and related brain structures were not activated at all when ANPs were exposed to these threat cues. However, in the EP, the emotional brain was strongly activated (Nijenhuis *et al.*, 1999a; Reinders *et al.*, in preparation; Van Honk *et al.*, 1999, 2001). While the EP selectively attends to threat cues, the ANP averts its gaze from threat and selectively attends to cues that matter to daily life functioning. It seems possible that the lateral amygdala is activated for a short time by means of input from the sensory thalamus when the ANP is exposed to threat. However, due to ANP's mental avoidance of threat cues and retraction of the field of consciousness to matters of daily life, the lateral amygdala could become readily subject to a form of negative feedback inhibition. When emotional systems that regulate daily life are in executive control, the amygdala — which has a role in selective attention (Gallagher, 2000) — and related structures may operate in a mode that is different from the mode associated with the defensive system.

Because ANPs are often depersonalized, studies of DID could help understand ANP reactivity to threat in various trauma-related disorders. Depersonalization is related to several negative somatoform dissociative symptoms, e.g., experiencing the body as a foreign object, and involves functional abnormalities along sequential hierarchical areas, secondary and cross-modal areas of the sensory cortex (visual, auditory, and somatosensory), as well as areas responsible for an integrated body schema (Simeon *et al.*, 2000). Perhaps the ANP's lack of sensory perception, including bodily and peripheral stress hormone feedback, could be instrumental in inhibiting the defensive system, hence, the insula and amygdala, and the responsivity it orchestrates. One way to study the presumed negative feedback and positive feedforward loops would be to apply functional MRI while ANPs and EPs are exposed to external and internal threat cues.

PSYCHOBIOLOGICAL DIFFERENCES AMONG DISSOCIATIVE PARTS OF THE PERSONALITY IN PTSD

Recent studies of PTSD have begun to appreciate that the condition in which the patient remains may affect psychobiological functioning. For example, in a recent functional MRI study using script driven imagery of traumatic situations, Lanius *et al.* (2000) found that a subgroup of PTSD patients developed a depersonalization response, while other PTSD patients relived their trauma. Both groups showed less activation of the thalami and the dorsolateral prefrontal cortices compared with healthy controls, but the depersonalization group also displayed activation of the right anterior cingulate. The depersonalization group may perhaps have represented the ANP, and the group that relived trauma, the EP. In any case, the Lanius study confirms that the activity in different brain regions depends on the dissociative part of the personality that is activated during testing. The same interpretation may apply to the finding that some PTSD patients produced (contrary to the expectation of the investigators) slower vocal responses to trauma cues in the emotional Stroop task, whereas others exhibited faster vocal responses to trauma-related than to neutral cues (Stewart *et al.*, 2000). Furthermore, Liberzon and Taylor (2000) reported that a PTSD patient who experienced a flashback in a symptom provocation study had very different regional cerebral blood flow from other PTSD patients and controls with greater uptake in subcortical regions than in cortical regions, in particular the thalamus. We conclude that future psychobiological studies of PTSD should control for the dissociative part of the personality that dominates during testing. However, controlled activation of ANPs and EPs of PTSD patients may be difficult. As a prototype that can be more readily self-controlled in ANP–EP switches, DID deserves far more study from a psychobiological angle than has been performed to date.

CONCLUSION

The integrative functions of the human mind can be hampered by overwhelming events, especially when these events begin early in life, are recurrent, involve threat to the body and to life itself, and are accompanied by compromized attachment, and lack of social recognition and support. While substances such as glutamate, norepinephrine, and CRF may have a role in dissociative processes, these substances in themselves do not define what dissociative structures ensue. Trauma-related dissociation does not split the personality in accidental ways. Clinical, empirical, and experimental evidence rather suggests that structural dissociation of the personality reflects a lack of integration among specific psychobiological systems, described in this chapter as emotional operating systems. The primary form of this structural dissociation involves failed integration between systems dedicated to daily life and survival of the species, and systems dedicated to the survival of the individual in the face of severe threat.

Key brain structures involved in responding to (perceived) threat include the amygdala, insula, locus coeruleus, HPA-axis, hippocampus, cingulate, medial prefrontal cortex, and orbitofrontal cortex, as well as the somatosensory association areas situated in the temporal, parietal and occipital cortex. The evidence to date suggests that in PTSD and the dissociative disorders, (re)activation of the defensive system — metaphorically addressed as the 'emotional' personality — by trauma-related cues implies increased activation of the amygdala, insula, and related structures, and decreased activation of the hippocampus, cingulate gyrus, medial prefrontal cortex, and perhaps other prefrontal areas as well. The amygdala orchestrates a range of unconditioned and conditioned reactions to threat, including sympathetic and parasympathetic nervous system activity, analgesia, defensive motor reaction patterns, subjective emotional feelings such as fear, and retraction of the field of consciousness to threat cues in the immediate, subjective present. These reactions seem to lack modulation by the hippocampus and prefrontal cortex. However, when the psychobiological systems that involve daily

life functioning — i.e., the 'apparently normal' personality — are dominant, threat cues are avoided (gaze aversion, mental inhibition), and attention is directed to cues that have a bearing on daily life. The depersonalization and negative somatoform dissociative symptoms that characterize the ANP may be related to disturbed metabolism in the somatosensory association areas. While structural dissociation may be adaptive when the integrative level is not sufficient to integrate both systems, continued structural dissociation is maladaptive when integration of traumatic experiences would be feasible.

To date, research of PTSD and most research of dissociative disorders has largely overlooked that findings may depend on the type of dissociative psychobiological system that dominates the functioning of the patient at the time of measurement. (It must be noted that in parallel dissociation, two or more dissociative personalities may be activated simultaneously, and conflicts among them may occur.) In this regard, at a minimum, the theory of structural dissociation can serve as a heuristic for future research of trauma-related dissociation. To date, we have studied global differences between ANP and EP, but future studies should also address emotional operating subsystems. As the theory predicts, EPs engaged in flight, freeze, fight, or total submission would have different psychobiological reactivity to threat cues and, for example, ANPs engaged in work or reproduction and caretaking would have different responses to attachment cues.

ACKNOWLEDGEMENT

We kindly thank E. Vermetten and J.A. Den Boer for their assistance in preparing this chapter.

The Psychobiology of Sexual and Gender Identity Disorders

Cindy M. Meston and Penny F. Frohlich

INTRODUCTION

Interest in human sexual function has increased in the past decade, in large part as a result of increased recognition of the sexual side effects of various medications, the high incidence of sexual dysfunction among men and women, and the highly publicized success of some treatments for sexual dysfunction (e.g., Viagra for erectile dysfunction). This paper will describe the present knowledge of the endocrine, neurotransmitter, and central and peripheral nervous system mechanisms governing sexual function and dysfunction. The primary focus will be the underlying physiological processes although it should be noted at the outset that it would be misleading to assume that sexual dysfunction is best conceptualized in this manner.

Psychological problems, such as depression or anxiety, and relationship issues, such as marital discord or stress, can have a profound effect on sexual functioning. Although such cognitive and emotional factors are often integral to a sexual problem, these aspects will be reviewed only briefly here.

SEXUAL DESIRE DISORDERS

Hypoactive Sexual Desire Disorder

Sexual desire is commonly defined as the broad interest in sexual objects or experiences. One of the difficulties in diagnosing inhibited desire is determining exactly what constitutes low desire. Sexual desire cannot be measured exclusively by frequency of sexual activity — a person may desire sexual activity a great deal more or less often than their actual level of activity. It is problematic to measure sexual desire based on a discrepancy between partners; a man who desires sexual activity once a day may be frustrated by a partner who desires sexual activity twice a week, yet both partners have a level of sexual desire that falls within the normal range. Because there is no objective physiological criterion for desire, it is generally inferred by self-reported frequency of sexual thoughts, fantasies, dreams, wishes, and interest in initiating and/or engaging in sexual experiences. However, it is also problematic to diagnose hypoactive sexual desire based on a simple comparison with typical levels of desire. A couple who both prefer sexual activity only once a month would be exhibiting levels of desire below normal, yet it is unlikely that they would be unsatisfied with their degree of activity (LoPiccolo and Friedman, 1988). In order to meet the Diagnostic and Statistical Manual of Mental Disorders, 4th edition (DSM-IV), criteria for hypoactive sexual desire disorder, the person must not only experience a persistent or recurrent deficiency or absence of sexual fantasies and desire for sexual activity, but the situation must create marked distress or interpersonal difficulty — indeed, it should be noted at the outset that in order to be diagnosed with any of the sexual disorders a person must be experiencing significant distress or interpersonal difficulty (American Psychiatric Association, 1994).

Hypoactive sexual desire disorder is much more common in women than in men. Thirty-two percent of women between the ages of 18 and 29 years old reported a lack of sexual interest compared to 14% of men in the same age group. Women did not demonstrate a change in rates of inhibited desire according to age while men were significantly more likely to report lack of sexual interest as they aged, particularly after age 50 years old. Women did not differ in rates of inhibited desire based on marital status whereas married men were significantly less likely to report inhibited desire compared to divorced or never married men. Women who had less than a high school level of education reported significantly higher rates of inhibited desire compared to women with more education. Perhaps more educated women are more open to improving sexual communication and sexual knowledge. Exploring what is sexually pleasurable, and communicating sexual needs are techniques used for enhancing sexual desire. Unlike women, men showed no significant differences in desire according to education. African-American women reported significantly higher rates of inhibited desire compared to Caucasian or Hispanic women whereas men demonstrated no ethnic differences in sexual desire (Laumann *et al.*, 1999).

Physiological Factors

Cases of low desire in men are often related to medical conditions or treatments that affect hormone levels. Hypogonadal men (i.e., men with deficient secretion of gonadal hormones) receiving testosterone replacement therapy demonstrated a significant drop in sexual interest following removal of the hormone treatment, and a return in sexual interest when the hormone treatment was resumed. This indicates that very low testosterone levels may impair sexual desire in men. Once testosterone levels reach a certain threshold, additional testosterone does not affect sexual desire — thus, testosterone administration to a male with normal testosterone levels will not increase sexual desire. In adolescent males, higher testosterone levels are associated with increased frequency of sexual fantasies and sexual activity but this relationship does not hold true in adult men. Perhaps during and around puberty internal factors (e.g., hormones) trigger sexual appetite while in adulthood external cues (e.g., relationship factors) play more of a central role. Some evidence suggests that oestrogen and progesterone administration reduces sexual desire in men with excessive or inappropriate desire,

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

although few studies have been published on this topic (Meston and Frohlich, 2000).

Unusually low testosterone levels that result from removal of the adrenal glands (adrenalectomy), removal of the ovaries (oophorectomy), or as a consequence of menopause, may impair sexual desire in women. Testosterone is effective in restoring sexual desire in these women with abnormally low testosterone levels. It should be noted that most women with hypoactive sexual desire disorder do not have abnormally low testosterone levels and administering exogenous testosterone to women with normal testosterone levels does not enhance sexual desire and can lead to a number of adverse side effects (e.g., acne, facial hair). Oestrogen levels do not significantly affect sexual desire in women and evidence is mixed regarding the affects of progesterone administration on sexual desire in women. Some evidence suggests that increases in prolactin levels that occur with breast-feeding may diminish sexual desire in women but myriad other psychological factors (e.g., post-partum depression) could account for these changes (Meston and Frohlich, 2000).

A variety of psychoactive medications affect sexual drive. Selective serotonin reuptake inhibitors (SSRIs, used most commonly for treating depression), which acutely increase the amount of serotonin in the synapse, produce a variety of sexual side effects including diminished libido in both men and women. Sexual dysfunction secondary to SSRI use is believed to result from the activation of the $serotonin_2$ receptor, although it is unclear whether activation of this specific receptor type is responsible for SSRI-induced loss of sexual drive *per se*.

Drugs that facilitate dopamine activity, such as the antiparkinsonian medication levodopa, tend to increase sexual desire in men. Dopamine activity also increases sexual drive in animals; selective dopamine agonists and apomorphine increased mounting behaviour in male rats (for review, see Meston and Frohlich, 2000). The role of dopamine activity in female sexual desire is not known although one report described a case of a middle-aged woman who exhibited increased sexual behaviour while receiving antiparkinsonian medication, and a return to normal sexual behaviour when the dosage was decreased (Uitti *et al.*, 1989). Long-term opioid (e.g., heroin) use diminishes libido in men and women, perhaps due to the testosterone and luteinizing hormone reducing properties of these drugs (Meston and Frohlich, 2000).

Although it is generally believed that sexual drive is controlled by the central nervous system, the specific brain regions and mechanisms controlling drive are not well understood. In male rats, lesion to the medial preoptic area impairs copulatory behaviour by disrupting the animal's ability to identify potential partners. Some evidence suggests that the medial amygdala plays an important role in sexual motivation in males. Large temporal lobe lesions have been reported to produce hypersexuality, although it is believed that damage to inhibitory neurons in the pyriform cortex may be responsible for these results (McKenna, 1999). It is feasible that activity in one or more of these regions may be abnormal in cases of hypoactive sexual desire.

Psychological Factors

Daily hassles (e.g., worrying about childcare, bills, etc.) and high stress jobs are probably the worst offenders for suppressing sexual desire, as are a multitude of relationship or partner-related issues. If the couple is experiencing conflict, one or both partners may experience a drop in desire. One member of a couple may experience a drop in desire because he or she no longer feels attracted to his or her partner. This typically occurs when the partner undergoes a dramatic change in appearance (e.g., significant weight gain). A person may experience a drop in sexual desire if their partner is unwilling to experiment sexually or lacks sexual skill, making the sexual experience frustrating, unpleasant, or in other ways unappealing. Differences in the desired amount of emotional intimacy or time spent together can impair sexual desire; one person may feel frustrated by the lack of closeness while the other may feel suffocated. Some people fear intimacy, perhaps as a result of being hurt in the past, and thus may have little desire for intimacy in the form of sexual activity. If one partner has more power in the relationship, the other partner may feel bullied or harassed, and may experience a drop in desire (LoPiccolo and Friedman, 1988). Religious concerns and certain psychological difficulties, such as depression or obsessive–compulsive disorder, may also be associated with inhibited desire.

Treatment

Treatment for inhibited sexual desire may be difficult because the person with low desire may be seeking treatment at the urging of their partner, and thus they may not be internally motivated for therapy. Provided physiological causes have been ruled out (e.g., low testosterone levels) it is essential that treatment begin by structuring the impaired desire as a couple problem, rather than as an individual problem (Pridal and LoPiccolo, 2000). Cognitive therapy is often used to restructure thoughts and beliefs about sexuality that may be inhibiting desire (e.g., good women should not desire sex) to reflect ideas more conducive to sexual enjoyment, and to address negative underlying relationship issues. Behavioural interventions are often used to treat physical expressions of affection and intimacy and to increase sexual communication. In some cases, couples have ceased not only sexual activity, but all physical affection — the partner with low desire may have stopped showing any affection for fear that it be interpreted as interest in sexual activity. In such cases, the couple is encouraged to begin expressing affection through non-sexual means such as holding hands, cuddling, hugging, and brief kissing, and then to gradually reintegrate sexual intercourse into their relationship.

Sexual Aversion Disorder

In the DSM-IV, sexual aversion disorder is defined as the recurrent or persistent extreme avoidance of or aversion to all, or nearly all, genital sexual contact with a sexual partner. The association between sexual aversion disorder and anxiety has led some to argue that sexual aversion disorder may be best conceptualized as a type of anxiety disorder, like a snake phobia or a fear of heights. Sexual aversions in some people may be related to a history of sexual trauma or unwanted sexual activity. Men may also develop sexual aversion as a result of fear of erectile failure and/or a desire to avoid unpleasant sensations associated with anxiety (Gold and Gold, 1993).

Sexual aversion disorders may be treated by addressing the underlying anxiety. Anxiolytic medications may be used to reduce the anxiety, sometimes in conjunction with sex therapy. If the sexual aversion appears to result from a history of sexual abuse, counselling directed at coming to terms with this history may be most effective. For men, treatment may involve sex education regarding realistic expectations about performance and female response (Gold and Gold, 1993).

SEXUAL AROUSAL DISORDERS

Closely connected with sexual desire, sexual arousal is defined in both psychological (e.g., 'feeling sexually excited') and physiological terms (e.g., genital blood flow). Physiological sexual arousal in males involves signals from central (brain and spinal cord) and peripheral nervous systems, and on a complex interplay between

neurotransmitters, vasoactive agents and endocrine factors. Within the penis is a central artery and veins that exit and drain the erectile bodies. The muscles that line the sinusoidal spaces and the central artery are contracted during the non-aroused state. Erection begins with muscle relaxation that is controlled by autonomic nerves and by the release of nitric oxide (described below). Smooth muscle relaxation reduces vascular resistance and the erectile bodies fill with blood. Once the erectile bodies become engorged with blood, the veins are compressed under the penis's tough fibroelastic covering and blood is trapped in the penis. Normally, detumescence (i.e., loss of erection) occurs with the release of catecholamines during orgasm and ejaculation.

Physiological sexual arousal in women begins with vasocongestion of the vagina, vulva, clitoris, uterus, and possibly the urethra, and can occur within only a few seconds of sexual stimulation. Vaginal lubrication occurs when the blood vessels of the vaginal epithelium (vaginal wall) become engorged with blood, causing fluid to pass between the cells of the vaginal epithelium and emerge on the vaginal wall as sweat-like droplets. These droplets can quickly build up to form a lubricating film that facilitates penetration of the penis. Nitric oxide has also been implicated in female sexual arousal (see below).

Female Sexual Arousal Disorder

According to the DSM-IV, a woman may have female sexual arousal disorder if she experiences repeated and persistent difficulty attaining or maintaining, until sexual activity is completed, a sufficient lubrication-swelling response of sexual excitement. As with many sexual disorders, female sexual arousal disorder can be subdivided into lifelong versus acquired types, generalized versus situational types, and due to psychological versus organic, or combined factors (American Psychiatric Association, 1994). Women of all ages may experience difficulty lubricating, although it tends to be more of a problem in later life, typically after menopause. Approximately 20% of women aged 18–49 years old reported problems lubricating compared to 27% of women aged 50–59 years old. Difficulty lubricating is not associated with marital status or level of education (Laumann *et al.*, 1999).

Physiological Factors

Oestrogen levels can have a profound effect on sexual arousal. This is most apparent through the menopause transition. Oestrogen levels decline during menopause, which results in atrophy of the vaginal epithelium (vaginal walls), and a decline in blood flow into the capillaries of the vaginal wall. A loss of oestrogen following menopause can also indirectly impair sexual arousal by impairing mood. Oestrogen replacement therapy can help remedy some of the vasomotor symptoms and vaginal atrophy in postmenopausal women (Sherwin, 1991). Several researchers have examined whether hormonal fluctuations across the menstrual cycle affect sexual arousal but failed to find any consistent relationship (Meuwissen and Over, 1992).

As noted earlier, some studies have shown that activation of the sympathetic nervous system can facilitate female sexual arousal. When sexually functional women and women with low sexual desire engaged in vigorous exercise (stationary cycling, which stimulates the sympathetic nervous system), they demonstrated significantly higher levels of physiological sexual arousal to an erotic film than without exercise (Meston and Gorzalka, 1995a, 1996). Physiological sexual arousal was measured using a vaginal photoplethysmograph, a tampon-like device that the woman inserts into her vagina, which measures blood flow in the vaginal capillaries. It is important to note that in these studies exercise alone did not facilitate sexual arousal — it was only when the women viewed an erotic film that vaginal blood flow was increased. This suggests that exercise somehow prepares the women's body for sexual arousal so that when she enters a situation she views as sexually appealing, her level of physiological sexual responding is intensified. Meston and Gorzalka (1995b) found a facilitatory effect of exercise at 15 and 30 minutes following exercise. Whether the effect remains past 30 minutes has not been examined. When the sympathetic nervous system is activated using a medication to increase sympathetic nervous system activity, such as ephedrine, physiological sexual arousal to an erotic film is also facilitated (Meston and Heiman, 1998). The reverse has also been shown; medications such as clonidine that block sympathetic nervous system activity impair sexual arousal (Meston *et al.*, 1997).

Animal studies and studies examining the physiology and side effects of medications suggest that neurotransmitters in the central nervous system and neuropeptides in the periphery of the body impact sexual arousal. Nitric oxide activity in the penile tissue triggers a cascade of events leading to increased blood flow into the penile capillaries. The medication Viagra, which is an orally administered treatment for erectile dysfunction, acts by initiating these events (the mechanism of action of Viagra will be described in more detail below under the erectile dysfunction section). Recent studies show that nitric oxide is also produced in clitoral tissue.

Convergent evidence suggests that serotonin activity in the periphery of the body may be involved in female sexual function and dysfunction. Serotonin is a powerful vasoactive substance that, depending on the site and tissue type, may produce vasodilation or vasoconstriction. Normal vaginal lubrication is dependent upon adequate vasocongestion of the genital tissue and it is feasible that serotonin may be involved in this process. If so, abnormalities in serotonin mechanisms may impair vaginal vasocongestion (e.g., with SSRI use). Serotonin is also active in several other peripheral mechanisms that are likely to affect sexual functioning such as nonvascular smooth muscle contraction, endocrine functions, and the spinal cord and peripheral nerves (Frohlich and Meston, 2000).

Mild abnormalities in cutaneous sensation, the sense of touch, have been associated with difficulty becoming lubricated. Cutaneous sensation was measured using Von Frey monofilaments, hair-like fibres that when pressed against the skin reliably apply a specific amount of force — the amount of force applied depends upon the diameter and length of the hair. College aged women with sexual arousal disorder required a higher degree of stimulation (more force) to their skin before they perceived the stimulation as compared to women with normal sexual functioning. This suggests that women with sexual arousal disorder may have mild abnormalities in peripheral nervous system functioning (Frohlich and Meston, 1999).

Very little research has been published regarding brain areas involved in female sexual arousal although several studies have implicated the paraventricular nucleus of the hypothalamus. Transneural viral labelling indicates that the clitoris and uterus are connected to the paraventricular nucleus and the findings from one study in rats suggests that the paraventricular nucleus is active during copulation. During sexual arousal, oxytocin produced in the paraventricular nucleus is secreted into the blood stream by the posterior pituitary (McKenna, 1999). It is feasible that paraventricular nucleus activity is abnormal in women with sexual arousal disorder.

Psychological Factors

In addition to affecting sexual desire, factors such as performance demand, anxiety, and expectancies can also affect physiological sexual arousal (i.e., vaginal vasocongestion and lubrication). Laan *et al.* (1993) found that sexually functional women became more sexually aroused after being asked to become as sexually aroused

as possible, versus being told their level of sexual arousal was not important to the study. This suggests that for women without sexual difficulties, performance demand can facilitate sexual arousal. Expectancies may interact with autonomic arousal to influence sexual arousal as well. Palace (1995) found that sexually dysfunctional women who were falsely informed that they displayed strong physiological sexual arousal to an erotic film, displayed greater physiological and self-reported sexual arousal to a subsequent erotic film. Moreover, this response was greater if the erotic stimulus was preceded by an anxiety/fear provoking film versus a neutral film. This suggests that sympathetic nervous system arousal paired with the expectation of sexual arousal may be effective in increasing physiological sexual arousal in women.

Because of the close link between sexual desire and sexual arousal in women, many of the same psychological factors that impair sexual desire also inhibit vaginal lubrication. Briefly, these include individual, relationship, and cultural factors. An estimated 49% of women who were sexually abused as children report impaired sexual arousal. Inadequate or inappropriate sexual stimulation may interfere with sexual arousal, as would negative emotions such as fear of rejection, anger, or relationship conflict (Morokoff, 1993).

Male Erectile Disorder

According to the DSM-IV, male erectile disorder is characterized by a persistent or recurrent inability to attain or maintain an adequate erection until completion of the sexual act. Erectile dysfunction may result when a medical problem or condition, such as diabetes mellitus, surgical injury, aging, or pharmaceutical intervention, affects vascular blood flow to the penis or neural innervations to and from the penis. Patients are diagnosed with erectile dysfunction when their erectile difficulties are exclusively psychogenic in nature, or are caused by a combination of psychological and medical factors (American Psychiatric Association, 1994).

Men of all ages occasionally have difficulty obtaining or maintaining an erection, but true erectile disorder is more common after age 50 years. Approximately 7% of men aged 18–29 years have erectile troubles compared to 18% of men aged 50–59 years. Level of education and ethnicity are not associated with erectile difficulties, but married men are less likely to report erectile problems compared to never married or divorced men (Laumann *et al.*, 1999).

Physiological Factors

Testosterone does not affect erectile functioning unless it falls below a critical level. Hypogonadal men, or men with unusually low testosterone levels, often experience erectile problems that are successfully treated with testosterone replacement therapy. Testosterone administration does not improve erectile response in men with normal testosterone levels. Prolactin levels also affect erectile functioning although the process is complex; men with abnormally high prolactin levels and men with abnormally low prolactin levels may experience erectile dysfunction (Besser and Thorner, 1975; Deutsch and Sherman, 1979). In normally functioning men, prolactin and oxytocin levels increase significantly during sexual arousal (Meston and Frohlich, 2000).

Acetylcholine, vasoactive intestinal peptide, and nitric oxide have also been implicated in penile tumescence (i.e., erection). Activation of cholinergic receptors produces relaxation of the penile smooth muscles, allowing blood flow into the penis, thus producing an erection (Saenz de Tejada *et al.*, 1988). Sexual stimulation leads to the production of nitric oxide in penile tissue. Nitric oxide stimulates guanylate cyclase release, which triggers the conversion of guanosine triphosphate to cGMP. cGMP activity relaxes the smooth muscles of the penile tissue allowing vasocongestion and erection (Burnett, 1995). The pharmaceutical company, Pfizer, capitalized on this process by developing the medication Viagra, which is designed to treat erectile dysfunction. Viagra potentiates the activity of cGMP by inhibiting phosphodiesterase type 5, the endogenous substance responsible for cGMP deactivation. This increases and prolongs cGMP activity, which increases and prolongs vasocongestion, and enables erection. Interestingly, Viagra was discovered by accident when researchers for Pfizer noticed that men taking an experimental drug for heart disease, which worked on nitric oxide systems, had erections as a side effect.

A variety of psychoactive medications produce erectile dysfunction. Antiparkinsonian medications are dopamine agonists and are reported to facilitate erection (Bowers *et al.*, 1971) while antipsychotic medications are dopamine antagonists and facilitate erection at low doses and impair erection at high doses (Aizenberg *et al.*, 1995; Marder and Meibach, 1994). Cocaine is a dopamine agonist and high doses can disrupt erectile capacity (Miller and Gold, 1988), perhaps due to its vasoconstrictive properties. Opioid abuse (e.g., heroin) can lead to erectile dysfunction.

Erection is dependent upon spinal reflexes and is controlled by descending inhibitory and excitatory input from the brainstem. This is most apparent when studying the effects of spinal cord injury. Transection of the spinal cord often facilitates erectile response (depending upon the region of the spinal cord injured) — animal and human studies suggest that following spinal cord injury, less stimulation is required to obtain erection and erection occurs more frequently (McKenna, 1999).

Several brain regions have been implicated in male erection. Animal studies indicate that oxytocin released from the paraventricular nucleus of the hypothalamus can produce erection as can electrical stimulation of the paraventricular nucleus of the hypothalamus and hippocampus. Electroencephalographic studies indicate that the right temporal lobe is activated when right-handed men are presented with visual sexual stimulation. Perhaps the most definitive study to date used positron emission tomography (PET scan) to examine brain activity in healthy men presented with visual sexual stimulation. The areas of the brain activated included visual, sensory, and neuroendocrine and autonomic areas. Specifically, visually presented information produced bilateral activation of the inferior temporal cortex, a visual association area, activation of the right inferior frontal cortex and right insula, paralimbic areas that relate motivational states with highly processed sensory information, and activation of the left anterior cingulated cortex, a paralimbic area that controls neuroendocrine and autonomic functions (McKenna, 1999).

Psychological Factors

It is common for men to have occasional episodes of erectile failure without it developing into a full blown erectile disorder. Barlow (1986) argued that men with erectile dysfunction respond differently in sexual situations compared to normally functioning males. When placed in a sexual situation, men with erectile dysfunction focus on non-sexual cues such as fears about inadequate performance, and worries about inability to control performance. These thoughts lead to increased anxiety, increased focus on non-erotic cues and fears of erectile failure. This process inhibits erection and thereby confirms the men's fears. Since the men's fears were confirmed, they are likely to repeat the process in subsequent sexual situations and a negative feedback loop develops. In contrast, when placed in a sexual situation, men with normal erectile responding focus on erotic cues and subsequently become aroused and are able to obtain and sustain an erection. They experience the sexual situation as pleasurable and look forward to future sexual situations creating a positive feedback loop.

Treatment

A variety of tools can be used to assess whether the erectile dysfunction is of psychological or physiological origin. If the male exhibits nocturnal erections, or obtains an erection when a vasoactive substance is injected into the corpora, the erectile problem is likely to be psychological in nature. Treatments for erectile dysfunction include vacuum devices and constriction rings, intracavernosal injections, intraurethral pharmacotherapy, topical pharmacotherapy, oral pharmacotherapy, and penile implants. The vacuum device consists of a tube that is placed over the penis, and a vacuum pump that draws blood into the penile arteries. A constriction ring is placed at the base of the penis to prevent venous outflow so that the erection is maintained until completion of the sexual act. Several medications are available that can be injected into the corpus cavernosum of the penis to induce erection including papaverine, phentolamine, and prostaglandin E_1. These all act to dilate penile capillaries, allowing blood to flow into the penis. Although intracavernosal injections are fairly effective (between 70–90%), between 50% and 80% of patients discontinue treatment, citing problems such as inconvenience, cost, and invasiveness of treatment. An intraurethral-administered medication, MUSE (Medicated Urethral System for Erection — active ingredient prostaglandin E_1), has recently been introduced. This medication is administered in suppository form and is absorbed through the urethral mucosa. It is most effective when used in conjunction with a constriction ring. Side effects of the medication include urogenital pain and urethral bleeding. Topical medications, such as Minoxidil, are also available, although these types of treatments are not commonly used, in part because their effects on vaginal mucosa are not well understood. Viagra, an orally administered treatment, was introduced to the market in 1998, and since then, many of these rather cumbersome and involved treatments have become less popular. Viagra is well tolerated by a variety of patients and is an effective treatment for both organic and psychogenic impotence (Montorsi *et al.*, 1999). Because sildenafil produces vasodilation and a minor drop in blood pressure, it may be contraindicated for patients diagnosed with or receiving treatment for cardiovascular disease. Data are not presently available regarding sildenafil-use in patients with certain cardiac conditions such as unstable angina, stroke, or recent myocardial infarction (heart attack) and/or arrhythmias. Nonetheless, sexual activity increases the likelihood of ischaemia or infarction and thus patients with cardiac risk factors are often referred for an exercise stress test prior to receiving sildenafil. Sildenafil can safely be administered in conjunction with some cardiovascular medications, such as most antihypertensives, but if it is taken in conjunction with organic nitrates, it can produce a major and life-threatening drop in blood pressure (Klonger, 2000).

Penile implants are considered a last resort and are used when tissue damage or deterioration is severe, and when other treatments have failed. Penile implants typically consist of a cylinder (implanted in the penis) that can be mechanically inflated and deflated (Rowland and Burnett, 2000).

Studies are currently underway to determine whether Viagra and other drugs that act as vasodilators on genital tissue will be effective for treating Female Sexual Arousal Disorder. The first Federal Drug Administration (FDA) approved treatment for female sexual arousal disorder was recently introduced to the market. The treatment is a hand-held battery-operated device, called the EROS-CTD, which contains a soft plastic cup and a suction device. When the cup is placed over the clitoral tissue and the device is activated it draws blood into the genital tissue.

ORGASM DISORDERS

The normal ejaculatory response typically occurs following sensory stimulation to the penis. The stimulation initiates a nerve signal that travels along the pudendal nerve (i.e., genital sensory nerve) and synapses at the sacral level of the spinal cord. The spinal cord input stimulates an autonomic and a somatic response. The autonomic response involves adrenergic neurons (within the sympathetic nervous system), which stimulate contraction of the smooth muscles of the vas deferens, seminal vesicles, and prostate. This leads to closure of the bladder neck and movement of seminal fluid into the urethral duct. In both men and women, orgasm is characterized by a peak in sexual pleasure that is accompanied by rhythmic contractions of the genital and reproductive organs, cardiovascular and respiratory changes, and a release of sexual tension. In men, during the emission stage of orgasm, seminal fluid is propelled into the bulbar urethra via the release of norepinephrine that acts on alpha-adrenergic receptors, the smooth muscles of the vas deferens, prostate, and seminal vessels. During the ejaculatory phase, which is mediated by a sacral spinal reflex, semen is released through the urethra via contractions of muscles that surround the bulbar urethra. The extent to which central neurophysiologic events are related to the intensity or experience of orgasm is not known. While orgasm is generally the result of both genital and psychological stimulation, evidence suggests central stimulation alone may trigger orgasm.

Female Orgasmic Disorder

Female orgasmic disorder is diagnosed when the woman experiences persistent or recurrent delay in, or absence of, orgasm following a normal sexual excitement phase. In order to meet DSM-IV diagnostic criteria, the woman's orgasmic capacity is less than would be reasonable for her age, sexual experience, and adequacy of sexual stimulation she receives (American Psychiatric Association, 1994). Between 22–28% of women ages 18 to 59 years report that they are unable to attain orgasm. Married women and women who have some college education are significantly less likely to report being unable to attain orgasm as compared to never married and divorced women, and women who have not attended college (Laumann *et al.*, 1999).

Physiological Factors

Among normally orgasmic women oxytocin levels were positively correlated with subjective intensity of orgasm, and prolactin levels were elevated for up to 60 minutes following orgasm (Meston and Frohlich, 2000). It is feasible that oxytocin and prolactin regulation is abnormal in women with orgasmic disorders, although a study examining oxytocin and prolactin levels in orgasmic disordered women has not yet been published.

The SSRIs frequently affect orgasmic functioning, leading to delayed orgasm or anorgasmia. The antidepressant, nefazodone, produces fewer sexual side effects in women (Feiger *et al.*, 1996), possibly because it increases serotonin activity in general while simultaneously inhibiting serotonin activity at the $serotonin_2$ receptor — the receptor implicated in SSRI-induced sexual dysfunction (Eison *et al.*, 1990). Cyproheptadine is also a $serotonin_2$ receptor antagonist and has been an effective antidote to SSRI-induced orgasmic dysfunction (although it is not an ideal antidote as it can disrupt the effectiveness of the antidepressant medication). Drugs that affect dopamine mechanisms, such as antipsychotics (which inhibit dopamine) or cocaine (which facilitate dopamine), delay or inhibit orgasm in women. Female heroin addicts also report delayed or inhibited orgasm. Taken together, these findings suggest that serotonin, dopamine, and opioid mechanisms may be functioning abnormally in orgasmic disordered women.

Studies examining blood plasma levels of neuromodulators before, during, and after orgasm suggest that epinephrine and norepinephrine levels peak during orgasm in normally functioning women (Exton *et al.*, 1999; Wiedeking *et al.*, 1979). This process

may be impaired in anorgasmic women. One study showed that when vigorous exercise (which stimulates the sympathetic nervous system) is followed by an erotic stimulus, sexual arousal is facilitated in normally functioning women, but inhibited in anorgasmic women (Meston and Gorzalka, 1996).

Brain and spinal cord mechanisms are integral to the orgasm response. The neuronal pathway connecting the genitals to the brain was identified via transneuronal labelling. Virus injected into the clitoris revealed that sexual afferent neurons synapse on neurons in the lumbosacral spinal cord and connect to the nucleus paragigantocellularis in the brainstem. Lesions to the nucleus paragigantocellularis and spinal cord transection can suppress tonic inhibition of the orgasm-like response, suggesting that this pathway exerts inhibitory control over orgasm. Neurons in this region stain positively for serotonin suggesting that it may be implicated in SSRI-induced anorgasmia in women. Studies in humans suggest that the paraventricular nucleus of the hypothalamus is also involved in the orgasmic response. The paraventricular nucleus produces oxytocin that is released from the posterior pituitary during arousal and orgasm (McKenna, 1999).

The neurological disease, multiple sclerosis, often results in orgasmic disorders. In multiple sclerosis patients, orgasmic problems are related to neurological problems such as changes in genital sensation, muscle weakness in the pelvis (Lundberg and Hulter, 1996), and brain abnormalities (in the pyramidal and brain-stem regions) (Barak *et al.*, 1996). It is feasible that similar anatomical structures are involved in orgasmic disorders, albeit non-disease related.

Psychological Factors

The degree to which a woman is distracted during sexual situations may affect orgasm ability. Orgasmic women tend to focus on their own arousal and their partners' arousal throughout the sexual situation, while anorgasmic women tend to focus on trying to attain orgasm, focus on non-sexual thoughts, and are more easily distracted by non-sexual thoughts. Anorgasmic women are also more likely to report discomfort with sex compared to orgasmic women; they are more likely to be uncomfortable discussing direct clitoral stimulation, and are more likely to have guilt about sex, to endorse sex myths, and to report negative attitudes about masturbation. Anorgasmic women are less likely to be aware of their physiological sexual arousal as compared to consistently orgasmic women (Stock, 1993).

Treatment

Treatment for anorgasmia involves education about female anatomy and physiology, self-exploration, and directed masturbation. The woman is encouraged to explore her body and identify regions and types of stimulation that produce sexual arousal, to experiment with different fantasies, and to use various tools (such as a vibrator) that may enhance arousal. Once she has successfully learned to attain orgasm during masturbation, she is encouraged to teach her partner which parts of her body and which types of stimulation are likely to bring her to orgasm. Directed masturbation is a highly effective treatment for anorgasmia, with outcome studies showing up to a 90% success rate (Heiman and Meston, 1998).

Male Orgasmic Disorder

DSM-IV criteria for male orgasmic disorder include recurrent or persistent difficulty obtaining orgasm, or inability to obtain orgasm, even after sufficient sexual stimulation. The clinician takes a variety of factors into account before making the diagnosis, such as age and amount of stimulation. In most cases of inhibited male orgasm the patient is able to attain orgasm but only through manual or oral stimulation, and when orgasm occurs through intercourse it is only possible after prolonged manual or oral stimulation (American Psychiatric Association, 1994).

For the patient and his partner (male or female), sexual activity is experienced as 'hard work' (Dekker, 1993). Very few studies of male orgasmic disorder have been published, likely due to the fact that it is a rare disorder. The prevalence in the general population is estimated at 1.5 in 1000, and among those presenting for sex therapy, 0–13 in 100 (Dekker, 1993).

What is presently known about the mechanisms underlying orgasm is drawn from animal studies and from studies examining side effects of recreational and pharmaceutical drugs. One of the more common side effects of SSRI medications is delayed or inhibited orgasm, suggesting that serotonin activity may play a role in normal orgasm functioning. Animal studies indicate that serotonin$_{1A}$ receptor activation facilitates orgasm (Bitran and Hull, 1987) — it is feasible that men with inhibited orgasm have abnormal serotonin$_{1A}$ receptor activity. Dopamine may also be implicated in orgasm functioning. Dopamine agonists, such as apomorphine and cocaine, have been reported to inhibit orgasm, although apomorphine has also been reported to facilitate orgasm. The fact that dopamine can both inhibit and facilitate orgasm may be a function of dose; in rats, a low dose of a dopamine agonist increased ejaculation latency while a high dose decreased ejaculation latency (Clark *et al.*, 1983). In normally functioning men, blood plasma levels of norepinephrine significantly increased at orgasm (Kruger *et al.*, 1998) and oxytocin levels were significantly positively correlated with subjective orgasm intensity (Carmichael *et al.*, 1994). Some evidence suggests that inhibited orgasm may result from spinal reflex abnormalities. Studies examining men with spinal cord injuries and normally functioning men suggest that the dorsal penile nerve and the perineal nerve are involved in the ejaculatory response. Stimulation to these nerves in normally functioning men resulted in contraction of the bulbocavernosus muscle, the muscle involved in ejaculation (Yang and Bradley, 1999).

The brain and spinal cord are regions implicated in orgasm. The neuronal pathway from the genitals to the brain was transneuronally labelled by injecting a virus into the penile tissue. Sexual afferents enter the lumbosacral region of the spinal cord and via interneurons and neurons connect to the nucleus paragigantocellularis in the brainstem. Lesions to the nucleus paragigantocellularis impair normal tonic inhibition of the orgasmic response. Neurons in this region stain positively for serotonin suggesting this region may be implicated in SSRI-induced anorgasmia in men. During arousal and orgasm in men, oxytocin produced in paraventricular nucleus of the hypothalamus is released from the posterior pituitary (McKenna, 1999). Single photon emission computed tomography was used to examine brain physiology during orgasm in eight healthy right-handed men. During orgasm, blood flow significantly increased in the right prefrontal cortex and decreased in all other cortical regions (Tiihonen *et al.*, 1994). Although these processes have been implicated in normal orgasmic functioning in men, no evidence is currently available on men with orgasmic disorders. Nonetheless, it is feasible that these regions and mechanisms function abnormally in men with orgasmic disorders.

Premature Ejaculation

When seminal fluid enters the urethral duct, it triggers a somatic response — known as ejaculatory inevitability. The bulbocavernosus and ischiocavernosus muscles contract and semen is ejaculated through the urethral opening. This event is typically associated with the subjective pleasure of orgasm (Rowland and Burnett, 2000). When ejaculation occurs with minimal sexual stimulation before, on, or shortly after penetration, it is referred to as premature ejaculation. The clinician determines whether a diagnosis should be

made after taking a variety of factors likely to affect ejaculation latency into account, such as age and novelty of partner. A diagnosis is only made if it is a recurrent or persistent problem (American Psychiatric Association, 1994).

Premature ejaculation is a fairly common problem. Approximately 30% of men ages 18 to 59 report that they orgasm too early. Marital status and ethnicity are not significantly associated with premature ejaculation, but men who have attended college or graduated from college have lower rates of premature ejaculation than men with less education (Laumann *et al.*, 1999).

Physiological Factors

As described above, several medications inhibit or delay orgasm suggesting that neurotransmitter activity affected by these medications may be involved in normal ejaculation and, possibly, premature ejaculation. Dopamine agonists such as apomorphine and cocaine have been reported to affect orgasm and SSRIs often delay ejaculation suggesting that abnormalities in serotonin and/or dopamine regulation may underlie premature ejaculation. Animal studies suggest that stimulation of the serotonin$_{1A}$ receptor decreases ejaculation latency (Ahlenius and Larsson, 1997). Usually ejaculations occur after several intromissions but in some animals the effects of serotonin$_{1A}$ stimulation are so pronounced that ejaculation occurs at the first intromission (Ahlenius *et al.*, 1981). It is feasible that the serotonin$_{1A}$ receptor is hypersensitive in men with premature ejaculation.

Kaplan (1974) proposed that men with premature ejaculation are more sensitive to erotic stimuli and thus become aroused and orgasm more quickly. They may also be less adept at perceiving the sensations leading to ejaculatory inevitability (i.e., the point when semen is in the base of the urethra and ejaculation cannot be stopped). Several studies have tested this hypothesis with mixed results. Spiess *et al.* (1984) found that men with and without premature ejaculation did not differ in how quickly they became aroused, the length of time it took for them to obtain their maximum erection, or their erectile response to an erotic film. Colpi *et al.* (1986) found that men with premature ejaculation had a more sensitive ejaculation reflex and Fanciullacci *et al.* (1988) found that men with premature ejaculation had larger areas of the somatosensory cortex devoted to the genital region compared to normal controls. Taken together, these studies suggest that some cases of premature ejaculation may be organic in nature.

Psychological Factors

Traditionally, anxiety has been implicated in the aetiology of premature ejaculation yet empirical studies have found conflicting evidence regarding its role. Strassberg *et al.* (1990) compared self-reported thoughts during sexual stimulation in men with and without premature ejaculation and found no differences in self-reported anxiety. Cooper and Magnus (1984) conducted a double-blind, placebo controlled, crossover study where men with premature ejaculation were randomly assigned to receive an anxiolytic medication versus placebo. Although the anxiolytic medication had the expected impact on anxiety (it reduced it), it did not affect ejaculation latency. Cooper *et al.* (1993) compared men with primary premature ejaculation (i.e., life-long premature ejaculation problem) to men with secondary premature ejaculation (i.e., developed the problem after a period of normal ejaculation latencies) and found that men with secondary premature ejaculation were significantly more likely to report anxiety during intercourse and scored significantly higher on a general measure of anxiety. This suggests that anxiety may play a role in secondary premature ejaculation but not primary premature ejaculation.

Treatment

Treatments for premature ejaculation include psychological as well as pharmacological interventions. The most common psychological treatment, the pause-and-squeeze technique, was introduced by Semens (1956) and popularized by Masters and Johnson (1970). This technique is fairly straightforward; the man is stimulated to a point close to orgasm, the stimulation is interrupted (pause) and firm pressure is placed under the glans of the penis (squeeze). The procedure is repeated several types (typically twice) before ejaculation is permitted. These behavioural strategies are often combined with other strategies aimed at increasing control over ejaculation such as increasing the range of sexual activities (i.e., other than intercourse) and increasing the awareness of physical sensations associated with approaching ejaculation (so that stimulation can be ceased prior to ejaculatory inevitability). Patients may also be encouraged to use sexual imagery and thoughts to slightly decrease arousal levels and thus help control ejaculation (e.g., mentally listing the players in a favourite sports team).

More recently, pharmaceutical agents that have the side-effect of delaying ejaculation have been used to treat premature ejaculation. These include antidepressants such as the SSRIs and tricyclic antidepressants, and anti-anxiety medications such as the benzodiazepines. These types of medications are often effective in delaying ejaculation, although the effectiveness can wear off after several weeks and some men do not experience any delay in ejaculation (often the men least likely to respond are also those who ejaculate the most quickly). In some people these medications can have unpleasant side effects such as gastrointestinal disturbance and headache. Topical creams that dull sensation, such as lidocaine, may also effectively delay ejaculation, although they are not appropriate for men who ejaculate prior to insertion, and the creams can be irritating to vaginal tissue (Metz and Pryor, 2000).

PAIN DISORDERS

Dyspareunia

The DSM-IV defines dyspareunia as recurrent or persistent genital pain associated with sexual intercourse. The diagnosis of dyspareunia is not given if the pain decreases or is eliminated by adequate vaginal lubrication.

Although dyspareunia is currently classified as a psychiatric disorder, experts contend that it may be better classified as a pain syndrome that results in sexual dysfunction rather than a sexual dysfunction (that involves pain). In a recent review, Binik *et al.* (2000) suggested that describing genital pain along several dimensions including location, quality, elicitors, course, intensity, and meaning could be useful in identifying the cause of the pain and directing the type and course of treatment. Some women report that the pain is localized, generalized, or wandering while some women are not able to identify the location of the pain. The pain may have a 'sharp', 'burning', 'dull', or 'shooting' quality that may reflect the type of pathology. The pain may be specific to intercourse, or may follow other types of stimulation (e.g., oral sex). It may begin before, during, or after stimulation, and may be mild, moderate, severe, or excruciating. Women may attribute meaning to the pain — they may believe it is related to a medical condition or a psychological source. Meana *et al.* (1999) found that women who attributed their pain to a psychological source rated the pain as more severe in intensity.

Dyspareunia may be caused by anatomical, pathological, iatrogenic, or psychological factors. A rigid hymen would be an anatomical factor that could result in genital pain during intercourse. Infections in the genitals could produce genital pain during intercourse, as could endometriosis and non-malignant and malignant

tumours. Surgical procedures (e.g., episiotomy) could also result in dyspareunia. Following menopause, atrophy of the vulva and vaginal tissue can increase the likelihood of dyspareunia. No one disease is associated with dyspareunia and a disease or disorder can be quite extensive without causing sexual pain. A variety of psychological factors may also lead to dyspareunia. For example, it may develop as a result of attitudes and values passed down from parents that lead to fear and anxiety in sexual situations, traumatic events where sexual or non-sexual contact with the genitals was experienced as painful, or emotional or relational factors, such as depression or discord between partners (Meana and Binik, 1994).

Recent evidence suggests that some forms of dyspareunia may be associated with abnormalities in pain sensation. The sense of touch and pain was measured in women with vulvar vestibulitis and control women (vulvar vestibulitis is a condition characterized by severe pain upon attempted intercourse or vestibular touch — the vestibule refers to the area of tissue below the clitoris, between the labia minora, and the vaginal opening). Touch and pain thresholds were obtained by applying small amounts of force to the skin; touch threshold was defined as the minimum amount of force needed for the women to consciously detect the stimulation, and pain thresholds were defined as the minimum amount of force that was experienced as painful. The women with vulvar vestibulitis were more sensitive to light touch and pain than the control women suggesting greater tactile and pain acuity (Pukall *et al.*, 2000). Women with vulvar vestibulitis also had more densely packed sensory nerves in the vestibule, which may account for their increased sensitivity (Westrom and Willen, 1998).

Treatment

Regardless of the cause of dyspareunia, the symptoms are most effectively treated with cognitive-behavioural therapy. Even when the pain is a direct result of a medical condition, the pain often continues after medical intervention (Schover *et al.*, 1982). Psychological treatment typically involves one or more of the following techniques: vaginal exercises, vaginal dilation, systematic desensitization, and couples therapy (education regarding communication and sexuality). The goal is for the woman and her partner to learn, through education and direct experience, that sexual contact and intercourse do not necessarily produce pain. Vaginal exercises involve the voluntary contraction of the vaginal muscles, allowing the women to gain familiarity and greater control over her muscle contractions. Vaginal dilation involves inserting increasingly larger dilators into the vagina until the woman is able to insert one that is a similar size to her partner's penis, without experiencing pain or anxiety. Vaginal dilation is one form of systematic desensitization but systematic desensitization can also be performed by fantasizing about pain producing activities. The woman is first asked to list activities in order from least painful or anxiety provoking to most painful and anxiety provoking. She is then instructed to fantasize about the least painful activity until she is able to picture it without discomfort. Once she is able to do this, she moves to the next item on the list, until she is able to fantasize about the most painful and anxiety provoking item on the list without feeling discomfort.

Vaginismus

The DSM-IV defines vaginismus as repeated and persistent involuntary spasm of the vaginal muscles that interferes with intercourse. For many women, this difficulty is not specific to intercourse; they are often unable to insert even tampons into their vaginas and fear and avoid gynaecological exams. The condition is not necessarily a generalized sexual problem; many women with vaginismus are able to enjoy sexual stimulation and orgasm that does not involve penetration of the vagina. The prevalence of vaginismus is not known. Laumann *et al.* (1994) interviewed a random sample of 1749 women and found that 10–15% of women reported sexual pain, either dyspareunia or vaginismus. Approximately 12–17% of women seeking sexual therapy present with symptoms of vaginismus (Spector and Carey, 1990).

Although the DSM-IV indicates that vaginismus involves spasm of the musculature of the outer third of the vagina, this description is based almost exclusively on self-report rather than physical examination. One study found no difference in vaginal muscular activity (measured via EMG) between women with vaginismus and control women (van der Velde and Everaerd, 1996). No empirical studies have explored what specifically occurs to prevent penetration. It is not clear whether muscle contraction prevents penetration or makes penetration difficult or painful, or whether penetration is not attempted due to anticipatory pain. The DSM-IV does not include pain as a characteristic of vaginismus, yet some experts in the field argue that the pain, or the anticipation of pain, may be central to the disorder (Reissing *et al.*, 1999).

Vaginismus has traditionally been thought to result primarily from psychological factors. A review of the family histories of women with vaginismus reveals similar backgrounds. Often women with vaginismus were raised by parents with oppressive or authoritarian attitudes (Tugrul and Kabakci, 1997) and had parents who were engaged in frequent conflict (Silverstein, 1989).

Many women with vaginismus report having fathers who were domineering or threatening, alcoholic, seductive, or overprotective, and mothers who disliked sex or viewed sex as an obligation. Approximately 40% of women with vaginismus report a history of sexual trauma (Silverstein, 1989).

Medical conditions that could lead to vaginismus include: vaginal surgery, prolapse of the uterus, endometriosis, vaginal tumours, vaginal lesions, vaginal atrophy, congenital abnormalities, sexually transmitted diseases, abnormalities of the hymen, and pelvic congestion. In such cases, the condition may produce genital pain that develops over time into vaginismus. Medical conditions are associated with vaginismus in 23–32% of cases (Reissing *et al.*, 1999).

Treatment

Vaginismus is treated with cognitive-behavioural therapy targetted at eliminating the erroneous beliefs and the vaginal spasms. Therapy involves identifying faulty beliefs (e.g., 'my vagina is too small to accommodate his penis') and educating the woman and her partner regarding normal sexual anatomy and physiology (e.g., in the aroused and non-aroused state, the vagina is capable of accommodating even a large penis). Vaginal spasms are treated with vaginal muscle exercises and progressive vaginal dilation. The woman and her partner insert dilators into her vagina, starting with very small sized dilators, progressively increasing the size until she is able to insert a dilator that is as large as an erect penis, and finally, attempting intercourse. Few well-controlled treatment outcome studies have been conducted making it difficult to evaluate the effectiveness of therapy, but estimates suggest that 60–100% of vaginismus cases are successfully treated with this type of intervention (Reissling *et al.*, 1999).

PARAPHILIAS

According to the DSM-IV, in order to be diagnosed with a paraphilia, one must demonstrate the following features.

- "Recurrent, intense sexually arousing fantasies, sexual urges, or behaviours generally involving 1) nonhuman objects, 2) the suffering or humiliation of oneself or one's partner, or 3) children

or other non-consenting persons, that occur over a period of at least 6 months."
- The behaviour, sexual urges, or fantasies cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

The DSM-IV lists eight types of paraphilic disorders but in practice, individuals displaying one paraphilia very often also exhibit other paraphilic behaviours. Incarcerated paedophiles often report, for example, that they have also engaged in other paraphilic behaviours (e.g., exhibitionism, voyeurism) and that deviant sexual behaviours other than pedophilia are their primary interest. The presence of paraphilic behaviour may represent an underlying sexual impulsivity disorder that is characterized by sexual compulsivity and hypersexuality, and in some cases, aggression (Kafka, 1997).

Fetishism

According to the DSM-IV, fetishism involves "recurrent, intense sexually arousing fantasies, sexual urges, or behaviours involving the use of nonliving objects" as sexual stimuli (American Psychiatric Association, 1994). Most fetishists are male and nearly one in four are homosexual. Common fetish items include shoes and lingerie and common materials include rubber and leather. Fetishists become aroused by stealing the object, viewing the object, or masturbating with the object. Most fetishists are aroused by a number of different objects. The aetiology of fetishism is not known. Two reported cases of fetishism have been associated with abnormalities in the temporal lobe. In one case the patient had temporal lobe epilepsy and in the other the fetish behaviour was linked to the development of a temporal lobe tumour (Wise, 1985). Some evidence suggests that fetishism may be a learned behaviour that results when a normal sexual stimulus is paired with the fetish item. Seven heterosexual males free from any prior fetish were repeatedly shown erotic stimuli paired with a slide of a black knee-length women's boot. When the slide of the boot was later shown alone, five of the seven men demonstrated penile erection, indicating that a boot fetish had been conditioned. The conditioned fetish was shown to generalize to other types of shoes in three of the men. That is, the men also became aroused when shown a slide of a high-heeled black boot and a low-heeled black shoe. They did not become aroused to a slide of a short brown boot, a brown string sandal, or a golden sandal, suggesting that the fetish only generalized to similar types of shoes (Rachman and Hodgson, 1968). A similar study was conducted in women to determine whether women could also be conditioned to become sexually aroused to a stimulus. Subjects were randomly assigned to repeatedly view an erotic film paired with a light stimulus versus an erotic film alone. No significant differences were found in physiological sexual arousal between the experimental and control groups when a light stimulus was later presented alone (Letourneau and O'Donohue, 1997). Meston and Rachman (1994) tried to condition sexual arousal to the sound of a male's voice. Even after repeated pairings of erotic video clips and the male's voice, later presentation of the male's voice alone did not produce sexual arousal. This suggests that sexual arousal is not readily classically conditioned in women and may explain why, like other paraphilias, fetishism occurs almost exclusively in men.

Transvestic Fetishism

Transvestic fetishism is diagnosed in heterosexual males who experience "recurrent, intense sexually arousing fantasies, sexual urges, or behaviours involving cross-dressing" (American Psychiatric Association, 1994). A distinction is drawn between transvestism (cross-dressing) and transvestic fetishism. A variety of people cross-dress but the behaviour is not considered a fetish unless the cross-dressing is associated with sexual feelings. For example, transsexuals, or people who feel that their external sex does not match their internal gender identity, may cross-dress in order to feel more congruent with their gender identity but do not find the cross-dressing sexually arousing. Similarly, homosexual males may cross-dress (e.g., drag-queens), but the cross-dressing is not considered to be a fetish unless it is sexually arousing.

Very few studies have been published regarding transvestic fetishism and those that have often grouped transvestic fetishists with transvestites who experienced little to no sexual arousal from cross-dressing. Doctor and Prince (1997) surveyed 1032 male transvestites between 1990 and 1992. They found that 40% of respondents found cross-dressing 'often' or 'nearly always' sexually exciting but only 9% described themselves as a "fetishist [who] favoured women's clothing". While keeping in mind that it is unclear what percentage of subjects would meet DSM-IV criteria for transvestic fetishism, the following characteristics were reported. Respondents ranged in age from 20 to 80 years of age, lived throughout the United States, and reported a range of religious affiliations (24% were Catholic, 38% were Protestant, 3% were Jewish, 10% were agnostic, and 25% were with other religious affiliations). The majority of respondents were well educated (65% had at least a BA), in committed relationships, and had children. Of those currently married, 83% reported that their wives were aware of their transvestic tendencies at present, but only 28% accepted the behaviour. The vast majority reported a heterosexual orientation (87%) although 29% reported having had homosexual experiences. The majority of respondents began cross-dressing before age 10 (66%) or between age 10 and 20 (29%), had been raised by both parents (76%), and reported that their father "provided a good masculine image" (76%).

A few cases have been reported of men with transvestic fetishism who had fathers or brothers who also cross-dressed. Since so few cases of familial co-occurrence have been reported in the literature, and because the occurrence of transvestic fetishism in the general population is not known, it is not clear whether family environment and/or genetics contributes to the likelihood of developing a cross-dressing fetish. Transvestic fetishism is associated with learning disabilities, and a few cases of transvestic fetishism have been associated with temporal lobe abnormalities (Zucker and Blanchard, 1997).

A number of studies have been published examining psychosocial causes of transvestic fetishism but most have serious methodological flaws that limit drawing confident conclusions. Some such studies suggest that adolescents with transvestic fetishism tendencies may have a history of separation from and hostility towards their mothers. The cross-dressing may serve as a means to make a connection with females, even if that connection often involves some expressions of anger and hostility (Zucker and Blanchard, 1997).

Pedophilia

Pedophilia is defined as intense and repeated sexually arousing fantasies, urges, or behaviours involving sexual activity with children, typically less than 14 years old (American Psychiatric Association, 1994). Since few paedophiles are likely to openly admit their preference, it is difficult to estimate the prevalence of pedophilia in the general population. Furthermore, individuals who feel sexual attraction to children may resist the temptation due to societal pressures, yet may nonetheless experience sexual fantasies involving children. Recent evidence suggests that pedophilia may be associated with homosexuality, mental retardation, and high maternal age. Homosexuality in the general population is estimated at 2% while homosexuality in paedophiles is estimated at up to 40%. When sexual orientation, intellectual functioning, and maternal age were measured in 991 male sex offenders, high maternal age and low intellectual functioning were significantly

associated with homosexual pedophilia. The association between low intelligence and pedophilia suggests that pedophilia may reflect a developmental disorder. The association between high maternal age and pedophilia is unclear, although it may reflect differences in birth order as homosexuality is associated with being later born (discussed below under gender identity disorder) (Blanchard *et al.*, 1999).

Some researchers have speculated that a childhood history of sexual abuse contributes to an adult preference for sexual activity with children. In a large sample of men who were child sex offenders, Freund *et al.* (1990) found that heterosexual and homosexual paedophiles were significantly more likely to report childhood sexual abuse by a male abuser (versus female abuser) as compared to controls. Freund and Kuban (1994) classified child sex offenders according to whether they demonstrated phallometric (increased penile volume) preference to photographs of nude children versus adults. They found that child sex offenders who demonstrated preference for children were significantly more likely to have a childhood history of sexual abuse. It should be noted that although reports indicate approximately 49% of paedophiles have a history of childhood sexual abuse, very few people with a history of childhood sexual abuse become paedophiles (Freund and Kuban, 1994).

Paedophiles may have difficulty with gender differentiation. Freund *et al.* (1991) showed slides of nude male and female children and adults to paedophiles and controls, and measured penile volume changes. The paedophiles demonstrated less differentiation between stimuli containing males versus females as compared to non-paedophiles. Although this pattern of undifferentiated arousal has also been noted in a case study of a 20-year-old woman with multiple paraphilias (Cooper *et al.*, 1990), few cases of female pedophilia have been reported in the literature.

Paedophiles may differ from non-paedophiles on several physiological dimensions as well. Baseline plasma cortisol, prolactin, and body temperature were significantly higher in paedophiles than controls. When both groups were administered a serotonin agonist, mCPP, versus placebo, plasma cortisol levels were more elevated and remained elevated longer for paedophiles compared to controls. The paedophiles reported experiencing side effects (e.g., dizzy, restless) of mCPP administration while the controls did not. Consistent with these findings, some researchers have speculated that pedophilia may be associated with disturbances in serotonin-related aggression and impulsivity (Maes *et al.*, 2001). It has also been suggested that pedophilia may be a subtype of obsessive–compulsive disorder; a problem that is marked by repetitive, irrepressible behaviour associated with serotonin dysregulation (Balyk, 1997).

Sexual Masochism and Sexual Sadism

The DSM-IV defines sexual masochism as "recurrent, intense sexually arousing fantasies, sexual urges, or behaviours involving the act (real, not simulated) of being humiliated, beaten, bound, or otherwise made to suffer" (American Psychiatric Association, 1994). In 1886, Krafft-Ebing coined the term, masochist, after Leopold von Sacher-Masoch, who wrote novels depicting men being humiliated and bound by females. Sexual sadism is characterized by "recurrent, intense sexually arousing fantasies, sexual urges, or behaviours involving acts (real, not simulated) in which the psychological or physical suffering (including humiliation) of the victim is sexually exciting to the person" (American Psychiatric Association, 1994). The term, sadism, was derived from writings of the Marquis de Sade, an 18th century author who wrote stories depicting sexual torture and brutality. A distinction is drawn between minor versus major sexually sadistic acts. Minor sexually sadistic acts would include, for example, humiliation and bondage of a willing sexual masochist while major sexually sadistic acts would involve acts such as sexual torture and rape of an unwilling participant. The key distinction here is whether the victim was consenting or not.

The practice of sadomasochism (referred to as S&M), or the consensual participation between sexual sadist and sexual masochist, involves carrying out predetermined sexual scenarios. These scenarios commonly involve several themes: flagellation (usually on the buttocks), bondage, 'water sports' (urophilia — attraction to urine, coprophilia — attraction to feces, and mysophilia — attraction to filth), and penis and nipple torture (Arndt, 1991). Sadomasochists interviewed in New York and San Francisco between 1976 and 1983 reported S&M activities that included elements of dominance and submission, role-playing (e.g., master and slave), consensuality (i.e., both participants were willing), and were of sexual context (i.e., the role-playing was sexual) (Weinberg *et al.*, 1984). Commonly reported S&M role-play themes include: "severe boss and the naughty secretary", "the queen and many slaves", "the male barber and his customer", and "arrest scenes and military training" (Sandnabba *et al.*, 1999). Although the sexual sadist appears to be in control, often the degree of domination and humiliation is agreed upon earlier, and it is the sexual masochist who indicates with a predetermined cue when he/she has reached his/her limit (Arndt, 1991).

Female sexual masochists and sadists are outnumbered by male sexual masochists and sadists and in many cases, the females are prostitutes who specialize in sadomasochism. One study found that approximately a quarter of female sexual sadists are prostitutes (Breslow *et al.*, 1985). Approximately 80% of sadomasochists reported that they were regularly engaging in sadomasochistic activities by age 30 years (Sandnabba *et al.*, 1999). Spengler (1977) obtained questionnaire data from 245 male sadomasochists recruited through S&M magazine advertisements and via S&M clubs. The majority of respondents reported that they met partners through sadomasochism advertisements, clubs, or bars. The sample contained 30% heterosexual sadomasochists, 31% bisexual sadomasochists, and 38% homosexual sadomasochists. The respondents came from all ages, socioeconomic backgrounds and levels of education. In most cases, the families knew little if anything about the respondents' S&M activities; 41% of married respondents ($n = 109$) reported that their wives knew nothing about the sadomasochistic activity.

When queried whether they thought the sadomasochistic behaviour was acceptable, 70% indicated acceptance of the behaviour, 85% reported that they "want to do it again", "it was fun" (84%), and "sexually satisfying" (79%). Although many of the respondents reported that they enjoyed non-sadomasochistic sexual activity, they reported being more likely to orgasm with sadomasochistic activity (79%) than without (45%). About a third of respondents reported fetishisms (e.g., boots and leather).

Very few studies have been conducted examining sexual sadists who target unwilling victims. Seto and Kuban (1996) examined penile volume changes in seven sadistic rapists compared to 14 non-sadistic rapists and 20 controls. The subjects were presented audiotapes depicting five different scenarios: (1) nonviolent, non-sexual interaction with a female; (2) consensual sexual activity with a female; (3) non-sexual violence against a female; (4) rape; and (5) violent rape. Compared to controls, the sadistic rapists and non-sadistic rapists were equally aroused by the different types of sexual contact — they were less likely to differentiate between consensual sexual activity, rape, and violent rape.

A subset of sexual sadists may have abnormal endocrine activity although hormone levels typically do not differ between sexual sadists and controls. In a review of individual cases, one sexual sadist had unusually high levels of luteinizing hormone (stimulates progesterone secretion) and follicle-stimulating hormone (stimulates estradiol in women and sperm development in men), another had low testosterone levels and another Klinefelter's syndrome (XXY chromosomes rather than the typical XY male pattern). Gross examination of brain functioning revealed no differences between sexual sadists and controls, but more careful examination

revealed a subtle but significant difference in the right temporal lobe. Forty-one percent of the sexual sadists had a slightly dilated right temporal horn, compared to 13% of controls. One sexual sadist had a slow growing tumour in the left frontal-temporal lobe, likely present since childhood. Another had enlargement of the ventricles, a condition typically associated with schizophrenia and suggestive of overall brain atrophy. In short, temporal lobe abnormalities may be implicated in sexual sadism, but more information is needed before any strong conclusions can be made (Langevin *et al.*, 1988).

Serial killing, which is often reported in the media and dramatized in movies, may reflect comorbid sexual sadism and antisocial personality disorder. Geberth and Turco (1997) examined records of 387 serial murderers within the United States and found that 248 had sexually assaulted their victims. These included famous cases of serial killing, such as Theodore (Ted) Bundy and the Green River Killer. Of these, they determined that 68 met DSM-IV criteria for both sexual sadism and antisocial personality disorder (in other cases, sufficient data were not available to make a determination). These 68 individuals displayed a pattern of behaviour characterized by childhood aggressiveness and antisocial behaviour, and a pattern of killing involving sexual violence, humiliation, domination and control. Examination of their records suggests that these 68 individuals engaged in sexual violence and killing because they derived pleasure from it.

Courtship Disorders: Voyeurism, Exhibitionism, and Frotteurism

Voyeurism, exhibitionism, and frotteurism may be different behavioural expressions of a single underlying courtship disorder. The overt behaviours differ, but can also be conceptualized as different stages on a continuum — different degrees of proximity to the victim. Voyeurism involves viewing the victim from a distance, exhibitionism involves approaching the victim, and frotteurism involves physically touching the victim. The preference for rape over consensual sexual activity (termed the preferential rape pattern) may represent the fourth phase in the courtship disorders (Freund *et al.*, 1983). A common aetiological factor has not been identified although evidence indicates that the courtship disorders are associated with a preference for eliciting an alarmed reaction from an unfamiliar target rather than any lack of interest in intercourse (Freund and Watson, 1990). A high degree of comorbidity exists between these disorders and even when no overt comorbid behaviour is present, some evidence suggests that presence of one disorder predisposes to another such disorder (Freund *et al.*, 1983).

Voyeurism

The DSM-IV defines voyeurism as "recurrent, intense sexually arousing fantasies, sexual urges, or behaviours involving the act of observing an unsuspecting person who is naked, in the process of disrobing or engaging in sexual activity" (American Psychiatric Association, 1994). Most men, if given the opportunity to view a woman disrobing, would not avert their eyes. A man who engages in an opportunistic 'peep' is not a voyeur, the peeping must be recurrent and the urges to do so intense. Voyeurs tend to be the youngest child in the family. Compared to other sex offenders and controls, voyeurs have fewer sisters, have a good relationship with both parents, but have parents who do not have a good marital relationship. Voyeurs are often underdeveloped socially and sexually. They tend to engage in sexual activity later than other groups, and are less likely to marry than controls and other sex offenders (Smith, 1976). The more sexually experienced a voyeur, the more frequently he is likely to engage in peeping behaviour (Langevin *et al.*, 1985). Some evidence suggests that voyeurs may be predisposed to other paraphilias as well (e.g., sadomasochism, zoophilia) (Langevin *et al.*, 1985).

Although voyeurism is rare in women, some evidence suggests that women have similar 'peeping' urges as men. Friday (1975) interviewed women from all ages (teen to retirement) and walks of life and found that women expressed fantasies about peeping and, in some cases, engaged in actual peeping behaviour.

Learning theorists have suggested that voyeurism develops when the subject is provided a voyeuristic opportunity, and then subsequently masturbates while fantasizing about the experience. Some evidence supports this hypothesis; 50% of voyeurs reported that prior to the onset of their peeping behaviour they believed that normal sexual relations were not likely to be an option for them, and so they fantasized about scenarios they believed to be more obtainable, such as peeping. In addition, 75% of voyeurs reported that the sexual scenario they envision while masturbating reflected their first peeping experience (Smith, 1976).

Exhibitionism

Exhibitionism is defined as "the exposure of one's genitals to an unsuspecting stranger" (American Psychiatric Association, 1994) and involves some form of sexual gratification. Exhibitionism occurs almost exclusively in men. Very few cases of female exhibitionists have been reported in the literature, but the characteristics of these women differed from typical male exhibitionists. Male exhibitionists tend to be timid and unassertive men who have underdeveloped social skills and who are uncomfortable with angry or hostile feelings. Some studies suggest that exhibitionists were more likely to have been raised in a sexually puritanical background. The few female exhibitionists described in the literature, and studies examining female strippers, would suggest that the majority of female exhibitionists gain no pleasure from exposing their genitals but do so either to gain money or attention (Blair and Lanyon, 1981).

Behavioural theory proposes that exhibitionism develops as a result of a learned behaviour that is subsequently reinforced. This theory has been applied successfully to the treatment of exhibitionism (i.e., a learned behaviour can be replaced with a more socially acceptable behaviour) but it is not clear whether this reflects the actually aetiology of exhibitionism. Attempts to identify a physiological cause of exhibitionism have thus far been unsuccessful.

Frotteurism

Frotteurism involves "intense sexually arousing fantasies, sexual urges, or behaviours involving touching and rubbing against a non-consenting person" (American Psychiatric Association, 1994). The majority of published articles on this disorder group frotteurism with other paraphilic disorders or report cases of men with multiple paraphilias, including frotteurism. Abel *et al.* (1987) examined 62 males diagnosed with frotteurism, as well as other paraphilic disorders, and found that, at the time of the interview, they had committed an average of 849 frottage acts. Rooth (1973) interviewed 561 nonincarcerated men with paraphilias and found that of those exhibiting frotteurism, 79% had other paraphilias, with an average of 4.8 paraphilias each.

It is unclear whether true frotteurism in women exists, perhaps in part because of the decreased likelihood that male victims would view the behaviour as unwelcome or threatening. A handful of case reports of sexual molestation of men by women have been reported in the literature. The molestation typically occurred subsequent to erectile failure or inhibited desire (Sarrel and Masters, 1982). Although these cases do not represent female frotteurism, they suggest that it is feasible that rare cases of female frotteurism may exist, but are rarely reported.

Treatment of Paraphilias

In the mid 1900s, some European countries used castration as a means of treating exhibitionism, pedophilia, and other forms of sexual crimes. In West Germany, psychosurgery, which involved removing the nucleus ventromedialis of the hypothalamus, was used as a treatment for male sex offenders. Published reports of these practices rarely provided sufficient information to determine whether this intervention was successful in eliminating the inappropriate sexual behaviour. Of course there are serious consequences to performing such extreme and permanent techniques.

Cognitive–behavioural therapies, such as aversion therapy, are often used to treat paraphilias. The arousing stimulus is paired with an aversive stimulus such as a shock or noxious odour until the paraphilic behaviour no longer produces sexual arousal. A review of the handful of studies and case reports published suggests that aversion therapy alone is effective in reducing arousal, but that relapse rates are high (Kilmann *et al.*, 1982). More recently, other forms of cognitive–behavioural therapy such as covert sensitization or orgasmic reconditioning, are being used. Orgasmic reconditioning involves fantasizing about the paraphilic behaviour while masturbating, and at the moment just before orgasm, switching the fantasy to a more acceptable stimulus, such as one's partner. The belief is that orgasm, being an intensely pleasurable sensation, will serve to reinforce the more accepted sexual fantasy. Few well-controlled treatment outcome studies have been published, however, making it difficult to determine whether these types of interventions are effective. Covert sensitization involves fantasizing about the paraphilic behaviour followed by imagining a noxious scenario, such as vomiting, or an undesirable consequence such as being discovered by one's family. It is not yet clear how successful these techniques are in eliminating the behaviour although a few reports indicate that they can be highly successful for some patients.

Pharmacological interventions include hormonal supplements or psychotropic medications. Hormonal treatments are designed to inhibit deviant sexual behaviour by reducing sexual drive and sexual arousal. They include the following: (1) oestrogen; (2) medroxyprogesterone acetate (MPA), which lowers plasma testosterone and reduces gonadotropin secretion; (3) luteinizing hormone-releasing hormone agonists (LHRH agonists), which produce the pharmacological equivalent of castration by significantly inhibiting gonadotropin secretion; and (4) antiandrogens such as cyproterone acetate (CPA), which blocks testosterone uptake and metabolism. Treatment outcome studies suggest that these treatments are effective in reducing deviant sexual behaviour provided that the treatment regimen is maintained, although more well-controlled treatment outcome studies are needed before the true effectiveness of these treatments can be determined. Psychotropic medications that affect the serotonin systems have recently been used to treat paraphilias. Clinical studies suggest that SSRIs such as Prozac are effective in reducing paraphilic arousal and may be effective in reorienting arousal to more socially acceptable scenarios. The effectiveness of SSRIs in reducing paraphilic fantasies and behaviours suggests that these disorders may have an obsessive–compulsive component, as SSRIs are often used to treat obsessive–compulsive disorders. As with hormone treatments, however, more well-controlled treatment outcome studies must be conducted before the true effectiveness of these treatments can be determined (Bradford, 2000).

GENDER IDENTITY DISORDER

The DSM-IV describes gender identity disorder as a persistent and strong cross-gender identification and a persistent unease with one's sex. Gender identity disorder is not diagnosed if these symptoms co-occur with a physical intersex condition. As with the sexual disorders, a diagnosis is only made if the symptoms produce marked distress or impairment. According to the DSM-IV, gender identity disorder can occur in childhood, adolescence, and adulthood. Sexually mature individuals may be heterosexual, homosexual, bisexual, or may feel little sexual attraction to either men or women (American Psychiatric Association, 1994). Gender identity disorder is often confused with transvestism (cross-dressing) although the two are distinct.

When biological males and females feel a cross-gender identification, it is termed male-to-female transsexualism (MF) and female-to-male transsexualism (FM), respectively. Prevalence estimates suggest that MF transsexualism is more common than FM transsexualism although a few studies have found a 1 : 1 ratio. Prevalence estimates range from 1 : 10,000 to 1 : 100,000 for MF and 1 : 30,000 to 1 : 400,000 for FM (Cohen-Kettenis and Gooren, 1999; Zucker and Green, 1992).

Studies examining the biological causes of gender identity disorder have typically examined the effects of prenatal hormones on prenatal brain development. During normal prenatal development, the presence of testosterone leads to the development of external male genitalia and to a male differentiated brain. It is hypothesized that for individuals with gender identity disorder, a discrepancy may exist between prenatal genital differentiation and brain differentiation such that the external genitals develop, for example, as male while the brain develops as female. The evidence to support this hypothesis is mixed. Genetic females exposed to high levels of testosterone *in utero* (e.g., congenital adrenal hyperplasia), rarely develop gender identity disorder. Similar prenatal exposure to antiandrogenic, androgenic, and oestrogenic drugs rarely leads to gender identity disorder in either genetic females or males although some of these individuals display abnormal gender role behaviour (Cohen-Kettenis and Gooren, 1999). The strongest evidence to suggest that abnormal prenatal brain differentiation may lead to gender identity disorder comes from a recent study examining hypothalamic brain nuclei in men with gender identity disorder. Zhou *et al.* (1995) found that the central subdivision of the bed nucleus of the stria terminalis (a region of the hypothalamus) was smaller in MF transsexuals compared to normal males but similar in size to normal females, a difference that was not accounted for by hormone therapy. Sadeghi and Fakhrai (2000) recently reported a case of 18-year-old monozygotic female twins requesting gender reassignment surgery. The twins had a childhood history of cross-dressing. Unfortunately they were lost to follow up after the initial evaluation but this case suggests that gender identity disorder may have a genetic component.

Recent studies indicate that, compared to controls, MF transsexuals have more older brothers (but not more older sisters) and a later birth order (Blanchard *et al.*, 1995; Zucker *et al.*, 1997). Conversely, FM transsexuals are more likely to have several younger sisters but not brothers compared to controls (Zucker *et al.*, 1998). The histocompatibility-Y antigen (H-Y antigen), which is responsible for the development of the male testes and brain differentiation, may be implicated in this process for males. With progressive male births, mothers may become immunized to the H-Y antigen, leading to increased production of H-Y antibodies, and a disruption in normal brain differentiation (Blanchard *et al.*, 1998).

Social, parental, or familial factors have been associated with mild gender disturbance. MF transsexuals often report over controlling, rejecting fathers. FM transsexuals often report mothers and fathers who were rejecting and mothers who were over protective. It is feasible, however, that these differences may have been the result of abnormal gender development, rather than the cause (Cohen-Kettenis and Gooren, 1999).

Childhood gender identity disorder may, in some cases, predict adult gender identity disorder. Fifty-five feminine boys with gender

identity disorder were followed into early adulthood. Five of the feminine boys were diagnosed with gender identity disorder, one as a transvestite, 21 as homosexual, 14 as heterosexual, and 14 that were not rated. This suggests that childhood gender identity disorder reflects a high likelihood of either adult gender identity disorder or homosexuality (Green, 1987).

In cases where gender identity disorder is present, if the individual displays only a mild tendency, displays serious psychopathology, or is not functioning well socially, psychotherapy rather than sex reassignment surgery may be advised. For those with extreme symptoms of gender identity disorder, who are free of from psychopathology, and who are functioning well in society, sex reassignment surgery is still not permitted until the person has lived full time as the preferred gender, often for a period of 2 years. During this period, candidates may be required to change their name, inform their family, boss, and co-workers, cross-dress full time, and receive hormone treatment. This period is considered to be essential for determining whether surgery is appropriate. The candidates have the opportunity to experience what it is like to live as the other gender and to determine whether they are fully prepared for and fully comprehend the impact of living the remainder of their lives as the other sex (Cohen-Kettenis and Gooren, 1999).

A review of sex reassignment surgery outcome studies suggests that in most cases, surgery resolves the gender identity disorder. Depending on the study, between 71% and 97% of subjects were successfully treated with surgery and less than 1% later took steps to reverse the sex reassignment. Factors that predict a poor outcome include: misdiagnosed transvestism, poor surgery outcome, poor social or work functioning, suicidal tendencies, and sex reassignment surgery late in life. This suggests that the current procedure for determining appropriateness of sex reassignment surgery is effective, when applied strictly (Cohen-Kettenis and Gooren, 1999). Male to female transsexuals who are attracted to men (MF homosexuals) seem to have a better post-surgery outcome compared to MF transsexuals who are attracted to women (MF heterosexuals). MF heterosexuals may have a poorer post-surgery outcome because of the added stigma of becoming homosexual after surgery, and because they typically present for surgery much later in life than MF homosexuals and thus are likely to have more male-role investments (e.g., husband, father). FM transsexuals in general have better post-surgery outcome than MF transsexuals (Cohen-Kettenis and Gooren, 1999).

Animal Models of Eating Disorders

Jeanette E. Johansen and Martin Schalling

INTRODUCTION

Eating disorders such as obesity, anorexia and bulimia are complex disorders displaying a variety of symptoms apart from an abnormal eating behaviour. Like many other motivated behaviours, feeding requires the integration of internal and external signals and it is not clear if the physiological correlates observed in these disorders are causes or effects of the altered eating behaviour. A good understanding of the physiology underlying feeding behaviour is therefore essential. This chapter deals with some of the many animal models that are being used to study feeding behaviour.

Early animal models of eating disorders include experimental studies of the effect of anorectic drugs on the amount of food consumed by rats. However, while successful in rats, pharmacological treatment of obesity is generally unimpressive in terms of weight loss in humans for a number of reasons.

That tumours in the region of the hypothalamus can cause obesity has been known for a long time. In 1940, Hetherington and Ranson confirmed the importance of the hypothalamus in the control of feeding and body weight. By performing electrolytic lesions in the hypothalamus of rats, they observed: 'A condition of marked adiposity characterized by as much as a doubling of body weight and a tremendous increase of extractable body lipids. . . ' (Hetherington and Ranson, 1940). The damaged regions included the dorsomedial and ventromedial hypothalamic nuclei (DMH and VMH), the arcuate nucleus (Arc), the fornix, the lateral hypothalamic area (LHA) ventral to the fornix and possibly also the ventral premammillary nucleus. They also noted that lesions in the adjacent lateral hypothalamus could lead to decreased food intake. Anand and Brobeck pursued this observation and showed that bilateral electrolytic lesions of the LHA caused loss of feeding and even death by starvation (Anand and Brobeck, 1951). Thus, the concept arose of the LHA serving as a 'feeding centre' and the VMH as a 'satiety centre' — the dual centre model. This hypothesis has been widely questioned, and among the observations speaking against the dual centre model are findings that damage outside the hypothalamus can produce syndromes similar to those seen after lesions of the LHA or VMH. As cell-specific lesion methods emerged the focus was once again put on the VMH and LHA, and several studies showed that the LHA indeed could have a phagic function (Saper, 1985; Saper *et al.*, 1986; Bittencourt, 1992). Today we know that hypothalamic cell populations and nuclei play important and specific roles in the regulation of food intake and other motivated behaviours.

Most of the population practices weight control, but in spite of that, weight seems to be stable in both lean and obese individuals. Dieting is usually not successful in the long run and most obese individuals eventually regain the lost weight (Wadden, 1993). The relative stability of weight in individuals indicates that there is a feedback loop controlling energy balance and maintaining constancy of total body energy stores. In 1953, Kennedy introduced his theory on a lipostatic mechanism that maintained energy homeostasis (Kennedy, 1953). He suggested that the size of the fat depots were sensed by a lipostat, which would regulate and adjust food intake and energy metabolism accordingly, to maintain body weight at a set point. He also proposed that an impaired lipostatic mechanism could lead to obesity. Further support for this hypothesis came from a study by Hervey (1958). He performed a series of parabiosis experiments, where the circulations of two animals are surgically joined, and showed that lesions in the VMH in one of the members in a parabiotic rat pair caused the lesioned rat to become obese as the unlesioned rat starved to death (Hervey, 1958). He suggested that the obese lesioned rat produced excessive amounts of a satiety factor that was transferred to the unlesioned rat, causing it to starve itself.

Over the past five years there has been a tremendous increase in the understanding of the genetic regulation of food intake and energy expenditure, using monogenic rodent models of obesity. Several genes have been cloned that, when mutated, cause obesity in the mouse and rat (Schalling *et al.*, 1999; Barsh *et al.*, 2000). These genes and their products have unravelled biochemical pathways involved in obesity. Some of these genes have been shown to be important for the regulation of food intake and/or metabolism also in humans. Crosses of mouse, rat, pig or chicken strains that are informative with regard to body mass or body fat have produced a number of quantitative trait loci (QTL) (Chagnon *et al.*, 2000) that have opened the door to polygenic approaches in the study of obesity in animals. As with the monogenic rodent models, these QTLs can be applied to a human genetic obesity map by identifying the syntenic chromosomal regions in the human.

There has been less of a focus on genetic models of anorexia. One reason might be that there are more genetic animal models that shift the regulation of food intake, satiety or metabolic turnover towards obesity than anorexia. A possible explanation for this could be that even a relatively mild anorectic phenotype could lead to malnutrition and/or death by starvation early enough in life to affect the number and viability of the offspring (see the anorexia mouse, the dopamine-deficient mouse and the HNF-3α deficient mouse below). A number of starvation, dehydration and chemically induced models have been developed and an example of each is discussed below. There are also numerous models of anorexia induced by either infection or cancer. Anorexia, or cachexia, is a frequent complication of malignant tumours and infectious and inflammatory diseases and is contributing significantly to the mortality of these disorders (Kotler *et al.*, 1985; Tisdale, 1997; Larkin, 1998). This type of anorexia will not be dealt with in this chapter.

There are very few animal models of bulimia or binge eating. The models that exist are all based on cycles of food restriction

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

and refeeding. The lack of animal models for bulimia and binge eating may be related to the opinion of many investigators that an animal model should mimic all the important aspects of human syndromes.

Because of the enormous toll on human health taken by eating disorders and their related disorders, there is a need for a better understanding of the underlying mechanisms for regulation of body weight and food intake. This chapter attempts to review some of the available animal models for studying eating disorders and the mechanisms behind the control of food intake. Because of the considerable uncertainty regarding the biological basis of eating disorders in humans, and the possibility that they are symptoms of personality traits, the development of animal models is complicated. Furthermore, for the same reasons validation of existing animal models of eating disorders is compromised. For face validity animal models of eating disorders should involve a change in body weight. However, there are many possible reasons why an animal lose or gain weight without having an altered eating behaviour. Therefore, measures of food intake are also required. One should also keep in mind that reduced or increased food intake is not necessarily the result of a change in appetite. Moreover, eating disorders in humans often occur under conditions where food is freely available and therefore it may be inappropriate to use models with restricted access to food as is often the case in pharmacological studies of rat feeding behaviour. Lack of potent pharmacological agents for treatment of human eating disorders make it difficult to assess predictive validity for animal models. Despite substantial research efforts, the nature of the underlying behavioural mechanisms for eating disorders remains unclear. Construct validity is therefore extremely hard to determine. A better description of the molecular mechanisms involved in human eating disorders would be invaluable to the animal modeller and paradoxically this valuable information may be gained from the study of animal models. Even though the animal models described in this chapter may not mimic all of the aspects of human eating disorders they may provide useful information on underlying causes and how to treat at least some of the symptoms. In fact, several animal models have been used as hypothesis generators and in some cases they have been most helpful in revealing the nature of specific human eating disorders.

A brief description of three genetic and three physiological models of anorexia, and one model of bulimia will be followed by a more comprehensive review of genetic models of obesity.

MODELS OF ANOREXIA

Genetic Models of Anorexia

The Anorexia Mouse

The autosomal recessive *anx* mutation arose at the Jackson laboratory (Bar Harbor, ME, USA) in 1976. Mutant mice (*anx/anx*) are characterized by poor appetite. Stomach contents are reduced compared to normal littermates at about post-natal day 5 and continue so until death (Maltais *et al.*, 1984). Interestingly, although the amount of food ingested is reduced, the daily pattern of food intake of *anx/anx* mice is very similar to that observed in normal littermates from birth to 20 days of age (Maltais *et al.*, 1984). These data indicate that *anx/anx* mice fail to properly regulate the amount of food consumed rather than failing to eat for other reasons. Other characteristics are reduced body weight, emaciated appearance and abnormal behaviour including body tremors, headweaving, hyperactivity and uncoordinated gait. The animals die at the age of 3 to 5 weeks depending on the genetic background. No organ abnormalities have been found using routine stained sections. Total RBC, hematocrits, haemoglobin and mean cell volume are within normal range (Maltais *et al.*, 1984). However, there are several dramatic alterations of peptide distributions in the hypothalamus of *anx/anx* mice, relevant to the regulation of feeding (Broberger *et al.*, 1997, 1998, 1999; Johansen *et al.*, 2000).

Abnormalities of feeding-related peptides have been described in the *anx/anx* mouse, particularly in the arcuate nucleus of the hypothalamus, which contains neuronal populations producing orexigenic as well as anorexigenic substances. The feeding stimulatory peptides neuropeptide Y (NPY) and agouti gene-related protein (AGRP) are distributed in a pattern suggestive of accumulation in the cell bodies in the arcuate nucleus of *anx/anx* mice instead of axonal transportation to their respective targets (Broberger *et al.*, 1997, 1998). Conversely, the pro-opiomelanocortin (POMC) derived peptides and cocaine- and amphetamine-regulated transcript (CART) peptides, which decrease food intake (Fan *et al.*, 1997; Kristensen *et al.*, 1998), are both decreased in the arcuate nucleus of the *anx/anx* mouse (Broberger *et al.*, 1999; Johansen *et al.*, 2000). In addition, morphological characteristics of POMC neurons are altered, as seen with immunohistochemical markers (Broberger *et al.*, 1999). Taken together these studies suggest that the reduced food intake and weight loss seen in the *anx/anx* mouse may be related to neurochemical alterations in the hypothalamus and particularly in the arcuate nucleus.

The abnormal behaviour of head weaving, body tremors, uncoordinated gait and hyperactivity of *anx/anx* mice is affected by serotonin (Maltais *et al.*, 1984). When treated with the serotonin precursor 5-hydroxy-DL-tryptophan (5-HTP) 15-day-old normal mice display the same type of abnormal behaviour as *anx/anx* mice. Similarly, 15-day-old anorexic mice show body tremors and head weaving typical for anorexic mice 18 days of age or older, when treated with 5-HTP. Conversely, treating a 20-day-old anorexic mouse with the serotonin neurotoxin 5,7-dihydroxytryptamine, diminishes the severity of the neurological symptoms (Maltais *et al.*, 1984). *anx/anx* mice have also been shown to have an increased number and density of serotonergic fibres in the forebrain and the arcuate nucleus (Son *et al.*, 1994; Jahng *et al.*, 1998), which would be consistent with the experimental data on eating and motor behaviour.

Taken together these results suggest that the abnormal feeding behaviour observed in *anx/anx* mice is caused by a CNS defect.

The Dopamine Deficient Mouse

Dopamine (DA) is a classical neurotransmitter in the central nervous system (CNS) that has been implicated in the regulation of food intake, but the neural pathways are not yet established. Some pharmacological reports suggest a stimulatory role for DA agonists, and an inhibiting role for DA antagonists in the control of food intake (Phillips and Nikaido, 1978; Dourish, 1983; Salamone *et al.*, 1990). However, opposite results have been obtained in other studies (Sanghvi *et al.*, 1975; Cooper and Al-Nasar, 1993).

Dopamine (DA) deficient mice (*DA*-/-) were created by disruption of the dopamine synthesizing enzyme tyrosine hydroxylase (TH) gene specifically in dopaminergic neurons (Zhou and Palmiter, 1995). *DA*-/- mice are born normal but gradually become hypoactive and aphagic and die prematurely at about three weeks of age (Zhou and Palmiter, 1995; Szczypka *et al.*, 1999). When *DA*-/- mice are born, they initiate suckling behaviours and nurse, however, after approximately 2 weeks, when normal mice begin to explore other sources of food, the *DA*-/- mice become lethargic and fail to eat and drink. Daily treatment with L-DOPA

normalizes feeding behaviour and restores locomotor activity in *DA-/-* mice (Szczypka *et al.*, 1999). It is unlikely that the aphagia is secondary to motor deficits as *DA-/-* mice can grasp and swallow food when put in their mouth (Zhou and Palmiter, 1995). Also, *DA-/-* mice can execute behaviours necessary to seek and ingest food (Szczypka *et al.*, 1999). The *DA-/-* mice provide further evidence for the importance of dopamine for normal feeding behaviour.

That dopamine plays an important role in the regulation of food intake is a conclusion that was reached many years ago by several investigators. Studies by Anand and Brobeck (1951) showed that bilateral electrolytic lesions of the LHA in rats produced aphagia and akinesia. Evidence that DA could be a critical player in the LHA-lesion syndrome came from the demonstration that most of the symptoms of LHA ablation could be reproduced by introducing bilateral lesion of midbrain dopaminergic pathways in rats by the use of 6-hydroxydopamine (6-OHDA) (Ungerstedt, 1971; Zigmond and Stricker, 1972; Fibiger *et al.*, 1973). Furthermore, multiple connections between LHA and midbrain DA neurons have been identified (Bunney and Aghajanian, 1976; Phillipson, 1979; Wright *et al.*, 1980). It is remarkable that the phenotypes resulting from 6-OHDA and LHA lesions are so similar to the genetic model described here, given that the damage produced by a lesion greatly exceeds that resulting from the removal of one enzyme.

The Hepatocyte Nuclear Factor 3α-Deficient Mouse

The hepatocyte nuclear factor 3 (HNF-3) family of transcription factors include three different genes designated HNF-3α, HNF-3β and HNF-3γ, which have been suggested to play a critical role in pancreatic islet function (Duncan *et al.*, 1998). HNF-3α has been shown to be of importance for pancreatic alpha-cell function, including glucagon gene expression (Kaestner *et al.*, 1999). Mice lacking HNF-3α expression, due to targetted disruption of this gene, develop a complex metabolic syndrome characterized by abnormal feeding behaviour, progressive starvation, hypoglycaemia, wasting and neonatal mortality between days 2 and 14 (Shih *et al.*, 1999). The molecular and physiological mechanisms by which HNF-3α regulates food intake are currently not understood. However, HNF-3α is highly expressed in the hypothalamus (Shih *et al.*, 1999). Thus, it cannot be ruled out that the abnormal feeding behaviour observed in HNF-3α deficient mice is caused by a CNS defect.

Conclusion

There is increasing evidence suggesting that anorexia nervosa is genetic in nature (see Chapter XXIII-9: 'The evolving genetic foundations of eating disorders' by Klump *et al.*). The genetic mouse models described here probably have their strength in being hypothesis generators more than being models mimicking the human situation. The diagnostic criteria for anorexia nervosa are body weight <85% of expected weight, amenorrhea, intense fear of weight gain and inaccurate perception of own body size, weight or shape (DSM-IV, 1994). The latter two criteria are impossible to measure in animals, resulting in a low face validity for any model of anorexia. In the three models described above the face validity will be even lower as they all die prematurely before reaching puberty and amenorrhea can thus not be detected. Furthermore, the low food intake observed in the described models, is most likely caused by a reduced appetite for food. This is not the case in the human situation where the reduced food intake seems to be driven by an intense fear of weight gaining. Thus, construct validity also scores low in these models. Nevertheless, these models have their strength in allowing the identification of novel pathways involved in regulation of food intake. Genes in these pathways could certainly serve as targets for future therapeutic interventions.

Physiological Models of Anorexia

Starvation Induced Hyperactivity in Rat

If young rats are restricted to 90 minutes access to food every day, they will adapt and eat sufficient amounts to survive in good health. However, if a running wheel is available and food is restricted, the rats will start to run (Epling *et al.*, 1983). The running distance increases rapidly day by day and at the same time food consumption decreases and the rats begin to lose weight. Running may exceed 15 000 m per day, while food consumption decreases to 1 g per day or less (Epling *et al.*, 1983). In this model starvation and hyperactivity mutually reinforce each other resulting in a vicious circle where the rats starve and run themselves to death. There are major differences between male and female rats. Female rats develop running activity much faster and their activity is modulated by the menstrual cycle (Pirke *et al.*, 1993). Eventually, the menstrual cycle disappears in female rats. The reproductive function is impaired in both male and female rats, as a consequence of the starvation-induced hyperactivity (Pirke *et al.*, 1993).

It has been suggested that endogenous opioids play a role in this excessive activity (Boer *et al.*, 1990). However, data on central endorphin turnover and more detailed studies of endorphin agonists and antagonists are needed to clarify the role of opioids in this animal model. Leptin (an adipocyte derived satiety factor) has also been implicated to play a role in starvation-induced hyperactivity. Interestingly, it has been shown that leptin suppresses starvation induced hyperactivity in rats (Exner *et al.*, 2000). Also, patients with anorexia nervosa rank their motor restlessness higher when hypoleptinaemic, in the emaciated state, than after reaching maximal leptin levels, after treatment (Exner *et al.*, 2000). Thus, it is possible that hypoleptinaemia may contribute to the hyperactivity associated with anorexia nervosa. It should, however, be noted that it is not known whether the patients are restless because of the emaciation or the hypoleptinaemia.

This experimental protocol provides an animal model for the human activity anorexia syndrome (Epling *et al.*, 1983; Epling and Pierce, 1985). One should, however, keep in mind that the interpretation of the hyperactive behaviour seen in patients with anorexia nervosa has been discussed. Some argue that anorectics increase their activity for the purpose of burning more energy although this cannot explain their total weight loss, other investigators believe that the increased activity could be biological and involuntary. In 1994, Davis *et al.* showed that anorectic patients have an increased urge to be active during accelerated weight loss. This animal model, where starvation and hyperactivity mutually reinforce each other, supports the view that the increased activity is involuntary. However, there is no clear evidence for the applicability of this model in human anorexia nervosa.

Dehydration-Associated Anorexia

Dehydration is a homeostatic challenge resulting in a series of well-characterized endocrine, autonomic and behavioural motor responses. These are directed towards minimizing the impact of dehydration as rapidly as possible. Such responses are for example modifications of the ingestive behaviours so that water seeking behaviours increase and food seeking behaviours decrease (Hsaio, 1967). Thirst is the most obvious effect of dehydration, but when prolonged, dehydration also generates anorexia (Watts *et al.*, 1999). Dehydration can be induced by replacing the drinking water with 2.5% saline. By pair-feeding non-dehydrated rats with the same

Table XXIII-1.1 Animal models of anorexia

Model	Phenotype	Cause	Face validity	Construct validity
anx/anx mouse	Reduced food intake, gait disturbance, hyperactivity, premature death.	Recessive mutation in the *anx* gene.	++	++
DA-/- mouse	Aphagic, hypoactive, motor deficits, premature death.	Knockout of the TH-gene in dopaminergic neurons.	+	+
HNF3α-/- mouse	Progressive starvation, hypoglycaemia, neonatal mortality.	Knockout of the hepatocyte nuclear factor 3α.	++	−
Hyperactivity anorexia in rats	Increased activity and reduced food intake.	Starvation-induced hyperactivity.	+++	++
Dehydration-associated anorexia	Decreased food seeking behaviour.	Dehydration induced.	++	−
TCDD anorexia	Reduced food intake, wasting, permanent inhibition of weight gain.	Induced by TCDD.	++(+)	+

Lack of potent pharmacological agents makes it difficult to assess predictive validity for the models described. The genetic models of anorexia have their strength in allowing the identification of novel pathways involved in regulation of food intake serving as targets for future therapeutic interventions. Perhaps the most useful approach would be to combine the results from studies of genetic, physiological and biochemical models of anorexia, despite the weaknesses of each individual model. The 'Hyperactivity anorexia in rats' model has gained popularity as it mimics many aspects of human anorexia.

amount of food eaten by dehydrated rats and compare the neuronal and endocrine effects, one can distinguish between mechanisms causing anorectic behaviour from those occurring as a consequence of anorexia (Watts, 2000; Watts *et al.*, 1999).

This model is not applicable to human anorexia but may very well serve as a hypothesis generator and provide new insights in the complex regulation of food intake.

TCDD Induced Anorexia and Wasting Syndrome

The common environmental trace contaminant 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) is one of the most potent anorexigens known (Pohjanvirta *et al.*, 1994). TCDD causes a starvation-like or wasting syndrome with food intake refusal and consequent body weight loss (Pohjanvirta and Tuomisto, 1994; Unkila *et al.*, 1993). A sublethal dose can cause permanent inhibition of body weight gain and the new body weight gain is defended against external manipulations (Seefeld *et al.*, 1984; Pohjanvirta and Tuomisto, 1990). This is suggestive of a specific effect of TCCD on body weight regulatory systems. Despite extensive studies, the physiological mechanisms behind this wasting syndrome are unknown.

Humans suffering from anorexia will gain weight once they start eating again. Thus, this model has little validity as a model for anorexia. However, the regulation of a 'body weight set point' is unknown and this model may provide valuable information on the mechanisms behind this complex system.

Conclusions on Models of Anorexia

As mentioned several times already all the models above have their strength as hypothesis generators. Taken together these models may be very informative despite the weaknesses of each model individually. Perhaps the most useful approach at this point in time would be to combine the results from studies of genetic, physiological and biochemical models of anorexia. With such a comprehensive approach it may be possible to gain insight into many, but not all, aspects of reduced food intake as a disease. We have attempted to evaluate these models comparatively in Table XXIII-1.1.

MODELS OF BULIMIA AND BINGE EATING

Not many animal models of binge eating and/or bulimia have been described; the few existing models are all based on cycles of food restriction and refeeding. In the model described by Hagan and Moss (1997) rats were subjected to 12 restriction-refeeding cycles of 6–8 days during an 84-day period. One group of animals was cycled in a bulimic-like pattern with restriction followed by palatable refeeding and one group was cycled through a non-bulimic-like pattern. Postcycling eating behaviour was tested under conditions of hunger, satiety and availability of palatable food in both groups. Rats with a history of cycles of restriction followed by hyperphagia (bulimic-like feeding) continued to exhibit persistent binge-eating behaviour even after a 30-day period of normalization (full feeding, no restriction). This effect was shown particularly with access to palatable food in sated conditions. This model implicates restriction and overeating as biological determinants of binge-eating behaviours.

Restriction alone cannot account for bulimia. Not everyone who restricts becomes bulimic. However, restriction does seem to be a major factor in the development of binge eating, an important feature of bulimia. This model may provide clues to possible mechanisms involved in the genesis of a bulimic episode.

MODELS OF OBESITY

The Leptin System

Obese (*ob*) and diabetes (*db*) are two recessive mutations in mouse that lead to hyperphagia, decreased energy expenditure and morbid obesity (Coleman, 1978). Parabiosis experiments with lean (wild-type) mice and obese (*ob/ob*) mice suppressed weight gain in the *ob/ob* mice, while parabiosis of lean (wild-type) mice and obese (*db/db*) mice caused hypophagia and weight loss in the former (Hausberger, 1959; Coleman and Hummel, 1969; Coleman, 1973, 1978). These results were interpreted as meaning that the *ob* mutation disrupted a circulating satiety factor. In the parabiosis experiment the normal lean mouse would deliver the satiety factor to the *ob/ob* mouse with subsequent weightloss. Similarly, the *db* mutation was believed to disrupt a component required for the response to a satiety factor. Through lack of feedback inhibition the *db/db* mouse was thought to over-express the satiety factor that it could not respond to. Consequently, excess satiety factor would be delivered to the normal mouse (with a fully functioning response) leading to profound weightloss in the normal mouse in the parabiosis experiment between *db/db* and normal mouse.

The *ob* gene was positionally cloned and named leptin (*Lep*) (Zhang *et al.*, 1994). There are two mutations of the *Lep* gene in mouse, Lep^{ob} and Lep^{ob2J}. The Lep^{ob} mutation results in a premature stop codon and synthesis of a truncated protein incapable of being secreted (Zhang *et al.*, 1994; Rau *et al.*, 1999). In the Lep^{ob2J} homozygous mouse mutant, a transposon inserted into the first intron of the *Lep* gene prevents the synthesis of mature *Lep* mRNA (Zhang *et al.*, 1994). In addition to obesity, the *ob* mutations in mouse also cause hyperinsulinemia, hypoglycaemia, hypercorticism, hypothalamic hypogonadism and hypothermia (Charlton, 1984). Mutations in the human *Lep* gene are rare but there are a few cases reported (Montague *et al.*, 1997; Strobel *et al.*, 1998; Rau *et al.*, 1999). The human *ob* mutations cause hyperphagia, obesity and hypothalamic hypogonadism, but unlike the *ob/ob* mice, hyperinsulinemia, hypoglycaemia, hypercorticism and hypothermia have not been reported in leptin deficient humans. This implies that although there are many similarities in the regulatory pathways, there are also distinct differences no doubt relating to the development of regulatory systems during the evolution of the respective species. This selection process will have to be taken into account when validating leptin mutations and their role as models for obesity.

The *db* mutation phenotypically mimics the *ob* mutation and was proposed to be a mutation in an *ob* receptor gene (Coleman, 1978). The cloning of the *db* gene confirmed that *db* indeed was a mutation in the leptin receptor gene (*Lepr*) (Tartaglia *et al.*, 1995; Lee *et al.*, 1996). Similar mutations in the *Lepr* gene have been shown to underlie the obese phenotypes of the *fatty* Zucker rat and the *corpulent* Koletsky rat (Chua *et al.*, 1996; Takaya *et al.*, 1996). There are five alternatively spliced forms of the receptor, Ob–Ra, Ob–Rb, Ob–Rc, Ob–Rd and Ob–Re (Lee *et al.*, 1996). Ob–Rb (or Ob–RL) is the longest form and has a long cytoplasmic region containing several motifs required for signal transduction (Chen *et al.*, 1996; Lee *et al.*, 1996). The other forms lack some or all of these motifs and may function as transport proteins (Lee *et al.*, 1996) or act in a buffering system for free, circulating leptin. Ob–R mutations are extremely rare in humans. There is, however, one report on a family with three obese sisters with a mutation in the *Lepr* gene (Clement *et al.*, 1998).

The Melanocortin System

Pro-opiomelanocortin (POMC) is a neuropeptide precursor molecule that is cleaved post-translationally in the hypothalamus to yield multiple peptides including α-melanocyte-stimulating hormone (α-MSH) (Smith and Funder, 1988). Melanocortin peptides have been demonstrated to inhibit food intake and recent data suggest that they may play a role in energy expenditure as well (Fan *et al.*, 1997; Haynes *et al.*, 1999).

α-MSH is the principle agonist of the neuronal melanocortin receptor isoforms, MC-3R and MC-4R (Gantz *et al.*, 1993a, 1993b). Both isoforms influence body weight, but they act through distinct and complementary mechanisms. MC-4R knockout mice ($Mc4r^{-/-}$) eat excessively resulting in maturity onset obesity syndrome associated with hyperphagia, hyperinsulinemia and hypoglycaemia (Huszar *et al.*, 1997). MC-3R knockout mice ($Mc3r^{-/-}$) show an increased body fat mass at the expense of a decreased lean muscle mass (Chen *et al.*, 2000). This is not caused by increased food intake, instead $Mc3r^{-/-}$ mice gain more fat per calorie of food consumed (Chen *et al.*, 2000). Mice lacking both receptor isoforms are more obese than mice lacking just MC-3R or MC-4R, probably because the double mutants not only eat more but also store ingested calories more efficiently (Chen *et al.*, 2000). Mutations in the MC-4R have also been reported to be associated with dominantly inherited pediatric obesity and hyperphagia in humans (Vaisse *et al.*, 1998; Yeo *et al.*, 1998).

The agouti gene was the first obesity gene cloned (Bultman *et al.*, 1992; Miller *et al.*, 1993). There are five known dominant mutations in the agouti gene that result in obesity and yellow pigmentation in mice. Normally agouti mRNA is expressed exclusively in the skin of neonatal mice, but mice carrying a dominant yellow allele have a ubiquitous expression pattern (Michaud *et al.*, 1994). The agouti protein is an antagonist of MC-4R in the brain and blocking of the receptor leads to increased food intake (Lu *et al.*, 1994; Fan *et al.*, 1997). This discovery led to the cloning of an agouti homologous protein normally expressed in the brain, the agouti-related protein (AGRP) (Shutter *et al.*, 1997). AGRP was shown to be an endogenous antagonist of MC-3R and MC-4R and overexpression causes obesity in mice (Fong *et al.*, 1997; Graham *et al.*, 1997; Ollmann *et al.*, 1997). No mutations in the AGRP gene have been found in humans.

The Fat Mouse

The fat phenotype includes obesity that develops between 6 and 8 weeks of age, hypoglycaemia and hyperinsulinemia (Coleman and Eicher, 1990). The hypoglycaemia only occurs in males and is transient whereas the hyperinsulinemia is consistent throughout life and associated with hypertrophy and hyperplasia of the islets of Langerhans in the pancreas (Coleman and Eicher, 1990). The syndrome does not progress to diabetes. This phenotype is the result of a missense mutation in the carboxypeptidase E (*Cpe*) gene (Naggert *et al.*, 1995). CPE is a secretory granule enzyme involved in dibasic cleaving of proproteins and prohormones including intermediates derived from proinsulin and pro-opiomelanocortin (Naggert *et al.*, 1995). The fat mutation (Cpe^{fat})results in a loss of CPE activity and proinsulin processing is aberrant in fat mutants (Naggert *et al.*, 1995). No mutations in the human *Cpe* gene have been reported. However, a mutation in the endopeptidase, prohormone convertase 1 (*PC1*) have been found in a patient with extreme childhood obesity (Jackson *et al.*, 1997). *PC1* acts proximally to *Cpe* in the pathway of post-translational processing of prohormones and neuropeptides. Thus, it has been suggested that defects in prohormone conversion may represent a generic mechanism for obesity both in humans and rodents.

The Tubby Mouse

The recessive tubby mutation (*tub*) causes maturity-onset obesity, including insulin resistance, accompanied by retinal and cochlear degeneration (Coleman and Eicher, 1990; Ohlemiller *et al.*, 1995; Ohlemiller *et al.*, 1997). The obesity of *tub/tub* mice is relatively mild and late in onset, resembling the weight gain in human populations more closely than that observed in the *ob/ob* and *db/db* mice. Weight gain occurs slowly and *tub/tub* mice reach about twice the weight of unaffected siblings. Tubby mice are not sterile but as they develop obesity they become infertile.

The tubby gene was identified by positional cloning (Kleyn *et al.*, 1996; Noben-Trauth *et al.*, 1996). The tubby phenotype is caused by a point mutation in a donor splice site resulting in a substitution of 44 amino acids in the carboxyterminal part of the Tub protein with 24 different amino acids encoded by the unspliced intron (Kleyn *et al.*, 1996). The aberrant transcript is expressed at elevated levels in tubby mice but expression at the protein level has not been investigated. The expression pattern of *tub* mRNA appears to be specific for the nervous system (Kapeller *et al.*, 1999) but the biochemical function remains unclear. However, structure-based functional analysis suggests that Tub is a bipartite transcription factor (Boggon *et al.*, 1999). It has not been established whether all tubby phenotypes (obesity, insulin resistance and retinal and cochlear degeneration) are attributable to the *tub* gene. It has not been ruled out that some features of the phenotype could be caused

by a tightly linked, but yet unidentified gene. No human examples of this mutation have been identified yet.

The Adult Mouse

The adult mutation (*Ad*) causes adult obesity and diabetes in a semidominant fashion (Wallace and MacSwiney, 1979). The obesity can be recognized at the age of 4 to 6 months and it is greater in homozygotes than in heterozygotes and it is more penetrant in heterozygote males than females (Wallace and MacSwiney, 1979). The mice are hyperinsulinemic but have normal blood glucose levels. The gene has not been identified and hence there are no known human examples of this mutation.

The 5-HT2CR Deficient Mouse

Serotonergic drugs are known to modulate appetite and serotonergic agonists with affinity for the serotonin (5-hydroxytryptamine, 5-HT) 2C receptor (5-HT2CR) such as mCPP, act as appetite suppressants (Kennett and Curzon, 1991; Kitchener and Dourish, 1994). Mice lacking 5-HT2CR, generated by the introduction of a nonsense mutation in the 5-HT2CR gene, are overweight as a result of overeating (Tecott *et al.*, 1995). 5-HT2CR transcripts have been detected in the paraventricular nucleus of the hypothalamus (Hoffman and Mezey, 1989), supporting the hypothesis of a central role for serotonin in the control of food intake. 5-HT2CR deficient mice provide a tool for elucidating some of the neurochemical pathways that underlie the regulation of food intake.

Psammomys Obesus

The sand rat *Psammomys obesus* (*P. obesus*) is a polygenic model of obesity and type II diabetes. In their native environment these animals remain lean and free from diabetes but when put on normal laboratory rodent diets a proportion of the animals develop metabolic abnormalities. These abnormalities include obesity, hyperinsulinemia, glucose intolerance, hyperleptinemia and diabetes (Barnett *et al.*, 1994a, 1994b; Collier *et al.*, 1997; Walder *et al.*, 1997). The spectrum of metabolic responses to obesity and the variability in the susceptibility to develop obesity in *P. obesus* makes this model more analogous to human obesity than the single gene obesity models.

The New Zealand Obese Mouse: A Model of the Metabolic Syndrome

New Zealand obese (NZO) mice exhibit a polygenic syndrome of hyperphagia and obesity associated with a type II diabetes-like syndrome of hyperinsulinemia and hypoglycaemia (Bielschowsky and Bielschowsky, 1953; Crofford and Davis, 1965; Veroni *et al.*, 1991). It has been shown that the NZO mouse has elevated levels of leptin in both adipose tissue and serum. Furthermore NZO mice fail to respond to peripheral recombinant leptin infusions with reduced food intake, indicating that they are leptin insensitive (Igel *et al.*, 1997). However, NZO mice respond to intracerebroventricular infusions of leptin with sensitivity similar to wild-type mice (Halaas *et al.*, 1997). It has therefore been suggested that the leptin resistance seen in NZO mice is the result of a diminished transport of leptin into the Cerebrospinal fluid (CSF) (Halaas *et al.*, 1997). Decreased levels of CSF leptin have been observed in some obese patients and the NZO mouse could thus have important implications for understanding the pathogenesis of human obesity (Schwartz *et al.*, 1996).

NZO mice also show symptoms of hypertension and hypercholesterolaemia (Ortlepp *et al.*, 2000). In humans, obesity associated with insulin resistance, dyslipidemia and hypertension is called the metabolic syndrome. The pathophysiological links between the different components of this syndrome is not fully understood and the NZO mouse presents a model for the study of these interactions.

Quantitative Trait Loci for Obesity

Quantitative trait loci (QTL) are produced by statistical analysis of genetic information derived from the offspring of crosses between informative strains with regard to, for example, body mass or fat content. It is believed that this will be a way of identifying susceptibility genes for complex disorders such as obesity. QTL

Table XXIII-1.2 Animal models of obesity

Model	Phenotype	Cause	Face validity	Predictive validity	Construct validity
ob/ob mouse	Obesity, hypoglycaemia, hypothermia, hyperinsulinemia, hypercorticism.	Recessive mutation in the *Lep* gene.	+++	+++*	+(+++)*
db/db mouse	Obesity, hypoglycaemia, hypothermia, hyperinsulinemia, hypercorticism.	Recessive mutation in the *Lepr* gene.	+++	n.d.	+(+++)*
fatty Zucker rat	Obesity, hyperphagia.	Recessive mutation in the *Lepr* gene.	+++	n.d.	+(+++)*
corpulent Koletsky rat	Obesity, hyperphagia.	Recessive mutation in the *Lepr* gene.	+++	n.d.	+(+++)*
Mc3r-/- mouse	Increased body fat mass.	Knockout of the *Mc3r* gene.	++	n.d.	+
Mc4r-/- mouse	Maturity-onset obesity, hyperphagia.	Knockout of the *Mc4r* gene.	++	n.d.	+(+++)*
Agouti yellow mouse	Obesity, yellow pigmentation.	Dominant mutations in the agouti gene.	++	n.d.	+
fat/fat mouse	Obesity, hyperinsulinemia.	Mutation in the *Cpe* gene.	+++	n.d.	+(+++)*
tub/tub mouse	Maturity-onset obesity, insulin resistance.	Recessive mutation in the *tub* gene.	+++	n.d.	+
Adult mouse	Adult obesity, diabetes.	Dominant mutation in the *Ad* gene.	+++	n.d.	+
5-HT2C-/- mouse	Obesity, hyperphagia.	Introduced nonsense mutation in the *5-HT2C-/-* gene.	++	n.d.	+
P. obesus sand rat	Obesity, type II diabetes.	Polygenic.	+++	n.d.	n.d.
NZO mouse	Obesity, type II diabetes.	Polygenic.	+++	n.d.	n.d.

*Excellent predictive and/or construct validity as models for subgroups of human obesity cases with related mutations. n.d.: not determined. Although there are several cases described where single gene mutation models have counterparts that cause obesity in the human, polygenic animal models will most likely best mimic the human situation. The monogenic models will probably have their strength as hypothesis generators and in the cases of the *ob, db, Mc4r* and *fat* mutations they have been most helpful in revealing the nature of specific human eating disorders.

analysis has become a method of choice for mimicking more closely the complex obesity in human. A total of 98 animal QTLs, from mouse, rat, pig and chicken, linked to body weight or body fat were reported in the 1999 update of 'The human obesity gene map' (Chagnon *et al.*, 2000). This number is constantly increasing as more QTL crosses are analysed. The main task of identifying and cloning the QTLs remains. Some of these QTLs will turn out to be more important than others and several will, in all likelihood, be proven to be false positives.

Conclusions on Obesity Models

Human obesity is a complex disorder influenced by both environmental as well as physiological and genetic factors. Although there are several cases described where single gene mutations cause obesity in the human the polygenic animal models will most likely mimic the human situation best. Table XXIII-1.2 contains a summary and a comparative evaluation of the models described.

CONCLUDING REMARKS

When producing valid animal models of eating disorders one is faced with two major obstacles, first the lack of accurate descriptions of the disorders and second the lack of effective treatments for these disorders. The central mechanisms of hunger and satiety are under complex physiological control. A good understanding of these mechanisms is necessary in order to understand the underlying causes for eating disorders. In this chapter we have reviewed some of the available animal models of eating behaviour that may provide clues to possible mechanisms involved in the regulation of food intake.

Given that eating disorders have become a major health concern, the combination of gene variants, mutations and environmental factors that contribute to these disorders need to be defined. Irrespective of the value of animal models for the understanding of the causes of human eating disorders, it is very probable that most of the molecules identified, using animal models, will be involved in biochemical processes regulating food intake and/or metabolism also in human. As such, these molecules constitute targets for the development of new classes of small drug pharmaceuticals that may be used to treat human eating disorders. There are thus great expectations that studies of animal models will result in new tools for the treatment and/or prevention of a major health hazard in the western world.

XXIII-2

Transmitter Systems in the Eating Disorders

Timothy D. Brewerton

INTRODUCTION

Investigations into the role of neurotransmitters and other neuromodulators in the eating disorders have been quite productive in the last few years, especially during the last decade. The eating disorders occur in a relatively small cohort of people, primarily young women and girls, across many cultures, and they are known to be associated with significant mortality and morbidity, both medical and psychiatric (Walsh and Devlin, 1998; Becker *et al.*, 1999). Despite popular beliefs, there is no convincing evidence that cultural factors alone cause eating disorders. Recent data clearly identify strong genetic factors in the aetiology of both anorexia nervosa (AN) and bulimia nervosa (BN), which appear to share common genetic vulnerabilities (Lilenfeld *et al.*, 1998; Strober *et al.*, 2000) possibly linked to obsessionality, perfectionism, anxiety and/or behavioural inhibition (Halmi *et al.*, 2000; Kaye *et al.*, 1999a, 1999b). Such information implicates primary neurotransmitter disturbances in both disorders. One powerful piece of evidence to support monoamine involvement in the eating disorders is the observation that antidepressant medications can be beneficial in controlled studies, not only in BN patients, but also in recovered AN patients (Kaye *et al.*, 1998b).

However, it is also clear that a number of secondary disturbances come about as a result of the profound eating disturbances characteristic of these disorders (Brewerton, 1995), which then in turn only worsen or perpetuate signs and symptoms (Pollice *et al.*, 1997). This perspective, taken together with the disorders' consequences, challenges and costs, compels us towards a better understanding of the biological mechanisms underlying all stages and types of eating disorders. The identification of the psychobiological underpinnings of these conditions may be useful in many ways, including the development of improved medical and psychopharmacologic interventions, improved education and psychotherapy for patients and their families, and improved prevention efforts at a primary level.

It must be emphasized that most measurements of neurotransmitter function provide only a glimpse into the state of the organism at that moment in time. Sorting out what is trait- and what is state-related has been a challenging focus of neurotransmitter research in the eating disorders.

MONOAMINES

The classical monoaminergic neurotransmitter systems, including serotonin (5-HT), norepinephrine (NE), and dopamine (DA), have been fairly extensively studied in the eating disorders using available techniques in biological psychiatry. Most of these studies have been conducted during the disease state, which has the disadvantage of being confounded by severe nutritional compromise. Dieting and/or semi-starvation clearly deplete central monoamines and lead to altered neurotransmitter levels and receptor sensitivity in animals and humans (Cowen *et al.*, 1996; Cowen and Smith, 1999; Goodwin *et al.*, 1987a, 1987b, 1990). To avoid this problem a more recent strategy has been to study 'recovered' eating disorder patients, i.e., AN and BN patients who have attained normalization of eating and weight, resumption of menses and/or normalization of gonadal hormone levels, and abatement of typical cognitive features to sub-clinical levels. This strategy attempts to minimize starvation-state-related effects and to reveal potential trait-related disturbances or vulnerabilities. However, the long-term effects of chronic malnutrition and disordered eating behaviours on the brain (similar to substance use disorders) should not be underestimated. Studies of transmitter function in at-risk pre-morbid individuals as well as non-affected identical and fraternal twins, siblings, and other first-degree relatives of ED patients, could begin to confirm trait-related disturbances.

Neurotransmitter function in patients with EDs have been investigated using a variety of existing techniques and methodologies, each of which has its own advantages and disadvantages. Studies of cerebrospinal fluid (CSF) concentrations of the major metabolites have been a popular strategy and include measures of 5-hydroxyindoleacetic acid (5-HIAA) for serotonin (5-HT), 3-methoxy-4-hydroxyphenylglycol (MHPG) for NE, and homovanillic acid (HVA) for DA. Some studies have also examined actual concentrations of 5-HT and NE, but not DA. Such studies measure transmitter metabolism of the whole brain and spinal cord and lack any anatomical specificity.

Neuroendocrine and other psychobiological response measures have been studied following acute challenges with various agents, including amino acid precursors, e.g., L-tryptophan (L-TRP) and 5-hydroxytryptophan (5-HTP) for 5-HT, pre-synaptic receptor agonists, e.g., dl-fenfluramine (dl-FEN) or d-fenfluramine (d-FEN) for 5-HT, post-synaptic receptor agonists, e.g., m-chlorophenylpiperazine (m-CPP) for 5-HT and isoproterenol (ISOP) for NE. Longer term challenges with receptor antagonists, e.g., antipsychotics for DA and 5-HT, and antidepressants, especially the serotonin-specific reuptake inhibitors (SSRIs), also illuminate the role of neurotransmitters in the eating disorders. Acute amino acid precursor depletion, most notably of L-TRP (Delgado *et al.*, 1990; Weltzin *et al.*, 1995; Smith, Fairburn and Cowen, 1999; Kaye *et al.*, 2000), has been another important source of information about the role of central 5-HT function in eating and related disorders.

Platelet (PLT) or leukocyte studies are possibly reflective of central neurotransmitter function but are always at least step removed from the nervous system, e.g., platelet 5-HT reuptake, ^{3}H-imipramine binding, ^{3}H-paroxetine binding, platelet MAO, platelet 5-HT content, as well as platelet receptor mediated aggregation (5-HT_2 and alpha-adrenergic).

Plasma concentrations of neurotransmitter precursors, e.g., L-TRP, L-tyrosine (L-TYR), and their competing large neutral amino acids (LNAA), neurotransmitters themselves, e.g., NE, DA,

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

and whole blood serotonin (WBS), as well as the usual metabolites, MHPG, HVA, and 5-HIAA.

Brain imaging-receptor-binding studies are a promising avenue but remain relatively unexplored in the eating disorders.

For each neurotransmitter, the results from controlled studies in humans will be reviewed and summarized for both AN and BN. Where applicable, comparisons between restricting AN patients, bingeing/purging AN patients, and normal-weight BN patients will be made.

NOREPINEPHRINE

There are a number of reasons to suspect NE involvement in the eating disorders. Most notably, NE pathways at the level of the hypothalamus are known to be involved in the initiation of feeding (Rowland, Morien and Li, 1996). Disturbances in these pathways may therefore be involved in the pathophysiology of the profoundly altered feeding behaviours classically associated with the eating disorders. In addition, NE's role in the modulation of mood, anxiety, neuroendocrine control, metabolic rate, sympathetic tone, and temperature make it a likely candidate of study (Jimerson *et al.*, 1987; Kaye *et al.*, 1988b, 1990a, 1990c; Lesem *et al.*, 1989; Pirke, 1996). It has been well recognized for quite some time that low-weight anorexic patients, and to some degree bulimic patients, have reduced body temperature, blood pressure, pulse and metabolic rate (Gross *et al.*, 1979; Lesem *et al.*, 1989; Obarzanek *et al.*, 1991). Investigations in this area have shown that low-weight AN patients have reduced measures of plasma, urinary and CSF MHPG (Gross *et al.*, 1979; Halmi *et al.*, 1978; Johnston *et al.*, 1984; Kaye *et al.*, 1984a, 1984b). In contrast, reports of plasma NE levels in the eating disorders has been more variable (Luck *et al.*, 1983; Kaye *et al.*, 1988a, 1988b), and this appears to be linked not only to weight but to the stresses associated with the illness (Lesem *et al.*, 1989). AN patients tend to have higher plasma NE levels at admission, which then decrease as treatment and weight gain progresses (Pahl *et al.*, 1985; Lesem *et al.*, 1989).

When ill, BN patients demonstrate lower values of plasma NE at baseline (Jimerson *et al.*, 1987; Obarzanek *et al.*, 1991) and in response to abstinence (Kaye *et al.*, 1990b), standing (Pirke *et al.*, 1985), testmeal challenge (Pirke *et al.*, 1992), and mental challenge (Pirke *et al.*, 1992). They also have other evidence of blunted sympathetic activation in response to mental stress (Koo-Loeb, Pedersen and Girdler, 1998). However, despite low baseline plasma NE levels, BN patients show normal responses to exercise (Pirke *et al.*, 1989) but reduced responses to orthostasis (Lonati-Galligani and Pirke, 1986).

In AN patients, depression has been found to be significantly worse in those patients with the lowest delta change in plasma NE concentrations to orthostasis (Pirke *et al.*, 1988). Reduced urinary MHPG levels have also been related to the presence of comorbid major depression (Biederman *et al.*, 1984a, 1984b; Halmi *et al.*, 1978). It is therefore important in such studies to control for psychiatric comorbidity.

Like the plasma NE studies, CSF NE levels have been reported to be no different in AN patients compared to controls at low weight and after short-term weight gain, but then significantly lower after weight recovery of at least 6 months (Kaye *et al.*, 1984a, 1984b, 1985; Pirke, 1996). In BN patients, reduced CSF NE levels have been reported during the active state of the illness (Kaye *et al.*, 1990a, 1990b). However, upon long-term recovery, concentrations of CSF MHPG have been reported to normalize in both AN and BN (Kaye *et al.*, 1999a, 1999b) despite earlier reports of lower levels (Kaye *et al.*, 1985). Given that CSF NE concentrations have not yet been reported in long-term (>1 year) recovered AN or BN patients, the extent to which adrenergic alterations seen in the eating disorders are trait-related is unclear. Nevertheless, available evidence suggests exquisite sensitivity of this system to malnutrition or stress.

Challenge studies using the beta-adrenergic agonist isoproterenol in underweight anorexic patients revealed erratic secretion of plasma NE in response to increasing doses (Kaye *et al.*, 1990a, 1990b). Bulimic patients demonstrated significantly increased chronotropic responses to isoproterenol (George *et al.*, 1990). Challenge studies with adrenergic agents in recovered patients have not been reported.

The number of platelet alpha-2-receptors has been reported to be reduced in both AN and BN compared to controls (Luck *et al.*, 1983; Heufelder, Warnhoff and Pirke, 1985), thereby suggesting increased post-synaptic receptor sensitivity which is probably secondary to dieting or semi-starvation. In summary, peripheral and central sympathetic nervous activity is reduced in both AN and BN, although it tends to normalize with recovery. Taken together, the preponderance of the evidence so far leads to the conclusion that these changes are a result of chronic starvation or intermittent dieting (Pirke, 1996). However, a trait-related disturbance of the adrenergic system cannot be ruled out at this time (Kaye *et al.*, 1990a, 1990b).

Studies of adrenergic receptors on human leukocytes have been another strategy to investigate adrenergic function in the eating disorders. Buckholtz *et al.* (1988) reported altered beta-adrenergic receptor affinity on circulating lymphocytes of BN patients compared to those of controls. However, in a similar study of a mixed group of eating disorder patients, Lonati-Galligani and Pirke (1986) reported lower receptor number (B_{max}) but normal affinity (K_d) in low-weight AN patients, while both measures were no different from controls in the BN patients and the weight-recovered AN patients. Gill and colleagues (1992) reported differential changes in alpha- and beta-adrenoceptor linked [$^{45}Ca^{2+}$] uptake in platelets from patients with anorexia nervosa, further documenting an adrenergic disturbance in eating disorder patients. However, the issue of cause vs. effect remains unanswered in platelet and leukocyte studies.

DOPAMINE

Dopamine (DA) is also suspect in the neuropathophysiology of the eating disorders given its reported involvement in the regulation of feeding, mood, activity, perception, sexual/social behaviour, hormone and peptide release and to some extent aggression (Hoebel, 1985; Jimerson *et al.*, 1992; Engstrom *et al.*, 1999; Kaye *et al.*, 1999a). Notably, DA is involved in the hedonic reward responses to eating and its maintenance as well as to other pleasurable activities (Hoebel, 1985; Hoebel *et al.*, 1989; Jimerson *et al.*, 1992).

The majority of studies of DA metabolism in the eating disorders have consistently shown that low-weight AN patients have reduced measures of peripheral and central DA activity, including decreased plasma (Gross *et al.*, 1979) and CSF HVA (Kaye *et al.*, 1984a, 1984b). In BN patients, reduced CSF HVA levels also have been reported in BN patients with frequent binge–purge episodes (Kaye *et al.*, 1990a; Jimerson *et al.*, 1992) but not in those less severely ill. Furthermore, binge frequency was inversely correlated with CSF HVA levels in one study (Jimerson *et al.*, 1992). Upon long-term recovery, normal concentrations of CSF HVA have been reported to normalize in BN (Kaye *et al.*, 1998a, 1998b), while a trend for decreased CSF HVA levels persisted in six restricting AN patients compared to controls and to bingeing and/or purging AN patients (Kaye *et al.*, 1999a). This suggests a possible trait-related disturbance specific to restricting AN, although this finding needs replication given the small sample size. These results could also

still be due to nutritional factors given that the patients in this study weighed significantly less than the BN group and may still have been at the low end of the normal weight range.

Anecdotal reports of the successful use of dopaminergic antagonists (typical anti-psychotic agents) in the treatment of AN patients (Dally and Sargant, 1960) have been generally followed by equivocal results in controlled studies (Vandereyken and Pierloot, 1982; Vandereyken, 1984). Atypical anti-psychotic agents may show more promise in the adjunctive treatment of AN given their combined anti-dopaminergic and anti-serotonergic effects (Hansen, 1999; Jensen and Mejlhede, 2000; LaVia, Gray and Kaye, 2000), but the results of placebo-controlled studies remain to be seen.

Genetic investigations into the role of DA have been limited to the Bal I DRD3 receptor polymorphisms in which no differences were found between AN patients and controls (Bruins-Slot *et al.*, 1998). However, the polymorphisms of other genes coding for DA receptors could be tested. Interestingly, Corcos and colleagues (1999) reported significantly lower IgG and IgM autoantibodies to DA in BN patients compared to controls. There was also a trend for lower levels of IgM autoantibodies to DA in the eating disordered group. The relevance of these findings to the pathophysiology of the eating disorders remains uncertain, but invokes possible autoimmune mechanisms.

SEROTONIN

There are several lines of reasoning that point to disturbances of serotonin (5-HT) function in the pathophysiology and neuropsychopharmacology of the EDs (Kaye and Weltzin, 1991b; Brewerton, 1995; Kaye *et al.*, 1999a, 1999b), including its role in feeding (Dourish *et al.*, 1988; Leibowitz, 1999), satiety (Brewerton *et al.*, 1994a, 1994b; Leibowitz and Alexander, 1998), dieting/fasting (Cowen *et al.*, 1996; Cowen and Smith, 1999), mood regulation (Delgado *et al.*, 1990), anxiety (Anderson and Mortimore, 1999), obsessive–compulsiveness/perfectionism/behavioural inhibition (Kaye *et al.*, 1984a), harm avoidance (Brewerton, Hand and Bishop, 1993; Waller *et al.*, 1993) impulsivity/aggression (Linnoila *et al.*, 1983; Coccaro *et al.*, 1989), motor activity (Brewerton *et al.*, 1995a; Epling and Pierci, 1988), gender (Carlsson *et al.*, 1985; Goodwin, Fairburn and Cowen, 1987a), seasonality (Brewerton, 1989; Brewerton *et al.*, 1988a, 1994a, 1994b), body image/perception (Goldbloom and Olmsted, 1993), and social status (Raleigh *et al.*, 1984, 1985; McGuire and Raleigh, 1985) (see Table XXIII-2.1).

Decreases in a variety of 5-HT parameters have been consistently reported in low-weight AN patients. Although no significant differences have been found in absolute plasma L-TRP levels (Russell *et al.*, 1967; Coppen *et al.*, 1976; Hassanyeh and Marshall, 1991), the plasma L-TRP/LNAA ratio is reduced in the low-weight state (Askernazy *et al.*, 1998; Kaye *et al.*, 1984a; Johnston *et al.*, 1984) but normalizes upon short-term weight recovery (Johnston *et al.*, 1984; Kaye *et al.*, 1988b). In BN, Gendall and Joyce (2000) reported that the L-TRP/LNAA ratio inversely correlated with the desire to binge eat. In addition, symptomatic bulimic relapse or worsening of symptoms has been reported following acute L-TRP depletion in BN (Weltzin *et al.*, 1995; Smith, Fairburn and Cowen, 1999; Kaye *et al.*, 2000).

Other significant findings include decreased CSF L-TRP levels (Gerner *et al.*, 1984) and decreased CSF 5-HIAA levels (Kaye *et al.*, 1988b, 1984a; Gillberg, 1983) during low-weight status with normalization of these levels with short-term weight recovery (STWR, goal weight maintenance $\geq$3 weeks). Following long-term weight recovery (LTWR, goal weight maintenance $\geq$6–12 months), Kaye and colleagues (1991a, 1999b) have reported increased CSF 5-HIAA levels, which is associated with obsessionality and behavioural inhibition.

In BN, reduced levels of CSF 5-HIAA are consistently reported only in the subgroup of patients with more frequent binge–purge frequencies (Kaye *et al.*, 1990a, Jimerson *et al.*, 1992). In addition, binge frequency was inversely correlated with CSF 5-HIAA concentrations (Jimerson *et al.*, 1992). In a small pilot study, Brewerton and colleagues (1995a, 1995b) have reported no difference in CSF 5-HT levels between BN patients and controls. However,

upon recovery for at least one year, BN patients have been reported to have elevated CSF 5-HIAA levels compared to healthy controls (Kaye *et al.*, 1998b). As in AN, this finding has been linked to obsessive–compulsive personality traits, perfectionism and behavioural inhibition.

Decreased prolactin (PRL) responses following m-CPP (Brewerton *et al.*, 1990; Brewerton and Jimerson, 1996; Hadagan *et al.*, 1996), L-TRP (Brewerton *et al.*, 1990; Brewerton and Jimerson, 1996), and fenfluramine (FEN) (Halmi *et al.*, 1993; Monteleone *et al.*, 1998b) have been reported in AN and indicate an anatomically specific alteration in 5-HT receptor sensitivity at the level of the hypothalamus, which could conceivably also occur in other brain pathways (Brewerton, 1995). Blunting of PRL following m-CPP persist into short-term weight recovery, although there are trends toward normalization with refeeding and weight gain (Brewerton and Jimerson, 1996). With at least a year of recovery, neurohormonal responses to m-CPP normalize in restricting AN patients (Kaye *et al.*, 1999b). Apparently, full normalization of PLR responsivity to serotonergic agents does occur after full weight restoration, normalization of hypothalamic-pituitary-gonadal function, and abatement of overt eating disorder symptoms (Kaye *et al.*, 1999b). However, the appetite-suppressing effect of FEN is significantly diminished in recovered AN patients despite normalization of hormonal release (Ward *et al.*, 1998).

In BN, there is a consistent pattern of PRL blunting following m-CPP (Brewerton *et al.*, 1992b, 1992c; Brewerton, 1995; Levitan *et al.*, 1997), fenfluramine (Halmi *et al.*, 1993; Jimerson *et al.*, 1997; McBride *et al.*, 1991; Monteleone *et al.*, 1998a), and 5-hydroxytryptophan (5-HPT) (Goldbloom *et al.*, 1996), but not L-TRP (Brewerton *et al.*, 1992b, 1992c; Brewerton, 1995). PRL responses following L-TRP are low only in the BN patients with concurrent major depression, again emphasizing the need to control for comorbidity. PRL responses following m-CPP are inversely correlated to baseline cortisol (CORT) (Brewerton, 1995). Self-reported binge frequency also has been reported to be inversely correlated to PRL responses following m-CPP (Brewerton, 1995) and fenfluramine (Jimerson *et al.*, 1997; Monteleone *et al.*, 1998a) in BN patients. Given that this presumed alteration in hypothalamic post-synaptic 5-HT functioning normalizes with recovery from BN (Kaye *et al.*, 1998a, 1998b; Wolfe *et al.*, 2000), these serotonergic abnormalities are likely a *result* of bingeing, purging, and/or dieting rather than a *cause* of these behaviours, although other vulnerabilities of the 5-HT system may also exist and interact with these psychosomatic behaviours. Dieting, bingeing and vomiting all may affect central 5-HT synthesis (Fernstrom, 1985; Goodwin *et al.*, 1987a, 1987b; Kaye *et al.*, 1988a, 1989) and could conceivably result in downregulation of post-synaptic 5-HT receptors and blunted PRL responses. In addition, these behaviours may involve activation of the HPA axis, which in turn appears to dampen 5-HT receptor sensitivity (Brewerton *et al.*, 1992b, 1992c; Brewerton, 1995).

Taken together, research findings from plasma, CSF, and pharmacologic challenge studies suggest reduced 5-HT synthesis, uptake, and turnover, as well as altered post-synaptic 5-HT receptor sensitivity during the active phases of both AN and BN. Consequently, most reported alterations in 5-HT function appear to be state-dependent, although they may play important biological roles in the perpetuation of symptoms, particularly the mood dysregulation, increased anxiety, obsessionality, impulsivity, self-aggression, and perhaps the resistance to and difficulty in learning healthier coping strategies (Riedel *et al.*, 1999).

Interestingly, other findings suggest heightened 5-HT receptor sensitivity in non-recovered eating disorder patients. Brewerton (1995) has reported enhanced temperature and migraine headache responses to m-CPP, but not L-TRP in BN patients (regardless of the comorbid presence of AN or MD) (Brewerton, 1995; Brewerton *et al.*, 1988b, 1992c). As discussed in detail elsewhere (Brewerton *et al.*, 1992c), the enhanced migraine-like HA responses in the BN patients may indicate enhanced 5-HT_2 receptor sensitivity in CNS vascular tissues. Enhanced 5-HT mediated platelet aggregation, a 5-HT_2 receptor mediated phenomenon, has also been reported in BN (Spigset *et al.*, 1999) and AN (Halmi *et al.*, 1993; McBride *et al.*, 1991; Spigset *et al.*, 1999) and lends further support to this hypothesis. The normal cortisol responses following m-CPP and L-TRP in AN and BN are compatible with this view given the involvement of both 5-HT_1 (facilitative) and 5-HT_2 receptors (inhibitive) in cortisol secretion. These presumed alterations in 5-HT receptor sensitivity, whether primary or secondary, demonstrate that 5-HT receptor sensitivity can be both decreased and increased in the same subjects depending on anatomical location of the receptor as well as receptor subtype. Brewerton (1995) has argued in favour of a dysregulation hypothesis of monoamine dysfunction in the eating and related disorders in which there is a failure in transmitter regulation in the face of a variety of psychobiological perturbations potentially affecting monoamine function, including dieting, fasting, purging, substance abuse, excessive exercising, medical illnesses, family stresses or losses, sociocultural pressures, traumatic events, puberty, other developmental tasks/challenges, and changes in the seasons.

A number of other platelet (PLT) studies contribute to the demonstration of serotonergic dysfunction in the eating disorders. Significant increases/reductions in PLT imipramine (IMI) binding (Weizman *et al.*, 1986b), but not PLT 5-HT uptake (Weizman *et al.*, 1986a; Zemishlany *et al.*, 1987) or PLT MAO content (Biederman *et al.*, 1984a, 1984b), have been reported in low-weight AN patients. However, a more recent study reported decreased PLT MAO in AN (Diaz-Marsa *et al.*, 2000), which was inversely correlated with impulsivity and positively correlated with persistence. In BN, platelet studies indicate reduced PLT IMI binding (Marazziti *et al.*, 1988) and PLT MAO (Hallman, Sakurai and Oreland, 1989). PLT 5-HT uptake has been reported to be increased in one study (Goldbloom, Hicks and Garfinkel, 1988) but not another (Hallman, Sakurai and Oreland, 1989). Steiger *et al.* (2000) reported reduced PLT paroxetine binding in a group of BN patients compared to healthy controls regardless of the presence of borderline personality disorder. Whether these changes reflect a central trait-related dysfunction remains unclear and awaits further studies in recovered patients.

In a novel study of indole metabolism, Finocchiaro and colleagues (1995) reported altered phytohaemagglutinin stimulated, light-induced [3H]thymidine incorporation into the DNA of peripheral blood mononuclear leukocytes in AN patients compared to controls. The authors concluded that the white cells of AN patients show a failure in the regulation of 5-HT and melatonin metabolism in response to light.

Genetic investigations into the role of 5-HT in the eating disorders have been more numerous and more promising than other monoamines. Collier *et al.* (1997) reported a statistically significant 5-HT2A-1438G/A receptor gene polymorphism in a group of restricting AN patients compared to healthy controls. This finding has been replicated in at least two other studies in AN (Nacmias *et al.*, 1999; Enoch *et al.*, 1998) as well as in OCD (Enoch *et al.*, 1998), but not in BN (Enoch *et al.*, 1998). Nacmias *et al.* (1999) reported that other serotonergic polymorphisms of the 5-HT2A as well as those of the 5-HT2C receptors showed no differences in AN patients compared to controls. Likewise, no differences between AN patients and controls have been reported for serotonin transporter gene linked polymorphisms (5-HTTLPR) (Hinney *et al.*, 1997; Sundaramurthy *et al.*, 2000), tryptophan hydroxylase polymorphisms (Han *et al.*, 1999), and 5-HT1Dbeta and 5-HT7 gene polymorphisms (Hinney *et al.*, 1999). 5-HT2C receptor polymorphisms showed no differences in allelic variations in a group of patients with BN or binge-eating disorder (BED) (Burnet *et al.*, 1999).

It is well known that serotonin-specific antidepressant medications can be beneficial in controlled studies of BN patients (Fluoxetine Bulimia Nervosa Collaborative Group, 1992), but not in low-weight AN patients (Attia *et al.*, 1998; Strober *et al.*, 1999). More recent data indicate a prophylactic effect of fluoxetine following weight gain in recovered AN patients (Kaye *et al.*, 1998). SSRIs don't work during the low-weight state, presumably because of central depletion of 5-HT and other monoamines with starvation. There is significantly less 5-HT centrally to inhibit the reuptake of.

Finally, recent evidence indicates significant anti-bulimic responses to 5-HT3 antagonists, such as ondansetron (Faris *et al.*, 1998, 2000). Although the authors attribute this therapeutic response to the drug's ability to reduce vagal tone, the role of the 5-HT3 receptor remains intriguing given its anti-anxiety effects (Roychoudhury and Kulkarni, 1997). These findings opens important new arenas for future research involving possible serotonergic–cholinergic mechanisms, which has been a relatively unexplored area in the eating disorders.

MAO/ISATIN

Isatin, or tribulin, is an endogenous indole associated with stress, which inhibits monoamine oxidase (MAO) (Glover *et al.*, 1988). Brewerton *et al.* (1995b) reported significantly higher CSF concentrations of isatin in BN patients compared to healthy controls. There was also a trend for CSF isatin concentrations to be inversely correlated with CSF concentrations of the serotonin metabolite, 5-hydroxyindoleacetic acid (5-HIAA) ($n = 14$, $\rho = -0.51$, $p = 0.06$), although CSF isatin levels were not significantly correlated with CSF MHPG or HVA. The increase in isatin levels has been hypothesized to be in response to the resultant monoamine depletion secondary to the effects of the illness on monoaminergic function. As noted previously, PLT MAO has been reported to be decreased in BN (Hallman, Sakurai and Oreland, 1989) and in AN (Diaz-Marsa *et al.*, 2000). This decrease may represent a compensatory change in response to monoamine depletion during the active state of the disorders.

RELATIONSHIP TO OTHER SYSTEMS

Neurotransmitter systems do not exist in a vacuum but are exquisitely interdependent with other brain and body systems and the environment as well. It is important to think about systems (e.g., 5-HT) and their subsystems (pre-synaptic, post-synaptic, receptor subtypes) in the context of larger systems (brain, environment) and interacting systems/subsystems (e.g., NE, DA, neurohormones, neuropeptides) with complex feedback and counter-feedback mechanisms at multiple anatomical levels. An extensive discussion of this rather far-reaching topic is beyond the scope of this chapter but is discussed in more detail elsewhere (Brewerton, 1995).

CONCLUSIONS

Taken together, available findings implicate abnormalities of all monoamine neurotransmitter systems during the active phases of both AN and BN. Upon normalization of weight and neurohormonal function, most transmitter abnormalities normalize, or at least improve. The strongest data show that dysregulation of 5-HT systems appears to persist and may be related to trait-related psychological characteristics found in both AN and BN that extend beyond classical eating disorder signs and symptoms, such as obsessionality, perfectionism, high harm avoidance and behavioural inhibition. Some evidence suggests prolonged alterations in NE metabolism, but this is most likely due to persistent low-grade dietary restraint following recovery. Preliminary data indicate a DA deficit in restricting AN patients, but this result remains to be replicated in larger samples. Recent findings also emphasize the importance of neurotransmitter precursor substrate availability to normal brain function and especially to the process of recovery from an eating disorder. Future research directions will include further exploration of neurotransmitter-related gene candidates, *in vivo* receptor imaging studies, and improved psychopharmacological interventions based on biological alterations characteristic of the different stages and features of these dangerous disorders.

Neuroendocrinology

Frances Connan

INTRODUCTION

Although over a single day food intake is poorly matched to energy expenditure, longer term food intake and energy expenditure can be extremely well balanced such that weight may remain remarkably stable over time (Edholm, 1977). However, the systems governing energy homeostasis appear to function more effectively to defend against starvation than they do in defence of overweight. Indeed, it has been argued that the capacity of the system to maintain healthy weight in the face of high availability of energy dense food and low physical activity levels is poor: there is a marked tendency to over consume, resulting in a high prevalence of obesity (Pinel *et al.*, 2000). In addition to the significant morbidity associated with obesity in its own right, a tendency toward overweight may be a vulnerability factor for the most common of the eating disorders, bulimia nervosa (BN) and binge-eating disorder (BED). These disorders are associated with elevated subjective reward value of food (Karhunen *et al.*, 1997a; Wisniewski *et al.*, 1997), reduced subjective sense of satiety (Kissileff *et al.*, 1996) and premorbid or family history of obesity (Fairburn *et al.*, 1997, 1998).

At the other end of the weight spectrum, anorexia nervosa (AN) is characterized by reduced food intake, but the question of whether appetite is impaired remains controversial and poorly researched. Studies employing subjective assessment have consistently reported reduced hunger and desire to eat and enhanced satiety and sensation of fullness in people with AN (e.g., Halmi and Sunday, 1991; Robinson, 1989). Furthermore, the subjective reward value of food is reduced (Drewnowski *et al.*, 1987; Sunday and Halmi, 1990), and the rate of eating is slow (Halmi and Sunday, 1991). Some authors argue that these findings reflect tight cognitive control of normal appetite (Palmer, 2000). However, relative to healthy comparison women, those with AN show reduced salivation (LeGoff *et al.*, 1988) and a heightened autonomic response to food (Leonard *et al.*, 1998). Images of food elicit fear and disgust (Ellison *et al.*, 1998). These objective data suggest that appetite may indeed be impaired in AN (Pinel *et al.*, 2000), although some capacity to respond to hunger and satiety cues clearly remains (Cugini *et al.*, 1998; Rolls *et al.*, 1992). A predisposition to leanness may be a risk factor for AN (Hebebrand and Remschmidt, 1995), supporting the notion that heritable risk for the disorder may be exerted through the biological systems regulating appetite and weight.

If we are to understand the neuroendocrinology of appetite and weight regulation in eating disorders, we must first understand the normal function of these systems and their responses to changes in body weight. It is well recognized that starvation causes profound changes in neuroendocrine systems and thus many of the findings associated particularly with AN, are liable to be consequence rather than cause of the disorder. Accordingly, the first section provides an overview of current models for understanding the neuroendocrine regulation of appetite and weight. Subsequent sections examine neuroendocrine data relating to each of the eating disorders in turn before presenting a synthesis and considering the implications for treatment and future research.

SECTION 1: REGULATION OF APPETITE AND WEIGHT

Leptin — A Peripheral Energy Sensor

The discovery of leptin in 1995 led to dramatic advances in the understanding of central pathways regulating appetite and weight. Leptin is a 146 amino acid protein that is synthesized and secreted by fat cells. When energy balance is stable, leptin concentration is proportional to fat mass (Considine *et al.*, 1996). However, acute changes in energy balance modulate leptin expression, such that fasting is associated with a greater fall in leptin than might be expected for the change in fat mass and conversely, overeating results in an enhanced postprandial rise in circulating leptin (Ahima *et al.*, 1996; Kolaczynski *et al.*, 1996a). The leptin system therefore responds to potential weight change before fat mass actually changes.

The importance of leptin as a signal of energy balance is demonstrated by genetic strains of mice lacking functional leptin (*ob/ob* mice) or its receptor (*db/db* mice). These animals are hyperphagic, hypothermic, hyperinsulinaemic and obese (Chua-SC *et al.*, 1996; Lee *et al.*, 1996; Zhang *et al.*, 1994). Although rare, genetic deficits of leptin signalling in humans are associated with a similar phenotype (Clement *et al.*, 1998; Montague *et al.*, 1997). Exogenous leptin administration reduces food intake and weight in normal and leptin deficient individuals (Farooqi *et al.*, 1999; Halaas *et al.*, 1997; Pelleymounter *et al.*, 1995). Thus, despite the obese phenotype, genetic leptin deficiency is actually a model of starvation: reduced leptin levels signal reduced fat mass and appetite is appropriately elevated.

Leptin enters the brain via an active transport mechanism and its functional long-arm receptors are located in areas of the hypothalamus, such as the arcuate, ventromedial, paraventricular and dorsomedial nuclei (Elmquist *et al.*, 1998): areas important for the function of neuroendocrine systems, including those regulating appetite and weight. The leptin system is therefore an excellent candidate for a peripheral signal of energy homeostasis and adequacy of fat stores to central systems coordinating the adaptive response to starvation.

Other Peripheral Signals of Energy Homeostasis

Several other peripheral hormones play a significant role in the central regulation of appetite. Insulin was one of the first hormonal signals known to be secreted in proportion to adipose mass. Insulin is actively transported across the blood–brain barrier and both insulin receptor mRNA and specific insulin binding sites

Biological Psychiatry: Edited by H. D'haenen, J.A. den Boer and P. Willner. ISBN 0-471-49198-5

have been demonstrated in regions of the brain important in the control of appetite such as the arcuate nucleus of the hypothalamus (Werther *et al.*, 1987). Chronic central infusion of insulin dose-dependently reduces daily food intake (Chavez *et al.*, 1995; Foster *et al.*, 1991). This effect is not immediate and is maximal only after 24 hours. Central administration of insulin not only reduces appetite but also activates brown fat thermogenesis and increases energy expenditure (Muller *et al.*, 1997). Animals that are insulin deficient show marked hyperphagia and this effect can be reversed by central administration of insulin (Sipols *et al.*, 1995). Central administration of anti-insulin antibodies enhances appetite and weight gain in normal animals (Strubbe and Mein, 1977).

Reciprocal regulatory effects have been demonstrated between leptin and insulin. Insulin has a delayed stimulatory effect on adipocyte leptin production (Kolaczynski *et al.*, 1996b; Utriainen *et al.*, 1996). Conversely, the hyperglycaemia, hyperinsulinaemia and insulin resistance of leptin deficient mice (*ob/ob* mice) is reversed by leptin replacement (Pelleymounter *et al.*, 1995), suggesting that leptin may modulate insulin expression and sensitivity. Recent evidence from the study of diabetic hyperphagia suggests that the role of leptin is more critical to energy homeostasis than that of insulin (Sindelar *et al.*, 1999).

Whilst leptin and insulin inhibit appetite, the recently identified peptide ghrelin stimulates appetite (Tschop *et al.*, 2000). This 28 amino acid peptide was identified in 1999 having been purified from rat stomach and subsequently cloned in man. Ghrelin is the endogenous agonist of the growth hormone secretagogue receptor (GHS-R), which is present in the hypothalamus. Recent work has demonstrated that serum ghrelin concentrations increase with fasting and fall with refeeding whilst intraperitoneal and intracerebroventricular injection of ghrelin increases food intake and body weight in rats and mice (Asakawa *et al.*, 2001; Tschop *et al.*, 2000). In obese humans, ghrelin levels are low and inversely correlated with serum leptin and insulin concentrations (Tschop *et al.*, 2001).

Hypothalamic Regulation of Appetite

First Order Neurones of the Arcuate Nucleus

The hypothalamus has long been recognized as a key component of the pathways regulating food intake. For example, destruction of the arcuate nucleus (ARC) causes hyperphagia and obesity (Olney, 1969). The ARC lies outside the blood–brain barrier and expresses receptors for leptin, insulin and ghrelin (Elmquist *et al.*, 1998; Tschop *et al.*, 2000; Werther *et al.*, 1987). It is therefore ideally placed to communicate peripheral signals to central pathways for energy regulation. Indeed, microinjection of leptin into the ARC reduces food intake (Satoh *et al.*, 1997) and if the arcuate nucleus is destroyed, there is no response to leptin (Dawson *et al.*, 1997).

A variety of orexigenic and anorexigenic peptides are expressed in the ARC. Neuropeptide Y (NPY) is perhaps the most powerful of the orexigenic peptides. Centrally administered NPY is a potent stimulant of feeding and reduces energy expenditure, but repeated administration is needed to elicit significant weight gain (Billington *et al.*, 1991; Stanley *et al.*, 1986). Agouti gene related peptide (Agrp) has a less potent, but more prolonged orexigenic activity, increasing feeding for up to a week after single central administration (Hagan *et al.*, 2000). NPY and Agrp are co-localized to a sub-population of neurones located in the medial ARC that up-regulate expression of both peptides in response to fasting (Broberger *et al.*, 1998; Hahn *et al.*, 1998).

The melanocortin system is perhaps the most important anorexigenic system of the hypothalamus. Mutations of the melanocortin (MC4) receptor gene in both mice (Huszar *et al.*, 1997) and humans (Vaisse *et al.*, 1998; Yeo *et al.*, 1998) are associated with a hyperphagic, obese phenotype, suggesting that activity of this receptor tonically inhibits appetite. Alpha melanocyte stimulating hormone (αMSH), cleaved from pro-opiomelanocortin (POMC), is an endogenous agonist at MC4 receptors (Mezey *et al.*, 1985), whilst Agrp exerts its orexigenic effect by antagonizing the effect of αMSH at this receptor (Ollmann *et al.*, 1997).

Cocaine- and amphetamine-regulated transcript (CART) is thought to be a second contributor to the anorexigenic system of the ARC. Intraventricular administration inhibits both normal and starvation induced feeding (Kristensen *et al.*, 1998). CART is co-expressed with αMSH in a sub-population of neurones in the lateral ARC (Elias *et al.*, 1998) and, as might be predicted, activity of these POMC/CART neurones is inhibited by fasting (Vrang *et al.*, 1999). More recently however, microinjection studies have demonstrated that whilst CART inhibits feeding when injected into the third ventricle, it has the opposite effect when administered directly into the ARC or other hypothalamic nuclei involved in the regulation of appetite (Abbott *et al.*, 2001). It appears therefore that POMC/CART neurones may have mixed anorexigenic and orexigenic activity.

Leptin receptors are expressed on both NPY/Agrp and POMC/CART neurones (Baskin *et al.*, 1999; Cheung *et al.*, 1997). Leptin inhibits the expression of NPY and Agrp (Mizuno and Mobbs, 1999; Stephens *et al.*, 1995) whilst stimulating activity in POMC/CART neurones (Elias *et al.*, 1998). Furthermore, if the fasting induced fall in leptin is prevented by administration of exogenous leptin, the rise in NPY expression is also prevented and the rate of weight gain during refeeding is blunted (Ahima *et al.*, 1996). Insulin also inhibits the expression of NPY mRNA (Schwartz *et al.*, 1992) whilst fasting induced ghrelin elevates NPY and Agrp expression (Asakawa *et al.*, 2001; Kamegai *et al.*, 2000). Thus the fasting induced fall in the peripheral signals leptin and insulin and rise in ghrelin stimulates NPY/Agrp neurones and inhibits POMC/CART neuronal pathways of the arcuate, generating an appropriate appetitive response.

Second Order Hypothalamic Pathways

NPY/Agrp and POMC/CART neurones of the ARC project to other areas of the hypothalamus thought to play a role in the regulation of appetite and weight, including the lateral hypothalamus (LH) and paraventricular nucleus (PVN) (Broberger *et al.*, 1998; Dall *et al.*, 2000; Elias *et al.*, 1999). Lesion studies indicate that bilateral ablation of the LH causes anorexia and weight loss (Stellar, 1954) whilst destruction of the PVN results in hyperphagic obesity (Weingarten *et al.*, 1985). Furthermore, almost all known orexigenic and anorexigenic peptides modulate appetite when injected into the PVN. Schwartz *et al.* (2000) have therefore proposed a two stage model of hypothalamic pathways regulating appetite: second order PVN and LH neurones function as down-stream effectors for the first order ARC neurones terminating in these regions.

Melanin concentrating hormone (MCH) is an orexigenic peptide (Herve and Fellmann, 1997) for which the LH is a major site of expression in the human brain (Viale *et al.*, 1997). The recently identified MCH receptor (MCH-R/SLC-1) (Shimomura *et al.*, 1999) is widely distributed in the CNS, including hypothalamic sites such as the ventromedial, dorsomedial and arcuate nuclei (Chambers *et al.*, 1999; Saito *et al.*, 2001). Expression of MCH and MCH-R is up-regulated by fasting, an effect that is blocked by central administration of leptin (Kokkotou *et al.*, 2001; Tritos *et al.*, 2001). If these are second order neurones, co-expression of NPY, MC4 and CART receptors should be demonstrable but this remains to be proven.

The orexins, first identified in 1998 (de Lecea *et al.*, 1998; Sakurai *et al.*, 1998), also stimulate feeding, albeit less potently than NPY and MCH (Edwards *et al.*, 1999). These peptides are

expressed in a distinct population of LH neurones that lie in close proximity to MCH neurones and NPY/Agrp nerve terminals (Broberger *et al.*, 1998). As with other orexigenic peptides, a fasting induced rise in the expression of orexin and its receptor can be prevented by the administration of leptin (Lopez *et al.*, 2000). Although orexin has been hypothesized to contribute to second order appetitive signalling, recent evidence suggests a role upstream of NPY: NPY-Y1 receptor antagonists block the feeding effect of exogenous orexin (Jain *et al.*, 2000). In addition to a role in appetite regulation, orexin increases arousal, locomotor activity and metabolic rate (Hagan *et al.*, 1999; Lubkin and Stricker-Krongrad, 1998). Orexin deficient mice exhibit narcolepsy, hypophagia and late onset obesity (Hara *et al.*, 2001). Orexin's primary role may therefore be regulation of the sleep–wake cycle and the modulation of appetite and energy expenditure in accordance with state of arousal (Willie *et al.*, 2001).

One last orexigenic peptide for consideration here is galanin (Smith *et al.*, 1994). Although preprogalanin mRNA is present in both ARC and PVN (Gundlach *et al.*, 1990), microinjection studies suggest that the orexigenic action of galanin may be restricted to the PVN (Kyrkouli *et al.*, 1990). Once more, expression is decreased by central administration of leptin (Sahu, 1998), as predicted for an orexigenic peptide.

The PVN is also rich in anorexigenic peptides, including thyrotrophin releasing hormone (TRH) and corticotrophin-releasing hormone (CRH). TRH expression is reduced by fasting, an effect that is mediated by low leptin levels and dependent upon an intact ARC (Legradi *et al.*, 1997; Legradi and Lechan, 1999; Seoane *et al.*, 2000). Leptin inhibits TRH expression directly via leptin receptors co-expressed on TRH neurones, and indirectly via regulation of αMSH and NPY which respectively stimulate and inhibit TRH expression (Fekete *et al.*, 2001; Nillni *et al.*, 2000).

The anorectic effect of leptin is at least partially mediated by CRH (Gardner *et al.*, 1998; Okamoto *et al.*, 2001; Uehara *et al.*, 1998) and several studies demonstrate enhanced expression of CRH in response to leptin (Costa *et al.*, 1997; Morimoto *et al.*, 2000; Schwartz *et al.*, 1996). However, leptin may also inhibit the expression of CRH (Arvaniti *et al.*, 2001; Heiman *et al.*, 1997) suggesting an indirect mechanism for leptin regulation of CRH. This hypothesis is supported by the finding that the fasting induced fall in CRH expression is mediated at least in part by reduced αMSH activity (Fekete *et al.*, 2001). These data are consistent with a putative role for TRH and CRH as second order anorectic effectors (Schwartz *et al.*, 2000). In addition to the anorectic effect of these neuropeptides, each also plays a role in peripheral energy regulation, via the thyroid and adrenal axis respectively (see below).

Integration of Anorexigenic and Orexigenic Signals within the PVN
